c-Src is expressed in Barrett's esophagus and esophageal adenocarcinoma as well as other head and neck cancers. c-Src is overexpressed in hyperproliferating regions of head and neck squamous cell carcinoma (HNSCC), dysplastic epithelium, papillomas, and inflamed normal tissues (Summy and Gallick 2003). Inhibition of c-Src leads to a universal decrease in HNSCC cell invasion, with more modest and variable effects on cell cycle arrest and apoptosis (Johnson et al. 2005). c-Src inhibition in HNSCC leads to reactivation of pSTAT3 expression, which is considered a mechanism for cellular resistance toward c-Src inhibitors (Sen et al. 2009). c-Src activity regulates invadopodia formation in HNSCC cell lines, thereby increasing invasiveness (Kelley et al. 2010). It has been shown that c-Src along with c-Met plays an important role in survival of head and neck cancer cells and that c-Met acts as direct c-Src substrate in HNSCC, which suggest that Src-dependent cell survival is also regulated by c-Met receptor activation (Sen et al. 2011).

Pancreatic Cancer

c-Src overexpression and increased c-Src kinase activity were observed in pancreatic cancer cell lines but not in normal pancreatic cells. Activated c-Src expression in pancreatic carcinoma cells results in elevated expression of the insulin-like growth factor-1 (IGF-1) receptor, which leads to increased IGF-1-dependent cell proliferation. c-Src-mediated reciprocal regulation

of E-cadherin expression also correlated with growth and progression of human pancreatic cancers (Summy and Gallick 2003).

Ovarian Cancer

c-Src may play very specific roles in the progression of ovarian cancer. c-Src expression is required for anchorage-independent growth and angiogenesis in ovarian cancer. c-Src activity appears to be important for SHC phosphorylation and Erk1/2 phosphorylation downstream of CXCR1/2 receptor stimulation in ovarian cancer (Summy and Gallick 2003). It has also been reported that c-Src inhibition enhanced paclitaxel cytotoxicity in ovarian cancer cells by caspase 9-independent activation of caspase 3. Recent data show the importance of c-Src and protein kinase G-alpha interaction in promoting DNA synthesis and cell proliferation in human ovarian cancer cells (Leung et al. 2010).

Bladder Cancer

c-Src kinase activity is upregulated in human bladder carcinoma cells. c-Src is involved in the epithelial-to-mesenchymal transition of bladder cancer cells in a rat bladder carcinoma model. Increased caveoline-1 expression and decreased c-Src expression and kinase activity correlated with bladder tumor aggressiveness (Thomas et al. 2011).

Gastric Cancer

c-Src kinase activity is greater in gastric carcinoma tissues than in normal mucosal samples. In a subset of gastric cancer cell lines, c-Src inhibition led to increased cell cycle arrest and apoptosis. The resistant gastric carcinoma cell lines had *c-Met* amplification, suggesting that this pathway is a possible mechanism of resistance (Okamoto et al. 2010).

Lung Cancer

Increased expression of c-Src has been reported in 60–80% of adenocarcinomas and bronchioloalveolar cancers and in 50% of squamous cell carcinomas isolated from patients with non-small cell lung cancer (NSCLC). High levels of c-Src kinase activity in NSCLC correlate with tumor size. The mitogenic effects of both nicotine and asbestos are mediated through c-Src. c-Src-mediated constitutive ▶ STAT3 activity has been found in multiple NSCLC cell lines. c-Src inhibition leads to STAT3 activation in multiple NSCLC cell lines, which is believed to be the alternative resistance mechanism for NSCLC cell survival upon c-Src inhibition (Byers et al. 2009). Studies have shown that activation of STAT3 and FAK by c-Src is required for anchorage-dependent and -independent growth in a range of human tumors, including NSCLC. Furthermore, stimulation of STAT3 by EGF, IL6, and hepatocyte growth factor in NSCLC all required c-Src activity. c-Src also activates the VEGF pathway via STAT3 (Johnson and Gallick 2007).

In human NSCLC, c-Src activity is associated with inhibition of anoikis, a form of cell death induced by detachment of adherent cells from the substratum. Following detachment from the primary tumor, c-Src activity is increased, which is able to compensate for the loss of survival signals from cell matrix. Under hypoxic conditions, SFK-dependent transcriptional upregulation of the endothelial PAS-domain protein-1 was observed. These data indicate that SFKs may be involved in regulation of signaling pathways that govern multiple aspects of lung cancer progression (Johnson and Gallick 2007; Summy and Gallick 2003).

Leukemia and Lymphoma

The SFK Lyn is expressed in lymphocytes and monocytes. Lyn was specifically activated in myeloid leukemia cell lines in response to IL3. Lyn is also responsible for phosphorylation of B-cell receptor (BCR) and its coreceptors Ig-alpha and Ig-beta. Lyn is also involved in IL6-mediated cell proliferation. Lck is expressed in T lymphocytes and plays an important role in T-cell hematopoiesis, proliferation, and receptor signaling (Johnson and Gallick 2007).

Clinical Trials with c-Src Inhibitors

Because of the extensive literature supporting the importance of c-Src in tumor progression, angiogenesis, and metastasis, as well as positive correlations between c-Src expression and cancer progression, c-Src is emerging as a promising target for anticancer therapy. Several small-molecule inhibitors of c-Src kinases are undergoing clinical trials after promising preclinical studies, such as the ATP-binding competitive inhibitors dasatinib (BMS-354825, Sprycel), bosutinib (SKI-606), ponatinib (AP24534), and bafetinib (INNO-406), and the substrate binding-site inhibitor Kxo-I (KX2-391) (Sen and Johnson 2011).

Dasatinib (BMS-354825; Bristol-Myers Squibb, New York, NY), an oral inhibitor of Abl, cKit, SFKs, PDGFR, Btk, Ephrin receptor A2 (EphA2), and other kinases, is currently used in the treatment of Bcr-Abl-positive leukemia and gastrointestinal stromal tumor. It is well tolerated by humans. It suppresses the invasion of HNSCC, NSCLC, and other epithelial cancers in vitro (Johnson and Gallick 2010). It is also able to greatly inhibit development of metastasis in an orthotopic mouse model of pancreatic cancer. The triple-negative subtype and EGFR-overexpressing breast cancer cell lines were particularly sensitive to dasatinib (Rothschild et al. 2010; Sen and Johnson 2011). On the basis of promising results of a phase I/II trial of the combination of dasatinib and docetaxel in patients with castration-resistant prostate cancer, this combination is now being studied in a phase III clinical trial (Rothschild et al. 2010). A phase I study of dasatinib in combination with capecitabine or paclitaxel has shown promising results in breast cancer patients. In a phase II study with dasatinib as a single agent in NSCLC had modest clinical activity that was lower than that generally observed in patients who receive standard chemotherapy. Marked activity in one patient and prolonged stable disease in four others suggested a potential subpopulation of patients with dasatinib-sensitive NSCLC (Johnson et al. 2010). Partial responses have been observed in a phase I/II study of dasatinib in combination with erlotinib in advanced NSCLC (Haura et al. 2010). Single-agent dasatinib failed to demonstrate significant activity in patients with advanced HNSCC, despite durable c-Src inhibition (Brooks et al. 2011).

Bosutinib (SKI 606; Wyeth Pharmaceuticals Inc., Madison, NJ) is an oral inhibitor of SFKs and Abl, with a lower affinity for cKit and PDGFR than dasatinib. It showed promising results in a colon cancer murine model and was well tolerated. In preclinical studies, bosutinib resulted in a dose-dependent reduction in proliferation, invasion, and migration of breast cancer cells. In a breast cancer mouse model, bosutinib significantly reduced metastasis to liver, spleen, and lung (Rothschild et al. 2010). In phase II trials, bosutinib either as single agent or in combination with exemestane, letrozole/capecitabine, or zolendronic acid has been well tolerated in patients with advanced breast cancer and has shown promising results (Sen and Johnson 2011).

Saracatinib (AZD 0530; AstraZeneca Pharmaceuticals, London, UK) is an oral inhibitor of SFKs and Abl. Despite promising preclinical studies, AZD0530 was withdrawn from further clinical development, likely because of its lack of clinical efficacy in multiple studies.

Other ATP-competitive tyrosine kinase inhibitors aimed at multiple targets, including SFKs, are being evaluated. XL999 is an oral inhibitor of SFKs, VEGFR, PDGFR, fibroblast growth factor receptor (FGFR), and fms-related tyrosine kinase 3 (FLT3) and has shown activity against solid tumors in phase I and phase II trials. XL228 targets the IGF receptor 1, aurora kinase, FGFR, and Abl. M475271 is another oral kinase inhibitor of c-Src and VEGFR that showed preclinical activity in lung adenocarcinoma cell lines. KX2-391 is an SFK inhibitor that targets the peptide substrate-binding site rather than the ATP-binding site of c-Src. It is not a tyrosine kinase inhibitor. It appears to have a wide spectrum of antitumor activity that is distinct from that of other tyrosine kinase inhibitors. In a phase I trial in patients with advanced solid tumors, KX2-391 was well tolerated (Rothschild et al. 2010).

Summary

A wealth of data indicates the importance of SFKs in the growth and development of various types of human cancers. The structure of c-Src and the mode of its regulation have been studied extensively since its discovery. To clarify and fully elucidate the normal physiological functions of c-Src and other SFKs, their interactions with specific substrates and binding partners in different subcellular environments should be characterized in detail. Phase I and phase II studies of c-Src inhibitors as single agents or in combination regimens in lung cancer, breast cancer, and prostate cancer are promising and warrant further investigation. A detailed comprehensive understanding is needed for the available inhibitors to improve our current approach to cancer therapy.

Historical Background

Human CX3CL1 was first cloned in 1997 and the mouse homolog in 1998. CX3CL1 is a relatively

large protein consisting of an amino-terminal domain, a mucin-like stalk attached to a transmembrane region that connects the molecule to the plasma membrane, followed by the intracellular domain. CX3CL1 is biologically active either as a membrane-bound protein or as a soluble protein upon proteolytic cleavage from cell membranes. CX3CL1 actions are mediated through interaction with its unique G-protein coupled receptor CX3CR1 (previously called chemokine receptor CKRBRL1, RBS11, or V28). Both CX3CL1 and CX3CR1 are highly abundant in central nervous system (CNS) tissues; CX3CL1 is produced by neurons and CX3CR1 is present on microglial cells. In the periphery, CX3CL1 is produced mostly by endothelial cells and CX3CR1 is expressed on peripheral leukocytes. CX3CL1 plays a role in chemotaxis, cell adhesion, and cellular activation. Notably, CX3CL1 and CX3CR1 have been implicated in modulation of microglial activation and are involved in a wide spectrum of biological functions in various tissues and pathologies.

CX3CL1 Expression Patterns

CX3CL1 and its unique receptor CX3CR1 are abundant in CNS tissues. Unlike most chemokines, CX3CL1 is expressed as a transmembrane protein present predominantly in neurons and on the surface of endothelial cells of selected tissues including heart, lung, kidney, and pancreas. Both human coronary artery and umbilical vein endothelial cells (ECs) express CX3CL1 mRNA and protein; however, CX3CL1 mRNA has not been detected in brain vasculature in healthy mice or upon autoimmune inflammation (Sunnemark et al. 2005). Treatment of human umbilical vein endothelial cell cultures with recombinant CX3CL1 caused proliferation, migration and tube formation suggesting an effect on angiogenesis. In HUVEC cells CX3CL1 induced phosphorylation of ERK, Akt, and eNOS as well as an increase of nitric oxide (NO) production (Lee et al. 2006), indicative of the activating effects upon CX3CR1 engagement.

Proteolytic cleavage is essential for regulation of the available pools of membrane-bound versus soluble CX3CL1, and in turn for defining its adhesive versus chemotactic properties. In the healthy CNS, low levels of CX3CL1 are detected in a constitutive fashion. Upon inflammation, both CX3CL1 and its receptor are upregulated in the inflamed CNS tissues during EAE (Huang et al. 2006) as well as in several other pathologies (Cardona et al. 2006; Savarin-Vuaillat et al. 2007). More specifically, TNF significantly increased CX3CL1 mRNA (>100-fold) and protein expression, which was associated with increased shedding of CX3CL1 from the cell membranes (Hurst et al. 2009). CCL2 also appeared to regulate CX3CL1 functions by regulating receptor expression. More specifically, monocytes stimulation with CCL2 increased their adhesion to immobilized CX3CL1, in a p38 MAPK dependent pathway (Green et al. 2006). Although in vitro studies suggest that lipopolysaccharide (LPS) can regulate expression of both CX3CR1 and CX3CL1 (Mizuno et al. 2003), the exact signaling pathways and players involved in the transcriptional and posttranslational regulation of CX3CL1 by cytokines in vivo remain to be clarified.

Release of CX3CL1 from cellular membranes is mediated by the alpha-secretase activity of two disintegrins and metalloproteases (MMPs), ADAM10 (Gough et al. 2004) and ADAM17 (also known as tumor necrosis factor converting enzyme, TACE) (Garton et al. 2001). ADAM10 mediates constitutive and ionomycin-induced cleavage of CX3CL1, whereas ADAM17 catalyzes the inducible release of the soluble domain of CX3CL1 upon phorbol myristate acetate (PMA) stimulation. Most recently it was demonstrated that cathepsins S and MMP2 are also involved in CX3CL1 shedding. Of interest is the report of CX3CL1 release by apoptotic lymphocytes, providing the first demonstration of chemokine/chemokine-receptor activity in the mobilization of macrophages toward apoptotic cells, suggesting a mechanism by which macrophages infiltrate tissues containing apoptotic lymphocytes (Truman et al. 2008).

Dendritic cells (DCs) also express CX3CL1, which functions to control NK cell activation (Pallandre et al. 2008). Recently, a new role of CX3CL1 receptor in DCs differentiation was reported (Lyszkiewicz et al. 2011). Using competitive adoptive transfer experiments it was demonstrated that CX3CR1 expression on hematopoietic progenitors promotes development of DCs and myeloid cells. Interestingly, this model was performed transferring precursor cells into non-irradiated and irradiated recipients to delineate the real role of CX3CR1 under steady-state conditions, compared to inflammatory conditions induced by irradiation (Chen et al. 2007; Xun et al. 1994). It is

proposed that irradiation might have a negative effect on the contribution of CX3CR1 signaling to the generation of DCs and monocytes/macrophages (Auffray et al. 2009; Lyszkiewicz et al. 2011). Based on the above, the role of CX3CR1 is mainly restricted to the steady-state generation of myeloid cells. Additionally, competitive adoptive transfer experiments were developed transferring CX3CR1-deficient precursors directly into the lymphoid target organs such as spleen and thymus, demonstrating similar competitive disadvantage when compared to CX3CR1-sufficient precursor cells. These data implicate CX3CR1 in developmental processes rather than homing of developing cells to lymphoid organs.

In mice the gene encoding CX3CL1 is located in chromosome 8. In humans, CX3CL1 is clustered on chromosome 16q13 together with monocyte derived chemokine (MDC, CCL22) and TARC (CCL17) (Hiroyama et al. 2001). The three human genes are separated by 6.3- and 28.5-kb intervening sequences, respectively, and reside in a head-to-tail orientation with respect to each other (GenBank acc. no. AC004382).

The CX3CL1 receptor (CX3CR1) is a membrane-bound protein and member of the G-protein coupled receptor family mainly produced by microglia. Outside the CNS, CX3CR1 resides mainly on specific leukocyte populations (Jung et al. 2000) including monocytes, NK cells, dendritic cells, and subpopulations of T cells.

CX3CL1/CX3CR1 in Microglial Function

Microglia are the resident macrophage of the CNS, which under resting conditions, constantly survey their microenvironment supporting their critical role in CNS homeostasis (Nimmerjahn et al. 2005). Under inflammatory conditions, microglial cells become activated and upregulate CD45, MHC and co-stimulatory molecule expression, phagocytic activity and are able to stimulate the proliferation of Th1 (▶ IFN-gamma-producing) and Th2 (Interleukin-4-producing) $CD4^+$ T cell lines (Carson et al. 1998). Activated microglia are responsible for the removal of cellular debris and pathogens during CNS injury, inflammation, and infections. In vitro studies have suggested that phagocytosis of myelin by microglia and macrophages could enhance neuroinflammation based on the release of pro-inflammatory cytokines and nitric oxide by these cells (Williams et al. 1994). Additionally, it has been suggested a dual role for microglial phagocytosis based on the need of myelin debris removal for remyelination (Neumann et al. 2009, Chastain et al. 2011).

Meucci et al. in 2000 showed for the first time the neuroprotective functions of CX3CL1 using hippocampal neurons. CX3CL1 conferred neuronal protection from HIV-1 gp120 induced neurotoxicity. Subsequently it was demonstrated that CX3CL1 inhibited release of pro-inflammatory mediators by microglia both in vitro and in vivo. Two knockout mouse models for CX3CL1 and four for CX3CR1 have been reported. These mice develop normally, and under healthy conditions, microglia of CX3CR1-deficient mice did not differ phenotypically from wild type microglia. However upon inflammation or neurodegeneration a distinct phenotype linked to defective CX3CR1 signaling was revealed. In response to systemic lipopolysaccharide injections *Cx3cr1*$^{-/-}$ microglia became highly activated and released pro-inflammatory mediators such as IL-1 that correlated with neuronal damage. Detrimental effects of CX3CR1-deficiency were also observed in models of Parkinson's disease, amyotrophic lateral sclerosis (Cardona et al. 2006), and most recently the absence of CX3CR1 was found to modulate beta-amyloid deposition in Alzheimer's disease models (Lee et al. 2010). Therefore, CX3CR1 appeared to be a key molecule involved in modulation of microglial activation. Interestingly, in a model of transient focal ischemia, Cx3cl1$^{-/-}$ mice showed a 28% reduction in infaction size and lower mortality rate when compared to wild type mice.

Recently, it has been found that soluble CX3CL1 (sCX3CL1), released from mouse cortical neurons damaged by glutamate excitotoxicity, enhances phagocytic uptake of neuronal debris by microglia (Noda et al. 2011). In this study, phagocytosis-related factors expressed by microglia in response to sCX3CL1 such as the PS receptor MFG-E8, was identified as the opsonin involved in clearance of apoptotic cells (Fuller et al. 2008). It was found that the enhanced phagocytosis and the clearance of damaged neurons by CX3CL1-treated microglia in turn promoted neuronal survival. Another finding was the activation of intracellular signaling pathways by sCX3CL1, such as ERK and JNK MAPK, being the last one an important signaling to drive the expression of the antioxidant

enzyme heme oxygenase-1 (HO-1) by microglia via Nrf2 nuclear translocation factor (Noda et al. 2011). Therefore, CX3CL1 plays an important neuroprotective role signaling through CX3CR1 on microglial cells.

CX3CL1/CX3CR1 in Peripheral Leukocytes

In peripheral blood CX3CR1 helps to distinguish "resident" monocytes (identified as LFA-1^{+}, L-Sel^{-}, Ly6C^{-}, *CCR2*$^{-}$, *CX3CR1*$^{+}$), whereas CCR2 marks the "inflammatory" monocyte subset (LFA-1^{-}, L-Sel^{+}, Ly6C^{+}, *CCR2*$^{+}$, *CX3CR1*$^{-}$) (Geissmann et al. 2008). During EAE, monocyte populations mirror this peripheral pattern (Saederup et al. 2010). It was demonstrated that CCR2 expression is controlled at a posttranscriptional stage in some Ly6C^{lo} monocytes and NK and T cells. Furthermore, Ly6C^{hi} monocytes fail to enter the CNS of CCR2-deficient mice during EAE and are mainly replaced by granulocytic cells, not Ly6C^{lo} monocytes. These findings suggest that CCR2+ Ly6C^{hi} monocytes initiate and maintain neuroinflammatory responses, while tissue remodeling is mediated by CX3CR1+ microglia. These studies provide further evidence of differential expression of CX3CR1 and CCR2 to distinguish monocyte/macrophage subsets and discriminate between resident microglia and infiltrating macrophages and DCs in the brain (Saederup et al. 2010, Mizutani et al. 2011).

Notably, multiple sclerosis (MS) patients show lower expression of CX3CR1 in peripheral NK cells when compared to healthy controls (Infante-Duarte et al. 2005) and a deficiency of CX3CR1^{+} PBMC correlated with disease activity. It was also shown the existence of distinct NK cell phenotypes depending on the magnitude of CX3CR1 expression (Hamann et al. 2011). The NK cell phenotypes defined by CX3CR1 expression differ in their cytolytic activity, cytokine profile, proliferative response, and their impact on monocyte functionality. Moreover, three different stages of NK cell maturation were identified based on the expression of CX3CR1 and CD56. While the CX3CR1^{neg} CD56^{bright} phenotype is exclusively characteristic for immature NK cells, the magnitude of CX3CR1 expression on CD56^{dim} NK cells discriminates between intermediary CX3CR1^{neg} CD56^{dim} and fully mature CX3CR1^{high} CD56^{dim} NK cells. Hence, these studies demonstrates that CX3CR1 can be used in conjunction with CD56 and with other novel maturation markers to delineate NK cell phenotypes characteristic for the sequential stages of human NK cell maturation.

Human CX3CR1 in Chronic Inflammation

The studies using CX3CR1-deficient mice become of particular relevance for humans as two single nucleotide polymorphisms in the human CX3CR1 loci produce four allelic receptor variants. Most individuals carry CX3CR1$^{V249/T280}$, and CX3CR1$^{I249/M280}$ is present in >20% of the population. These changes decrease CX3CL1 affinity and correlate with protection from atherosclerosis (Nassar et al. 2008; McDermott et al. 2001; Moatti et al. 2001; McDermott et al. 2003) making CX3CR1 a potential attractive target for therapeutic intervention in cardiac disease. Contrasting this protective effect in atherosclerosis, variant M280 receptor was reported to correlate with enhanced susceptibility to age-related macular degeneration (Chan et al. 2005). Interestingly, CX3CR1 clears its ligand from circulation and tissues acting as a scavenger receptor. Therefore, CX3CL1 elevation could possibly function as a biomarker to assess CX3CR1 dysfunction. CX3CL1/CX3CR1 have also been implicated in the pathology of autoimmune diseases such as systemic lupus erythematosus and patients with neuropsychiatric involvement showed higher serum levels of CX3CL1 (Yajima et al. 2005). Similar findings were reported in rheumatoid vasculitis and osteoarthritis patients (Klosowska et al. 2009).

CX3CL1/CX3CR1 in Cancer

Binding of CX3CL1 to CX3CR1 present on prostate cancer cells led to activation of anti-apoptotic signaling pathways, thereby enhancing survival and persistence of malignant cells. Therefore, CX3CR1 might support tumorigenic responses which translate into worse prognosis. In addition CX3CR1 signaling on tumor cells mediated cytotoxicity of malignant cells against endothelial cells expressing membrane-bound CX3CL1 and therefore enhancing pathology. CX3CR1 on tumor cells from patients with pancreatic ductal adenocarcinoma (PDAC) mediated chemotactic migration of PDAC cells toward CX3CL1 in vitro, as

well as adhesion to neural cells expressing the ligand CX3CL1. High CX3CR1 expression was associated with perineural invasion and with earlier local tumor recurrence in PDAC patients correlating with worse prognosis (Marchesi et al. 2010). In a separate context, combination of CX3CL1 and IL2 gene transfer into tumor cells was shown to reduce tumor size and liver metastasis in an animal model of neuroblastoma. Similarly, expression of CX3CL1 on the surface of tumor cells, via a chimeric immunoglobulin-chemokine construct, reduced incidence and size of lymphoma (Lavergne et al. 2003). These results suggest that the oncogenic effects of CX3CL1 toward tumor cells vary depending on the predominant expression of CX3CL1 or the receptor by the malignant cell type.

Summary

CX3CL1 is a unique chemokine that plays important roles in myeloid cells and in CNS microglia. CX3CL1 functions go beyond the original proposed role of chemokines in cellular recruitment. CX3CL1/CX3CR1 are key modulators of microglial function, play important roles in the development of myeloid cells and expression levels appeared altered in inflammatory conditions including autoimmune inflammation, atherosclerosis, and cancer. CX3CL1/CX3CR1 provides an example of neuronal/microglial communication. Due to its unique peripheral pattern of expression, this chemokine/receptor pair might confer a CNS/peripheral communication system whose tight functions are now recognized as critical for myeloid cells and its effect in other cell types are yet to be defined.

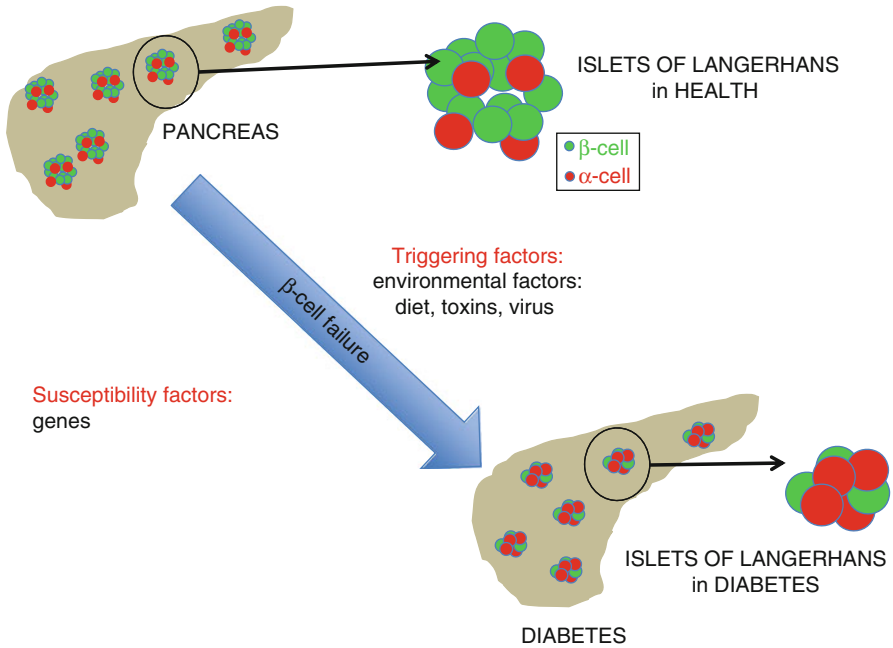
Historical Background

Chemokines/chemoattractant cytokines are small proteins with a mass of 8–10 kDa. Cytokines and chemokines are effector molecules that play a pivotal role in orchestrating both the innate and acquired immune responses. Additionally, they are involved in cell differentiation, division, and repair. The chemokine's nomenclature has been established



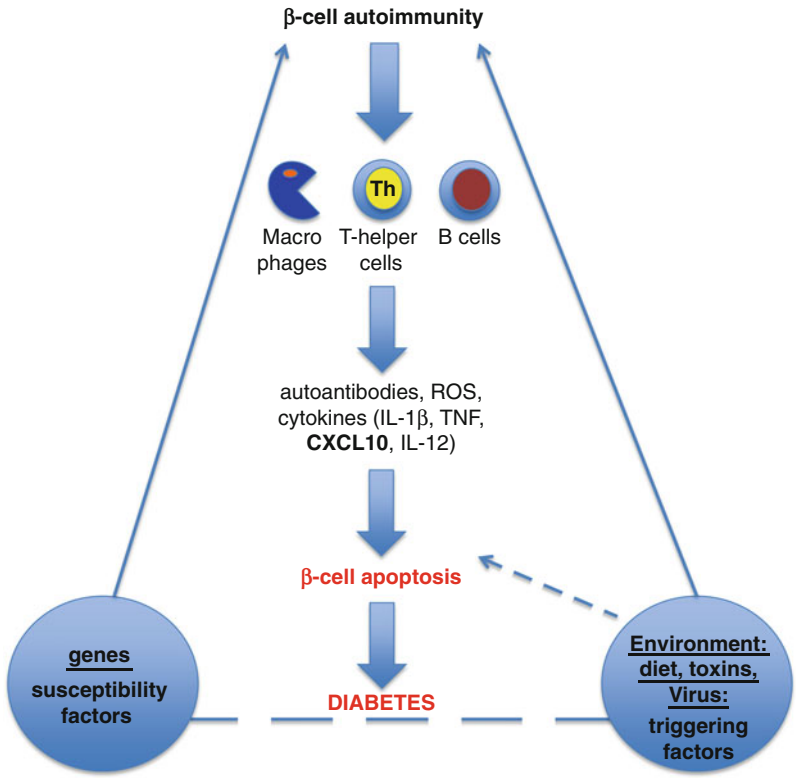
CXCL10, Fig. 1 Diabetes is caused by β-cell destruction triggered by environmental factors in genetically predisposed individuals

in the early 1990s at the International Symposium on Chemotactic Cytokines in Baden (Lindley et al. 1993) on the base of the N-term conserved cysteine motif. Chemokines are classified into four families: C, CC, CXC, CX3C, where X represent any amino acid residue. CXCL10, also called interferon-γ-inducible protein 10 (IP-10), has been initially identified as a chemokine induced by interferon-γ and secreted by a variety of tissues, for example, endothelial cells, monocytes, fibroblasts, and keratinocytes (Luster and Ravetch 1987). CXCL10 has been classified as inflammatory chemokine due to its ability to strongly attract lymphocytes, lack of the ELR motif (glutamic acid-leucine-arginine) which abolishes neovascularization, and function as angiostatic chemokine (Strieter et al. 1995). CXCL10 as well as CXCL9 (MIG) and CXCL11 (ITAC) exerts its action of immune response activator through its natural receptor CXCR3, but CXCL10 also binds to a member of the Toll-like receptor family, TLR4, shown in pancreatic β-cells (Schulthess, Paroni et al. 2009). Over the past few years, both serum levels and tissue expression of CXCL10 were monitored and correlated with various autoimmune diseases such as rheumatoid arthritis, systemic sclerosis, autoimmune thyroid disease, and diabetes mellitus (Hanaoka et al. 2003; Rotondi et al. 2007). Diabetes is a metabolic disease in which the body is unable to produce sufficient amounts of insulin to maintain normoglycemia. Diabetes was reported by Greek physicians already in 250 B.C. and is the Greek word for "syphon," referring to the severe condition of polyuria, the production of large amounts of urine. The complete term "diabetes mellitus" was established later in the seventeenth century. Mellitus is Latin for honey, which is how the physician Thomas Willis described the taste of urine in patients.

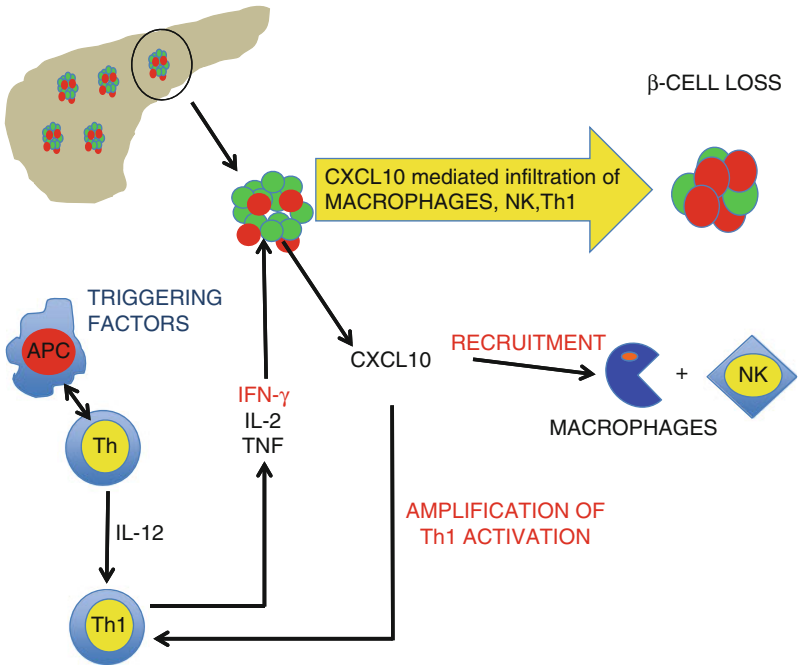
Blood glucose levels are controlled by pancreatic hormones produced by different cell types within the organized structures of the islets of Langerhans that form the endocrine portion of the pancreas. In particular, the hormone insulin, produced by the β-cells, is responsible for decreasing blood glucose by inducing its uptake into target tissues after meals. Diabetes manifests when β-cells fail to produce sufficient amounts of insulin, due to a loss of function and the loss of β-cells themselves. A number of studies over the years, either performed on mouse models or by investigating autopsy material from human pancreata, show that a hallmark of diabetes in both autoimmune type 1 diabetes (T1DM) as well as obesity-related type 2 diabetes (T2DM) is the loss of insulin-producing β-cells by apoptosis (Donath and Halban 2004) (Fig. 1).

CXCL10 in T1DM

In T1DM, β-cell apoptosis is the result of an autoimmune attack. Interaction between antigen-presenting cells and T-cells leads to a prolonged presence of intra-islet inflammatory mediators (cytokines, chemokines, reactive oxygen species (ROS)), finally resulting in β-cell destruction (Paroni et al. 2009). T-helper 1 (Th1) cells are suggested to be crucial in triggering and amplifying such immune attack (Delovitch and Singh 1997) (Fig. 2). The production of IL-12 promotes the development of Th1 cells that produce IFN-γ, IL-2, and TNF-β (Frigerio et al. 2002). IFN-γ activates the transcription, production, and secretion of CXCL10 on target cells that in turn enhances the activation of the immune system (Th1 cells) in a paracrine way (Christen and Von Herrath 2004). $CXCR3^+$ T-cells are recruited to β-cells within the islets. Increased CXCL10 serum levels in patients with T1DM as well as in at-risk individuals were shown in several studies (Shimada et al. 2001; Nicoletti et al. 2002). In contrast, one study reported no statistically significant differences in CXCL10 serum levels in a similar patient collective (Rotondi et al. 2003a, 2003b). In pancreatic tissue from a patient with recent onset of T1DM, CXCL10 expression was measured within islets and lymphocytes (Roep et al. 2010). A positive correlation has been shown between CXCL10 and IFN-γ serum levels and GAD-reactive-IFN-γ producing $CD4^+$ cells (Shimada et al. 2001). In contrast, disease duration and CXCL10 serum levels are negatively correlated (Shimada et al. 2001), similarly to most of the immune markers, which cannot or can rarely be detected in long-standing T1DM. Measurements of inflammatory markers at different time points after diagnosis of the disease may be one reason for the data variation in different studies (Fig. 3). In the non-obese diabetic (NOD) mouse model for T1DM, CXCL10 is produced in pancreatic islets even before detectable insulitis (Cardozo et al. 2003; Li et al. 2005). Inhibition of CXCL10 delayed immune-mediated diabetes in the



CXCL10, Fig. 2 β-cell destruction in T1DM is triggered by inflammatory mediators. Activation of the immune system leads to increased levels of reactive oxygen species, autoantibodies and cytokines. Secreted cytokines act on the β-cell and/or via potentiation of the immune system activation



CXCL10, Fig. 3 Potentiation of the immune system activation by CXCL10. Triggering factors (virus, toxins) lead to T-cell differentiation and maturation. Cytokines produced by Th1 activated cells (IFN-γ, TNFα and IL-12) target β-cells leading to CXCL10 secretion. CXCL10 production and secretion is then boosted through a positive feedback leading to a further recruitment of macrophages and NK cells within the islets. Enhanced activation of the immune system leads to the immuno-mediated β-cell loss

NOD mouse (Morimoto et al. 2004) and transgenic mice expressing CXCL10 in β-cells show spontaneous infiltration of lymphocytes as well as impairment of β-cell function (Rhode et al. 2005).

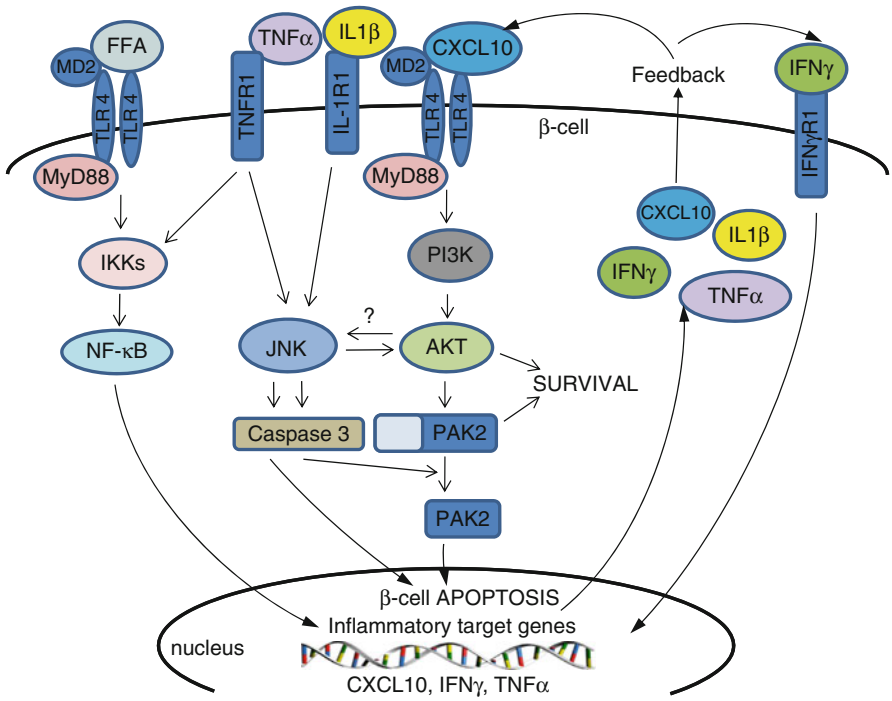
CXCL10 in Virus-Mediated Diabetes

Basic and still unresolved questions regarding the onset of diabetes are how endogenous β-cell antigens become immunogenic and whether environmental factors such as viruses play a causative role in this process. Infection with viruses with a tropism for pancreatic islets highly increases CXCL10 levels both in vivo and in vitro. Mouse studies suggest a pivotal role of CXCL10 during virus-induced diabetes (Christen et al. 2003; Morimoto et al. 2004). Abolishing CXCL10 signaling using specific antibodies leads to a reduction of diabetes incidence (Morimoto et al. 2004). The reduction of diabetes incidence in mice is rather chemokine-specific than a redundant immune system effect. The protective effect is due to less lymphocyte infiltration combined with a reduction of CD8+ lymphocyte activation. In contrast, CXCL10 expression in mice is insufficient to trigger significant autoimmune damage of β-cells. CXCL10 was able to abrogate autoimmunity when it was expressed outside the pancreas (Christen and Von Herrath 2004).

CXCL10 in T2DM

Recently, the presence of immune cell infiltration within islets was also observed in T2DM (Ehses et al. 2007); elevated levels of cytokines in the serum and within islets and apoptotic β-cells characterize the disease. High serum levels of the chemokine CXCL10 have been found in patients with manifest T2DM and with a high risk to develop the disease (Nicoletti et al. 2002; Xu et al. 2005; Herder et al. 2006). CXCL10 does not only act as chemoattractant for the immune system but also triggers β-cell apoptosis in isolated human islets (Schulthess et al. 2009). CXCL10 expression was observed in islets in diabetes as well as in islets from obese patients (Schulthess et al. 2009) and in high-fat diet-fed mice (unpublished observation). Also in adipose tissue from obese individuals (Herder et al. 2007a) and obese mice, CXCL10 is increased.

Obesity is characterized by high levels of circulating free fatty acids (FFA) that stimulate the production of cytokines including CXCL10 that can be



CXCL10, Fig. 4 Hypothetical model of CXCL10 mediated β-cell apoptosis. CXCL10, as well as IFN-γ, IL-1β and TNF-α potentiate their effect via a self activation loop that can be further enhanced by the free fatty acids (FFA). CXCL10 mediated activation of TLR4 leads to activation of the PI3K/Akt pathway followed by JNK and PAK2 cleavage, which reverses the signaling from survival to apoptosis (Adapted from Paroni et al. (2009)

further amplified by IFN-γ which is also elevated in obesity (Shimabukuro et al. 1998; Herder et al. 2007b). In β-cells CXCL10 acts as pro-apoptotic effector through the alternative receptor TLR4 (Schulthess, Paroni et al. 2009). The canonical signaling pathway PI3K/Akt is essential for β-cell survival. Upon CXCL10/TLR4 interaction, Akt is at first activated and promotes β-cell survival together with transcription and secretion of cytokines like TNF-α, IFN-γ, IL-1β, and CXCL10, which then initiate a cascade and potentiate the apoptotic effect through a paracrine/autocrine effect. The CXCL10-TLR4 cascade activates JNK, induces caspase 3 cleavage, which in turn cleaves activated protein kinase 2 (PAK-2), which is downstream of Akt and reverses Akt signaling from proliferation/survival to apoptosis (Fig. 4). These data implicate an important role of CXCL10 in the disease progression of diabetes and suggest blocking CXCL10 signaling as a new therapeutic strategy for diabetes.

Summary

There is strong evidence that CXCL10 plays a causative role for the onset and development of diabetes. However, serum levels of CXCL10 during the development of the disease are discordant among studies. Such discrepancy can be produced by limitation of the analysis as well as the comparison groups (sex, age and especially duration of the autoimmune disease). Serum levels of CXCL10 may not reflect its expression within the islet of Langerhans, observed in obesity, T1DM and T2DM. Different tissue vascularization and time and duration of CXCL10 expression during the disease are important considerable variables. The dual effect of initiation/maintenance or abolition of the immune response and its relation to time and location of CXCL10 expression was already described in mice during virus-induced diabetes (Christen and Von Herrath 2004). Such a complex scenario is strengthening the role of CXCL10 during the onset of both T1DM and T2DM. Due to its potential role as diagnostic marker as well as its intriguing apoptotic activity, further studies are required in order to: (1) establish a consistent analysis method to bring uniformity in the results among different studies, (2) further elucidate the activation pathways that lead β-cells to undergo apoptosis upon CXCL10 signaling activation, and (3) clarify the extent of the contribution of CXCL10 in vivo during the onset of autoimmune disease.

Cyclic ADP-Ribose Hydrolase

► CD38

Cyclin A

Randy Y. C. Poon
Division of Life Science, Hong Kong University of Science and Technology, Kowloon, Hong Kong

Synonyms

CCNA1; CCNA2

Historical Background

Cyclins are first discovered as proteins that varied in abundance during the cell cycle (Hunt, 2004). Cyclin A is one of the first members of the cyclin family to be cloned. Classical cyclins are activating subunits for cyclin-dependent kinases (CDKs) and are essential components of the cell cycle engine (Morgan 2007). Some members of the cyclin family are also known to perform functions unrelated to cell cycle control.

Two cyclin A are present in vertebrates. Cyclin A1 is the "embryonic" form, expressing mainly in early zygotes and testis. Cyclin A2 is the "somatic" form and is widely expressed in most growing cells. In the literature, "cyclin A" generally refers to cyclin A2. Notable exceptions are papers on *Xenopus* embryonic cells, in which "cyclin A" generally refers to cyclin A1.

Cyclin A is expressed periodically during the cell cycle, accumulating from early S phase and disappearing during mitosis. It is generally accepted that cyclin A functions in both S phase and mitosis. Two CDKs, CDK1 (also called CDC2) and CDK2, are catalytically activated by cyclin A. Cyclin A is also believed to play important roles in targeting CDKs to their specific substrates.

Cyclin A1

The only physiological function of cyclin A1 seems to be for spermatogenesis (Fung and Poon 2006). Disruption of cyclin A1 in mice leads to a block of the first meiotic division in male mice. These mice have significantly smaller testes than the wild type littermates and are sterile because of an arrest of spermatogenesis at the latter stages of meiotic prophase. Spermatocytes also undergo apoptosis in the absence of cyclin A1, in part through ▶ p53-dependent mechanisms.

Cyclin A1 is implicated in the tumorigenesis of several cancers, including myeloid leukemia, testicular cancer, breast cancer, and prostate cancer (Yam et al. 2002). As the expression of cyclin A1 is normally suppressed in most somatic cells, reactivation of cyclin A1 is believed to deregulate cell proliferation. Ectopic expression of cyclin A1 has also been reported to induce apoptosis.

Cyclin A2

Cyclin A2 is ubiquitously expressed in proliferating somatic cells and plays essential functions during the cell cycle. Disruption of cyclin A2 in mice causes early embryonic lethality. Cyclin A2-null embryos develop normally until about day 5.5, possibly because of the persistence of a maternal pool of cyclin A2 or compensation by cyclin A1 during early embryo development. Experiments with conditional ablation of cyclin A2 indicated that while cyclin A2 is redundant in fibroblasts, it is essential for cell cycle progression in hematopoietic and embryonic stem cells (Kalaszczynska et al. 2009).

Deregulated expression of cyclin A2 is believed to contribute to tumorigenesis. Although an increased expression of cyclin A2 has been detected in many types of cancer, it is uncertain if this merely reflects the highly proliferative nature of cancers (Yam et al. 2002).

Functions of Cyclin A

Unique among the vertebrate cyclins, cyclin A is both an S-phase cyclin and an M-phase cyclin, functioning in both S phase and mitosis, respectively. Furthermore, both CDK1 and CDK2 can be activated by binding to cyclin A.

Activation of CDKs

CDK1 and CDK2 are expressed at a constant level during the cell cycle. Their activity is determined predominantly by the fluctuation of the cyclin subunit. Activation of cyclin A-CDK complexes also requires the phosphorylation of a residue on the T-loop of the kinase subunit (Thr161 in CDK1; Thr160 in CDK2). Nevertheless, the activity of the enzyme responsible for this phosphorylation (CDK-activating kinase, CAK) does not appear to be regulated during the cell cycle (Morgan 2007).

Under several checkpoint conditions, such as after DNA damage and replication block, the activity of cyclin A-CDK is suppressed (Wohlbold and Fisher 2009). This is carried out by the phosphorylation of Thr14 and Tyr15 of the CDK subunit by WEE1 and MYT1. While WEE1 specifically phosphorylates Tyr15, MYT1 displays a stronger preference for Thr14. During unperturbed cell cycle, cyclin

A2-CDK1, but not cyclin A2-CDK2, is regulated by Thr14/Tyr15 phosphorylation. After checkpoint activation, however, both CDK1 and CDK2 complexes are inactivated by Thr14/Tyr15 phosphorylation (Chow et al. 2003). Inhibition of cyclin A-CDK2 complexes is also carried out by binding to members of the $p21^{CIP1/WAF1}$ family of CDK inhibitors ($p21^{CIP1/WAF1}$, $p27^{KIP1}$, and $p57^{KIP2}$). Members of this family of CDK inhibitors share a highly conserved N-terminal region, which interacts with both cyclin A and CDK2 at the same time.

DNA Replication

Cyclin A is predominantly localized to the nucleus. A proportion of cyclin A is more specifically detected at sites of DNA replication. In fact, cyclin A shuttles between the nucleus and the cytoplasm, but nuclear export is slower than the import, resulting in the nuclear localization of the protein.

DNA replication in eukaryotes involves first the formation of pre-replicative complexes (components include ORC proteins, CDC6, CDT1, and MCM proteins) on the origins of replication. Components of the pre-replicative complexes are then phosphorylated by protein kinase complexes including cyclin A-CDK2 and ▶ DBF4-CDC7, allowing the loading of CDC45 onto the origins. The pre-replicative complexes are disassembled after the firing of the origins, thereby preventing the re-firing of the same origin during the same cell cycle.

Cyclin A is implicated in two steps during DNA replication (Woo and Poon 2003). The first step involves the initiation of DNA replication, presumably for the loading of CDC45 onto origins of replication. The second step involves the inhibition of assembly of the pre-replicative complex to ensure that origins are fired only once per cell cycle. Several components of the pre-replicative complex including CDC6, ORC1, MCM4, and CDT1 are phosphorylated by cyclin A-CDK2, thereby preventing them from forming the pre-replicative complex. The underlying mechanisms include both proteolysis and nuclear export. For instance, phosphorylation of CDC6 promotes its nuclear export by a CRM1-dependent mechanism. On the other hand, phosphorylation of ORC1 and CDT1 promotes their degradation by SCF^{SKP2} complexes. Phosphorylation of MCM4 also directly inhibits the helicase activity of the MCM complexes.

Mitosis

Although cyclin A is clearly required for mitosis, its precise role is not fully understood. One hypothesis is that cyclin A itself is a component of M-phase-promoting factor (MPF). The alternative hypothesis is that cyclin A is part of the machinery that triggers the activation of MPF (Lindqvist et al. 2009). Once a portion of MPF is activated, it is essentially an auto-amplifying system.

Other Functions

Other functions attributed to cyclin A include the regulation of several transcription factors, DNA double-strand break repair, the p53-response pathway, and centrosome duplication (Poon and Fung 2007).

Regulation of Cyclin A During the Cell Cycle

Expression of cyclin A is highly regulated during the cell cycle. Cyclin A protein starts to accumulate at early S phase, continues through S phase and G_2 phase, and disappears during mitosis. In relation to other cyclins during the cell cycle, cyclin A is synthesized and destroyed after cyclin E, but is slightly earlier than cyclin B. The periodic expression of cyclin A is regulated at the levels of transcription and proteolysis.

Transcription

Cyclin A mRNA is regulated during development as well as during the cell cycle. The cyclin A promoter is repressed during G_1 phase and highly active during S phase and G_2/M (Fung and Poon 2005).

Cyclin A1 promoter contains GC boxes, which bind to members of the SP1 family. Transactivation of the cyclin A1 promoter by B-MYB also depends on the SP1 binding sites. B-MYB can be phosphorylated and activated by cyclin A1–CDK2, suggesting the possibility of a positive-feedback regulation. The cyclin A1 promoter can also be transactivated by ▶ C-MYB, which interacts with the MYB-binding sites in the promoter.

One of the mechanisms that controls developmental-specific expression of cyclin A1 may involve methylation. The CpG islands of cyclin A1 promoter are highly methylated in certain tissues and somatic cell lines. However, although methylation of cyclin A1 promoter is correlated with gene silencing in somatic

cell lines, it has little correlation with the tissue-specific repression of the promoter. In early embryos, cyclin A1 expression is also regulated at the level of mRNA stability. The maternal cyclin A1 mRNA is destabilized once transcription is initiated in the zygote. The destabilization of cyclin A1 mRNA is due to deadenylation and relies on the 3′-untranslated region of the maternal transcript. In addition, deadenylation also causes direct translational repression of the cyclin A1 mRNA.

Several regulatory elements in cyclin A2 promoter (CCAAT boxes, NF-Y and B-MYB binding, and CHR) are also found in promoters of other genes involved in G_2/M control, including cyclin B, CDK1, and CDC25C. The promoter of cyclin A2 contains CCAAT boxes, which bind the transcriptional activator NF-Y. Expression of cyclin A2 is also stimulated by B-MYB, a transcription factor controlled by E2F during G_1/S transition. Expression of B-MYB is further enhanced during S phase through phosphorylation by cyclin A2–CDK2.

During G_1 phase, cyclin A2 promoter is repressed by the occupation of a repressor element containing an E2F-binding site. E2F associates with pRb and two closely related proteins p107 and p130 during G_1. These pRb-related proteins repress E2F-responsive promoters by recruiting the histone deacetylase HDAC and the chromatin remodeling complex SWI/SNF to the promoter. Interestingly, HDAC activity is dispensable but ▶ SWI/SNF is required for pRb to repress the cyclin A2 promoter. The activation of cyclin D/E-CDK complexes during G_1 leads to the hyperphosphorylation of pRb, releasing E2F and allowing the activation of the cyclin A2 promoter.

Transcription factors other than E2F are also known to regulate cyclin A2 transcription. In addition to the E2F-binding repressor element, another element termed the cell cycle genes homology region (CHR) is also important for the repression of cyclin A2 transcription in G_1 (Muller and Engeland 2010). Only putative CHR-binding activities, which are unrelated to E2F, have been identified so far. TAFII250, a subunit of TFIID, can stimulate cyclin A2 transcription through an enhancer element. Transcription of cyclin A2 can be negatively regulated by p53, but probably not through the direct interaction of p53 with its cognate consensus sequence. Finally, cyclin A2 transcription can be stimulated by cAMP or repressed by transforming growth factor-β through an activating transcription factor/cAMP-response-element-binding protein (ATF/▶ CREB) site in the promoter.

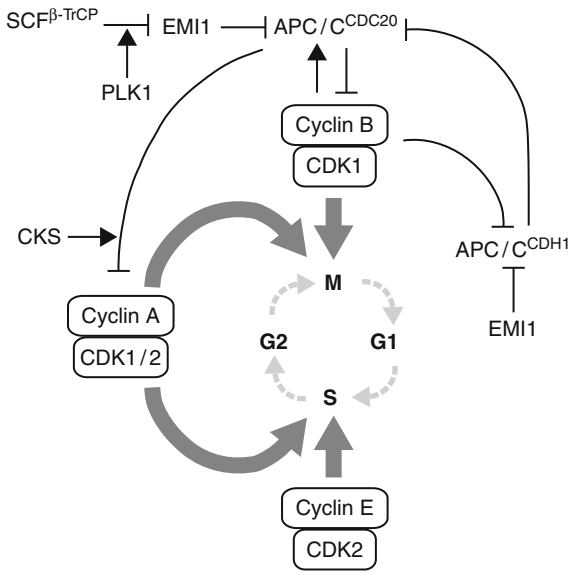
In addition to transcriptional control, the expression of cyclin A2 is also regulated at the level of mRNA stability. For example, the Wilms tumor 1-associating protein (WTAP) interacts with the 3′-untranslated region of cyclin A2 mRNA and stabilizes the mRNA.

Degradation

Degradation of cyclin A2 starts during prometaphase and is complete at metaphase. This differs from that of cyclin B, which is degraded only before the onset of anaphase. The timely destruction of cyclin A2 is in part conferred by a short sequence at the N-terminal region known as the destruction box (D-box). D-box-containing proteins are targeted for ubiquitination by a ubiquitin ligase called the anaphase-promoting complex/cyclosome (APC/C) (Skaar and Pagano 2009). Degradation of cyclin A2 during mitosis involves the APC/C targeting subunit CDC20 as well as the CDK-interacting protein CKS.

In contrast to the well-established mechanism for cyclin B degradation, precisely how the degradation of cyclin A2 by APC/C is regulated is less well understood. In fact, there are important differences between the degradation processes of the two mitotic cyclins, including the extent of the sequences required for D-box function. During unperturbed mitosis, cyclin A2 is destroyed slightly earlier than cyclin B. Another hallmark of cyclin A2 is that its destruction can occur even when the APC/C is inhibited by the spindle-assembly checkpoint (Di Fiore and Pines 2010).

After the cell exits mitosis, APC/C becomes associated with another targeting subunit called CDH1. Unlike APC/C^{CDC20}, APC/C^{CDH1} is activated only after mitosis because its formation is suppressed by CDK-dependent phosphorylation during mitosis. The activated APC/C^{CDH1} then degrades CDC20 and is important for curbing the unscheduled accumulation of cyclins during G_1 phase. During late G_1 to early S phase, the re-accumulation of cyclin A2-CDK complexes causes the phosphorylation of CDH1 and prevents its association with the APC/C core. The inactivation of APC/C^{CDH1} during S phase then allows the re-accumulation of regulators of the subsequent mitosis, including proteins such as cyclin B and PLK1. How cyclin A2 can accumulate in the presence of APC/C^{CDH1} is an important issue. One mechanism



Cyclin A, Fig. 1 Cyclin A and the cell cycle. Together with cyclin E-CDK2 and other kinases, cyclin A-CDK1/2 are important for the initiation of DNA replication and prevention of re-replication. Cyclin A-CDK1/2 are also essential for mitosis, probably as part of the mechanism for kick-starting the main mitotic engine (cyclin B-CDK1). During mitosis, APC/C^{CDC20} is activated by cyclin B-CDK1 and is responsible for degrading cyclin A, a process also involves CKS. Cyclin B itself is degraded later once the constraint of the APC/C^{CDC20} from the spindle-assembly checkpoint is lifted, thereby driving mitotic exit. At the same time, the inhibition of APC/C^{CDH1} by cyclin B-CDK1 is removed. The high activity of APC/C^{CDH1} during G_1 phase keeps the expression of cyclin A and cyclin B low. This continues until late G_1, when APC/C^{CDH1} is turned off by EMI1. EMI1 is eventually degraded by a PLK1- and SCF-dependent mechanism, allowing the mitotic cyclins to accumulate for the next mitosis

may involve the self-destruction of the APC/C E2 ligase UbcH10. Another mechanism is through the inhibition of APC/C^{CDH1} by a protein called EMI1, which begins to accumulate at the G_1/S transition. During mitosis, EMI1 is targeted to ubiquitin-mediated degradation by SCF$^{\beta\text{-TrCP}}$ and PLK1-dependent phosphorylation, thereby resetting the APC/C system for the next cell cycle (Lindqvist et al. 2009). Figure 1 summarizes the relationship between cyclin A and the pathways for its degradation.

Summary

Cyclin A is an essential regulator of the cell cycle. Cyclin A binds and activates the cyclin-dependent kinases CDK1 and CDK2. The complexes are important for the regulation of DNA replication as well as mitosis. During S phase, cyclin A-CDK complexes are critical for the loading of replication factors for the initiation of replication. Cyclin A-CDK complexes have a further role in S phase in preventing the re-firing of the same origins of replication. The functions of cyclin A in mitosis is less understood, but it may be involved in kick-starting the main mitotic engine. Cyclin A starts to accumulate at early S phase and disappears during mitosis. The periodic regulation of cyclin A during the cell cycle is achieved through transcriptional control and proteolysis. Transcriptional control of cyclin A promoter involves multiple transcriptional factors that display cell cycle-dependent activities. Destruction of cyclin A during mitosis is carried out by APC/C.

More works are required to provide a comprehensive picture of the functions of cyclin A. In particular, the precise role of cyclin A during mitosis should be deciphered. In this connection, many substrates of cyclin A-CDK remain to be discovered. Understanding a more complete repertoire of cyclin A-CDK's targets will be the key to unravel the mysteries surrounding cyclin A. Also very little is known about the epigenetic control of the promoters of cyclin A1 and cyclin A2. As both cyclin A1 and cyclin A2 are frequently deregulated in cancers, it is vital to understand how they are controlled during tumorigenesis. Cyclin A is likely to be useful as a target for cancer diagnostic and treatment.

DAPK; Death-associated protein kinase

Historical Background

Death-associated protein kinase (DAPK) is the inaugural member of a class of Ser/Thr protein kinases whose members exhibit homologous catalytic domains as well as share cell death-associated functions (Bialik and Kimchi 2006). DAPK was discovered by Kimchi and co-workers as a tumor suppressor gene whose expression is lost in multiple tumor types (Cohen and Kimchi 2001). This attracted the interest of several investigators resulting in an impressive body of literature concerning its function, regulation, and involvement in various diseases and conditions. For example, DAPK participates in apoptotic pathways initiated by interferon-γ, TNFα, activated Fas, and loss of attachment to the extracellular matrix (Bialik and Kimchi 2006). By activating p53 in a p19ARF-dependent fashion, DAPK is an intrinsic tumor suppressor that opposes early stage oncogenic transformation (Raveh et al. 2001). However, hypermethylation of the DAPK promoter inactivates this pathway in tumorigenesis such as found in multiple myeloma (Chim et al. 2007) and other cancers (Michie et al. 2010).

Domain Structure of DAPK and Regulation of Enzymatic Activity

DAPK has several functional domains (Fig. 1). These include a series of ankyrin-repeat domains as well as a "death" domain and catalytic and calmodulin-regulatory domains that are similar to other calmodulin-dependent protein kinases (Lukas et al. 1998). DAPK activation requires calmodulin (CaM), but it is further modulated by phosphorylation at sites within and outside of the CaM regulatory domain (Bialik and Kimchi 2006). Phosphorylation at two sites decrease DAPK activity, Ser-308 (CaM regulatory domain) and Tyr-491/492 in one of the ankyrin repeat

DAP Kinase, Fig. 1 Domain structure of DAPK. Shown are the locations of the kinase catalytic (*yellow*), calmodulin regulatory (*light blue*), ankyrin repeats (*green*), cytoskeletal binding (*blue*), and death domain (*red*). Phosphorylation sites at residues 491 and 735 are shown in *bold*. The calmodulin regulatory domain is expanded to show the amino acid sequence and the location of the Ser-308 phosphosphorylation site

domains (Fig. 1). As with smooth muscle/nonmuscle myosin light chain kinase (MLCK), phosphorylation within the CaM regulatory domain (Ser-308) of DAPK desensitizes CaM activation. Ser-308 is dephosphorylated by the protein phosphatase PP2a (Gozuacik et al. 2008), allowing CaM activation. Phosphorylation of Ser-735 by activation of ▶ MAP kinase (ERK1 & 2) results in an increase in DAPK activity (Michie et al. 2010). It is thought that this tight control over DAPK activation is one of the checkpoints for committing a cell to an apoptotic/necrotic death.

Regulation of DAPK Expression

The upstream genetic sequences that contain the promoter(s) for the human DAPK gene are diagrammed in Fig. 2a. There are two transcriptional start sites that are controlled by independent promoters. Two alternative translational start sites at -1,025 and -622 are followed by termination codons within exon 1 and 1b, respectively, rendering them nonfunctional. These sites precede the active start site in exon 2. There is no TATA box in either promoter, but there are several of transcription factor binding sites including AP2, E-box, CAAT box, AP1, and nuclear factor kappa B (NF-kB) (Pulling et al. 2009). A CpG island of 590 bp containing 46 CpG dinucleotides is directly upstream of the translational start site. An additional 100 CpGs are located 1,000 bp upstream of this region. Exon 1b contains 17 CpG dinucleotides that may also be methylated in cancer cells (Fig. 2b). Both promoters are active in multiple cell types. Promoter 1 (Exon 1) activity was 40–50% higher than promoter 2- Exon 1b-intron promoter using reporter constructs (Fig. 2c) (Pulling et al. 2009). Methylation analysis in 5 of 15 tumor cell lines revealed that 51–91% of the CpGs in the promoter 1-exon 1 region were methylated and associated with a complete loss of transcription from exon 1. Similarly, there was a good correlation with methylation of promoter 2-exon 1b-intron constructs and loss of expression in 9 of 15 tumor cell lines. The methylation status and location within the DAPK promoters varies greatly in cultured cells but methylation at multiple sites correlates with a decrease or loss of expression. Because of the dual promoters, DAPK expression in one cell type may be more susceptible to methylation than another cell type where the alternative promoter is used. This perhaps explains variability in DAPK promoter hypermethylation in tissue biopsy samples where a mixture of cell types (metastatic vs nonmetastatic) is analyzed. However, the association

of DAPK methylation with tumor aggressiveness and disease progression (poor prognosis) is significant (Pulling et al. 2009; Katzenellenbogen et al. 1999; Chim et al. 2007).

Signal Transduction Pathways Involving DAPK and Its Protein Substrates

Because of its multiple protein interacting domains, DAPK is involved in several cellular processes. Two primary areas of investigative focus are apoptosis and autophagy (Bialik and Kimchi 2006). A summary of the known DAPK substrates is given in Table 1. DAPK phosphorylates regulatory myosin light chains and is involved in membrane blebbing that occurs during programmed cell death (apoptosis) (Bialik and Kimchi 2006). Calmodulin-regulated kinase kinase (CaMKK) is a neuronal protein substrate of DAPK. Its phosphorylation site (Ser-511) is near the CaM recognition domain and results in an attenuation of CaM stimulated activity (Schumacher et al. 2004). Another neuronal substrate is Syntaxin 1A where phosphorylation of Ser-188 is proposed to decrease binding of syntaxin-1A to Munc18-1, a syntaxin binding protein that regulates a complex (known as the SNARE complex) that is necessary for synaptic vesicle docking and secretion (Tian et al. 2003). Thus, if DAPK is activated in presynaptic neurons, two processes may be affected that relate to cellular homeostasis. DAPK phosphorylation of CaMKK is proapoptotic because this kinase is responsible for activating survival pathways through phosphorylation of the kinase known as AMPK (Fogarty et al. 2010), while phosphorylation of syntaxin-1A can lead to inhibition of neurotransmitter secretion (Bialik and Kimchi 2006). DAPK

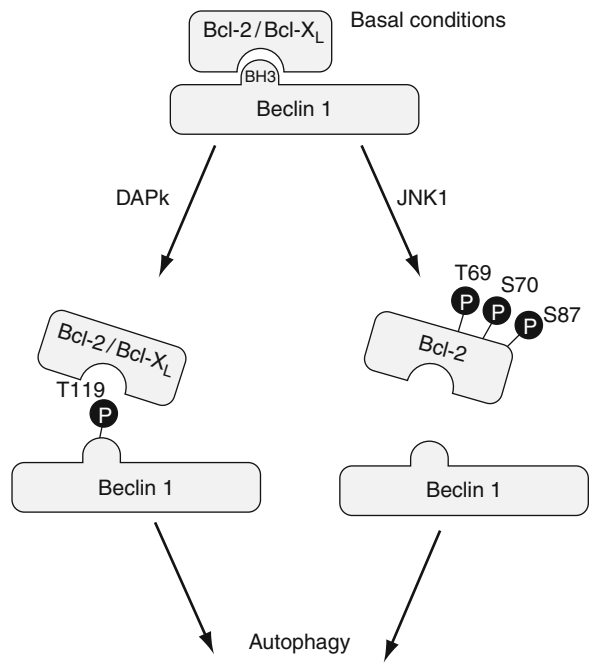
DAP Kinase, Table 1 Functional substrates of DAPK

Substrate	Sequence	In vivo?	Function	Reference
DAPK	RKKWKQ-**S**-VRL	Yes	Inhibits activation	(Shohat et al. 2001)
MLC	RPQRAT-**S**-NVF or RPQRA-**T**-SNVF	Yes	Activates myosin/membrane blebbing	(Bialik and Kimchi 2006)
Zip Kinase	RRRLK-**T**-RL YTIK-**S**-H-**S**-**S**-L PNN-**S**-YADFERF-**S**-K	Yes	Localization and Dimerization, proapopototic	(Shani et al. 2004)
Syntaxin 1A	GHMDSSI-**S**-KQA	Yes	Synaptic vesicle membrane fusion	(Bialik and Kimchi 2006)
CaMKK	RREERSL-**S**-APG	Yes	Inhibits activation	(Schumacher et al. 2004)
Beclin 1A	SRRLKV-**T**-GDLF	Yes	Dissociates Beclin from Bcl-xL proteins	(Zalckvar et al. 2009)
MCM3	TIERRY-**S**-DLT	?	Unknown	(Bialik et al. 2008)

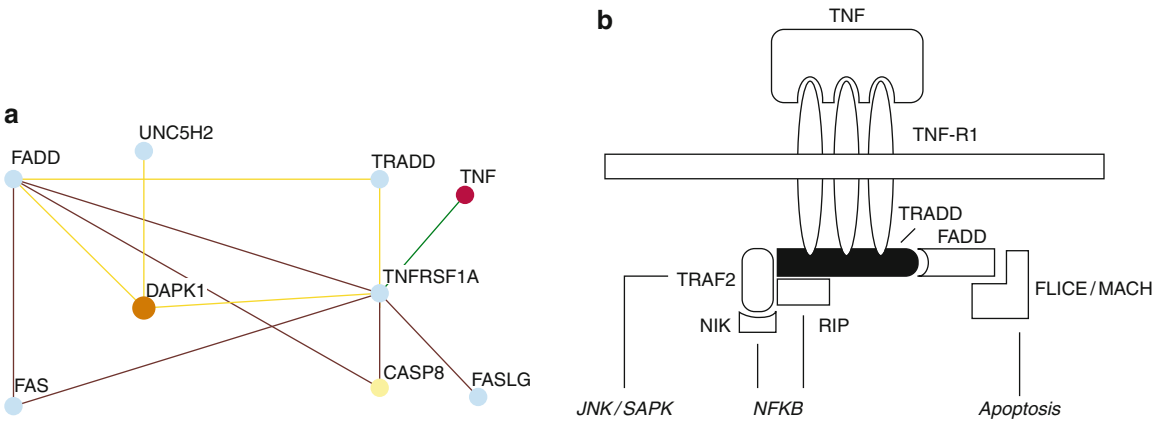
phosphorylation of Zip kinase (DAPK3) activates this kinase leading to changes in cell morphology characteristic of apoptotic cells (Shani et al. 2004). Finally, in a screening assay, DAPK was found to phosphorylate MCM3, a protein that may be involved in the regulation of DNA replication (Bialik et al. 2008).

DAPK, Autophagy and Apoptosis

Figure 3 summarizes one phase of autophagy and the role that DAPK and its substrate Beclin 1 play in this process. Autophagy is a highly conserved process that is characterized by the formation of membrane enclosed "autophagosomes" that function to engulf intracellular organelles and other constituents and deliver them to the lysosomes for degradation. Thus, autophagy is the cell's intrinsic "recycling" machinery that serves to provide material for cell metabolism during periods when extracellular sources of nutrients are low. Beclin 1 is an essential autophagic protein that binds ▶ BcL-2 family proteins through its BH3 domain. The phosphorylation site for DAPK (Thr-119) is located within the BH3 domain, and phosphorylation promotes dissociation of Beclin 1 from proteins Bcl-XL and BcL-2. Dissociated BcL-XL promotes activation of autophagic machinery by interacting with a complex centered upon phosphatidylinositol-3-kinase. This multiprotein complex participates in autophagosome nucleation. Phosphorylation of Bcl-2 by JNK1 kinase also leads to autophagy by a similar mechanism. Beclin 1, itself, has been proposed to interact with several autophagy activators in the complex including AMBRA1, UVRAG, and Bif-1 (Zalckvar et al. 2009). Chronic activation of autophagy can lead to cell death through nutrient depletion (Zalckvar et al. 2009).



DAP Kinase, Fig. 3 A model showing two phosphorylation events which regulate the interaction between Beclin 1 and its inhibitors. DAPK-mediated phosphorylation on Beclin 1's T119 residue, and JNK1-mediated phosphorylation on residues T69, S70, and S87 of Bcl-2, each reduces Beclin 1's interaction with its inhibitors leading to autophagy. Reproduced from Zalckvar et al. (2009) by permission from the Authors



DAP Kinase, Fig. 4 DAPK and apoptosis. (**a**) DAPK engages several proteins in a complex that receives inputs from potential death signals (FADD, TNF receptor 1) as well as survival signals (UNC5H2 –Netrin receptor). (**b**) Schematic representation of TNF-R1 (TNF receptor 1) and its signal transducers. Upon ligand-induced trimerization, the adaptor TRADD and the downstream signal transducers FADD, TRAF2, and RIP are rapidly recruited to TNF-R1. The JNK/SAPK pathway is associated with cellular stress response, NFκβ with cytoprotection, and the FLICE/MACH1 complex directly activates Caspase 8, an apoptosis initiating protease. Used with permission from Natoli et al. (1998)

DAPK is linked through direct binding to a number of proteins that participate in apoptosis by one or more pathways (Cohen et al. 1999) outlined in Fig. 4a. Not all of these pathways are functional in a given cell type. The first pathway is through the binding of Fas to the death-initiator, FADD. DAPK interacts with FADD by way of its death domain (Fig. 1). This interaction results in the downstream activation of caspases that leads to cell death (Fig. 4a). The involvement of DAPK was established in multiple ways. (1) Expression of a fragment of DAPK containing the death domain protects cells from Fas-mediated cell death; (2) Expression of a DAPK mutant lacking the death domain does not promote cell death; (3) DAPK mutants that lack CaM regulation (deletion of CaM segment) resulted in massive apoptosis (Shohat et al. 2001). Thus, both the death domain and DAPK catalytic activity are necessary for Fas-mediated cell death. Apoptosis mediated by DAPK is also initiated from other signals such as UNC5H2. UNC52B (netrin 1 receptor) when bound to ligand blocks DAPK activation (Llambi et al. 2005). However, when netrin is absent, UNC5H2 reduces the phosphorylation of DAPK at Ser-308 which induces its activation by Ca^{2+} CaM (Shohat et al. 2001). Thus, netrin1/UNC5H2 functions as a DAPK switch. (Llambi et al. 2005). In the second pathway, apoptosis is mediated by the ▶ TNFα pathway which has multiple branches (Fig. 4b). DAPK activity is not strictly required in this pathway (Bialik and Kimchi 2006), but, DAPK is part of a large complex that includes the TNFα receptor and several accessory proteins including TRADD, FADD, and FLICE2/MACH (Natoli et al. 1998). Note that none of these proteins are known substrates of DAPK (Table 1). Thus, the function of DAPK in this pathway may be related to its ability to serve as a scaffold for the assembly of proteins in the TNFα receptor complex and facilitate the induction of apoptosis. In some cell types, however, depletion of DAPK by mRNA interference can promote apoptosis (Jin and Gallagher 2003). This may be mediated by a DAPK isoform that has a truncation near the C-terminus of the protein that inhibits the activity of the death domain (Bialik and Kimchi 2006). It is not clear what mediates the expression of this isoform called DAPKβ, but additional work in this area is needed to reveal the complexity of DAPK expression and activity.

Summary

DAPK is a fascinating kinase with respect to its involvement in multiple cellular processes that have not been fully studied. For example, although some substrates have been identified, the timing and duration of DAPK activation may be critically important with respect to cellular commitment to apoptosis.

Synonyms

Darpp32; DARPP-32; Dopamine and adenosine 3′,5′-monophosphate-regulated phosphoprotein, 32 kDa; Dopamine and cAMP-regulated

phosphoprotein; Dopamine- and cAMP-regulated phosphoprotein, Mr32 kDa; Ppp1r1b; Protein phosphatase 1 DARPP-32 inhibitor protein; Protein phosphatase 1, regulatory (inhibitor) subunit 1B

Historical Background

Recent studies using behavioral analysis of animal models suggest that alterations in critical intracellular signaling pathways have an important role in the pathophysiology and treatment of complex neuropsychiatric disorders. The hypothesis is that, if the vast majority of psychiatric medications exert their primary therapeutic actions in the first week of treatment, the therapeutic effects involve transcriptional changes initiated and maintained by critical intracellular signaling pathways.

The dopaminergic neurotransmission system has been the focus of much research throughout the last few decades, including psychiatric and neurological disorders, and drug action mechanisms. Dopamine is associated with motor behavior, pleasure and reward, cognition, among other functions. It is well known that dopamine plays an important role in the coordination and regulation of the two output pathways by acting in a bidirectional manner. Five different dopamine receptors were cloned in humans, and classified in two subgroups: D_1 and D_2 receptors. Many electrophysiological and gene transcriptional data, obtained in vitro and in vivo, suggest that dopamine exerts stimulatory effects via D_1 receptors and inhibitory effects via D_2 receptors (West and Grace 2002). All of dopaminergic receptors are metabotropic and alter cAMP signaling: D_1 receptor subtypes (D_1, D_5) stimulate adenylyl cyclase, whereas D_2 receptor subtypes (D_2S, D_2L, D_3, D_4) inhibit adenylyl cyclase (Svenningsson et al. 2004).

Initially discovered as the major target for dopamine-activated adenylyl cyclase and PKA in striatum, DARPP-32 is now well known for playing a central role in the biology of dopaminoceptive neurons in the central and peripheral nervous system (reviewed by Reis et al. 2007). The phosphorylation by PKA at Thr34 converts DARPP-32 into a potent high-affinity inhibitor of the multifunctional serine/threonine protein phosphatase, PP-1 (Svenningsson et al. 2004). DARPP-32 is also phosphorylated at Thr75 by Cdk5 converting DARPP-32 into an inhibitor of PKA. Furthermore, the state of phosphorylation of DARPP-32 at Thr34 is fine-tuned by the phosphorylation state of two serine residues, Ser102 and Ser137, which are phosphorylated by CK2 and CK1, respectively. Thus, by the virtue of its unique ability to modulate the activity of both PP-1 and PKA, DARPP-32 is critically involved in regulating electrophysiological, transcriptional, and behavioral responses to physiological and pharmacological stimuli, including antidepressants, neuroleptics, and drugs of abuse (Svenningsson et al. 2004).

The serotonergic neurotransmitter system, together with the dopaminergic system, regulates emotion, mood, reward, and cognition. Detailed studies in striatal slices and whole animals have shown that serotonin causes increase in phosphorylation of DARPP-32 at Thr34 and Ser137, and decreased phosphorylation at Thr75. The actions of serotonin in regulating phosphorylation of DARPP-32 at Thr34 and Thr75 were mediated primarily via activation of 5-HT4 and 5-HT6 receptors, whereas the regulation of phosphorylaion at Ser137 was mediated primarily via 5-HT2 receptors. DARPP-32 phosphorylation is also modulated by glutamate, GABA, neuromodulators, and neuropeptides (Svenningsson et al. 2004).

DARPP-32 Knockout and Mutant Mice

The generation of DARPP-32 knockout (KO) mice (Fienberg et al. 1998) and mutant mice with point mutations in phosphorylation sites of DARPP-32 (Svenningsson et al. 2003) has provided a powerful tool for the search of the DARPP-32 roles in both behavioral and neurobiological basis of several diseases. Overall, studies have shown that DARPP-32 is required for the physiological actions of dopamine. A well-accepted molecular explanation for this function is the reduced induction of gene expression after treatment with D_1 receptor agonist in mice lacking DARPP-32 (Svenningsson et al. 2000).

In this context, studies using DARPP-32 KO mice have indicated that DARPP-32-dependent pathways are involved in the modulation of the short, and perhaps long, term actions of drugs of abuse (Svenningsson et al. 2005). In fact, addictive properties of most drugs of abuse are mediated via dopaminergic pathways, particularly through post-synaptic neurons within the striatum, which contains high levels

of DARPP-32. For example, cocaine preference (Zachariou et al. 2002), ethanol reward (Risinger et al. 2001), and stimulatory effects of caffeine on motor activity (Lindskog et al. 2002) are reduced in mice lacking DARPP-32. In addition, the exaggerated locomotor response to d-methamphetamine in mice lacking PDE1B was blocked in PDE1B x DARPP-32 double-KO mice (Ehrman et al. 2006). Similar results were reported showing distinct roles of phosphorylation sites of DARPP-32 in mediating behavioral and biochemical actions of cocaine in the Thr34 and Thr75 mutant mice (Zachariou et al. 2002).

Other lines of evidence have shown a critical role for DARPP-32 in the drug therapeutic actions. Beneficial responsiveness to fluoxetine, which increases phosphorylation of DARPP-32 at Thr34, was strongly reduced in DARPP-32 knockout mice (Svenningsson et al. 2002). In addition, there is evidence for a functional role of DARPP-32 in learning and memory (Heyser et al. 2000). For more detailed information, see Fienberg and Greengard (2000).

DARPP-32 and Human Genetics

Since the function of DARPP-32 is endogenously regulated by the action of neurotransmitters and neuromodulators, and exogenously by cocaine and therapeutic drugs, it has been long viewed as potential candidate gene for the most of psychiatric disorders. However, few studies have examined variations in the gene encoding DARPP-32 (*PPP1R1B*; located on 17q12), demonstrating a weak association between *PPP1R1B* genetic polymorphisms and the diseases studied. The initial evidence that a chromosomal region within 17q, which includes the *PPP1R1B* gene, increases risk for schizophrenia (Cardno et al. 2001) and bipolar disorder (Dick et al. 2003) has offered a useful starting point for genetic studies.

Several studies have reported abnormalities in DARPP-32 expression in the brain of psychiatric disorder patients (Reis et al. 2007). Because of this evidence, genetic association studies were performed with schizophrenia, bipolar disorder, nicotine dependency, cognitive ability, attention-deficit hyperactivity disorder (ADHD), and breast cancer. Among them, positive associations were found only with nicotine dependence (Beuten et al. 2007), reinforcement learning (Frank et al. 2007), and in one out of five schizophrenia studies (Meyer-Lindenberg et al. 2007). In these studies, weak-to-moderate associations were reported. However, the inconsistencies in the *PPP1R1B* genetic findings can be partially due to the different samples, particularly the ethnicity effects, and not assessing the same genetic alterations.

In a sample of 2,037 subjects, Beuten et al. (2007) found that a *PPP1R1B* haplotype formed by rs2271309-rs907094-rs3764352-rs3817160 was significantly associated with smoking quantity in European-Americans, but not in African-Americans (Beuten et al. 2007). This data not only suggest that nicotine addiction risk is predisposed by *PPP1R1B* genetic variations, but also that it may be influenced by ethnic diversity. Using a translational genetics approach, Meyer-Lindenberg et al. (2007) found that the same schizophrenia-related *PPP1R1B* variants that impact cognitive functions, also predict the expression of DARPP-32 mRNA. Interestingly, in an independent sample of healthy Caucasian subjects, these same polymorphisms were associated with different patterns of neostriatal morphology and function (Meyer-Lindenberg et al. 2007). Corroborating with this hypothesis, another finding provided evidence that rs907094, which was shown to be associated with striatal dopamine function (Meyer-Lindenberg et al. 2007), may predict mechanisms in human reinforcement learning as well (Frank et al. 2007). Thus, the ability of how genetic variations in the *PPP1R1B* affects learning and decision-making processes, as well as addiction and striatal function, may have substantial implications on several disorders such as ADHD and schizophrenia.

Psychiatric Disorders and Neurological Diseases

Abnormalities in the neurotransmitter systems are hallmark physiological features in the brain of patients with psychiatric disorders. However, the complexity of neuronal signaling is based not only in the regulation of receptors activity at the synaptic membrane, but also in the integration of many intracellular signaling cascades. Because of this, DARPP-32 emerged as strong candidate involved in the manifestation of psychiatric disorders. In the last decade, several studies reported abnormalities in the DARPP-32 expression in the brain of patients with schizophrenia, bipolar disorder, depression, ADHD, and Parkinson disease.

DARPP, Table 1 DARPP-32 and psychiatric and neurological disorders – summary of DARPP-32 expression patterns in samples from psychiatric and neurologic disorder patients

Disorder	Sample	DARPP-32 alteration
Schizophrenia	Dorsolateral prefrontal cortex	Decrease: protein (Albert et al. 2002; Ishikawa et al. 2007); mRNA in suicidal patients (Feldcamp et al. 2008) No alteration: mRNA (Baracskay et al. 2006)
	Anterior cingulate cortex	No alteration: mRNA (Baracskay et al. 2006)
	Thalamus	No alteration: mRNA (Clinton et al. 2005)
	Lymphocytes	Decrease: protein (Torres et al. 2009)
Bipolar disorder	Dorsolateral prefrontal cortex	Decrease: protein (Ishikawa et al. 2007)
	Lymphocytes	Decrease: protein (Torres et al. 2009)
Parkinson disease	Putamen	Decrease: protein (Cash et al. 1987); No alteration: protein (Girault et al. 1989)
	Substantia nigra pars reticulate	Decrease: protein (Cash et al. 1987)
	Substantia nigra pars compacta	Decrease: protein (Cash et al. 1987)
	Caudate nucleus	No alteration: protein (Girault et al. 1989)

Schizophrenia: Abnormalities in the dopamine and glutamate neurotransmitter systems are involved with schizophrenia. The DARPP-32 signaling pathway is regulated by both neurotransmitters' signaling. Several studies, using postmortem brain from drug treated schizophrenic patients, have reported alterations in the DARPP-32 levels (See Table 1). The studies using postmortem brain of patients demonstrated a decrease in the protein levels, but not mRNA, in the dorsolateral prefrontal cortex of patients, a region suggested to be associated with negative symptoms and cognitive impairments of schizophrenia. Also, no alterations were demonstrated in the mRNA levels in the anterior cingulated cortex and thalamus, regions respectively involved in the decision-making and in the integration of different neural circuit activities, of schizophrenic patients.

Several studies showed that blocking D_2 receptors, the main target of antipsychotics, can increase the phosphorylation of DARPP-32(Thr34), affecting motor behavior. This modulation of motor behavior by antipsychotics is impaired in DARPP-32 KO mice (reviewed by Reis et al. 2007). However, both in vitro and in vivo experiments demonstrated that antipsychotics do not regulate the expression of DARPP-32, suggesting that the decrease of DARRP-32 in the prefrontal cortex of schizophrenic patients is related to the disease, and not to the pharmacological treatment (Souza et al. 2008, 2010).

Furthermore, recently, levels of DARPP-32 were shown to be decreased in lymphocytes of drug treated schizophrenic patients, suggesting DARPP-32 as a potential biomarker for this illness (see Table 1).

Bipolar Disorder: Recently, two studies reported alterations of DARPP-32 levels in bipolar disorder patients. The levels of DARPP-32 are decreased in the dorsolateral prefrontal cortex of bipolar disorder patients, indicating that DARPP-32 might be involved in the neurotransmission imbalance in the patients' brain. Furthermore, DARPP-32 levels are decreased in the lymphocytes of patients, pointing to DARPP-32 as a putative biomarker for bipolar disorder (See Table 1).

Depression: Much evidence supports the involvement of dopamine and serotonin in depression, for example, pharmacological treatment and dopamine metabolite levels. Acute treatment with fluoxetine increases the phosphorylation of DARPP-32 in many regions of the mouse brain. Chronic treatment with lithium and antidepressants increases DARPP-32 levels in the prefrontal cortex of rats (reviewed by Reis et al. 2007). A recent study reported that chronic electroconvulsive stimulation, which is very effective for depression, increases the levels of DARPP-32 in rats' hippocampus and striatum (Rosa et al. 2007).

Attention Deficit and Hyperactivity Disorder (ADHD): Dopamine signaling is the main target of pharmacological treatment of ADHD. It was recently

reported that methylphenidate treatment regulates the expression of DARPP-32 in rats' brain. Interestingly, this regulation is dependent on drug posology and the age of the rats, and it is region specific as well (Souza et al. 2009). This regulation of DARPP-32 expression by methylphenidate might be important in the improvement of ADHD symptoms.

Parkinson Disease: It is well known that dopamine signaling abnormalities are involved in the Parkinson Disease. Two studies reported different results regarding the levels of DARPP-32 in the brain of Parkinson Disease patients. One reported decreased levels of DARPP-32 in the putamen and substantia nigra of patients. However, no alterations in DARPP-32 levels were found in the putamen and caudate nucleus of a different group of Parkinson Disease patients (reviewed by Reis et al. 2007) (see Table 1).

DARPP-32 and Drugs of Abuse

It is well established that the dopaminergic system plays an important role in reward-related behaviors, and drugs with reinforcing properties share the ability to increase dopaminergic transmission (Svenningsson et al. 2005).

Cannabis: The major psychoactive components of marihuana and hashish are cannabinoids. Fernández-Ruiz et al. (2010) showed that the effects of cannabinoids on dopamine transmission and dopamine-related behaviors are generally indirect and affected by the modulation of GABA and glutamate inputs received by dopaminergic neurons. Recent evidence suggests, however, that certain eicosanoid-derived cannabinoids may directly activate TRPV1 receptors. These receptors have been found in some dopaminergic pathways, what allows a direct regulation of DA function by cannabinoid signaling. In the brain, cannabinoids interact with neuronal CB1 receptors, thereby producing a marked reduction of motor activity. These receptors are coupled to Gs protein, that enhances cAMP levels and, consequently, leads to the phosphorylation of DARPP-32 at Thr34. Point mutation of Thr75 does not affect the behavioral response to CP55940, a selective CB1 receptor agonist. On the other hand, catalepsy induced by CP55940 is reduced in both DARPP-32 knockout mice and in Thr34-Ala DARPP-32 mutant mice. Activation of CB1 receptors, either by an agonist or by inhibition of reuptake of endogenous cannabinoids, stimulates phosphorylation at Thr34 (reviewed by Reis et al. 2007; Andersson et al. 2005).

Cocaine: Acute treatment with cocaine increases the phosphorylation of DARPP-32(Thr34) and decrease the phosphorylation ofDARPP-32(Thr75). On the other hand, chronic treatment with cocaine increases phosphorylation of DARPP-32(Thr75) and decreases phosphorylation of DARPP-32(Thr34) (Svenningsson et al. 2004).

Chen et al. (2009) demonstrated that acute stimulation with cocaine activates the dopamine D_1 receptors, consequently leading to DARPP-32(Thr34) phosphorylation in the striatum. Several studies have shown that DARPP-32 participates in the progressive development of behavioral sensitization to cocaine. Knockout of DARPP-32 or DARPP-32 mutation (threonine 34 replaced by alanine) in mice attenuated the hyperlocomotor activity induced by acute cocaine treatment. Moreover, chronic treatment with cocaine decreased phosphorylation at Thr34 but increased at Thr75. This latter effect was due to enhanced Cdk5.

Opiates: Opiates act on the dopaminergic system in the brain via the μ-receptor and modulates the expression of DARPP-32, which represents an exciting nexus for drug-induced changes in neural long-term synaptic plasticity. Mahajan et al. (2009) showed that heroin significantly increased both D_1 and DARPP-32 gene expression. Also, it was shown that gene silencing DARPP-32 by siRNA in cultured normal human astrocyte cells modulated the activity of downstream effector molecules, such as PP-1. Opiates, such as morphine, bind to opioid receptor subtypes (mu, delta, and kappa) that are abundant in striatum. Mu- and delta-receptors are coupled to Gi protein, which decreases phosphorylation of DARPP-32 at Thr34 and modulates both dopamine and adenosine receptor activation (reviewed by Reis et al. 2007).

Nicotine: Nicotine is the critical component in tobacco smoke that is involved in addiction. It has been shown that nicotine modulates dopaminergic neurotransmission mainly by enhancing dopamine release in nigrostriatal and mesolimbic dopaminergic systems. Abdolahi et al. (2010) demonstrated incubation of drug seeking following extended access to nicotine self-administration and suggested that enhanced PKA signaling in the insular cortex via phosphorylation of DARPP-32 at Thr34 is associated with this effect. At low concentrations, nicotine decreases

phosphorylation of DARPP-32 at Thr34 in mouse neostriatal slices. In the other hand, high concentrations of nicotine increased the phosphorylation of DARPP-32 at Thr34. Therefore, different concentrations of nicotine lead to different amounts of dopamine release and, consequently, distinct activation patterns of dopamine receptors (reviewed by Reis et al. 2007).

Ethanol: Ethanol does not have a clearly defined site of action. It can act directly as agonist of $GABA_A$ and antagonist of NMDA receptors, and indirectly as agonist of dopamine D_1 receptor. Studies with DARPP-32 knockout mice showed DARPP-32 involvement in ethanol reward induced behavior in both place preference and self-administration tests (Risinger et al. 2001). It has been demonstrated that moderate levels of ethanol increase phosphorylation of DARPP-32 at Thr34 in striatal slices. Ethanol administration was found to increase phosphorylation of DARPP-32(Thr34) in the nucleus accumbens (NAc) and amygdala (but not in the striatum) of wild-type and transgenic mice, with a greater effect in the amygdala of transgenic mice. It was found also to increase DARPP-32(Thr75) in the amygdala of the wild-type mice only, and in the NAc and striatum of both the transgenic and wild-type mice. The authors concluded that the effect of ethanol on the balance of DARPP-32 phosphorylation, especially in the amygdala, may contribute to differential motivational effects of ethanol (Goodman 2008).

Summary

The importance of DARPP-32 arises from its relationship with several different signaling systems/cascades involved in important intracellular functions such as gene expression, cell differentiation, metabolism, and neuronal plasticity. The protein is an integrator of cellular function, and as such a putative target to fine-tune those functions. In addition, research should be conducted to gather information from animal models such as the *Caenorhabditis elegans, Drosophyla melanogaster, Aplysia* sp. and *Zebrafish*. An example, in *Caenorhabditis elegans* "Area-Restricted Search" behavior is controlled by a dopaminergic response to food deprivation that modulated glutamatergic signaling. Dopaminergic pathway compounds are not entirely described, and, like humans, this behavior time course is on the order of minutes, so a similar process might explain, and a DARPP-32 like protein could be part of it.

Future research will certainly shed more light on the roles of DARPP-32 in different biological processes, as well as potential new functions. Nanotechnology is having an increasing impact in the healthcare industry. The combination of diagnostic (imaging) and therapeutic capability enables the "real-time" monitoring of therapeutic progression, thus bringing "personalized medicine" closer to clinical reality. Bonoiu et al. (2009) introduced a nanotechnology approach that utilizes gold nanorod-DARPP-32 siRNA complexes that target to dopaminergic signaling pathway in the brain. Gene silencing of the nanoplexes in dopaminergic neuronal cells was evidenced by the reduction in the expression of key proteins, as DARPP-32, belonging to this pathway, with no observed cytotoxicity. Since these nanoplexes were shown to transmigrate across an in vitro model of the blood–brain barrier, it appears to be suited for brain-specific delivery of appropriate siRNA for therapy of drug addiction and other brain diseases. Nevertheless, the available collection of evidence suggests that DARPP-32 lies at the nexus of multiple signaling pathways that modulate important signaling states of a given cell type, thus, assuring that it will continue to be an important molecule in quest to find new pharmacological targets.

Dbf4

Hisao Masai
Genome Dynamics Project, Department of Genome Medicine, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan

Synonyms

ASK (activator of S phase kinase)/huDbf4 (human); Chiffon (*Drosophila*); Dbf4 (dumbbell former 4)/DNA52 (*Saccharomyces cerevisiae*); Dbf4l1; Dfp1/Him1/Rad35 (*Schizosaccharomyces pombe*), Spo6 (a second Dbf4 homologue in *S. pombe*); Drf1/ASKL1 (a second activator of Cdc7 in human and *Xenopus*); nimO (*Aspergillus*)

Historical Background

dbf4 (dumbbell former 4) mutation was originally identified in the screening for budding yeast temperature-sensitive mutants which arrest with dumbbell-shaped phenotype at the nonpermissive temperature (Johnston and Thomas 1982). The terminal phenotypes of *dbf4*(ts) strain at a nonpermissive temperature were very similar to those of ▶ *cdc7*(ts), encoding a serine-threonine kinase known to be essential for initiation of DNA replication. Later, *dbf4* was rediscovered as a multi-copy suppressor of ▶ *cdc7*(ts), suggesting physical and functional interactions between ▶ Cdc7 and Dbf4 (Kitada et al. 1992). Following this finding, Dbf4 was shown to bind to ▶ Cdc7 and stimulate its kinase activity, establishing that Dbf4 is the activation subunit for ▶ Cdc7 kinase (Jackson et al. 1993). The presence of ▶ Cdc7 homologues in species other than budding yeast was first reported in fission yeast (*hsk1*; Masai et al. 1995). Following this discovery, an ortholog of Dbf4 was reported in fission yeast (Brown and Kelly 1998, Dfp1/Him1). The orthologs of Dbf4 from vertebrates were also identified and found to form complexes with cognate ▶ Cdc7 (Kumagai et al. 1999).

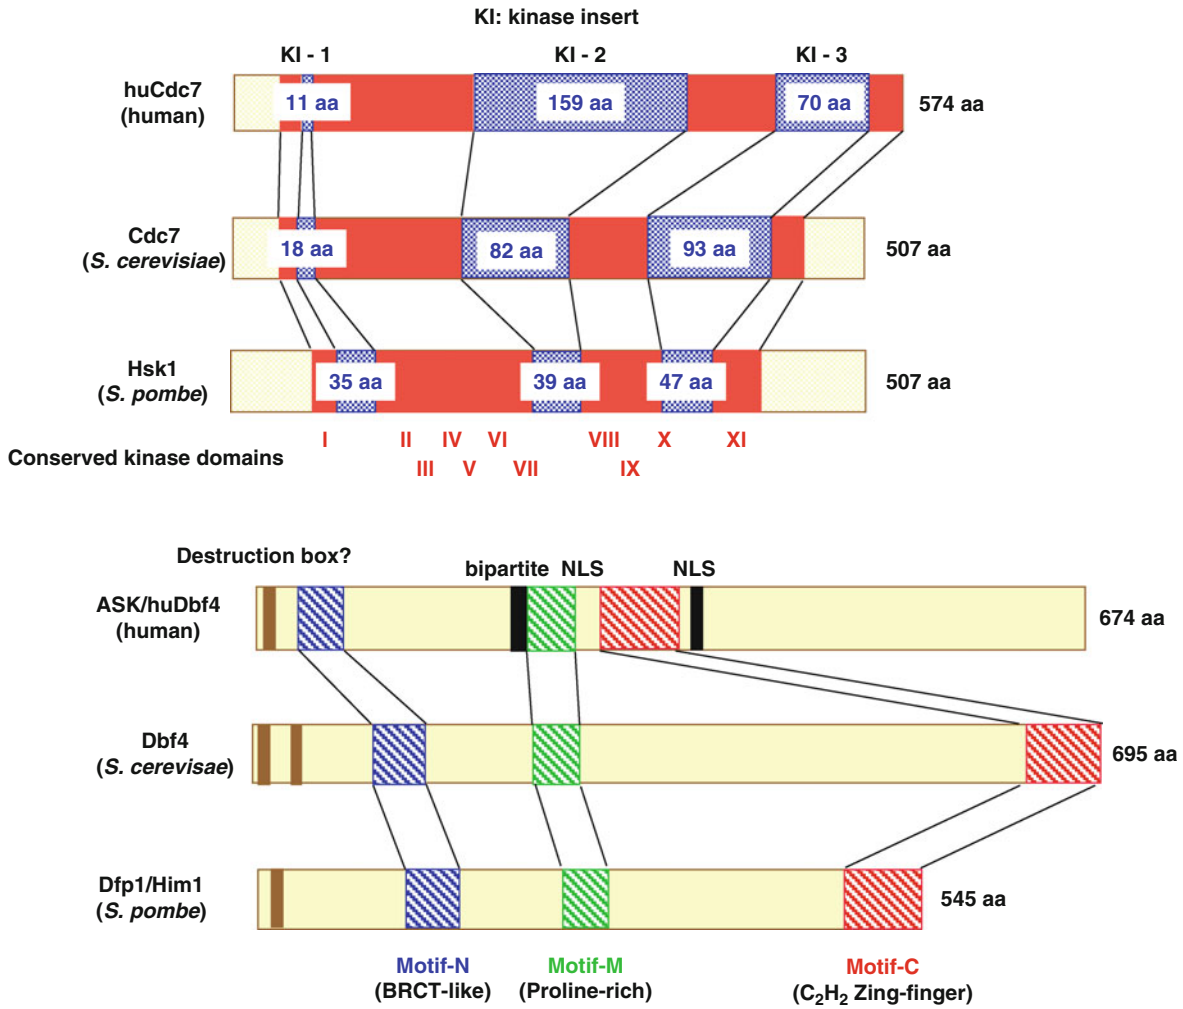
Identification of Orthologs of Dbf4 in Other Species

Purification of Hsk1 kinase from fission yeast led to identification of Dfp1, the fission yeast ortholog of Dbf4 (Brown and Kelly 1998). Two-hybrid screening with Hsk1 as a bait also led to the identification of Him1, identical to Dfp1. Interestingly, *dfp1/him1* was found to be allelic to *rad35*, a radiation-sensitive mutant, implicating Dbf4 in DNA damage response pathway (Takeda et al. 1999). In *Aspergillus*, a mutant called *nimO* was isolated and was shown to encode a Dbf4 homologue (James et al. 1999). Human homologue of Dbf4, ASK (activator of S phase kinase), was isolated by two-hybrid screening using huCdc7 as a bait (Kumagai et al. 1999).

A second Dbf4 subunit in human was identified and named Drf1 or ASKL1 (Montagnoli et al. 2002; Yoshizawa-Sugata et al. 2005). Drf1/ASKL1 can bind and activate huCdc7, but its role during cell cycle may be secondary. Drf1/ASKL1 is present also in *Xenopus*. In *Xenopus* egg extracts or during early development of *Xenopus*, XDrf1/ASKL1 rather than XDbf4 plays a major role as an activator of XeCdc7, whereas XDbf4 replaces the XDrf1/ASKL1 in somatic cells (Takahashi and Walter 2005). In fission yeast, a second set of ▶ Cdc7-Dbf4, Spo4-Spo6, is present which functions specifically during the sporulation/second meiotic division stage of meiosis (Nakamura et al. 2000). No functional homologues of Spo4-Spo6 have been identified in other species.

Activation of ▶ Cdc7 Kinase by Dbf4 Protein

Analysis of sequences of Dbf4 and its orthologs revealed the presence of three conserved motifs, motif-N, -M, and -C (Masai and Arai 2000; Fig. 1). Further analyses indicated that motif-M and -C can bind to ▶ Cdc7 independently. Binding of both motifs to ▶ Cdc7 is required for full activation of



Dbf4, Fig. 1 *Comparison of the primary structures of Cdc7 and Dbf4/ASK proteins from human, budding yeast, and fission yeast*. The sequences of human, *S. cerevisiae*, or *S. pombe* Cdc7 or Dbf4/ASK were aligned and the conserved segments are indicated. *Upper*: *Red* regions are kinase conserved domains which are similar between the three species. Blue regions are kinase insert sequences and are not conserved. *Lower*: Motif-N, -M and -C, shown in *blue*, *green*, and *red*, respectively, are conserved across the species

► Cdc7 kinase. The sequences and length connecting motif-M and motif-C can be varied without affecting the kinase activity, suggesting that they serve as a linker sequence (Ogino et al. 2001). Motif-M is a proline-rich motif with no apparent similarity to known motifs. Motif-C is a C_2H_2-type zinc finger-like structure. Motif-N is composed of a single copy of a BRCT-like sequence, which could be uniquely replaced by the BRCT motif from Rev1 (Harkins et al. 2009). Motif-M alone can sustain mitotic viability (Fung et al. 2002), but both motif-M and -C are required for viability through meiosis in fission yeast (Ogino et al. 2001). On the other hand, motif-N is not essential for viability, although it is involved in conferring resistance to genotoxic agents. In mammalian cells, motif-M and motif-C are sufficient for maximum kinase activity, but motif-N is also required for viability (Yamashita et al. 2005).

Functions of Dbf4/ASK During Cell Growth

A temperature-sensitive mutant of *dbf4* in budding yeast ceases growth at the onset of S phase, an identical position with that of ► *cdc7*(ts) cells. The arrested cells can reversibly enter the S phase upon return to

a permissive temperature. Analyses of a temperature-sensitive mutant of *nimO*, the *Aspergillus* homologue of Dbf4, showed that NimO is required for initiation of DNA synthesis and for efficient progression through S phase as well as for DNA replication checkpoint coupling S and M phases (James et al. 1999). *Drosophila* homologue of Dbf4, Chiffon, is required for chorion gene amplification. Hypomorphic mutant alleles of the chiffon gene cause thin, fragile chorions and female sterility. Null alleles of chiffon had the additional phenotypes of rough eyes and thin thoracic bristles, phenotypes often associated with disruption of normal cell cycle (Landis and Tower 1999).

Dbf4 and Dfp1/Him1 are hyperphosphorylated in response to replication stress (such as treatment with hydroxyurea, which inhibits cellular nucleotide reductase and depletes cellular nucleotide pool). This phosphorylation of Dbf4 or Dfp1/Him1 depends on both ▶ Cdc7/Hsk1 and checkpoint kinase Rad53 or Cds1, respectively (Takeda et al. 2001; Brown and Kelly 1999). It has been proposed that this phosphorylation somehow inhibits the function of Dbf4, which contributes to suppression of firing of late origins. However, the nature of this inhibition is still unknown. Extensive mutagenesis of potential phosphorylation sites on Dbf4 rendered the mutant Dbf4 refractory to the checkpoint inhibition and combination of the Dbf4 mutant with a similar phosphorylation site mutant of Sld3 abrogated the checkpoint inhibition of late origin firing, showing that Dbf4 is a critical target of DNA replication checkpoint (Lopez-Mosqueda et al. 2010; Zegerman and Diffley 2010). Human Dbf4/ASK may also be hyperphosphorylated by replication stress (Heffernan et al. 2007).

In mouse ES cells, conditional knockout of Dbf4/ASK is lethal and cells undergo cell death, as was observed in ES cells in which the ▶ *Cdc7* gene was conditionally knocked down.

Functions During Meiosis

Initial characterization of budding yeast ▶ *cdc7*(ts) indicated the essential role of ▶ Cdc7 for meiotic recombination, but not for premeiotic DNA replication. In fission yeast as well, cells are arrested with one nucleus in a *hsk1*(ts) cells. In both fission yeast and budding yeast, initiation of meiotic recombination, i.e., induction of DSB (double-stranded DNA breaks) does not occur in the absence of Hsk1/▶ Cdc7 (Ogino et al. 2006). Furthermore, Mer2, a factor essential for loading of DSB endonuclease Spo11, was identified to be a critical target of ▶ Cdc7 (Sasanuma et al. 2008; Wan et al. 2008). Premeiotic DNA replication can proceed albeit at slightly slower rate in *hsk1*(ts) mutant or *cdc7* as in which ▶ Cdc7 can be chemically inactivated.

On the other hand, repression of dbf4$^+$ expression regulated by the tet promoter suppressed premeiotic DNA replication in budding yeast when it was suppressed before meiosis was induced, but DNA replication was observed if dbf4$^+$ expression was suppressed later, presumably due to inadequate suppression of dbf4$^+$ expression. This result suggests that Dbf4 function is required for premeiotic DNA replication. In the latter cells, premeiotic S phase completed but the meiosis was still arrested before anaphase I. This arrest was relieved by *rec8* deletion, suggesting a crucial role of ▶ Cdc7 during meiotic chromosome segregation (Valentin et al. 2006). Indeed, Rec8 cleavage by separase is regulated by phosphorylation mediated by ▶ Cdc7 or casein kinase 1 (Katis et al. 2010). ▶ Cdc7 also regulates monopolar attachment of sister kinetochores by regulating the recruitment of the monopolin complex to kinetochores through phosphorylation of monopolin subunit Lrs4 (Matos et al. 2008). Thus, Dbf4, in a complex with ▶ Cdc7, may regulate multiple steps of meiotic cell cycle.

Other Dbf4-Related Molecules

Another ▶ Cdc7-Dbf4-related complex, the Spo4 (Cdc7-like)-Spo6(Dbf4-like) complex, is expressed in fission yeast during late meiosis and is specifically required for the sporulation stage (Nakamura et al. 2000). Kinase complexes related to Spo4-Spo6 have not been found in other species.

A second Dbf4/ASK-like molecule, Drf1/ASKL1 was identified in silico on the human genome and was shown to function as an activation subunit for human ▶ Cdc7 kinase (Montagnoli et al. 2002; Yoshizawa-Sugata et al. 2005). The expression level of Drf1/ASKL1 increases during late S/G2 and inhibition of its expression resulted in accumulation of late S-G2/M populations. In contrast to Dbf4/ASK, Drf1/ASKL1 is present mostly in the nuclear soluble fractions, not in chromatin-bound fractions. The homologue of Drf1/ASKL1 was indentified in *Xenopus* and was shown to be predominantly expressed in *Xenopus* egg extracts, while XDbf4 is the major form of the ▶ Cdc7

activation subunit in somatic cells (Takahashi and Walter 2005). Drf1/ASKL1 has been identified only in human and Xenopus.

Association of Dbf4 with Origin Sequences in Budding Yeast

One-hybrid assays showed that Dbf4 interacts with the replication origin sequences in budding yeast (Dowell et al. 1994). Mapping of the interacting segment on Dbf4 indicated motif-N as the origin-interacting domain. Thus, Dbf4 targets ▶ Cdc7 kinase at the origin of DNA replication. At the origin, ▶ Cdc7 targets pre-replicative complex (pre-RC) which is generated on chromatin during early G1. Among the components of pre-RC, MCM is the critical and conserved substrate of ▶ Cdc7 (Lei et al. 1997; Sato et al. 1997). See the section of "▶ Cdc7" for details on how ▶ Cdc7-mediated phosphorylation may activate initiation of DNA replication.

Interaction of Dbf4 with Other Replication Factors

Yeast two-hybrid analyses indicated the interaction of mouse Dbf4/ASK with Orc1, 2, 5, and 6 as well as with MCM2, 3, 4, and 7, consistent with the interaction of Dbf4 with pre-RC assembled at origins in budding yeast (Kneissl et al. 2003). In the same report, mouse ▶ Cdc7 was reported to interact with Orc1 and 6 and with MCM2, 4, 5 and 7 in two-hybrid assays.

Regulation of Expression of Dbf4 During the Cell Cycle

Expression of Dbf4 is cell cycle regulated. Regulation is generally on both transcription and protein levels. In budding yeast, transcription of Dbf4 is regulated during cell cycle, peaking during G1 (Chapman and Johnston 1989). The promoter contains a MluI cell cycle box (or MCB) and may be regulated by the MCB-binding factor (MBF). Furthermore, the budding yeast Dbf4 protein is degraded by APC during G1 phase. The protein is present during S through G2 phase, coinciding with the active ▶ Cdc7-Dbf4 kinase activity during this period. The potential degradation signal was identified in the N-terminal segment of Dbf4. Similar regulation is likely to operate for the fission yeast Dfp1/Him1 gene, which is expressed specifically during S through G2/M phase (Brown and Kelly 1998; Takeda et al. 1999).

Expression of mammalian Dbf4/ASK is also cell cycle regulated. The transcript is repressed in the quiescent cells and induced after growth stimulation. A 63-base pair ASK promoter segment was identified, which is sufficient for mediating growth stimulation (Yamada et al. 2002). This minimal promoter segment contains an Sp1 site but no canonical E2F site, but can be activated by ectopic E2F expression. Within the 63-base pair region, the Sp1 site as well as other elements are essential for stimulation by growth signals and by E2F, whereas an AT-rich sequence proximal to the coding region may serve as an element required for suppression in quiescence. Another report proposed the presence of MCB in the core promoter region of human Dbf4/ASK (Wu and Lee 2002). The Dbf4/ASK protein levels decrease during G1 phase, and a part of this may be attributed to cell cycle–dependent protein degradation.

Developmental Role of Dbf4

A role of Dbf4 in heart/eye development was suggested in *Xenopus* (Brott and Sokol 2005). Dbf4/ASK inhibits the canonical Wnt signaling pathway, possibly through interacting with Frodo. This role of Dbf4 does not involve its ability to activate Cdc7 kinase, since the Dbf4-motif-M, which is known to be essential for Cdc7 kinase activation, is not required for its role in heart development. Expression of Drf1/ASKL1 and Dbf4/ASK molecules is developmentally regulated in *Xenopus*. Drf1/ASKL1 is predominantly expressed in early development, but is later replaced by Dbf4/ASK in somatic cells (Takahashi and Walter 2005).

Those who are interested in learning more about eukaryotic DNA replication are recommended to read the reference (Masai et al. 2010).

Summary

Dbf4 is the activation subunit for Cdc7, a conserved kinase essential for initiation of DNA replication. Dbf4 is evolutionally conserved and carries three conserved motifs, motif-N, -M and, -C. Motif-M or -C interacts with Cdc7 on its own, but motif-M alone can support mitotic growth in yeast. Motif-C, the most conserved segment, is required together with motif-M for full kinase activation as well as for meiotic function of Cdc7-Dbf4. Motif-N of Dbf4 is involved in interaction with chromatin of the Cdc7-Dbf4 complex. Dbf4 may induce conformational change of Cdc7 and facilitate

its binding to ATP as well as its association with the critical substrate of the Cdc7-Dbf4 kinase complex (Kitamura et al. 2011). Second Dbf4, Drf1/ASKL1, has been discovered in human and *Xenopus*. Abundance of Dbf4 is cell cycle regulated and contributes to cell cycle oscillation of Cdc7 kinase activity.

Synonyms

GluRδ1; GluRδ2; GluD1; GluD2

Historical Background

The δ1 glutamate receptor (GluRδ1; GluD1) and the δ2 glutamate receptor (GluRδ2; GluD2) were cloned by homology screening in 1993 at the end of the "gold rush" for cloning of ionotropic glutamate receptor (iGluR) cDNA. They were regarded as orphan receptors for a long time since their endogenous ligands were unknown. GluD1 is highly expressed in hair cells of the auditory and vestibular systems in adult mice. Indeed, deletion of a gene encoding GluD1 (*grid1*) in mice leads to deficit in high-frequency hearing. In contrast, GluD2 is highly expressed in cerebellar Purkinje cells and deletion of a gene encoding GluD2 (*grid2*) results in cerebellar ataxia and characteristic phenotypes at parallel fiber (PF)–Purkinje cell

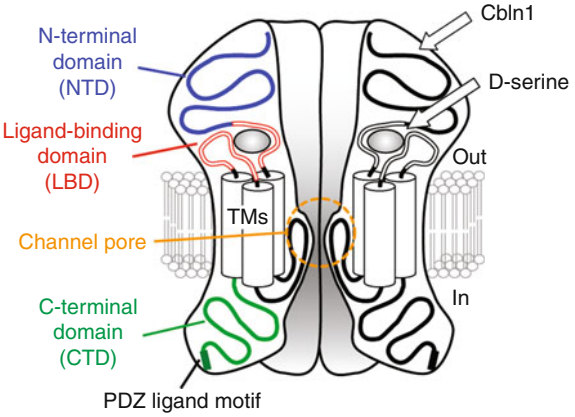
synapses. Functionally, long-term depression (LTD) of synaptic transmission, which is thought to underlie motor coordination and motor learning, is completely blunted. Morphologically, approximately 40% of dendritic spines of *grid2*-null Purkinje cells remain uninnervated by PF terminals. Although these characteristic phenotypes of *grid1*-null and *grid2*-null mice point to essential roles played by GluD1 and GluD2, mechanisms by which GluD1/2 mediate these functions have remained mostly unclear. For some original references, which have been omitted in this entry for the sake of space, please refer to reviews elsewhere (Yuzaki 2008).

Genes and Expression

The size of *grid1* and *grid2* genes is much larger (~760 kb for *grid1* and ~1.4 Mb for *grid2*) than sizes of genes encoding other iGluRs (~200 kb). This large size and a high percentage of purine nucleotides within the locus are thought to render *Grid2* susceptible to frequent spontaneous mutations in mice, called *hotfoot* (Yuzaki 2008). No spontaneous mutant mouse linked to the *grid1* locus is known so far. However, recent genome-wide association studies indicated linkage of the *GluD1* gene with bipolar disorder, major depressive disorder, and schizophrenia (Fallin et al. 2005; Guo et al. 2007; Treutlein et al. 2009). Furthermore, genome-wide copy number variation studies have implicated that *GRID1* may be associated with autism spectrum disorder (Glessner et al. 2009; Smith et al. 2009). No human diseases have been associated with the *GRID2* locus.

In addition to its high expression in hair cells, GluD1 mRNA is present at a low level in pyramidal and dentate granule cell layers of the hippocampus in adult mice. The mRNA level of GluD1 is much higher especially in caudate-putamen and anteroventral thalamic nucleus in younger mice, suggesting its role in neuronal development. Since GluD1-specific antibody is not available, there has been no immunohistochemical study describing GluD1 expression in the brain.

GluD2 expression is also not confined to cerebellar Purkinje cells. Immunohistochemical analyses of wild-type and *lurcher* mice indicate that GluD2 is expressed in several other brain regions, such as the midbrain-spinal cord (Yuzaki 2008). Quite recently, using Purkinje cell–specific *Grid2*-null mice, Yamasaki et al. reported that interneurons in the cerebellum expressed GluD2 (Yamasaki et al. 2011).



Delta Glutamate Receptor (*GluD1*, *GluD2*), Fig. 1 Presumed membrane topology of GluD2. The ligand-binding domain (LBD) is separated by transmembrane (TM) domains 1 through 3. The ligand-binding pocket, to which D-serine binds, is indicated by an *arrow*. Cbln1 binds to the most N-terminal domain (NTD) outside of the LBD (indicated by an *arrow*). The channel pore is indicated by a *dotted circle*. The most C-terminal domain (CTD) of GluD2 constitutes a PDZ ligand motif, to which PDZ proteins such as PSD-93, PTPMEG, S-SCAM, n-PIST, and delphilin bind

Structure and Function

On the basis of sequence homology with other iGluRs, the topology of GluD1/2 in the cell membrane is predicted to be similar to that of other iGluRs, which are composed of an N-terminal domain (NTD) and a bipartite ligand-binding domain (LBD) on the extracellular side of the plasma membrane, three transmembrane (TM) domains (TM1, TM3, and TM4), an ion channel-forming re-entrant loop segment (TM2 or P-loop), and a cytoplasmic C-terminal domain (CTD) (Fig. 1). GluD2 and GluD1 likely form a homomeric complex in vivo, although it is possible that a small proportion of GluD1 or GluD2 exists as a heteromer with other iGluRs, as observed in vitro (Yuzaki 2008).

Extracellular N-Terminal Domain (NTD)

The NTD of iGluRs contributes to receptor assembly and efficient surface transport of the receptor. Similarly, various small in-frame deletions in the NTD of GluD2 found in many *hotfoot* mutant mice impair the homomeric oligomerization of GluD2 and its

Delta Glutamate Receptor (*GluD1*, *GluD2*), Table 1 Summary of the phenotypes of *grid2*-null mice expressing various GluD2 transgenes

subsequent exit from the endoplasmic reticulum to reach the cell surface (Yuzaki 2008). These findings suggest that, like other iGluRs, the NTD of GluD2 is essential for receptor assembly, and that unstable oligomers may be retained in the endoplasmic reticulum by the quality control mechanism.

Virally mediated expression of wild-type GluD2 or chimeric glutamate receptor 6 (GluK2) that had the NTD of GluD2 completely rescues impaired PF synaptogenesis in *grid2*-null mice, while expression of GluD2 lacking the NTD or the chimeric GluD2 with the NTD of GluK2 does not (Table 1). Thus, the NTD of GluD2 is necessary and sufficient for synapse formation between PFs and Purkinje cells (Kakegawa et al. 2009). Recently, the NTD of GluD2 was shown to bind to ▶ Cbln1, which is secreted from cerebellar granule cells (Matsuda et al. 2010). ▶ Cbln1 also binds to neurexin on the presynaptic terminals (Matsuda and Yuzaki 2011). These findings indicate that the NTD of GluD2 plays a crucial role in formation and maintenance of PF synapses by forming a tripartite complex consisting of GluD2, ▶ Cbln1, and neurexin at PF-Purkinje cell synapses. Since ▶ Cbln1 also bind to the NTD of GluD1 to promote synaptogenesis in cultured hippocampal neurons (Matsuda et al. 2010; Matsuda and Yuzaki 2011), the NTD of GluD1 may also play a similar role in neurons expressing GluD1.

Extracellular Ligand-Binding Domain (LBD)

An arginine (R) residue highly conserved in the LBD of iGluRs is essential for binding to amino acid ligands, including glutamate, aspartate, glutamine, glycine, lysine, serine, arginine, ornithine, and histidine. Surprisingly, the mutant GluD2 transgene (GluD2$^{R/K}$), in which the conserved arginine is replaced by lysine (K) to lose the ability of ligand binding, still rescues all the abnormal phenotypes of adult *grid2*-null mice (Table 1) (Hirai et al. 2005). Therefore, no L-glutamate analog binding is likely required for GluD2 to achieve its functions at least in adult mice.

The LBD of GluD2 was crystallized and shown to bind to D-serine (Fig. 1) in a manner dependent on the arginine residue (Naur et al. 2007). Thus, D-serine fails to bind to GluD2$^{R/K}$. Interestingly, *grid2*-null mice expressing GluD2$^{R/K}$ exhibited impaired LTD and motor dyscoordination during development (Kakegawa et al. 2011). Indeed, D-serine is released from Bergmann glia after the burst stimulation of PFs in immature, but not mature, cerebellum because of developmental upregulation of D-amino acid oxidase (DAO), a D-serine-degrading enzyme. These findings indicate that D-serine serves as an endogenous ligand for GluD2 in immature cerebellum. Although D-serine also binds to GluD1 (Yadav et al. 2011), its physiological significance remains to be determined.

Channel Pore-Forming Domain

A point mutation in the TM3 of GluD2 ($GluD2^{Lc}$) makes GluD2 channel constitutively open, causing Purkinje cell death in *lurcher* mice (Zuo et al. 1997). The Ca^{2+} permeability of $GluD2^{Lc}$ is abolished by replacing glutamine (Q) with arginine (R) at the Q/R site ($GluD2^{Q/R}$) (Kohda et al. 2000; Kakegawa et al. 2007a). However, when a mutant $GluD2^{Q/R}$ transgene is introduced into *grid2*-null Purkinje cells, LTD and other major abnormalities of *grid2*-null mice are rescued (Table 1). These finding indicate that although cerebellar LTD depends on Ca^{2+} influx, GluD2 unlikely serves as a Ca^{2+}-permeable channel (Kakegawa et al. 2007a).

The channel activity of $GluD2^{Lc}$ is abolished by replacing valine (V) with arginine (R) at one position upstream of the Q/R site ($GluD2^{V/R}$) (Kakegawa et al. 2007b). Surprisingly, expression of $GluD2^{V/R}$ in *grid2*-null Purkinje cells by Sindbis virus completely restored LTD and motor coordination (Table 1), indicating that channel activity of GluD2 is not required for inducing LTD. Together, although there is still a possibility that GluD2 might function as an ion channel under some circumstances, channel activities are not required to achieve major functions of GluD2 at PF-Purkinje cell synapses.

Cytoplasmic C-Terminal Domain (CTD)

The cytoplasmic CTD of GluD2 binds to many intracellular proteins such as Shank, PICK1, and the adaptor protein complex ▶ AP-4. In addition, the most CTD of GluD2 constitutes a PDZ ligand motif, to which PDZ proteins, such as PSD-93, PTPMEG, S-SCAM, n-PIST, and delphilin, bind (Yuzaki 2008). When the mutant GluD2 lacking the C-terminal seven amino acids ($GluD2^{\Delta CT7}$) is expressed in *grid2*-null PCs, it fails to rescue abrogated LTD and impaired delayed eyeblink conditioning, a cerebellum-dependent motor learning, in *grid2*-null mice (Table 1) (Kohda et al. 2007; Kakegawa et al. 2008). Furthermore, D-serine binding to GluD2 failed to induce LTD when the CTD is deleted (Kakegawa et al. 2011). In contrast, the mutant transgene $GluD2^{\Delta CT7}$ completely restores abnormal PF synapse formation (Kakegawa et al. 2008). These findings indicate that signaling via the CTD of GluD2 is not necessary for morphological integrity at PF synapses, but absolutely required for the induction of LTD and motor learning.

Summary

Although GluD2 was referred to an orphan receptor for a long time, it now has two unusual endogenous ligands – ▶ Cbln1 and D-serine. The extracellular NTD of GluD2 plays a crucial role in the formation and maintenance of PF synapses by forming a tripartite complex with ▶ Cbln1 and its presynaptic receptor neurexin in the cerebellum. On the other hand, the LBD of GluD2 binds to D-serine, which is released from cerebellar Bergman glia during early developmental period, to regulate LTD and motor learning. Although signaling via the CTD of GluD2 is required for the induction of LTD and motor learning, how this is achieved by intracellular proteins that bind to the CTD remains unclear. In addition, whether ▶ Cbln1 binding to the NTD and D-serine binding to the LBD interact with each other and induce conformational changes to the whole GluD2 complex remains to be determined. Finally, although ▶ Cbln1 (and Cbln2) and D-serine bind to GluD1, it is currently unclear whether GluD1 regulates synaptic functions similar to those exerted by GluD2 in various brain regions in vivo.

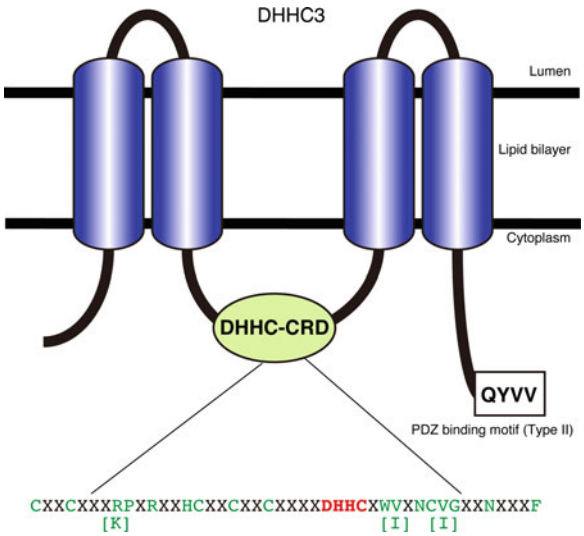
Synonyms

Palmitoyl acyl transferase (PAT); Palmitoylating enzyme; zDHHC proteins

Historical Background

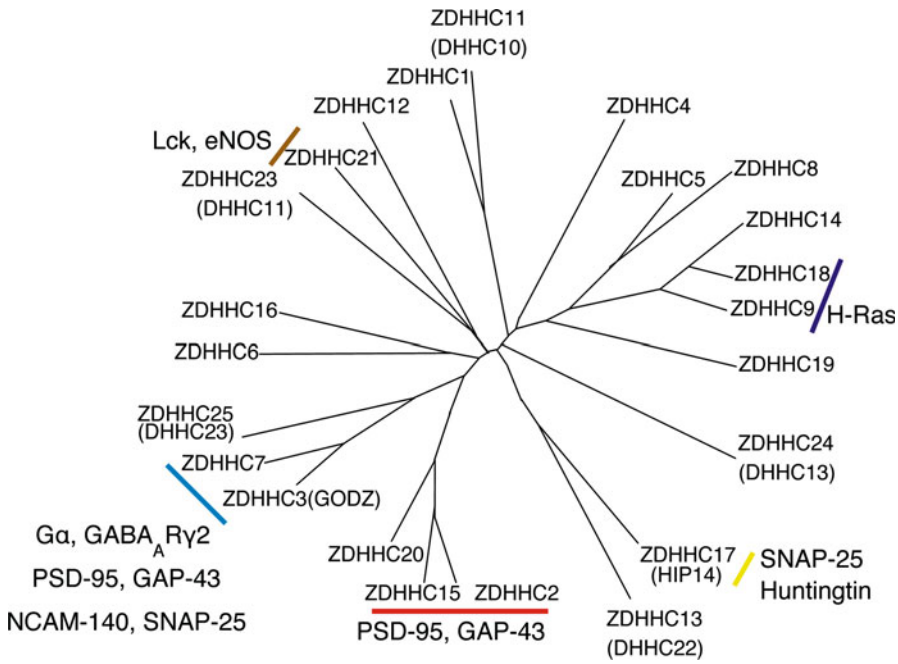
Protein palmitoylation is the first discovered and the most common lipid modification. This posttranslational change involves addition of the saturated 16-carbon palmitate to specific cysteine residues by a labile thioester linkage (Linder and Deschenes 2007). Although reversible palmitoylation was discovered over 30 years ago, the enzymes that add palmitate to proteins (palmitoyl acyl transferases, PATs) and those that cleave the thioester bond (palmitoyl protein thioesterases, PPTs) had been elusive. In 2002, genetic screening in yeast identified proteins that mediate PAT activity. Erf2/4 (Lobo et al. 2002) and Akr1 (Roth et al. 2002) were identified as PATs for yeast Ras2 and Yck2, respectively. Erf2 and Akr1 share a conserved DHHC (Asp-His-His-Cys) cysteine-rich domain (CRD) (Fig. 1) and have four or six transmembrane domains. The DHHC sequence and its surrounding CRD sequence are essential for their enzymatic activity. In 2004, 23 kinds of mammalian DHHC proteins were systematically isolated and some of them were characterized as PATs (Fukata et al. 2004). DHHC proteins have now emerged as evolutionally conserved PATs from plants, yeast (7 genes), *Caenorhabditis elegans* (15 genes), *Drosophila melanogaster* (22 genes) to mammals (24 genes).



DHHC Proteins, Fig. 1 The domain structure of DHHC3, a prototype of mammalian DHHC proteins. DHHC proteins contain four or six transmembrane domains and a conserved DHHC (Asp-His-His-Cys) motif in the cytoplasmic cysteine-rich domain (CRD). Some members of DHHC proteins have unique motif/domain, such as PDZ-binding motif (in DHHC3). The consensus sequence of DHHC-CRD is indicated (*green* and *red*). X, a variety of amino acids

Subfamily Classification of Mammalian DHHC Proteins

The large family of DHHC proteins can be classified into several subfamilies based on the homology of the DHHC-CRD core catalytic domains. DHHC2 and DHHC15 belong to one subfamily, while DHHC3 and DHHC7 form another subfamily. Importantly, DHHC proteins in the same subfamily often share their substrates (Fig. 2) (Fukata and Fukata 2010; Greaves and Chamberlain 2011). DHHC3/7 subfamily palmitoylates most of palmitoyl-proteins, such as PSD-95, GAP43, Gα, SNAP-25, NCAM-140, and $GABA_A$ receptor γ subunit. In contrast, DHHC2/15 subfamily more specifically palmitoylates PSD-95 and GAP43 (Fukata et al. 2004), but not Gα, NCAM-140 nor $GABA_A$ receptor γ subunit (Fig. 2). H/N-Ras is the only well-established substrate for DHHC9/18 subfamily. Because the number of identified substrate-enzyme pairs is limited, enzymatic activities of some DHHC proteins, such as DHHC1/10 subfamily, still remain undocumented.



DHHC Proteins, Fig. 2 Phylogenetic tree of mammalian DHHC protein family members. 23 DHHC proteins can be categorized into several subfamilies based on the homology of the catalytic DHHC domains. For example, DHHC2 and DHHC15 belong to one subfamily (in *red*), while DHHC3 and DHHC7 form another subfamily (in *blue*). The discovery of this mammalian DHHC protein family and the establishment of simple screening system using DHHC protein library have facilitated identification of palmitoyl substrate-enzyme pairs. Importantly, the same subfamily of DHHC proteins often shares substrates, for example, DHHC2/15 subfamily specifically palmitoylates PSD-95 and GAP-43. DHHC3/7 subfamily palmitoylates most of palmitoyl-proteins, such as PSD-95, GAP-43, Gα, GABA$_A$Rγ2, and SNAP-25. DHHC9/18 subfamily (in *purple*) palmitoylates H-Ras, DHHC21 (in *brown*) palmitoylates Lck and eNOS, and DHHC17 (in *yellow*) palmitoylates SNAP-25 and huntingtin. Note that some DHHC clone numbers initially collected by Fukata et al. (2004) are different from a current standard nomenclature (ZDHHC clone numbers) (Fukata and Fukata 2010). At present, 24 zDHHC genes have been annotated in the mouse genome (ZDHHC22 is recently annotated)

Enzymatic and Regulatory Mechanisms for DHHC Proteins

DHHC-CRD region is the catalytic core site as mutation of the cysteine in the DHHC motif makes DHHC proteins catalytically inactive. Cysteines in this DHHC-CRD region are often autopalmitoylated (Roth et al. 2002; Fukata et al. 2004). Two mechanisms for palmitate transfer to a substrate have been proposed: (1) DHHC protein directly transfers palmitate from palmitoyl-CoA to the substrate and (2) DHHC protein first forms a thioester intermediate with palmitate (i.e., autopalmitoylation of DHHC proteins), followed by the transfer of the palmitate to the substrate. Recent mutational analysis in yeast revealed that palmitoylation reaction by DHHC proteins, at least yeast Erf2, is mediated by the latter two-step reaction (Mitchell et al. 2010). In addition to the catalytically critical DHHC-CRD domain, some DHHC proteins have regulatory regions such as SH3 domain and ankyrin repeats at the C-terminal or N-terminal cytoplasmic regions. These domains may recruit specific substrate proteins to the DHHC enzyme. In fact, ankyrin repeats of DHHC17/HIP14 contribute to determining the substrate specificity (Huang et al. 2009).

DHHC3/7, 17, and 2/15 subfamily members do not require additional proteins (cofactors) for their PAT activity. In contrast, yeast Erf2 and its mammalian ortholog DHHC9 are inactive PATs in the absence of accessory proteins, Erf4 (for Erf2) or GCP16 (for DHHC9; Golgi complex protein of 16 kDa) (Swarthout et al. 2005). So far, the regulatory mechanism that directly activates or inactivates DHHC PAT activity is not known.

Akin to protein phosphorylation, protein palmitoylation is a reversible reaction that can be

regulated by specific extracellular signals, for example, β-adrenergic receptor activation accelerates depalmitoylation and palmitoylation levels of $G\alpha_s$ (Degtyarev et al. 1993; Wedegaertner and Bourne 1994). Palmitoylation of ▶ LAT, linker for activation of T-cells, is reduced by T-cell receptor activation by ionomycin (Hundt et al. 2006). Also, glutamate-induced synaptic activity induces depalmitoylation of PSD-95 scaffolding protein (El-Husseini et al. 2002) and Cdc42 small GTPase (Kang et al. 2008). It is conceivable that unidentified PPTs, rather than DHHC-PATs, might play dominant roles in these processes. In contrast, blockade of neuronal activity rapidly increases PSD-95 palmitoylation. This dynamic palmitoylation is mediated by synaptic translocation of a PSD-95 PAT, DHHC2. This contrasts with the constitutive PSD-95 palmitoylation mediated by Golgi-resident DHHC3. Thus, the large family of DHHC palmitoylating enzymes are differentially localized and regulated in polarized cells (Noritake et al. 2009).

Inhibitors of DHHC Proteins

Several lipid-based compounds including 2-bromopalmitate (2BP), tunicamycin, and cerulenin have been used to inhibit protein palmitoylation (Ducker et al. 2006). Among them, the palmitate analog 2BP has been the most widely used. 2BP irreversibly inhibits DHHC-mediated palmitoylation directly acting on DHHC proteins in vitro (Fukata et al. 2004; Jennings et al. 2009), although 2BP also inhibits fatty acyl-CoA ligase and other enzymes involved in lipid metabolism in cells. In addition, 2-(2-hydroxy-5-nitrobenzylidene)-benzo[b]thiophen-3-one (Compound V) reversibly inhibits DHHC-mediated palmitoylation (Jennings et al. 2009). Because these inhibitors are not specific for individual DHHC-PATs, development of DHHC member-specific inhibitors is awaited.

Pathophysiological Significance of DHHC Proteins

DHHC protein members are linked to several human diseases (Table 1). DHHC8 is one of susceptibility genes for schizophrenia. Originally, microdeletions of human chromosome 22q11.2 locus, containing the DHHC8 gene, were reported to cause cognitive deficits and be associated with a high risk of developing schizophrenia. DHHC8 knockout mice showed behavioral phenotypes, a deficiency in prepulse inhibition and decreased exploratory activity in a new environment, and abnormalities in dendritic spines of neurons (Mukai et al. 2004; Mukai et al. 2008). DHHC17/HIP14 is an associated protein with huntingtin protein, which is a causal gene for Huntington's disease. DHHC17 palmitoylates huntingtin and regulates its trafficking and function (Yanai et al. 2006). Polyglutamine expansion of huntingtin gene reduces interaction of huntingtin protein with DHHC17, resulting in decreased huntingtin palmitoylation. Knockout mice of DHHC17/HIP14 display behavioral, biochemical, and neuropathological defects that are reminiscent of Huntington's disease (Singaraja et al. 2011). Finally, mutations of DHHC9 and DHHC15 have been reported to be associated with X-linked mental retardation.

DHHC Proteins, Table 1 Human disorders associated with DHHC proteins

DHHC protein	Disorders associated with DHHC-PATs
DHHC2	Colorectal cancer
DHHC8	Schizophrenia
DHHC9	X-linked mental retardation
	Colorectal cancer
DHHC11	Bladder cancer
DHHC15	X-linked mental retardation
DHHC17/HIP14	Huntington's disease

Summary

DHHC proteins are evolutionally conserved palmitoylating enzymes and add palmitates to proteins at specific cysteine residues by a reversible thioester linkage. DHHC proteins are integral membrane proteins with DHHC-CRD domain as a catalytic domain. Enzymatic activity and subcellular distribution of DHHC proteins can be dynamically regulated by extracellular stimulations. However, signal transduction pathways from receptors on the plasma membrane to DHHC proteins are poorly understood. Because mutations of DHHC proteins are closely associated with human diseases like schizophrenia and cancers, it would be beneficial to develop drugs acting on a specific DHHC protein for human health.

Historical Background

DLK is a serine/threonine kinase that belongs to the mixed-lineage kinase (MLK) family of mitogen-activated protein kinase kinase kinases (MAPKKKs) (Gallo and Johnson 2002). It was discovered in 1994 as a protein differentially expressed during the retinoic-acid-induced neuronal differentiation of human NT2 teratocarcinoma cells and originally denoted zipper protein kinase (ZPK, Reddy and Pleasure 1994). Parallel and subsequent studies led to the identification and cloning of the mouse and rat homologs of ZPK, respectively termed DLK (Holzman et al. 1994) and MAP kinase upstream kinase (MUK, Hirai et al. 1996).

Structure, Expression, and Subcellular Localization

DLK is a 120 kDa protein that shares with other MLKs structural characteristics unique among the protein kinase family, namely a catalytic domain hybrid between those found in serine/threonine and tyrosine kinases, and two leucine zipper motifs involved in protein dimerization and activation (Gallo and Johnson 2002). DLK also possesses glycine-, serine-, and proline-rich sequences located upstream and downstream of the catalytic domain that are presumably important for mediating protein interactions and/or for controlling subcellular localization (Fig. 1).

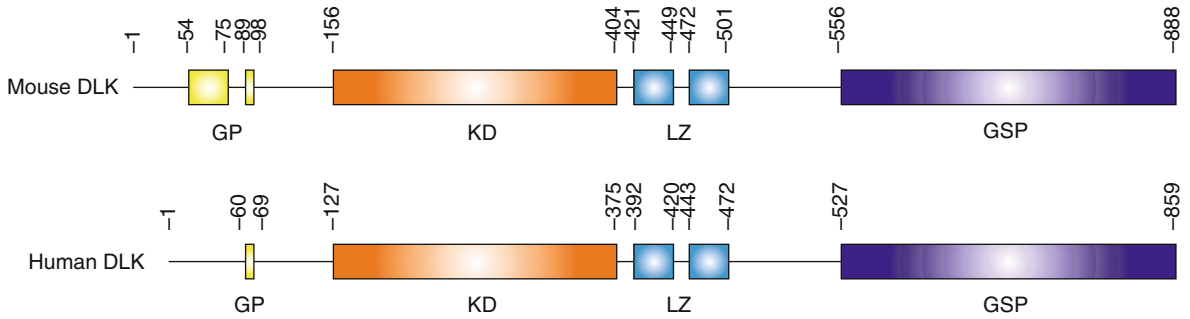
Based on Northern blot analysis of human and mouse tissues, the highest levels of DLK mRNA were observed in brain and kidney (Reddy and Pleasure 1994; Holzman et al. 1994). DLK mRNA was also detected by in situ hybridization in mouse skin, stomach, small intestine, liver, pancreas, and testis (Nadeau et al. 1997). In all these tissues, the expression of DLK mRNA increases with development and correlates with areas occupied by differentiated rather than proliferating cells (Nadeau et al. 1997). For example, in developing mouse skin, DLK mRNA expression was detected in the suprabasal cell layers of the epidermis but not in the innermost basal layer, which contains mitotically active cells. Consistently, the DLK protein is specifically expressed in the differentiated granular layer of human epidermis (Robitaille et al. 2005).

During mouse brain development, the DLK protein is most abundant in neurons of the subventricular zone and intermediate zone, and found to be preferentially localized in axons, where it is tightly associated with the microtubules (Hirai et al. 2002). DLK also localizes on Golgi apparatus in cultured embryonic cortical cells and NIH 3T3 fibroblasts (Hirai et al. 2002).

Signaling Properties and Regulation

DLK is a MAPKKK that serves as a pivotal component of the mitogen-activated protein kinase (MAPK) pathways, of which the best characterized in mammals are: extracellular signal-regulated kinases (ERKs), p38 kinases, and c-Jun N-terminal kinases (JNKs) (Gallo and Johnson 2002). The MAPKs are essential for transducing extracellular signals that regulate different cellular responses such as growth, differentiation, migration, survival, death, and metabolism (Gallo and Johnson 2002). Similar to other MLKs, DLK preferentially activates JNK, potentially by phosphorylating the JNK direct upstream activators MAPK kinase (MKK) 4 and/or 7 (Fig. 2) (Gallo and Johnson 2002). DLK also causes weak activation of p38 MAPK when overexpressed in COS and NIH 3T3 cells (Gallo and Johnson 2002). More recently, DLK was found to be required for platelet-derived growth factor (PDGF)-stimulated ERK activation in NIH 3T3 cells (Daviau et al. 2009).

To date, very little is known about the molecular mechanisms regulating DLK activation and signal suppression. Current evidence suggests that dimerization or oligomerization of DLK mediated by the leucine zipper motifs is a prerequisite for autophosphorylation, activation, and stimulation of the JNK pathway (Gallo and Johnson 2002). Another important mechanism by which DLK is proposed to be regulated is through changes in its phosphorylation status. This idea is supported by the observation that a fraction of cellular DLK is phosphorylated under normal conditions in vivo, and that phosphorylation increases substantially in response to okadaic acid, an inhibitor of protein phosphatases 1 and 2A (PP1 and PP2A) (Gallo and Johnson 2002). Recent work also indicates that vanadate, a protein tyrosine phosphatase inhibitor, and



DLK (Dual Leucine Zipper-Bearing Kinase), Fig. 1 Primary structures of mouse and human DLK. Both proteins share 99% identity within their catalytic domains and 95% identity throughout their overall primary structure. The most significant difference between mouse and human DLK resides in the amino (N)-terminal extracatalytic region, where an additional stretch of 33 amino acids is found in the murine sequence. Numbers indicate positions relative to the first amino acid. *GP* Gly, Pro-rich domain; *KD* Kinase domain; *LZ* Leucine zipper motif; *GSP* Gly, Ser, Pro-rich domain

PDGF induce ▶ Src-dependent tyrosine phosphorylation and activation of endogenous DLK in mouse NIH 3T3 cells (Daviau et al. 2009).

Work from a number of laboratories has also established that the regulation of DLK is achieved by heterologous interactions with various cellular proteins. The binding of DLK to these proteins, in particular the scaffold JNK-interacting protein (JIP)-1 and MUK-binding inhibitory protein (MBIP), plays an important role in DLK regulation by preventing its dimerization and activation (Gallo and Johnson 2002; Fukuyama et al. 2000). Furthermore, other studies carried out in mouse fibroblasts have revealed that the active form of DLK interacts with C terminus of Hsc70-interacting protein (CHIP), a U-box-dependent E3 ubiquitin ligase that promotes its ubiquitination and subsequent degradation (Daviau et al. 2006). Ubiquitin-mediated degradation constitutes a significant mechanism for regulation of DLK levels, as its fly and worm orthologues are down-regulated by an E3 ubiquitin ligase, termed Highwire/RPM-1, which is required for synaptic growth (Nakata et al. 2005; Collins et al. 2006). Other mechanisms besides degradation may also play a role in controlling the steady-state level of DLK. For example, it was shown in cell lines from different origins that apoptotic stimuli promote the stabilization of JNK pathway components like ▶ MLK3, DLK, and JIP (Xu et al. 2005). Interestingly, inhibition of JNK activity or expression blocked this effect, suggesting that JNK contributes to MLK stabilization through a positive feedback loop mechanism. Taken together, these results suggest that the decision of whether DLK undergoes degradation or stabilization probably depends on the nature and duration of the stimulus, the cell type, as well as the identity of its signaling partners.

Biological Functions

In vitro studies with different types of cells, including neurons, fibroblasts, epithelial cells, and preadipocytes,

identified a role for DLK in regulation of apoptosis, differentiation, and axonal growth. For example, in rat pheochromocytoma PC12 cells and sympathetic neurons, ectopic expression of DLK induces apoptosis, whereas kinase-deficient DLK severely inhibits death caused by nerve growth factor deprivation (Xu et al. 2001). Additionally, down-regulation of DLK by RNA interference in mouse NIH 3T3 fibroblasts and human MDA-MB-231 breast cancer epithelial cells blocks the apoptotic response induced by calphostin C (Robitaille et al. 2008). As stated above, DLK exhibits a differentiation-associated localization in skin epidermis. Consistently, DLK overexpression in poorly differentiated normal keratinocytes is sufficient to induce phenotypic changes associated with keratinocyte terminal differentiation, including up-regulation of filaggrin expression, DNA fragmentation, activation of transglutaminases, and formation of corneocytes (Robitaille et al. 2005). Other evidence suggests that DLK may also play a role in adipocyte cell differentiation. In 3T3-L1 cells induced to undergo adipocyte differentiation, DLK expression is up-regulated, and its loss by RNA interference completely blocks the accumulation of lipid droplets as well as the expression of the adipogenic markers adiponectin and fatty acid synthase. In agreement with this, cells lacking DLK show significantly less expression of the master regulators of adipogenesis, peroxisome proliferator-activated receptor (PPAR)-γ2 and the CCAAT enhancer-binding protein (C/EBP)α (Couture et al. 2009). Finally, using knockdown approaches, it was recently observed that DLK is required for neurite extension in both PC12 cells and mouse primary cortical neurons (Eto et al. 2010). Taken together, these data indicate that DLK may fulfill different functions, depending on the cell type and/or the stimuli.

Considerable progress has also been made within the last few years in understanding the *in vivo* biological functions of DLK. In mice, the knockout of the *DLK* gene results in a lethal phenotype around birth (Hirai et al. 2006), suggesting that it might have a crucial role during embryogenesis and organogenesis. Embryos lacking DLK show abnormal development of the brain characterized by defects in anterior commissure formation and axon growth of neocortical pyramidal neurons (Hirai et al. 2006). In addition, these mice display reduced JNK activity and reduced phosphorylation of the microtubule-associated protein doublecortin. In parallel to the knockout studies, Miller et al. (2009) generated mice with a gene-trap mutation of *DLK* and showed that axons of this mouse were protected from degeneration after transection, demonstrating an absolute requirement for this enzyme in the neuronal response to injury. Interestingly, this function seems to be conserved throughout evolution, since a dramatic defect in axon degeneration or regeneration after injury has been noticed in *Drosophila* and *C. elegans* mutants defective in *Wallenda* and *DLK-1*, the fly and worm orthologues of DLK respectively (Miller et al. 2009; Hammarlund et al. 2009). Thus, DLK appears to be a pivotal signaling component for regulation of axon growth and stress response in neuronal cells.

Summary

DLK is a serine/threonine kinase that functions as an upstream activator of the MAPK pathways. It is expressed in a tissue-specific manner and regulated by mechanisms that involve phosphorylation, interactions with different protein partners, and ubiquitin-mediated degradation. The functions of DLK are diverse and include regulation of development, cell differentiation, and apoptosis. Recent findings from analyses of mouse, fly, and worm mutants defective in *DLK* or its invertebrate orthologues show interestingly that this enzyme may also be required for the neuronal response to injury. Thus, DLK seems to be a key regulator for various fundamental biological processes, although the precise molecular mechanisms by which it mediates such effects are still elusive.

Acknowledgments We thank the Natural Sciences and Engineering Research Council of Canada for its financial support. We also apologize to our colleagues whose work could not be cited due to space limitations.

DOCK2; Dedicator of Cytokinesis 2

Hiroshi Nishihara
Graduate School of Medicine, Laboratory of Translational Pathology, Hokkaido University, Sapporo, Japan

Synonyms

FLJ46592; KIAA0209

Historical Background

DOCK2 was initially designated by Nishihara et al. in 1999 (Nishihara et al. 1999) as a hematopoietic cell-specific homologue of the CDM (*c*ed-5 of *Caenorhabditis elegans*, *D*OCK180 of humans, and *m*yoblast city of *Drosophila melanogaster*) family proteins. The name "DOCK" was originally designated as "*D*ownstream *o*f *CRK*" for DOCK180, an archetype of CDM family proteins in 1996 (Hasegawa et al. 1996).

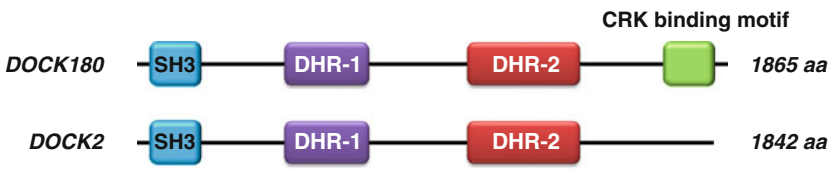
Molecular Mechanism of DOCK2 as a Rac-Specific GEF (Guanine Nucleotide Exchange Factor)

In mammals, 11 DOCK180-related proteins have been identified, and the family members can be subcategorized into four groups denoted DOCK-A, -B, -C, and -D, and DOCK2 belongs to DOCK-A as well as DOCK180 (Fig. 1a) (Cote and Vuori 2007). The structural analysis revealed that DOCK2 consists of

a

Subgroups	***DOCK-A***	DOCK-B	DOCK-C	DOCK-D
Human DOCK -related proteins	DOCK180 ***DOCK2*** DOCK5	DOCK3 DOCK4	DOCK6 DOCK7 DOCK8	DOCK9 DOCK10 DOCK11
Target GTPase	Rac	Rac	Rac Cdc42	Cdc42

b



DHR: DOCK homology region, aa; amino acids.

DOCK2; Dedicator of Cytokinesis 2, Fig. 1 (**a**) The four subfamilies of human DOCK180-related proteins (DOCK-A, -B, -C, and -D) and the target small GTPases are indicated. DOCK2 belongs to DOCK-A and exclusively activates Rac, but not Cdc42. (**b**) Schematic diagram of the structure of the human DOCK180 and DOCK2. The DHR-1 domain is a unique evolutionarily conserved domain in all DOCK180-related proteins, and in the case of DOCK180, the DHR-1 domain was revealed to mediate a specific interaction with PtdIns (3, 5)P_2 and PtdIns (3, 4, 5)P_3 signaling lipids. The DHR-2 domains have been shown to interact with the GTPases of the Rho family including Rac1, 2 and Cdc42 leading to the exchange of GDP for GTP. Inactivation of the DHR-2 domain in DOCK180 has been shown to abrogate Rac activation, cell migration, and phagocytosis, highlighting the significance of this domain in the biological function of the DOCK180-related proteins. DOCK2 lacks the Crk-binding motif in the C-terminus which is an indispensable region in DOCK180 for binding to CRK, while CrkL was identified as a binding partner to DOCK2 through its SH3 domain in the N-terminus

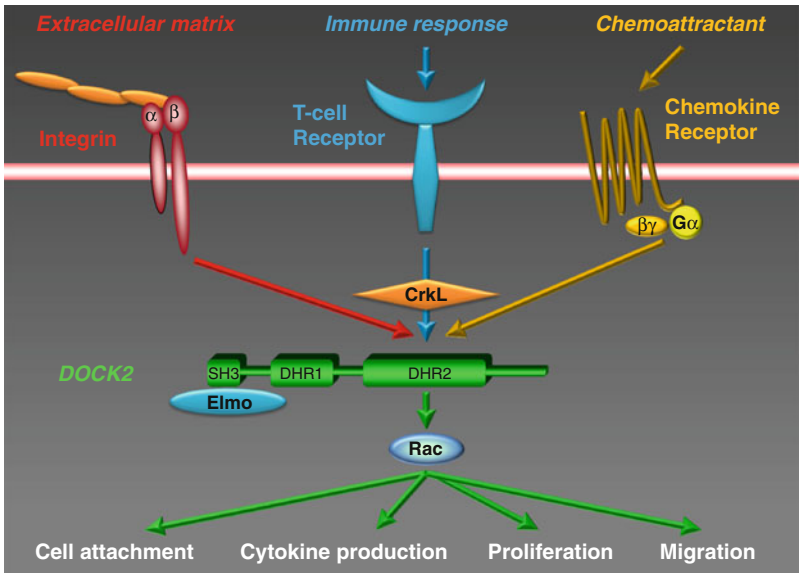
an SH3 domain in the N-terminus and DHR (DOCK homology region) -1/2 in the middle to C-terminus (Fig. 1b) (Cote and Vuori 2002). DHR-2 is highly conserved throughout DOCK180-related proteins and identified as a Rac-specific GEF in DOCK2, although DHR-2 in other family proteins, such as DOCK3, may activate Cdc-42. DOCK2 lacks the PXXP motif in the C-terminus which is an indispensable region in DOCK180 for binding to CRK (Hasegawa et al. 1996), while CrkL was identified as a binding partner to DOCK2 through its SH3 domain in the N-terminus (Fig. 2) (Nishihara et al. 2002a). Similar to DOCK180, the interaction of DOCK2 with ELMO1, which was shown to increase the catalytic activity of DOCK180 toward Rac (Lu et al. 2004), was reported (Janardhan et al. 2004; Sanui et al. 2003b).

DOCK2 in Cytoskeletal Regulation and Tumorigenesis

DOCK2 regulates the motility of lymphocytes through actin-cytoskeletal reorganization and also cell proliferation in several types of B lymphocytes through the activation of Rac (Nishihara et al. 2002a; Sanui et al. 2003b; Wang et al. 2010), although DOCK2 itself, and even Rac, seems to lack the oncogenic ability. DOCK2-knockdown of the B-cell lymphoma cell lines using shRNA represented abrogated tumor formation in nude mice, suggesting the prominent role of DOCK2 in the progression of hematopoietic malignancy through DOCK2-Rac-ERK pathway (Wang et al. 2010). In fact, the high-level expression of DOCK2 mRNA in the leukemia/lymphoma cells obtained from the patients' blood samples has been ascertained (unpublished data).

The Immunomodulatory Role of DOCK2 in Lymphocytes

Because of the exclusive expression of DOCK2 in hematopoietic cells (Nishihara et al. 1999), a hematopoietic cell-specific function such as regulation of immunity had been estimated. The analysis using DOCK2 knockout mice revealed the failure of T- and B-lymphocyte migration toward cytokines in vitro and the lack of their homing into the lymph nodes and the spleen in vivo



DOCK2; Dedicator of Cytokinesis 2, Fig. 2 The signal transduction through DOCK2. DOCK2 transmits the signals from the several types of the integrins and receptors to small GTPase Rac, and regulates the cell motility, proliferation, and immune reaction of the hematopoietic cells. The protein interaction with CrkL and Elmo has been noted in the regulation of these cellular functions

(Fukui et al. 2001). The activation of DOCK2-Rac pathway is indispensable for CXCL12 (SDF-1)-stimulated human T-lymphocyte adhesion which is mediated by alpha4beta1 integrin (Gollmer et al. 2009), and also CCL21-mediated co-stimulation in CD4 (+) T cells (Garcia-Bernal et al. 2006). In addition, the role of DOCK2 in T-cell receptor (TCR) has been clarified: The in vitro analysis using the dominant negative form of DOCK2 confirmed that DOCK2 mediates TCR-dependent activation of Rac2 leading to the regulation of IL-2 (interleukin-2) promoter activity (Nishihara et al. 2002b), and in DOCK2$^{-/-}$ T cells, antigen-induced translocation of TCR and lipid rafts was significantly impaired, resulting in a marked reduction of antigen-specific T-cell proliferation (Sanui et al. 2003a). Furthermore, DOCK2 seems to be required in T-cell precursors for development into natural killer T cells (Kunisaki et al. 2006b). Taken together, these results indicate that DOCK2 is a key regulator of immunity, and explain the fact that cardiac allografts in DOCK2 knockout mice across a complete mismatch of the major histocompatibility complex molecules were not rejected by preventing potentially alloreactive T cells from recruiting into secondary lymphoid organs (Jiang et al. 2005).

DOCK2 in Myeloid Cell Lineage

Dendritic cells (DCs), macrophages, and neutrophils are also key players in immune response. The equivalent expression of DOCK2 during the maturation from CD34 (+)-myeloid precursor cells to these cells has been observed (unpublished data); therefore, the ubiquitous cellular functions of DOCK2 in this cell lineage are anticipated. In fact, the migration of neutrophil and plasmacytoid DCs was significantly abrogated in DOCK2$^{-/-}$ mice, although myeloid DCs did not show any defects in migration, suggesting the presence of alternative molecules to activate Rac during chemotaxis in myeloid DCs (Gotoh et al. 2008; Kunisaki et al. 2006a). Furthermore, DOCK2 is essential for toll-like receptor (TLR) 7- and 9- mediated interferon-alpha induction in plasmacytoid DCs, which play a key role in antiviral immunity (Gotoh et al. 2010).

Summary

As shown above, DOCK2, i.e., activation of Rac by DOCK2, plays indispensable roles in the regulation of immune response and also in the development of hematopoietic malignancy (Fig. 2). The activation of Rac is modulated by DHR-2, and several effectors for activated Rac have been identified, although the molecular mechanism of the activation of DOCK2 is still unclear. In DOCK180, autoregulation of GEF activity by its SH3 domain, ubiquitylation, and phosphorylation associated with Elmo are regarded, although the details including the upstream molecules remain undefined (Cote and Vuori 2007).

Because deficiency of DOCK2 resulted in impairment of the immune system, pharmacological inhibition of DOCK2 could be beneficial in the treatment for autoimmune diseases (Gotoh et al. 2010) and in preventing graft rejection (Jiang et al. 2005), as well as in the regulation of the progression of hematopoietic malignancy including malignant lymphoma and leukemia (Wang et al. 2010). In addition, DOCK2+ microglia which are associated with human Alzheimer's disease have been identified in a recent report (Cimino et al. 2009), suggesting that DOCK2 could be a possible therapeutic target for neurodegenerative disorders.

DAP kinase-related apoptotic kinase 2; STK17B

Historical Background

► DRAK2 is a serine/threonine kinase of the death associate protein kinase (DAPK) family. Of this family, DRAK2 is most similar to DRAK1, and these two kinases may represent a unique family. DRAK1 and DRAK2 were originally identified using a polymerase chain reaction (PCR) screen to identify additional DAPK members, and was first thought to be primarily involved in promoting apoptosis (Sanjo et al. 1998). While humans have genes for both DRAK1 and DRAK2, mice lack a DRAK1 gene. Although ectopic expression of DRAK2 in cell lines does induce apoptosis (Sanjo et al. 1998; Matsumoto et al. 2001), it is unlikely that apoptotic induction is its key physiologic function since DRAK2-deficient mice demonstrate no obvious defects in apoptotic signaling (McGargill et al. 2004; Friedrich et al. 2005). Instead, DRAK2 has been shown to negatively regulate calcium signaling in primary T cells. Since its catalytic activity is itself induced by calcium influx, DRAK2 may serve to maintain calcium homeostasis (Friedrich et al. 2007; Newton et al. 2011). DRAK2 (and likely its ortholog DRAK1) has been found to be an important immunomodulatory serine/threonine kinase, serving to a) set the initial threshold for thymic and peripheral T cell activation and later, to maintain the survival of effector T cells. In this capacity, mice lacking DRAK2 are resistant to organ-specific autoimmunity (see below). Thus, the development of small molecule antagonists will be of significant value to efforts aimed at combating such immune system diseases.

DRAK2 Expression

DRAK2 mRNA expression in humans and mice is fairly limited in adults. DRAK2 is highly enriched in lymphoid tissues including bone marrow, thymus, lymph nodes, and spleen. In particular, T cells and B cells express very high levels of DRAK2 mRNA and protein, and it has been demonstrated to be a critical regulator of T and B cell biology (Gatzka and Walsh 2008). During T cell development in the thymus, DRAK2 expression initiates at the single positive stage and is maintained in the periphery. Stimulation of the T cell receptor (TCR) and co-receptor CD4 leads to acute expression of DRAK2 mRNA and protein in double positive thymocytes (Friedrich et al. 2005). Similar to T cells, B cells also begin to express DRAK2 at the mature B cell stage of development, where it regulates cellular functions in these immune cells also (McGargill et al. 2004; Al-Qahtani et al. 2008).

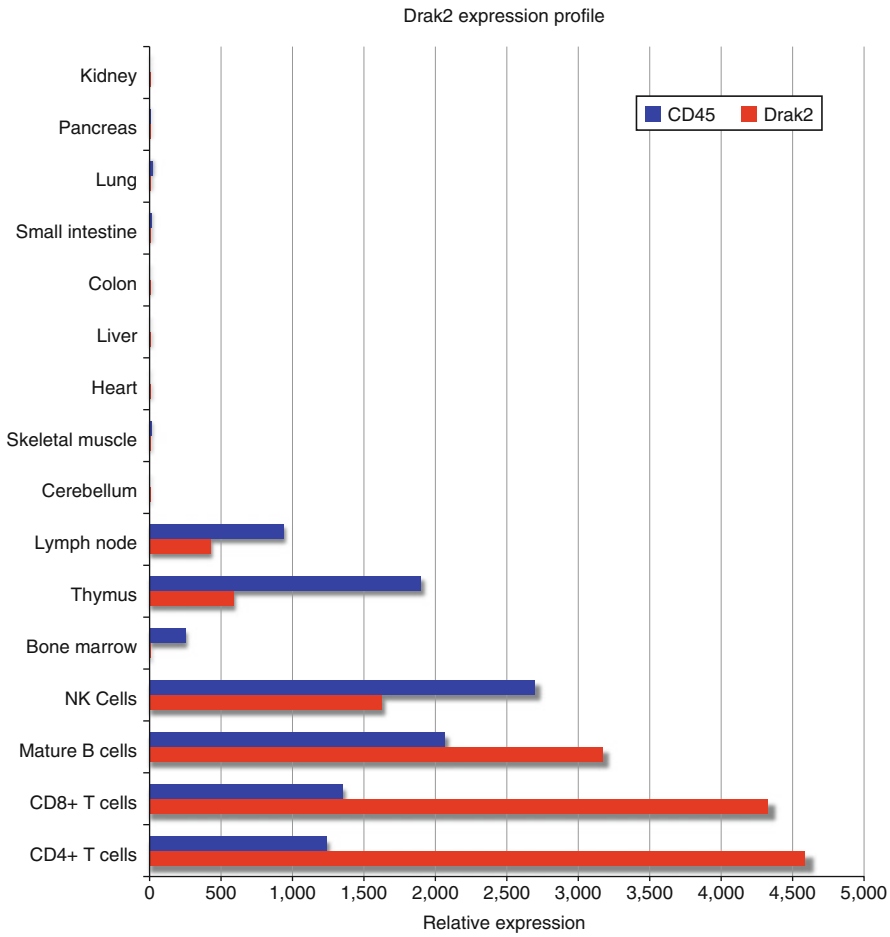
The original discovery of DRAK2 resulted from screens of human placenta and liver cDNA libraries (Sanjo et al. 1998), although the role of DRAK2 in tissues outside of the lymphoid compartment is not well understood. DRAK2 expression has been found to be very high within parts of the brain, including the Purkinje cells of the cerebellum cortex as well as the olfactory lobe, ventricular zone, pituitary, and superchiasmatic nuclei (Mao et al. 2006). During mouse development, DRAK2 mRNA expression is ubiquitous until mid-gestation stage E14, but wanes by E18 in all tissues except those of the immune system. In addition to healthy tissue expression, colorectal cancer cells have been shown to downregulate DRAK2 expression as a means to enhance transformed cell survival. Treatment with Cyclooxygenase-2 (COX-2) inhibitors resulted in enhanced expression of DRAK2, and induction of apoptosis in the HCA7 colorectal cancer cell line (Doherty et al. 2009). Evaluation of DRAK2 expression using an online expression atlas demonstrates a similar pattern of expression between DRAK2 and DRAK1, with greatest expression found in lymphoid tissues and in B cells and T cells (Wu et al. 2009). DRAK2 also has a similar expression pattern as the hemopoietically restricted phosphatase CD45 (see Fig. 1).

DRAK2's Role in Apoptosis

As a member of the ▶ DAP kinase family, DRAK2 was thought to also be important for initiation of apoptosis. Following isolation from human placental tissue, studies demonstrated that DRAK2 could, in some instances, induce apoptosis. Initial reports suggested that overexpression of DRAK2 in cells lines such as 3T3 fibroblasts, Cos7 cells, rat NRK cells, and human Caco-2 cells all led to enhanced apoptosis (Sanjo et al. 1998; Kuwahara et al. 2006). The requirements for induction of apoptosis by DRAK2 in these various cell lines is not well understood, although in some instances DRAK2 kinase activity and localization to the nucleus seems to be required (Kuwahara et al. 2006). Besides overexpression studies, DRAK2 siRNA treatment in ACL-15 and NRK cells led to diminished apoptosis following exposure to UV-irradiation, further suggesting a role for DRAK2 in apoptosis in cell lines (Kuwahara et al. 2006).

Although apoptosis can be enhanced and prevented in cell lines overexpressing or lacking DRAK2 respectively, several DRAK2 mouse models have been constructed to further elucidate the role of DRAK2 in cellular processes. First, a DRAK2 knockout mouse was created in which DRAK2 expression was abolished from all tissues. Surprisingly, DRAK2 knockout mice did not have any defects in apoptosis induction or embryonic development (McGargill et al. 2004). In particular, mice did not develop any signs of autoimmunity, cancer, or lymphadenopathy, which would be expected upon deletion of proteins involved in apoptosis. On the contrary, deletion of DRAK2 resulted in survival defects particularly in T cells and B cells. In T cells, DRAK2 has important non-apoptotic functions regulating signals transduced through the T cell receptor, and more detail as to how these processes are regulated will be covered in depth later in this entry.

Besides a DRAK2 knockout mouse, two DRAK2 transgenic mice have been studied. First, DRAK2 expression linked to a human beta actin promoter was constructed, which enhanced expression of DRAK2 roughly fivefold in all adult mouse tissues. As noted before, DRAK2 is not normally expressed in all tissues, and is generally enriched in the immune system. Nonetheless, DRAK2 transgenic mice were shown to



DRAK2, Fig. 1 DRAK2 mRNA expression profile obtained from GeneAtlas (Wu et al. 2009) (http://biogps.gnf.org/#goto=genereport&id=9262) is shown compared to CD45 expression in various mouse tissues. DRAK2 is highly enriched in tissues and cells of the immune system, similar to CD45

have enhanced T cell apoptosis following stimulation, which was dependent on high levels of cytokine exposure. Spleen size was enhanced in these mice, but no other defects were noted (Mao et al. 2006).

A second DRAK2 transgenic mouse was generated in which overexpression occurred only in the T cell compartment. Specifically, DRAK2 was linked to the lck promoter, which begins to be expressed at the double negative stage of thymocyte development. DRAK2 expression was very high in the thymus during development, and subsequently returned to wild-type levels in the periphery. In this mouse, thymocytes did not exhibit enhanced spontaneous or stimuli-induced apoptosis, and negative selection was diminished. Additionally, apoptosis of peripheral T cells was not enhanced following stimulation, although these cells were hypersensitive to stimuli (Gatzka et al. 2009).

Overall, although DRAK2 is a member of the DAP kinase family, it has controversial roles in apoptosis. Cell lines become sensitized to apoptosis when DRAK2 is overexpressed, yet DRAK2 deletion in mice does not confer resistance to apoptosis or manifest as disease pathology. Additionally, overexpression of DRAK2 in the thymus has no effect on apoptosis, while overexpression in the periphery enhanced apoptosis of stimulated T cells. It is important to note that DRAK2 seems to only enhance apoptosis in cells when overexpressed to very high levels, thus we do not expect DRAK2 to have a specific role in apoptosis under normal physiological conditions.

Structure/Function of DRAK2

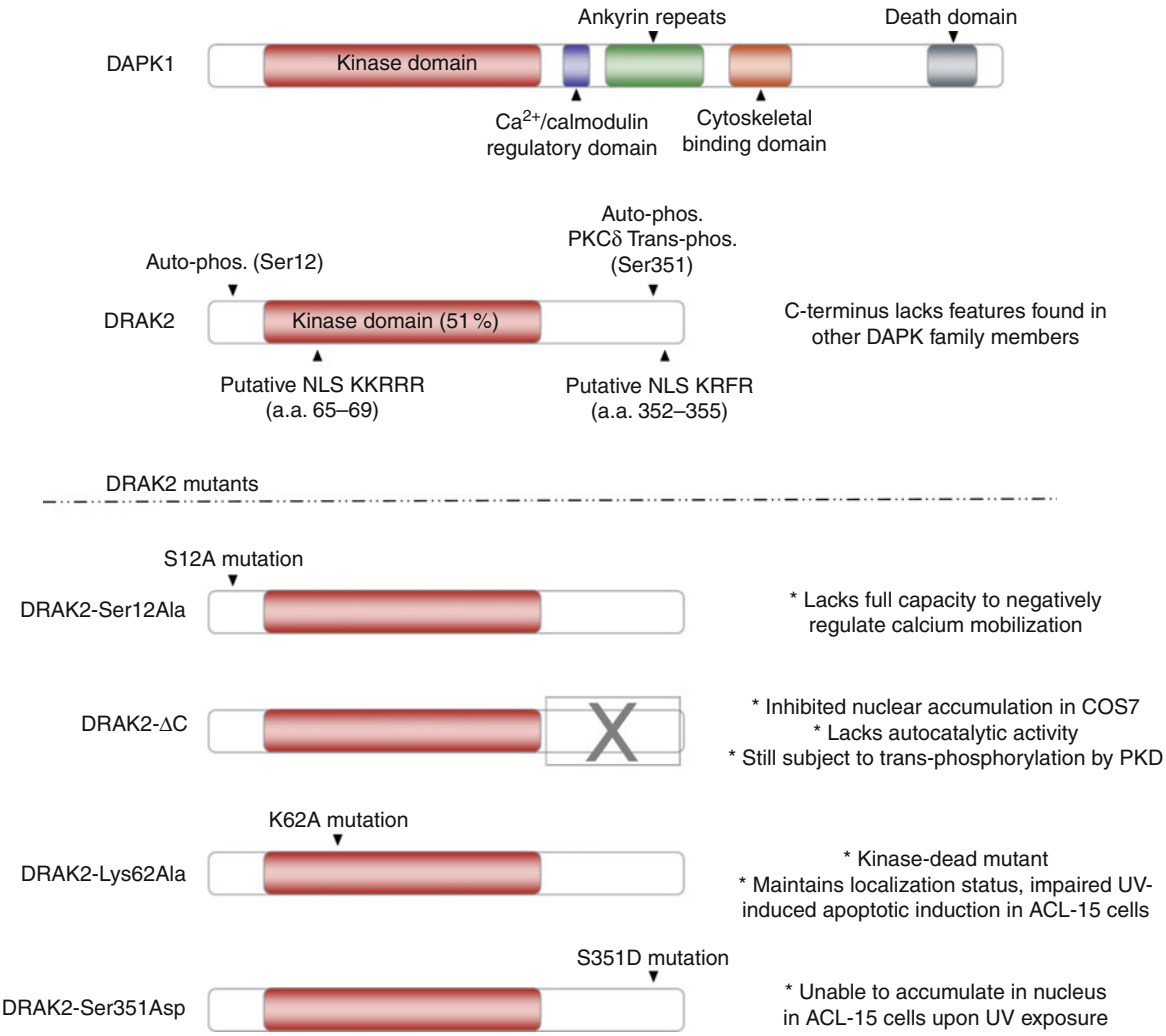
Within the DAPK family of Ca2+/calmodulin-regulated serine/threonine kinases, DAPK, DRP-1,

and Zip Kinase (ZIPK) comprise a highly homologous subfamily, whereas DRAK1 and DRAK2 represent a more distantly related group (Bialik and Kimchi 2006). DRAK2 has been the focus of intense study not only because orthologs for DRAK1 are present only in higher order primates, but because of its unique role in T cell activation. While DRP-1 and ZIPK share 80% and 83% homology, respectively, to the founding member of this family, ▶ DAPK, DRAK1 and DRAK2 share only 48% and 51%, respectively. Another important attribute that distinguishes the DRAKs from other members of this family is the complete lack of C-terminal features that command the regulation and apoptosis-promoting function of these kinases. Outside of its kinase domain, DRAK2 lacks homology with all other proteins, containing a short N-terminal region subject to autophosphorylation and a C-terminus important for its subcellular localization and its ability to induce apoptosis upon ectopic expression in various carcinoma cell lines.

In stably transfected Jurkat T cells, DRAK2 was localized primarily within the nucleus (Friedrich et al. 2005). This has also been shown to be the case in NIH3T3, NRK, and Caco-2 cell lines, whereas ACL-15, HeLa, and WI-38 cells have exhibited DRAK2 localization within the cytoplasm (Kuwahara et al. 2006). DRAK2 has been shown to contain putative nuclear-localization signals (NLS) in both its kinase domain (Friedrich et al. 2005) and C-terminal region (Kuwahara et al. 2006), the differential regulation of which potentially explaining this cell type-dependent translocation (Fig. 2). Upon stimulation of Jurkat cells with PMA plus PHA to mimic antigen receptor stimulation, DRAK2 translocated to the cytoplasm, whereas in ACL-15 cells, DRAK2 nuclear accumulation could be induced with UV-irradiation. In the latter cell type, this nuclear accumulation was not only dependent on an intact NLS within the C-terminus of DRAK2, but on phosphorylation of Ser350 mediated by protein kinase C (PKC) delta, the blockade of which prevented nuclear accumulation of DRAK2 and UV-induced apoptosis (Kuwahara et al. 2008). Interestingly, Ser350 was identified as a prominent site of autophosphorylation in studies (designating this residue as Ser351) aimed at understanding how this kinase is regulated in lymphocytes (Friedrich et al. 2007). These studies also revealed an important role for autophosphorylation of Ser12 in the ability of DRAK2 to affect T cell activation, indicating that, like other members of the DAPK family, DRAK2 autophosphorylation modulates DRAK2 activity and function.

As immature thymocytes transit through developmental stages in the thymus to become mature T cells, DRAK2 upregulation occurs and directly affects the degree of calcium mobilization elicited through antigen receptor stimulation. In the mature T cell compartment, where DRAK2 protein levels are highest, loss of DRAK2 leads to substantially enhanced calcium responses (McGargill et al. 2004). Reconstitution of DRAK2-deficient T cells with wild-type DRAK2 restored negative regulation of calcium mobilization, whereas expression of a Ser12Ala DRAK2 mutant was not sufficient to reestablish this negative regulation, indicating the importance of autophosphorylation on Ser12 for DRAK2 biological function (Friedrich et al. 2007). The generation of DRAK2-transgenic mice in which DRAK2 transgene levels are driven specifically within the immature T cell population also lends support to the role of DRAK2 in directly modulating calcium responses. Whereas immature thymocytes ectopically expressing DRAK2 exhibited dampened calcium responses to antigen receptor stimulation, restoration of normal DRAK2 levels within the peripheral T cell compartment in these mice resulted in normal calcium responses (Gatzka et al. 2009). Finally, knockdown of DRAK2 within the clonal T cell line D10 recapitulated the exacerbated calcium response phenotype seen in DRAK2-deficient T cells, arguing against a developmental defect upon loss of DRAK2, and for a role in DRAK2 signaling to regulate this aspect of T cell activation (Newton et al. 2011).

Autophosphorylation on Ser12 is itself elicited by calcium mobilization, implicating DRAK2 in a negative feedback loop whereby calcium influx is necessary for autocatalytic activity on Ser12 and is required for DRAK2 to limit calcium influx, and not ER calcium store release. This process has been shown to be dependent on protein kinase D (PKD), potentially through direct transphosphorylation of DRAK2 by ▶ PKD, suggested by in vitro kinase assays. Association of DRAK2 with PKD has been demonstrated in T cells in response to stimuli that activate PKD, and is enriched within mitochondria. Immunofluorescence images of endogenous DRAK2 in primary T cells have revealed DRAK2 punctae formation localized



DRAK2, Fig. 2 Comparison of DRAK2 and DAPK, and various DRAK2 mutants generated that have provided functional insight. The percentage within the kinase domain indicates the degree of amino acid identity to the kinase domain of DAPK. *NLS* nuclear localization signal

to staining of mitochondria in response to thapsigargin to provoke calcium mobilization, and autophosphorylation on Ser12 was induced directly through generation of mitochondrial reactive oxygen species. Together with data showing that association of PKD and DRAK2 is disrupted by molecules that scavenge reactive oxygen species, activation of DRAK2 by PKD is thought to be dependent on calcium-induced mitochondrial reactive oxygen generation in response to antigen receptor stimulation (Newton et al. 2011).

How DRAK2 down-modulates calcium influx is currently unknown, and few substrates have been identified. In vitro, DRAK2 targets myosin light chain (MLC), a result that was anticipated based on its high level of homology in its kinase domain with ▶ MLCK, and based on DAPK's ability to target MLC in vivo. DRAK2 has been shown to interact with calcineurin homologous protein (CHP) in a manner that negatively regulates its autocatalytic activity and its activity toward MLC (Matsumoto et al. 2001). Although this interaction of CHP was not shown to be dependent on calcium, the suppression of DRAK2 catalytic activity by CHP was. S6K1 has been shown to be targeted by DRAK2 on the same residue (Thr389) as targeted by ▶ mTOR, leaving a role for DRAK2 in S6K1 signaling in T cells to be determined (Mao et al. 2009).

An incredibly important tool for understanding not only what lies downstream of DRAK2, but for the selective targeting of T cell responses given the unique function of DRAK2 and its role in immune system, will be the development of specific inhibitors to target this kinase. The solved crystal structure with 2.8 Å resolution will undoubtedly aid in the discovery of novel inhibitors that offer the possibility to disrupt a pathway central to the exquisite control of T cell activation and tolerance yet dispensable for key immunological events that maintain resistance toward a multitude of pathological threats.

Role in Immune System

Since DRAK2 is highly expressed in lymphoid tissues, its role in the immune system has been extensively studied. DRAK2 expression is developmentally regulated during thymocyte maturation and its expression is increased following activation of the T cell receptor (TCR) of double positive thymocytes (Friedrich et al. 2005). DRAK2 is involved in setting the threshold for TCR signaling during thymocyte selection as evidenced by the increased calcium flux of DRAK2−/− thymocytes following the double positive stage (Friedrich et al. 2005). To study if DRAK2 plays a role in positive or negative selection, DRAK2-deficient mice have been bred with various TCR transgenic mice (McGargill et al. 2004). DRAK2-deficient mice crossed to OT-II and AND mice have slight increases in CD4 single positive T cells and slight decreases in double positive T cells. Interestingly, there was no effect on CD8 single positive distribution when DRAK2-deficient mice were crossed to OT-I or P14 mice. Although DRAK2-deficiency led to enhanced positive selection, DRAK2 does not seem to play a role in negative selection as DRAK2 deficiency did not affect the loss of self-reactive T cells under the AND or H-Y TCR transgenic backgrounds. In addition, double positive DRAK2−/− T cells from OT-I and OT-II backgrounds had slight increases in activation markers. Therefore, DRAK2 is necessary for proper TCR activation during thymocyte selection.

In peripheral tissues, CD4+ and CD8+ T cells express similar levels of DRAK2 protein. Not surprisingly, DRAK2−/− peripheral T cells also have an increased calcium flux following TCR stimulation (McGargill et al. 2004; Friedrich et al. 2005). In addition, DRAK2−/− T cells have been observed to hyperproliferate to suboptimal stimulation and to a greater rate with weak agonist. The increased calcium flux and hypersensitivity of DRAK2−/− T cells is characteristic of T cells deficient in a negative regulator. In accord with the increase in proliferation, DRAK2−/− T cells produce higher amounts of IL-2. In addition, activated DRAK2−/− T cells produce higher amounts of IFN-γ and IL-4. Suboptimal stimulation results in higher surface expression levels of the costimulatory markers CD25, IL-7R, ICOS, CD27, OX40, and 41BB in DRAK2−/− T cells compared to wild-type T cells. Interestingly, the addition of exogenous anti-CD28 restores the levels of costimulatory markers and the observed hyper-proliferation of activated DRAK2−/− T cells back to wild-type levels (McGargill et al. 2004; Ramos et al. 2008). These studies support the hypothesis that DRAK2 is a negative regulator of T cell activation.

B cells express the highest level of DRAK2 protein and similar to T cells, DRAK2 expression increases following B cell maturation (McGargill et al. 2004; Friedrich et al. 2005). Following immunization of mice with a T-dependent antigen, the loss of DRAK2 in B cells results in up to a fivefold decrease in germinal centers and, consequently, a decrease in high affinity antibodies (Al-Qahtani et al. 2008). DRAK2−/− B cells proliferate similar to wild-type B cells and have no defects in somatic hypermutation and class switch DNA recombination. Further analysis indicates that the defects in DRAK2−/− B cells is a direct consequence of a loss of DRAK2 in T cells since a T-dependent antigen was used to cause the germinal center reaction. To study any B cell intrinsic defects due to the loss of DRAK2, T-independent antigen immunizations should be conducted.

Deletion of negative regulators of T cell activation often leads to increased sensitivity to autoimmune diseases (Pentcheva-Hoang et al. 2009). Based on studies on T cell negative regulators, it was predicted that DRAK2-deficient mice would also be more vulnerable to autoimmune disease. To the contrary, DRAK2-deficient mice were less susceptible to autoimmunity than wild-type mice. Aged DRAK2-deficient mice were not predisposed to spontaneous autoimmunity since there were no differences in the levels of cellular infiltrates in major organs and autoantibodies compared to wild-type (McGargill et al. 2004).

DRAK2-deficient mice were also resistant to MOG-induced experimental autoimmune encephalomyelitis (EAE), a mouse model of multiple sclerosis (McGargill et al. 2004, 2008; Ramos et al. 2008, 2007). Overexpression of DRAK2 in mice via the LCK promoter results in spontaneous autoimmunity and increased susceptibility to EAE (Gatzka et al. 2009). However, this is most likely due to ectopically expressing DRAK2 in double positive thymocytes, which may result in altered thymic selection. In addition, DRAK2−/− mice were resistant to type 1-diabetes when bred to the NOD strain of mice that spontaneously develop autoimmune diabetes (McGargill et al. 2008). The resistance is not due to developmental defects in Th17 or antigen-specific effector T cells (Ramos et al. 2008; McGargill et al. 2008). DRAK2−/− mice were susceptible to collagen-induced arthritis and systemic lupus erythematosus, both of which are mediated by autoantibodies (McGargill et al. 2008). DRAK2−/− mice were also susceptible to autoimmune diseases that depend on mast cells and neutrophils (McGargill et al. 2008). Hence, DRAK2−/− mice remain susceptible to autoimmune diseases caused by autoantibodies or cells of the innate immune system but are resistant to autoimmune diseases where pathogenesis is primarily mediated by T cells.

The response to virus has also been studied in DRAK2-deficient mice. DRAK2-deficient mice had antiviral responses to Lymphocytic Choriomeningitis Virus (LCMV) (McGargill et al. 2004) and Murine Hepatitis Virus (MHV) (Ramos et al. 2007) that were indistinguishable from wild-type mice. Interestingly, DRAK2−/− mice were also capable of efficiently eliminating West Nile Virus, but did not succumb to the lethal encephalomyelitis, suggesting that while DRAK2 is not required for antiviral responses, it does promote entry of antiviral T cells into the brain. As stated above, activated DRAK2−/− T cells respond similar to activated wild-type T cells following addition of exogenous costimulation. During a viral infection the amount of costimulation is probably maximal and this may explain why DRAK2-deficient mice mount a normal immune response to viral infection. In addition, studies with MHV showed that DRAK2-deficient mice have enhanced memory T cell function on a per cell basis (Schaumburg et al. 2007). Hence, the absence of DRAK2 does not result in generalized suppression of the immune system and blockade of DRAK2 may be useful in treating T cell–dependent autoimmune diseases and enhance antiviral responses. The role DRAK2 plays in T cell survival likely explains the mechanism behind the restoration of DRAK2−/− T cells to a wild-type phenotype with the addition of costimulation (Ramos et al. 2008).

Summary

While the catalytic targets of DRAK2 (and DRAK1) remain to be fully clarified, this serine/threonine kinase offers a unique opportunity to control autoimmunity and potentially cancer. The elucidation of the targets of the kinase, as well as the structural features of the kinase, will be of great value for understanding how DRAK2 controls cellular physiology. While DRAK2 and DRAK1 clearly share significant homology with other members of the DAPK family, ongoing studies should help to determine the functional roles these serine/threonine kinases serve in distinct organ systems. Given the significant autoimmune resistance, but overtly normal antiviral immunity that DRAK2-deficient mice possess, it is likely that small molecule antagonists of the DRAK kinases will be valuable weapons in the arsenal to control autoimmune and other autoinflammatory diseases.

Pebble (PBL) in *Drosophila melanogaster*

Historical Background

Ect2 is a guanine nucleotide exchange factor (GEF) of the Rho GTPases (Tatsumoto et al. 1999). It was isolated as a cDNA clone with capability of converting mouse fibroblasts to malignantly transformed cells (Miki et al. 1991, 1993). Transforming Ect2 variants lacked the N-terminal regulatory domain, and efficiently induced focus formation, anchorage-independent cell growth, and cell invasiveness in mouse fibroblasts. Injection of athymic nude mice with Ect2 transformants resulted in tumor formation. While full-length Ect2 is localized only in the nucleus, its oncogenic variants are detected in the cytoplasm as well. In M phase, Ect2 distributes in the entire cells after nuclear membrane breakdown, and is concentrated on mitotic spindles and then central spindles. In the last stage of M phase, Ect2 translocates to the midbody, which is formed between two emerging daughter cells. Perturbation of Ect2 function in M phase resulted in the inhibition of cytokinesis (cellular division) without major effects on mitosis (Tatsumoto et al. 1999). These findings established that Ect2 is a critical regulator of cytokinesis. Subsequent studies on Ect2 as well as the Rho negative regulator MgcRacGAP clarified the molecular mechanisms of cytokinesis (Yuce et al. 2005; Kamijo et al. 2006); chromosome separation initiates the formation of central spindles where MgcRacGAP and MKLP1 (mitosis-specific motor protein) form a tight complex. Recruitment of Ect2 to this complex activates Rho at the cell equator leading to cytokinesis.

Structural Properties

The full-length Ect2 contains several structural motifs (Fig. 1). The C-terminal half of the molecule contains the

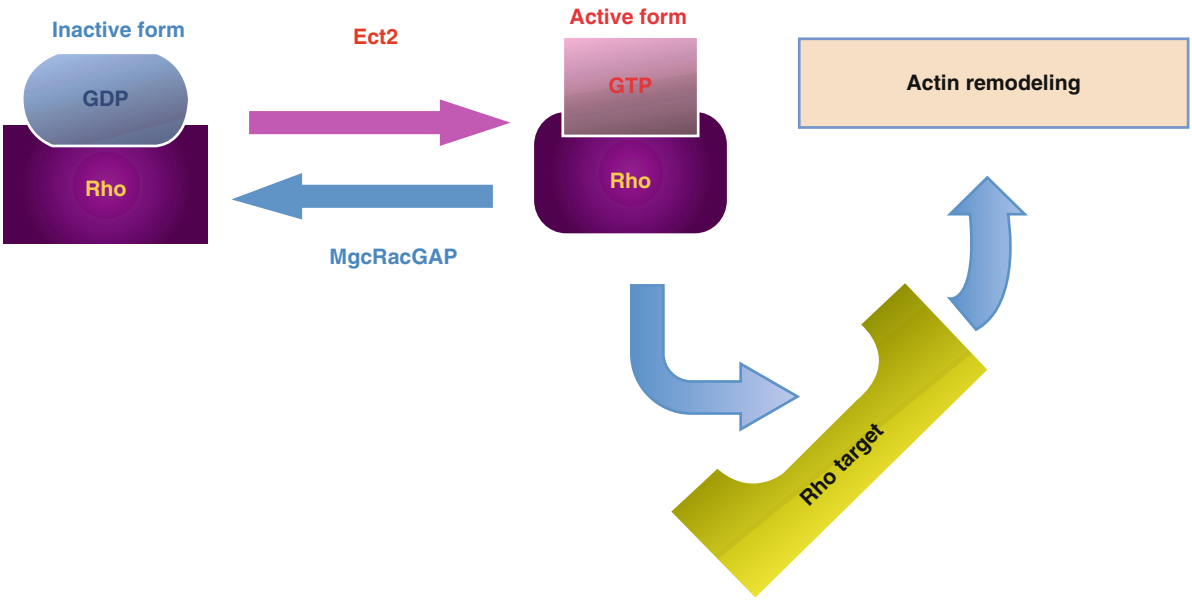
Ect2 (Epithelial Cell Transforming 2 Oncogene), Fig. 1 Schematic view of Ect2 protein: Full-length Ect2 molecule constitutes of the N-terminal regulatory and C-terminal catalytic domains as well as the central S domain. The major motifs are shown. *Triangles* denote nuclear localization signals. The region carried by oncogenic Ect2 is shown by a *line*

Dbl (diffuse B-lymphoma oncogene)-homology (DH) and Pleckstrin-homology (PH) domains, which are motifs of the guanine nucleotide factor (GEF) of the Rho GTPases. Most of Rho GEFs contain each of the domains, and usually the DH domain is located at the N-terminus of the PH domain. While the Rho GEF motif is the combination of the DH and PH domains, there are a number of proteins containing the PH domain alone, most of which function as a phosphatidylinositol binding site as well as a membrane anchoring site. The very C-terminal region of Ect2 is a serine- and threonine-rich domain and functions as a regulator of cell transformation. Transforming Ect2, which was identified as cDNA clone capable of transforming NIH 3T3 fibroblasts, lacks the N-terminal half and thus contains only the C-terminal half of the full-length Ect2 (Miki et al. 1993).

The N-terminal half of Ect2 contains the BRCA1 terminal repeat (BRCT) domains (Tatsumoto et al. 1999). Identification of the fission yeast *cut5* gene revealed a new homology region between Cut5 and the N-terminal half of Ect2. This region consists of two BRCT domains. Cut5 contains four repeats, whereas Ect2 has two. Fission yeast *cut5* mutants show a very peculiar phenotype: no coordination between mitosis and cytokinesis, which results in the induction of cytokinesis during mitosis. The BRCT domains of Ect2 have at least two functions. First, they associate with the catalytic domain of Ect2, which renders the molecule inactive. Both the BRCT domains are considered essential to this function, as the expression of both the repeats, but not the either single repeat blocks cytokinesis as a dominant-negative mutant of Ect2. The central S domain may function as a joint of the N- and C-terminal halves, and phosphorylation of the S domain is known to affect the configuration (Hara et al. 2006). Since the BRCT sequence is known to function as a phosphospecific protein-binding motif, the Ect2 BRCT domains may function after the C-terminal domain is phosphorylated. A second function of the Ect2 BRCT domains is to interact with the Rho regulator MgcRacGAP (Yuce et al. 2005). Presumably, the conversion of the closed Ect2 structure to the open form stimulates the binding to MgcRacGAP. Phosphorylation of MgcRacGAP by Plk1 also stimulates Ect2-MgcRacGAP association (Wolfe et al. 2009).

Biochemical Functions

Ect2 functions as an activator of the Rho family of small GTPases, which are represented by RhoA, Rac1, and Cdc42 (Miki et al. 2002). Rho GTPases function as molecular switches in cells and alternate between two states: an active GTP-bound state and an inactive GDP-bound state (Fig. 2). Ect2 converts inactive Rho to active Rho by replacing bound GDP by GTP. The GTP-bound form of Rho is specifically recognized by target/effector proteins to transmit the signals further downstream. As the biological functions of RhoA, Rac1, and Cdc42 are regulation of the formation of actin stress fibers, membrane ruffling, and filopodia, respectively, most of the Rho-mediated signals involve actin remodeling. Among the known Rho targets, Rho kinase (ROCK), Citron kinase, and mDia are involved in Ect2-mediated signaling. Inactivation of a Rho GTPase is carried out through the enhancement of its intrinsic GTPase activity by a cognate GTPase activating protein (GAP). A Rho GAP, designated MgcRacGAP, is known to function together with Ect2 to regulate cytokinesis and chromosome separation (Minoshima et al. 2003).



Ect2 (Epithelial Cell Transforming 2 Oncogene), Fig. 2 Biochemical function of Ect2. Ect2 replaces bound GDP by GTP on Rho GTPases, and therefore activates Rho to specifically associate with Rho targets, which in turn transmits the signal further downstream to regulate actin remodeling

Biological Functions

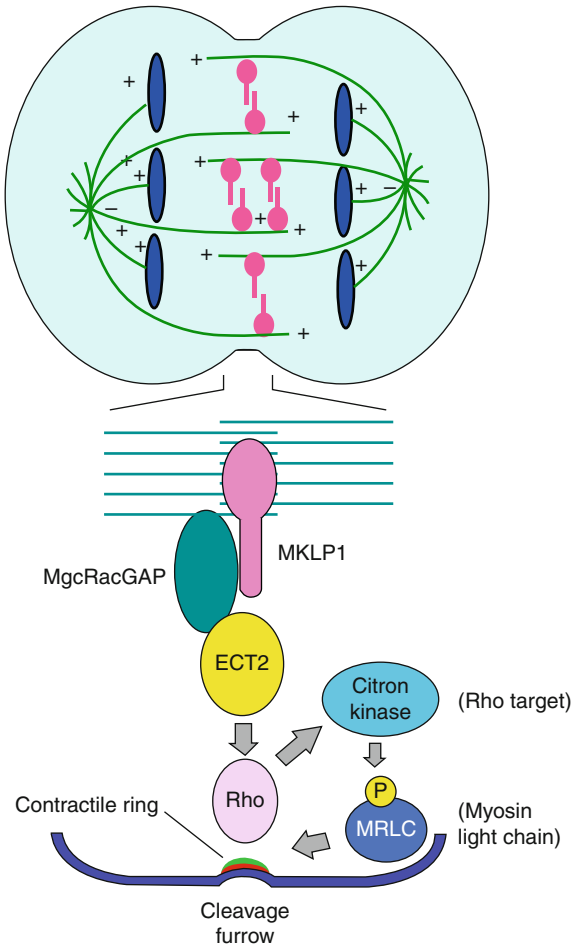
Inhibition of Ect2 function in cultured cells strongly inhibits cytokinesis without visible effects on mitosis, generating binucleate cells. Therefore, Ect2 is a critical regulator of cytokinesis (Miki 2005). In *Drosophila*, a known gene (*pebble*), whose mutation results in cytokinesis defects, was shown to encode the fly ortholog of the human *ECT2* (Prokopenko et al. 2000). Ect2 is localized in the nucleus in interphase. Upon nuclear membrane breakdown in M phase, Ect2 is found in the entire cells and then concentrated at the central spindle (Fig. 3). The Rho negative regulator MgcRacGAP and the plus-end directed motor protein MKLP1 form a stable complex and associate with the central spindle. As described below, a set of complex phosphorylation/dephosphorylation events on both Ect2 and MgcRacGAP appear to induce the association of Ect2 to MgcRacGAP on the central spindle (Yuce et al. 2005; Hara et al. 2006). The Ect2 protein that has been recruited to the central spindle then activates Rho GTPases by guanine nucleotide exchange, and activated Rho translocates to the cell equator, where it activates the Rho target Citron kinase. Citron kinase then phosphorylates the regulatory subunit of myosin heavy chain kinase. These biochemical events induce contractile ring formation and contraction (Kamijo et al. 2006).

Although Ect2 knockdown mainly inhibits cytokinesis, it also impairs the attachment of mitotic spindles to the kinetochores, leading to a delay of prometaphase and abnormal chromosomal separation (Oceguera-Yanez et al. 2005). MgcRacGAP is involved in this function as well. While RhoA is a critical molecular switch in cytokinesis regulation, Cdc42 mainly functions in chromosome alignment in this mitotic role of Ect2.

Ect2 might play a role in epithelial cell polarity. The polarity regulator Par6 was identified as an Ect2-interacting protein (Liu et al. 2004). Ect2 also associates with the other polarity complex components, consisting of Par3, atypical protein kinase (PKCiota or PKCzeta), and Cdc42 (see Fig. 5). Coexpression of Ect2 and Par6 efficiently activates Cdc42, and overexpression of Ect2 activates aPKC activity. In epithelial cells, Ect2 localization was detected at the cell–cell junction as well as the nucleus. Thus, Ect2 appears to involve epithelial cell polarity, although the other Rho GEF Tiam-1 plays a major role.

Regulation of Ect2 by Phosphorylation and Protein Associations

The central domain of Ect2, designated the S domain, functions as a joint of the catalytic C-terminal and the regulatory N-terminal halves. It contains several phosphorylation sites, which may function as switches for



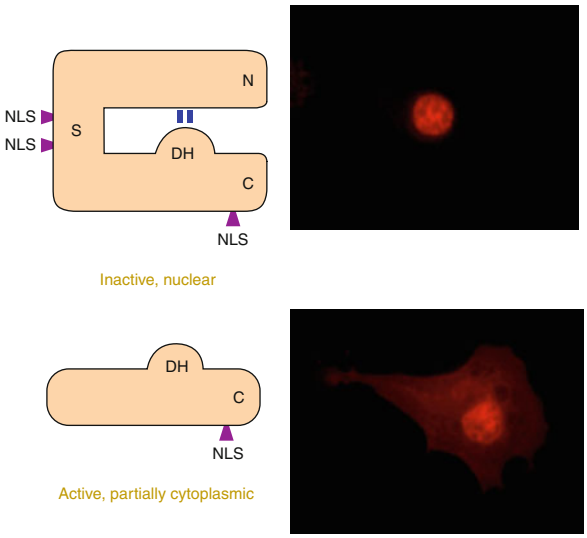
Ect2 (Epithelial Cell Transforming 2 Oncogene), Fig. 3 Biological function of Ect2: At the metaphase–anaphase transition, Ect2 associates with MgcRacGAP, which forms a tight complex with MKLP1 at the central spindle. Subsequent activation of Rho, Citron kinase, and MRLC (myosin regulatory light chain) causes the contractile ring formation, leading to cytokinesis

configuration changes (Miki et al. 2009). Phosphorylation at T341 of Ect2 by Cdk1 in M phase affects configuration of the molecule (open and closed forms) and may control the accessibility of Ect2-binding proteins (Hara et al. 2006). Phosphorylation of T412 by Cdk1 also induces binding of another M phase kinase Plk1, leading to phosphorylation of Ect2 by Plk1 (Niiya et al. 2006). It is known that this phosphorylation is required for the exchange activity of Ect2. Plk1 appears to have multiple functions in M phase. Its N-terminal half contains the regulatory Polo-box domain (PBD), which can associate with phosphorylated peptides. Cdk1 functions as a "priming kinase" in this case: Cdk1 phosphorylation stimulates Plk1 binding through the PBD domain, and the kinase domain of Plk1 subsequently phosphorylates the substrate that the Plk1 has bound. Through this mechanism, Plk1 is recruited to various cellular compartments during M phase. Plk1 phosphorylation of Ect2 and MgcRacGAP is critical for cytokinesis regulation. The N-terminal domain of Ect2 mainly consists of two BRCT repeats, which are capable of binding to phosphorylated proteins. This domain functions to localize Ect2 to the central spindle. On the other hand, Ect2 is in a closed conformation in its inactive state through the interaction of the N- and C-terminal halves. The phosphorylation status of T431 regulates the configuration. Inhibition of Plk1 by a chemical inhibitor prevents Ect2 association to the central spindle as well as binding to MgcRacGAP (Wolfe et al. 2009). Thus, Plk1 phosphorylates MgcRacGAP, which may help Ect2 to associate with MgcRacGAP. On the other hand, Ect2 is also phosphorylated by Plk1, which is required for its activity. Complex phosphorylation events might regulate cytokinesis through these protein kinases.

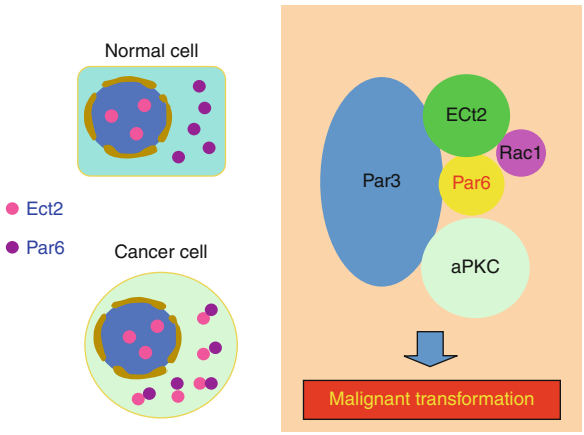
Involvement of Tumor Formation

Although full-length Ect2 is a nuclear protein, its transforming variants display various degrees of cytoplasmic localization (Fig. 4). Subsequent analysis revealed that main nuclear localization signals located at the S domain are lost in these transforming variants (Saito et al. 2004; Justilien and Fields 2009). Whereas the possible nuclear functions of Ect2 should be clarified, Ect2 might be sequestered in the nucleus not to activate Rho GTPases in interphase. Transforming variants of Ect2 that are partially located in the cytoplasm can activate Rho GTPases leading to malignant transformation. Detailed analyses indicate that deletion of the main nuclear localization signals induces only a fraction of transforming activity of Ect2. Other factors, including phosphorylation status and configuration changes, are also important for the transforming activity of Ect2. Nonetheless, nuclear localization of Ect2 is a critical factor of Ect2 transforming activity.

Despite the cytoplasmic mislocalization of transforming variants of Ect2, deletion or rearrangement of the *ECT2* gene in human cancers has not been reported. Recent analyses of huge number of human cancers using microarray analyses revealed that Ect2 is a prognostic marker of several cancers



Ect2 (Epithelial Cell Transforming 2 Oncogene), Fig. 4 Cytoplasmic mislocalization of Ect2 induces its transforming activity: (*upper*) Inactive Ect2 forms a closed structure and it is localized at the nucleus (*red*). (*Lower*) Oncogenic Ect2 (see Fig. 1) displays cytoplasmic localization although it also localizes to the nucleus. NLS, nuclear localization signal



Ect2 (Epithelial Cell Transforming 2 Oncogene), Fig. 5 Association of Ect2 with the polarity complex activates Rac1, leading to malignant transformation. In normal cells, Ect2 is localized to the nucleus, whereas it associates with Par6 in the cytoplasm of some cancer cells

including breast cancer. It is also reported that Ect2 expression inversely correlates to prognosis of glioblastomas (Sano et al. 2006). As described above, Ect2 associates with the tertiary complex consisting of the polarity determinant protein Par6, an atypical protein kinase C, and a scaffold protein Par3 (Liu et al. 2004, 2006) (Fig. 5). The gene for an aPKC, PKCiota, is located at the proximity of the *ECT2* gene in human chromosome 3. Both the loci are co-amplified in several cancers including non-small cell lung carcinomas (NSLCs). Interestingly, Ect2 is mislocalized to the cytoplasm in these cancer cell lines, reminiscent of the phenotype of transforming Ect2. When either Par6 or PKCiota is knocked down in these cells, however, Ect2 localization returns to the nucleus. Thus, upregulation of the polarity complex appears to retain Ect2 in the cytoplasm in these cancer cell lines. It is well established that the Rho family GTPases, Cdc42 and Rac1, are involved in cell polarity. Ect2 knockdown in these cells inhibits tumorigenicity and invasiveness, indicating that Ect2 activates the Rac1 pathway through the polarity complex in these cells leading to malignant transformation.

Space limitations preclude comprehensive referencing. See also references therein.

Summary

Ect2 was originally isolated as a cDNA clone with an ability to morphologically transform mouse fibroblasts. The catalytic domain (C-terminal half) catalyzes guanine nucleotide exchange on Rho GTPases, whereas the regulatory domain (N-terminal half) contains two BRCT domains, which regulate the catalytic activity and also function to interact with other signaling molecules such as MgcRacGAP. Ect2 is a critical regulator of cytokinesis. Ect2 also interacts with the polarity determinants containing Par3, Par6, aPKC, and Rac1. In some cancer cells, amplification of a chromosomal region containing the genes for Ect2 and aPKC results in overproduction of these proteins. Cytoplasmic localization of Ect2/Par complex appears to cause malignant transformation of the cells.

Endothelin A Receptor (ETAR)

Randa Hilal-Dandan and Laurence L. Brunton
Pharmacology, University of California San Diego, San Diego, CA, USA

Synonyms

A-type endothelin receptor; EDNRA; ETA; ETRA; ETR; Endothelin receptor eta; Endothelin receptor type A; Endothelin type A receptor; Endothelin-A receptor; ETA receptor; ETA type endothelin receptor; ETA-R; ETAR; ETR ETA; Type A endothelin receptor

Historical Background

Endothelin-1 (ET-1) is a 21-amino-acid vasoactive peptide (see structure in Table 1) that was first isolated and identified in 1988 from porcine aortic endothelial cells. The endothelin family consists of three isoforms: ET-1, ET-2, and ET-3. ET-1 is the principal isoform and is a very potent vasoconstrictor and growth promoter. The physiological effects of the ET system are many and include regulation of vascular tone, renal function, and cell proliferation. ET exerts its effects through two types of endothelin receptors: type A (ETAR) and type B (ETBR). ETAR and ETBR are G-protein-coupled receptors (GPCRs) that share homology with the rhodopsin family. ETAR is pharmacologically distinguished from ETBR by ligand selectivity to the ET isoforms and cardiotoxic peptides isolated from snake venoms sarafotoxins 6b and 6c (S6b, S6c). ETAR binds ET-1 and ET-2 isoforms with much greater affinity than ET-3 (ET-1 $\geq$ ET-2 $>$ S6b $>$ ET-3), while ETBR binds ET-3 and the venoms S6b and S6c with the same affinity as ET-1 and ET-2 (ET-1 $=$ ET-2 $=$ ET-3). A third receptor subtype specific for ET-3, termed the endothelin C receptor (ETCR), has been cloned and characterized from *Xenopus laevis* but is absent in mammalian species (Barton and Yanagisawa 2008; Davenport 2002).

ETAR is expressed in many tissues and organs. It is the principal receptor subtype in the cardiovascular system mediating vasoconstriction, vascular cell proliferation, and the hypertrophic effects and positive inotropic effects of ET-1 in cardiac myocytes. In contrast, ETBR is the predominant receptor on endothelial cells and its activation opposes many of the effects mediated by ETAR stimulation; thus ETBR stimulation results in vasodilation (NO and prostacyclin release from endothelial cells), natriuresis, and clearance of ET-1 from the circulation. Endothelin binds irreversibly to ETAR and, depending on cell type, couples to multiple G proteins ($G_{q/11}$, G_i, $G_{12/13}$) activating a network of signaling pathways. Activation of ETAR is important in wound healing and is implicated in many of the pathophysiological effects of ET-1, including cardiovascular disease, pulmonary and systemic hypertension, atherosclerosis, fibrotic diseases, renal disease, diabetes, cancer, inflammation, pain, and hyperalgesia (Schneider et al. 2007; Barton and Yanagisawa 2008; Khimji and Rockey 2010; Bagnato et al. 2011).

Localization of the ETA Receptor

ETAR is the predominant subtype expressed in vascular smooth muscle cells and cardiac myocytes, but is absent in endothelial cells. ETAR is present in cells and tissues of the lungs, kidneys, liver, CNS, adrenal glands, eyes, and ovaries. Confocal microscopy and immunohistochemical analysis demonstrate that ETAR is largely localized on cell surface on plasma

ET-1 is a 21-amino acid peptide composed of nonpolar(●), polar (●), negatively charged (●), and positively charged (●) amino acids, and stabilized by two disculfied bonds.

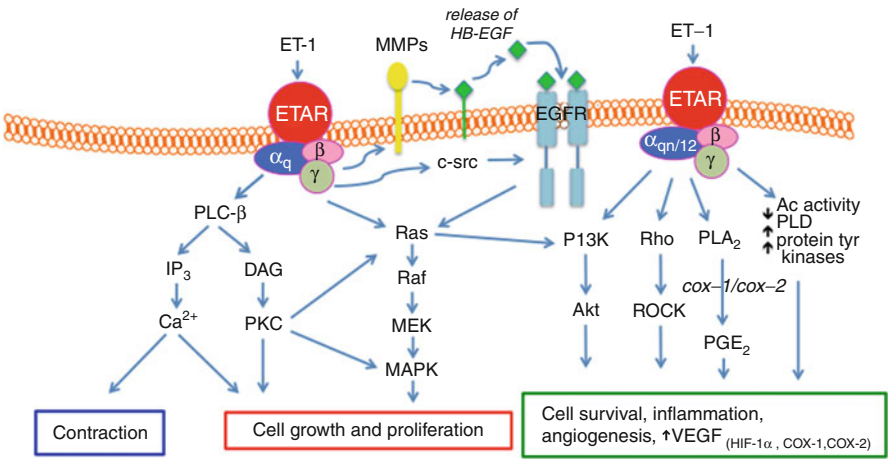
ET, endothelin; S6, sarafotoxin; ETAR, endothelin receptor type A

membranes, and the cytoplasmic tail of ETAR is important for proper localization. In cardiac myocytes, ETAR is present on the sarcolemma, transverse-tubules and, when internalized, is located in the nuclear envelope of ventricular myocytes (Kuc et al. 2006; Bkaily et al. 2011; Hilal-Dandan and Brunton 2010).

ETAR-Activated Signaling Pathways

ET-1 stimulation of ETAR may induce a variety of physiological responses, depending on the differentiated properties of the target cells. ETAR can couple to multiple G proteins, principally G_q, G_i, and likely G_{12} to modulate a large array of signaling pathways (Hilal-Dandan et al. 1997; Takigawa et al. 1995; Ivey et al. 2008). Takigawa and colleagues (1995) co-expressed ETAR with different G-protein α subunits in COS-7 cells and found that ETAR coupled to $G_{q/11}$, $G_{12/13}$, and G_s. There are a few reports of physiological coupling of ETAR activation to elevation of cyclic AMP, but this is likely not direct but mediated by paracrine mechanisms such as ET-stimulated eicosanoid production (Ivey et al. 2008).

Vasoconstrictor and growth-promoting effects of ET-1, mediated via G_q, result in the activation of phospholipase C-β and generation of inositol triphosphate (IP_3) and diacylglycerol. These molecules induce Ca^{++} release and activate protein kinase C (PKC), mitogen-activated protein kinases (MAPKs), and small G proteins (Ivey et al. 2008; Rosano et al. 2009; Khimji and Rockey 2010). In smooth muscle, IP_3 induces Ca^{++} release from the sarcoplasmic reticulum, triggering further elevation of intracellular Ca^{++} and contraction. Cell growth and proliferation are induced through coupling to G_q signaling; G_i and G_{12} signaling can also regulate activation of MAPKs and induction of immediate early genes (Fig. 1). For example, in cardiac myocytes, coupling of ETAR to G_q and pertussis-sensitive G_i pathways contribute to the hypertrophic response (Hilal-Dandan et al. 1997). ETAR mediates the activation of ▶ phospholipase D (PLD), phospholipase A_2 (PLA_2), and the release of arachidonic acid and production of prostaglandins. Depending on the cell type, ETAR may couple to G_i to inhibit ▶ adenylyl cyclase activity, resulting in a decrease in cyclic AMP production. Signaling through ETAR also induces activation of Rho, Ras, Rac, MAPK, JNK, p38 MAPK, PI-3-K-dependent Akt activation, and stimulation of several protein tyrosine kinases. The effects vary with the cell type and may contribute to inflammation, cell growth, survival and proliferation, cell invasion and migration, and inflammation (Ivey et al. 2008; Rosano et al. 2009).



Endothelin A Receptor (ETAR), Fig. 1 *ET-1 signaling via the ETAR*. ETAR couples principally to G_q and G_i, with coupling to G_{12} also possible. Cellular responses are complex due to multiplicity of G protein coupling in a single cell, cross talk amongst pathways, transactivation of the EGFR, and influence of paracrine signaling in response to activation of phospholipases and subsequent eicosanoid production

The mitogenic effects of ET-1, mediated through ETAR, may be amplified by cross talk and activation of EGFR. Stimulated ETAR can induce translocation of β-arrestin to the plasma membrane to form ETAR/β-arrestin complex. β-arrestin acts as a scaffold that recruits intracellular signaling molecules. The ETAR/β-arrestin complex interacts with c-►Src to stimulate transactivation of EGFR and tyrosine phosphorylation of β-catenin, and with axin (a negative regulator of the Wnt signaling pathway) to inactivate glycogen synthase kinase (GSK)-3β and stabilize ►β-catenin. The pathways that link ETAR with β-catenin induce Ras-dependent MAPK activation and are associated with cell migration and plaque formation in atherosclerosis, as well as the progression and invasiveness of ovarian cancer (Rosano et al. 2009).

Ligand Binding, Internalization, and Regulation of Activity

Human ETAR is located on chromosome 4, is 427 amino acids long, and shares ~60% sequence homology with ETBR. The intracellular third loop and carboxyl-terminal domains are required for binding and signaling. Based on chimeric experiments between human ETAR and ETBR, the transmembrane (TM) helices 4–6 seem to determine isoform selectivity, whereas portions of TM 1–3 and 7 plus adjacent extracellular loop regions bind the ETAR-selective antagonist BQ-123 (reviewed by Davenport 2002; Hilal-Dandan and Brunton 2010). The selectivity of ETAR binding to ET isoforms and the snake venoms S6b and S6c pharmacologically distinguishes ETAR from the nonselective ETBR. The order of potency for ETAR binding and activation is ET-1 ≥ ET-2 > S6b > ET-3; S6c is inactive (Hilal-Dandan et al. 1997). Numerous ETAR-selective and nonselective antagonists have been developed, including both peptide and non-peptide ligands (see Table 1).

The binding of ET-1 to ETAR is quasi-irreversible and the primary effects on G_q and G_i pathways are sustained and cannot by removed by washing cells exposed to ET-1 (Hilal-Dandan et al. 1997). Thus, attempts to reverse ET-1 action at ETAR using competitive inhibitors are not successful, whereas simultaneous addition of receptor antagonists and ET-1 is effective at reducing ET-1's subsequent effects. Following ligand binding, conformational changes induce receptor internalization and recycling. Ligand-bound ETAR remains intact for up to 2 h following internalization, and maintains G-protein-coupled signaling. Internalization of ligand-bound ETAR follows the β-arrestin–dynamin–caveolae and clathrin-coated pit pathways. The internalized receptors co-localize with transferrin and are recycled to the surface. Internalized ET-1/ETAR complexes can localize in perinuclear structures. The cytoplasmic C-terminal tail of ETAR determines its intracellular trafficking through a pericentriolar pathway for recycling. Truncation of the C-terminal tail causes ETAR to be directed toward lysosomal degradation (Paasche et al. 2005; Bkaily et al. 2011; see review Hilal-Dandan and Brunton 2010).

Modifications of ETAR include glycosylation, phosphorylation, and palmitoylation. Palmitoylation of the cysteine residues in the cytoplasmic tail modulates ETAR's activity in coupling to G_q signaling, ERK activation, and G_i signaling, but has no effect on ligand binding. Homologous desensitization of ETAR can be induced by GRK2- and GRK3-mediated phosphorylation in vascular smooth muscle cells and cardiac myocytes; the specific residues that are phosphorylated have not been identified (for review see Hilal-Dandan and Brunton 2010).

ETAR can form homodimers or heterodimers with ETBR but the functional significance is not clear. ETAR–ETBR heterodimers in certain cell types have been reported to modify ligand binding and transmembrane signaling, which may explain nontypical receptor behavior. Pharmacologically, selective antagonists to both ETAR and ETBR may be required to inhibit the function of heterodimers (Evans and Walker 2008). For example, there is an increased sensitivity to the contractile actions of ET-1 in rat and human ischemic cerebral arteries following subarachnoid hemorrhage (Edvinsson and Povlsen 2011). In these ischemic arteries, ETBR but not ETAR is upregulated. While the ETBR agonist S6c does not elicit any contractile responses in these arteries, antagonists to ETBR attenuate ET-1-induced contraction; these results suggest possible interaction or dimerization between ETAR and ETBR that enhances sensitivity to ET-1 (Edvinsson and Povlsen 2011). ETAR can form a complex with β-arrestin that interacts with c-Src to stimulate transactivation of EGFR (Rosano et al. 2009).

Genetic Variants

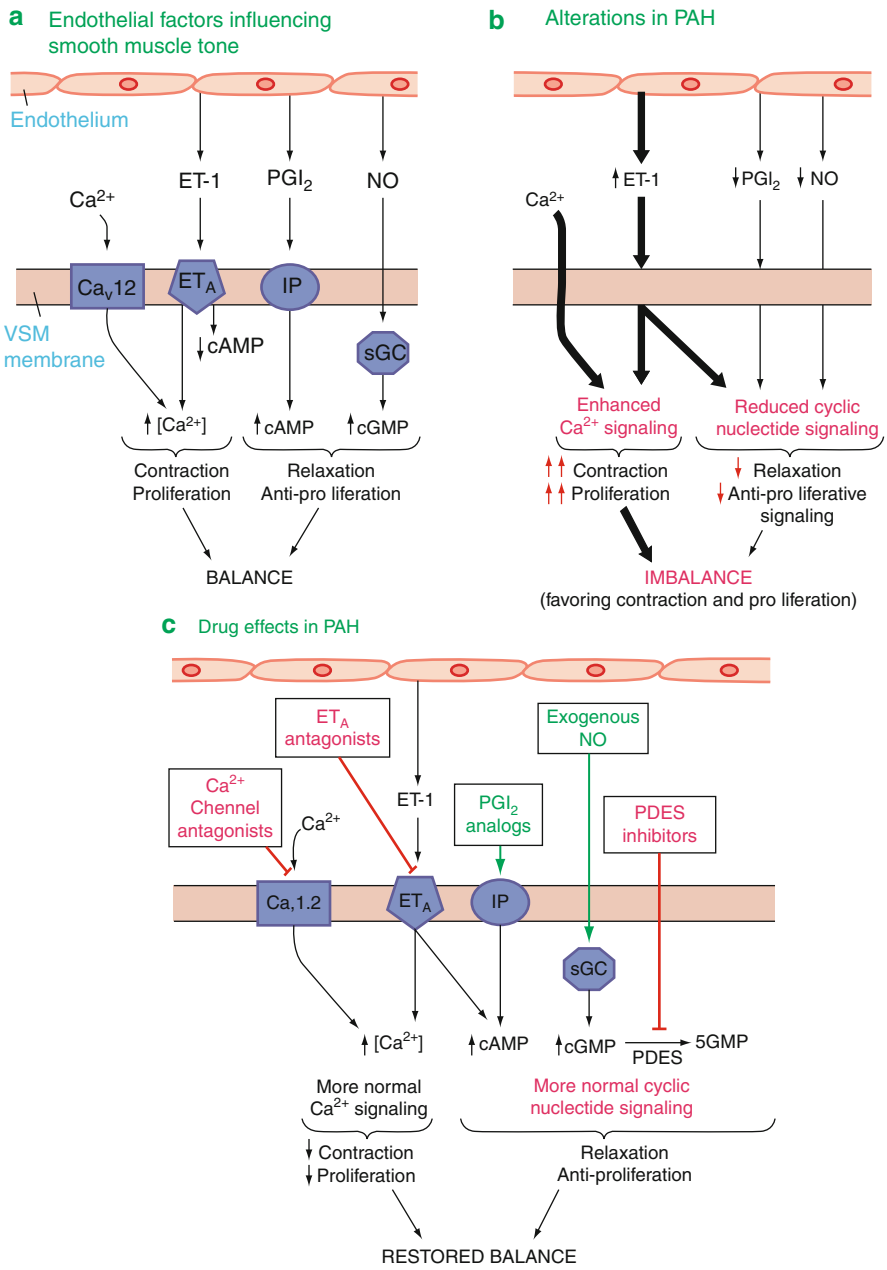
The human ETAR gene has eight exons and seven introns. Alternative mRNA transcripts of ETAR translate into truncated and nonfunctional receptors. Splice variants of ETAR isolated from human tissue include two alternative transcripts designated ETARΔ4 and ETARΔ3,4 (with deletions corresponding to exon 4 and exons 3 and 4, respectively) that result in nonfunctional receptors; a third mRNA transcript designated ETARΔ3 (deletion corresponding to exon 3), identified in human placental tissue, results in a truncated and nonfunctional ETAR. The function of these splice variants is not clear and may involve regulation of ETAR expression and function (reviewed by Davenport 2002; Hilal-Dandan and Brunton 2010).

Genetically engineered homozygous ETAR knockout mice are not viable and resemble ET-1-knockout mice. $ETAR^{-/-}$ mice have defects in cephalic neural crest cell derivatives. Abnormalities include craniofacial deformities, a poorly formed mandible, abnormal development of the middle ear structures, and tracheal narrowing. Cardiovascular defects include a defective aortic septum and defects in cardiac outflow tract with abnormalities in the aortic arch and great vessels. Signaling through ETAR is important for proper development of pharyngeal arches and aortic arch patterning. ET-1/ETAR signaling is responsible for a choice of morphogenetic program that determines maxillary and mandibular structures. The loss of ET-1/ETAR signaling affects homeotic genes, causing transformation of lower jaw into upper jaw structures, whereas constitutive activation of ETAR has the opposite effect, conversion of maxillary structures into mandibular structures (Sato et al. 2008).

ETAR in Disease

Signaling through ETAR is anti-apoptotic and induces cell growth, hypertrophy and proliferation, cell invasiveness and migration, fibrosis, and inflammation; thus, endothelin and the activation of ETAR are implicated in numerous pathological conditions.

Elevated tissue and plasma immunoreactive levels of ET-1 are associated with the severity and prognosis of congestive heart failure following myocardial infarction. In addition, upregulation of ETAR reportedly occurs in human and animal experimental models of heart failure (Schneider et al. 2007). In animal models, ETAR antagonists are beneficial in protecting against hypertensive heart failure and myocardial ischemia. Antagonism of ET_A receptor reduces cardiac hypertrophy induced by aortic stenosis in rats and improves survival in rat models with chronic heart failure by improving cardiac output and decreasing left ventricular hypertrophy. In humans, however, clinical studies have been inconclusive with regard to any long-term advantages of ETAR blockade in treating patients with hypertension and heart failure (Schneider et al. 2007). On the other hand, ET-1 levels and ETAR are upregulated in experimental and human pulmonary



Endothelin A Receptor (ETAR), Fig. 2 *Rationale for use of ET-1 antagonists in treating PAH*. (**a**) In healthy pulmonary artery, there is an appropriate balance between contractile/proliferative and relaxant/anti-proliferative influences. (**b**) In PAH, vascular tone is altered to favor contraction and proliferation. Excess ET-1 signaling via the ETAR receptor may be one of the pathogenic factors. (**c**) Pharmacotherapy to restore appropriate balance may include the use of ETAR antagonists such as ambrisentan (This diagram is reproduced with permission from *Goodman & Gilman's The Pharmacological Basis of Therapeutics*, 12th edition; see Barnes 2011. For details, consult the original reference

arterial hypertension (PAH), and blockade of ETAR is clinically beneficial in reducing pulmonary arterial pressure and reversing arterial remodeling (Schneider et al. 2007; Abman 2009). Figure 2 shows the cell-cell and paracrine interactions involved in therapy of PAH and suggests how ETAR antagonists form one facet of a multi-agent approach. Bosentan and ambrisentan are currently approved for treatment of PAH in the USA (Motte et al. 2006; Abman 2009). Sitaxsentan, approved in Europe since 2006, was withdrawn in 2010 by Pfizer due to toxic liver damage.

Downregulation of ETAR may also occur as a consequence of elevated ET-1 plasma levels. Downregulation of ETAR in the heart, aorta, and pulmonary arteries is reported in hypertension induced by adenovirus-mediated gene transfer of ET-1, and in $ETBR^{-/-}$ deficient mice that have elevated circulating ET-1 levels due to reduced clearance by ETBR

(Kuc et al. 2006). About 20–50% downregulation in ETAR levels has been observed in the aorta and pulmonary arteries of some human diseased hearts, and this has been suggested to be a compensation for elevated plasma ET-1 levels (Kuc et al. 2006).

Both ET-1 levels and ETAR are elevated in chronic kidney disease (CKD) and acute renal failure (Kohan 2010). The ET system is involved in regulation of renal blood flow, reabsorption of Na^+ and water, cell proliferation, and extracellular matrix accumulation. Preclinical studies indicate that selective blockade of the ETAR increases renal blood flow and reduces proteinuria, blood pressure, and arterial stiffness in CKD (Dhaun et al. 2011). Increased ET-1 levels are reported in dysfunctional podocytes that will cause an increase in kidney damage and protein filtration. Blockade of ETAR reverses glomerulosclerosis and inhibits release of ET-1 and the shedding of podocyte-specific protein nephrin that is elevated in CKD. Clinical studies are currently assessing the long-term effects of ETAR blockade on morbidity and mortality of patients with CKD and diabetic nephropathy (Kohan 2010).

Upregulation of the ET system and activation of ETAR are associated with proliferation of VSMC. The mitogenic effects of ET-1 are amplified by synergistic interactions with growth factors such as epidermal growth factor (EFG), insulin, transforming growth factor-β (TGF-β), basic fibroblast growth factor (b-► FGF), platelet-derived growth factor (PDGF), and release of cytokines, which contribute to the development of atherosclerotic plaques (Schneider et al. 2007; Ivey et al. 2008; Khimji and Rockey 2010). In animal models, ETAR blockade inhibits formation of atherosclerotic plaques and improves NO-mediated vasodilation (Barton and Yanagisawa 2008).

In many cancers, the ET system is upregulated and the levels correlate with the severity and progression of the disease (Bagnato et al. 2011). Increased expression of ET-1 and ETAR is associated with tumor growth and progression, neovascularizaion, and metastasis in several cancers including ovarian, prostate, breast, cervical, colon, and lung cancers (Bagnato et al. 2011). The mitogenic effects, mediated through ETAR, are enhanced by transactivation of the EGF receptor (EGFR) through activation of matrix-metalloproteinases (MMPs) that release precursor ligands of EGFR such as the heparin binding EGF-like growth factor (HB-EGF), or through direct phosphorylation by c-Src. Transactivation of EGFR potentiates cell proliferation, cell survival, and tumorigenesis by activating protein tyrosine kinases, PI3-kinase-dependent Akt activation, and Ras–MAPK pathways (Ivey et al. 2008; Rosano et al. 2009). ZD4054, an ETAR-specific antagonist, reportedly inhibits EGFR transactivation and metastasis and enhances tumor regression in ovarian cancer cell xenografts (Rosano et al. 2009). Also, silencing of β-arrestins 1 and 2 prevents ETAR-induced Src activation, transactivation of EFGR, and metastasis (Rosano et al. 2009). Neovascularization and tumor progression correlate with vascular endothelial growth factor (VEGF) levels. ETAR stimulation enhances VEGF levels by increasing the protein levels of hypoxia-inducible factor 1α (HIF-1α) and increasing expression of cyclooxygenase (COX)-1 and COX-2 and the production of PGE_2 (Bagnato et al. 2011). Clinical trials using the ETAR antagonist ZD4054 in patients with prostate cancer have reported improved overall survival (Bagnato et al. 2011). More studies are under way to evaluate the therapeutic value of ETAR antagonism in cancer treatment.

Injection of ET-1 in both human and animals induces spontaneous pain and hyperalgesia (increased sensitivity to pain). The nociceptive and hyperalgesic effects of ET-1 are predominantly mediated through ETAR activation, while ETBR may elicit either pain responses or analgesic effects through release of endorphins (Khodorova et al. 2009). The ETAR is localized on the cell bodies of small diameter sensory neurons of the dorsal root ganglia (DRG) which are associated with pain impulses. ETAR antagonists can ameliorate ET-1-induced acute pain in humans and animal models (Khodorova et al. 2009). Antagonists of ETAR are being tested for their potential analgesic effects in cancer-related pain (Bagnato et al. 2011).

Summary

Endothelin works through ETAR and ETBR to regulate multiple physiological events such as vascular tone, renal function, and cell growth and proliferation. Most of the studied pathophysiological effects of ET-1 are mediated through ETAR. Activation of ETAR is implicated in cardiac hypertrophy and congestive heart failure, ischemic heart disease, pulmonary and systemic hypertension, atherosclerosis, and renal disease. ETAR antagonists are being clinically evaluated in

a number of diseases. Both ETAR-selective and nonselective blockers have proved to be beneficial and are currently in use for treatment of pulmonary hypertension. Given the significant pathophysiological role that has emerged of ET-1/ETAR activation in nociception, inflammation, and the progression and metastasis of many cancers, ETAR-selective blockade may provide a promising target of intervention in analgesia and cancer therapy.

Synonyms

ATP diphosphohydrolase; ATPDase; CD39; Ecto-ADPase; Ecto-apyrase; Ecto-ATPase; E-NTPDase; GDA1; NTPDase; Nucleoside triphosphate diphosphohydrolase

Historical Background

Nucleoside triphosphate diphosphohydrolases (NTPDases), originally ATP diphosphohydrolases (ATPDases) with the common name apyrase, are by definition enzymes which split the γ- and β-phosphate residues of triphospho- and diphosphonucleosides such as ATP and ADP, respectively. Before the cloning of the gene, the common name apyrase was generally used for enzymes that exhibit this activity in plants and invertebrates while the terms ecto-ATPase and ATP diphosphohydrolase (ATPDase) were rather used in vertebrates. Shortly after cloning the first gene encoding such an enzyme, the nomenclature was unified in mammals to NTPDase, which better reflects the ability of these enzymes to convert not only ATP and ADP, but also other triphospho- and diphosphonucleosides.

A first apyrase was discovered in potato tubers in 1944, and was extensively characterized in the following years, although its function was unknown. Apyrases were later reported in other plant tissues such as in various peas and in cabbage leaves. Beginning in 1979, and mostly during the 1980s, apyrases were found in the salivary glands and saliva of bloodsucking animals such as ticks, mosquitoes, fleas, sand flies, and in the medicinal leech. The function of apyrase in these hematophagous animals was suggested to relate to feeding while preventing coagulation. Indeed, ADP is a major platelet aggregation agent, and the hydrolysis of this nucleotide by apyrase therefore has an anticoagulating effect.

Ectonucleotidases have long been known in vertebrate tissues, but the true identification of an ATPDase first happened in 1980 by A.R. Beaudoin's group (Sherbrooke, QC, Canada). They demonstrated the presence of this enzyme in the pig pancreas from which they purified the enzyme to a high degree and studied its kinetics in detail. Cytochemical and biochemical observations showed that this enzyme is associated with the zymogen granule and plasma membrane of acinar cells (Beaudoin et al. 1996). In certain conditions, one could find the enzyme associated with microvesicles secreted from the gland. Until the cloning of ATPDase genes, several papers reported the presence of enzymes with ATPDase activity in virtually all vertebrate tissues. During that period, whether one or two enzymes were responsible for the hydrolysis of ATP and ADP was intensely debated. The definitive identification of these proteins came with the cloning.

Handa and Guidotti in 1996 (Boston, MA, USA) cloned a soluble ATP diphosphohydrolase (apyrase) from potato tubers and noted that similar genes exist in some protozoans, in yeast and in mammals which were related to a human gene called CD39 cloned 2 years earlier. Following this work, Wang and Guidotti again in 1996 reported that CD39 encodes a protein with ecto-apyrase activity (Wang and Guidotti 1996). Independently and at the same time, several peptide sequences of purified ATPDases were obtained which also showed homology to CD39: an ATPDase from human umbilical vessels (S. Christoforidis and coll., Ioannina, Greece), and ATPDases from porcine pancreas and bovine aorta (A.R. Beaudoin's group). Then the groups of Drs. Beaudoin and Robson (Boston) joined their efforts to clone and characterize the gene responsible for encoding this enzyme with ATPDase activity. They came up with the conclusion that CD39 and ATPDase were identical (Kaczmarek et al. 1996). The enzyme is now known as NTPDase1. Shortly after this discovery, H. Zimmermann's group (Frankfurt am Main, Germany) and, independently, T.L. Kirley's group (Cincinnati, OH, USA) cloned

another related gene (Kirley1997; Kegel et al. 1997), now known as NTPDase2. Then, by analyzing expressed sequence tags (ESTs), Chadwick and Frischauf showed three more related genes in humans. We now know that this family comprises eight members in mammals, which are referred to as NTPDase1–8 since 2000 (Zimmermann et al. 2000; Bigonnesse et al. 2004; Robson et al. 2006).

Owing to the cloning of the NTPDase genes, homologous genes that encode enzymes with similar biochemical properties were found throughout the evolutionary tree. Apyrases have been found so far in vertebrates, plants, insects, protozoa, yeasts as well as in bacteria. A more detailed history of apyrase and NTPDases from different species can be consulted in excellent reviews (Beaudoin et al. 1996; Robson et al. 2006; Plesner 1995; Knowles 2011). This entry will henceforth focus exclusively on the mammalian enzymes, using the accepted nomenclature as NTPDases. The genes corresponding to human NTPDase1-8 are *ENTPD1-8*.

General Characteristics

Members of the E-NTPDase family, also called the CD39 family and sometimes, GDA1 family, are major enzymes that dephosphorylate nucleotides such as ATP and ADP. The "E-" stands for "ecto," which may be a little confusing since of the eight members of the E-NTPDase family, four, namely, NTPDase1, -2, -3, and -8, are specifically expressed on the cell surface and hydrolyze extracellular nucleotides. These enzymes are therefore called ectonucleotidases. On the other hand, NTPDase4-7 are attached to intracellular organelles, via one or two transmembrane domains, with their active site facing the intraorganellar lumen. Therefore, these enzymes, if not ecto, are at least "exo" for exocytoplasmic (or extracytoplasmic), as the catalytic site of NTPDases has never been found to face the cytosol, that is, they always face the extracellular medium or a compartment topologically identical to the extracellular medium.

Although heterologous expression showed that NTPDase5 and -6 undergo secretion via proteolytic cleavage, they have a weak activity and a low affinity toward nucleotides compared to the plasma membrane–bound NTPDases, which raises the question as to whether these enzymes significantly contribute to the hydrolysis of extracellular nucleotides in vivo. Other ectonucleotidases also involved in the conversion of nucleotides in the extracellular milieu include nucleotide pyrophosphatases/phosphodiesterases, acid and alkaline phosphatases, as well as ecto-5'-nucleotidase/CD73 (Kukulski et al. 2011; Yegutkin 2008). These enzymes differ by their biochemical properties but most importantly, by their cellular localization. This entry will focus on the four E-NTPDase members that have been clearly demonstrated to contribute to the hydrolysis of extracellular nucleotides and which appear as the dominant ectonucleotidases in physiological conditions (i.e., at pH ~7.4).

NTPDase1, -2, -3, and -8 (EC 3.6.1.5) are type II transmembrane proteins of about 500 amino acid residues. These NTPDases are firmly anchored to the plasma membrane via two transmembrane domains, one near each end of the protein, which delineate a large extracellular loop containing the active site and 10 conserved Cys residues that are obviously important for the tertiary and quaternary structure of these proteins. These four enzymes also encompass about 6–10 *N*-linked glycosylation sites, depending on the protein and species. Members of this enzyme family share five apyrase-conserved regions (ACRs). NTPDase1, -2, -3, and -8 readily form homo-oligomeric assemblies. They have indeed been observed as homodimers to tetramers, whereas hetero-oligomeric complexes between NTPDases have not been reported thus far. Homo-oligomeric assemblies appear to be important for the biochemical activity of the enzymes (Robson et al. 2006).

NTPDases catalyze the hydrolysis of the γ- and β-phosphate residues of triphosphonucleosides (e.g., ATP, UTP) and diphosphonucleosides (e.g., ADP, UDP). Optimal NTPDase activity requires low millimolar concentrations of divalent cations (Ca^{2+} and/or Mg^{2+}). NTPDase1, -2, -3, and -8 are all active at physiological pH, and a few of them are active in a wider set of pH values (see below) (Kukulski et al. 2005). The most important difference between these four NTPDases is their ability to hydrolyze diphosphonucleosides, NTPDase1 and NTPDase2 being the most and least efficient forms, respectively. NTPDases are distinct from other ATPases and are insensitive to inhibitors of F-, P-, and V-type ATPases, and of alkaline phosphatases.

The presumptive major role of plasma membrane–bound NTPDases, and more specifically of

NTPDase1-3 and -8, is the regulation of the concentration of extracellular nucleotides that are released by cells in a regulated manner as well as during cell death and cell lysis (Yegutkin 2008). Through such an action, NTPDases modulate the biological effects triggered by these nucleotides via the activation of several nucleotide receptors, namely, $P2Y_{1,2,4,6,11\text{-}14}$, P2X1-7, and three other receptors that are also activated by nucleotides, namely, cysteinyl leukotriene receptor-1 and -2 (CysLT1 and CysLT2) and GRP17. Indeed, micromolar concentrations of UDP have been shown to activate the last three receptors.

Like other ectonucleotidases, NTPDases are involved in multiple aspects of nucleotide (P2) and adenosine (P1) receptor signaling which include termination of P2 receptor activation, protection of susceptible P2 receptors such as $P2Y_1$ and P2X1 from desensitization, and promote the activation of some P2 receptors as well as of P1 receptors. More specifically, by hydrolyzing ATP, NTPDases terminate P2X1-7 activation as well as $P2Y_2$ and $P2Y_{11}$ activation. Moreover, by hydrolyzing UTP, NTPDases end $P2Y_2$ and $P2Y_4$ receptor activation. These enzymes, and more specifically NTPDase2, can also generate the agonist of some receptors from the hydrolysis of ATP and UTP. Indeed, ADP is the ligand of $P2Y_1$, $P2Y_{12}$, and $P2Y_{13}$, while UDP is the agonist of $P2Y_6$. In addition, the final product of NTPDase activity on ATP, AMP, is converted to adenosine by ecto-5'-nucleotidase and/or alkaline phosphatases. The latter process is of high biological significance, since adenosine is the ligand of the four P1 receptors (A_1, A_{2A}, A_{2B}, A_3). By contributing to the generation of adenosine, NTPDases not only participate in the regulation of P1 receptor activation but they also contribute to replenish ATP stores. Indeed, once released from the cells, nucleotides cannot be re-accumulated as long as they bear a negative charge. In other words, all phosphate groups must be removed before the nucleoside core of the molecule can reintegrate into the cell. Then, nucleosides such as adenosine can reenter the cell by active or passive transport across the membrane via specific permeases, namely, concentrative nucleoside transporters (CNTs) and equilibrative nucleoside transporters (ENTs), respectively. These nucleotide salvage pathways are especially important for tissues and cells such as brain, bone marrow, erythrocytes, and intestinal mucosa, which cannot synthesize these valuable molecules de novo.

As almost every cell expresses more than a single type of P1 and P2 receptors, nucleotides and adenosine have functions in all organs. Therefore, the regulation of the identity and concentration of the receptor ligands by enzymes which metabolize these agonists is critical and should be appropriate for each tissue or cell (Kukulski et al. 2011; Yegutkin 2008; Deaglio and Robson 2011).

Specific Properties

NTPDases differ from each other by their subtle biochemical properties and their cellular localization. Although PCR experiments, which detect low levels of mRNAs, often display the expression of multiple NTPDases by the same tissue/cell, immunohistochemistry with specific antibodies (http://ectonucleotidases-ab.com) most often show that NTPDase1, -2, -3, and -8 are expressed by different cells, with the expression of two of these NTPDases by the same cell being the exception.

A great deal of effort is currently dedicated to the development of specific NTPDase inhibitors. Although some progress has been made, much work remains to be done. The inhibitors that have been developed and utilized thus far have been summarized in a recent review (Kukulski et al. 2011). It is also noteworthy that monoclonal antibodies have recently been developed and two of them specifically inhibit human NTPDase3 and human NTPDase2, respectively (http://ectonucleotidases-ab.com).

Key information toward the design of novel inhibitors is expected from the current work of Dr Sträter's team (Universität Leipzig, Germany). They recently crystallized the extracellular and soluble portion of NTPDase2 (Zebisch and Strater 2008). This already confirmed the importance and localization of the 10 conserved Cys residues in the extracellular domain of plasma membrane–bound NTPDases (members 1, 2, 3, and 8) (Ivanenkov et al. 2005) and the contribution of all 5 ACRs to the catalytic activity of the enzyme. These data represent only a prelude to the actual crystallization of NTPDases as this original work was performed on an extracellular domain produced by *E. coli* which does not glycosylate proteins, and because the transmembrane domains also appear to be important for the activity of NTPDase1, -2, -3, and -8 (Knowles 2011; Grinthal et al. 2006).

This section presents the distinct biochemical properties of the plasma membrane–bound form of the E-NTPDase family members, their general cellular localization, and their demonstrated and/or presumed functions. NTPDase functions involve the regulation of the concentration of P2 receptor ligands. In agreement, all the functions so far reported for these enzymes have been directly, or at least indirectly, linked to the regulation of nucleotide and nucleoside receptor activation. Therefore, the functions described below will be in line with the assumption that they implicate P2 receptors. This by no means excludes the possibility that NTPDases might have functions unrelated to ATP receptors, but due to the lack of clear evidence at the moment, I will not dwell on such hypothetical roles in this entry.

Therefore, the identity and localization of the NTPDase(s), together with the identity of the neighboring P2 and P1 receptors, the signaling pathway coupled with the activation of this (these) receptor(s) in a given cell type, as well as the identity and concentration of the nucleotide released will dictate a precise response and function in a given tissue. The current state of knowledge on the various cellular sources of nucleotides has been very well covered by Yegutkin et al. (2008). The signaling and various functions played by P1 and P2 receptors have also been extensively covered in a number of reviews.

NTPDase1

Characterization

NTPDase1 (aka CD39, ATPDase, ecto-apyrase, ecto-ATPase, or ecto-ADPase) is the best characterized NTPDase thus far, and its involvement in the regulation of several distinct biological processes has been clearly demonstrated (see below). The cDNA encoding NTPDase1 was originally cloned from human tissue. In 1994, Maliszewski et al cloned what was known at the time as CD39, a lymphocyte activation antigen with unknown function. Partial protein sequences obtained at about the same time by different groups from apyrases/ATPDases purified from different tissues finally allowed two groups to independently clone and express CD39 cDNA as a functional ATPDase (Wang and Guidotti 1996; Kaczmarek et al. 1996). This protein was renamed NTPDase1 in the following years. This was the first identification of a gene encoding a protein with true ecto-ATPase activity. The gene encoding human NTPDase1 is now named *ENTPD1* (or *CD39*) and maps to chromosome 10q24 (GeneBank access. no. U87967) (Robson et al. 2006).

Two variants, most probably originating from alternative splicing, have been observed in human placenta. One of them bearing a small modification at the N-terminus was shown to be active. The second isoform is probably inactive. Although NTPDase1 expression often appears to be constitutive, it was shown to be modulated by inflammatory cytokines, oxidative stress, hypoxia, cAMP response elements, glucocorticoids as well as by nucleotides (via $P2Y_1$ receptors).

NTPDase1 hydrolyzes all nucleotides with a similar efficacy. These include the P2 receptor ligands, namely, ATP, ADP, UTP, and UDP. NTPDase1 converts ATP to ADP, and then to AMP. In contrast to the other NTPDases, there is only a minimal transient release of ADP, as the processing step to AMP is favored. Importantly, this property of NTPDase1 makes it the most efficient to convert ATP to adenosine as it not only rapidly generates AMP, the substrate for ecto-5'-nucleotidase, but it also allows the concentration of two inhibitors of the latter enzyme, namely, ATP and ADP, to rapidly decrease. It is noteworthy that, in contrast to adenine nucleotides, NTPDase1 hydrolyzes UTP to UMP with a transient accumulation of UDP, which may favor the transient activation of the UDP receptor ($P2Y_6$). Finally, NTPDase1 has the narrowest range of pH preference for activity, being active between pH 7 and 10 (Kukulski et al. 2005).

The N-terminal intracytoplasmic domain of NTPDase1 is subject to palmitoylation, which targets a subpopulation of enzyme molecules to cholesterol-rich lipid rafts/caveolae. The presence of NTPDase1 in these structures might be of physiological importance due to their association with G-protein-coupled receptor signaling and to their colocalization with some P2 receptors and ecto-5'-nucleotidase. Although its association with caveolae does not appear to be essential for enzyme activity, cholesterol depletion results in a strong inhibition of NTPDase1. Oxidative stress has also been reported to inhibit NTPDase1 activity in vivo, which affects its normal antiplatelet function such as that observed in transplantation models (Deaglio and Robson 2011).

The N-terminus of human NTPDase1 has been shown to interact with truncated Ran-binding protein

M (RanBPM = RanBP9). RanBPM contains conserved SPRY (repeats in splA and RyR) domains which appear to be crucial for its interaction with NTPDase1. RanBPM is known to interact with Sos and to regulate ERK/Ras signaling. Such functions might therefore be altered or regulated by NTPDase1, which may therefore represent a novel, albeit hypothetical function of the enzyme (Robson et al. 2006).

Localization and Function

NTPDase1 is the predominant ectonucleotidase in blood. It is expressed in endothelial cells, smooth muscle cells as well as in leukocytes, including neutrophils, monocytes, and lymphocytes (e.g., B lymphocytes, Tregs, memory lymphocytes, natural killer T cells, and natural killer cells) (Kukulski et al. 2011). NTPDase1 has also been immunodetected in macrophages and resident macrophages such as microglia and Kupffer cells, in Langerhans and dendritic cells (Mizumoto et al. 2002), as well as in some epithelial cells, for example, in the zymogen granule membrane of pancreatic acini where it was originally demonstrated in mammals. This protein is also secreted in an active form into the pancreatic juice together with a particulate fraction (shed from the membrane) (Beaudoin et al. 1996; Robson et al. 2006).

As a result of its nucleotide hydrolysis activity, NTPDase1 has been associated with several functions through its regulation of P2 receptor activation and desensitization. For example, NTPDase1 protects P2X1 and $P2Y_1$ receptors from desensitization. *Entpd1*$^{-/-}$ mice, which are deficient in NTPDase1 expression, display abnormal platelet activation due to $P2Y_1$ receptor desensitization in platelets (Enjyoji et al. 1999). However, it must be noted that this phenotype was observed in NTPDase1-deficient animals which subsisted despite this anomaly. Such protection against P2X1 and $P2Y_1$ receptor desensitization contrasts with another important function of NTPDase1, namely, the prevention of platelet aggregation by removal of ADP, the agonist for $P2Y_1$ and $P2Y_{12}$ receptors in platelets (Robson et al. 2006; Deaglio and Robson 2011). NTPDase1 probably also contributes to this effect by hydrolyzing ATP, the ligand of the P2X1 receptor, which is also expressed in platelets and is also important for their activation in vivo. Therefore, the regulation of the level and duration of NTPDase1 activity should play a crucial role in the overall regulation of P2 receptor activity (activation vs. desensitization).

The function of the endothelial NTPDase1 is not limited to platelet aggregation. It also influences inflammatory processes (see below) as well as vascular tone. Although *Entpd1*$^{-/-}$ mice do not show a global defect in vasomotion, in vitro experiments with arteries from these mice showed that the effects of both exogenous and endogenous nucleotides on vasodilation were dramatically potentiated when NTPDase1 activity is lacking. This regulation was shown to involve the regulation of endothelial $P2Y_1$, $P2Y_2$, and $P2Y_6$ receptors by NTPDase1. Interestingly, the absence of NTPDase1 in vascular smooth muscle cells made the mice more susceptible to vasoconstriction via $P2Y_6$ receptors expressed on smooth muscle cells (Kukulski et al. 2011). These data clearly show the importance of the compartmentalization of nucleotide release as well as the fine regulation of their levels by NTPDase1, which dictates their final output on the biological system, namely, the vascular tone in the latter example.

Illustrations of the role(s) of NTPDase1 in immune responses have grown exponentially in recent years since the enzyme has been shown to be the major ectonucleotidase in leukocytes, including lymphocytes such as Tregs and natural killer cells, as well as macrophages, dendritic cells, and Langerhans cells (Mizumoto et al. 2002). In at least a subset of these cell types, NTPDase1 expression protects from ATP-induced cell death, and affects angiogenesis, leukocyte trafficking as well as the expression and release of several cytokines (Kukulski et al. 2011). NTPDase1-null mutant mice have revealed various functions of the enzyme in immune responses. *Entpd1*$^{-/-}$ animals show amplified inflammatory responses to irritant chemicals due to the lack of NTPDase1 suppressive properties, and present defective stimulation of hapten-reactive T cells (Mizumoto et al. 2002). Also in mouse, NTPDase1 is a Treg cell surface marker which appears to affect cellular immunoregulation (Deaglio and Robson 2011). Modulated nucleotide signaling was also shown to impact NKT-mediated mechanisms that result in liver immune injury. The few observations presented above on NTPDase1-deficient animals clearly suggest that the role of the enzyme in immune reactions is complex. In addition, NTPDase1 has been shown to affect cancer progression, an effect which could be attributed, at least in some models, to NTPDase1 activity in Tregs. Note that NTPDase1 activity detected in some cancers may also

be the result of NTPDase1 expression by cancer cells. Altogether, the inhibition of NTPDase1 enzymatic activity has been proposed as an adjunct therapy for primary and secondary malignancies. However, the underlying mechanism is likely very complex, as spontaneous tumors develop in old *Entpd1*$^{-/-}$ mice, in contrast to the data obtained above with models of more malignant cancers.

Not only NTPDase1 deficiency is linked to distinct anomalies, but the full range of expression and activity for the enzyme also appears to be important for the normal regulation of biological processes, as suggested above. An interesting example of this is an *ENTPD1* polymorphism that was reported in human which is associated with reduced NTPDase1 mRNA expression and which correlates with increased susceptibility to Crohn's disease. In agreement with the latter, severe colitis has been observed in NTPDase1-deficient mice in an experimental model of inflammatory bowel disease (Friedman et al. 2009). The functions of NTPDase1 have been extensively reviewed in recent papers (Kukulski et al. 2011; Deaglio and Robson 2011).

NTPDase2

Characterization

NTPDase2 (= CD39L1 or ecto-ATPase) was originally cloned from chicken and rat (Kirley 1997; Kegel et al. 1997). The *ENTPD2* human gene is located on chromosome 9q34 (AF144748). Two inactive splice variants have been observed so far in human and one such form in rat which has the main characteristics of the original NTPDase2 transcript species, with some differences. Fluctuations in NTPDase2 expression have often been noted but these may be related, as for NTPDase1, to the cell type involved. For example, in mouse hepatoma cells, transcription of NTPDase2 can be induced by 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), an environmental contaminant. Interestingly, the NTPDase2 core promoter reveals constitutive transcriptional activity that is independent of TCDD. Moreover, TCDD failed to induce NTPDase2 in a variety of other cell lines derived from various species. In rat Sertoli cells, NTPDase2 is upregulated by follicle-stimulating hormone and cAMP. In the liver, NTPDase2 is selectively downregulated in biliary cirrhosis. In portal fibroblasts, the expression of NTPDase2 is downregulated by IL-6 at the transcriptional level (Robson et al. 2006; Kukulski et al. 2011).

NTPDase2 is a preferential nucleoside triphosphatase. It converts very efficiently ATP and UTP to the respective diphosphate derivative. Although NTPDase2 can further dephosphorylate these diphosphates to their monophosphate derivatives, the latter's activity is relatively inefficient. Therefore, NTPDase2 facilitates the termination of ATP- and UTP-specific receptor activation in favor of ADP- and UDP-specific receptor activation, respectively. This enzyme is mostly active in the physiological range (as for other NTPDases) as well as in more acidic conditions, but is inactive at pH > 9 (Kukulski et al. 2005).

Localization and Function

The major distribution of NTPDase2 is on the adventitial surface of blood vessels and different types of glial cells in both central and peripheral nervous systems (e.g., astroglia, Schwann cells). NTPDase2 has also been detected in the Bowman's capsule and in some pericytes as in the heart. Interestingly, NTPDase2 is expressed by "glial-like" type I cells of taste buds, and antibodies to this protein have already become a most efficient way to identify these cells (http://ectonucleotidases-ab.com) (Kukulski et al. 2011).

NTPDase2 expression on the outer surface of blood vessels has been suggested to preserve vascular integrity by favoring the activation of ADP receptors expressed in platelets, namely, $P2Y_1$ and $P2Y_{12}$ (Sévigny et al. 2002). Indeed, upon vascular tissue disruption, ATP is released from damaged cells and platelets, which are normally found inside vessels, then come in contact with the released nucleotides as well as with NTPDase2, which does not normally face the luminal side where platelets are found under physiological conditions (Deaglio and Robson 2011).

A most fascinating observation was made by Massé et al. who showed the short but key participation of NTPDase2 in eye development in *Xenopus laevis* (Massé et al. 2007). Hydrolysis of ATP to ADP resulting from the overexpression of NTPDase2 caused the development of ectopic eye-like structures and, accordingly, increased the expression of eye field transcription factors. Neither NTPDase1 nor NTPDase3 could replace NTPDase2 for normal eye formation.

Zimmermann's group reported the expression of NTPDase2 in the subventricular zone and rostral migratory stream of adult rat brain, and suggested that together with an alkaline phosphatase, the enzyme played a role in neural development and differentiation. In the liver, NTPDase2 has also been associated with the regulation of cell proliferation, albeit at a different level. Thus, bile duct cell proliferation was prevented by NTPDase2 expressed in portal fibroblasts in coculture and, conversely, increased when NTPDase2 expression was downregulated. As mentioned above, NTPDase2 is selectively downregulated in biliary cirrhosis and accordingly, IL-6 downregulates NTPDase2 transcription. Interestingly, the latter phenomenon might represent a mechanism accounting for the aberrant proliferation of bile duct cells observed in biliary cirrhosis, where IL-6 is indeed markedly upregulated. NTPDase2 has also been shown to affect IL-8 secretion in HT29 colon carcinoma cells via the regulation of $P2Y_{11}$ receptor activation, and its reconstituted expression in a glioma cell line dramatically increased tumor growth in vivo (Robson et al. 2006; Kukulski et al. 2011).

NTPDase3

Characterization

NTPDase3, previously named in different studies as CD39L3 and HB6, was originally cloned from human brain (Smith and Kirley 1998). The *ENTPD3* gene is located on chromosome 3p21.3 (AF034840). An inactive splice variant has been identified in a human lung cDNA library. When coexpressed by heterologous transfection with the normal form in the same cells, the inactive splice variant could reduce the biochemical activity of the original form (Robson et al. 2006; Knowles 2011).

NTPDase3 converts both ATP and UTP to the monophosphate derivative with a transient accumulation of the diphospho derivative, leading to the transient activation of ADP- and UDP-specific receptors. NTPDase3 is the E-NTPDase family member which exhibits the broadest spectrum of pH for activity (from 5 to 11) (Kukulski et al. 2005).

Although much less information is available on NTPDase3 than on the two previous isoforms, Kirley's group (Cincinnati, OH) generated a large number of enzyme mutant forms in order to characterize the biochemistry of the enzyme. These studies have also been helpful to understand the general structure of the plasma membrane–bound NTPDases, which share a common general tridimensional conformation (Knowles 2011).

Localization and Function

Kirley's group also reported the expression of NTPDase3 in brain neurons, in which they suggested that the enzyme might be involved in the modulation of feeding and sleep-wake behaviors. NTPDase3 was also reported in peripheral neurons such as along rodents' bowels. In addition, it was reported in rodents in certain epithelial cells of the digestive, reproductive, renal, and respiratory systems. In the kidney, NTPDase3 is expressed in thick ascending limb, distal tubules, and in cortical and outer medullary collecting ducts. In the pancreas, NTPDase3 is expressed in all Langerhans islet cells. The pharmacological inhibition of NTPDase3 was shown to increase insulin secretion in low glycemia in the rat β-INS-1 (832/13) insulinoma cell line. NTPDase3 has also been immunolocalized in some enteroendocrine cells of the gastric antrum (Kukulski et al. 2011).

NTPDase8

Characterization

NTPDase8, (= liver canalicular ecto-ATPase or hATPDase), was originally cloned from mouse liver (Bigonnesse et al. 2004). The cDNA clone obtained had a homology with a gene previously cloned from chicken oviduct (Knowles 2011). The *ENTPD8* gene is located in proximity of *ENTPD2*, mapping also to chromosome 9q34 (AY430414) (Robson et al. 2006).

Like NTPDase3, NTPDase8 converts both ATP and UTP to the corresponding monophosphates, with transient accumulation of the intermediary, diphospho derivative. An interesting characteristic of NTPDase8 is its ability to hydrolyze nucleotides both at physiological and acidic pH (Kukulski et al. 2005).

Localization and Function

Mammalian NTPDase8 is expressed in liver canaliculi, and in the apical membrane of some epithelial cells such as in the brush border membranes (presumably on proximal tubules) of the kidney (Kukulski et al. 2011). The presence of NTPDase8 mRNA was also detected in the organ of Corti of the inner ear. Although no specific function has yet been demonstrated for this

last discovered E-NTPDase family member, its localization in the apical surface of the above structures suggests that NTPDase8 might be important for nucleotide salvaging. Indeed, the liver is likely the main source of purines for tissues incapable of de novo synthesis as mentioned in the section "General Characteristics." The presence of NTPDase8 in parallel with ecto-5'-nucleotidase and nucleoside permeases in the canalicular domain of hepatocytes is in support of a role for NTPDase8 in nucleotide salvaging in the liver.

Summary and Perspectives

The E-NTPDase members -1, -2, -3, and -8 are major enzymes responsible for the hydrolysis of nucleoside triphosphates and diphosphates at the cell surface, which regulate P2 receptors and, by extension, adenosine receptor activation as well as the recycling of purines for tissues and cells deficient in de novo synthesis. The study of the functions of these enzymes will be facilitated with the availability of inhibitors for these enzymes, thanks to the current efforts made in several drug discovery laboratories. Although some progress has been made in the last few years, more potent and specific inhibitors are still very much needed. The recent cloning, production of antibodies, as well as generation of gene-deficient animals recently achieved for each of these enzymes should prove very useful in the near future to help in defining the exact functions of these enzymes, and especially for NTPDase2, -3, and -8. Indeed, a great deal of information about NTPDase1 function has come from mice deficient in the protein which were generated about 10 years ago. In addition, the current intense research activity on nucleotide release modes, on nucleotide and adenosine receptors and on nucleoside transporters that are all part of the *purinome* system, should be very fruitful for NTPDase research as well.

Eph Receptor

Kwok-On Lai and Nancy Y. Ip
Division of Life Science, Molecular Neuroscience Center and State Key Laboratory of Molecular Neuroscience, The Hong Kong University of Science and Technology, Kowloon, Hong Kong

Historical Background

The first Eph receptor, which was found to be overexpressed in *e*rythropoietin-*p*roducing *h*epatocellular carcinoma cell line (hence, the name Eph), was identified by homology cloning using the kinase domain of the viral oncogene v-fps as a probe for low-stringency hybridization (Hirai et al. 1987). Since then, other homologous members were cloned by low-stringency cross-hybridization or PCR with primers based on conserved sequences in the kinase domain. There are a total of fourteen homologous Eph receptors identified in mammals to date, comprising the largest family of RTK. They are generally categorized as either EphA or EphB receptor based on ligand specificity (see below).

During the early days when their ligands had not yet been identified, Eph receptors were often described as "orphan receptors" with unknown function. The first Eph receptor ligand, named at that time B61, was cloned as a cytokine-inducible gene (Holzman et al. 1990), although it was not recognized as a ligand of Eph receptor until several years later (Bartley et al. 1994). Using Fc-tagged soluble Eph receptors to screen expression libraries, other Eph receptor ligands have been cloned and collectively called ephrins (derived from *Eph*-inter*a*ct*i*n*g* proteins; Eph Nomenclature Committee 1997). Although B61 was first described as a secreted protein, it turns out that all ephrins are membrane proteins. The eight different ephrins can be subdivided into two families based on the type of membrane anchorage: ephrinAs (ephrinA1 to A5) are linked to the plasma membrane via a glycosyl-phosphatidyl inositol (GPI) moiety, and ephrinBs (ephrinB1 to B3) anchor to the plasma membrane through the presence of a transmembrane domain. In general, ephrinAs bind to EphA receptors (EphA1 to A8 and A10), while EphB receptors (EphB1 to B4 and B6) are preferentially activated by ephrinBs. The notable exceptions are EphA4, which binds to both the A- and B-class ephrins with high affinity, and EphB2, which also binds to ephrinA5 in addition to the transmembrane ephrins.

Multiple Eph receptors and ephrins have also been identified in other vertebrates such as zebrafish and *Xenopus*. However, there is only a single Eph receptor being identified from the invertebrates *C. elegans* and *Drosophila* (Drescher 2002), and a partial sequence of Eph receptor has been cloned from the sea slug *Aplysia californica*. It therefore appears that Eph receptors and ephrins are ancient and evolutionarily conserved, but the divergence of the *eph* ancestor gene into multiple genes might occur during the evolution of vertebrates.

Characteristics of Ephrins and Eph Receptors

Full-length Eph receptors are ~120 kD. The extracellular domain of Eph receptors can be subdivided into the amino-terminal ephrin-binding domain, the cysteine-rich region, and two fibronectin-type III repeats. This is followed by a single transmembrane domain rich in hydrophobic amino acids for membrane anchorage and the intracellular domain that can be functionally segregated into the juxtamembrane region, the kinase domain, the sterile alpha motif (SAM) protein-protein interaction domain, and the PDZ-binding motif. Almost all Eph

receptors have tyrosine kinase activity, except EphB6 which lacks certain conserved amino acid residues in the kinase domain and therefore does not possess catalytic activity. However, it is possible that EphB6 can still function in a kinase- dependent manner, probably through heterodimerization with other EphB receptors or interaction with other tyrosine kinases such as Cbl.

The full-length ephrins contain ~120 amino acids and anchor to the plasma membrane through the GPI-linkage (ephrinAs) or transmembrane domain (ephrinBs). The membrane attachment of ephrins is believed to be essential for mediating the cell contact-dependent functions of the Eph receptors (see below), although there are soluble isoforms of ephrins as a result of alternative splicing. Another unique feature of ephrins is their ability to transduce reverse signaling: upon interaction between ephrins and Eph receptors from opposing cells, not only the Eph receptors can trigger signal transduction via its catalytic kinase domain ("forward signaling"), but at the same time, both the ephrinA and ephrinB can also induce signal transduction in the ephrin-expressing cell, and this "reverse signaling" of ephrin is crucial in nervous system development and functioning, including axon guidance, synapse formation, and synaptic plasticity. The capability of transmembrane ephrinB to transduce reverse signaling is largely attributed to the presence of conserved tyrosine residues in the intracellular domain, which are phosphorylated after binding to Eph receptor by the Src family of tyrosine kinases. The phosphorylated tyrosine residues in ephrinB intracellular domain in turn recruit specific signaling molecules such as Grb4 via interaction with SH2 domain, leading to the propagation of signaling that regulates actin cytoskeleton dynamics (Cowan and Henkemeyer 2002). In addition to tyrosine phosphorylation, the carboxyl-terminal of ephrinB also contains PDZ-binding motif that is critically involved in synapse formation (Klein 2009; Lai and Ip 2009). Compared to the B-class ephrins, much less is known about how the GPI-anchored ephrinA transduces reverse signaling after binding to EphA receptor. The tyrosine kinases Fyn and ▶ Src can be activated by ephrinA5 reverse signaling to regulate cell adhesion, but the detailed mechanisms remain to be elucidated. EphrinA might also recruit the neurotrophin receptors p75 and TrkB as coreceptors for reverse signaling.

Function of Eph Receptors in the Nervous System

Ephrins and Eph receptors are crucial mediators of cell-cell communication in the nervous system, where they play indispensible roles both in neural development (e.g., axon guidance and formation of topographic mapping, synapse formation) and functioning of the matured brain (e.g., synaptic plasticity for learning and memory). Ephrin/Eph are also involved in a wide range of functions outside the nervous system, including cell sorting during embryonic segmentation, formation of blood vessels, maturation of the immune system, and bone formation (Pasquale 2008). Moreover, increasing evidence indicates that Eph receptors are critical determinants of cancer progression (Pasquale 2010). This chapter will focus on the function of ephrin/Eph in the nervous system.

Axon Guidance and Topographic Mapping

It has been known for long time that neurons from the retina connect to the optic tectum (or the superior colliculus in mammals) in a highly precise manner, such that retinal axons from the nasal side of the retina selectively project to the posterior side of the tectum, while the temporal retinal axons specifically innervate the anterior tectum. The identity of the molecules responsible to establish this precise retinotectal map remained obscure for many years until the discovery of the ephrin and Eph receptor. Three important lines of evidence indicate that ephrin represents the major repulsive guiding cue during retinotectal mapping. First, ephrins and Eph receptors are expressed in complementary gradients, with ephrinA2 and ephrinA5 expressed in a gradient from low (anterior) to high (posterior) across the tectum, while the expression of EphA3 is high in the temporal retinal and low in nasal retina. Second, in an in vitro stripe assay, ephrinA5 induces growth cone collapse of temporal retinal neurons, but not nasal retinal neurons. These observations therefore suggest that the countergradient of ephrinA and EphA in the tectum and retina is responsible for establishing the characteristic retinotectal map in a repulsive manner, such that the low expression of EphA3 in the nasal retina allows the projection of the axons into the posterior tectum where the expression of ephrinA2 and A5 is high, whereas the high expression of EphA3 in the temporal retina limits its axons to innervate the anterior tectum

where the level of ephrinAs is low. Finally, knockout mice lacking ephrinA2 or ephrinA5 show disrupted retinotectal connectivity, thus indicating the essential role of ephrin/Eph in topographic mapping in the retina.

In addition to retinotectal mapping, ephrin/Eph also participates in axon guidance and topographic mapping in other brain areas, including the hippocampus-septum, and midline crossing by the commissural axons that connect the two halves of the hemisphere. It is noteworthy that in the latter situation, it is the ephrinB reverse signaling rather than Eph receptor forward signaling that mediates the axonal repulsion.

Synapse Formation and Synaptic Plasticity

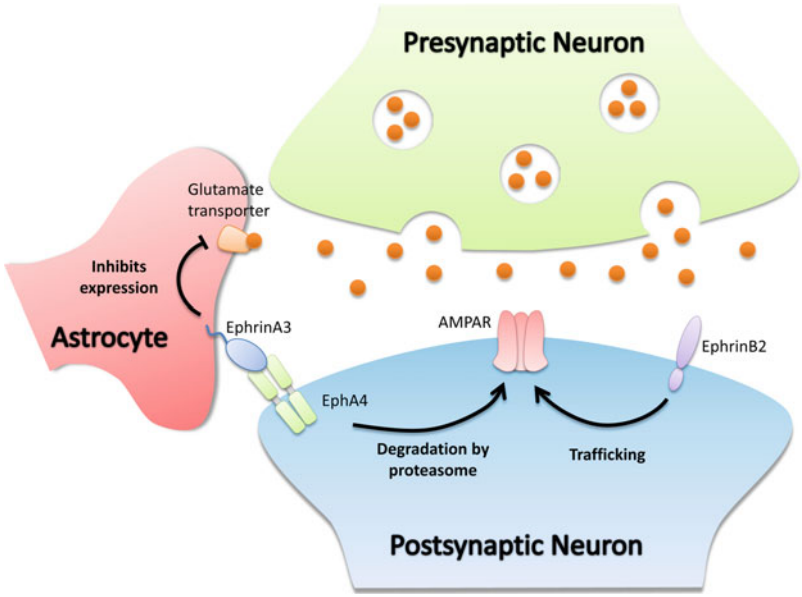
Both ephrinA and ephrinB regulate synapse formation and synaptic function, but their effects and the underlying mechanisms appear to be very different (Klein 2009; Lai and Ip 2009). The importance of EphB in synapse formation is illustrated by the observation that triple knockout mice lacking EphB1/B2/B3 neurons in the hippocampus fail to form dendritic spines, the tiny specialized dendritic protrusions where majority of excitatory neurotransmission takes place. EphrinB-EphB interaction promotes synapse formation by means of several mechanisms: (1) their high-affinity binding provides adhesion to stabilize the initial axon/dendrite contact during synapse formation; (2) both ephrinB and EphB receptor contain PDZ-binding motif at their C-termini that allows simultaneous clustering of PDZ domain-containing scaffold proteins at nascent pre- and postsynaptic specialization; (3) EphB forward signaling increases the motility of immature spines (filopodia), which in turn facilitates the axon-dendrite contact during synapse formation; (4) EphB enhances the function of NMDA receptor, the subtype of ionotropic ▶ glutamate receptor that mediates activity-dependent synapse formation during development; and (5) transsynaptic activation of ephrinB reverse signaling also promotes maturation of dendritic spines as well as formation of presynaptic termini.

In contrast to EphB forward signaling which promotes the formation and maturation of dendritic spines, activation of EphA forward signaling results in spine retraction and loss of functional synapses in cultured hippocampal neurons (Fu et al. 2007). It has been proposed that ephrinA3 localized on astrocytic processes that are in close proximity of dendritic spines activates EphA4 in the postsynaptic neuron to organize dendritic spines and prevent their unlimited growth (Murai et al. 2003). This was supported by the observations that hippocampal neurons in EphA4 knockout organotypic slices display disorganized dendritic spines. Activation of EphA4 forward signaling also leads to loss of functional synapses by triggering the polyubiquitination of AMPA receptors, the major subtype of glutamate receptors for excitatory neurotransmission. This results in degradation of AMPA receptors by the proteasome and subsequent reduction of glutamatergic neurotransmission (Fu et al. 2011).

Activity-dependent changes in synaptic strength (synaptic plasticity) form the cellular basis for learning and memory in adult animals. In particular, synaptic plasticity such as long-term potentiation (LTP) and long-term depression (LTD) in the hippocampus is closely correlated with the formation of spatial memory. Ephrin/Eph interaction is required for synaptic plasticity of hippocampal neurons (Fig. 1). Studies with different transgenic mice have indicated that EphB2 and EphA4 are crucial for hippocampal LTP and LTD, but intriguingly, they regulate activity-dependent synaptic plasticity in a kinase-independent manner. This suggests a possible involvement of ephrinB reverse signaling, a notion that is supported by the findings that transgenic mice lacking the intracellular domain or tyrosine phosphorylation sites of ephirnB2 display defects in LTP and LTD (Grunwald et al. 2004). Indeed, ephrinB2 reverse signaling can directly regulate the trafficking of AMPA receptors, whose abundance is critically regulated during LTP and LTD. Another mechanism that underlies the regulation of synaptic transmission by ephrin/Eph involves glutamate reuptake by transporters expressed in glial cells. Activation of ephrinA3 in astrocytes by EphA4 in postsynaptic neurons controls the expression level of glial glutamate transporters. Notably, hyperexpression of glutamate transporters in EphA4 knockout hippocampus leads to LTP deficit that can be rescued by inhibition of glutamate transporter, indicating the essential role of EphA4 in synaptic plasticity by regulating glutamate reuptake (Filosa et al. 2009).

Adhesion Versus Repulsion: Modulation of Ephrin/Eph Interaction and Function

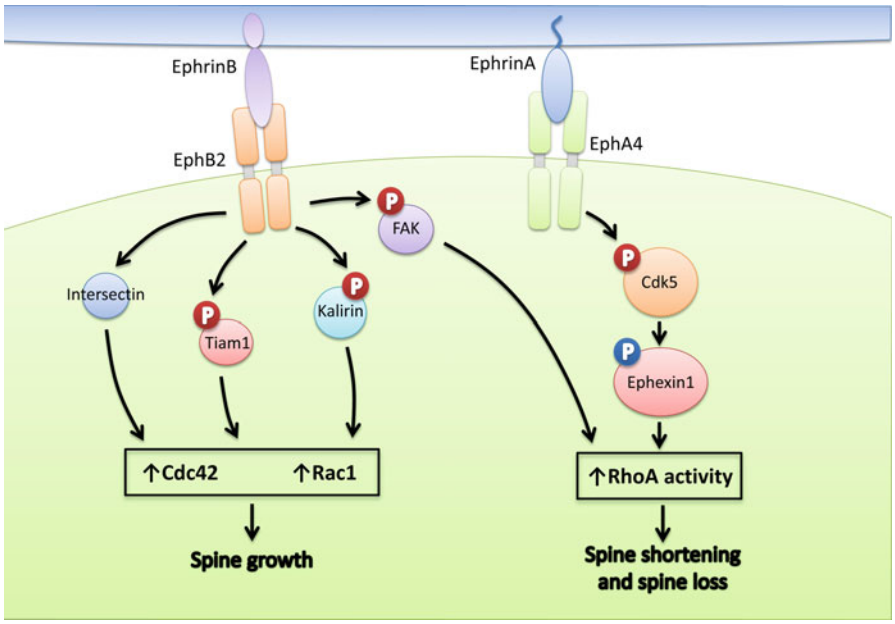
Most of the functions performed by ephrin/Eph within or outside the nervous system involve repulsive cell-cell



Eph Receptor, Fig. 1 Ephrin/Eph regulates synaptic transmission through multiple mechanisms. Excitatory neurotransmission is mediated by the neurotransmitter glutamate, which is released from presynaptic terminal and binds to the ionotropic AMPA receptor (*AMPAR*) that leads to membrane depolarization of the postsynaptic neuron via influx of Na^+. The abundance of AMPAR is regulated by (1) EphA4 forward signaling, which promotes degradation of the GluA1 subunit of AMPAR by the proteasome, and (2) ephrinB2 reverse signaling, which reduces internalization of AMPAR by increasing their interaction with synaptic scaffold protein such as GRIP. In addition, the reuptake of glutamate in the synaptic cleft is mediated by glutamate transporter, whose expression level is reduced by ephrinA3 reverse signaling in astrocytes

interaction (e.g., growth cone collapse, spine retraction, segmentation). However, ephrin/Eph interaction can also be adhesive in specific cellular context (e.g., synaptogenesis, endothelial cell attachment, and capillary assembly). One interesting topic on the study of ephrin/Eph signaling therefore involves understanding how the same family of proteins can generate both adhesive and repulsive signals in a context-dependent manner and how the initial high-affinity trans-interaction between ephrin/Eph on opposing cells switch to become repulsive. Two major mechanisms that modulate the ephrin/Eph interaction have been proposed to potentially explain the switch from adhesion to repulsion. One is internalization of the intact ephrin/Eph complex into their expressing cells by trans-endocytosis. Another mechanism involves extracellular cleavage of ephrin by the metalloprotease ADAM10/Kuzbanian. Both endocytosis and proteolytic cleavage are expected to terminate the interaction between ephrin and Eph receptor and hence allow cell retraction subsequent to the initial cell-cell contact.

Besides endocytosis and proteolytic cleavage, ephrin/Eph interaction can also be modulated by several other mechanisms that can fine-tune the adhesive and repulsive effect. For example, cis-binding between EphA3 and ephrinA5 expressed on the same cell can inhibit transactivation of the receptor by ephrinA5 expressed in neighboring cells, and this modulatory effect of ephrinA5 *cis*-binding is involved in retinotectal mapping. In addition, it has been shown that alternatively spliced isoforms of EphA7 that lack kinase domain can determine the outcome of adhesion and repulsion during neural tube formation in early development. Similarly, soluble forms of ephrin due to alternative splicing also exist, although it is not clear if they can compete with membrane-bound ephrin and inhibit the transactivation of Eph receptor. Taken together, ephrin/Eph cis-binding and the generation of inhibitory isoforms of ephrin/Eph by alternative splicing can potentially increase the diversity of interactions between ephrin and Eph receptor and hence fine-tune the adhesive and repulsive effect of ephrin. This property might be particularly advantageous for their function as positional cues (e.g., during topographic mapping) to guide cell position and connections in a highly precise manner.



Eph Receptor, Fig. 2 Regulation of actin cytoskeleton by Eph receptor signaling through Rho-GTPases. Stimulation of EphB receptor increases phosphorylation and hence activity of the Rac-GEFs TIAM1 and Kalirin, leading to Rac1 activation and formation of dendritic spines. EphB activation also promotes spine growth via the GEF intersectin and the corresponding GTPase Cdc42. On the other hand, activation of EphA4 phosphorylates and activates Cdk5, which then enhances activity of the Rho-GEF ephexin1, leading to spine loss through increased RhoA activity. EphB forward signaling also increases RhoA activity by FAK, which might be involved in shortening of dendritic spines during spine maturation

Signal Transduction of Eph Receptor

Regulation of Actin Cytoskeleton

Substantial evidence indicates that Eph receptor signaling is related to the regulation of actin cytoskeleton, which mostly involves modulating activities of the Rho family of small GTPases such as Rac1, RhoA, and Cdc42 (Fig. 2). Activation of Rac1 and Cdc42 leads to increased actin polymerization that underlies the growth and maturation of dendritic spines and increased motility of filopodia in response to EphB activation. Upon stimulation by ephrinB, tyrosine phosphorylation and clustering of the Rac1-specific guanine nucleotide exchange factors (GEF) Kalirin and Tiam1 are induced, which promote the exchange of GDP for GTP and thereby activate Rac1. The active Rac1 in turn acts on the serine/threonine kinase PAK in EphB-mediated spine and synapse formation. EphB2 also interacts with the Cdc42-specific GEF intersectin, which works together with ▶ N-WASP to promote spine formation. In addition to its effect on GEFs, EphB forward signaling also regulates activity of the Rho-GTPase RhoA through activation of focal adhesion kinase (FAK).

On the other hand, activation of EphA forward signaling leads to inhibition of Rac1 and activation of RhoA, both of which are central to the effect of ephrinA on growth cone collapse and dendritic spine loss. Activation of EphA4 reduces Rac1 activity via the GTPase-activating protein (GAP) α2-chimaerin, which is phosphorylated by EphA4 and becomes activated, leading to the increased GAP activity toward Rac1 and hence the reduction of Rac1 activity during EphA4-dependent growth cone collapse (Shi et al. 2007). In addition, stimulation by ephrinA1 triggers tyrosine phosphorylation and activation of the proline-directed serine/threonine kinase Cdk5, which then phosphorylates the RhoA-specific GEF ephexin1, leading to increased RhoA activity. The significance of Cdk5 and ephexin1 in mediating EphA4 signaling is verified by the observation that ephrinA1 stimulation fails to induce spine loss in neurons lacking Cdk5 or ephexin1 (Fu et al. 2007). EphA4 forward signaling also regulates actin cytoskeleton through phospholipase Cγ1, which

becomes activated after tyrosine phosphorylation and induces membrane dissociation of the actin depolymerization factor cofilin during EphA4-mediated loss of dendritic spines.

Cross Talk with Adhesion Molecules

Besides actin cytoskeleton, another major target of ephrin/Eph signaling is adhesion molecules. Cross talk between Eph signaling and adhesion molecules has been implicated in the control of cell migration, cell sorting, and spine morphology (Arvanitis and Davy 2008). Depending on cellular context and modes of stimulation, both enhancement and inhibition of integrin-mediated cell adhesion by ephrin/Eph signaling have been reported. Signaling molecules that link ephrin or Eph receptor activation to the integrin pathway have also been identified. For example, reverse signaling of ephrinA2 or ephrinA5 increases cell adhesion to laminin that requires Src tyrosine kinase. EphA8 also enhances integrin-mediated cell adhesion via phosphatidylinositol-3 kinase. Moreover, EphA4 interacts directly with integrin in platelets to enhance cell attachment. Intriguingly, another study showed that integrin signaling is inhibited upon EphA4 activation during dendritic spine remodeling in neurons and involves reduced phosphorylation of downstream targets of integrin signaling such as Crk-associated substrate (Cas) and the tyrosine kinases FAK and Pyk2.

Ephrin/Eph also regulates cell sorting through the adhesion molecules cadherin and claudins. EphB activation regulates membrane localization of E-cadherin, which is required for the compartmentalization of colorectal cancer cells by ephrinB1 expressed on the intestinal cells. On the other hand, claudins present at the tight junction interact directly with EphA2 and ephrinB1, and EphA2-mediated tyrosine phosphorylation of claudin-4 regulates its localization and affects paracellular permeability.

Cross Talk with NMDA Receptor and Regulation of AMPA Receptor Trafficking

Glutamate is the major neurotransmitter of excitatory neurons in the brain. There are multiple subtypes of glutamate receptors in neurons, including the ionotropic NMDA and AMPA receptors, as well as the G-protein-coupled metabotropic glutamate receptor. One major mechanism underlying how Ephrin/Eph regulates synapse formation and synaptic function involves regulating the function of NMDA receptor and localization of AMPA receptor. EphB receptor physically interacts with NMDA receptor via the extracellular domain, and this interaction is crucial to mediate the enhancing effect of ephrinB on synapse formation. Activation of EphB also facilitates the function of NMDA receptor, as indicated by the increased Ca^{2+} influx and resulting induction of gene expression. In addition, ephrinB reverse signaling triggers Src-mediated tyrosine phosphorylation of NMDA receptors during LTP of hippocampal neurons.

Ephrin/Eph signaling directly modulates neurotransmission by regulating the localization and trafficking of AMPA receptor. Exogenous expression of EphB2 induces clustering of AMPA receptors in primary cortical neurons, which requires the PDZ-binding motif in the carboxyl-terminus of EphB2. Furthermore, ephrinB2 reverse signaling also regulates AMPA receptors trafficking by two different mechanisms: (1) increasing AMPA receptor interaction with the synaptic scaffold protein GRIP and thus preventing their internalization and (2) counteracting the internalization of AMPA receptors by reducing Ser880 phosphorylation of GluR2 subunit of AMPA receptor.

Regulation of Protein Expression Via Transcription, Protein Synthesis, and Degradation

Emerging evidence suggests that ephrin/Eph also controls the abundance of specific proteins by regulating gene transcription, protein synthesis, and protein degradation. For example, both EphA forward and ephrinB reverse signaling can activate the transcription factor ▶ STAT3, which might have an implication in cancer progression (Lai et al. 2004). EphrinA also regulates the expression of acetylcholinesterase in muscle fibers, which hydrolyses the neurotransmitter acetylcholine at the neuromuscular junction. On the other hand, ephrinA-induced growth cone collapse involves inhibition of local translation of mRNA such as β-actin in the growth cone via phosphorylation of the GTPase-activating protein Tsc2, which leads to depression of the protein kinases ERK and ▶ mTOR (Nie et al. 2010). Finally, recent studies revealed that Eph receptor forward signaling activates specific ubiquitin ligases such as APC2/Cdh1 and Ube3A. This results in the ubiquitination and proteasome-dependent degradation of specific proteins such as AMPA receptor and the Rho-GEF ephexin5, which is essential for homeostatic plasticity and excitatory synapse formation, respectively (Fu et al. 2011; Margolis et al. 2010).

Future Perspectives

Since their identification in the early 1990s, there has been substantial interest in studying this unusual class of receptor tyrosine kinases (RTK) (Lackmann and Boyd 2008). As a result, significant progress has been made on elucidating their molecular properties and how they participate in different biological functions. The studies on ephrin/Eph have undoubtedly generated many surprises and greatly increased the horizon of our understanding of cell-cell communication in a wide range of biological systems. It is also becoming clear that our knowledge on ephrin/Eph interaction and signaling might prove to be useful in the design of therapeutic agents against various diseases. For example, abnormal expression of ephrin/Eph has been reported in different types of tumors. Given their capability of regulating cell adhesion, cell migration, and vascular formation, it is generally believed that ephrin/Eph plays important role in tumor formation and invasion. Their role in tumor formation, however, appears to be highly complicated: they can either promote or suppress tumorigenesis, depending on the types of tumor (Pasquale 2008). Nonetheless, inhibition of ephrin/Eph function might be useful for antiangiogenic therapies for cancer, and small molecules that inhibit Eph receptor kinase activity or ephrin-Eph interaction have been designed and shown to reduce tumor growth in animal models (Pasquale 2010).

In addition to tumor growth and malignancy, recent study also raises the exciting possibility of targeting EphB receptor in Alzheimer's disease therapy. EphB2 interacts with NMDA receptor and regulates its function in synapse formation and plasticity. It was recently reported that β-amyloid binds to the fibronectin-type III repeat of EphB2 and promotes its degradation by the proteasome, and EphB2 expression in the hippocampus is reduced in hAPP transgenic mice, an animal model of Alzheimer's disease. Remarkably, reversing EphB2 depletion by exogenous expression of EphB2 using lentivirus recues the synaptic and cognitive deficits of hAPP mice (Cisse et al. 2011). This study therefore suggests that small peptide that blocks the interaction between β-amyloid and EphB2 might represent a potential pharmaceutical agent for the disease.

Historical Background

A fragment of EphA3 was first cloned in 1991 by Sajjadi et al., in an expression-cloning screen of a chicken embryonic cDNA library using antibodies against phosphotyrosine (Sajjadi et al. 1991). Using this cDNA fragment as a probe, full-length cDNA from both chicken and mouse embryos were identified (Sajjadi et al. 1991). Human EphA3 was independently isolated as a cell surface antigen of a pre-B-cell leukemia cell line (Boyd et al. 1992; Wicks et al. 1992). EphA3 is a member of a large family of tyrosine kinase receptors, which plays many critical roles in both physiological and pathological conditions (Pasquale 2008).

EphA3 Protein

The full-length human EphA3 protein consists of 983 amino acids, organized into the typical extracellular, transmembrane, and intracellular domains as that of other Eph family tyrosine kinase receptors (Wicks et al. 1992). A splice variant, which contains only the extracellular domain, was also identified in the mouse (Sajjadi et al. 1991). The relative abundance and difference in function between the full-length and truncated receptors have not been analyzed at present. Since the truncated form lacks intracellular signaling capacity but is capable of binding to Eph ligands (see the Ligands section for details), it may serve to down modulate EphA3 receptor function. Due to promiscuity of ligand–receptor interactions in the Eph family, it is possible that this truncated form may regulate functions of many other Eph receptors. Similar truncated form has been identified for TrkB, the receptor for the neurotrophic factor brain-derived neurotrophic factor, and has been shown to inhibit full-length TrkB receptor function in developing mouse brain (Carim-Todd et al. 2009).

EphA3 Expression

EphA3 is expressed both in the nervous system and in nonneural tissues. In the developing mouse brain, EphA3 expression is detectable as early as E12, but is undetectable after P10 (Kilpatrick et al. 1996; Kudo et al. 2005; Lai and Lemke 1991). Both mRNA and protein were detected in the developing cerebral cortex, ganglionic eminence, and presumptive caudate-putamen at E12. Expression was also found in the dorsal thalamus and in spinal motor neurons (Iwamasa et al. 1999; Kilpatrick et al. 1996; Kudo et al. 2005; Mackarehtschian et al. 1999). High levels of protein expression were found in the thalamocortical axons.

What is intriguing is that there is an extensive overlap with the adhesion molecule L1 expression, suggesting that EphA3 and L1 interact or at least regulate similar targets. Indeed it has been shown that EphA3 is physically associated with L1, and requires L1 protein for ephrin-A5-induced growth cone collapse (Demyanenko et al. 2011). It will be extremely interesting to examine how EphA3 and L1 interact to regulate axon guidance.

The most striking expression patterns of EphA3 were found in the developing chick and wallaby retina with a nasal (low) to temporal (high) gradient (Cheng et al. 1995; Stubbs et al. 2000). This gradient plays a critical role in the specification of retinotectal topographic axon projection map as discussed in the *Biological Functions* section. How this graded expression is regulated is not entirely clear at present. There is evidence suggesting that two homeobox transcription factors, SOHo1 and GH6, expressed in opposing gradients as that of EphA3 in the retina, inhibit EphA3 transcription, defining the expression in the temporal region (Schulte and Cepko 2000). Indeed, ecotopic expression of either transcription factor resulted in inhibition of EphA3 expression and a partial disruption of retinal axon guidance to the tectum. Two members of the winged-helix (WH) transcription factors, chick brain factor (CBF) 1 and 2, have also been shown to influence EphA3 expression in the chick retina, with CBF1 inhibiting and CBF2 inducing EphA3 expression (Takahashi et al. 2003; Takahashi et al. 2009). Extracellular signals have also been shown to regulate EphA3 expression. For example, the T-cell co-stimulatory signal CD28 and the type 1 insulin-like growth factor can enhance both EphA3 protein levels (Smith et al. 2004b). In contrast, interleukin-1β reduces the expression (Li et al. 1998). However, the regulation of EphA3 expression is incompletely understood, and it remains unclear how different signals coordinate the expression important for its biological functions.

EphA3 mRNA was also detected in a number of nonneural tissues during embryogenesis including axial muscles, heart, cartilage, and bones (Iwamasa et al. 1999; Kilpatrick et al. 1996).

Ligands and Mechanisms of Interaction with EphA3

Two ephrins, ephrin-A1 (initially named B61) and ephrin-A2 (Elf-1), were identified as ligands of EphA3 in 1994 using EphA3 extracellular domain fusion proteins as affinity probes in expression screening experiments (Beckmann et al. 1994; Cheng and Flanagan 1994). Two new ligands, ephrin-A3 and ephrin-A4, were identified by Kozlosky and colleagues using similar methods in the following year (Kozlosky et al. 1995). An additional ligand, ephrin-A5, was identified as a retinal axon guidance molecule (RAGS) (Drescher et al. 1995), and as an expressed sequence tag with homology to ephrin-B1 (Cerretti et al. 1995). Ephrin-A5 was also independently isolated by Lackmann and colleagues from the conditioned medium of human placenta (Lackmann et al. 1996). This ligand was found to be identical to AL-1, a ligand purified with affinity chromatography using the extracellular domain of the related receptor EphA5 from the conditioned medium of a human breast cancer cell line BT20 (Winslow et al. 1995). It is now known that the ligand–receptor interactions of the Eph family are highly promiscuous, and thus EphA3 receptor can interact with all the A-subclass ephrins. A careful study by Lackmann and colleagues in 1997 showed that while different bivalent ephrin-A-Fc fusion proteins interact with EphA3 with similar high affinity, the monomeric form of ephrin-A5 can form a much more stable complex with EphA3 than that of ephrin-A3 (Lackmann et al. 1997), suggesting that ephrin-A5 is the preferred high affinity ligand. Whether ephrins interact with Eph receptors in dimeric/oligomeric forms or monomeric form in vivo is not clear at present. Although nearly all functional assays reported have used multimeric forms of ephrins, monomeric ephrins may indeed have important functions in development or adult, since both ephrin-A1 and ephrin-A5 have been isolated initially from conditioned media as released monomeric form (Holzman et al. 1990; Lackmann et al. 1996; Winslow et al. 1995), it would not be surprising if novel functions were discovered for released monomer ephrins in the future.

The interaction of EphA3 with the ligand ephrin-A5 has been extensively analyzed (Lackmann et al. 1998; Smith et al. 2004a). The ligand-binding domain of EphA3 is located to the N-terminal region to the first IgG domain, encoded by exon III (Lackmann et al. 1998). This is consistent with findings in other Eph receptors (Himanen and Nikolov 2003; Labrador et al. 1997). Ligand–receptor interaction involves a high affinity and a low-affinity binding site. The former is responsible for ligand–receptor dimerization, and the

latter facilitates ligand–receptor tetramer formation (Himanen et al. 2001; Himanen and Nikolov 2003; Smith et al. 2004a). In addition, a ligand independent receptor dimerization domain has also been identified using both protein domain deletion and functional mutagenesis approaches in the cysteine-rich hinge region of the receptor (Lackmann et al. 1998; Smith et al. 2004a). Similar analysis also identified three domains in ephrin-A5 that play key roles in interaction with EphA3 receptor (Day et al. 2005). Two of the sites interact with the high- and low-affinity interaction domains identified in EphA3 receptor, and a third novel interface, which was proposed to bind to the cysteine-rich receptor domain of Eph receptors in adjacent ligand–receptor tetramers, allowing polymerization of large number of the ligand–receptor complexes and effective functional activation.

What is interesting about ephrin–Eph interaction is that simple ligand–receptor binding is not sufficient to fully activate the receptors (Pabbisetty et al. 2007; Stein et al. 1998; Vearing and Lackmann 2005). It has been shown that addition of monomeric ephrin-A5 failed to induce EphA3 kinase activation as assayed by autophosphorylation on tyrosine (Vearing et al. 2005). In contrast, dimeric ephrin-A5-Fc was found to be sufficient to induce EphA3 autophosphorylation. This difference is in part explained by the observation that monomeric ligands have a much lower binding affinity than the dimeric ligands (Pabbisetty et al. 2007). However, ephrin-A5 dimer-induced partial EphA3 activation is not enough to induce a cellular response as demonstrated by actin cytoskeleton contraction, which required additional receptor clustering (Vearing et al. 2005). Similar observations have been reported for ephrin-B1 (Stein et al. 1998). Correlated with the ability to affect cellular functions, only the fully activated Eph receptors are capable of recruiting downstream signaling molecules, although much remains uncharacterized (Stein et al. 1998; Vearing and Lackmann 2005). However, it is not known whether highly clustered ephrins are necessary to induce the full range of biological functions of all Eph receptors. For example, it has been reported that no differences were observed in EphA2 receptor autophosphorylation or endothelial cell migration by dimer or further cross-linked ephrin-A1-Fc (Brantley-Sieders et al. 2004). This issue is complicated by the possibility that different Eph receptors may respond differently to ephrin dimers. In addition, few studies have addressed this issue carefully since ephrin-Fc preparations may contain a mixture of dimers and larger aggregates. Adding to the complexity of ephrin–Eph interactions, it has been shown that interaction of ephrin-A5 and EphA3 in cis silences EphA3 receptor activation, possibly modulating concentration of actively signaling EphA3 receptor molecules (Carvalho et al. 2006).

Since both the EphA3 receptor and its ephrin ligands are membrane anchored, the question of how the ligand–receptor complex can be internalized by endocytosis becomes an interesting question. Elegant mutational and crystallographic studies by Nikolov and colleagues (Janes et al. 2005) showed that although the protease ADAM10 (A disintegrin and metalloprotease 10) is constitutively associated with EphA3, association of ephrin-A5 to EphA3 receptor creates a new binding site for ADAM10, and allows the cleavage of ephrin-A5 releasing the EphA3/ephrin-A5 complex for internalization. In addition, only ephrin-A5 ligand expressed in trans to ADAM10 can be cleaved after EphA3 binding. Such a mechanism ensures only ligands interacting with the receptor are cleaved.

Activation and Signal Transduction

Similar to other receptor tyrosine kinases, EphA3 is activated by ligand binding. Upon ligand binding, the two tyrosine residues located at the juxtamembrane segment of EphA3 become phosphorylated. Crystallographic analysis showed that the unphosphorylated juxtamembrane domain tyrosine residues interact with the active site to prevent adoption of a catalytically active confirmation of the catalytic site (Davis et al. 2008). Mutagenesis studies showed that mutation of Y596F but not Y602F leads to the loss of EphA3 kinase activity as well as the ability to inhibit cell migration and induce cellular process and neuronal growth cone retraction (Davis et al. 2008; Hu et al. 2009; Shi et al. 2010). In contrast, restoration of the negative charge of phospho-Y596 with an Y596E mutation restores EphA3 kinase activity, suggesting that phosphorylation of Y596 is necessary to release inhibition of EphA3 kinase activity. The activation mechanism of EphA3 kinase is likely to be complex and involve many other amino acid residues in both the juxtamembrane domain and the kinase domain. Significantly, both Y742 and S768 also contribute to the regulation of EphA3 kinase activity (Davis et al. 2008).

Although phospho-Y602 is not required for EphA3 kinase activity, it is necessary for its biological functions as measured with either morphological changes (membrane blebbing and cellular process retraction) or cell migration (Hu et al. 2009; Lawrenson et al. 2002; Shi et al. 2010). In fact, Y779 phosphorylation is also important for these biological activities. Both Y602F and Y779F mutations cause a partial loss of biological activity, while the double mutant Y602/779F resulted in a complete loss of biological activity while maintaining its kinase activity (Shi et al. 2010). These observations are consistent with the notion that phosphorylated Y602 and Y779 serve as docking sites for downstream signaling molecules that mediate EphA3 biological effects, and that different tyrosine residues together with their respective signaling pathways collaborate to achieve full biological activity for the receptor.

Downstream of the receptor, activation of EphA3 in T cells by ephrin-A1 results in tyrosine phosphorylation of c-cbl proto-oncogene (Sharfe et al. 2003). The process is dependent on the ▶ Src family kinases, indicating that Src mediates effects of EphA3 activation on c-cbl phosphorylation. c-cbl may serve as a regulator of receptor ubiquitination and degradation, thus downregulating EphA3 protein levels upon activation by ephrins (Sharfe et al. 2003).

It has also been shown that the adaptor protein Nck binds to the phosphotyrosine residue Y602 through its Src Homology domain 2 (SH2), and blocking Nck signaling also reduces EphA3-mediated inhibition of cell migration and process retraction (Hu et al. 2009). Nck is known to interact with multiple signals that regulate cytoskeleton dynamics, including p21-activated kinase (▶ PAK1), and the Wiskott–Aldrich syndrome family proteins that control actin reorganization (Li et al. 2001).

Biological Functions

EphA3 is widely expressed in both neural and nonneural tissues during development and plays multiple roles during embryogenesis.

Substrate detachment and adhesion. Binding of EphA3 by clustered ephrin-A5 has been shown to induce detachment and rounding of HEK293 cells and melanoma cells, but promote adhesion of pre-B and T-cell leukemic cells (Lawrenson et al. 2002; Wimmer-Kleikamp et al. 2008). The opposing effects in these two different types of cells are due to the presence of a protein tyrosine phosphatase activity in the leukemic cells, which prevents autophosphorylation of EphA3. The emerging model is that when EphA3 is fully activated and autophosphorylated on the tyrosine residues, it triggers the activation of Rho-GTPase and leads to cell detachment and repulsion (Lawrenson et al. 2002). In contrast, when receptor activity is down modulated by phosphatase activity, interactions between EphA3 and its ligands lead to cell adhesion. Although the identity of the phosphatase that dephosphorylates EphA3 in pre-B leukemia cells has yet to be identified, evidence indicates that PTP1B may play a similar role in EphA3 dephosphorylation in HEK293 cells and in glioblastoma cells by interacting with the activated receptor at the plasma membrane as well as in endosomal vesicles (Nievergall et al. 2010).

Axon guidance. The earliest hint for a critical function of EphA3 and its ligands in embryonic development came when ephrin-A5 was found to be the repulsive axon guidance signal (RAGS) responsible for generating the topographic retinal axon termination map in the optical tectum in the brain (Cheng et al. 1995; Drescher et al. 1995). The landmark study by Drescher and colleagues, together with the studies by Cheng and colleagues, which demonstrated the expression of EphA3 and ephrin-A2, another ligand, are expressed in opposing gradients in the projecting retina and the target tectum, unraveled an age-old mystery of how axon terminals are topographically mapped onto target brain tissues. Further studies demonstrated that ephrin-A2 and ephrin-A5 together serve as repulsive axon guidance signals for the formation of the retinotectal project map (Ciossek et al. 1998; Feldheim et al. 2000), and that EphA3 as well as other EphA receptors mediate the effects of these ephrins (Brown et al. 2000; Feldheim et al. 2004). Further studies now show that ephrin–Eph interactions play a general role in the specification of topographic maps in several other axon pathways including hippocamposeptal projections (Yue et al. 2002), thalamocortical projections (Dufour et al. 2003; Uziel et al. 2002, 2006), the dopaminergic pathways (Cooper et al. 2008; Passante et al. 2008; Sieber et al. 2004; Yue et al. 1999) and possibly throughout the nervous system. In addition to guiding axons, EphA3 has been shown to play a role in the segregation of axial motor and sensory axon tracks during development through interaction with ephrin-A–EphA transaxonal interaction (Gallarda et al. 2008).

Heart development. EphA3 plays critical roles in development of extraneuronal tissues as well during embryogenesis. One clearly defined function is heart development (Stephen et al. 2007). Inactivation of EphA3 resulted in perinatal heart failure and death in about 75% of newborn mice. Postmortem examinations showed that the EphA3-null mice had enlarged atria and presence of blood in the lung and liver due to capillary disruption caused by exceedingly high cardiac filling pressure. The EphA3-deficient heart showed defects in the atrioventricular valves and in the atrioventricular septum, which separates the right atrium from the left ventricle. Analysis of EphA3 expression in early embryos revealed that the receptor is transcribed in the developing atrioventricular and outflow tract endocardial cushions at E10.5, and in the mesenchymal cap of the developing septum primum at E12.5. The endocardial cushions later generate the atrioventricular valves and septa. A ligand, ephrin-A1, was found to be expressed in the neighboring cells. In the EphA3-null embryos, the endocardial cushions appear to be smaller, possibly due to cell migration defects from an altered cytoskeletal structure of these cells. Consistent with ephrin-A1 expression in the developing heart, deletion of the gene also results in heart defects (Frieden et al. 2010). However, ephrin-A1 KO hearts showed thickened aortic and mitral valves and elevated mesenchymal marker expression, a different phenotype than that of EphA3-null mice, suggesting distinct functions. These observations, together with results from studies in the nervous system, indicate that EphA3 receptor and the ephrin-A ligands, may participate in the development and function of many different tissues and organs during embryogenesis and in adult.

Cancer. In addition to functions in normal animals, EphA3 mutations have been associated with tumor formation. EphA3 has been identified as a melanoma tumor antigen, and is overexpressed in several other tumors including lung cancer, kidney tumors, and brain tumors (Chiari et al. 2000). EphA3 mutations have been identified in primary lung and colon cancer in tumor genome sequencing projects (Wood et al. 2006; Ding et al. 2008). Mutational profiling of kinases in cancer also identified an EphA3 mutation in the cys-rich extracellular domain involved in ligand binding and receptor tetramerization in human pancreatic cancer (Corbo et al. 2010). EphA3 mutations have also been reported in glioblastoma, melanoma, and liver tumor samples (Bae et al. 2009; Balakrishnan et al. 2007). Mutations were identified in both the extracellular and kinase domains, with no hotspot preferences. Although the exact nature of these mutations are currently unknown, it has also been shown that EphA3 is among genes mutated or lost in the loss of heterozygocity in head and neck squamous cell carcinoma suggesting that this receptor serves as a tumor suppressor (Lee et al. 2010).

Summary

EphA3, a tyrosine kinase receptor of the Eph family, plays critical roles in the regulation of both physiological and pathological processes. The receptor is required for axon guidance to proper targets in the nervous system, and for heart development. EphA3 mutations have been detected in many different types of tumors. Since EphA3 expression is found in many different tissues during embryonic development, it is within reason that new functions will be attributed to this receptor in the future. However, understanding of EphA3 function and how it conveys the signals in the cells are at their infant stage. For example, the role EphA3 plays in carcinogenesis remains undefined, since both overexpression and mutations have been found in tumors. In addition, downstream signaling pathways for EphA3 are poorly understood at present. It is not clear whether EphA3 uses similar signaling strategies as that of other Eph receptors or uses unique pathways. Furthermore, roles of the truncated receptor in development and disease remain to be elucidated.

Historical Background

Eps8 (EGFR pathway substrate #8) is an actin-binding and signaling molecule with a molecular weight of 97KDa encoded by a gene comprising 21 exons located on the human chromosome 12p12. It was originally identified through an expression cloning approach designed to isolate intracellular substrates for the tyrosine kinase of the Epidermal Growth Factor Receptor (EGFR) (Fazioli et al. 1993). Eps8 is efficiently phosphorylated on tyrosine residues by a variety of both receptor and non-receptor tyrosine kinases (Fazioli et al. 1993). Following stimulation with neurotrophic factor BDNF, which critically controls growth and differentiation processes in the brain during development, through the activation of Trk tyrosine kinase receptors, Eps8 can also be phosphorylated, in a MAPK-dependent manner, on serine and threonine residues. Notably, while the physiological and functional implication of Eps8 tyrosine phosphorylation remains to be identified, BDNF induced, MAPK-dependent phosphorylation of S624 and T628 of mouse Eps8 are critical for regulation of its localization and functions (Menna et al. 2009) (see below).

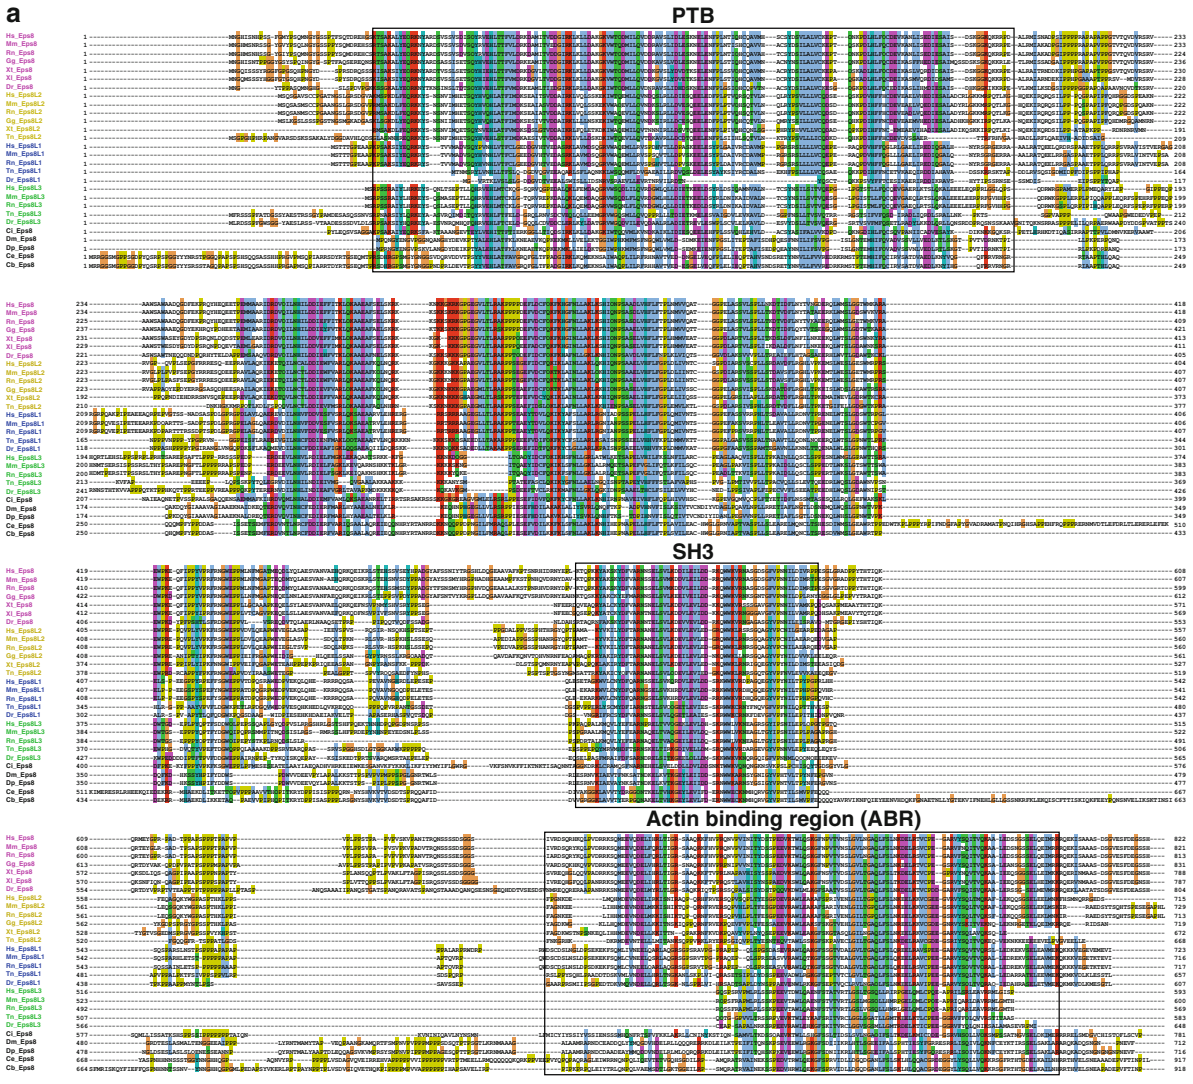
Eps8 is the founding member of a family of eps8-related proteins, comprising three additional gene products in vertebrates, named eps8L1, eps8L2, and eps8L3 (Fig. 1a-b). All Eps8Ls display collinear topology and 27–42% identity to Eps8, sharing a similar modular organization into distinct structural and functional domains that comprise an N-terminal Phosphotyrosine Binding domain (PTB), a central Src homology-3 domain (SH3), two Proline rich regions, and a C-terminal "effector actin-binding region" (ABR) that mediates Eps8 interactions with actin filaments (Offenhauser et al. 2004). EPS8-like orthologues are also present in nonmammalian species (Fig. 1a-b). In *Drosophila melanogaster* there are two like genes called *arouser* and LP01469p. A single *eps8* gene is, instead, present in *Caernorabditis elegans* that gives rise to two splicing isoform *eps-8A* and *eps-8b*, differing at their carboxyl termini. While the function of *eps8* in the fly is unknown, in the nematode, *eps-8* is essential for embryonic development (Croce et al. 2004). Furthermore, EPS-8A, but not EPS-8B protein, is specifically required for proper morphogenesis of intestinal cells. This latter phenotype could be precisely correlated with the evolutionarily conserved actin-binding

activity, which is present in the C terminus of the EPS-8A isoform, providing genetic evidence that the actin-related properties of EPS-8 are critical for its function in the whole organism.

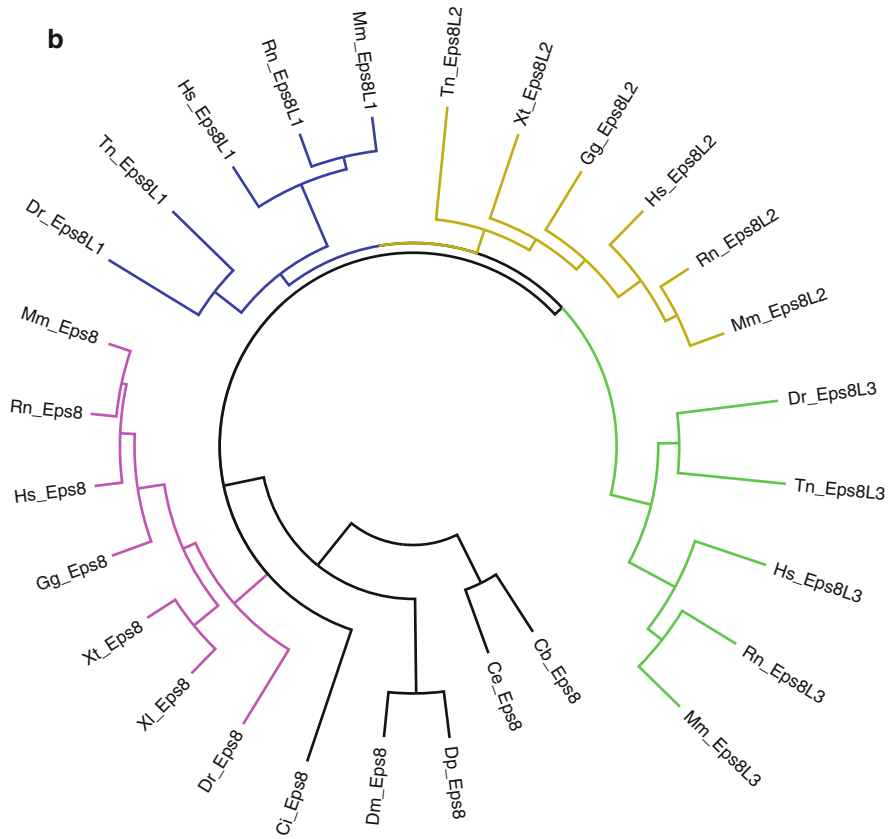
Domain Organization and Interacting Partners

The modular organization of Eps8 and its family members supports the notion that Eps8L family proteins generally act as adaptors for the assembly of macromolecular complexes required for the transduction of signals from receptor tyrosine kinases (RTKs) leading to regulation of actin remodeling and cell migration (Fig. 1a). This section will describe what is currently known about the PTB and SH3 domain of Eps8, while more detailed information on the effector ABR will be provided in the section entitled "Eps8 and Actin Dynamics."

Among the distinctive protein:protein interaction domains, the least functionally characterized is the N-terminal PTB domain. Originally, PTB domains were identified as protein–protein interaction modules, binding to a variety of NPXY containing motifs with high affinity when the tyrosine residue is



Eps8 (Epidermal Growth Factor Receptor Pathway Substrate 8), Fig. 1 (continued)



Eps8 (Epidermal Growth Factor Receptor Pathway Substrate 8), Fig. 1 The C-terminal region of EPS8 is highly conserved among metazoan homologues. (**a**) Multiple sequence alignment of EPS8 homologues. Protein sequences were identified by BLAST searches against all known protein sequences at NCBI or predicted from the genomic sequences of the specific organism using the GeneWise software (http://www.ebi.ac.uk/Wise2/). Sequences were aligned using the ClustalW program and the picture was produced using Jalview. Domains are boxed and indicated. PTB, phosphotyrosine binding domain; SH3, Src homology domain 3; ABR, Actin-binding region, EPS8 possesses a barbed end capping activity encoded by its evolutionarily conserved, C-terminal region (residues 648–821 for murine EPS8) (Fig. 1a). This region of EPS8 displays no sequence similarity with other known capping proteins or actin-binding motifs, but displays a similarity (similarity, E = 60.8; confidence E = 2.4) with the profile of the SAM Pointed (SAM_PNT) domain (Fig. 1a). SAM_PNT domains, which belong to the larger family of sterile alpha motif (SAM) (Slupsky et al. 1998), are present in a subset of the ETS-like transcription factors, including mammalian Ets1, Ets2, Erg, Fli1, GABPa, and Tel, and *Drosophila* Pnt and Yan (Slupsky et al. 1998). The C-terminal portion of EPS8 and its family members can be aligned with known SAM_PNT domain sequences, and its predicted secondary structure is superimposable to that determined for Ets1 (not shown). (**b**) Phylogenetic tree was produced with ClustalW and illustrated with FigTree (software by Andrew Rambaut, http://evolve.zoo.ox.ac.uk/software.html/id=figtree). GenBank accession numbers for each protein or coordinates of the genomic sequences from where they were reconstructed are provided in Table 1

phosphorylated, such as in response to RTK stimulation. This latter feature, however, is not shared by the majority of PTB domains that bind NPXY motifs irrespective of ligand phosphorylation or preferentially recognize unphosphorylated ligands, such as the PTB of the endocytic adaptor NUMB (Forman-Kay and Pawson 1999). The high structural homology between Eps8 and the latter PTB domain suggests that also Eps8 PTB may preferentially recognize unphosporylated NPXY motifs (Smith et al. 2006). In vitro evidence in this direction has, indeed, been provided; however, the lack of physiological validation of any of the putative binding partners of Eps8 PTB domain has prevented not only to validate the mode of binding of Eps8 PTB domain, but also to elucidate the functional consequence of this interaction module.

A canonical SH3 fold consists of two antiparallel beta sheets packed against each other at an approximate right angle. The first crystal structure of the SH3 domain of Eps8 revealed an intertwined dimer,

characterized by "strand exchange," in which the two antiparallel beta sheets are contributed by different polypeptide chains (Kishan et al. 1997). Surprisingly, this results in half-dimers whose folds are superimposable to that of a canonical SH3 module. An important consequence of the dimeric configuration is that the proline helix-binding groove is partially occluded in the context of the hybrid-dimer, impeding

binding to ligands (Kishan et al. 1997). More recently, a monomeric structure of the SH3 domain of Eps8 has been reported, as obtained from crystals grown at low pH. In this case, the SH3 domain of Eps8 displays a canonical SH3 fold (Kishan et al. 2001). While this latter configuration is likely the one adopted under physiological conditions, dimerization of Eps8 SH3 domain may occur under some circumstances and might function as an "OFF" signal, which can be switched "ON" as the molecule becomes monomeric thereby allowing protein–protein interactions at the sites occluded in the dimer to occur. It should be noted, however, that the formation of a strand-exchanged dimeric Eps8–SH3 domain results in an extensive dimerization interface, much greater than usually observed for reversible regulated protein–protein associations in signal transduction. Thus, the physiological relevance of a dimer–monomer equilibrium in vivo remains to be established.

The identification of the optimal binding peptides for the SH3 domain of Eps8 provided another unexpected result. In spite of the overall conservation of the primary structure and the similarity to the canonical SH3 fold, the SH3 domain of Eps8 binds preferentially to peptides containing a PXXDY, instead of the XPXXP, consensus sequence (Mongiovi et al. 1999). This binding specificity is conserved among the three related genes (Mongiovi et al. 1999). Solution by NMR of the Eps8L1 SH3 domain in complex with the PPVPNPDYEPIR peptide from the CD3epsilon cytoplasmic tail further highlighted the specific molecular requirements at the basis of this unusual mode of binding (Aitio et al. 2008). Indeed, the polyproline peptide binds Eps8L1 SH3 in a class II orientation, but neither adopts a polyproline II helical conformation nor engages the first proline-binding pocket of the SH3 ligand-binding interface. Critical conserved residues in the SH3 domain of Eps8L family members, that are unique with respect to the other SH3 domains, account for this specificity. Most notably, an Eps8L-conserved isoleucine (I531 in EpsL1) is present instead of Y or F in the hydrophobic pocket rendering it nonoptimal for binding to conventional PxxP peptides. Furthermore, specific electrostatic and hydrogen bonding between the D and Y residue of the ligand peptide with positive charge of R and carboxyl group of E in the SH3 domain of Eps8L1, respectively, account for the critical role of the PxxDY motif tyrosine residue in binding to Eps8 family SH3 (Aitio et al. 2008). Thus, the SH3 of Eps8 represents the prototype of a unique family of SH3 modules, which do not bind to canonical XPXXP-containing peptides, and contract specific and distinct interactions in the signaling network. This contention is further supported by the isolation of two physiological interactors of the SH3 domain of Eps8, Abi1 (Abelson Binding Interactor 1) and RN-tre (a GAP for the endocytic Rab5) which display the PXXDY motif and, as it will be discussed later on, establish a novel network involved in the regulation of RTK-dependent signaling.

Recently, the human lanthionine synthetase C-like protein 1 (LanCL1), a eukaryotic homologue to prokaryotic lanthionine cyclases, has been identified as a novel interactor of the SH3 domain of Eps8 (Zhang et al. 2009). Lanthionine cyclase in prokaryotic cells is a peptide-modifier enzyme frequently required to generate antibiotic peptides. However, the function of LanCL1 in mammalian cells remains ill defined. Remarkably, the interaction with Eps8 appears to be required for LanCL1-mediated neuritogenesis (Zhang et al. 2009). Furthermore, the biochemical basis of the association is unusual since it is not mediated by a linear PXXDY motif of LanCL1, but presumably requires an extensive molecular surface interaction from both of these molecules, and is regulated by redox signaling, thus establishing a novel paradigm in the binding and regulation of SH3-mediated protein:protein interactions (Zhang et al. 2009).

Multiple Functions of Eps8 in the Small GTPase Pathways Control Actin Dynamics–Based Processes

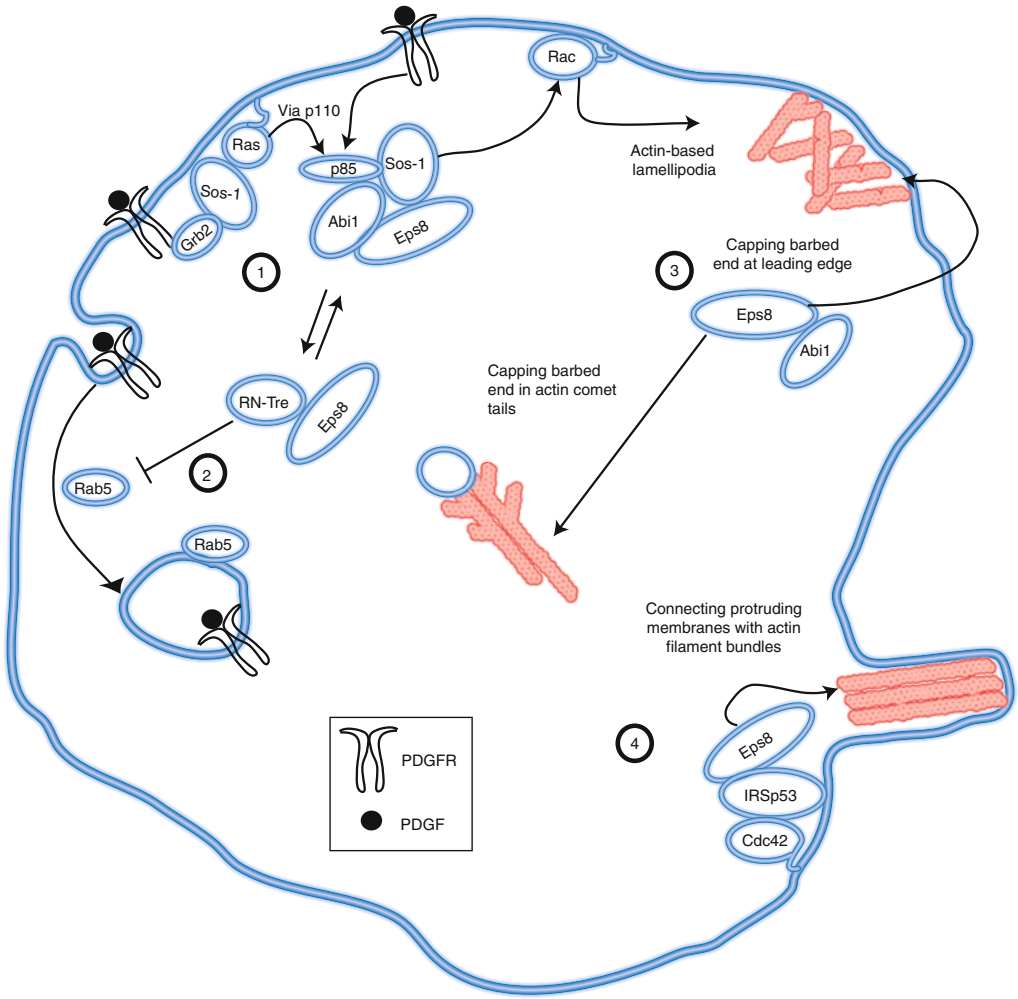
Eps8 has emerged as a key regulator in controlling actin cytoskeleton remodeling. The structural organization of Eps8 in multiple protein–protein interaction domains suggests that it acts both by participating in signaling cascades downstream RTKs receptors, through its interaction with Abi1, Sos-1, and RN-tre, and by directly controlling the actin cytoskeleton dynamics and structural organization through its capping and a bundling activity. It is noteworthy that virtually all these functions are mediated by Eps8 C-terminal domain (aa 648–821), where both the Sos-1 and the actin-binding surfaces are located.

Eps8 in the Rho GTPase signaling cascade. Eps8 as a molecular adaptor participates in the RTKs signaling

cascade leading to Rac-dependent actin cytoskeleton remodeling. At the molecular level, Eps8 was shown to enter into a multimolecular complex with Abi1, p85, and Sos-1 (for a review of this pathway see Di Fiore and Scita (2002)). Abi1 is the non-catalytic subunit of PI3K, and Sos-1 is the dual GEF for Ras and Rac (Fig. 2). Within this complex, Abi1 acts as a scaffold facilitating the interaction between Eps8, p85, and Sos1 (Di Fiore and Scita 2002). The assembly of this signaling unit is critical to unmask the otherwise silent Rac-specific GEF activity of Sos-1, through mechanisms that remain to be fully elucidated, mediating actin cytoskeleton remodeling in response to growth factors stimulation (Di Fiore and Scita 2002). Notably, the C-terminal region of Eps8 mediates in vitro a direct, low-affinity interaction with Sos-1, sufficient to activate the Rac-specific GEF of the latter protein in cells, suggesting that this region acts as a bona fide effector region within Eps8, mediating all the functions so far ascribed to this protein both as signal adaptors and actin regulatory binding interactors (Di Fiore and Scita 2002).

The above scenario became more complex with the identification of another Eps8 interactor, IRSp53, which primarily acts as downstream effector of Cdc42 (Fig. 2). IRSp53 was originally discovered as a substrate of the insulin receptor. Subsequently, IRSp53 was shown to participate in the formation of various Cdc42- and Rac-dependent, actin-based protrusions, including filopodia and lamellipodia, neurites and dendritic spines, through a mechanism that remains to be fully elucidated. The role of IRSp53 in filopodia is more clearly established. Filopodia are actin-rich, finger-like structures that protrude from the cell membrane of a variety of cell types and play important roles in cell migration, neurite outgrowth, and wound healing (Scita et al. 2008). They are characterized by a small number of long and parallel actin filaments that deform the cell membrane, giving rise to protrusions. Within this context, IRSp53 is thought to connect actin regulatory complexes with the extending membranes. In keeping with this notion, IRSp53 possesses an N-terminal helical domain, which belongs to the BAR (Bin-amphipysin-Rvs) family of domains and folds into zeppelin-shaped dimers. BAR domains themselves are banana-shaped structures that induce curvature in membranes via their concave face promoting membrane invagination and the generation of tubules and vesicles important in endocytic and intracellular trafficking processes. In contrast to these standard BAR domains, the I(inverted)-BAR domain of IRSp53 induces negative curvature in membranes, thus inducing protrusions rather than invagination and contributing to the formation of filopodia (Scita et al. 2008). In this latter process, IRSp53 is thought to act as an effector of Cdc42, which in its activated GTP-bound form can bind to a Cdc42-specific CRIB-like sequence of IRSp53. This interaction leads to relocalization of IRSp53 to sites where filopodia are initiated. At this location, IRSp53 can physically link the protruding membrane to the underlying actin filaments by binding, through its SH3 domain, a number of regulators of actin dynamics and architectural organization, including Dia1, Mena, WAVE2, and Eps8 (Scita et al. 2008). It is noteworthy that, among these interactors, Eps8 is the only protein that can form a stable complex with IRSp53 both in vitro and in vivo (Hertzog et al. 2010). The assembly of a Eps8::IRSp53 complex endows this unit with actin bundling activity in vitro, that may initiate, in vivo, the formation of actin bundles, which would subsequently become tightly cross-linked by other more efficient bundlers, such as fascin. Thus, Eps8 together with IRSp53 may act at the interface of membranes and the actin cytoskeleton, initiating in a Cdc42-dependent fashion the bundling of filaments, which may subsequently elongate and become tightly bundled supporting filopodia extension.

Eps8 and Rab5 endocytic networks. Eps8 involvement in endocytic processes derives from its ability to bind yet another SH3 interactor, RN-tre. RN-tre is a GAP specific for Rab family proteins, including Rab5 (Lanzetti et al. 2000), indicating its involvement in trafficking processes. Most notably, RN-tre was originally demonstrated to function both in vitro and in vivo on Rab5 (Lanzetti et al. 2000), which is in turn essential for regulating multiple steps of internalization of various membrane receptors, including early endocytic events and early endosomal formation, maturation, and trafficking. In particularly, Rab5 is essential for EGF receptor endocytosis upon ligand binding. Interaction between Eps8 and RN-tre has been shown to be required for the activation of the Rab5-GAP specific activity of the latter protein. This leads to the inhibition of the small GTPase accompanied by increased EGFR at the cell surface due to impaired receptor internalization and increased signaling (Lanzetti et al. 2000) (Fig. 2).



Eps8 (Epidermal Growth Factor Receptor Pathway Substrate 8), Fig. 2 Eps8-based complexes in the midst of GTPases signaling controlling actin dynamics–based processes. The presence of multiple protein–protein interaction domains enables Eps8 to form diverse multimolecular complexes that act on various small GTPases-dependent pathways. (1) Through its unique SH3 domain, Eps8 can bind to Abi1, which forms the scaffold for a larger complex together with Eps8, Sos-1, and p85 the regulatory subunit of phosphatidyl-inositol-3- kinase (PI3K) mediating the propagation of signaling leading to Rac activation and Rac-dependent actin remodeling from activated PDGFR either directly or through the Grb2-Sos-1-Ras pathways (Di Fiore and Scita 2002). (2) The SH3 domain of Eps8 mediates also the interaction with RN-tre, a GAP for the small G protein Rab5 (Lanzetti et al. 2000), which, in turn, controls RTK internalization and trafficking, thus regulating the duration and cellular localization of RTK signaling, resulting in the formation of specialized actin-rich membrane protrusion (not shown) (Lanzetti et al. 2004). (3) Through its C-terminal actin-binding region, Eps8, which is localized at the very leading edge of actin-rich lamellipodial protrusions as well as in rocketing tails propelling endosomal vesicles and intracellular pathogens (Disanza et al. 2004), binds and caps actin filaments thereby controlling their dynamic and architectural organization. Remarkably, the capping activity of full-length Eps8 is inhibited and can be induced, at least in vitro, through binding to Abi1, which is also localized at the very leading edges of lamellipodia. (4) Eps8 can also cross-link actin filament when it is bound to IRSp53 (Hertzog et al. 2010; Disanza et al. 2004). IRSp53 dimerizes, thus enabling the formation of Eps8 clusters that may act to enhance the cross-linking activity of the complex, which can be recruited by activated Cdc42 to plasma membrane sites for filopodia initiation resulting from the combined membrane deformation ability of IRSp53 and actin-binding property of Eps8. It is of note that the actin-related activities of Eps8 are conserved throughout evolution and have been shown to mediate the morphogenesis of intestinal microvilli in nematodes (Hertzog et al. 2010) and mice (Tocchetti et al. 2010) as well as the development of stereocilia (not shown). Both microvilli and stereocilia are formed by parallel array of bundled filaments whose elongation is tightly controlled by a variety of actin regulatory proteins

Thus, Eps8 may regulate Rac activity either directly through assembly of a plasma-membrane-localized signaling complex that promotes optimal transmission of motogenic RTK signaling, and indirectly through endocytsosis that confers a spatial dimension to signaling that is ultimately required for the regulation of polarized function, first and foremost actin dynamics–based directional migration.

Eps8 and Actin Dynamics

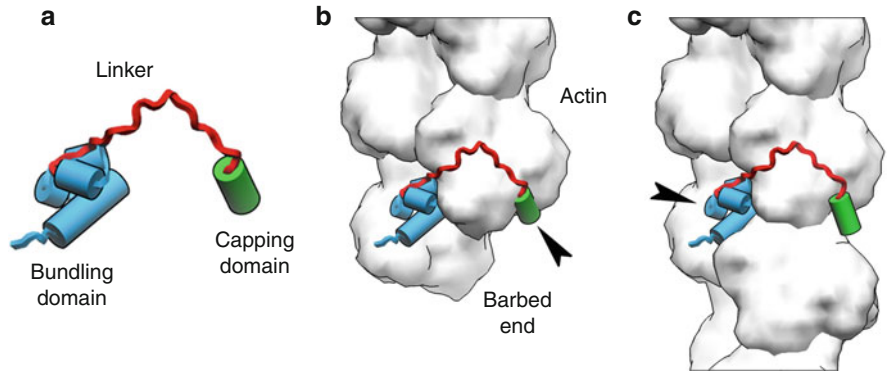
Eps8 is able to directly control actin cytoskeleton remodeling through inherent capping and bundling activities. Eps8 can accelerate actin treadmilling by blocking polymerization at filaments ends, acting as a capping protein. Eps8 can also regulate the architectural organization of the actin cytoskeleton by cross-linking actin filaments, in this case acting as a bundling protein. These properties in conjunction with in vivo localization data suggest that Eps8 critically participates both in the regulation of cell motility and in the architectural organization of specific actin-based structures, including cell protrusions at the leading edge of migrating cells, microvilli of intestinal cells, and stereocilia. Both capping and bundling activities are mediated and retained by the C-terminal region of the protein (amino acids 648–821) but the full-length protein is tightly regulated by protein–protein interactions. The bundling activity can be isolated and attributed to the C-terminal four helices of the region (Hertzog et al. 2010). The capping activity can also be isolated and can be attributed to the first helix of the region that is tethered to the C-terminal four helices by a flexible linker (Hertzog et al. 2010). Thus, the C-terminal effector region of Eps8 contains two structurally distinct actin-binding modules, one responsible for capping and one responsible for bundling (Fig. 3a).

Eps8 capping activity. In vitro, the conserved C-terminal region of Eps8, in substoichiometric amounts with respect to actin, inhibits barbed end growth by up to 90% and enables propulsion of N-WASP-coated beads in the absence of gelsolin or other cappers (Disanza et al. 2004). In vivo, Eps8 localizes in rocketing tails propelling phosphatidylinositol-4,5-phosphate-(PI45P) enriched vesicles or intracellular pathogens such as *Listeria monocytogenes* or *Shighella flexneri* (Disanza et al. 2004). Structurally, the Eps8 capping activity is mediated by binding of the amphipathic first helix of the Eps8 C-terminal region within the hydrophobic pocket at the barbed ends of actin (Hertzog et al. 2010). Occupation of this site on actin filaments by the helix blocks further addition of actin monomers (Fig. 3b). The capping activity of full-length Eps8 is regulated by interactions with Abi1 (Disanza et al. 2004). While the exact mechanism of this regulation remains obscure, it is likely that the binding of Abi1 induces a conformational change in full-length Eps8 that exposes the amphipathic first helix within the C-terminal region and makes it available for interactions with the filament barbed ends.

Eps8 bundling activity. The C-terminal four-helix region of Eps8 binds to the sides of actin filaments as a compact helix bundle (Hertzog et al. 2010) and possesses bundling activity in vitro when dimerization domains such as GST are attached to the construct (Disanza et al. 2006). The four-helix bundle interacts with three adjacent subunits along the short-pitch helix of the actin filament (Fig. 3c). Full-length Eps8 can form a constitutive, stable complex with IRSp53 that bundles actin filaments (Disanza et al. 2006). While Eps8 expression alone has no effect on filopodia formation in vivo, the concomitant expression of the two proteins leads to a dramatic increase in filopodia number and length (Disanza et al. 2006). The Eps8:IRSp53 interaction mediates the bundling activity of the side-bound full-length Eps8 most likely through dimerization of IRSp53, with a possible contribution from the inherent, weak actin-binding activity of the N-terminal IMD domain of IRSp53, which is auto-inhibited in full-length IRSp53 but may be released by Eps8 binding.

Physiological Roles of Eps8: From Cells to Multicellular Organisms

The dissection of the biochemical and signaling properties of Eps8 together with its ability to participate in various, distinct macromolecular complexes has provided a rational framework to account for a number of apparently unrelated and diverse cell biological phenotypes associated with this protein. Thus, for example, the presence of Eps8 in actin dynamics–based motile structures (Hertzog et al. 2010; Disanza et al. 2004) reflects the ability of this protein to cap the barbed ends of actin filament. Conversely, Eps8 localization to microspikes and filopodia is accounted for, at least in part, by the ability to form a complex with



Eps8 (Epidermal Growth Factor Receptor Pathway Substrate 8), Fig. 3 Eps8 C-terminal actin-binding region. (**a**) Structure of the conserved C-terminal region of Eps8 shown in cartoon representation. The region contains two distinct actin-binding sites responsible for bundling (blue) and capping (green) respectively. These regions are connected by a flexible linker (red). (**b**) Low resolution representation of an actin filament barbed end (white surface) with the Eps8 C-terminal domain bound and the capping domain occupying the hydrophobic groove of the barbed end actin subunit (arrowhead). This interaction prevents the addition of new filament subunits. (**c**) Low resolution representation of an actin filament (white surface) with the Eps8 C-terminal domain bound to the side (arrowhead), contacting three successive actin subunits. In conjunction with dimerization, this interaction is responsible for the bundling activity of Eps8. The capping domain does not occupy the hydrophobic groove of actin in the configuration

IRSp53 at the plasma membrane where Eps8 may both "protect" plus ends from stronger cappers, such as CP, while promoting the convergent association and bundling of filament ends, a presumably limiting step in filopodia initiation (Hertzog et al. 2010). This context allows to begin rationalizing how the actin-related activities of Eps8, controlled by distinct molecular partners in different cellular contexts, may account for seemingly paradoxical and opposite effects on filopodia whereby genetic removal of Eps8 reduced filopodia in HeLa cells (Disanza et al. 2004), but increased them in hippocampal neurons (Menna et al. 2009). It is likely that the dynamic and context-dependent interactions established by Eps8, IRSp53, and Abi1 with actin filaments generate a flexible signaling network that governs the multifunctional activities of its components in the formation of diverse actin-based structures: a notion that is being supported by computational modeling of this network (GS personal communication). Whatever the case, Eps8 capping and bundling activities are emerging as critical in diverse phenotypes both at the cellular and organism levels, revealing the involvement of actin dynamics in a variety of diverse and frequently unexpected physiological processes. Specific impairment of bundling activity, for example, of the only EPS-8 family member in nematodes leads to a severely altered intestinal morphogenesis that correlates with a disruption of the stereotypical orderly organization of actin-bundle-rich microvilli (Croce et al. 2004). This specific function appears evolutionary conserved since also 8 null mice display shorter intestinal microvilli (Tocchetti et al. 2010). Notably, this alteration is accompanied by a defective intestinal fat absorption that results in calorie-restricted metabolism and increased life span, providing genetic evidence of actin dynamics as a novel variable in the determination of longevity (Tocchetti et al. 2010). It is also noteworthy that the three other Eps8L family members do not compensate for the lack of Eps8 in the intestine suggesting that differential tissues expression and cellular localization (in this case to microvilli) contribute to functional specificity within the Eps8L family. A similar situation may also account for the recent discovery that eps8 null mice are deaf. Hearing impairment is a consequence of disrupted stereocilia morphology, where Eps8 localizes together with the Myosin XVa and the adaptor protein whirlin (Manor et al. 2011). While the specific contribution of Eps8 actin-related activities to proper stereocilia elongation has not yet been established, it is reasonable to assume that, in analogy to intestinal microvilli, which share a similar architectural organization in parallel actin bundles with stereocilia, the actin cross-linking property of Eps8 is

responsible for the phenotype. However, a role of Eps8 capping in fine-tuning filament elongation at the basis of the precise staircase pattern of stereocilia cannot be ruled out at the present stage.

Finally, a specific functional role of Eps8 with unexpected physiopathological consequences has emerged when the function of this protein was analyzed in the central nervous system. Eps8 is uniquely expressed in the hippocampus as well as the cerebellum (Offenhauser et al. 2006). In cerebellar neurons, Eps8 is significantly more abundant. Consistently, genetic removal of 8 alters actin dynamics, particularly at postsynaptic sites, where Eps8 is part of the N-methyl-D-aspartate (NMDA) receptor complex. Moreover, in Eps8 null mice, NMDA receptor currents and their sensitivity to inhibition by ethanol are abnormal. In addition, 8 null cerebellar neurons are resistant to the actin-remodeling activities of NMDA and ethanol (Offenhauser et al. 2006). These alterations presumably explain why 8 null mice are resistant to acute intoxicating effects of ethanol and show increased ethanol consumption (Offenhauser et al. 2006), further supporting the notion that proper regulation of the actin cytoskeleton by Eps8 is a key determinant of cellular and behavioral responses to ethanol.

In cortical neurons, the capping activity of Eps8 is, instead, required downstream of Brain Derived Neurotrophic Factor (BDNF) for the regulation of axonal filopodia: a process with crucial impacts on neuronal development and synapse formation (Menna et al. 2009). In this cell system, Eps8 capping activity is negatively regulated by BDNF-mediated, MAPK-dependent Eps8 phosphorylation, which reduces the affinity of the Eps8:Abi1 complex for barbed ends, thus promoting the elongation of uncapped actin filament and the generation of axonal filopodia (Menna et al. 2009). Notably, filopodia and short axonal branches are frequently extended and retracted to form boutons onto postsynaptic structures, or to originate en passant boutons, which are added and eliminated along the axonal shaft: all processes that characterize synaptic plasticity. Consistent with this possibility, *eps8* null brains display a significantly higher number of presynaptic boutons (Scita 2008) that might originate from the increased axonal filopodia during neuronal development, thus suggesting a role of the protein in controlling synapse formation and presynaptic plasticity phenomena in the developing brain and, possibly, in the adult brain.

Eps8 and Cancer

While the involvement of Eps8 in cytoskeletal reorganization and its molecular modes of action are gradually being elucidated, experimental evidence has also accumulated supporting the implication of Eps8 in tumorigenesis. Since its discovery, Eps8 was shown to enhance mitogenesis and, in some circumstances, also cell transformation in response to growth factor treatment (reviewed in (Di Fiore and Scita 2002)). Furthermore, constitutive tyrosine phosphorylation of Eps8, frequently accompanied by the elevated phosphotyrosine levels of a number of RTK signaling molecules, was detected in a large variety of tumor cells (reviewed in (Di Fiore and Scita 2002)). These initial observations supported the notion that Eps8, presumably through its signal-transducing adaptor functions, may be relevant in promoting mitogenic signaling particularly in those tumors where RTKs signaling is elevated. This latter contention was subsequently extended by the finding that constitutive tyrosine phosphorylation of Eps8 was also frequently coupled to elevated protein expression, such as in cells transformed by non-receptor tyrosine kinases, v-SRC (reviewed in (Di Fiore and Scita 2002)), and in a variety of human tumors, including colorectal (Maa et al. 2001), cervical (Chen et al. 2008; Wang et al. 2009), pituitary (Xu et al. 2008), pancreatic (Welsch et al. 2007), and oral cancers (Yap et al. 2009). Consistent with this, the overexpression of Eps8 confers the ability of fibroblasts to form foci in culture dishes and to grow tumors in mice (Maa et al. 2001). These findings confirm the initial observations and further corroborate the oncogenic potential of Eps8. In agreement with this notion, Eps8 attenuation retarded cellular growth in v-SRC transformed cells and human cancer cells (Maa et al. 2007). Frequently, Eps8 overexpression in tumors correlates with increased MAPK and/or AKT signaling. While the mechanisms and pathways through which Eps8 mediates these effects remain ill defined, it is reasonable to propose that it is the ability of Eps8 to form diverse multimolecular signaling complexes acting in the Ras-PI3K-Rac (Di Fiore and Scita 2002) or RTK-p66 shc (Bashir et al. 2010) transduction cascades that accounts for its role in promoting mitogenesis or increased resistance to apoptosis. It should be noted, however, that an additional, much less explored possibility, is that deregulated levels of Eps8 may disturb

the endocytosis or intracellular trafficking of RTKs, in turn, affecting the duration and spatial localization of RTK-dependent signaling, ultimately resulting in enhanced tumorigenesis. In this latter respect, it is noteworthy that in *C. elegans* elevated and basolaterally localized EPS-8 in vulval precursor cells (VPCs) blocks EGFR internalization, leading to enhanced signaling. Conversely, low levels of EPS-8 in the neighboring secondary VPCs result in the rapid degradation of the EGFR, allowing these cells to adopt a secondary cell fate (Stetak et al. 2006). Thus, Eps8 regulation of EGFR trafficking may be an evolutionary conserved mechanism to control signaling in pattern formation during normal organogenesis or to promote enhanced mitogenic signaling, when its levels are deregulated, such as in tumor development.

Finally, it is important to point out that at least in specific tumor types, EPS8 expression levels correlate with an increase in their capacity to migrate and invade surrounding tissues. This is the case for head and neck squamous cell carcinomas (HNSCCs) (Yap et al. 2009) and for a subset of colon carcinoma (Maa et al. 2007). In HNSCC, Eps8 is upregulated in 32% of primary tumors compared with normal oral mucosa, and its expression significantly correlated with lymph node metastasis, suggesting a disease-promoting effect. Consistent with this notion, the ablation of Eps8 from high-expressing HNSCC derived from tumor patients impaired cell migration and invasion both in in vitro organotypic and in mouse model systems (Wang et al. 2009; Yap et al. 2009). Some of these effects of Eps8 were attributed to elevated Rac activity (Yap et al. 2009; Bashir et al. 2010) or to indirect regulation of transcription factors, such as FOXM1, in turn controlling signaling proteins important for cell cycle progression and cell migration (Wang et al. 2010). However, it is tempting to speculate that the actin regulatory activities of Eps8 may directly contribute to the acquisition of highly migratory and invasive properties of advanced stage of squamous cell carcinoma. The possibility to dissect at the molecular levels the diverse actin regulatory functions of Eps8 will be instrumental in the years to come to test this hypothesis.

Summary

Eps8, originally identified as a substrate of the EGFR, is the founding member of a family of proteins that includes three additional members in mammals. They all display a modular organization into various protein–protein interaction domains that suggest the involvement of this protein family in the transduction of receptor tyrosine kinases (RTKs) signals. Consistently, Eps8 can participate in various, distinct macromolecular complexes that either mediate the activation of small GTPases Rac and Rac-dependent actin remodeling or regulate RTK signal duration by controlling receptor internalization and trafficking. Remarkably, Eps8 is able to bind to actin filaments and to control actin dynamics, through its ability to associate with and block the plus growing ends of filaments. Eps8 can also regulate the architectural organization of actin meshworks and bundles by cross-linking adjacent filaments. These two properties can be dissected in vitro and are differentially regulated by Eps8 interactors: Abi1 activates actin capping, and IRSp53 promotes actin bundling. Thus, Eps8 by participating in multiple and distinct molecular complexes plays roles in a variety of actin-based processes, including motile cellular protrusions such as lamellipodia, rocketing tail, and filopodia, as well as sensory structures such as microvilli and stereocilia. The cellular roles of Eps8 are mirrored at the organism level by the requirement of Eps8 in diverse and specific physiological actin-based processes. Thus, Eps8 null mice display a range of actin-dependent phenotypes ranging from defective extension of neuronal filopodia and synaptogenesis that can result in deregulation of behavioral responses to ethanol or altered morphogenesis of intestinal microvilli and stereocilia that can cause fat malabsorption and deafness, respectively. Finally, emerging evidence implicates Eps8 in tumourigenesis whereby elevated levels of this protein either favors cell proliferation or enhances cell migration and invasion of various cancer cells. Thus, Eps8 represent a unique actin regulatory protein endowed with signal-transducing properties accounting for its pleiotropic functional roles.

Synonyms

DERK (*Drosophila melanogaster*); Extracellular regulated kinase 1 and 2; Fus3 (*Saccaromyces cerevisiae*); Kss1 (*Saccaromyces cerevisiae*); Mitogen-activated protein kinase 1 and 2; MPK-1 (*Caenorhabditis elegans*); p42/p44 MAPK; Spk1 (yeast *Saccaromyces pombe*)

Historical Background

Several years prior to ERK1 and ERK2 cloning, respectively, in 1990 and 1991 (Boulton et al. 1991), the close correlation between mitogen action and the increased double phosphorylation of two proteins of 41 and 43 kDa on a phosphotyrosine residue and a phosphothreonine/phosphoserine was revealed by two-dimensional polyacrylamide-gel electrophoresis (reviewed in Chambard et al. [2007]). Because of the sustained phosphorylation during the critical part of G0/G1 phase of the cell cycle, these two proteins known as p41 and p43 were suspected of playing a key role in cell cycle entry. Finally ERK1 was purified and cloned as a protein that phosphorylates microtubules-associated protein2 (MAPK2) during the global hunt of substrates of tyrosine kinase receptors in the late 1980s. Just after the discovery of ERK it was demonstrated in fibroblasts that ERK activation occurred in two phases, a rapid one in response to many stimuli, and a late phase lasting several hours induced by mitogenic agonists; moreover blocking ERK expression was shown to block cell cycle entry (Pages et al. 1991). ERK activation requires double phosphorylation on the TEY sequence, hence ERK1 is the protein that was called p43 (44 kD) and ERK2 is the protein that was called p41 (42 kD).

As soon as ERK1 was cloned, its similarity with two yeast proteins, Fus3 and Kss1 was revealed (cited in Boulton et al. [1991]), hence ERK is a kinase that is conserved from yeasts to humans. Interestingly, the two proteins in yeast are not linked one to one with ERK1 and ERK2 since Fuss3 and Kss1 appeared consequently to a genome duplication in the yeast phylla. This is evidenced by the fact that the yeast saccharomyces pombe which did not undergo the yeast genome duplication has only one ERK (Spk1). As for most isoforms in human genome, ERK1 and ERK2 appeared during two genome duplications in paleovertebrates when cartilaginous fish appeared. Incidentally, the most primitive living vertebrate, the lamprey and also invertebrates such as flies and worms, have only one ERK since their genomes did not undergo these two duplications.

By a combination of genetic studies in flies and worms, and biochemical studies in xenopus and mammalian cells, it was established that ERK is one element in the signaling cascade Ras/Raf/▶ MEK/ERK. Due to space limitations, this presentation will focus only on mammalian ERKs, excellent reviews are available to learn more on yeast, plants, and invertebrate ERKs. ERK plays a central role in this cascade of activation because all upstream members have few substrates or effectors, to the point that ERK is the only known substrate of MEK. On the contrary, ERK can phosphorylate hundred of substrates, furthermore ERK is the first molecule of this cascade able to remain in the nucleus, hence ERK has substrates in all cell compartments unlike all other upstream components of this cascade.

Structure of ERK Activation

ERK is a member of the CMGC Ser/Thr protein kinase family, which encompasses the **C**DKs, **M**APK, **G**SK, and **C**DK-like (respectively, cyclin-dependent kinases, mitogen-activated kinases, glycogen synthase kinase, and cyclin-dependent-like kinase). ERK is a member of the MAPK cluster, the closest kinase to ERK1/2 is ERK5 which lies on a distinct signaling cascade.

ERK can phosphorylate substrates on a serine or a threonine residue, the consensus phosphorylation site was defined by phosphorylated peptide banks, it is: PXS/TP (X can be any amino acid). ERK is a proline-directed kinase since there is an absolute requirement for +1proline for the phosphorylation site of substrates (reviewed in Lee et al. [2004]). This requirement was closely analyzed: it results from a close association of Ala-187 of ERK2 after remodeling of ERK2 to convert a small depression on the surface to a deep pocket where the proline of the substrate interacts. Interestingly ERKs are resistant to activating point mutations, and there are no known associated oncogenes. Replacement of either or both phosphorylation site residues by negatively charged amino acids does not lead to activation unlike many kinases. It is thought that the interaction of proline +1 of substrates is key to prevent undesired activation of ERK, since this step requires the formation of an energetically unfavorable structure. Similarly to all proline-directed kinases, ERK phosphorylation sites can integrate information from different signaling cascades via isomerization of the proline close to the phosphorylation site as it is the case for ▶ c-Myc. C-myc is phosphorylated on serine 62 by ERK then it can be phosphorylated on threonine 58 by GSK-3β. The doubly phosphorylated c-Myc is then recognized by Pin-1 which isomerizes the serine 62-proline 63 bond. This isomerization increases the activity of the phosphatase PP2A to dephosphorylate serine 62, leading ultimately to poly-ubiquitinylation and degradation of c-Myc.

ERK is a compact protein encompassing two lobes. The active site of the kinase is located within the cleft between the two lobes. In the inactive state, the two lobes are rotated in comparison with the two lobes of PKA (constitutively active subunit), which is probably key for inactive ERK to display very low specific activity unless the kinase is doubly phosphorylated (cited in Lee et al. [2004]). Activation of ERK is a combination of rotation of the two lobes upon double phosphorylation by MEK of the activation lip on threonine 193 and thyrosine 195, and remodeling of ERK by binding of the +1proline of the substrate.

Many kinases are proline directed, such as the CDKs, hence the sequence of the phosphorylation site is not sufficient to provide substrate specificity. Indeed substrates must harbor at least one of two types of docking motifs to be specifically phosphorylated by ERK. Firstly, substrates containing the FXFP site (or DEF domain, for Docking site for ERK, FXF) bind to a hydrophobic pocket formed by residues located close to the small depression where the +1proline of the substrates binds (Lee et al. 2004). As a consequence of the proximity between the FXFP/DEF binding site and the small depression for docking to the +1Proline on substrates, the phosphorylation site is usually located close to the FXFP docking site (on its C-terminal side). When ERK is inactive (not doubly phosphorylated) this hydrophobic pocket is occluded, hence substrates cannot bind to inactive ERK via this site. On the contrary, the secondly binding site to ERK, the D docking motif (also called DEJL or KIM for Kinase Interacting Motif), binds to ERK when it is active or inactive (cited in Ebisuya et al. [2005] and Murphy and Blenis [2006]). Furthermore, the D docking motif is found in all types of ERK partners: substrates, activator (MEK), and inhibitors (MAP kinase phosphatases). The D motif consists of a cluster of basic amino acids at the N-term of a hydrophobic motif on substrates and partners. This D motif binds to the CD domain (Common Docking), a docking groove located on the back of ERK (the front of the kinase being the active site) (reviewed in Ebisuya et al. [2005]; Murphy and Blenis [2006]). This docking groove is found in all MAP kinases, the binding specificity for ERK is provided by the sequence of amino acids that constitute this groove and few adjacent amino acids. The fact that the CD domain is located on the back of the kinase allows greater flexibility for the localization of the D domain on substrates (respectively to the phosphorylation site).

Subcellular Localization of ERK

ERK accumulates in the nucleus after acute stimulation of the cell. Nuclear translocation of ERK is required for cell cycle entry. This was demonstrated upon retaining ERK in the cytoplasm by expression of inactive MKP3/DUSP6 that binds tightly to ERK and remains strictly located in the cytoplasm. Retention of ERK in the cytoplasm was shown to alter neither ERK kinase activity nor phosphorylation of cytoplasmic substrates while ERK-dependent transcription and cell proliferation were blocked (reviewed in Chambard et al. [2007]).

MEK behaves as the cytoplasmic anchor for ERK such that MEK co-overexpression maintains the cytoplasmic localization of overexpressed ERK, whereas saturating levels of the ERK-binding site of MEK abrogates ERK export from the nucleus (reviewed in Ebisuya et al. [2005]). MEK is sequestered in the cytoplasm as a consequence of active export out of the nucleus mediated by its NES sequence (Nuclear Export Sequence). MEK binds to inactive ERK in resting cells, hence inactive ERK localization in the cytoplasm is mainly driven by MEK. The natural regulation of ERK translocation has also been demonstrated by differential expression of cytoplasmic anchors such as PEA15 and Sef or nuclear anchors such as DUSP5 and Vanishing (reviewed in Ebisuya et al. [2005]). It has been shown that the stimulation-induced nuclear accumulation of ERK requires the synthesis of short-lived nuclear anchors (reviewed in Chambard et al. [2007]). If protein synthesis is blocked during stimulation, ERK enters inside the nucleus but cannot accumulate in it. Regulation of ERK nuclear translocation is an essential feature of the Raf/MEK/ERK signaling cascade. As an example, cytoplasmic retention of ERK by ▶ PEA-15 has been linked to Ras-induced senescence in fibroblasts (reviewed in Ebisuya et al. [2005]).

How does ERK enter into the nucleus? ERK lacks a nuclear localization sequence (NLS), leading to the suggestion that ERK may enter by a piggyback mechanism via binding to NLS-containing proteins. NLS-dependent mechanisms require energy for Ran-dependent cycling of importins. However, reconstituted import assays have shown that ERK can bind directly to FxFG-repeated sequences of nucleoporin in the lumen of the NPC (Nuclear Pore Complex), indicating that it may enter the nucleus in the absence of energy sources or cytosolic factors (reviewed in Ebisuya et al. [2005] and Lidke et al. [2010]). Point mutations of ERK revealed that inactive and active ERK interact with nucleoporins via different domains; thus both active and inactive ERK can be transported across the nuclear pore in an energy-independent fashion (Yazicioglu et al. 2007). However, in a reconstituted import assay, thiophosphorylated ERK2 import increased in the presence of energy. Overall, these observations suggest a role for both an energy-dependent and an energy-independent mechanism (via direct binding to nucleoporins) in ERK cytoplasmic-nuclear translocation. Since ERK was shown to form dimers when crystallized and when purified in vitro, the possibility that ERK dimerization could play a role in nuclear entry was scrutinized. Several independent studies have failed to detect existence of ERK dimers in vivo, either by lack of FRET between GFP-ERKs of different colors (Burack and Shaw 2005) or by advanced microscopic techniques such as emFRET and fluorescence correlation spectroscopy (Lidke et al. 2010). An ERK "dimerization-mutant" that failed to dimerise in vitro was shown to be activated more slowly than wild-type ERK and to enter more slowly in the nucleus, but this mutant accumulated normally in the nucleus (Lidke et al. 2010). These experiments confirm that the activation step is central for ERK nuclear entry, not dimerization. Half-maximal nuclear accumulation of ERK is reached within 3 min (movie in supplemental data of Lidke et al. [2010]).

Interestingly, ERK has been shown to phosphorylate several nucleoporins such as NUP50 which was shown to reduced its affinity for importin-beta family proteins, importin-beta and transportin, hence ERK activation can regulate nucleocytoplasmic transport (Kosako et al. 2009). These interactions can have a mutual relationship since it was shown that the nuclear pore complex protein Tpr is both a substrate and a scaffold for activated ERKs, hence Tpr is facilitating ERK transport across the nucleus while ERK regulates global nucleocytoplasmic transport via phosphorylation of Tpr (Vomastek et al. 2008).

Concerning cell motility, active ERK is targeted to newly forming focal adhesion after integrin engagement or activation of v-Scr, where it could phosphorylate substrates specifically located in focal adhesion (cited in Pullikuth and Catling [2010]). Several studies have demonstrated a requirement for ERK signaling in the disassembly of focal adhesions of migrating cells, in part through the activation of calpain proteases that can downregulate focal adhesion kinase signaling (cited in Pullikuth and Catling [2010]). On the contrary, ERK activity was shown to be required for fibronectin-stimulated Rho-GTP loading, Rho-kinase function, and the maturation of focal adhesions in spreading cells via phosphorylation of the C-terminus of p190A RhoGAP via regulation of its localization and activity (Pullikuth and Catling 2010).

Functions and Substrates of ERK

ERK can phosphorylate many substrates, it was demonstrated that ERK activation is required for cell

proliferation, cell growth, cell differentiation, development, memory formation, senescence, and apoptosis. Antiproliferative mechanisms triggered by ERK activation are reviewed in Cagnol and Chambard (2010) and proliferative roles of ERK are reviewed in Chambard et al. (2007) and Torii et al. (2006). Instead of listing the many proven substrates of ERK, the consequences of ERK activation to trigger biological responses will be illustrated. A special emphasis will be put on how to convert a gradual ERK signal to an on/off switch, such as the decision for an individual cell to proliferate or not.

In fibroblasts ERK activation occurs in two phases: an initial rapid phase lasting about 30 min in response to many stimuli and a late phase lasting several hours that is induced only by the persistent presence of mitogenic agonists. Whereas mitogenic and non-mitogenic agonists can activate ERK efficiently during the rapid phase, only long-lasting stimulation of ERK induces the robust accumulation of immediate-early gene products (IEG products), such as c-Fos protein that ultimately leads to cyclin D1 expression and cell cycle entry (reviewed in Murphy and Blenis [2006]). Typically, in quiescent cells, activation of surface receptors leads to ERK activation and immediate entry of ERK in the nucleus to phosphorylate preexisting transcription factors, such as Elk-1, which in turn induce transcription of IEGs, such as c-fos. When ERK stimulation is transient, the c-Fos protein is not accumulated enough prior to the decline of ERK activation. On the contrary, sustained ERK activity can phosphorylate C-terminal phosphorylation sites on c-Fos, which in turn unmasks an FXFP site/DEF domain which increases c-Fos binding to ERK to ensure phosphorylation of other sites for full stabilization of the c-Fos protein. Consequently, persistent activation of ERK leads to persistent expression of c-Fos in the nucleus versus almost no c-Fos protein expressed during transient activation of ERK, converting the duration of ERK activation to an on/off switch.

In order to increase markedly transcription of IEGs, ERK also induces chromatin remodeling and increases protein translation (directly or indirectly by activating downstream kinases such as RSK, MSK, and MNK) (substrates reviewed in Chambard et al. [2007] and Yoon and Seger [2006]).

Another way for ERK to "sense" the duration of activation occurs via the downregulation of antiproliferative genes (Yamamoto et al. 2006). As soon as ERK activation decreases, these genes are reexpressed and block cell cycle progression, only persistent ERK activation and persistent downregulation of these genes allow proliferation.

Interestingly, in PC12 cells, a transient ERK stimulation leads to cell division (contrarily to fibroblasts) whereas long-lasting ERK activation is required for differentiation. Hence for a given cell type, a given cell fate is driven by a unique combination of duration, localization, and strength of ERK activation (reviewed in Chambard et al. [2007], Ebisuya et al. [2005], and Murphy and Blenis [2006]).

When scrutinizing the role of ERK in differentiation, up to 284 proteins were identified by quantitative proteomics to bind to ERK (von Kriegsheim et al. 2009). Furthermore, 60 of these proteins were shown to change their binding to ERK during differentiation. Considering that several downstream kinases increase markedly the repertoire of ERK targets, this work illustrates why ERK is central in the cascade of activation to drive cell-surface receptor activation (on the contrary, upstream of ERK, MEK has only one proven substrate, for example).

It is important to mention that ERK2 was shown, in 2009, to bind directly to DNA on the sequence G/CAAAG/C in a manner independent of kinase activity. ERK2 can behave as a transcriptional repressor of interferon signaling, which increases markedly the multiplicity of ERK functions (Hu et al. 2009).

ERK in Human Pathologies

As discussed earlier, so far no activating mutations of ERK have been found. However, very often the signaling cascade leading to ERK activation is constitutively activated in human diseases at the level of cell surface receptors (such as the EGF-R2 receptor), at the level of Ras (e.g., K12V mutation), at the level of Raf (e.g., V600E mutation), and even when ERK phosphatases such as DUSP6 are deleted. There are also indices that modulators of ERK cascade such as Sprouty and Sef may play a role in tumorigenesis (Torii et al. 2006).

Around 70% of human melanomas display activating mutations of Raf, hence ERK cascade is constitutively active (Pratilas et al. 2009; Dhomen et al. 2009; Dankort et al. 2009), in many other melanomas the ERK cascade is also constitutively activated via Ras mutations. However, measuring the activation level of

ERK has not been demonstrated to correlate with cancer progression (Pratilas et al. 2009). This is likely due to the fact that feedback inhibitions can normalize ERK activation even when the signaling cascade is pathologically active. Surprisingly, it was shown that extremely elevated and long-lasting ERK activation blocks cell proliferation by increasing the levels of the cell cycle inhibitor p21 (reviewed in Chambard et al. [2007], Murphy and Blenis [2006] and Torii et al. [2006]). As a consequence, when a cell has to cope with constitutive activation of the Ras/Raf/MEK/ERK pathway, the cell must evolve to overcome this cell cycle block to become oncogenic. At the level of ERK, retro-inhibition can be done by phosphorylation of Sos or Raf or MEK by ERK to reduce the input signal. Furthermore, ERK has been shown to induce transcriptionally MKPs/DUSPs phosphatases that dephosphorylate and inactivate ERK directly (Keyse 2008). Indeed it was demonstrated recently that the transcriptional output of tumors with mutant BRaf and those with receptor tyrosine kinase (RTK) activation is very different, despite the fact that these tumors have similar levels of phosphorylated ERK (Pratilas et al. 2009). In fact, only V600E-BRaf cells display very high transcriptional activity of many genes, including negative feedback inhibitors of the pathway such as MKPs/DUSPs phosphatases and Sprouty gene family members. On the other hand, physiologic feedback inhibition of Raf/MEK signaling down-regulates ERK output in cells with mutated RTK without resorting to massive transcriptional induction of ERK regulators.

On the opposite, diminution of ERK activation during development has also negative consequences on human health. For example, several children with a 1 Mb microdeletion on chromosome 22q11.2 encompassing the ERK2 gene were identified (Samuels et al. 2008). These children have reduced ERK2 levels and exhibit microcephaly, impaired cognition, and developmental delay, which is expected considering the multiple roles played by ERK on synaptic plasticity and memory (Kelleher et al. 2004). Blocking ERK activity also plays a role in the pathogenicity of Bacillus anthracis infection. This bacterium secretes lethal factor (a component of anthrax lethal toxin) that inactivates MEK family members through proteolysis of their amino termini (Duesbery et al. 1998). Proteolysis of MEK1/2 reduces interaction of MEK with ERK and also the phosphorylation of ERK by MEK, which leads to total loss of ERK activity in the cell during infection.

Specific Roles of ERK1 and ERK2

ERK activation is carried by ERK1 and ERK2 that are 84% identical at the amino acid level in humans. No agonist is known to more specifically activate ERK1 over ERK2, and both ERK1 and ERK2 were shown to translocate to the nucleus upon stimulation. MEK1/2 can indiscriminately phosphorylate ERK1 and ERK2 on their identical TEY sequence. Both ERK1 and ERK2 phosphorylate substrates on the consensus PXS/TP sites with similar specific activities in vitro, measured with bacterially expressed ERKs and with immuno-precipitated ERKs (reviewed in Lefloch et al. [2009] and Voisin et al. [2010]). The CD docking domain diverge only for a leucine instead of an isoleucine between ERK1 and ERK2, and the FXFP/DEF docking is fully conserved between ERK1 and ERK2. More recently, 284 partners of ERKs that were identified by quantitative proteomics following immunoprecipitation were shown to associate as well with ERK1 and ERK2 (von Kriegsheim et al. 2009).

Therefore, why mammals express ubiquitously ERK1 and ERK2 if they appear redundant? In fact it is unlikely that each ERK performs an essential function in vertebrates since it was found that frogs and birds have only one ERK after loosing one isoform during evolution (Lefloch et al. 2009). However, invalidation of ERKs in mice gave strikingly opposite results, lack of ERK2 led to early embryonic cell death whereas mice lacking ERK1 live and reproduce normally. Reproducibly, mice lacking ERK1 display minor phenotypes such as behavioral excitement; they also present abnormal responses to stresses such as resistance to obesity when fed a fat-rich diet or reduced occurrence of skin papilloma triggered by DMBA and TPA treatment (reviewed in Lefloch et al. [2009] and Voisin et al. [2010]). However, one allele of either Erk1 or Erk2 in endothelial cells was necessary and sufficient for embryonic development (Srinivasan et al. 2009), and similarly one allele of ERK1 or ERK2 is sufficient but necessary in granulosa cells for maturation of oocytes (Fan et al. 2009). In most cells, ERK2 is more expressed than ERK1, and usually deletion of ERK2 has more pronounced effects than deletion of ERK1. In fact ERK activation is concentrated on the remaining isoform as a compensatory effect. When these compensatory effects were taken into account it was concluded that both ERK isoforms convey proliferative signals according to their relative expression

level (Lefloch et al. 2009). This was confirmed genetically recently in mouse embryo fibroblasts that can proliferate in the absence of one or the other ERKs, but stop growing without ERK (Voisin et al. 2010). A direct correlation between the rate of proliferation and the extent of total ERK activation after 5 min stimulation was established in this study.

At this point, the data tend to indicate that for major functions such as proliferation and differentiation, ERK1 and ERK2 are redundant in a given cell; however one cannot exclude that ERK isoforms possess a unique role and interact with a few isoform-specific substrates. A good ERK1-specific candidate could be p62, signaling adapter p62/sequestosome1, that plays a role in mature-onset obesity and insulin resistance. P62 was demonstrated recently to bind specifically to ERK1 but not to ERK2 and genetic invalidation of ERK1 in the context of p62 knockout, reversed the increased adiposity and adipogenesis (Lee et al. 2010). These data are in accordance with the observation that mice lacking ERK1 have decreased adiposity and fewer adipocytes than wild-type animals (cited in Lee et al. [2010]).

Summary-Perspectives

ERK is a central player in the Ras/Raf/MEK/ERK cascade from its unique ability to phosphorylate a number of substrates in all cell compartments. The efforts to study ERK stemmed initially from the recognition that it is a key downstream target of tyrosine kinase receptors activated during G1 phase of cell cycle; interest for ERK remained elevated when this signaling cascade was found to be abnormally activated in about 30% of all cancers. Strikingly, it was recently demonstrated that a single activating point mutation of one upstream activator or ERK (BRaf V600E) is sufficient to initiate melanoma in mice (Dhomen et al. 2009; Dankort et al. 2009).

Concerning the specific roles of ERK isoforms, progress needs to be made to identify isoform-specific substrates and measure precisely the phosphorylation kinetics and binding affinities of ERK isoforms to these unique substrates (if they exist). How does ERK2 binding to DNA act to repress transcription? Can ERK1 bind to DNA? Does ERK1 bind to the same DNA sequence as ERK2? Why do ERK1 and ERK2 have these unique N-terminal ends, almost consisting of stretches of alanine and glycine residues: MAAAAAQGGGGG- for human ERK1 and MAAAAAAGAG- for human ERK2?

ERK plays ambivalent roles in different cells: how to reconcile that long-term activation of ERK triggers proliferation in some cells while it switches other cells to stop proliferating and enter differentiation? Moreover ERK can play ambivalent roles in the same cells types: how to understand the role of ERK in brain since it is implicated both in promoting neuronal cell death and neuronal plasticity? Hopefully advances in "omics" technologies will allow us to grasp a wider picture by knowing at the same time: the level of regulators of ERK, the level and phosphorylation status of ERK substrates and the level of proteins whose genes are induced by ERK activation. For many aspects of ERK regulation, modeling will be required to take into account the multiplicity of players. For example, ERK can be inactivated by many phosphatases: threonine phosphatases such as PP2A, tyrosine phosphatases such as STEP, and MKPs/DUSPs (MAPK phosphatases that dephosphorylate both the tyrosine and threonine residues). At least 11 DUSPs can bind specifically to MAPKs and most of them can inactivate ERK in vitro. When these phosphatases were invalidated individually in the whole animal unexpected results/specificities were observed such as during DUSP2/PAC1 invalidation in mice (reviewed in Keyse [2008]).

Several mathematical models of ERK activation have been published. Some are elaborated since they have measured the concentration of cascade members, localization, and dissociation kinetics with fluorescent probes (Fujioka et al. 2006); however, all models are still simple solely because none take into account the widespread multiplicity of cascade members, multiplicity of feedback inhibitors, and multiplicity of localization partners; hopefully models will be refined and will suggest experimental settings to validate them.

During the reviewing process of this manuscript, it was reported the first success of the ERK pathway inhibitor vemurafenib to increase overall and progression-free survival of patients with metastatic melanoma (Chapman et al. 2011). Vemurafenib inhibits BRaf mutant V600E specifically. Unfortunately, very often melanoma becomes resistant to treatment by vemurafenib via mutation of MEK1 (C121S) that renders the ERK cascade insensitive to Raf and MEK inhibitors (Wagle et al. 2011). Combinatorial

therapy may prove to be the solution, for example synergistic effects were reported in tumor xenografts by combining MEK inhibition with microtubule-destabilizing agents (Watanabe et al. 2011). It would be invaluable to dispose of ERK inhibitors as efficient as these MEK inhibitors. Indeed by directly targeting ERK kinase activity, it may be possible to avoid resetting the basal ERK activation level during long-term treatment (consequent to the decrease of ERK-driven retro-inhibitions). Hopefully better modeling of ERK actions will allow us to design new strategies to tackle cancer more efficiently by combining existing drugs.

Due to extreme space limitations we were unable to cite directly many excellent contributions to this field. We would like to apologize to all authors whose work was only cited indirectly from more recent publications.

Mapk4 (Erk4); Mapk6 (Erk3)

Historical Background

Extracellular signal-regulated kinase 3 (Erk3) and Erk4 are atypical members of the mitogen-activated protein (MAP) kinase family of serine/threonine kinases. The *Erk3* and *Erk4* genes were originally identified in 1991 and 1992, by homology cloning with probes derived from the MAP kinase Erk1 (Boulton et al. 1991; Gonzalez et al. 1992). In human, Erk3 is encoded by the *MAPK6* gene located on chromosome 15q21.2. The *MAPK4* gene present on chromosome 18q21.1 encodes Erk4. The high sequence identity of Erk3 and Erk4 proteins and the similar organization of their genes indicate that the two proteins are true paralogs. It is noteworthy that *MAPK6* and *MAPK4* are the only ▶ MAP kinase genes that are restricted to the vertebrate lineage.

Structure of Erk3 and Erk4

Erk3 and Erk4 are related protein kinases of 100 and 70 kDa, respectively, that define a distinct subfamily of ▶ MAP kinases (Coulombe and Meloche 2007). They are characterized by the presence of a catalytic kinase domain at the N-terminal end, which is 73% amino acid identical, and a long C-terminal extension. Although highly conserved in vertebrate evolution, the function of the C-terminal domain remains to be defined. By contrast to classical MAP kinases like ▶ Erk1/Erk2, which are activated by dual phosphorylation of the threonine and tyrosine residues in the conserved Thr-Xxx-Tyr motif of the activation loop, Erk3 and Erk4 contain a single phospho-acceptor site (Ser-Glu-Gly sequence) in their activation loop. In addition, they bear the sequence Ser-Pro-Arg instead of Ala-Pro-Glu in kinase subdomain VIII, and are the only protein kinases in the human genome to have an arginine residue at this position. The impact of these structural features on the regulation of Erk3 and Erk4 is unknown.

Expression of Erk3 and Erk4

Erk3 is expressed ubiquitously in adult mammalian tissues, whereas Erk4 shows a more restricted expression profile. The level of expression of the two kinases varies considerably between tissues, but the highest

expression is found in the brain (Boulton et al. 1991; Kant et al. 2006; Turgeon et al. 2000). In the mouse embryo, they share a similar temporal pattern of regulation with a peak of expression at embryonic day 11, coincident with the time of early organogenesis (Rousseau et al. 2010). In vitro studies have shown that Erk3 mRNA is upregulated upon differentiation of P19 embryonal carcinoma cells to the neuronal or muscle lineage (Boulton et al. 1991).

At the subcellular level, Erk3 and Erk4 exhibit distinct localization. Erk3 is found in both the cytoplasm and the nucleus of a variety of cell types, whereas Erk4 is localized mainly in the cytoplasmic compartment (Aberg et al. 2006; Julien et al. 2003; Kant et al. 2006). The cytoplasmic localization of Erk3 and Erk4 requires an active nuclear export by a Crm1-dependent mechanism. In contrast to classical MAP kinases, the cellular distribution of Erk3 and Erk4 does not change in response to common mitogenic or stress stimuli. However, Erk3 localization is regulated through its interaction with ▶ MAP kinase-activated protein kinase 5 (MK5) (Schumacher et al. 2004; Seternes et al. 2004). MK5 is a member of the MAP kinase-activated protein kinase family of protein kinases that lie downstream of ▶ MAP kinase signaling cascades. The formation of a complex between Erk3 and MK5 results in the nuclear to cytoplasmic redistribution of both proteins. The kinase activity of either protein is dispensable for this relocalization. In addition to its effect on localization, MK5 also affect endogenous Erk3 expression. Embryonic fibroblasts prepared from MK5-deficient mice or HeLa cells transfected with a si-RNA targeting MK5 exhibit a marked reduction of Erk3 protein level (Seternes et al. 2004).

Interestingly, Erk3 and Erk4 proteins display different stability. Whereas Erk4 is a relatively stable protein, Erk3 was shown to be a highly unstable protein in proliferating cells, with a half-life of about 30 min (Aberg et al. 2006; Coulombe et al. 2003; Kant et al. 2006). Erk3 is constitutively degraded by the ubiquitin-proteasome pathway, and two regions in the N-terminal lobe of the kinase domain are both necessary and sufficient to target Erk3 for proteolysis (Coulombe et al. 2003). Thus, Erk3 biological activity is regulated at the level of cellular abundance. The short half-life of Erk3 has a physiological significance since the protein is stabilized and accumulates to high levels in the course of cellular differentiation and during mitosis. Indeed, Erk3 stability increases with time during the neurogenic and myogenic differentiation of PC12 and C2C12 cells, respectively, leading to protein accumulation (Coulombe et al. 2003). Upregulation of Erk3 during muscle differentiation is concomitant to accumulation of the cell cycle inhibitor $p21^{Cip1}$ and cell cycle exit. Recent findings have shown that phosphorylation of four residues located in the extreme C-terminal extension stabilizes Erk3 protein, leading to its accumulation in mitosis (Tanguay et al. 2010).

Regulation of Erk3 and Erk4 Activity and Substrates

Little is known about the regulation of Erk3 and Erk4 biological activity. In intact cells, Erk3 and Erk4 are phosphorylated on Ser189 and Ser186, respectively, in the Ser-Glu-Gly motif of their activation loop (Cheng et al. 1996; Coulombe et al. 2003; Deleris et al. 2008; Perander et al. 2008). Unlike classical ▶ MAP kinases, this phosphorylation event is detected in resting cells and is not modulated by common mitogenic or stress stimuli.

Classical ▶ MAP kinases like Erk1 are multifunctional kinases that phosphorylate a vast array of substrates. However, Erk3 and Erk4 do not phosphorylate generic MAP kinase substrates such as myelin basic protein, microtubule-associated protein-2, c-Jun, or Elk-1 (Cheng et al. 1996), suggesting that they have a more restricted substrate specificity. The identification of MK5 as specific interaction partner and substrate of both Erk3 and Erk4 was an important step toward a better characterization of these kinases. Binding of Erk3 or Erk4 to MK5 results in the phosphorylation of MK5 on Thr182, and its resulting enzymatic activation (Aberg et al. 2006; Kant et al. 2006; Schumacher et al. 2004; Seternes et al. 2004). While the catalytic activity of Erk4 is required to activate MK5, its activation by Erk3 appears to depend both on the kinase activity of Erk3 as well as on a cytoplasmic scaffolding role of Erk3 with subsequent MK5 autophosphorylation. Importantly, Erk3 and Erk4 are bonafide physiological regulators of MK5 activity. The endogenous activity of MK5 is partially reduced in cells deprived in either Erk3 or Erk4, and the combined knockdown of the two kinases results in a greater reduction of MK5 activity (Aberg et al. 2006; Seternes et al. 2004).

Recently, a more complex interaction between Erk3/Erk4 and MK5 has been proposed (Deleris et al. 2008; Perander et al. 2008). According to these studies, the interaction between Erk3/Erk4 and MK5 recruits and/or contributes to the activation of Erk3/Erk4 activation loop kinase, resulting in the enhancement of Erk3/Erk4 phosphorylation on Ser189/Ser186. This, in turn, leads to the stabilization of Erk3/Erk4-MK5 complexes, the full enzymatic activation of Erk3/Erk4, and the phosphorylation of MK5 on activation loop Thr182. Activated MK5 reciprocally phosphorylates Erk3 and Erk4 on unidentified sites located outside the activation loop. The finding that the interaction between Erk3/Erk4 and MK5 requires activation loop phosphorylation of Erk3/Erk4 indicates that the mechanism by which these atypical MAP kinases bind to effector kinases is distinct to that of classical MAP kinases. Indeed, ▶ Erk1/Erk2 and p38 interact with downstream MAP kinase-activated protein kinases through the common docking (CD) domain, a cluster of negatively charged amino acids located near the kinase domain of MAP kinases. The conserved CD domain within Erk3 and Erk4 is dispensable for MK5 interaction.

Physiological Functions of Erk3 and Erk4

Much remain to be learned about the cellular functions of Erk3 and Erk4. However, in vitro studies in different model cell lines and in vivo analysis of mice deficient for Erk3 or Erk4 have started to shed light on the potential roles of these kinases. All these studies suggest that Erk3 and Erk4 are likely to be involved in the control of cell proliferation and differentiation. Erk3 expression is upregulated during differentiation of P19 and PC12 cells into neurons and of C2C12 cells into myotubes, in association with proliferation arrest (Boulton et al. 1991; Coulombe et al. 2003). It has been reported that the overexpression of stable forms of Erk3 in fibroblasts inhibits S-phase entry (Coulombe et al. 2003). Moreover, Erk3 was shown to interact with the cell cycle regulatory proteins cyclin D3, cell-division cycle 14A (Cdc14A) and Cdc14B through its C-terminal extension (Hansen et al. 2008; Sun et al. 2006; Tanguay et al. 2010). The phosphorylation of Erk3 also varies during the cell cycle. Erk3 is phosphorylated in the C-terminal extension during entry into mitosis and dephosphorylated at the M- to G1-phase transition. Cdc14A and Cdc14B phosphatases reverse the C-terminal phosphorylation of Erk3, and the mitotic kinase cyclin B1/cyclin-dependent kinase 1 (Cdk1) is most likely responsible for the phosphorylation of these sites. A potential role of Erk3 in insulin secretion has also been reported in another study (Anhe et al. 2006). Prolactin treatment of isolated rat pancreatic islets was found to increase Erk3 expression. This hormone is involved in the adaptive response of pancreatic β-cells toward peripheral insulin resistance during pregnancy. Silencing of Erk3 in isolated pancreatic islets prevents glucose-stimulated insulin secretion.

The study of mice deficient for Erk3, Erk4, and both Erk3 and Erk4 has provided important clues about their physiological roles. Loss of Erk3 leads to intrauterine growth restriction, delayed lung maturation associated with decreased sacculation and defective type II pneumocyte differentiation, and neonatal lethality (Klinger et al. 2009). Whereas the lung maturation defect can be overcome by in utero glucocorticoid administration, the newborn mice cannot be rescued from neonatal death. This indicates that additional physiological alterations contribute to the neonatal lethality. Erk3-deficient mice have reduced levels of insulin-like growth factor 2 (IGF-2) in the serum, suggesting that Erk3 might be a regulator of IGF-2 levels. Erk4-deficient mice are viable, develop normally, and show no gross physiological anomalies (Rousseau et al. 2010). Interestingly, behavioral analysis revealed that Erk4 mutant mice manifest depression-like behavior. In these mice, the loss of Erk4 is not compensated by increased activity or level of Erk3. Also, additional deletion of Erk4 in Erk3-deficient mice does not aggravate the fetal growth restriction and pulmonary immaturity phenotypes. This indicates that Erk3 and Erk4 protein kinases have acquired specific nonredundant functions through evolutionary diversification.

To date, MK5 remains the only identified substrate of Erk3 and Erk4, but the function of MK5 is still elusive. Of note, a recent study reported that mice deficient for MK5 display enhanced skin carcinogenesis after dimethylbenzanthracene (mutagen causing activating Ras mutations) application and compromised senescence induction (Sun et al. 2007). It remains to be determined whether Erk3 and Erk4 play a role in Ras-induced senescence and tumor suppression. The identification of additional substrates of Erk3 and Erk4 will help to better characterize the biological functions of these kinases and the signaling pathways in which they are involved.

Summary

Erk3 and Erk4 were among the first MAP kinases to be identified in the early 1990s. However, the characterization of these protein kinases has progressed much slower than that of classical MAP kinase family members such as ▶ Erk1/Erk2. Much still remains to be learned about their regulation, the identity, and spectrum of their substrates, their physiological roles, and their putative involvement in human diseases.

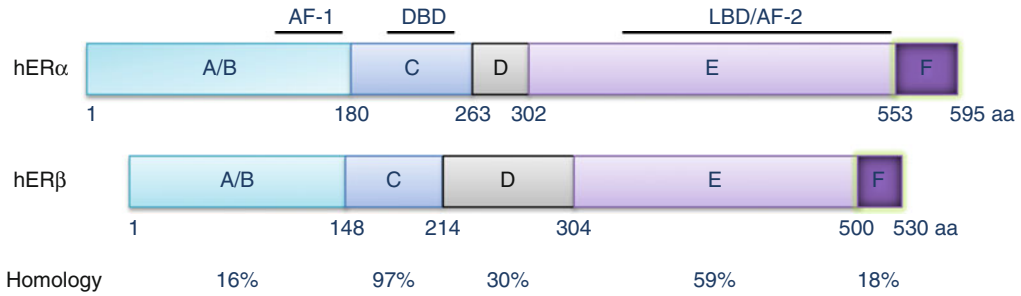
Historical Background

In 1896, physician George Beatson observed that removal of the ovaries caused regression of mammary tumors in women. His experiments were the first to establish a link between ovarian secretions and breast cancer. Later in the early 1930s, the "female" sex hormones, estrone and estriol, could be isolated from human pregnancy urine, followed by isolation of a third estrogen, estradiol (E2), from pig follicular fluid. Shortly thereafter, a number of estrogenic compounds were synthesized and used therapeutically, but the mechanisms of estrogen action remained obscure. However, in 1958 Elwood Jensen produced a major breakthrough when he used a radioactive marker to demonstrate that only estrogen-responsive tissues were able to concentrate injected estrogen from the blood, suggesting the existence of estrogen-binding components, which were called "estrogen receptors (ERs)." Further on, Noteboom and Gorski reported that the estrogen receptor is stereospecific and probably a protein. In 1966, the cytosolic estrogen-binding component was isolated from rat uterus. By treating the estrogen receptor with proteolytic enzymes, binding of estrogen was abolished, indicating that this component was a protein. Later in 1968, O'Malley observed changes in ovalbumin mRNA levels upon estrogen stimulation of the chick oviduct, indicating that ER functions as a transcription factor. In 1986, an ER was cloned from the uterus and its role as a ligand-dependent transcription factor was established (Welboren et al. 2007). This receptor, now known as ERα (NR3A1), was long believed to be the only existing ER that mediates estrogenic effects, until a second ER, now denoted ERβ (NR3A2), was cloned from rat prostate in 1996 (Kuiper et al. 1996). The first ERα knockout mouse was created in 1993, while the ERβ knockout mice became available in 1998. It is known today that ERs are members of the superfamily of nuclear receptors and specifically the family of steroid receptors that act as ligand-regulated transcription factors.

ER Gene and Protein Structure

ERα and ERβ are transcribed from different genes located on distinct chromosomes. The human ERα gene is located on chromosome 6q25.1 spanning a total of 140 kb, while the human ERβ gene is located on chromosome 14q23.2 spanning 60 kb. Both ERs consist of eight coding exons. In humans, ERα is expressed in the reproductive tissues (e.g., uterus, testis, breast), kidney, bone, white adipose tissue, and liver. ERβ has been found to be expressed in the ovary, prostate, lung, gastrointestinal tract, bladder, and hematopoietic and central nervous systems (Matthews and Gustafsson 2003).

ERs share common structural characteristics with other members of the nuclear receptor family including five distinguishable domains, named the A/B, C, D, E, and F domains, respectively (Fig. 1). The N-terminal A/B domain is the most variable region and the human ERα and ERβ share less than 20% amino acid identity in this region, indicating that this domain may contribute to ER subtype specific actions on target genes. This region harbors an activation function (AF-1) that is ligand-independent and shows promoter- and cell-specific activity. The central C-domain is the DNA-binding domain (DBD), which is involved in specific DNA binding and receptor dimerization. This domain is highly conserved between ERα and ERβ and shares 95% amino acid identity. The D-domain works as a flexible hinge between the DBD and the



Estrogen Receptor, Fig. 1 Schematic structural comparison of ERα and ERβ. The domains A–F are made up of activation function domains (AF-1 and AF-2), DNA-binding domain (DBD), and ligand-binding domain (LBD). Full-length ERα is 595 amino acids long whereas ERβ is 530 amino acids long

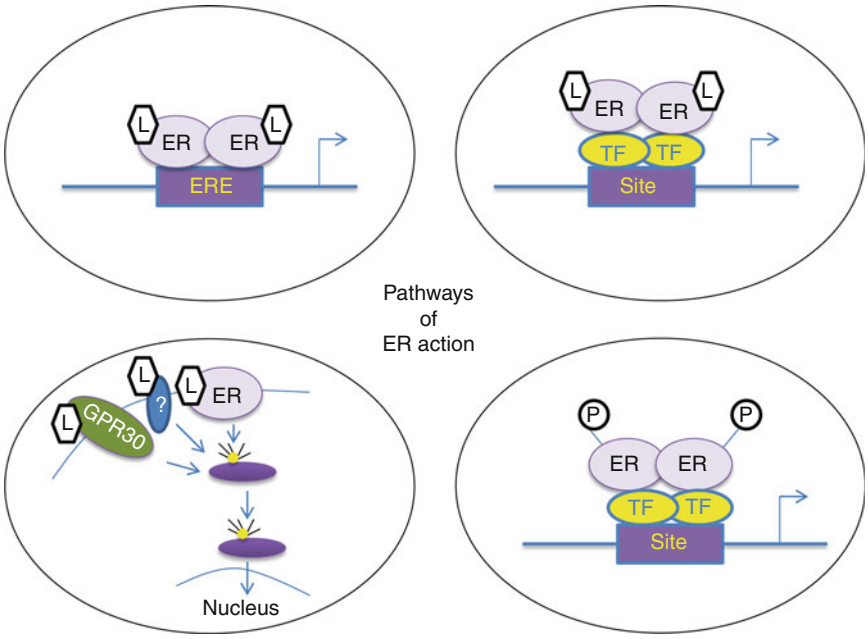
ligand-binding domain (LBD), and is thus referred to as the hinge domain. This domain, which is not well conserved between ERα and ERβ (30%), appears to be important for nuclear translocation and has been reported to contain a nuclear localization signal. The E-domain is referred to as the LBD, and the ERα and ERβ share approximately 59% amino acid identity in this region. The LBD contains a hormone-dependent activation function (AF-2) and is responsible for ligand binding and receptor dimerization. The LBDs of ERα and ERβ have very similar three-dimensional structures. However, the amino acids lining the ligand-binding cavities of ERα and ERβ differ in two positions. Furthermore, the ligand-binding cavity of ERβ is significantly smaller (∼20%) than that of ERα, and this may have implications for the selective affinity and pharmacology of ligands. The F-domain has less than 20% amino acid identity between the two ER subtypes, and the functions of this domain remain undefined (Zhao et al. 2008).

Mechanisms of ER Signaling

Estrogen action is exerted in target tissues via binding to one or both of the two ERs, ERα and ERβ. Like other steroid hormone receptors, ERs act as dimers to regulate transcriptional activation. Full transcriptional activity of the ERs is thought to proceed through a synergism between two activation domains, AF-1 at the N terminus and AF-2 in the LBD. Both ERα and ERβ contain a potent AF-2 function, but unlike ERα, ERβ seems to have a weaker corresponding AF-1 function and thus depends more on the ligand-dependent AF-2 for its transcriptional activation function (Dahlman-Wright et al. 2006). These AFs have been shown to exhibit distinct transactivation properties that depend on both cell and promoter contexts.

ERs, upon ligand activation, can regulate biological processes by divergent pathways (Fig. 2). The classical signaling occurs through direct binding of ER dimers to estrogen-responsive elements (EREs) in the regulatory regions of estrogen-responsive genes, followed by recruitment of coregulators to the transcription start site. The consensus ERE consists of a 5-bp palindrome with a 3-bp spacer: GGTCAnnnTGACC. However, many natural EREs deviate substantially from the consensus sequence (O'Lone et al. 2004). Estrogen also modulates gene expression by a second mechanism in which ERs interact with other transcription factors, such as activating protein-1 (AP-1) and stimulating protein-1 (Sp-1), through a process referred to as transcription factor cross-talk. Estrogen may also elicit effects through nongenomic mechanisms, which occur much more rapidly. This action has been shown to involve the activation of downstream cascades such as protein kinase A (PKA), protein kinase C (PKC), and ▶ MAP kinase, via membrane-localized ERs. Recently, an orphan G protein-coupled receptor (GPR)30 in the cell membrane was reported to mediate nongenomic estrogen signaling. Subsequent studies by others demonstrated that the activities of GPR30 in response to estrogen were through its ability to induce expression of ERα36, a novel variant of ERα, and ERα36, in turn, acts as an extranuclear ER to mediate nongenomic estrogen signaling (Kang et al. 2010).

In addition to these ligand-induced transcriptional activities of ERs, ligand-independent pathways to activate ERs have been described. Growth factor signaling or stimulation of other signaling pathways leads to activation of kinases that can phosphorylate and thereby activate ERs or associated coregulators in the absence of ligand. For example, it has been shown that the HER2 downstream signaling



Estrogen Receptor, Fig. 2 Four different pathways of ER action. (**a**) In the classical signaling, ER dimers directly bind to estrogen-responsive elements (EREs) following ligand activation. (**b**) ERs, upon ligand binding, interact with other transcription factors (TFs), such as activating protein-1 (AP-1) and stimulating protein-1 (Sp-1), through a process referred to as transcription factor cross-talk. (**c**) Estrogen may elicit effects through nongenomic mechanisms via ERα or GPR30 in the cell membrane, involving interactions with cytoplasmic signal transduction proteins. (**d**) ER activity can be regulated through a ligand-independent pathway in which ERs are phosphorylated by activated kinases

molecules ERK1 and ERK2 can phosphorylate ER, leading to ligand-independent receptor activation (Martin et al. 2005).

Genome-Wide Profiling of ER Gene Expression Programs

There have been a number of studies in the past few years aimed at comprehensively unraveling the complete estrogen-regulated gene expression programs in cancer cells. These reports can be attributed to the introduction of microarrays for global gene expression profiling. DNA microarray technology allows quantitative monitoring of changes in the expression of thousands of genes simultaneously and has been described in several configurations including oligonucleotide arrays and microarrays of cDNAs spotted on glass slides. During the past few years, the development of high throughput DNA sequencing (HTS) methods for global gene expression profiling, also known as "RNA-Seq," has challenged microarray technology because of its superior capability for detection of low-expressed genes, alternative splice variants, and novel transcripts (Cloonan et al. 2008). However, to our knowledge, no studies that explore HTS to assay genome-wide transcriptional regulation by estrogen have been reported.

Several reports have described the gene expression profiles in ERα-expressing breast cancer cell lines in response to E2 treatment. The available studies have reported different numbers of E2/ERα-regulated genes in MCF7 breast cancer cells, ranging from ∼200 to ∼1,500. These discrepancies can be attributed to differences in the length of the E2 treatment, application of different microarray platforms and different analysis strategies (Kininis and Kraus 2008). Two studies that aimed to identify E2/ERα-direct targets by short-term E2 treatment (3 h) in MCF7 cells identified similar numbers of E2 target genes. In one of the studies, 122 genes were identified as stimulated by E2 and 95 genes were identified as inhibited by E2 (Kininis et al. 2007). In the other study, 134 genes were up-regulated and 141 genes were down-regulated after E2 treatment (Carroll et al. 2006). However, a comparison of the E2-regulated genes between the

studies has not been reported. Overall, gene expression profiling and candidate gene analysis have identified several well-known estrogen-regulated genes in breast cancer cells such as *TFF1*, *CCND1*, *IGFBP4*, *C3*, *ADORA1*, *GREB1*, and *MYC*. Furthermore, gene expression profiling has identified categories of genes regulated by estrogen, including those that modulate the cell cycle, transcriptional regulation, morphogenesis, and apoptosis, compatible with a role of estrogen in inducing breast cancer cell proliferation and survival (Carroll and Brown 2006).

Due to the lack of high levels of endogenous ERβ in breast cancer cell lines, gene expression profiling studies aimed at revealing the genes regulated by ERβ have been performed in breast cancer cell lines stably expressing ERβ. Of the categories of genes downregulated by ERβ, the "regulation of cell proliferation" category was the most overrepresented one, consistent with the observations that ERβ expression was associated with suppression of breast cancer cell proliferation (Williams et al. 2008). Gene expression profiles for ER-subtypes showed that ERα and ERβ share some common target genes, although each receptor also appears to have distinct sets of downstream target genes.

ER and Breast Cancer

Estrogen is essential for growth and development of the mammary glands and has been associated with promotion and growth of breast cancer. ERβ is found in both ductal and lobular epithelial and stromal cells of the rodent, whereas ERα is only found in the ductal and lobular epithelial cells and not in stroma. The presence of significant amounts of ERα in breast cancer at the time of diagnosis is taken as an indication of hormone dependence. On this basis, treatment with ERα antagonistic compounds, such as tamoxifen, is first line for adjuvant therapy. ERα is also an important prognostic factor in breast cancer. ERα-negative breast cancers are associated with poor prognosis and a more aggressive phenotype (Spears and Bartlett 2009).

To date, ERβ expression in normal human breast and breast cancer specimens and the relationship between ERβ and clinicopathological features and response to endocrine treatment has been extensively investigated at both mRNA and protein levels. Overall, these studies suggest a protective role of ERβ in breast cancer development. ERβ is lost in a majority of breast tumors, which has been shown to be correlated with ERβ promoter methylation in breast cancer cells (Zhao et al. 2003). Promoter methylation is frequently observed for cancer suppressor genes. Several studies have demonstrated that ERβ is an important modulator of proliferation and invasion of breast cancer cells, thus supporting the hypothesis that loss of ERβ expression could be one of the events leading to breast cancer development. Currently, only the ERα form is measured for clinical decision-making and treatment of breast cancer patients.

SERMs in Breast Cancer Treatment

Selective estrogen receptor modulators, referred to as SERMs, are a class of compounds with mixed ER-agonist/antagonist activities. Tamoxifen is the most commonly used SERM for treating all stages of ERα-positive breast cancer. In primary breast cancer, adjuvant tamoxifen significantly decreases relapse rates and mortality in pre- and postmenopausal patients, and the therapy benefit from 5 years of adjuvant tamoxifen is maintained, even >10 years after the primary diagnosis. Tamoxifen has also been used as a chemopreventive agent in women who have high risk for breast cancer. The mechanism behind the antitumorigenic function of tamoxifen is through competing with estrogens for the LBD of ERα, thereby inhibiting ERα-mediated mitogenic estrogen signaling in the breast. However, tamoxifen has been shown to have an agonistic effect on endometrium and thus may increase the risk for endometrial cancer.

Raloxifen is a newly developed SERM and has been shown to be as effective as tamoxifen in reducing the incidence of breast cancer in postmenopausal women who are at increased risk of the disease. Because of its nonproliferative effects in the uterus and estrogenic effects on bone, this drug has also been approved for prevention of osteoporosis in high-risk women. Aromatase inhibitors, which potently suppress estrogen synthesis in postmenopausal women, are now considered to be more effective in treating metastatic breast cancer in postmenopausal women than tamoxifen. Fulvestrant (ICI 182,780) is a new class of compounds for endocrine treatment, functioning as a pure ER-antagonist with no agonist effects.

Despite substantial improvements in the treatment of breast cancer, resistance to therapy remains a major clinical problem. Approximately one third of the patients with ERα-positive tumors fail to respond to tamoxifen treatment due to intrinsic or de novo

resistance of the tumor. Furthermore, even patients who initially respond eventually acquire tamoxifen resistance, leading to tumor progression and death. Several mechanisms have been proposed to account for the observed resistance, including changes in the expression of ERα or ERβ, altered levels of co-regulatory proteins, and the influences of cellular kinase signal transduction pathways (Ring and Dowsett 2004). Today, circumvention of endocrine resistance represents a major challenge for clinicians and cancer researchers.

Summary

Estrogens are thought to exert their biological effects predominantly via ERs through their interactions with DNA. Interestingly, more evidence has indicated that estrogens, like androgen and progesterone, can exert nongenomic effects. Nongenomic steroid activity typically involves the rapid induction of secondary messengers of signal transduction cascades via membrane-localized ERs, including activation of protein kinase A (PKA), protein kinase C (PKC), and ▶ MAP kinase. Interestingly, recent studies have suggested that GPR30 functions as a novel type of extranuclear ER that mediates nongenomic estrogen signaling. It is still possible that additional membrane receptors for estrogen are involved in mediation of the nongenomic estrogen action. The mechanistic details of activation through these nongenomic pathways, such as target genes, remain to be characterized.

Gene expression profiling has furthered our understanding of the role of ERs and provided important glimpses into the molecular basis of ER-mediated estrogen action in target cells. Future studies will need to explore time courses of estrogen-regulated genes thus facilitating the identification of primary, secondary, and higher order estrogen-regulated genes, finally revealing the gene regulatory networks affected by estrogen signaling.

Currently only ERα status is an important marker for routine prognostic and predictive evaluation in breast cancer. Over the last decade, the role of ERβ in estrogen action in breast cancer involving cooperation, as well as competition with ERα, has been revealed. Future studies should include validation of ERβ as a target for breast cancer and exploration of ERβ as a marker for clinical decision-making and treatment. The discovery of clinically useful ERβ-agonists might hold great promise. Furthermore a better understanding of the biological pathways of tamoxifen resistance should allow the circumvention of tamoxifen resistance using rational therapeutic approaches.

Historical Background

Founding members of the fibroblast growth factor (FGF) family are FGF1 (acidic FGF or aFGF) and FGF2 (basic FGF or bFGF), which were initially purified from cow brain and pituitary gland as mitogens for fibroblasts (Gospodarowicz et al. 1978). Mouse Fgf3 (int-2) was cloned and characterized as a proto-oncogene aberrantly upregulated in mammary tumors due to proviral integration of mouse mammary tumor virus (MMTV) (Dickson et al. 1984). Human FGF4 (K-FGF) was cloned and characterized as a proto-oncogene following transfection of genome DNA of Kaposi sarcoma into mouse NIH 3T3 cells (Delli Bovi et al. 1987). Additional 18 FGFs were then cloned and characterized based on their homology to FGF1 ~ FGF4 (Reviewed in Katoh 2002). Because *CCND1 – ORAOV1 – FGF19 – FGF4 – FGF3* locus at human chromosome 11q13.3 is conserved in chicken and zebra fish genomes, and is syntenic to rodent *Ccnd1 – Oraov1 – Fgf15 – Fgf4 – Fgf3* locus, it was concluded that human FGF19, chicken fgf19, and zebra fish fgf19 are orthologs of rodent Fgf15 (Katoh and Katoh 2003). Therefore, 22, but not 23, *FGF* family genes are conserved in mammalian genomes.

FGF family members with conserved FGF core domain of about 120 amino acid residues are classified into the following seven subgroups (Popovici et al. 2005): subgroup A consisting of

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,

FGF (Fibroblast Growth Factor), Table 1 FGF family

Subgroup	FGF	FGF receptor	Hereditary human disease
A	FGF1	FGFR1b, FGFR1c, FGFR2b, FGFR2c, FGFR3b, FGFR3c, FGFR4	
	FGF2	FGFR1b, FGFR1c, FGFR2c, FGFR3b, FGFR3c, FGFR4	
B	FGF3	FGFR1b, FGFR2b	Deafness associated with complete absence of inner ear structures, microtia, and microdontia
	FGF7	FGFR2b	
	FGF10	FGFR1b, FGFR2b	Autosomal-dominant lacrimo-auriculo-dento-digital syndrome
	FGF22	FGFR2b	
C	FGF4	FGFR1c, FGFR2c, FGFR3c, FGFR4

G	FGF19	FGFR1c, FGFR2c, FGFR3c, FGFR4	
	FGF21	FGFR1c, FGFR2c, FGFR3c, FGFR4	
	FGF23	FGFR1c, FGFR2c, FGFR3c, FGFR4	Autosomal-dominant hypophosphatemic rickets

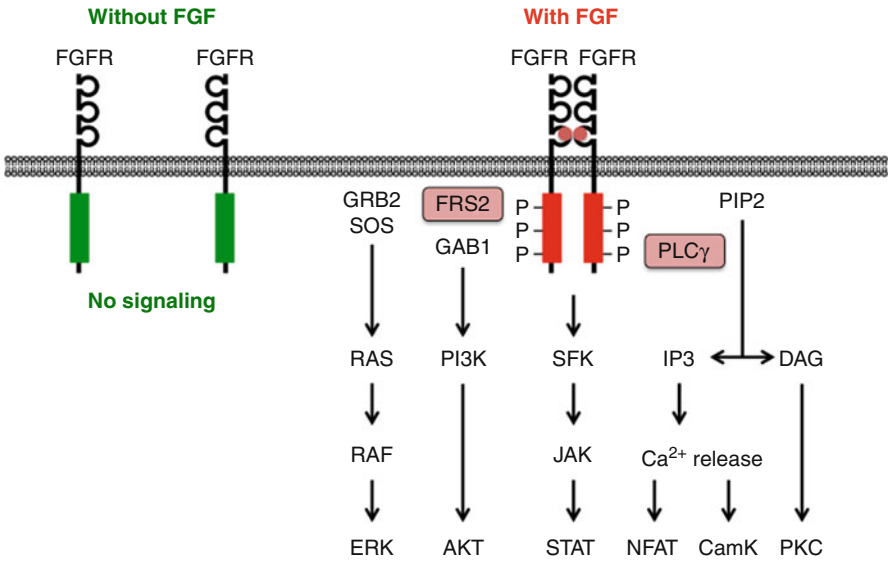
FGF family members are classified into seven subgroups. Receptors and hereditary human disease associated with each FGF are listed

FGF1 and FGF2; subgroup B consisting of FGF3, FGF7 (KGF), FGF10, and FGF22; subgroup C consisting of FGF4, FGF5, and FGF6; subgroup D consisting of FGF8, FGF17, and FGF18; subgroup E consisting of FGF9, FGF16, and FGF20 (FGF-20); subgroup F consisting of FGF11, FGF12, and FGF13, and FGF14; subgroup G consisting of FGF19, FGF21, and FGF23. Members of subgroups A, B, C, D, E, and G are extracellular FGFs transducing signals through cell-surface FGF receptors (FGFRs), whereas members of subgroup F are intracellular FGFs functioning in an FGFR-independent manner (Table 1).

FGF Signaling Cascades

Signals of 18 extracellular FGFs are transduced through FGFR1b, FGFR1c, FGFR2b, FGFR2c, FGFR3b, FGFR3c, or FGFR4, which share the common domain architecture consisting of extracellular immunoglobulin (Ig)-like domains and cytoplasmic tyrosine kinase domain (Eswarakumar et al. 2005). *FGFR1*, *FGFR2*, *FGFR3* genes encode two receptor isoforms with distinct ligand specificity due to alternative splicing in the third Ig-like domain, while *FGFR4* gene encodes a single receptor (Table 1). For example, FGFR2b on epithelial cells functions as the receptor for FGF1, FGF3, FGF7, FGF10, and FGF22, whereas FGFR2c on mesenchymal cells functions as the receptor for FGF1, FGF2, FGF4, FGF6, FGF9, FGF16, FGF17, FGF18, and FGF20 (Eswarakumar et al. 2005; Zhang et al. 2006).

Extracellular FGFs utilize heparan sulfate proteoglycan (HSPG) and/or Klotho-type co-receptors to fine-tune their interaction with FGFRs. FGF-mediated dimerization and stepwise autophosphorylation of FGFRs result in phosphorylation of adaptor molecule, FGFR substrate 2 (FRS2), and also recruitment and activation of phospholipase C-γ (PLCγ) (Dailey et al. 2005; Katoh 2009; Bae and Schlessinger 2010). FRS2 phosphorylation leads to GRB2 recruitment, and following activation of RAS-ERK and PI3K-AKT



FGF (Fibroblast Growth Factor), Fig. 1 FGF signaling cascades. FGF signals are transduced through FGFRs to RAS-ERK, PI3K-AKT, PKC, and JAK-STAT signaling cascades for survival, proliferation, differentiation, or migration of target cells

signaling cascades. PLCγ-mediated catalysis of phosphatidylinositol diphosphate (PIP2) gives rise to inositol triphosphate (IP3) for Ca^{2+} release from endoplasmic reticulum, and also diacylglycerol (DAG) for activation of protein kinase C (PKC). In addition, FGF signals activate JAK-STAT signaling cascade via SRC family kinases. FGF signals are transduced to RAS-ERK, PI3K-AKT, PKC, and JAK-STAT signaling cascades to induce survival, proliferation, differentiation, or migration of target cells (Fig. 1). Therefore, FGF signals are involved in a variety of cellular responses, such as self-renewal of stem cells, proliferation or differentiation of progenitor cells, angiogenesis, would healing, and tumor invasion.

Physiological Roles of FGF Signaling

Embryonic stem cells (ESCs), epiblast-derived stem cells (EpiSCs), and induced pluripotent stem cells (iPSCs) are characterized by potentials for self-renewal and differentiation of three germ layers to generate whole body. Human ESCs and mouse EpiSCs are supported by FGF2 and Activin/Nodal, whereas mouse ESCs by LIF (Katoh 2008).

Mesenchymal stem cells (MSCs) are somatic stem cells with the potential to differentiate into mesoderm-derived chondrocytes, osteoblasts, adipocytes, fibroblasts, myocytes as well as non-mesoderm-derived hepatocytes, and neurons. FGF signals are required for osteoblastic differentiation of MSCs, and adipocytic differentiation of preadipocytes (Katoh 2008).

Subgroup B members of the FGF family, including FGF3, FGF7, FGF10, and FGF22, preferentially transduce signals through FGFR2b and/or FGFR1b to function as local regulators involved in fetal morphogenesis, axon guidance, and wound repair (Katoh 2009). On the other hand, subgroup G members, including FGF19, FGF21, and FGF23, are secreted into circulation to function as endocrine hormonal factors involved in metabolism of glucose, lipid, bile acid, inorganic phosphate (Pi), and vitamin D (Kharitonenkov 2009).

Pathological Roles of FGF Signaling

Missense mutations of human *FGF* family members are involved in pathogenesis of several hereditary diseases (Table 1) (Krejci et al. 2009). For example, *FGF23* gene at human chromosome 12p13.32 is the causative gene for autosomal-dominant hypophosphatemic rickets (ADHR), featured by rickets, osteomalacia, and lower limb deformity. Missense mutations of *FGF23* around proteolytic cleavage site lead to elevation of serum FGF23 level. FGF23 is associated with Klotho to transduce signals through FGFR1c, FGFR3c, and FGFR4 to the RAS-ERK signaling branch. Because FGF23 is an osteocyte-derived

hormonal factor to downregulate reabsorption of inorganic phosphate (Pi) from the proximal convoluted tubules in the kidney, missense mutations of FGF23 in ADHR patients result in hypophosphatemia due to decreased Pi reabsorption (Marsell and Jonsson 2010).

FGF20 gene at human chromosome 8p22 is located within the susceptibility locus of Parkinson's disease. Clinical features of Parkinson's disease, such as resting tremor, cogwheel rigidity, bradykinesia, and impaired postural reflexes, are caused by the loss of dopaminergic neurons in substantia nigra. FGF20 secreted from substantia nigra activates the RAS-ERK signaling branch to induce differentiation of dopaminergic neurons. SNP rs12720208 at the 3'-UTR of *FGF20* mRNA is associated with the risk of Parkinson's disease due to the creation of miRNA-433 target sequence (Kirikoshi et al. 2000; Wang et al. 2008).

FGFR1, *FGFR2*, or *FGFR3* are the causative genes for congenital skeletal abnormalities, such as Crouzon syndrome, Jackson-Weiss syndrome, Apert syndrome, Pfeiffer syndrome, Beare-Stevenson syndrome, or Saethre-Chotzen syndrome (Wilkie et al. 2002). Missense mutations of FGFRs around the third Ig-like domain lead to ectopic FGFR2 activation due to altered ligand-binding specificity, whereas those within the tyrosine kinase domain results in ligand-independent FGFR signaling activation due to release of FGFR from autoinhibition.

Fgf3, Fgf4, and *Fgf10* are upregulated due to MMTV proviral integration during mouse mammary carcinogenesis. Interestingly, *Fgf3* and/or *Fgf4* are activated by MMTV, because *Fgf3* and *Fgf4* genes are clustered as mentioned above. *Fgf3* was demonstrated as a proto-oncogene involved in mouse mammary carcinogenesis based on tumorigenesis in the MMTV-*Fgf3* transgenic mice expressing *Fgf3* transgene under the control of MMTV promoter. Mammary carcinogenesis in the MMTV-*Fgf3* transgenic mice is accelerated due to *Wnt10b* upregulation based on additional MMTV proviral integration, and that in the MMTV-*Wnt1* transgenic mice due to *Fgf3* upregulation. FGF signals promote mouse mammary carcinogenesis in cooperation with canonical WNT signals (Katoh 2011).

In human, the *CCND1 – ORAOV1 – FGF19 – FGF4 – FGF3* locus at chromosome 11q13.3 region is amplified in breast cancer, and other types of tumors. *CCND1*, but not *FGF3* nor *FGF4*, is overexpressed in human tumors due to copy-number gain. Because *CCND1* gene encodes Cyclin D1, involved in cell-cycle progression, *CCND1* within the 11q13.3 amplicon is the driver gene of human carcinogenesis.

Instead of *FGF* genes, *FGFR* genes are involved in human carcinogenesis (Katoh 2009). *FGFR1* is activated due to overexpression associated with gene amplification in ER-positive breast cancer, and ovarian cancer, and also due to chromosomal translocation in myeloproliferative syndrome. *FGFR2* is activated due to overexpression associated with gene amplification in triple-negative breast cancer and diffuse-type gastric cancer. Single-nucleotide polymorphisms (SNPs) in an intronic region of *FGFR2* gene are associated with increased risk of breast cancer through altered *FGFR2* transcription due to SNP-based creation of transcription factor–binding sites. *FGFR3* is activated due to chromosomal translocation in multiple myeloma. In addition, SNP in an exonic region of *FGFR4* gene, resulting in Gly388Arg amino acid substitution, is associated with a poor prognosis in breast cancer and lung cancer. *FGFR* genes are aberrantly activated in human tumors due to gene amplification, chromosomal translocation, and missense mutation (summarized in Katoh 2010).

Together these facts indicate that aberrant FGF signaling is involved in a broad spectrum of pathologies, such as endocrine disease, neurodegenerative disease, skeletal abnormality, and cancer (Katoh 2009).

Summary

FGF signals are transduced through FGFRs to the RAS-ERK, PI3K-AKT, PKC, and JAK-STAT signaling cascades for survival, proliferation, differentiation, or migration of target cells (Eswarakumar et al. 2005; Dailey et al. 2005; Katoh 2009). FGF signaling cascades cross-talk with WNT, Notch, Hedgehog, and TGFß/BMP signaling cascades to constitute the stem-cell signaling network, which is involved in fetal-tissue morphogenesis, adult-tissue homeostasis, and tumorigenesis (Katoh and Katoh 2007). Because FGFs are involved in self-renewal of stem cells, proliferation or differentiation of progenitor cells, angiogenesis, would healing, and tumor invasion, FGF signaling cascades are therapeutic target in the fields of regenerative medicine, endocrinology and metabolism, and clinical oncology. Recombinant FGF7 and

FGF20 proteins are applicable for treatment of mucosal injury associated with chemotherapy or radiotherapy, whereas recombinant FGF2 protein and FGF4 expression vector are applicable for therapeutic angiogenesis (Katoh and Katoh 2006). Small-molecule compounds targeted to FGFRs and other receptors, such as Cediranib, TKI258, Ki23057, MK-2461, and brivanib, are applicable to cancer therapeutics (Katoh 2009).

Synonyms

c-FGR; Gardner-Rasheed feline sarcoma viral (v-fgr) oncogene

Historical Background

FGR is a cytoplasmic protein-tyrosine kinase belonging to the ▶ SRC family of protein tyrosine kinases. This kinase was originally described in the context of a feline sarcoma virus isolated from a spontaneous sarcoma of a domestic house cat and named GR-FeSV (Gardner-Rasheed feline sarcoma virus), whose primary translation product was shown to be a 70 kDa gag-fgr fusion peptide (Rasheed et al. 1982). Later studies identified this peptide as having a portion with amino acid homology with actin and another one related to a tyrosine kinase homologous to gene sequences present in the DNA of diverse invertebrate species (Naharro et al. 1984; Naharro et al. 1983). FGR is expressed in human and murine hematopoietic cells including granulocytes, monocytes/macrophages, natural killer cells, platelets, and erythrocytes (Berton 2006; Lowell 2004). Its function has been mainly characterized in innate immunity cells and in particular in granulocytes and monocyte/macrophages (Berton et al. 2005; Lowell 2004).

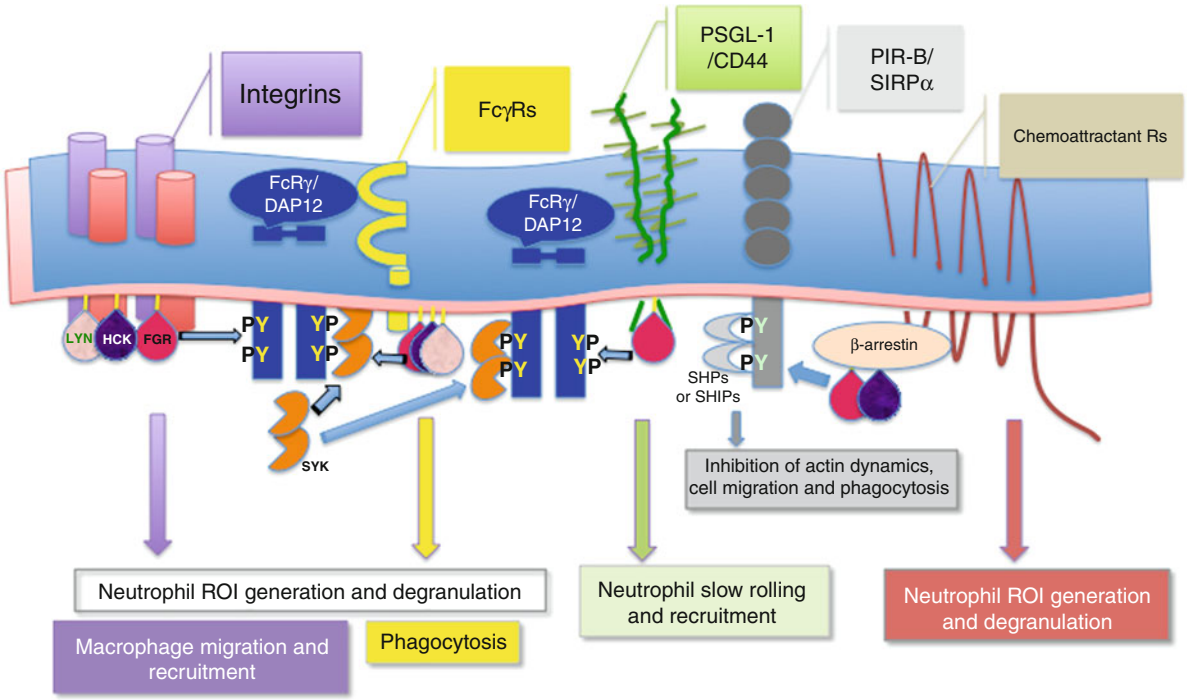
FGR Functions: An Overview

Studies in mice with the genetic deficiency of FGR established the concept that this kinase serves both specific functions and functions emerging from its combined action together with other members of the ▶ SRC family of protein tyrosine kinases (SFKs). A paradigm emerged on the role of SFKs in immune cell responses is that they are implicated in activating and inhibitory pathways (Lowell 2011). Consistent with this scenario, FGR deficiency has been reported to result either in defective or enhanced cell responses. In contrast, multiple deficiency of SFKs expressed at the highest level in innate immunity cells, i.e., FGR, HCK and/or LYN, or nonselective inhibition of SFK activities by inhibitory compounds, invariably result in a marked defect in signal transduction and cell activation by different surface receptors.

Four major signaling pathways have been identified as being regulated by FGR in innate immunity cells (Fig. 1): (1) the signaling pathway triggered by receptors belonging to the wide family of immune receptors; (2) "outside-in" integrin signaling; (3) signaling by trimeric G protein-coupled receptors for chemoattractants and chemokines; and (4) the P-selectin glycoprotein ligand-1 (PSGL-1)/CD44-dependent pathway triggered by granulocyte interaction with E-selectin or P-selectin and regulating neutrophil slow rolling and recruitment.

Immunoreceptor Signaling

The immunoreceptors represent a wide family of receptors including antigen receptors expressed by T (TCR) and B lymphocytes (BCR), receptors for the Fc portion of IgE (FcεRs) and IgG (FcγRs), and other ones (Lowell 2004, 2011). Most of them consist of one or more transmembrane proteins implicated in ligand recognition and noncovalently associated homo/heterodimeric signaling adapters such as the FcγR-associated γ chain (FcRγ) or DAP12 (ITAM-Contaning Signal Adaptors). Classical immunoreceptor engagement leads to activation of SFKs, which in turn phosphorylate a tyrosine residue present in the immunoreceptor tyrosine-based activation motif (ITAM) present in the signaling adapters or, in the case of FcγRIIA, in its cytoplasmic tale; phosphorylated ITAMs recruit and activate the



FGR (Gene Name), Fig. 1 Major signal transduction pathways implicating FGR in myeloid leukocytes. Signal transduction by integrins, immunoreceptors, and PSGL-1 requires phosphorylation of tyrosine residues of the ITAM-containing adaptors FcRγ or DAP12 by FGR or other SFKs (HCK and LYN). Binding to phosphorylated ITAMs (yellow Y), together with its tyrosine phosphorylation by SFKs, activates SYK kinase activity. SFKs may associate with the integrin β chain and be activated upon integrin interaction with the ligand and/or integrin clustering. Alternatively, fatty acid bound to the SFK N-terminus can induce colocalization of receptors and SFKs in lipid rafts (see Yago et al. 2010). In the chemoattractant receptor signal transduction pathway, SFKs (FGR and HCK) may bind to β-arrestin associated to the receptor cytoplasmic tail. Major responses triggered by the different receptors are highlighted using the same color for the receptor, the arrow pointing to a specific cell response and the cell response itself. Both integrins and FcγRs lead to neutrophil ROI generation and degranulation (*in white*). In the integrin signal transduction pathway, FGR and other SFKs are involved in regulation of migration and recruitment in macrophages and of phagocytosis in neutrophils (first two arrows from the left). In chemoattaractant receptor, but also FcγR (not illustrated in the figure) signaling, FGR, and other SFKs, can phosphorylate ITIM-containing receptors and inhibit some myeloid cell responses (see text). For SFK and SYK substrates or interacting partners, see text and (Abram and Lowell 2009; Baruzzi et al. 2008; Berton et al. 2005; Lowell 2011)

tyrosine kinase SYK (Berton 1999; Lowell 2004, 2011). FGR, HCK, LYN and, based on inhibitory studies, other SFKs, have been implicated in macrophage IgG-mediated phagocytosis (Berton 1999; Berton et al. 2005). However, studies with myeloid leukocytes with the sole deficiency of FGR demonstrated that, whereas this kinase is essential for optimal FcγR-dependent phagocytosis in neutrophils, it negatively regulates the phagocytic response in macrophages (Gresham et al. 2000). This inhibitory function involves the immunoreceptor tyrosine-based inhibitory motifs (ITIM)-containing receptor SIRPα which binds the inhibitory tyrosine phosphatase SHP-1 in a FGR-dependent manner. Phosphorylation of tyrosine residues in the ITIM sequence of surface receptors such as FcγRIIB, SIRPα, PIR − B represents the best characterized mechanism of transduction of inhibitory signals by SFKs (Lowell 2004, 2011). Mechanisms underlying a predominant stimulatory or inhibitory effect of the different SFKs, or of one specific SFK like FGR in dependence of the cell context, for example, in neutrophils compared to macrophages (see above), are still unclear (Lowell 2011; Scapini et al. 2009).

Integrin Signaling

Integrins are heterodimeric transmembrane proteins consisting of an α and a β subunit implicated in cell-extracellular matrix or cell–cell interaction. The integrin receptor family includes at least 19 α subunits and 8 β subunits which associate to form at least 25 distinct receptors, several of which are expressed at variable levels in leukocytes. Innate immunity cells express members of the β1, β2, and β3 families and these regulate essential cell responses, including recruitment into inflamed tissues, reactive oxygen intermediate (ROIs) generation, degranulation, cytokine expression and release (Berton and Lowell 1999). Following the demonstration that β2 integrin engagement activates FGR in human neutrophils (Berton et al. 1994), a great deal of information has been accumulated on the role of SFKs in integrin signal transduction in myeloid leukocytes (Abram and Lowell 2009; Berton and Lowell 1999; Berton et al. 2005; Lowell and Berton 1999; Schymeinsky et al. 2007). Studies with mice with the single or multiple genetic deficiency of SFKs established the paradigm that within the integrin signaling pathway FGR appears to work in concert with other SFKs and more specifically to play a redundant role with HCK and, to a minor extent, LYN. The double deficiency of FGR and HCK results in an almost total suppression of several integrin-mediated responses including neutrophil ROI generation and degranulation (Abram and Lowell 2009; Berton et al. 2005; Lowell and Berton 1999; Schymeinsky et al. 2007) and macrophage migration (Baruzzi et al. 2008; Berton et al. 2005). Several components of the myeloid leukocyte integrin signaling pathways that are substrates of FGR/HCK have been identified, including c-CBL, SYK, FAK/PYK2, the p85 subunit of PI3-kinase, cortactin, paxillin SLP-67, and p190RHOGAP (Abram and Lowell 2009; Berton et al. 2005). A direct association of FGR with some of these proteins (c-Cbl, cortactin, SYK, FAK/PYK2) has been reported (Berton 2006).

A major advance in the understanding of integrin signaling in myeloid leukocytes has been the recent demonstration that, similarly to classical immunoreceptors, it involves the ITAM-containing adaptors DAP12 and FcRγ, establishing the paradigm that integrins signal though a SFK/ITAM-containing adaptors/SYK module (Jakus et al. 2007; Lowell 2011).

Signaling by Trimeric G Protein-Coupled Receptors

Several reports implicated SFKs in signal transduction by trimeric G protein-coupled receptors for chemoattractants or chemokines (Berton 1999; Berton et al. 2005; Lowell 2011). Neutrophils deficient of FGR and HCK or FGR, HCK, and LYN, or treated with SFK inhibitors, manifest a marked defect in both superoxide anion generation and degranulation in response to formylated peptides. Similarly, leukocyte responses to several chemokines including CXCL1, CXCL8, CXCL12 and CCL11 were reported to require FGR, HCK, or LYN. However, in analogy with what seen in ITAM/ITIM-containing adaptor-mediated signaling, also within the trimeric G protein-coupled receptor signaling pathway a possible inhibitory role of FGR and HCK in some myeloid leukocyte responses to different chemokines was established (Lowell 2011). Notably, FGR plays a major role in this inhibitory pathway compared to other SFKs and acts via phosphorylation of the ITIM-containing adaptor PIR-B (see Fig. 1 and (Lowell 2011). These contradictory findings may be reconciled emphasizing differences in specific cell responses to trimeric G protein-coupled receptor stimulation. ROIs generation and degranulation seem to require SFKs, whereas activation of integrin adhesiveness and cell migration occur independently of or are even inhibited by SFKs.

E- and P-Selectin-Induced Signaling

The latest advance in the understanding of the role of FGR in regulation of myeloid leukocyte function has been its implication in a signaling pathway triggered by engagement of E- or P-selectin by neutrophil counter-receptors (PSGL-1 and CD44) and regulating β2 integrin LFA-1-dependent slow rolling (Kuwano et al. 2010; Yago et al. 2010; Zarbock and Ley 2009). FGR seems to play a predominant role in the context of this pathway, although, in analogy with other signaling pathways, HCK and LYN are also involved. Notably, the SFK/ITAM-containing adaptors/SYK module identified to be essential for immunoreceptor and integrin signaling is also required for PSGL-1/CD44 signal transduction. Regulation by FGR and other SFKs of selectin-mediated slow rolling represents

one of the several mechanisms by which this tyrosine kinase family plays a central role in myeloid leukocyte recruitment into inflammatory sites (Baruzzi et al. 2008; Zarbock and Ley 2009).

Summary

FGR and related SFKs have emerged as essential upstream components of several signal transduction pathways regulating myeloid cell responses. Accumulating evidence suggests that several of these pathways share a common module consisting of SFKs, ITAM-containing adaptors and SYK wherein SFKs phosphorylate ITAM tyrosine residues causing binding and activation of SYK. Due to the pleiotropy of SFKs effects, a major challenge of future research is to dissect components of distinct signaling pathways leading to a specific cell response. Additionally, a question that needs to be addressed concerns the mechanisms of activation of SFKs. In fact, although direct or indirect binding to the receptor cytoplasmic tail or codistribution within lipid rafts likely represent a prerequisite for SFK activation, mechanisms responsible for this activation are still elusive. One of the most intriguing aspects of FGR and SFK functions is certainly their capability to activate or inhibit specific cell responses on the basis of their targeting "activation" or "inhibitory" motifs. The balance between these two different actions in the context of a specific SFK or cell function is certainly an issue that deserves more efforts in the future. The present knowledge favors the view that the combined action of different SFKs is essential for activation of a series of cell responses that is critical for the recruitment and activation of myeloid leukocytes into inflammatory sites. If so, it is tempting to speculate that inhibition of this upstream signaling component would tone down responses that are essential for inflammation-based pathologies. Targeting of SFKs as a new strategy to control inflammation is a major challenge for future research.

Fragile histidine triad gene

Historical Background

To date, approximately 80 common fragile sites (CFS) have been identified in the human genome (Ruiz-Herrera et al. 2006). Unlike rare fragile sites, which map to sites that are genetically altered in individuals, CFS occur at consistent genomic locations in particular cell types, which are defined by the paucity of replication initiation events at these loci (Letessier et al. 2011). DNA breaks at CFS, referred to as expression of the fragile site, can be induced *via* treatment with inhibitors of DNA replication, carcinogens, and environmental stresses (Lukusa and Fryns 2008). Several CFS colocalize with common deletions and translocations in tumors. Early efforts to find tumor suppressor genes encoded within fragile sites focused on *FRA3B* at chromosomal location 3p14.2, the most frequently expressed human CFS. Perturbations at 3p14.2 had been noted in many cancers and the site includes the t(3;8) translocation breakpoint associated with hereditary clear cell renal carcinoma (cRCC) (Cohen et al. 1979; Dreijerink et al. 2001). Positional cloning identified the fragile histidine triad gene, *FHIT*, as the gene that spans *FRA3B* (Ohta et al. 1996). In addition to losses of *FHIT* on the short arm of chromosome 3, many cRCC malignancies have been subject to gene losses including *RASSF1A* at 3p21.3 (Dreijerink et al. 2001) and *VHL* at 3p25 (Latif et al. 1993).

FHIT is a Tumor Suppressor Gene

Numerous cancer cell lines and primary tumors exhibit both homo- and hemizygous deletions within the *FHIT* gene. These deletions are concomitant with loss of mRNA expression in esophageal, stomach, colon, kidney, breast, and lung cancer cells. Immunohistochemistry of several types of primary tumors, including esophageal cancers, colon lesions, and cervical and lung cancers show frequent loss or absence of Fhit protein expression (Saldivar et al. 2010). This evidence notwithstanding, acceptance of *FHIT* as a tumor suppressor gene initially met with resistance, as loss of genetic material at a fragile site could be attributed as a consequence of genomic instability rather than a cause of cancer. However, accumulated evidence indicates that loss of Fhit is selected in carcinogenesis.

Mouse modeling and functional analysis has been used to show that *FHIT* mutations are drivers of malignancy. The murine *Fhit* locus shares key similarities with human *FHIT*: *Fhit* encompasses a fragile site, *Fra14A2*, and *Fhit* expression is altered in several murine cancer cell lines, suggesting that a mouse model of *Fhit* inactivation would be relevant to human disease (Glover et al. 1998). Mice heterozygous and homozygous at *Fhit* alleles have been established. These mice are fertile, live normal life spans, and do not present with gross defects, although an immune deficiency related to a low granulocyte count has been noted (Zanesi et al. 2001). *Fhit* heterozygous mice possess increased susceptibility to development of carcinogen-induced tumors. Oral administration of the carcinogen *N*-nitrosomethylbenzylamine (NMBA) produces tumors in 25% of a wild-type cohort of mice, while administration of an equivalent dose produces tumors in 100% of *Fhit* heterozygotes (Fong et al. 2000). *Fhit* heterozygous and *Fhit*-deficient mice are also more susceptible to spontaneous tumor development (Zanesi et al. 2001).

Gene therapy studies established that *Fhit* re-expression not only prevents development of cancer, but also contributes to tumor regression via apoptosis. Delivery of *Fhit* via adenovirus (Ad-*Fhit*) or adeno-associated virus (AAV-*Fhit*) significantly inhibits tumor development after NMBA treatment (Dumon et al. 2001). Immunohistochemical staining of tissue resected from sacrificed animals showed opposite Bax and Bcl2 staining in control versus Fhit-expressing animals, suggesting that failure to induce apoptosis contributed to tumor development in control animals while apoptosis due to delivery of Fhit in vector-treated animals contributed to tumor regression (Ishii et al. 2003).

Fhit Encodes a Dinucleoside Polyphosphate Hydrolase

Fhit and its homologs constitute one branch of histidine triad (HIT) proteins that have been strongly conserved throughout evolution. HIT proteins encode enzymes that bind and hydrolyze or phosphorylyze unusual nucleotide substrates. The HIT motif (His-Ø-His-Ø-His-Ø-Ø, in which Ø is a hydrophobic amino acid) forms part of the active site (Brenner 2002). Fhit protein and its orthologs are dinucleoside polyphosphate hydrolases, enzymes which bind and cleave a class of dinucleotides, typically containing two adenosines joined by 5′-5′ bridges of 3–5 phosphates. The favored substrate of Fhit is ApppA (Barnes et al. 1996) and the substrate typically used in vitro is GpppBODIPY (Draganescu et al. 2000). Hydrolysis of such compounds produces a nucleoside monophosphate product (e.g., AMP or GMP) plus the other nucleotide or analog (e.g., ADP or ppBODIPY).

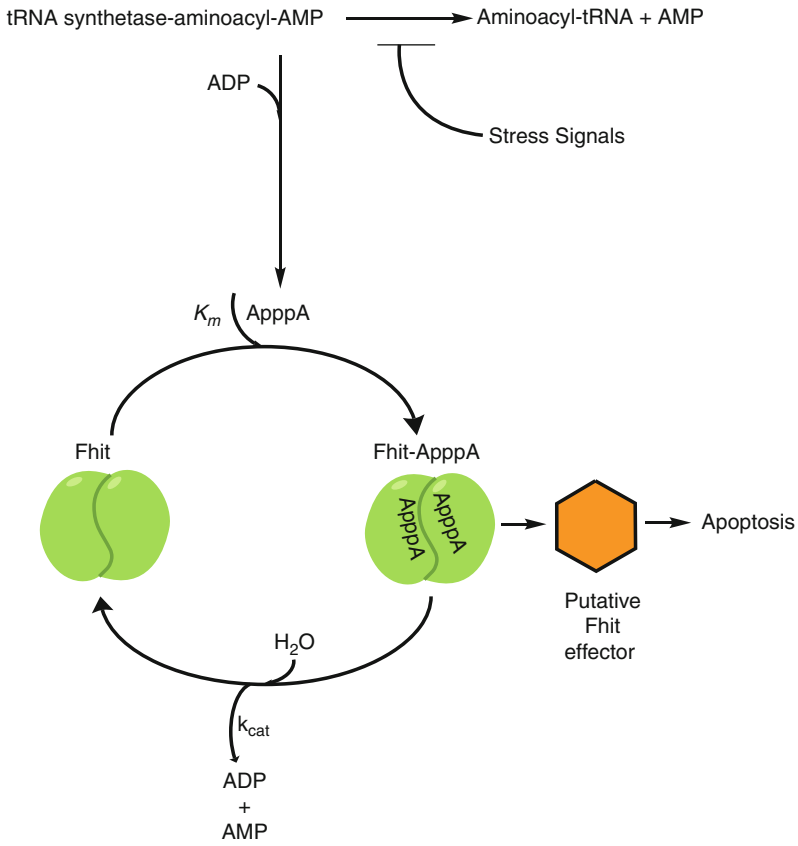
Fhit is a dimer, which contains two ApppA-binding sites per dimer. (Pace et al. 1998). ApppA molecules are by-products of reactions catalyzed by tRNA synthetases and are proposed to have several intracellular functions, including signaling stress responses (Campiglio et al. 2006). Interestingly, intracellular concentration of ApppA increases in mammalian cells exposed to the carcinogenic metal cadmium and the apoptosis-inducing topoisomerase poison etoposide (Fisher and McLennan 2008). Experiments were designed to determine whether the tumor-suppressing function of Fhit depends on ApppA-binding, hydrolysis, or both Appp-binding and hydrolysis. Re-expression of Fhit in Fhit-null cancer cells suppresses tumorigenicity in a manner that is largely insensitive to mutation of the active-site His (His96) to Asn (Siprashvili et al. 1997). This result suggested that the tumor suppressing function of Fhit might be independent of the ApppA substrate. However, a Fhit allele series was created to test the hypothesis that substrate binding but not hydrolysis is limiting for the pro-apoptotic activity of Fhit re-expression. Indeed, as mutations were created to reduce substrate binding, the pro-apoptotic activity of Fhit re-expression was reduced. In contrast, in mutations targeted to the active site His, which reduced catalytic activity by as much as 100,000-fold and reduced substrate binding by two-fold, only modest reductions in apoptotic activities were observed (Trapasso et al. 2003). As illustrated in Fig. 1, these data were interpreted to suggest that formation of a Fhit-ApppA substrate complex is limiting for interaction with a pro-aptoptic effector (Pace et al. 1998).

The Fhit Protein Interactome

Protein association studies have attempted to place Fhit into specific cellular pathways that might depend on diadenosine polyphosphates for signaling. Both wild-type Fhit and the catalytically inactive H96N mutant were shown to interact with tubulin in vitro and promote microtubule assembly in the presence of the microtubule binding proteins MAP2 and Tau (Chaudhuri et al. 1999). In addition, yeast two-hybrid data suggest that Fhit interacts with the SUMO conjugating enzyme, Ubc9 (Shi et al. 2000). Biochemical assays have confirmed an interaction in vitro with one report (Golebiowski et al. 2004) but not another (Shi et al. 2000) indicating ApppA-dependent protein binding. Another appealing model is that Fhit may bind and destablize Mdm2, an E3 ubiquitin ligase that marks p53 for degradation (Nishizaki et al. 2004).

Fhit and a member of the nitrilase superfamily are encoded as fusion proteins in worms and flies (Pekarsky et al. 1998), suggesting that Fhit and Nit1, the ortholog of the nitrilase-related domain may participate in the same pathway and associate as seen in the crystal structure of the worm NitFhit protein (Pace et al. 2000). The data suggest that like Fhit, Nit1 functions as a tumor suppressor. The *Nit1* knockout mouse shows increased susceptibility to NMBA-induced carcinogenesis and increased cell growth in culture (Semba et al. 2006). Moreover, loss of Fhit and loss of Nit1 are apparently additive for tumor suppression (Sun et al. 2009).

The Holy Grail in the molecular oncology of Fhit would be a set of protein interactions that provide a mechanism by which epithelial cells acquiring inactivating mutations in *FHIT* would obtain a survival advantage. The mechanism would also have to account for how Fhit re-expression induces apoptosis in a manner that depends on diadenosine polyphosphate binding. Though it is almost axiomatic that no unifying theory is accepted, there is one proposed mechanism notable for its far-reaching scope. According to this mechanism, Fhit transits to mitochondria *via* interaction with Hsp60 where it interacts



FHIT, Fig. 1 Stress is proposed to inhibit completion of the tRNA synthetase-catalyzed reaction, resulting in increased cytoplasmic ApppA. Fhit dimers, normally in the inactive state, now bind ApppA, forming pro-apoptotic Fhit-ApppA complexes. Fhit-ApppA complexes signal apoptosis *via* a putative Fhit effector. Cleavage of ApppA is proposed to terminate the pro-apoptotic state of Fhit

with and stabilizes ferredoxin reductase (Fdxr) (Trapasso et al. 2008). Fdxr transfers electrons from NADPH to cytochrome P450 via ferredoxin. Under stress, Fdxr levels increase, leading to depletion of NADPH, which is required to detoxify reactive oxygen species (ROS), thereby inducing ROS-mediated apoptosis. Consistent with the expectation that diadenosine polyphosphate binding is limiting for the tumor suppressing function of Fhit, the investigators have shown that mutations that reduce substrate binding also reduce mitochondrial localization, association with Hsp60 and Fdxr, and cellular responses to oxidative damage (Pichiorri et al. 2009).

Summary

Genetic analysis of Fhit has indicated that reintroduction of this protein induces apoptosis in cancer cells with *FHIT* deletions, which are a common cancer genotype. Challenges remain in defining the specific consequences of Fhit inactivation in the preneoplastic epithelial cells from which Fhit is typically lost and in defining the relationship between diadenosine polyphosphate signaling and cellular survival in cells, early in the process of carcinogenesis.

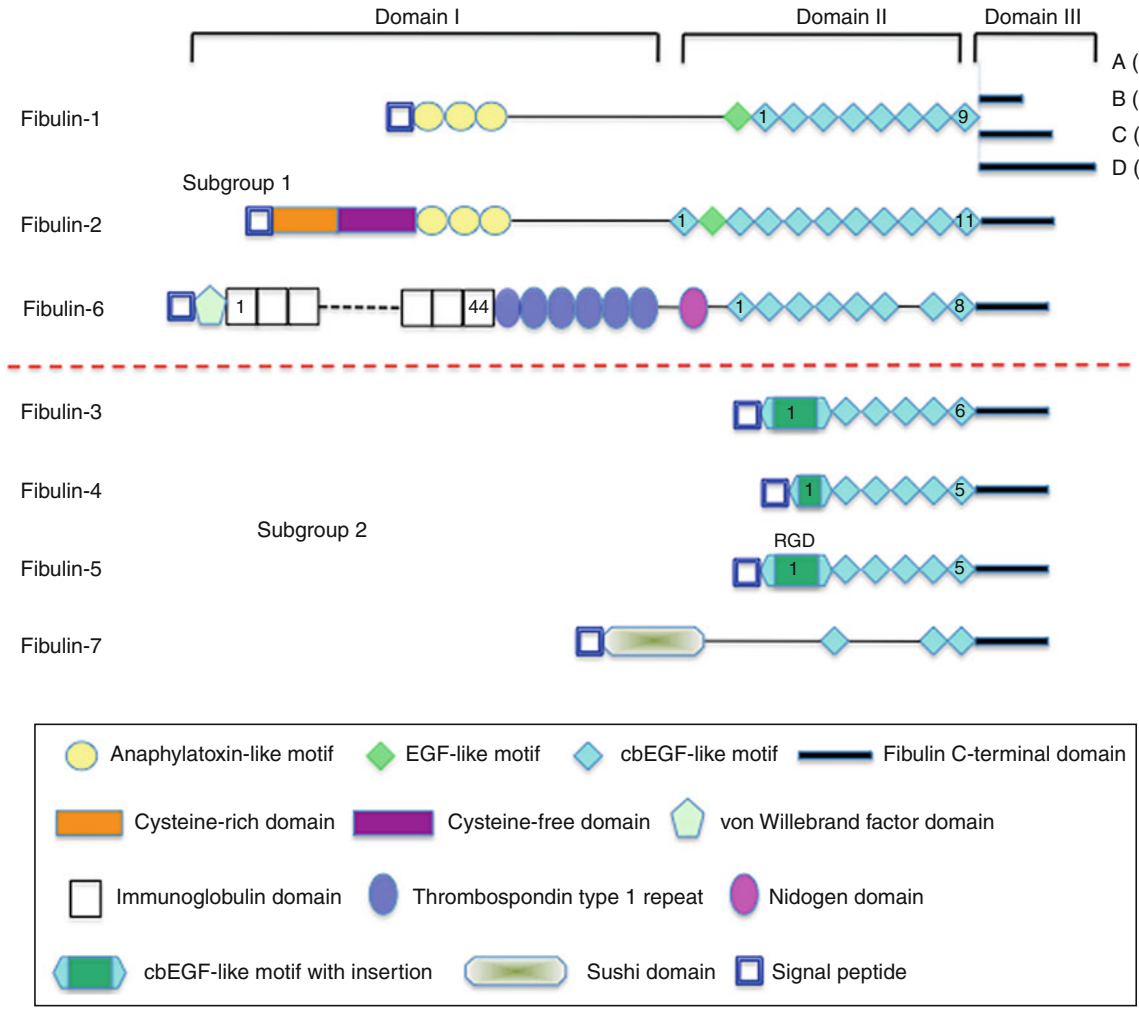
Historical Background

The extracellular matrix (ECM) is very diverse in its nature and composition in vertebrates, and is essential for normal development and maintenance of the microenvironment of embryonic and adult tissues. Many ECM proteins are secreted into extracellular milieu where they aggregate with existing matrix molecules to form supramolecular structures. The functions of the ECM include supporting cells, regulating intercellular communication, controlling cell motility, growth, and development, overseeing wound healing, and directing fibrosis (Albig and Schiemann 2005; de Vega et al. 2009; Timpl et al. 2003). These ECM proteins have been classified into several families based on their domain structures and/or functions, with fibulins now being recognized as one such family of ECM molecules. Fibulins share a common structural organization with tandem repeats of a calcium-binding epidermal growth factor (cbEGF)-like module and a unique C-terminal fibulin-type module (Albig and Schiemann 2005; Gallagher et al. 2005). The first fibulin (fibulin-1) was discovered two decades ago by affinity chromatography as an interacting molecule with the cytoplasmic tail of the β subunit of the fibronectin receptor (also known as β1 integrin receptor) (de Vega et al. 2009; Timpl et al. 2003). At first, fibulin-1 was considered to function as a bridging element between β1 integrin and intracellular molecules. Later, fibulin-1 nucleotide sequencing and immunohistochemistry showed this ECM protein to be secreted and present in the fibril matrix in fibroblasts, and in the blood. Since the discovery of fibulin-1, six additional fibulin family members have been reported. Fibulin-2 was identified from a mouse fibroblast cDNA library by comparative sequence analysis. Fibulin-3 (also known as S1-5, Efemp1) was first isolated from the screening of differentially expressed genes between senescent and quiescent human fibroblasts, and fibulin-4 (also known as Efemp2) was identified as a member of the fibulin family by sequence homology. Fibulin-5 (also known as EVEC, DANCE) was identified independently by searching for genes that regulate the transition of vascular smooth muscle cells from quiescent to proliferative states, and by searching for novel secreted molecules involved in the control of cardiovascular development and disease using signal sequence trap method. Hemicentin-1, the gene product of the him-4 locus in *Caenorhabditis elegans*, has been designated as fibulin-6 based on its cbEGF-like domain and C-terminal fibulin-type module. Recently, fibulin-7 (also known as TM14) was identified as the newest member of fibulin family by differential hybridization using tooth germ cDNA microarrays (de Vega et al. 2009; Timpl et al. 2003; Gallagher et al. 2005).

Fibulins are ECM proteins that collectively play important roles in the biology of tissue organogenesis and vasculogenesis, as well as in the pathology of fibrogenesis, tumorigenesis, and other genetic diseases. Herein we describe the multifunctional nature of fibulins in regulating the development of cancer and genetic diseases in humans, as well as their interactions with other ECM molecules and regulation of cellular signaling systems.

Fibulin Protein Structure and Their Interaction with Other Proteins

Structurally, fibulins contain a N-terminal (Domain I), which is variable among fibulin family members, and sequential repeats of cbEGF-like modules (Domain II), which is followed by a globular C-terminal fibulin-type module (Domain III) (Fig. 1). The fibulin family can be further subdivided into two distinct subgroups based on their size and the absence or presence of additional functional domains (Albig and Schiemann 2005). For instance, subgroup 1 consists of fibulin-1, fibulin-2, and fibulin-6. Fibulin-1 and fibulin-2 are larger and more structurally complex because they house more cbEGF-like modules in Domain II and three anaphylatoxin (AT) modules in domain I, which are components of the complement system involved in inflammation and defense against parasites. In addition, fibulin-2 has an extra N-terminal domain with that contains cysteine-rich and cysteine-free segments. Fibulin-6 contains largest N-terminal domain with more than 40 repeats of immunoglobulin motifs, six thrombospondin type I repeats, and a von Willebrand factor domain. Subgroup 2 contains the remaining family members, namely, fibulin-3, 4, 5 and fibulin-7, which collectively are smaller and structurally simpler. Fibulin-7 contains a sushi domain, which is known to be involved in protein–protein interactions and in the regulation of the complement system and blood coagulation (de Vega et al. 2009; Timpl et al. 2003; Gallagher et al. 2005). Although fibulins represent a small gene family, their genetic and biological diversity is increased significantly by their



Fibulins, Fig. 1 Schematic presentation of fibulin family proteins. Fibulins 1, 2, and 6 comprise subgroup 1, while fibulins 3, 4, 5, and 7 comprise subgroup 2. Although fibulins 1–4 are subject to alternative splicing, only fibulin-1 splice variants are shown. Fibulin-5 contains a unique evolutionarily conserved RGD (arginine-glycine-aspartic amino acid) sequence in the first cbEGF-like motif. The 44 immunoglobulin repeats in fibulin-6 are shown. Parenthesized number indicate amino acids present in alternatively spliced fibulin-1C-termini

propensity to undergo alternative mRNA splicing. Indeed, alternative splicing of fibulin-1 mRNA produces four splice variants (A, B, C, and D) in humans, and two splice variants (C and D) in mice, chickens, zebrafish, and nematodes. Splice variants of fibulin-1 differ exclusively in Domain III, such that fibulin-1A completely lacks this domain, while variants B, C, and D possess varying sequences throughout Domain III. In fibulin-2, the third EGF-like module is either or absent or present *via* alternative splicing; however, the functional consequences of these two variants remain unknown. Alternative splicing produces five variants of fibulin-3, all of which have a partial or complete absence of Domain I. Like fibulin-3, fibulin-4 also exhibits a splice variant that lacks a signal sequence in Domain I (de Vega et al. 2009; Gallagher et al. 2005).

As a member of the ECM, fibulins interact physically with a growing list of ECM and other secreted proteins in the matrix (Table 1). Fibulin-1 and fibulin-2 are localized in basement membranes in various tissues. Basement membranes are specialized sheet-like structures of the ECM that separates cells from the surrounding connective tissue; they also provide the

Fibulins, Table 1 Overview of fibulins: interaction, human pathologies, and cancer association

Proteins	Synonyms	Interacting proteins	Heritable disease	Cancer association
Fibulin-1	BM-90	Fibronectin, fibrinogen, nidogen	Synpolydactyly	Yes
		Laminin, aggrecan, versican	Giant platelet syndrome	
		Extracellular matrix protein1 (ECM1)	Vitroretinal dystrophy	
		Angiogenin, tropoelastin		
		ADAMTS-1(disintegrin-like and metalloproteinase with thrombospondin motifs), fibulin-7,		
		Sex-hormone binding globulin (SHBG)		
		β-amyloid precursor protein		
Fibulin-2	-	αIIβ3, αVβ3 integrin, laminin,	Unknown	Yes
		Fibrilin, fibronectin, nidogen		
		Aggrecan, versican, prelecan, SHBG		
Fibulin-3	S15	Tropoelastin	Malattia leventinese	Yes
	T16		Doyne honeycomb retinal dystrophy	
	EFEMP1		Age-related macular degeneration	
Fibulin-4	MBP1	Tropoelastin	Autosomal recessive cutis laxa	Yes
	EFEMP2	Mutant p53	Arachnodactyly	
	UPH1		Aortic aneyrysm	
	H411			
Fibulin-5	DANCE	Tropoelastin, Lox-like protein-1 (Loxl-1), Loxl-2, Loxl-4, emilin-1, fibrilin-1	Autosomal dominant cutis laxa	Yes
	EVEC	Latent TGF-β binding protein 2 (LTBP2)	Age-related macular degeneration	
	UP50	Extracellular superoxide dismutase		
		(ecSOD), Lipoprotein A,		
		αVβ1, αVβ3, αVβ5, α4β1, α9β1 integrin		
Fibulin-6	Hemicentin	Not available	Age-related macular degeneration (uncertain)	Not described
	Him4			
Fibulin-7	TM14	Fibronectin, heparin, fibulin-1	Unknown	Not described
		Dentin sialoprotein (DSP)		

essential scaffolding for cells and tissues during tissue morphogenesis that affects cell adhesion, migration, proliferation, and differentiation (Yanagisawa and Davis 2010). Basement membranes contain a vast array of proteins, such as laminin, perlecan, nidogen, and other molecules that interact with one another to form supramolecular structures (Yanagisawa and Davis 2010). Fibulin-1 and fibulin-2 bind to several basement membrane components including laminin, nidogen, perlecan, and fibronectin. The extensive network of interactions between basement membrane proteins and fibulin-1 and -2 plays an important scaffold function that supports the integrity and function of tissues. Fibulin-1 and fibulin-2 are also localized in elastic fibers, which provide the scaffold for connective tissues essential for the function of the skin, lungs, arteries, and other organs. The tropoelastins are deposited on microfibrils in an orderly manner and cross-linked by ▶ lysyl oxidases (LOXs) during the elastic fiber assembly (de Vega et al. 2009; Yanagisawa and Davis 2010). Aggrecan and versican are expressed in cartilage and provide mechanical strength to resist compression in the joints through the formation of large aggregates with hyaluronan that link proteins in the cartilage matrix (de Vega et al. 2009; Yanagisawa and Davis 2010). The binding of fibulin-1 and fibulin-2 to tropoelastin, aggrecan, and versican suggests that these fibulins play an important role in elastic fiber

assembly, as well as in the stabilization and function of cartilage matrix. While fibulin-1 and fibulin-2 interact with dozens of proteins, the other members of fibulin family typically display reduced ability to bind other proteins with the notable exception of fibulin-5, which exhibits overlapping binding affinities with fibulin-1 and fibulin-2. Fibulin-7 binds to dentin sialoprotein (Dsp), fibronectin, heparin, and fibulin-1, while no protein interactions have been reported for fibulin-6. Fibulin-3 and fibulin-4 bind to tropoelastin and play important roles in the assembly of elastic fibers during development (de Vega et al. 2009). Fibulin-5 not only binds to tropoelastin, but also interacts physically with a growing list of ECM and secreted proteins through three different mechanisms (Albig and Schiemann 2005; Yanagisawa et al. 2009). First, fibulin-5 binds αvβ3, αvβ5, α5β1, α4β1, and α9β1 integrins through an integrin-binding RGD motif that is unique amongst the fibulin family. The integrin-binding RGD motif of fibulin-5 is conserved in chicken, mouse, and rat, suggesting an important function in fibulin-5 biology. Second, cbEGF-like domains bind calcium with moderate-to-high affinity, which aids in maintaining protein stability, and in mediating protein–protein interactions. Fibulin-5 binds to LTBP-2 (latent TGF-β binding protein-2) through cbEGF-like modules, and in doing so, LTBP-2 may determine which microfibrils fibulin-5 becomes deposited on during elastic fiber assembly. The calcium-dependent binding of fibulin-5 to tropoelastin suggests that fibulin-5 structure and function also are dependent on calcium binding by its cbEGF-like domains. Fibulin-5 binds to the monomeric form of elastin through distinct N- and C-terminal elastin-binding regions, and to preexisting matrix scaffolds through cbEGF-like modules. Thus, fibulin-5 serves as an adaptor molecule that links monomeric elastin to matrix scaffolds to facilitate elastic fiber assembly. Fibulin-5 also binds the elastin-binding protein, elastin microfibril interface-located protein (EMILIN)-1, whose genetic ablation in mice induces mild elastinopathy reminiscent of that observed in fibulin-5-deficient mice. Whether fibulin-5 interacts physically with EMILIN-1 via its cbEGF-like domains remains to be determined. Finally, fibulin-5 interacts with apolipoprotein A, extracelluar superoxide dismutase (ecSOD), and lysyl oxidase-like 1, 2, and 3 (LOXL1-3) via its C-terminal fibulin-type module. The interaction between ecSOD and fibulin-5 is required for ecSOD binding to vascular tissues, thereby regulating vascular superoxide levels. The binding of fibulin-5 to LOXL1 appears essential for normal elastogenesis of the uterus, lung, skin, and vasculature. It has been reported that a fibulin-5 fragment lacking its C-terminus cannot be deposited on microfibrils and causes inactivation of the elastogenic activities of the full-length fibulin-5. Interestingly, the concentration of this fibulin-5 fragment actually increases with age, while the presence of full-length fibulin-5 is actually reduced in the skin of mouse. Since elasticity in tissue is thought be reduced with aging, C-terminal truncation of fibulin-5 by proteolysis may be involved in the deterioration of tissue elasticity during aging. Taken together, the extensive interactions of fibulins with other ECM proteins suggests that fibulins are indeed multifunctional proteins that couple the ECM to its formation of supramolecular structures, as well as its regulation of cellular processes.

Fibulins and Cancer

Oncogenic and tumor suppressive roles of fibulin family members have been proposed (Albig and Schiemann 2005; Gallagher et al. 2005; Argraves et al. 2003). A tumor suppressive role for fibulin-1 was proposed due to the fact that the overexpression of fibulin-1D in fibrosarcoma cells lowered their ability to grow in soft agar and invade reconstituted basement membranes in vitro. More importantly, expression of fibulin-1D delayed tumor formation in vivo and inhibited papillomavirus-E6 protein-mediated transformation. These findings support the conclusion that fibulin-1D acts as a tumor suppressor. However, fibulin-1 protein expression is progressively increased in the stroma adjacent to carcinoma cells during ovarian tumor progression. In addition, increased expression of fibulin-1 mRNA and protein was observed in primary breast carcinomas as compared with normal breast tissue. Furthermore, findings from DNA microarray studies of lung adenocarcinomas showed that fibulin-1 is consistently associated with matrix metalloproteinase 2 expression, a protein that promotes tumor invasion and metastasis (Gallagher et al. 2005; Argraves et al. 2003). These findings seem paradoxical to the idea that fibulin-1 is the product of a tumor suppressor gene. An explanation may come from findings that fibulin-1C and fibulin-1D splice variants are differentially expressed in ovarian carcinomas. Of the four fibulin-1 splice

variants, fibulin-1C and -1D transcripts are predominately expressed in most cell and tissue types, and it was shown that the ratio of fibulin-1C to -1D mRNA is increased in ovarian carcinomas relative to normal ovaries, suggesting that the fibulin-1C variant might play a role in carcinogenesis. In fact, it has been hypothesized that fibulin-1C variants possess oncogenic properties, while fibulin-1D variants exhibit tumor suppressive properties. Along these lines, genetic alterations of fibulin-1D have been linked to a congenital disorder that is typified by limb malformations, suggesting a functional independence of fibulin-1C and fibulin-1D variants. Precisely how fibulin-1C and fibulin-1D differentially impact cell behavior remains unknown. The splice variants of fibulin-1 all share the first 566 residues from the N-terminus, at which point they diverge to encode differing C-terminal polypeptide segments that add 0 (1A), 35 (1B), 117 (1C), and 137 (1D) residues, respectively. Thus, the difference in the C-terminal fibulin-type modules between fibulin-1 splice variants may account for the differential functions of fibulin-1C and fibulin-1D, possibly by modifying the repertoire of protein–protein interaction signatures. Likewise, a second possible mechanism to explain the imbalances that favor fibulin-1C expression over that of fibulin-1D in tumors has recently been proposed. Indeed, fibulin-1 expression is regulated by estrogen and its receptor at both the transcriptional and post-transcriptional levels in ovarian cancer cell lines. While estradiol treatment selectively decreased the half-life of fibulin-1D mRNA, the same treatment had no effect on fibulin-1C mRNA in ovarian cancer cells in vitro. This suggests that the oncogenic and tumor suppressive roles of fibulin-1 are governed by variant-specific expression in response to estrogens, which specifically destabilizes fibulin-1D mRNA. At present, the generality of this mechanism to other types of tumors, including those of breast, remains to be determined definitively.

To date, there exists little evidence that links fibulin-2, -6, and -7 with cancer; however, elevated fibulin-2 expression has been associated with the acquisition of metastatic phenotypes during adenocarcinoma progression. Fibulin-3 expression is altered in some human tumors and its constitutive expression in endothelial cells inhibited their proliferation, invasion, and angiogenic sprouting, as well as their response to vascular endothelial growth factor (Albig et al. 2006). The rat homologue of fibulin-3 associates with DA41, which interacts with the tumor suppressor protein DAN. Thus, fibulin-3 might have an indirect role in regulating cell growth through a network of molecular interactions. In addition, fibulin-3 prevented angiogenesis and vessel infiltration, as well as decreased vessel growth and density in tumors produced by MCA102 fibrosarcoma cells (Albig et al. 2006). Fibulin-4 expression is elevated in human colon tumors. Although fibulin-4 is clearly a secreted protein, recent work has identified a mutation in its signal sequence (i.e., Ala5Thr) that prevents its efficient secretion from cells, raising the possibility that aberrant subcellular localization of fibulin-4 contributes to tumorigenesis in humans. Accordingly, the intracellular form of fibulin-4 enhances cellular transformation and proliferation by interacting physically with mutant ▶ p53 proteins. Fibulin-5 was identified independently as a novel fibroblast and endothelial cell gene target of the tumor suppressor, transforming growth factor (TGF)-β (Albig and Schiemann 2005). Fibulin-5 mRNA expression is downregulated dramatically in the majority of human tumors, such as kidney, breast, ovary, and colon compared to corresponding normal tissues. Also, fibulin-5 has been established as a multifunctional signaling molecule that (1) regulates the proliferation, motility, and invasion of normal and malignant cells both in vitro and in vivo; (2) antagonizes endothelial cell activities coupled to angiogenesis both in vitro and in vivo; and (3) inhibits the growth of fibrosarcomas in mice (Lee et al. 2008). These findings suggest that the loss or inactivation of fibulin-5 may participate in cancer progression. Epithelial-mesenchymal transition (EMT) is a normal physiological process that regulates tissue development, remodeling, and repair; however, aberrant EMT also elicits disease development in humans, including lung fibrosis, rheumatoid arthritis, and cancer metastasis (Wendt et al. 2009). TGF-β is a master regulator of EMT in normal mammary epithelial cells (MECs), wherein this pleiotropic cytokine also functions as a potent suppressor of mammary tumorigenesis (Tian and Schiemann 2009). Since fibulin-5 is expressed in a developmentally regulated manner to regions of EMT during tissue development, and is a target of TGF-β, fibulin-5 has been considered an important and novel regulator of normal EMT during embryonic development, as well as an inducer of oncogenic EMT during the development and progression of

human breast cancers. Indeed, mammary epithelial cells engineered to ectopically expression fibulin-5 acquired an EMT phenotype as measured by monitoring alterations in the actin cytoskeleton, as well as by alterations in the expression of various markers of EMT (Lee et al. 2008). In addition, overexpression of fibulin-5 in 4T1 breast cancer cells increased their invasiveness by enhancing TGF-®-induced EMT and matrix metalloproteinase (MMP) expression (Lee et al. 2008). These alterations led to increased tumor growth in vivo when these cells were implanted into normal wild-type mice. Given the differential effects of fibulin-5 on cells of epithelial versus mesenchymal origin, the overall effect of fibulin-5 on tumor development must be carefully evaluated. Taken together, these findings suggest that fibulins play important roles in tumor development by functioning as tumor suppressors or tumor promoters through mechanisms that remain to be fully elucidated.

Fibulins and Human Genetic Diseases

Several human genetic diseases associated with the mutation of fibulin genes have been identified (Table 1). For instance, the fibulin-1 gene is disrupted in patients from one family with a rare dominantly inherited malformation of the distal limbs. Moreover, it has been reported that a defect in fibulin-1D expression is associated with the autosomal dominant giant platelet syndromes, which represent a group of disorders with combinations of deafness, renal disease, and eye abnormalities (de Vega et al. 2009; Gallagher et al. 2005; Argraves et al. 2003). Both genetic diseases are caused by the specific absence fibulin-1D transcripts, suggesting that the C-terminal fibulin-type motif of fibulin-1 plays an important causative role in initiating these pathologies. Along these lines, mice lacking fibulin-1 expression die shortly after birth, suggesting an essential function of this ECM in organism survival. In stark contrast, no human diseases have been linked to fibulin-2, and as such, fibulin-2 knockout mice are viable, fertile, and free of anatomic abnormalities (de Vega et al. 2009; Gallagher et al. 2005; Argraves et al. 2003). These findings suggest that fibulin-2 possesses functional redundancy with other matrix proteins that compensate for the absence of fibulin-2 during development. A fibulin-3 missense mutation (R345W) is associated with malattia leventinese (ML), which is a dominant macular degenerative disease characterized by the appearance of yellow deposits beneath the retinal pigment epithelium. The association of fibulin-3 mutation with ML was further supported by knock-in mice containing the R345W mutation, which develop early onset of macular degeneration in both heterozygous and homozygous mice. A fibulin-4 missense mutation (G169A) is associated with autosomal recessive cutis laxa, which is a connective tissue disorder characterized by cutaneous abnormalities such as loose skin. This mutation also affects elastic fiber densities in internal organs, such as the lung and the arteries. Moreover, fibulin-4 knockout mice showed lung and vascular malformations due to defects in elastic fiber formation, indicating a key role of fibulin-4 in vascular homeostasis.

Defects in the fibulin-5 gene are associated with cutis laxa and age-related macular degeneration (AMD). Two homozygous missense mutations (S227P and C217R) have been found in autosomal recessive cutis laxa families. Both fibulin-5 mutations decrease its binding to tropoelastin; they also significantly decreased its synthesis and secretion from cells, as well as impaired its association with fibrillin-1. As expected, defects in elastic fiber development were also evident under these conditions, suggesting that fibulin-5 is essential for proper elastic fiber formation. Accordingly, fibulin-5 knockout mice developed disorganized elastic fibers, which is reminiscent of the cutis laxa syndrome observed in humans that express fibulin-5 mutants. Heterozygous missense variations in fibulin-5 (G412E, G267S, I169 T, and Q124P) are associated with AMD and showed decreased fibulin-5 secretion. However, the causal relationship between heterozygous missense mutations in fibulin-5 and AMD needs to be further investigated. Fibulin-6 mutation (Q5346R) is proposed as a causal mutation for AMD pedigree; however, there is no supporting evidence for this hypothesis. At present, no human diseases have yet to be associated with the fibulin-7.

Summary

The fibulin family is comprised of matricellular proteins that clearly contribute to the structural development of elastogenic tissues, as well as mediate various cellular functions required for the maintenance of tissue homeostasis. Seven fibulin family members have been found in mammals, all of which interact with

various ECM molecules to stabilize supramolecular structures and to oversee various cellular processes, such as cell growth, differentiation, angiogenesis, and tumorigenesis. The variety of cellular activities attributed to fibulins are often cell-type specific and/or in a context-dependent manner, suggesting that the specific interactions between fibulins and ECM proteins leads to various cell behaviors and outcomes. Therefore, it remains to be determined precisely how fibulins mediate or antagonize intracellular signaling events and whether the modulation of fibulins possesses therapeutic potential to alleviate fibulins-related pathologies. Finally, new insight into the regulated steps of elastic fiber assembly from the study of fibulins may provide new opportunities to explore novel therapeutic regimens, including the regeneration of damaged elastic fibers, the prevention of elastic fiber-degenerative conditions, and the development of efficient artificial blood vessels.

Synonyms

Reggie-2 (Reg-2)

Historical Background

Flotillin-1 was originally identified in 1997, when Bickel et al. analyzed caveolin-rich membrane fractions from mouse lung and isolated a 45 kDa protein that was microsequenced. Degenerate primers were designed from the peptide sequences and used for PCR of mouse lung cDNA. The PCR-product was then used as a probe for screening of a 3T3-L1 adipocyte cDNA library. The characterized sequence showed similarity to the ESA protein. An anti-peptide antibody identified a 47 kDa protein on Western blots. Because this protein was detected in *flo*ating, caveolin-rich, Triton X-100-insoluble membrane fractions, it was termed "*flo*tillin-1." The similar ESA protein (47% identity) was renamed as "flotillin-2." Also in 1997, Schulte et al. identified and characterized two proteins that were induced in *reg*enerating fish retinal ganglion cell axons after injury and thus were named "*reg*gie-1" and "*reg*gie-2." In 1998, Lang et al. cloned the rat reggie proteins and found that rat reggie-1 is 99% identical to human flotillin-2, while rat reggie-2 is 98% identical to human flotillin-1. Reggie-2/flotillin-1 was identified at the plasma membrane of neurons and non-neuronal cells in non-caveolar micropatches co-clustering with its homologue reggie-1/flotillin-2 and GPI-anchored cell adhesion molecules. These micropatches localize along the axon and in lamellipodia and filopodia of growth cones. In 1999, Volonté et al. presented co-immunoprecipitation data that identified flotillin-1, flotillin-2, caveolin-1, and caveolin-2 in one complex. This led to the hypothesis that flotillins are resident components of caveolae; however, this hypothesis could not be verified by several groups, as reviewed in Langhorst et al. (2005). In 2001, Stuermer et al. identified clusters of reggies/flotillins with GPI-anchored proteins and Fyn kinase in non-caveolar plasma membrane microdomains of neurons and astrocytes. These microdomains had a diameter of less than 100 nm. In Jurkat cells, cross-linking of Thy-1 induced colocalization of Thy-1, reggie/flotillin proteins, GM1, the T cell receptor, and Fyn kinase, suggesting the formation of a raft-associated signal transduction center. Reggies/flotillins were also found in lysosomes, suggesting that the signaling complex becomes subject to degradation, as reviewed in Langhorst et al. (2005). More details on the historical background can be found in Salzer and Prohaska (2011).

Protein Structure and Domain Organization

Mammalian flotillin-1 is a highly conserved, 48 kDa monotopic integral membrane protein of 427 amino acids that is divided into two large domains of similar size, an N-terminal "stomatin/prohibitin/flotillin/HflC/K" (SPFH) domain, also known as "prohibitin homology domain" (PHB) or "band 7 domain," and a C-terminal "Flotillin domain" (Morrow and Parton 2005; Rivera-Milla et al. 2006; Babuke and Tikkanen 2007). The N-terminus of flotillin-1 contains two hydrophobic regions, residues 10–35 and 134–151, respectively, that are thought to be associated with the cytoplasmic face of the bilayer but not spanning it. Both flotillins are not cleaved when proteinases are added to intact cells (Morrow and Parton 2005). It is not known if these hydrophobic regions adopt "hairpin loops" similar to caveolin-1 or the related stomatin. Such structures appear less likely in flotillin-1 due to interspersed charged and hydrophilic residues. For additional hydrophobic interaction, the N-terminal region contains three cysteine residues, Cys-5,

Cys-17, and Cys-34 that are likely to be palmitoylated (Rivera-Milla et al. 2006). In Vero cells, palmitoylation of Cys-34 was shown to be essential for plasma membrane targeting along a Golgi-independent pathway and for providing the necessary affinity for raft association (Morrow et al. 2002). In differentiated 3T3-L1 adipocytes, mutation of Cys-34 to Ala did not affect plasma membrane targeting, whereas the second hydrophobic region was found to be essential for plasma membrane localization (Liu et al. 2005). Intact Cys-34 was however suggested to play a role in lipid raft association. It is possible that cell type–specific differences are the causes of these differing results. The structure of the SPFH domain of the mouse homologue flotillin-2 was determined by NMR analysis in solution (PDB ID: 1WIN; MMDB ID: 30602) and revealed a compact ellipsoid structure built from four β-strands on one side and four α-helices on the other. The crystal structure of the SPFH domain of an archaeal stomatin is surprisingly similar and both structures can be superposed very well (PDB ID: 3BK6; MMDB ID: 62565), showing the high conservation of this domain from archaea to mammals. This evolutionary conservation suggests an important function but this is currently not clear. Because many SPFH-domain proteins are lipid raft associated, it is possible that this domain itself mediates raft association (Morrow and Parton 2005). The crystal structure shows that the membrane-facing surface of this domain contains hydrophobic patches that would favor interactions with membrane lipids. Moreover, the interaction with cortical actin of one SPFH-domain α-helix has been predicted and identified (Rivera-Milla et al. 2006). The C-terminal flotillin domain is characterized by three contiguous blocks of coiled-coil heptad motifs that contain multiple GluAla repeats as well as charged residues at the heptad positions 2, 3, and 5 (Rivera-Milla et al. 2006). This coiled-coil domain is predicted to form dimers, trimers, and oligomers. Using chemical cross-linking, it was determined that flotillins form homo- or hetero-tetramers as building blocks of larger oligomeric complexes (Solis et al. 2007). Moreover, it was shown that flotillin-1 is stabilized by flotillin-2 in hetero-oligomeric complexes. Near the C-terminal end, a conserved PDZ3-binding consensus was recognized that could be involved in regulating oligomerization of both flotillins (Rivera-Milla et al. 2006). A schematic model of the flotillin/reggie structural and functional domains (Rivera-Milla et al. 2006; Stuermer 2010) is shown in the flotillin-2 entry.

Interactions

Flotillin-1 interacts with a variety of proteins in different tissues. It appears that most interactions described for flotillin-1 actually involve the hetero-oligomers of flotillin-1 and flotillin-2; however, the relevance of this hetero-oligomerization has been recognized only recently and was ignored in the past. A list of described interaction partners is shown in Table 1.

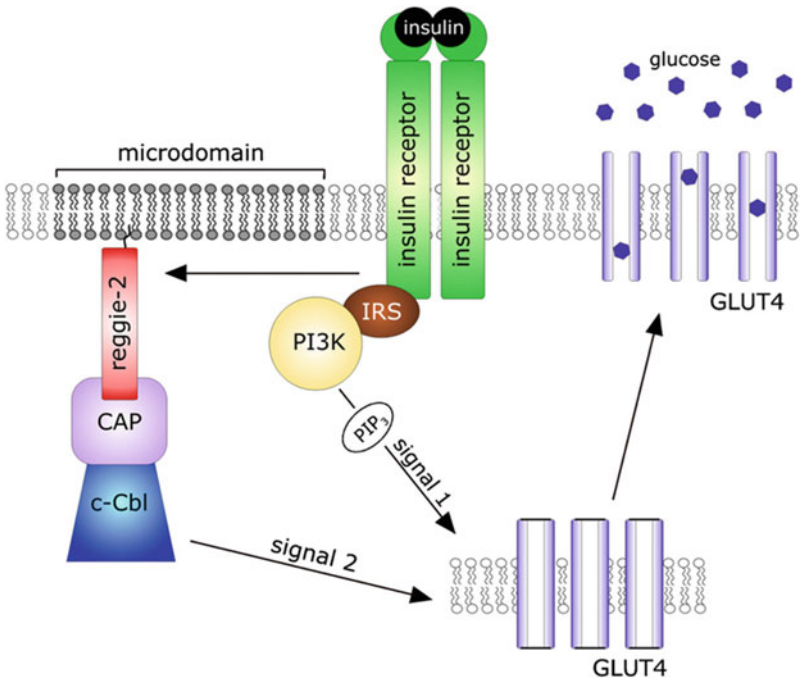
Flotillin-1 preferentially forms hetero-oligomers with flotillin-2 by interacting with the C-terminal coiled-coil domains (Solis et al. 2007). Hetero-oligomerization is essential for flotillin-1 stability, because flotillin-2 depletion induces flotillin-1 degradation by proteasomes (Solis et al. 2007). Flotillin-1 defines a specific, clathrin-independent endocytic pathway in mammalian cells; however, hetero-oligomerization with flotillin-2 is required for this clathrin- and caveolin-independent endocytosis (Frick et al. 2007). This process is regulated by Fyn kinase, which phosphorylates Tyr-160 in flotillin-1 and Tyr-163 in flotillin-2 (Riento et al. 2009). The region between the two N-terminal hydrophobic domains of flotillin-1 appears to be necessary for the interaction with Fyn (Liu et al. 2005). An important interaction of flotillin-1 with the multifunctional adapter protein c-Cbl-associated protein (CAP) and c-Cbl in a ternary complex was found to induce a second signaling pathway required for insulin-stimulated glucose transport via GLUT4 (Baumann et al. 2000). An outline of these insulin signaling pathways is shown in Fig. 1. The flotillin-1 interaction site on CAP was identified as the sorbin homology (SoHo) domain. This domain is also present in vinexin α and ArgBP2, enabling these proteins to interact with flotillin-1 in the same way. All three members of this SoHo family of adaptor proteins contain three SH3 domains within their C-termini. The functional significance of these interactions can be seen in the recruitment of signaling proteins to flotillin-specific lipid rafts (Babuke and Tikkanen 2007; Stuermer 2010).

Flotillin-1 and -2 were found to associate with Niemann-Pick C1-like 1 (NPC1L1) in a complex with clathrin heavy chain (CHC) and AP2 subunit μ2

Flotillin-1 (*flot1*), Table 1 Flotillin-1 interaction partners

Interacting protein	Location	Function	Remarks
Flotillin-2	Plasma membrane lipid rafts	Hetero-oligomerization	Flotillin-2 is essential for flotillin-1 stability
Fyn kinase	Lipid rafts	Tyr phosphorylation	Induces endocytosis
Lyn kinase	Basophilic leukemia cells	Enhances kinase activity	Involved in IgE-receptor signaling
NPC1L1	Plasma membrane lipid rafts	Cholesterol endocytosis and transport	Involves clathrin heavy chain and AP2
CAP/ponsin	Plasma membrane lipid rafts	Insulin signaling via c-Cbl, CrkII, and C3G.	Binding of flotillin-1 to the SoHo domain of CAP
	Focal adhesion sites	Regulation of actin cytoskeleton	
Vinexin α	Cell adhesion sites	Integrin-mediated cell adhesion	Binding to the SoHo domain of vinexin α
ArgBP2	Lipid rafts	Regulation of the actin cytoskeleton	Binding to the SoHo domain of ArgBP2
PTOV1 (Prostate tumor overexpressed gene 1)	Plasma membrane rafts and nucleus	Mitogenic complex	Recruitment to the nucleus in S phase
Aurora B kinase	Nucleus	Mitotic regulator	Flotillin-1 regulates Aurora B abundance and activity
Neuroglobin	Lipid rafts	Protects neurons from hypoxia	Inhibits Gα proteins
NMDAR (*N*-methyl-D-aspartate receptor)	Neuronal plasma membrane	Glutamate-binding calcium channel	NR2A/B subunits bind to SPFH domain
Gαq	Lipid rafts	Gαq-induced p38 MAPK activation	Depends on Src-family kinases
APP (amyloid precursor protein)	Lipid rafts	APP recruitment and processing in lipid rafts	APP binds to flotillin-1 C-terminus
Myocilin	Eye	Mutated in primary open-angle glaucoma	Binding to myocilin C-terminal domain
TRIM5α	Cytoplasmic bodies	Antiviral tripartite motif family	Dependent on cholesterol
LGI3 (Leucine-rich glioma inactivated 3)	Endosomes	Vesicle trafficking and endosome formation	Regulates APP trafficking
PSGL-1 (P-selectin glycoprotein ligand 1)	Plasma membrane	Involved in the polarization of neutrophils	Both flotillins and PSGL-1 accumulate in uropods
Arginase	Erythrocyte membrane	Involved in NO signaling	Upregulates arginase activity
ABCA1 (ATP-binding cassette transporter A1)	Plasma membrane rafts, phagosomes	Cellular cholesterol efflux, phagocytosis	Complex with ABCA1 and syntaxin 13
Syntaxin 13	Plasma membrane rafts, endosomes, phagosomes	Phagocytosis	Complex with ABCA1 and syntaxin 13
PrP^c (prion protein)	Plasma membrane, lipid-rich vesicles	Clustering at cell-cell contacts, focal adhesions	Complex with both flotillins
DAT (Dopamine transporter)	Lipid rafts	PKC-triggered endocytosis of DAT-flotillin-1 complex	Flotillin-1 residues Cys-34 and Ser-315 are essential

(Ge et al. 2011). The localization of this complex is cholesterol-dependent. Cholesterol depletion causes transport of flotillins and NPC1L1 to the plasma membrane, whereas cholesterol replenishment leads to endocytosis of both. Thus, flotillins play a role in NPC1L1-mediated cellular cholesterol uptake and regulation of lipid levels. Knockdown of flotillin-1, flotillin-2, or both, dramatically decreased NPC1L1 endocytosis and cholesterol uptake and reduced the association between the CHC-AP2 complex and NPC1L1. Because the knockdown of CHC had no effect on the flotillin-NPC1L1 association, it appears that flotillins are required for recruitment of the CHC-AP2 complex to NPC1L1 and thus act upstream to



Flotillin-1 (*flot1*),
Fig. 1 Role of flotillin-1/reggie-2 in insulin signaling. In adipocytes and muscle cells, insulin receptor activation triggers the classic signaling cascade through phosphatidylinositol 3-kinase, PI3K. A second signaling route proceeds through membrane rafts and involves a ternary complex c-Cbl/CAP/reggie-2. Both pathways mediate the recruitment of the glucose transporter GLUT4 to the plasma membrane and uptake of glucose into the cell (Figure reprinted from Babuke and Tikkanen (2007) with permission from Elsevier)

mediate the internalization of NPC1L1 and cholesterol (Ge et al. 2011). The NPC1L1-binding drug Ezetimibe was found to disrupt the flotillin-NPC1L1 complex. This study reveals an important functional role of the flotillins as mediators of cholesterol absorption via flotillin-NPC1L1-generated, cholesterol-enriched membrane microdomains (Ge et al. 2011). Flotillins were also found to interact with the tetrameric *N*-methyl-D-aspartate receptor (NMDAR), an ionotropic glutamate receptor, with the subunits NR1, NR2A, and NR2B. The distal C-terminus of NR2B interacted with both flotillin-1 and flotillin-2, whereas the C-terminus of NR2A bound only flotillin-1. Both flotillins were found to colocalize with NMDARs in hippocampal neurons (Swanwick et al. 2009). Flotillins also interact with the guanine nucleotide-binding protein Gq subunit alpha (Gαq), independent of the Gαq nucleotide-binding state (Sugawara et al. 2007). The N-terminal regions of both flotillins are essential for Gαq binding. Knockdown of flotillins attenuated the UTP-induced activation of ▶ p38 mitogen-activated protein kinase (MAPK). Because activation of MAPK depends on ▶ Src-family kinases and intact lipid rafts, these results suggest that flotillins mediate Gαq-induced MAPK activation through ▶ Src-kinases in lipid rafts (Sugawara et al. 2007). In leukocytes, flotillins interact with P-selectin glycoprotein ligand-1 (PSGL-1), also known as SELPLG or CD162 (Rossy et al. 2009). When neutrophils are activated, flotillins rapidly form caps and later accumulate in the uropods of the polarized cells. While PSGL-1 accumulates in the uropods concomitantly, other uropod components such as ▶ CD43 and ERM-proteins accumulate at a slower pace. Flotillins accumulate in uropods even in the absence of PSGL-1, indicating that PSGL-1 accumulation depends on flotillins (Rossy et al. 2009). This study was extended by using neutrophils from the flotillin-1 knockout mouse (Ludwig et al. 2010). Flotillin-2 was affected by the lack of flotillin-1, showing only weak, uniform staining of the plasma membrane and absence from detergent-resistant membranes. Importantly, the recruitment of flotillin-1-deficient neutrophils toward the chemoattractant fMLP was strongly reduced. Immunoisolation of tagged flotillin-2 followed by mass spectrometry of co-isolated proteins revealed the association of flotillins with cytoskeletal proteins, such as α- and β-spectrin and ▶ myosin IIa (Ludwig et al. 2010). The authors conclude that this association is important for neutrophil migration, uropod formation, and regulation of ▶ myosin IIa. Recently, flotillin-1 was found to be required for protein kinase C (PKC)-regulated internalization of the dopamine transporter (DAT) and the glial glutamate transporter EAAT2 (Cremona et al. 2011).

Flotillin-1 associates with DAT in plasma membrane lipid rafts and is required to maintain DAT in rafts. For internalization of the DAT-flotillin-1 complex, palmitoylation of flotillin-1 at Cys-34 and phosphorylation at Ser-315 is essential (Cremona et al. 2011). More details on flotillin-1 interactions are described in Salzer and Prohaska (2011).

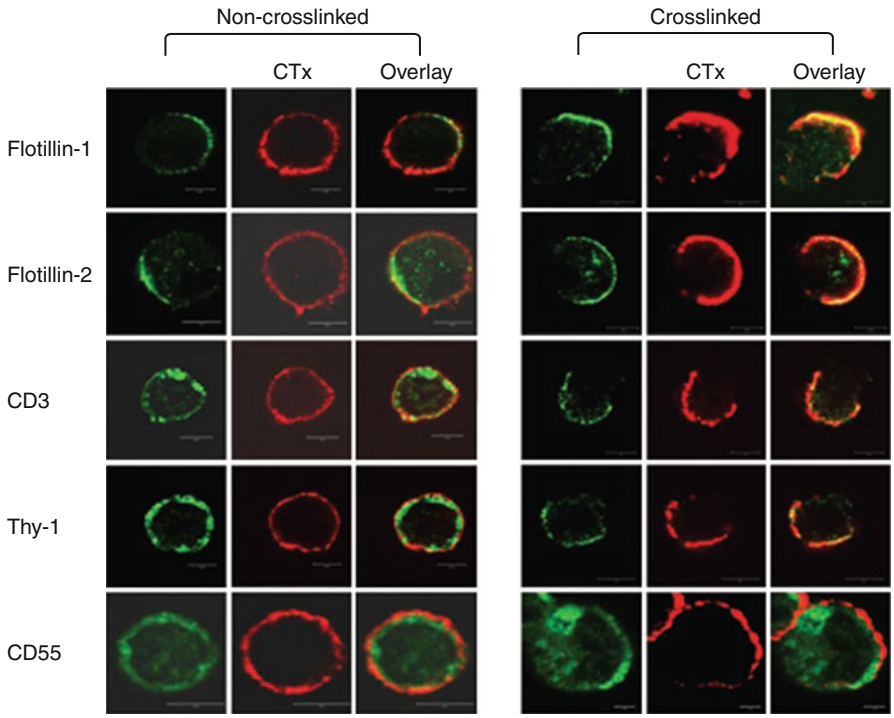
Cellular and Subcellular Localization

Both flotillins are expressed ubiquitously in virtually all tissues and cell types but have been studied particularly in neurons, hematopoietic cells, and adipocytes (Babuke and Tikkanen 2007; Stuermer 2010). Gene expression analyses by quantitative PCR of human and mouse (Mouse Genome Informatics MGI:1100500) tissues have shown flotillin-1 expression in all tissues analyzed. In cells, flotillin-1 is localized to the plasma membrane and internal vesicles such as Golgi vesicles, lipid droplets, recycling endosomes, multivesicular bodies, exosomes, late endosomes, lysosomes, phagosomes, and centrosomes, respectively (Langhorst et al. 2005). Moreover, it can translocate to the nucleus when interacting with the mitogenic protein PTOV1 (Prostate tumor overexpressed gene 1) or with the mitotic regulator Aurora B kinase. At the plasma membrane of neuronal cells, flotillin-1 is found in micropatches along the axons, in filopodia and lamellipodia of growth cones, and at synapses (Stuermer 2010). Flotillin hetero-oligomers accumulate at cell-cell contacts of many cell types (Langhorst et al. 2005; Stuermer 2010). These hetero-oligomers in plasma membrane microdomains are eventually endocytosed (Frick et al. 2007; Babuke et al. 2009; Riento et al. 2009) and apparently recycle back to the plasma membrane. Endocytosis takes place either in a clathrin- and caveolin-independent way (Riento et al. 2009) or in association with clathrin and NPC1L1 (Ge et al. 2011). In hematopoietic cells such as the B cell lines Raji and Ramos, T leukemic Jurkat cells, and the promonocytic cell line U937, both flotillins are asymmetrically localized in stable, preassembled platforms of the plasma membrane, to which signaling components are recruited on activation (Rajendran et al. 2003). An example for this extraordinary phenomenon is shown in Fig. 2.

In T lymphocytes, one stimulus for T cell receptor (TCR) complex association with the preassembled platform is the clustering of GPI-anchored proteins by antibody cross-linking. Thy-1 or cellular prion protein (PrP) cross-linking leads to their selective association with the flotillin platform. This induces the MAPK pathway and calcium signaling, resulting in recruitment of the TCR-CD3 complex. Thus, the flotillin membrane domains serve as platforms for cluster formation, signaling, cytoskeletal rearrangement, and recruitment of ▶ CD3 (Stuermer 2010). In chemoattracted neutrophils, flotillin microdomains accumulate rapidly in the uropod (Rossy et al. 2009) due to specific interaction with the cytoskeletal proteins α- and β-spectrin and ▶ myosin II (Ludwig et al. 2010). More details on flotillin-1 localizations are described in (Salzer and Prohaska 2011). The role of flotillin membrane microdomains in signaling, cytoskeletal regulation, and endocytosis, was reviewed and discussed recently (Otto and Nichols 2011).

Regulation of Expression and Activity

In fish and mammals, both flotillins are upregulated in retinal ganglion cells during axon regeneration after optic nerve section; reviewed in Langhorst et al. (2005), Stuermer (2010). Flotillin-1 stability depends on flotillin-2 expression (Solis et al. 2007). Conversely, flotillin-2 expression correlates with flotillin-1 expression (Ludwig et al. 2010). Both flotillins co-assemble at the plasma membrane in roughly equal amounts and act together to generate microdomains (Frick et al. 2007), which are endocytosed after Fyn-dependent tyrosine phosphorylation together with GPI-anchored proteins (Riento et al. 2009). Mutation of flotillin-1 residue Tyr-160 and flotillin-2 residue Tyr-163 prevents Fyn-induced internalization and leads to reduced uptake of GPI-anchored proteins. Thus, the uptake of flotillin microdomains is established as a tyrosine-kinase-regulated, endocytic process (Riento et al. 2009). Deletion of flotillin-1 apparently results in complete destruction of flotillin microdomains (Ludwig et al. 2010). The localization of the flotillin-1 and -2 complex with NPC1L1 and clathrin heavy chain and AP2 μ2 is regulated by the cholesterol level in the plasma membrane. Cholesterol depletion causes transport to the plasma membrane, whereas cholesterol replenishment leads to endocytosis. Thus, flotillins play a role in NPC1L1-mediated cellular cholesterol uptake and regulation of lipid levels (Ge et al. 2011).



Flotillin-1 (*flot1*),
Fig. 2 *Flotillin preassembled platforms*. Lipid raft clustering recruits raft-associated signaling molecules to the preassembled platforms and activates T cells. Non-cross-linked T cells (*Left*) show uniform distribution of GM1 (Cholera toxin-B, *red*), CD3, Thy-1, and CD55 (*green*) but very polarized expressions of flotillins-1 and -2. GM1 cross-linking (*Right*) by Cholera toxin-B (*red*) induces patching and recruits signaling molecules CD3 and Thy-1, but not CD55, (*green*) to preassembled flotillin platforms (Figure reprinted from Rajendran et al. (2003) with permission from PNAS)

For the PKC-triggered endocytosis of the lipid raft-associated dopamine transporter-flotillin-1 complex, palmitoylation of flotillin-1 at Cys-34 and phosphorylation at Ser-315 is essential (Cremona et al. 2011). In many biological processes, flotillins act as platforms associated with membrane receptors or transporters and the cytoskeleton to mediate signaling and endocytosis, as described above and reviewed in Morrow and Parton (2005), Langhorst et al. (2005) Babuke and Tikkanen (2007) Stuermer (2010), Salzer and Prohaska (2011).

Summary

Flotillin-1, also known as reggie-2, is a highly conserved, oligomeric, lipid-raft-associated, integral membrane protein of 48 kDa that is widely expressed in different tissues and cell types. It is associated with the cytosolic side of the plasma membrane and endosomes due to hydrophobic interaction and palmitoylation. Flotillin-1 is mainly found in a hetero-oligomeric complex with its homologue flotillin-2, also known as reggie-1. Both flotillins/reggies are members of the SPFH (stomatin/prohibitin/flotillin/HflC/K) superfamily, more recently termed PHB (prohibitin homology domain) superfamily. Hetero-oligomerization is required for endocytosis of flotillin microdomains either in a clathrin- and caveolin-independent way, such as Fyn kinase-regulated endocytosis of GPI-anchored proteins, or in a clathrin-dependent way, such as cholesterol uptake mediated by Niemann-Pick C1-like 1 (NPC1L1). In neurons, flotillins/reggies control axon growth and growth cone elongation by coordinating the assembly of signaling complexes that regulate cortical cytoskeleton remodeling. In neutrophils, flotillin interaction with cytoskeletal components is required for normal migration and uropod formation. Flotillin microdomains thus constitute scaffolding platforms interacting with signaling components, cytoskeleton, and/or membrane proteins in various cellular processes.

Synonyms

Epidermal surface antigen (ESA); ESA1; Membrane component, Chromosome 17, Surface marker 1 (M17S1); Reggie-1 (Reg-1)

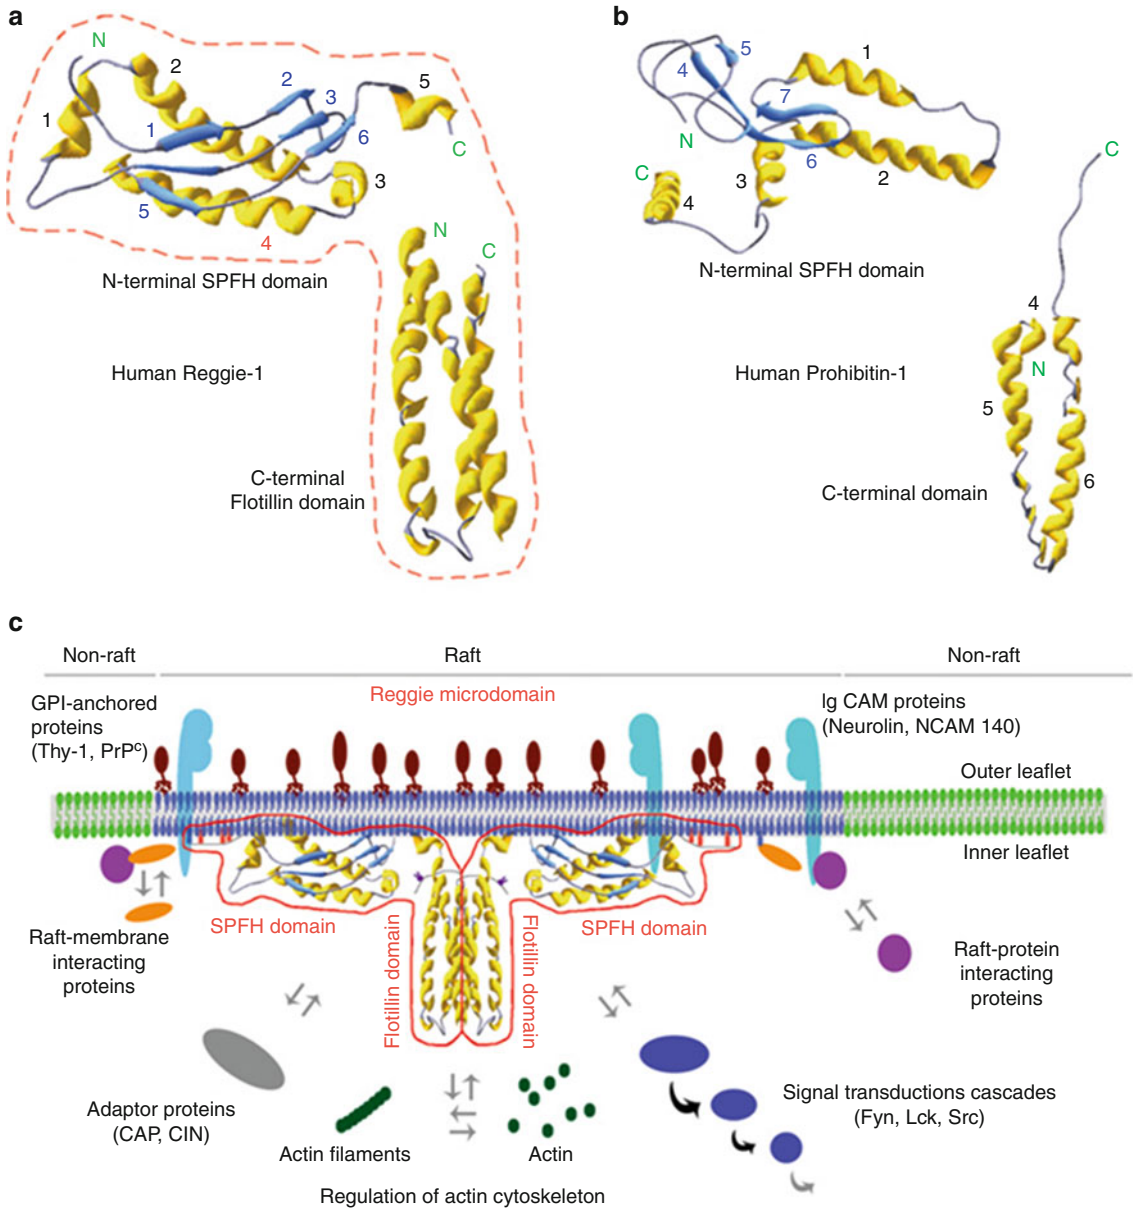
Historical Background

Flotillin-2 was originally cloned in 1994 by Schroeder et al. by immunoscreening of a human keratinocyte cDNA library using the monoclonal antibody ECS-1 against cultured keratinocytes. ECS-1 stained human epidermis and caused keratinocyte detachment in vitro, leading to the hypothesis that ECS-1 antigen may play a role in epidermal cell adhesion. Therefore, the immunoisolated cDNA and deduced protein was termed "epidermal surface antigen" (ESA), reviewed in Langhorst et al. (2005) and Morrow and Parton (2005). Western blot analysis identified a 35 kDa protein. In 1997, Bickel et al. analyzed caveolin-rich membrane fractions from mouse lung and isolated a 45 kDa protein. Microsequencing yielded novel and ESA-specific peptide sequences. Degenerate primers were used for PCR of mouse lung cDNA and the PCR product was then used as a probe for screening of a 3T3-L1 adipocyte cDNA library. The identified clone was characterized and its sequence showed similarity to the ESA sequence (47% identity). An anti-peptide antibody identified a 47 kDa protein on Western blots. Because this protein was detected in *flo*ating, Triton X-100-insoluble

membrane fractions together with caveolin-1 and ESA, it was termed "*flo*tillin-1" while the homologous ESA was renamed to "*flo*tillin-2." It turned out that the original, immunoisolated ESA was not the real ECS-1 antigen and not an epidermal surface antigen; therefore, this name was no longer appropriate. Also in 1997, Schulte et al. identified two proteins that were induced in *reg*enerating fish retinal ganglion cell axons after injury and thus were named "*reg*gie-1" and "*reg*gie-2." A striking 80% identity of fish reggie-1 and human flotillin-2 was recognized. In 1998, Lang et al. cloned the rat reggie proteins and found that rat reggie-1 is 99% identical to human flotillin-2, while rat reggie-2 is 98% identical to human flotillin-1. Reggie-1/flotillin-2 was identified at the plasma membrane of neurons and nonneuronal cells in non-caveolar micropatches co-clustering with reggie-2/flotillin-1 and GPI-anchored cell adhesion molecules. These micropatches localize along the axon and in lamellipodia and filopodia of growth cones. In 1999, Volonté et al. presented co-immunoprecipitation data that identified flotillin-1, flotillin-2, caveolin-1, and caveolin-2 in one complex. This led to the hypothesis that flotillins are resident components of caveolae; however, this hypothesis could not be verified by several groups, as reviewed in Langhorst et al. (2005). In 2001, Stuermer et al. identified clusters of reggies/flotillins with GPI-anchored proteins and Fyn kinase in non-caveolar plasma membrane microdomains of neurons and astrocytes. These microdomains had a diameter of less than 100 nm. In Jurkat cells, cross-linking of the GPI-anchored protein Thy-1 induced the colocalization of Thy-1, reggie/flotillin proteins, GM1, the T-cell receptor, and Fyn kinase, thus suggesting the formation of a raft-associated signal transduction center. Reggies/flotillins were also found in lysosomes, suggesting that the signaling complex becomes subject to degradation, reviewed in Langhorst et al. (2005). More details on the historical background can be found in Salzer and Prohaska (2011).

Protein Structure and Domain Organization

Mammalian flotillin-2 is a highly conserved, 48 kDa monotopic integral membrane protein of 428 amino acids that is divided into two large domains of similar size, an N-terminal "stomatin/prohibitin/flotillin/HflC/K" (SPFH) domain, also known as "prohibitin homology domain" (PHB) or "band 7 domain," and a C-terminal "flotillin domain" (Rivera-Milla et al. 2006). The N-terminal end of flotillin-2 contains a conserved hydrophobic region of about 30 amino acids that is associated with the cytoplasmic face of the bilayer but not spanning it. Both flotillins are not affected when proteinases are added to intact cells (Morrow and Parton 2005). It is not known if the hydrophobic region forms a "hairpin loop" similar to caveolin-1 or the related stomatin. Such a structure appears less likely in flotillin-2 due to several interspersed charged and hydrophilic residues. However, the N-terminus is truly membrane bound due to extensive modification by myristate at Gly-2 and palmitate at Cys-4, Cys-19, Cys-20, and probably Cys-38 (Neumann-Giesen et al. 2004; Rivera-Milla et al. 2006). The proximal SPFH/PHB/Band 7 domain is an ancient domain found in archaea and other prokaryotes; it comprises about 200 amino acids (Morrow and Parton 2005; Rivera-Milla et al. 2006). The solution structure of the mouse flotillin-2 SPFH domain was determined by NMR analysis (PDB ID: 1WIN; MMDB ID: 30602) and reveals a compact ellipsoid structure built from four β-strands on one side and four α-helices on the other. The crystal structure of the SPFH domain of an archaeal stomatin is surprisingly similar and both structures can be superposed very well (PDB ID: 3BK6; MMDB ID: 62565). The function of this domain is not clear. Because many SPFH-domain proteins are lipid raft associated, it is possible that this domain mediates raft association (Morrow and Parton 2005). Indeed, the membrane-facing surface of this domain contains hydrophobic patches that would favor interactions with membrane lipids. Moreover, the interaction with cortical actin of one SPFH-domain α-helix (see Fig. 1) has been predicted and identified (Rivera-Milla et al. 2006). The C-terminal "flotillin domain" is characterized by three contiguous blocks of coiled-coil heptad motifs that contain multiple Glu-Ala repeats as well as charged residues at the heptad positions 2, 3, and 5 (Rivera-Milla et al. 2006). This domain is predicted to form dimers, trimers, and oligomers. Using chemical cross-linking, it was determined that flotillins form homo- or hetero-tetramers as building blocks of larger oligomeric complexes (Solis et al. 2007). Moreover, it was shown that flotillin-2 stabilizes flotillin-1. Apparently, flotillin-2 homo-oligomers are relatively stable but flotillin-1 homo-oligomers are not. Downregulation of flotillin-2 causes the concomitant loss of flotillin-1 due to proteasomal degradation but not vice versa (Solis et al. 2007). A conserved PDZ3-binding consensus was



Flotillin-2 (*FLOT2*), Fig. 1 *Schematic model of flotillin*. Schematic model of flotillin structural and functional domains. (**a**) Predicted 3D models of human flotillin-2/reggie-1 SPFH- and flotillin-domains, based on 1win.pdb and Swiss-Model server (swissmodel.expasy.org//SWISS-MODEL.html). α-helices (in *yellow*) are numbered in *black*, with the exception of α-helix 4, which is predicted to interact with actin and is numbered in *red*. β-sheets are drawn and numbered in *blue*, with the exception of human β-sheet 4 (located between β-1 and β-5, not shown). The amino (N) and carboxyl (C) ends are indicated by *green letters* and are truncated. (**b**) For comparison, the ribbon diagram of the human prohibitin-1 SPFH and C-terminal domain is shown, based on 1lu7.pdb. Numbering of α-helices and β-sheets as in A (β-1 to β-3 are not shown). (**c**) Two-dimensional model for the assembly of a reggie/flotillin microdomain, showing the proposed basic interaction between two adjacent flotillin/reggie molecules within a larger hetero-oligomer. Lipid rafts (*blue*) have distinct lipid compositions that differ from non-raft membrane domains (*green*). A hetero-tetrameric cluster of flotillin-2/reggie-1 and flotillin-1/reggie-2, highlighted in *red*, is expected to interact with the inner leaflet of the plasma membrane via its SPFH domain and acylation (*jagged blue* and *red* features). The C-terminal flotillin domain coiled-coil structures are assumed to stabilize the tetrameric complex (Figure and legend taken from Rivera-Milla et al. (2006) by courtesy of Springer Netherlands)

recognized near the C-terminal end and could be involved in regulating oligomerization of both flotillins (Rivera-Milla et al. 2006). A schematic model of the flotillin/reggie structural and functional domains is shown in Fig. 1.

Interactions

Flotillin-2 forms homo-oligomers as well as hetero-oligomers with flotillin-1 by interacting with the C-terminal coiled-coil domains (Neumann-Giesen et al. 2004; Solis et al. 2007). Hetero-oligomerization is essential for flotillin-1 stability, because flotillin-2 depletion induces flotillin-1 degradation by proteasomes (Solis et al. 2007). Hetero-oligomerization is further required for flotillin endocytosis (Frick et al. 2007; Babuke et al. 2009), a process that is regulated by phosphorylation via EGF receptor/▶ Src (Neumann-Giesen et al. 2007) or Fyn kinase (Riento et al. 2009). ▶ Src phosphorylates Tyr-163 in flotillin-2 (Neumann-Giesen et al. 2007), Fyn phosphorylates Tyr-163 in flotillin-2 and Tyr-160 in flotillin-1 (Riento et al. 2009). Both flotillins were found to associate with Niemann-Pick C1-like 1 (NPC1L1) in a complex with clathrin heavy chain (CHC) and AP2 subunit μ2 (Ge et al. 2011). The localization of this complex is cholesterol dependent. Cholesterol depletion causes transport of flotillins and NPC1L1 to the plasma membrane, whereas cholesterol replenishment leads to endocytosis of both. Thus, flotillins play a role in NPC1L1-mediated cellular cholesterol uptake and regulation of lipid levels. Flotillin knockdown dramatically decreased NPC1L1 endocytosis and cholesterol uptake and reduced the association between the CHC-AP2 complex and NPC1L1. Because the knockdown of CHC had no effect on the flotillin-NPC1L1 association, it appears that flotillins are required for recruitment of the CHC-AP2 complex to NPC1L1 and thus act upstream to mediate the internalization of NPC1L1 and cholesterol (Ge et al. 2011). The NPC1L1-binding drug Ezetimibe was found to disrupt the flotillin–NPC1L1 complex. In this study, an important functional role of the flotillins was elucidated, namely, as mediators of cholesterol absorption via flotillin-NPC1L1-generated cholesterol-enriched membrane microdomains (Ge et al. 2011). Flotillins were also found to interact with the tetrameric *N*-methyl-D-aspartate receptor (NMDAR) by two-hybrid screening and co-immunoprecipitation with the subunits NR1, NR2A, and NR2B. The distal C-terminus of NR2B interacted with flotillin-1 and flotillin-2, whereas the C-terminus of NR2A bound only flotillin-1. Both flotillins were found to colocalize with NMDARs in hippocampal neurons (Swanwick et al. 2009). Moreover, both flotillins were shown to interact with the guanine-nucleotide-binding protein Gq subunit alpha (Gαq), independent of the Gαq-nucleotide-binding state (Sugawara et al. 2007). The flotillin N-terminal regions were essential for Gαq binding. Knockdown of flotillins, particularly flotillin-2, attenuated the UTP-induced activation of ▶ p38 mitogen-activated protein kinase (MAPK). Because the activation of MAPK depends on ▶ Src-family kinases and intact lipid rafts, these results suggest that flotillins mediate Gαq-induced MAPK activation through ▶ Src kinases in lipid rafts (Sugawara et al. 2007). In leukocytes, flotillin-2 interacts with P-selectin glycoprotein ligand-1 (PSGL-1), also known as SELPLG or CD162 (Rossy et al. 2009). When neutrophils are activated, flotillins rapidly form caps and later accumulate in the uropods of the polarized cells. While PSGL-1 accumulates in the uropods concomitantly, other uropod components such as ▶ CD43 and ERM proteins accumulate at a slower pace. Flotillins accumulate in uropods even in the absence of PSGL-1, indicating that PSGL-1 accumulation depends on flotillins (Rossy et al. 2009). This study was extended by using neutrophils from the flotillin-1 knockout mouse (Ludwig et al. 2010). They found that flotillin-2 was affected by the loss of flotillin-1, by showing weak, uniform staining of the plasma membrane and absence from detergent-resistant membranes. Importantly, the recruitment of flotillin-1-deficient neutrophils toward the chemoattractant fMLP was strongly reduced. Immunoisolation of tagged flotillin-2 followed by mass spectrometry of co-isolated proteins revealed the association of flotillin-2 with cytoskeletal proteins such as α- and β-spectrin and ▶ myosin IIa (Ludwig et al. 2010). The authors conclude that this association is important for neutrophil migration, uropod formation, and regulation of ▶ myosin IIa. More details on flotillin-2 interactions are described in Salzer and Prohaska (2011).

Cellular and Subcellular Localization

Flotillin-2 is expressed ubiquitously in tissues and diverse cell types. Gene expression analyses by

quantitative PCR of human and mouse (Mouse Genome Informatics MGI:103309) tissues have shown the expression in all tissues. In particular, flotillin-2 is highly expressed in hematopoietic cells (BioGPS GeneAtlas U133A, 201350_at), adipose tissue, spinal cord, and dorsal root ganglia (BioGPS GeneAtlas MOE430, 1417544_a_at). In cells, it is localized to the plasma membrane and internal vesicles such as Golgi vesicles, late endosomes and lysosomes (Neumann-Giesen et al. 2007; Langhorst et al. 2008), as well as centrosomes (Langhorst et al. 2005). At the plasma membrane, flotillin-2 is found in filopodia and lamellipodia, particularly when overexpressed (Neumann-Giesen et al. 2004; Langhorst et al. 2008). Flotillin hetero-oligomers in plasma membrane microdomains are endocytosed (Frick et al. 2007; Neumann-Giesen et al. 2007; Babuke et al. 2009; Riento et al. 2009) and apparently recycle back to the plasma membrane (Langhorst et al. 2008). Endocytosis takes place either in a clathrin- and caveolin-independent way (Riento et al. 2009) or in association with clathrin and NPC1L1 (Ge et al. 2011). Eventually the flotillin hetero-oligomeric complexes are transferred to the late endosomal compartment. In various cell types, flotillins are localized to recycling endosomes, late endosomes, multivesicular bodies, exosomes, lysosomes, phagosomes, and lipid droplets (Langhorst et al. 2005). In hematopoietic cells, flotillins are asymmetrically localized in stable, preassembled platforms of the plasma membrane, to which signaling components are recruited on activation (Rajendran et al. 2003). In chemoattracted neutrophils, flotillin microdomains accumulate rapidly in the uropod (Rajendran et al. 2009; Rossy et al. 2009) due to specific interaction with the cytoskeletal proteins α- and β-spectrin and ▶ myosin II (Ludwig et al. 2010). The role of flotillin microdomains in signaling, cytoskeletal regulation, and endocytosis, was reviewed and discussed recently (Otto and Nichols 2011).

Regulation of Expression and Activity

In fish and mammals, both flotillins are upregulated in retinal ganglion cells during axon regeneration after optic nerve section, reviewed in Langhorst et al. (2005). Flotillin-2 expression is essential for flotillin-1 stability (Solis et al. 2007) and flotillin-1 expression also correlates with flotillin-2 expression (Ludwig et al. 2010). Both flotillins co-assemble at the plasma membrane in roughly equal amounts and act together to generate microdomains (Frick et al. 2007), which are endocytosed after Fyn-dependent tyrosine phosphorylation (Riento et al. 2009). Deletion of flotillin-1 apparently results in destruction of flotillin microdomains (Ludwig et al. 2010). Flotillin-2 was found to be a direct transcriptional target of the ▶ p53 family members p73 and p63 (Sasaki et al. 2008) due to a specific response element in the human *FLOT2* gene. Expression of flotillin-2 was upregulated by p73 or p63 but not by ▶ p53. Moreover, transcription was activated in response to cisplatin but dependent on endogenous p73. siRNA, designed to target p73, silenced endogenous p73 and abolished the induction of flotillin-2 transcription following cisplatin treatment. A p73/p63 binding site located upstream of the *FLOT2* gene was identified and found to be responsive to the ▶ p53 family members. The flotillin-2 knockdown inhibited p63-mediated ▶ STAT3 activation. These data reveal a novel link between the ▶ p53 family and signal transduction via lipid rafts (Sasaki et al. 2008).

Variants and Mutants

There are three flotillin-2 isoforms described in the UniProtKB/Swiss-Prot database, accession number Q60634 (FLOT2_MOUSE). Isoform 1 (Q60634-1) has been chosen as the "canonical" sequence. Isoform 2 (Q60634-2) shows eight amino acid exchanges within the region of residues 50–68, the cause of which is unknown, and isoform 3 (Q60634-3) is missing the N-terminal 49 residues. The formation of isoform 3 may be caused by alternative splicing (skipping of exon 4, which is the first coding exon) and alternative translation initiation at Met-50. In *Drosophila*, flotillin-2 loss of function results in reduced spreading of the morphogens Wnt and Hedgehog (Hh), whereas its overexpression stimulates secretion of Wnt and Hh and expands their diffusion. The resulting changes in the morphogen gradients differently affect the short- and long-range targets. Apparently, flotillin-2 is an important component of the Wnt and Hh secretion pathway dedicated to formation of the mobile pool of these morphogens (Katanaev et al. 2008). In N2a neuroblastoma cells, the expression of a trans-negative flotillin-2 deletion mutant (R1EA), which interferes with flotillin oligomerization, inhibits insulin-like growth factor-induced

neurite outgrowth and impairs in vitro differentiation of primary rat hippocampal neurons (Langhorst et al. 2008). This mutant strongly perturbed Rac1 and Cdc42 activation caused by impaired recruitment of flotillin-associated CAP/ponsin to focal contacts.

Summary

Flotillin-2, also known as reggie-1, is a highly conserved, oligomeric, lipid-raft-associated, integral membrane protein of 48 kDa that is widely expressed in different tissues and cell types. It is associated with the cytosolic side of the plasma membrane and endosomes due to myristoylation, palmitoylation, and hydrophobic interaction. Flotillin-2 is mainly found in a hetero-oligomeric complex with its homologue flotillin-1, also known as reggie-2. Both flotillins and reggies are members of the SPFH (stomatin/prohibitin/flotillin/HflC/K) superfamily, more recently termed PHB (prohibitin homology domain) superfamily. Hetero-oligomerization is required for endocytosis of flotillin membrane microdomains either in a clathrin- and caveolin-independent way, such as Fyn-kinase-regulated endocytosis of GPI-anchored proteins, or in a clathrin-dependent way, such as cholesterol uptake mediated by Niemann-Pick C1-like 1 (NPC1L1). In neurons, flotillins/reggies control axon growth and growth cone elongation by coordinating the assembly of signaling complexes that regulate cortical cytoskeleton remodeling. In neutrophils, flotillin interaction with cytoskeletal components is required for normal migration and uropod formation. Flotillin microdomains thus constitute scaffolding platforms interacting with signaling components, cytoskeleton, and/or membrane proteins in various cellular processes.

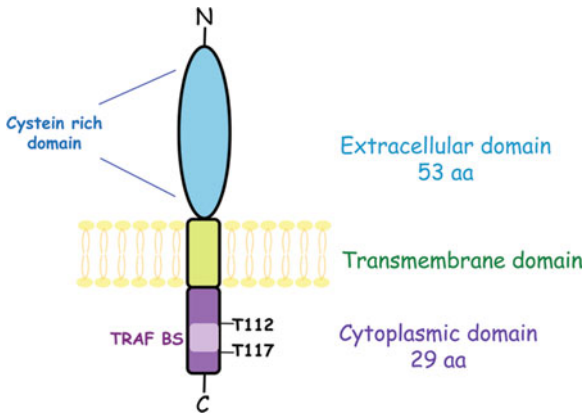
Historical Background: Discovery and Structure

Numerous cellular processes, such as migration, proliferation, inflammation, and apoptosis are regulated by cytokines belonging to Tumor necrosis factor superfamily (TNFSF). TNFSF cytokines bind members of the TNF receptor superfamily (TNFRSF) (Bossen et al. 2006). TNFSF ligands are type II transmembrane proteins with a homology domain in the extracellular region that assemble as homotrimers. One trimeric ligand usually binds to three monomeric receptors, and this is a key step for signaling transduction. TNFRSF are type I transmembrane proteins characterized by the presence of several extracellular cystein-rich domains that mediate ligand binding. The TNFRSF protein Fn14 is the Tumor necrosis factor-like weak inducer of apoptosis (TWEAK) receptor.



Fn14, Fig. 1 *Structural features of human Fn14*. Fn14 is a 129-aa type I transmembrane protein that is processed by signal peptidase into a mature 102-aa receptor. *TRAF BS* TRAF-binding sites, *T* Threonine phosphorylation sites

Fn14 was described in fibroblasts as Fibroblast Growth Factor–inducible-14, an immediate-early response gene to growth factors (Meighan-Mantha et al. 1999). Two years later, a cDNA clone encoding a TWEAK-binding cell surface molecule was named TWEAK receptor, and shown to have 100% sequence identity with Fn14 (Wiley and Winkles 2003). Phylogenetically Fn14 is much conserved and there is a 90% homology between the mouse and human protein (Wiley and Winkles 2003). The human Fn14 gene is localized at chromosomal position 16p13.3 and encodes a type I transmembrane protein of 129 aa, that is processed into a mature 102-aa protein. The molecular mass of mature Fn14 is 13,637 Da. Fn14 has structural features characteristic of TNFRSF members and is the smallest member of the family (Wiley and Winkles 2003) (Fig. 1). The extracellular domain (53-aa) that contains a cystein-rich domain, characteristic of TNFRSF members, is necessary

for TWEAK binding. The intracellular domain (29-aa) is the shortest of TNFRSF members, contains TNFR-associated factor (TRAF)-binding sites, but lacks a death domain (DD), thus differing from many TNFRSF members (Wiley and Winkles 2003). Fn14 does not contain asparagine or tyrosine residues, but it has two putative threonine phosphorylation sites in the cytoplasmic domain that may play a role in Fn14-TRAF association.

The only ligand for Fn14 is TWEAK (Wiley and Winkles 2003). Human TWEAK is a type II transmembrane glycoprotein of 249-aa. TWEAK contains an extracellular C-terminal domain with the receptor-binding site and an intracellular N-terminal domain with a potential protein kinase C phosphorylation site and several nuclear localization sequences (Chicheportiche et al. 1997). The extracellular domain is proteolytically processed, probably, at one or both of two furin consensus cleavage sites. As a result 156-aa soluble TWEAK (sTWEAK) is generated. Cells can express both full-length membrane-anchored TWEAK (mTWEAK) and sTWEAK.

The TWEAK/Fn14 system can regulates multiple functions with physiopathological relevance, such as, cell proliferation, cell death, cell migration, cell differentiation, tissue regeneration, neoangiogenesis, and inflammation (Winkles 2008). Moreover, TWEAK/Fn14 play a role in injury in different organs, including the central nervous system, liver, gut, the vasculature, skeletal muscle, heart, and kidney.

Fn14 Expression

Fn14 is expressed by many cell types, including epithelial, mesenchymal, and endothelial cells (Burkly et al. 2007). Fn14 was initially described as a fibroblast growth factor (FGF)-inducible immediate-early response gene in murine NIH 3T3 cells (Meighan-Mantha et al. 1999), and later it was observed that Fn14 expression is also quickly upregulated by additional cytokines, growth factors, serum, inflammatory cytokines, hormones, angiotensine II, or phorbol ester treatment in different cell types (Wiley and Winkles 2003; Sanz et al. 2009). Fn14 regulation is stimulus- and cell type-specific. Its own ligand, TWEAK, may upregulate Fn14 expression in glioma cells lines, suggesting the existence of a positive feedback loop that may amplify TWEAK/Fn14 signaling (Winkles 2008).

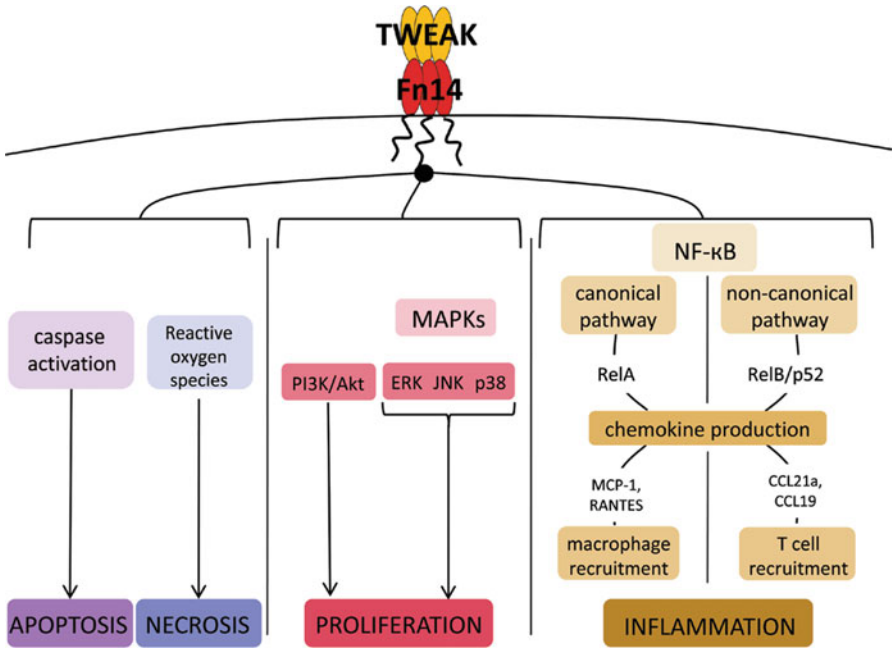
The human Fn14 promoter region contains several potential transcription factor-binding sites, including AP1 sites and an NFκB site, but the molecular mechanisms that regulate Fn14 expression are not well defined. In glioma cells Rac1 mediated basal Fn14 expression and TWEAK-induced Fn14 expression is mediated by Rac1/IKKβ/NFκB pathway (Winkles 2008; Burkly et al. 2007). The Rho/ROCK pathway is implicated in Fn14 upregulation in human aortic smooth muscle cells (hASMCs) and in cardiomyocytes (Ortiz et al. 2009; Chorianopoulos et al. 2010).

At the tissue level, Fn14 is expressed during mouse development and in adult tissue. In adults, murine Fn14 expression was high in heart and ovary, intermediate in kidney, lung, and skin, and low in brain, skeletal muscle, and testis (Meighan-Mantha et al. 1999). Despite this observation, Fn14 expression is relatively low in most resting tissues, but is considerably upregulated in injured tissues. There are numerous experimental models where high Fn14 expression has been observed, such as, chronic liver injury, denervation-induced skeletal muscle atrophy, myocardial infarction, colitis, autoimmune encephalomyelitis, the vasculature after balloon catheter injury, acute kidney injury, and others (Winkles 2008). Fn14 is also upregulated in human tissue injury and inflammation, including adipose tissue in severe obesity, periodontitis, ischemic stroke, atherosclerosis, and cancer (Winkles 2008). Finally, Fn14 is upregulated during tissue regeneration, as observed in experimental kidney or liver growth, following unilateral nephrectomy or partial liver resection, respectively (Sanz et al. 2009).

Fn14 Signaling

Most TNFRSF members contain a DD and signal through the DD, but Fn14 lacks this domain. However, Fn14 contains a TRAF-binding domain in the cytoplasmic tail that can associate with TRAFs 1, 2, 3, and 5 (Wiley and Winkles 2003). TRAF proteins can lead to the activation of cellular signaling pathways, such as MAPKs (ERK, p38, JNK), PI3K/Akt, and transcription factor NFκB (Winkles 2008) (Fig. 2).

Classical NFκB activation mediated by Fn14 required the Fn14 TRAF-binding domain and TRAF



Fn14, Fig. 2 *Fn14-induced intracellular signaling pathways*. Upon activation by the TWEAK cytokine Fn14 activates different signaling cascades. NF-κB activation has been observed in most of cultured cell types where it has been studied. Other pathways may be cell type-dependent

proteins 1, 2, 3, and 5 (Wiley and Winkles 2003). NFκB is a pleiotropic transcription factor that regulates the transcription of hundreds of genes that are involved in inflammation, immunity, apoptosis, cell proliferation, and differentiation. NFκB is composed of homo- and heterodimers of five members of the Rel family: p50 (generated from p105), p52 (generated from p100), RelA (p65), RelB, and c-Rel. The classical NFκB pathway results in nuclear migration of mainly a heterodimer formed by p50 and p65 (RelA) subunits, and the alternative NFκB pathway results in nuclear migration of a complex formed by p52 and RelB subunits (Sanz et al. 2010). Fn14 engagement, in contrast to TNF, activates both the classical and alternative NFκB pathways. Fn14-activated classical NFκB pathway occurs in numerous cell types and is usually an early, transient event that peaks at 1–6 h (Winkles 2008). However, alternative pathway activation does not occur in all cells. In fact, Fn14 activation of the alternative NFκB pathway was observed in MEFs and in renal tubular epithelial cells (Sanz et al. 2010). Alternative NFκB pathway activation by Fn14 is a late event that peaks at 24 h. In some cases, Fn14 stimulation by TWEAK leads to activation of different pathways in the same cellular line, but, the activated pathways may differ between the different cellular types.

Biological Activity

The cell response to Fn14 activation is stimulus- and cell type-specific. The cell response may include inflammation, proliferation, cell death, cell differentiation, and migration. The biological processes activated by Fn14 in each cell type likely depend of the intracellular signaling activated in these cells. Fn14-induced inflammation, cell death, and proliferation are reviewed.

Inflammation

Proinflammatory actions of Fn14 activation have been observed in numerous cell types, both in culture and in vivo. The first evidence of the inflammatory effect of TWEAK was induction of IL-8 secretion in tumor cell lines (Chicheportiche et al. 1997). Then, many studies showed that TWEAK, through Fn14 activation, induces chemokine, cytokine, and matrix metalloproteases production in various cell types, such as, endothelial cells, dermal and gingival fibroblasts, nervous system cells, mesangial and tubular renal cells, and others (Burkly et al. 2007; Ortiz et al. 2009).

The proinflammatory effect of Fn14 is mediated, mainly, by classical NFκB signaling. In this regard, NFκB blockade prevented Fn14-induced

chemokine production in human bronchial epithelial cells, macrophages, and renal tubular epithelial cells (Ortiz et al. 2009). Other intracellular pathways activated by Fn14 also promote inflammation. In this sense, PI3K mediates Fn14-induced ICAM and VCAM production in human gingival fibroblasts, alternative NFκB pathway activation mediates CCL21 and CCL19 production in renal tubular cells (Sanz et al. 2010), and MAPKs are involved in regulating chemokine production by mesangial cells and podocytes (Gao et al. 2009). Fn14 activation also promotes inflammatory in vivo. Intraperitoneal injection of recombinant TWEAK in mice induces cytokine and chemokine production in kidneys leading to inflammatory cells infiltration (Ortiz et al. 2009). Exogenous TWEAK administration in ApoE−/− mice increases chemokine expression as well as macrophage infiltration in atherosclerotic plaques and renal lesions (Munoz-Garcia et al. 2009). Intracerebral injection of TWEAK in wild-type mice induces matrix metalloproteinase-9 expression in the brain (Yepes 2007). The capacity of Fn14 activation to induce inflammation suggests a role in acute tissue inflammatory injury, as well as in autoimmune diseases.

Proliferation

Fn14 activation by TWEAK induces proliferation in different cell types, including endothelial, epithelial, tumor, and progenitor cells (Winkles 2008; Sanz et al. 2009; Tirnitz-Parker et al. 2010; Novoyatleva et al. 2010). Moreover, Fn14 activation can also induce proliferation in vivo. Thus, exogenous TWEAK injection induce proliferation in renal tubular cells (Sanz et al. 2009). TWEAK overexpression promotes proliferation in liver progenitor cells (Burkly et al. 2007; Tirnitz-Parker et al. 2010), and liver progenitor cell numbers are reduced in Fn14 knockout mice with chronic liver injury (Tirnitz-Parker et al. 2010).

Signaling for Fn14-induced proliferation may be cell type-specific. The principal mechanisms implicated include MAPKs, PI3K/Akt pathway and NFκB activation. In some cases, growth factors potentiate Fn14-induced proliferation. For example, renal epithelial cells Fn14 activation by TWEAK in presence of serum show higher rate of proliferation than cells cultured serum-free and a similar response is observed in human endothelial cells co-stimulated with TWEAK and FGF-2 (Winkles 2008; Sanz et al. 2009). Upregulation of Fn14 expression and positive regulation of intracellular pathways implicated in Fn14-induced proliferation, such as MAPKs signaling by growth factors may contribute to this observation. The ability of Fn14 activation to induce cell growth suggests a role in tissue repair after acute injury, as well as a role in pathological hyperplasia, such as cancer.

Cell Death

TWEAK was named for its capacity to induce apoptosis in interferonγ-treated HT29 adenocarcinoma cells (Chicheportiche et al. 1997) and later this effect of TWEAK was observed in different tumor cell lines. As is the case for other biological activities, TWEAK-induced cell death is mediated by Fn14 activation (Burkly et al. 2007). Fn14 activation promotes apoptosis in numerous cell types, including neurons, monocytes, tumor cell lines, resident renal cells, and others (Michaelson and Burkly 2009; Ortiz et al. 2009).

Fn14-induced cell death is relatively weak, characterized by a requiring long incubation periods, relatively high ligand concentrations and co-incubation with other sensitizing agents. As an example, in renal tubular cells Fn14 activation promotes proliferation, not death, in the absence of additional stimuli, but in presence of TNFα and interferonγ Fn14 activation promotes apoptosis (Ortiz et al. 2009; Sanz et al. 2009). Since, Fn14 does not contain a DD, the exact mechanism leading to Fn14-induced cell death is not well-known. Multiple context-dependent mechanisms have been characterized, including caspase-dependent apoptosis, caspase-independent death with features of both apoptosis and necrosis, and cathepsin B-dependent necrosis (Burkly et al. 2007).

The ability of Fn14 to induce cell death has pathophysiological relevance. When the TWEAK/Fn14 axis is targeted, cell death is prevented in different models of tissue injury, such as experimental acute kidney injury or cerebral ischemia (Yepes 2007; Sanz et al. 2009; Hotta et al. 2010).

The capacity of Fn14 to induce cell death in tumor cells could become in a strategy for cancer treatment.

Studies in Experimental Models and in Human Diseases: Fn14 Expression, Function, and TWEAK/Fn14 Targeting

The biological processes mediated by TWEAK/Fn14 described above suggest that this system may have a pathophysiological relevance in various disease conditions in which these processes play a key role. In this regard, functional experimental studies and descriptive human approaches have characterized the role of TWEAK/Fn14 in disease.

Acute Tissue Injury and Tissue Repair

Fn14 is extremely upregulated following acute tissue injury, both in animal experimental models, such as acute kidney injury (AKI), myocardial infarction, middle cerebral artery occlusion and colitis, and in human disease, including ischemic stroke and atherosclerosis.

Most of the pathologies studied present an initial inflammatory process and cell death. In this regard, functional approaches including TWEAK or Fn14 knockout mice and neutralizing anti-TWEAK or anti-Fn14 antibodies support a role for Fn14 in disease. For example, Fn14 or TWEAK blockade during acute kidney injury decrease renal inflammation and renal tubular cell death and improve renal function (Ortiz et al. 2009; Sanz et al. 2010; Hotta et al. 2010) and Fn14-Fc fusion protein or neutralizing anti-TWEAK inhibited features of atherosclerotic plaque progression (Schapira et al. 2009; Munoz-Garcia et al. 2009). Moreover, Fn14 knockout mice present reduced inflammatory responses after skeletal muscle injury (Burkly et al. 2007), and reduced cell death and inflammation after cerebral ischemia (Yepes 2007). All these studies indicate that TWEAK/Fn14 axis could be a therapeutic target in acute tissue injury.

Some of the diseases studied are also characterized by a regeneration phase. Fn14 activation induces proliferation in some progenitor cells and could play a role in tissue regeneration. In addition, inflammation can also contribute to tissue regeneration after an acute injury. First evidence of the contribution of Fn14 to tissue regeneration was suggested by its increased liver expression following partial hepatectomy, and confirmed by the oval cell hyperplasia observed in transgenic mice overexpressing TWEAK in hepatocytes and by the reduced oval cell proliferation in Fn14 knockout mice following partial hepatectomy (Burkly et al. 2007). TWEAK activates Fn14 to induce mitosis in liver progenitor cells in a model of chronic liver injury (Tirnitz-Parker et al. 2010). However, Fn14 role in muscle regeneration is unclear. Fn14 knockout mice exhibited reduced inflammatory response and delayed muscle fiber regeneration compared with wild-type mice in a model of cardiotoxin-induced skeletal muscle injury (Burkly et al. 2007). However, TWEAK knockout mice show enhanced muscle regeneration (Mittal et al. 2010). A potential explanation for the discrepancy is TWEAK-independent Fn14 activation and functions during muscle regeneration.

Autoimmune Disease

TWEAK attenuates the transition from innate to adaptive immunity and there is functional evidence for a role of TWEAK/Fn14 in autoimmune disease tissue injury (Burkly et al. 2007). However, there is little evidence for the participation of Fn14 in the genesis of autoimmunity and its role appears limited to involvement in tissue injury secondary to autoimmunity.

Autoimmune Neurological Disease: Multiple Sclerosis

Fn14 is expressed by astrocytes, and in these cells Fn14 activation results in inflammatory molecule release and proliferation, suggesting a Fn14 role in brain inflammatory diseases (Yepes 2007). Both, TWEAK and Fn14 are upregulated in multiple sclerosis brains compared with control brain samples (Serafini et al. 2008). Severity of experimental allergic encephalomyelitis (EAE), a mouse model of multiple sclerosis was enhanced in soluble TWEAK-overexpressing transgenic mice (Yepes 2007). In addition targeting the TWEAK/Fn14 system with different approaches ameliorated EAE (Yepes 2007). These results indicate that TWEAK/Fn14 may be a therapeutic target in CNS autoimmunity.

Systemic Lupus Erythematosus

Systemic lupus erythematosus is a multisystem autoimmune disease featuring autoantibody production, often with involvement of kidneys as lupus nephritis. Absence of Fn14 or TWEAK blockade decreased the severity of glomerulonephritis, glomerular IgG

deposition, kidney cytokine expression, and macrophage infiltration in a chronic murine model of lupus nephritis (Ortiz et al. 2009). The role of Fn14 expressed by resident kidney cells or by myeloid cells that infiltrate the kidney in lupus nephritis was approached using two groups of chimeric mice. One chimera expressed Fn14 only in kidney resident cells, while bone marrow-derived cells lacked Fn14. In the other chimera Fn14 expression was restricted to bone marrow-derived cells. Fn14 expressed only by kidney resident cells was enough to promote an early inflammatory response and glomerular injury, while Fn14 from bone marrow-derived cells plays a role at a later stage of the disease (Molano et al. 2009). This suggests that resident kidney cell Fn14 contribute to initiation of nephritis while infiltrating macrophage Fn14 is active only after localization of these cells to the kidney and that Fn14 is a therapeutic target in lupus nephritis. Urinary TWEAK (uTWEAK) correlated positively with lupus nephritis activity, indicating local inflammatory activity (Burkly et al. 2007). These data suggest that Fn14 may mediate kidney damage promoting local inflammation and could be a therapeutic target in this disease.

Rheumatoid Arthritis

Rheumatoid arthritis is an autoimmune disease characterized by chronic joint inflammation that leads to cartilage and bone destruction. Fn14 activation induces a proinflammatory process in cultured human dermal fibroblasts and synoviocytes (Burkly et al. 2007). Fn14 is expressed on other human joint cell types, such as chondrocytes, and osteoblast, that respond to TWEAK activation of Fn14 by expressing inflammatory mediators. Moreover, in an experimental model, TWEAK blockade reduced various arthritogenic mediators in serum and in joint and prevented arthritis (Burkly et al. 2007). In synovial cell isolated from rheumatoid arthritis patients Fn14 activation-induced proliferation and inflammatory cytokine production (Kamijo et al. 2008). Finally, serum levels of TWEAK were elevated and TWEAK and Fn14 expression is increased in synovial tissue of patients with rheumatoid arthritis (van Kuijk et al. 2010). Based on this evidence, clinical trials are underway for BIIB023 neutralizing anti-TWEAK antibodies in rheumatoid arthritis.

Cancer

There is evidence for a role of the TWEAK/Fn14 system in cancer. Thus, Fn14 is upregulated in numerous tumors (Michaelson and Burkly 2009). Fn14 may have pro-tumorigenic effects, promoting angiogenesis and cell survival, migration, proliferation, and in some tumor cells such as in glioma cells and in hepatocellular carcinoma cells. These data suggest that TWEAK/Fn14 targeting could be beneficial in cancer treatment. However, TWEAK was described as a cytokine that induced cell death in tumor cells. In this sense, Fn14 activation induces apoptosis in various tumor cell lines, such as adenocarcinoma cells, endometrial cancer cells, and human colon carcinoma cells (Michaelson and Burkly 2009; Dionne et al. 2010). Indeed, the lethal effect of Fn14 activation appears to be higher in tumor cells than in normal cells. Thus, Fn14 activation could be a therapeutic strategy for cancer treatment. An elegant approach to solve this conundrum was the development of a monoclonal anti-Fn14 antibody that both activates Fn14 and promotes antibody-mediated T cell cytotoxicity (Culp et al. 2010). This antibody can induce apoptosis in tumor cells sensitive to Fn14 activation-induced death and also in Fn14-expressing tumor cells resistant to Fn14 activation-induced death. This approach was successfully tested in cultured cells and in experimental animals in vivo (Culp et al. 2010). Indeed, phase I clinical trials in patients with solid tumors are underway.

Summary

Fn14 is the receptor for TWEAK, a cytokine of the TNF superfamily. Fn14 and TWEAK are broadly expressed and may regulate cell proliferation, cell death, cell differentiation, and inflammation. The pathways activated by TWEAK/Fn14 signaling include alternative and classic NFκB, MAPKs, and PI3K/Akt pathway. Fn14 lacks the DD domain, characteristic of the TNFR superfamily, but signals through TRAF-binding domains. In vivo, Fn14 expression in various healthy tissues is low, but is significantly upregulated after injury. Functional studies targeting TWEAK and or Fn14 implicate the system in promoting acute and chronic tissue injury, including in the course of autoimmune disease, as well as in cancer biology. Fn14 activation can also contribute to tissue

repair and any therapeutic intervention should consider this possibility. In this regard, while current preclinical data indicate that the TWEAK/Fn14 system may be a therapeutic target in various diseases, clinical trials are underway. A neutralizing anti-TWEAK antibody, BIIB023, is being tested in rheumatoid arthritis and PDL192 anti-Fn14 antibodies in subjects with advanced solid tumors. These results will provide the first data on the safety of targeting TWEAK/Fn14 in humans and will accelerate translational research in human disease.

Historical Background

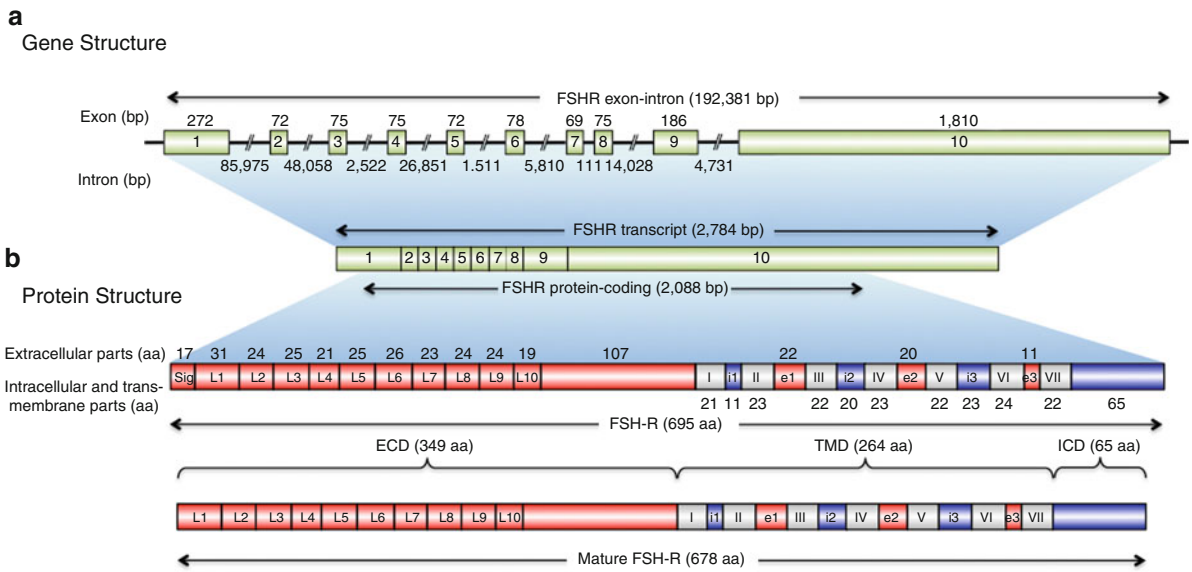
Although the importance of FSH in the reproduction has been well recognized for many years, FSH receptor (FSH-R) had not been identified until 1970s. High affinity, low capacity binding sites for FSH were demonstrated in 1972 using rat testicular tubules incubated with radiolabeled FSH (Simoni et al. 1997). In the following years, FSH-R was identified, isolated and purified in several species and cellular localization, ligand-receptor interaction and intracellular signaling molecules associated with the receptor were studied extensively (Simoni et al. 1997). FSH-R gene (*FSHR*) was cloned in 1990 by screening rat Sertoli cell cDNA library. Since then, *FSHR* has been cloned in several species ranging from human to reptile (Simoni et al. 1997). These findings led to identification of FSH-R mutations that either enhance (activating or gain-of-function mutation) or impair (inactivating or loss-of-function mutation) the function of the receptor (Lussiana et al. 2008). Advent in the molecular biology has made it possible to produce site-directed mutagenesis (Vassart et al. 2004) and *FSHR* knock out mouse, contributing to clarification of functional structure and physiological importance of FSH and FSH-R. The stereochemical structure and activating mechanism of FSH-R have not been fully clarified yet. Further understanding in the structure and the structure–function relationship of FSH-R will allow researchers to develop effective antagonists and agonists that can be used for better management of human and animal reproductive health.

Structures and Function of FSH-R

FSH-R, as for closely related glycoprotein hormone receptors, LH/hCG receptor and TSH receptor, is a member of the rhodopsin-like G protein-coupled receptor (GPCR) family. FSH-R is a glycoprotein that consists of a large N-terminal extracellular domain, a transmembrane domain, and an intracellular domain (Vassart et al. 2004) (Fig. 1b).

The human *FSHR* spans more than 192 kbp and constitutes of ten exons separated by nine introns (Fig. 1a). The exons 1–9 encode most of the extracellular domain whereas the exon ten encodes C-terminal part of the extracellular domain, transmembrane domain, and intracellular domain. Sequence homologies are high among glycoprotein hormone receptors with the homologies around 40% for the extracellular domain and 70% for the transmembrane domain (Vassart et al. 2004), indicating common evolutionary origin of these receptors (Dias et al. 2002). The mature human FSH-R constitutes of 678 aa (695 aa with N-terminal 17 aa signal peptide) with the calculated molecular mass around 78 kDa (UniProt 2010: Fig. 1b).

The extracellular domain of the receptor constitutes of 349 aa and is essential for FSH binding. This domain contains ten loosely related motifs called leucine-rich repeats (LRRs: Ensembl 2010). Together, they form a horseshoe-like structure that provides hydrophilic binding interface specific to FSH (Vassart et al. 2004;



Follicle Stimulating Hormone Receptor (FSHR), Fig. 1 Structural organization of the human FSH-R. (**a**) Gene structure. Human *FSHR* spans more than 192 kbp, constituting of ten exons and nine introns. *FSHR* transcript is 2,784 bp, of which 2,088 bp are translated. (**b**) Protein structure. FSH-R constitutes of 695 amino acids (*aa*), organized into the signal peptide (*Sig*), the extracellular domain (*ECD*), the transmembrane domain (*TMD*), and the intracellular domain (*ICD*). ECD contains ten leucine-rich repeats (LRR: L1-L10). TMD contains seven membrane spanning hydrophobic α helices (T1-7) connected by intra- (*i1-3*) and extracellular loops (*e1-3*). *Red* indicates extracellular potions of FSH-R whereas *blue* indicates intracellular potions of the receptor. Based on the online database (Ensembl 2010; UniProt 2010)

Fan and Hendrickson 2005: Fig. 2). The transmembrane domain constitutes of 264 aa and contains seven membrane spanning hydrophobic α helices connected by intra- and extracellular loops, the structure characteristic to the members of GPCR family (Figs. 1b and 2). The intracellular domain constitutes of 65 aa. Together with the intracellular loops of the transmembrane domain, this domain interacts with G proteins and other signaling molecules involved in signal transduction and receptor internalization (Ulloa-Aguirre et al. 2007: Fig. 2).

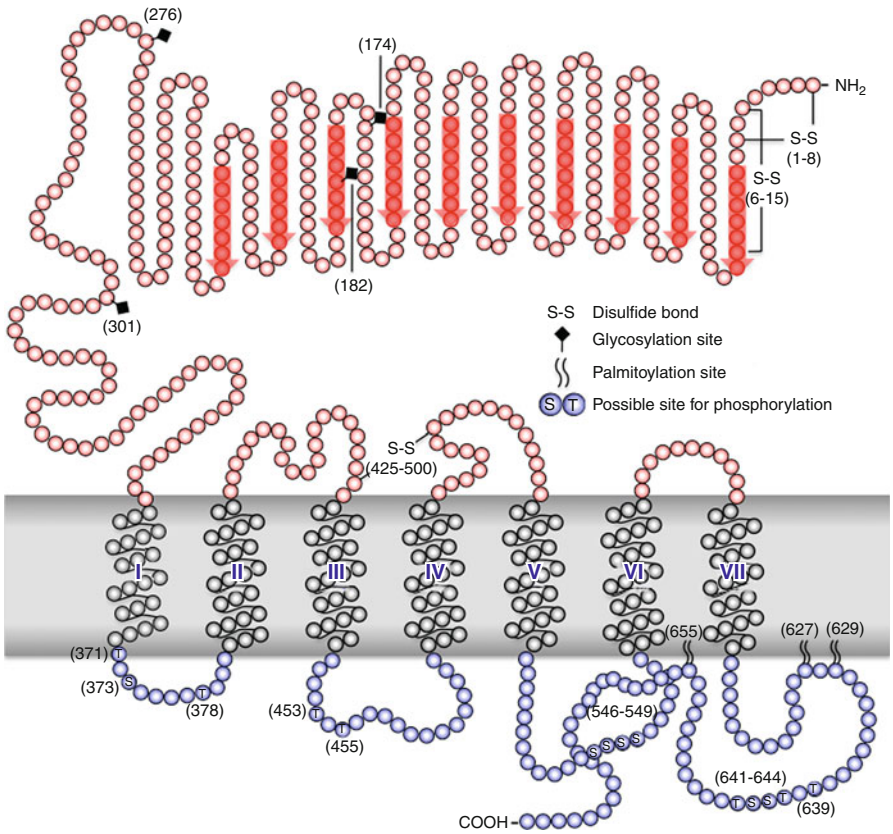
FSH-R is subjected to extensive post-translational modifications such as glycosylation, disulfide formation, palmitoylation and phosphorylation (Fig. 2). These modifications are essential for protein folding, trafficking, cell surface expression, activation, sequestration, and signal transduction of the receptor (Ulloa-Aguirre et al. 2007).

Accumulating evidences indicate that the FSH-R occurs as di/oligomeric units on the cellular membrane (Fan and Hendrickson 2005; Ulloa-Aguirre et al. 2007; Vassart 2010). The transmembrane α helices and the extracellular domain appear to be involved in di/oligomerization of the receptor (Vassart 2010). Although physiological significance of the receptor di/oligomerization is not well understood, it may enable positive cooperativity among receptor molecules (Ulloa-Aguirre et al. 2007).

FSH binding to the extracellular domain causes conformational change of the domain and triggers the FSH-R activation and subsequent signal transduction (Vassart et al. 2004). Although the exact mechanism that activates FSH-R has not been fully elucidated, interaction between the FSH-bound extracellular domain and the transmembrane domain appears to be necessary for full conformational change required for the activation (Vassart et al. 2004; Ulloa-Aguirre et al. 2007). This in turn causes conformational change of the transmembrane and intracellular domain, leading to the activation of associated G proteins and down-stream signaling pathways (see below).

Temporal and Special Expression of FSH-R

Temporal and special expression of FSH-R has been examined in several species including mouse, rat, cattle, and human by using various techniques



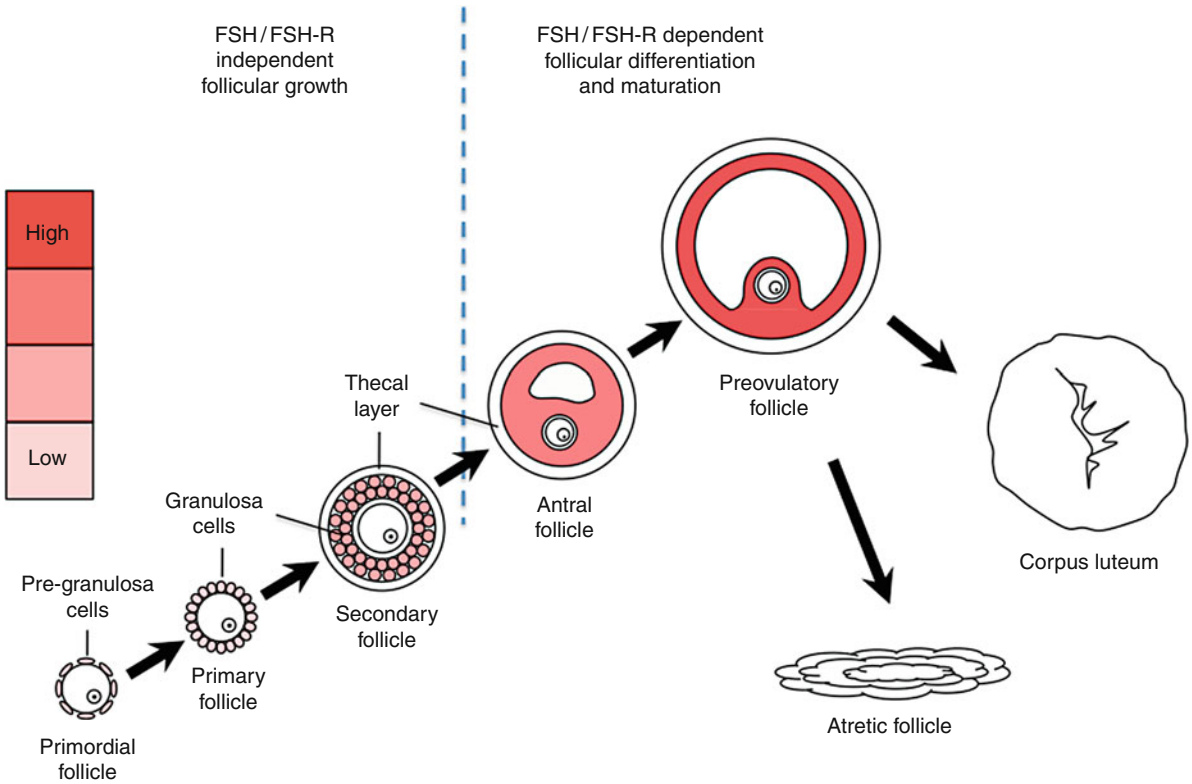
Follicle Stimulating Hormone Receptor (FSHR), Fig. 2 Schematic representation of the human FSH-R with post-translational modifications. ECD and extracellular loops are modified with three disulfied bonds and four glycosylations, whereas ICD and intracellular loops are modified three palmitoylations and several phosphorylations. Ten consecutive LRRs are indicated by *red arrows*. Numbers represent amino acid position in mature FSH-R (678 aa). Modified from Ulloa-Aguirre et al. (2007) using the data obtained from the online database (UniProt 2010)

such as ligand-binding study, in situ hybridization, immunohistochemistry, and quantitative RT-PCR. Irrespective of species examined, FSH-R is localized on the cellular membrane of the ovarian granulosa cells and the testicular Sertoli cells. The expression of FSH-R is developmentally regulated in both cell types (Simoni et al. 1997; O'Shaughnessy et al. 1996; Dias et al. 2002). In female mice and rats, FSH-R mRNA appears to be expressed in the fetal ovary and undifferentiated granulosa cells of primordial follicle. The presence of the functional FSH-R has been confirmed in small preantral follicles of various species and its expression increases as follicular development and maturation progress (O'Shaughnessy et al. 1996: Fig. 3). The expression of FSH-R sharply declines in preovulatory follicles after preovulatory LH-surge and in atretic follicles. Corpus luteum does not express FSH receptor (Simoni et al. 1997; O'Shaughnessy et al. 1996: Fig. 3).

In the rat, FSH-R mRNA is expressed in the fetal testis as early as fetal day 16.5 but it is not clear whether it plays any functional role (Simoni et al. 1997; O'Shaughnessy et al. 1996). In immature rats, number of FSH-R increases until day 7, and stays constant for 2 weeks (Simoni et al. 1997). The increase in FSH-R number coincides with the proliferation of Sertoli cells, indicating the functional role for FSH in this process. The expression of FSH-R decreases dramatically around day 40 when major initiation of spermatogenesis occurs (Simoni et al. 1997).

Spermatogenesis can be classified into several stages, defined by combination of germ cells at different stages of development in the seminiferous tubule. In the rat, where the spermatogenesis is organized into 14 stages, FSH-R is expressed stage dependently, being highest in stages XIII, XIV, and I, and lowest in VII and VIII (Simoni et al. 1997: Fig. 4). FSH responsiveness of the cells, in terms of cAMP production, follows similar pattern but a few stages behind the expression pattern, being highest in stages IV and V (Simoni et al. 1997: Fig. 4).

Ectopic expression of FSH-R has been reported in some tissues such as myometrium, prostate, bone, and ovarian surface epitherium (Simoni et al. 1997;



Follicle Stimulating Hormone Receptor (FSHR), Fig. 3 Expression of FSH-R during folliculogenesis. FSH-R is expressed in small growing follicles despite these follicles do not require FSH. FSH is absolutely necessary for antrum formation and subsequent follicular maturation. FSH-R expression increases as follicular maturation progresses whereas it decreases dramatically in corpora lutea and atretic follicles

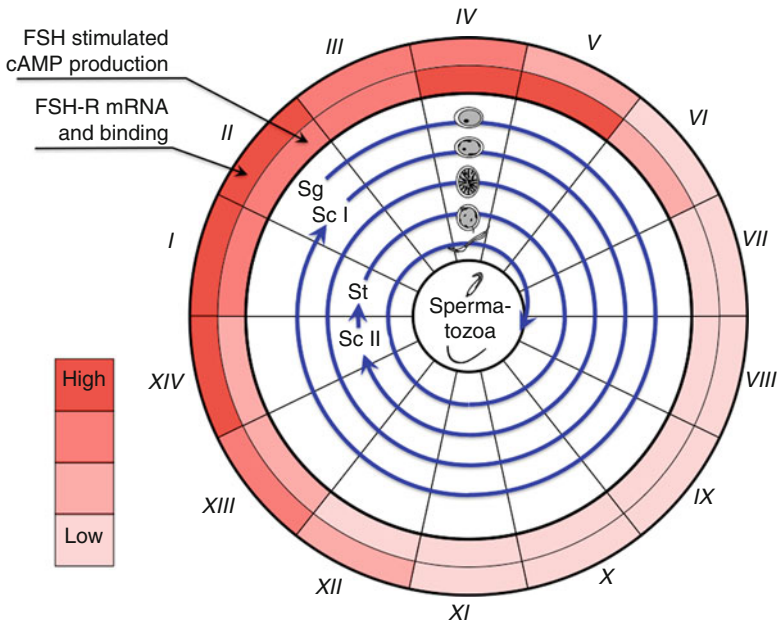
Dias et al. 2002; Ulloa-Aguirre et al. 2007; Bose 2008). Physiological significance of FSH-R in these tissues is not well understood but FSH-R may be involved in the development of osteoporosis (Ulloa-Aguirre et al. 2007) and ovarian cancer (Bose 2008).

Regulation of FSH-R Expression

The sensitivity of the target cells to FSH is determined by the number of functional receptor on the cells, which in turn is regulated by two mechanisms, the level of receptor expression and the rate of receptor turnover.

The expression of FSH-R is regulated by various endocrine, paracrine, and autocrine factors. FSH appears to be a prime hormone that regulates FSH-R expression. Effect of FSH on the receptor expression differs among species and between sexes. In male rats and mice, FSH down-regulates expression of FSH-R in Sertoli cells both *in vivo* and *in vitro* (Simoni et al. 1997). In the female, FSH effect appears to be biphasic; treatment of immature or hypophysectomized rats with eCG or FSH increased FSH-R mRNA and FSH binding, whereas subsequent treatment to induce ovulation with hCG or high dose of FSH down-regulated FSH-R mRNA and FSH binding (Simoni et al. 1997). In cultured rat granulosa cells, FSH prevented FSH-R down-regulation that otherwise occurs in the absence of FSH (Simoni et al. 1997). FSH was also shown to induce a dose-dependent decrease in FSH-R mRNA expression in cultured rat granulose cells (Minegishi 2004). These findings suggest that the expression of FSH-R is auto-regulated by FSH to maintain optimum levels of FSH stimulation.

Number of locally produced factors, either alone or together with FSH, modulate FSH-R expression in granulosa cells (Simoni et al. 1997; Minegishi 2004). Transforming growth factor (TGF)β increased while TGFα decreased basal expression of FSH-R mRNA



Follicle Stimulating Hormone Receptor (FSHR), Fig. 4 Stage specific FSH-R expression in the rat during spermatogenesis. In the rat, spermatogenesis is organized into 14 stages, defined by combination of germ cells at different stages of development in the seminiferous tubule. Germ cells therefore experience 4–5 cycles of the spermatogenic cycle to attain maturity. FSH-R is expressed stage dependently, being highest in stages *XIII*, *XIV*, and *I*, and lowest in *VII* and *VIII*. FSH responsiveness of the cells, in terms of cAMP production, follows similar pattern but a few stages behind the expression pattern, being highest in stages *IV* and *V*. Sg, spermatogonia; *Sc I*, spermatocytes in the first meiotic division; *Sc II*, spermatocytes in the second meiotic division; St, spermatids. Based on Simoni et al. (1997)

and protein in cultured rat granulosa cells. TGFα also dose dependently suppresses the effect of TGFβ. Epidermal growth factor (EGF) and basic ▶ fibroblast growth factor (bFGF) suppressed FSH stimulated FSH-R mRNA expression without affecting basal expression. Retinoic acid similarly suppressed FSH action without affecting basal expression of FSH-R (Minegishi 2004). GnRH likewise antagonized FSH action on the expression of FSH-R. Insulin-like growth factor I, on the other hand, synergistically increased FSH stimulated FSH-R mRNA expression without affecting the basal expression. Activin was shown to increase FSH-R mRNA level through increasing expression rate and mRNA half-life (Minegishi 2004).

The mechanism responsible for the transcriptional regulation of *FSHR* has been extensively studied in the mouse, rat, and human (Simoni et al. 1997; Hermann and Heckert 2007). Transient transfection experiments using sequential deletions of the 5'-flanking region revealed that only short promoter sequence immediately up-stream of the transcriptional start site is required to maintain transcriptional activity. When longer DNA constructs were used, this transcriptional activity was markedly suppressed, indicating the presence of repressor elements at the up-stream of the promoter region (Simoni et al. 1997; Hermann and Heckert 2007). The *FSHR* promoter region equips with a promoter element E-box (CACGTG) but does not equip usual TATA and CCAAT promoter elements. The E-box is bound by the basic helix-loop-helix transcription factors upstream stimulatory factor 1 (Usf1) and Usf2. Usf1 and 2 form homo- or heterodimer and initiate transcription in coordination with other transcription factors that bind proximal promoter elements (Hermann and Heckert 2007).

The expression of FSH-R is also affected by the alternate splicing (O'Shaughnessy et al. 1996). Many forms of *FSHR* splicing variants are reported in various species. The splicing variants are mostly formed by exon removal; in the human, short FSH-R isoform lacking 62 aa is formed by removal of exon 9. Physiological significance of these splicing variants is not clear but they may act as receptors with altered affinity for FSH or with altered response to FSH binding.

In fetal and neonatal mice, short splicing variants of *FSHR* have been reported both in male and female. In the bovine granulose cells undergoing luteinaization, the full length *FSHR* transcript disappears while the transcripts encoding the extracellular domain persist (O'Shaughnessy et al. 1996). These results indicate that the FSH action is also regulated at the post-transcriptional splicing step.

Receptor desensitization occurs through uncoupling of the receptor from the associated G protein followed by sequestration of the receptor from the membrane surface (Dias et al. 2002; Misrahi et al. 1996; Luttrell 2008). The intracellular domain and intracellular loops of the transmembrane domain play important roles in this process (Ulloa-Aguirre et al. 2007). Within seconds of ligand binding, the intracellular parts of the receptor are phosphorylated (see Fig. 2) that triggers an assembly of proteins responsible for receptor endocytosis. Once internalized, the receptor is taken into the endosome where it is sorted either for degradation or for resensitization and returns to the membrane surface (Misrahi et al. 1996; Luttrell 2008).

FSH-R Signaling Pathway

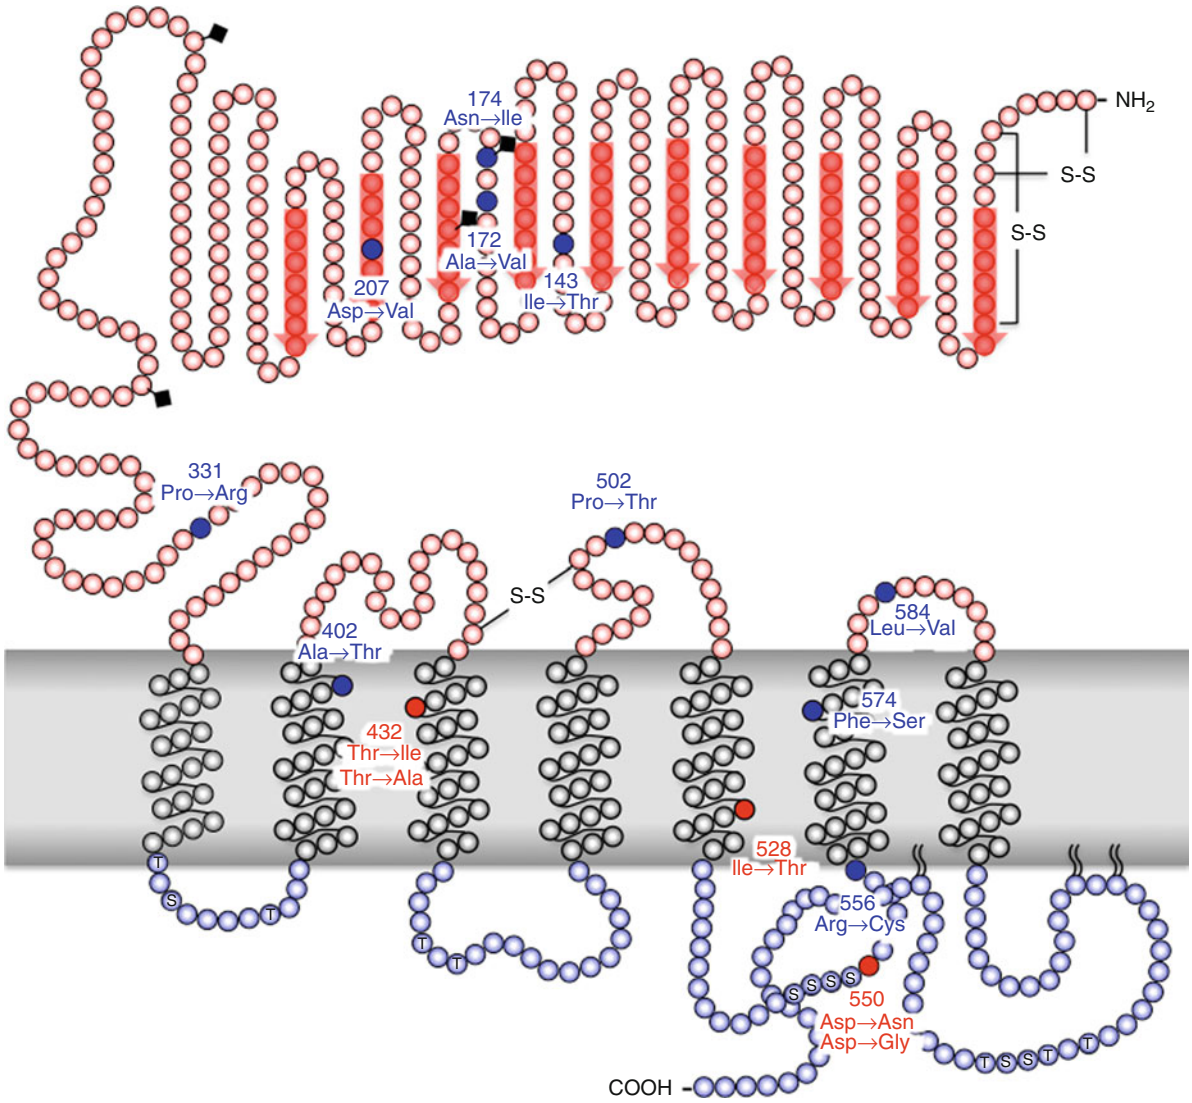
Upon activation, FSH-R transmits the activating signal into the target cells through series of events mediated by various protein kinases, second messengers and transcription factors. The most notable FSH-R signaling pathway is mediated by cAMP dependent protein kinase (PKA). Ligand binding induces a conformational change of the receptor, which activates heterotrimeric Gs proteins coupling with the intracellular domain of the receptor. The activated G proteins dissociate into ▶ G protein α and G protein β/γ heterodimer, and the former activates membrane-bound enzyme ▶ adenylyl cyclase, leading to synthesis of a second messenger cAMP. Cyclic AMP in turn activates PKA, which phosphorylates transcription factors such as cAMP responsive element (CRE) binding proteins (CREBs) and CRE modulators (CREMs), initiating transcription of FSH target genes (Simoni et al. 1997). Many lines of evidences indicate that the FSH-R led signal transduction is far more complicated with multiple signaling pathways interacting each other at various signaling steps. For example, PKA activates not only above mentioned transcription factors but also various ▶ mitogen-activated protein kinase (MAPK) cascades (Ulloa-Aguirre et al. 2007; Zhang et al. 2009). FSH-R also activates multiple kinases through PKA-independent signaling pathways. Some of these signaling pathways are also coupled with other receptor systems such as that of IGF-I and EGF, indicating FSH action is intricately modulated by the interacting factors at various signaling steps (Dias et al. 2002; Ulloa-Aguirre et al. 2007). Moreover, FSH has been shown to increase intracellular Ca2+ through cAMP-dependent and cAMP-independent signaling pathways in granulosa and Sertoli cells (Ulloa-Aguirre et al. 2007). These multiple signaling pathways allow FSH to exert complex, multiple facets effects on cellular functions of the ovarian granulosa and the testicular Sertoli cells.

Abnormality of FSH-R

FSH-R is indispensable for follicular development and maturation; using *FSHR* knockout female mice, it was demonstrated that the follicular development was blocked at the preantral stage and estradiol production was greatly reduced (Kumar 2005).

Unlike in the female, FSH-R is not absolutely necessary for spermatogenesis in the male. *FSHR* knockout caused smaller testis and accessory glands, decrease in testosterone production and reduction in qualitative and quantitative aspects of spermatogenesis, but they were nevertheless fertile (Kumar 2005; Sairam and Krishnamurthy 2001).

Mutagenesis may alter expression and function of FSH-R; mutagenesis in the promoter region may compromise promoter activity (Hermann and Heckert 2007), while that in the coding region may result in substitutions of amino acids that enhance (activating mutations) or impair (inactivating mutations) receptor functions. Amino acid substitutions may alter structural and/or physicochemical nature of the receptor that in turn alter binding affinity or specificity to hormones, or alter conformational change required for FSH-R activation. Reported activating mutations of human occur at the transmembrane domain (Fig. 5). Nevertheless, the mutations increase sensitivity to FSH or other tropic hormones such as hCG and TSH, allowing promiscuous activation of the receptor. Patients with these mutations suffer from spontaneous or iatrogenic ovarian hyperstimulation syndrome. The other type of activating



Follicle Stimulating Hormone Receptor (FSHR), Fig. 5 Schematic representation of amino acid substitutions in human FSH-R. Activating mutations are indicated with *red circles* whereas inactivating mutations with *blue circles*. Numbers represent amino acid position in mature FSH-R (678 aa). Modified from Ulloa-Aguirre et al. (2007) using the data obtained from Lussiana et al. (2008)

mutation causes ligand-independent constitutive activation of the receptor even in the absence of FSH. Inactivating mutations occur at any of the three domains (Fig. 5). These mutations may reduce the receptor response to FSH through altering FSH-R expression on the cell surface, reducing signal transduction efficiency, or impairing FSH binding. Patients carrying these mutations suffer from symptoms such as primary/secondary amenorrhea and precocious ovarian failure (Lussiana et al. 2008).

Summary

FSH-R is a transmembrane glycoprotein that directs FSH signal to the intracellular signaling pathways. FSH-R consists of three functional domains, extracellular, transmembrane, and intracellular domains. The extracellular parts of FSH-R, i.e., the extracellular domain and extracellular loops of the transmembrane domain, are responsible for high affinity specific binding to FSH, whereas the transmembrane and intracellular potions of the

receptor act as a switch to activate the intracellular signaling molecules, such as G proteins.

Ovarian granulosa cells and testicular Sertoli cells are primary cell types that express FSH-R where it plays pivotal roles in female and male reproduction. Expression of FSH-R is developmentally regulated in relation to the stages of folliculogenesis and spermatogenesis by various endocrine/paracrine/autocrine factors, such as FSH and growth factors. Upon activation, FSH-R transmits the signal through signal transduction pathways mediated by PKA and other signaling molecules, and stimulates cellular proliferation and differentiation. Mutations of *FSHR* may disrupt structural organization of the receptor, which result in partial or total loss of fertility. Structure–function relationship of FSH-R has been extensively studied in recent years by using molecular biological and biophysical techniques such as site-directed mutagenesis and crystallization, revealing complex ingenious molecular mechanism that regulates cellular response to FSH. Further understanding in the FSH-R will benefit to develop agonists/antagonists for better management of human and animal reproductive health.

Formyl Peptide Receptor

Erica L. Southgate and Richard D. Ye
Department of Pharmacology, University of Illinois College of Medicine, Chicago, IL, USA

Synonyms

FMLPR; FPR; NFPR

Historical Background

Formyl peptide receptor 1 (FPR1) was first discovered on human neutrophils through its ability to bind N-formylated peptides with high affinity (Schiffmann et al. 1975). Rabbit neutrophils exhibit similar binding properties. The 350-amino acid human FPR1 receptor was the first cloned leukocyte chemoattractant receptor (Boulay et al. 1990). Genes with homologous sequence (FPR2 and FPR3) were identified through low-stringency hybridization using the FPR1 cDNA. The FPR2 cDNA encodes a 351-residue protein and shares approximately 69% sequence identity with FPR1. FPR2 is a low-affinity receptor for the prototypic formyl peptide, N-formyl-Met-Leu-Phe (fMLF). It binds lipoxin A4 and therefore is termed FPR2/ALX (Ye et al. 2009). FPR3 encodes a 7TM receptor of 352 amino acids that shares 56% sequence identity with FPR1 but does not bind fMLF. Although these three human members of the formyl peptide receptor family are relatively similar in terms of sequence identity and receptor structure, they are quite divergent with respect to agonist selectivity and cellular and tissue distribution, indicating a variety of biological functions (Migeotte et al. 2006; Ye et al. 2009).

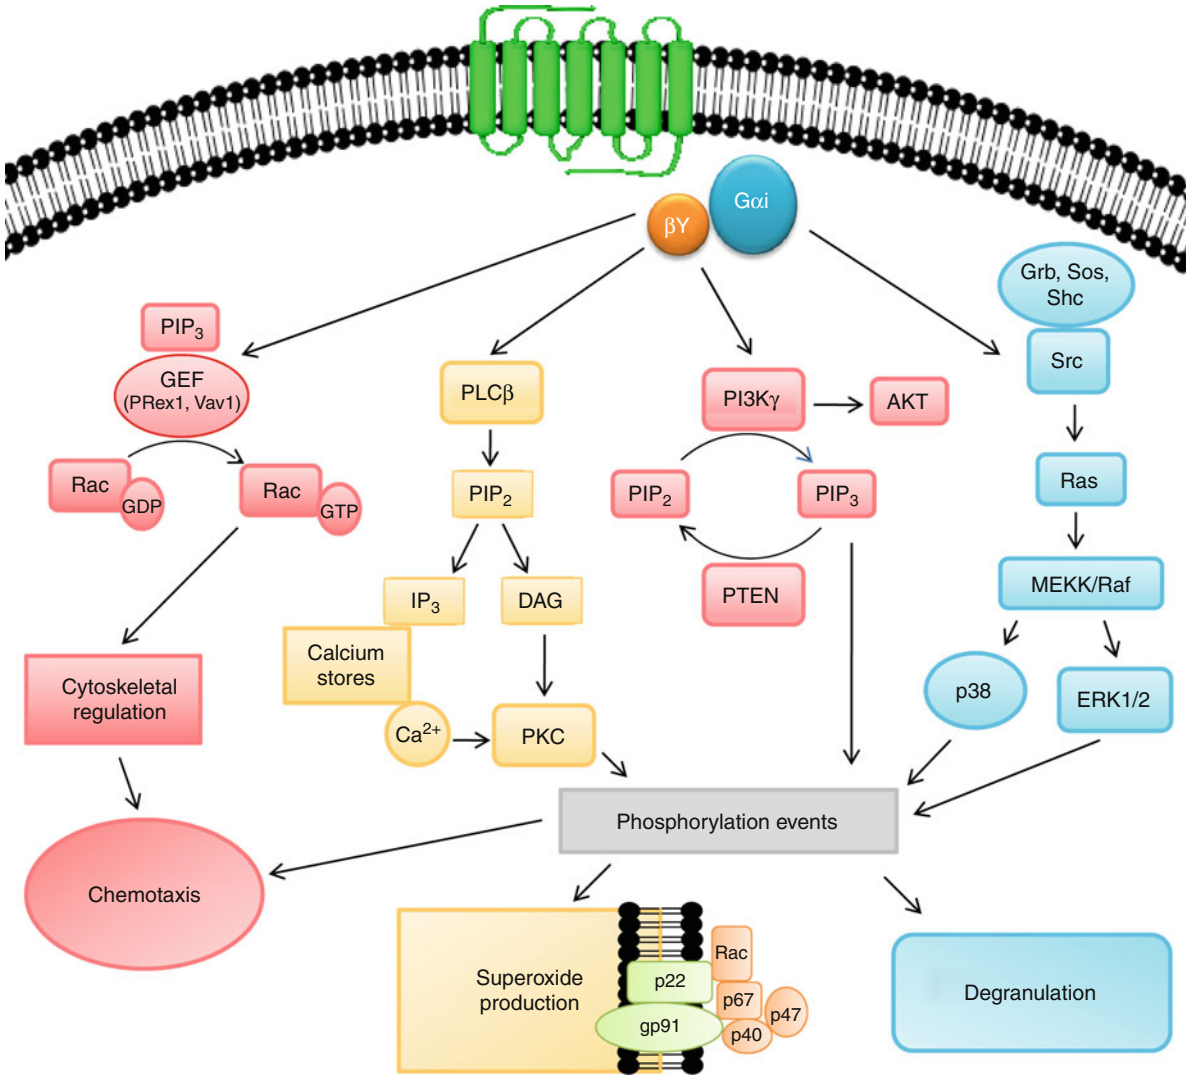
Activation of FPR1 was first described through ligation with N-formylmethionyl peptides (Schiffmann et al. 1975). The identification of the formyl peptide, fMLF, derived from *E. coli*, suggests that a major function of FPR1 is to detect bacterially derived formyl peptides (Marasco et al. 1984). Further discovery of numerous formyl peptides derived from various bacterial sources, such as *L. monocytogenes*, *S. aureus*, and even human mitochondria indicates that the agonists of this family are potent activators of FPR1 signaling (Rabiet et al. 2005). Although formyl peptides appear to be the dominant agonist for FPR1, this is not the case for other members of the FPR family such as FPR2. Even FPR1 has been shown to be activated by a variety of non-formylated microbe-derived peptides and synthetic peptides such as HIV-1 envelope proteins and WKYMVm, respectively (Le et al. 2002). Although a diverse group of agonists activate the FPR family as a whole, N-formyl peptides induce responses that are best characterized in neutrophils. This essay describes FPR1 for its signaling properties in neutrophils. A schematic representation of the major pathways downstream of an activated FPR1 is shown in Fig. 1.

Basic Signaling

Being the first characterized leukocyte chemoattractant receptor, FPR1 is extensively studied for its signaling mechanisms. FPR1 proves to be extremely important because of its ability to facilitate a number of downstream events in neutrophils leading to microbial killing. It has been known that different levels of FPR1 occupancy can lead to signaling pathways that vary between chemotaxis and cytotoxic functions such as degranulation and superoxide production (Korchak et al. 1984). However, the initial phase of receptor activation is similar for every aspect of FPR1 activation after fMLF binds to the receptor. After ligand binding, FPR1 undergoes a conformational change that enables the receptor to interact with the pertussis toxin (PTX) sensitive heterotrimeric G protein of the Gi family. Upon activation, there is an exchange of GDP for GTP in the Gαi subunit which leads to dissociation of the Gα and βγ subunit complex (Bokoch 1995). Following dissociation from the α subunit, the βγ subunit activates phospholipase C β2 ($PLC\beta_2$) and ▶ phosphoinositide 3-kinase γ (PI3Kγ). Activation of $PLC\beta_2$ hydrolyzes phophoinositiol-4,5-bisphosphate (PIP_2) into diacylglycerol (DAG) and inositiol trisphosphate (IP_3). Both hydrolyzation products are important second messengers, DAG activates protein kinase C (PKC), whereas IP3 binds the IP3 receptor on intracellular stores and mobilizes Ca^{2+}. The activation of PI3Kγ converts the membrane phosphoinositol-4,5-bisphosphate (PIP_2) into phosphoinositiol-3,4,5-trisphosphate (PIP_3). Activation of PKC, as well as numerous calcium-sensitive protein kinases, leads to further downstream signaling, which has been shown to account for a variety of neutrophil functions to aid in microbial killing (Bokoch 1995). For the remainder of this entry, the distinct signaling pathways for FPR1-activated processes such as chemotaxis, superoxide production, and degranulation will be identified separately to avoid confusion, although significant cross talk exists between these pathways.

FPR1-Mediated Phagocyte Functions

Chemotaxis. The directed migration, or chemotaxis, of neutrophils by N-formyl peptides was one of the initially identified functions mediated by FPR1 (Prossnitz and Ye 1997). Human neutrophils can detect a chemotactic gradient of N-formyl peptides which produces a bell-shaped curve in dose–response experiments indicating that past



Formyl Peptide Receptor, Fig. 1 A schematic representation of major signaling pathways downstream of FPR1 activation. Agonist binding to the receptor leads to dissociation of Gα and βγ subunits of the heterotrimeric Gi protein that couple to the receptor. The released βγ subunits activate downstream signaling pathways that involves GEFs for the Rho family small GTPase, PLCβ and PI3Kγ, which are critical to cellular functions including chemotaxis, superoxide production, and degranulation (see text for details). In addition, the α subunit is involved in the regulation of other pathways downstream of the activated receptor

optimal chemoattractant concentrations chemotaxis is reduced (Ye et al. 2009). Two mechanisms have been proposed to contribute to this phenomenon. First, saturation of these receptors with a high concentration of agonists eventually eliminates the chemoattractant gradient, thereby reducing chemotaxis. Secondly, FPR1 is desensitized at high concentrations of agonists, specifically fMLF, therefore reducing responsiveness to additional agonist stimulation (Prossnitz and Ye 1997). A number of events occur to aid in the chemotaxis activity such as polarization of the cell, integrin-mediated adhesion, and physical rearrangements of the cytoskeleton, requiring a variety of different signaling pathways. As previously mentioned, the initiation of chemotaxis through FPR1 activation begins with signaling from Gβγ. The βγ subunit activates PI3Kγ, which increases membrane concentration of PIP3 and helps distinguish leading edge of the chemotactic neutrophil from the

trailing edge, termed uropod. The exposure of neutrophils to a chemoattractant gradient creates an intracellular gradient of signaling molecules such as PIP3. The regulation of PIP3 at the leading edge of neutrophils during chemotaxis is also facilitated by the phosphatidylinositol-3 phosphatase, ▶ PTEN, converting PIP3 back to PIP2. PTEN is localized to the side and the back of a migrating cell and therefore the cell maintains a higher concentration of PIP3 at leading edge, allowing it to migrate. The localization of PTEN to these areas of the neutrophil appears to involve the p38 MAPK, although the direct mechanism of localization is unclear (Heit et al. 2008). The mechanisms that regulate PIP3 localization at the leading edge are important for polarization and forward migration of the cell have been shown to incorporate a number of downstream signaling molecules and an important feedback loop involving some of these molecules. One of these downstream signaling molecules is Akt (PKB). In a number of studies involving the Pleckstrin homology domain of Akt, there was evidence that PIP3 generation by PI3K was crucial for the translocation of Akt to the leading edge of the plasma membrane. Further studies involving knockouts of Akt isoforms, indicating that Akt2 translocation was vital for polarization and chemotaxis of neutrophils after chemoattractant stimulation. Generation of PIP3 has been indicated to be involved in the positive feedback loop involving the Rho GTPases Rac and Cdc42. The activation of Rac has been linked to actin filament formation and subsequent membrane ruffling, therefore inducing the protrusion of the pseudopod and aiding in chemotaxis toward chemoattractants. Additionally, concentration of PIP2 to the uropod from the PTEN conversion of PIP3 to PIP2 mediates the activation of Rho, which regulates stress fiber and focal adhesions and therefore aiding in the uropod movement. In addition to the regulation of Rho by PIP3, there have been other signaling molecules implicated in the complex action of chemotaxis. Gα12 and Gα13 have been shown to be involved in a divergent pathway from the canonical Gαi pathway activated by FPR1, and have been directly linked to activating Rho, a Rho-dependent kinase (p160-ROCK), and myosin II and aiding in the "backness" of the neutrophil (Xu et al. 2003). In addition to the described mechanisms of chemotaxis in neutrophils after FPR1 activation, directed cell movement has also been linked to alternative pathways for its regulation. One of the pathways involves tyrosine kinases such as Src. It is thought that the first dissociation of the βγ subunit which activates PI3K can also increase the activity of Src-like kinases. Further characterization of this pathway was shown to involve the activation of the Shc-Grb2-Sos-Ras pathway, which leads to enhancement of the MAPK pathway involving Raf-MEK-ERK. Although the mechanism of this pathway is biochemically sound, the functional outcome of the activation of this pathway has not been specifically implicated in chemotaxis or other functions of neutrophils (Rabiet et al. 2007).

Degranulation. Degranulation is an important mechanism of host defense against invading microorganisms. However, proper regulation of granule release in neutrophils is vital to evade tissue damage and excess inflammation. Generally four types of granules are distinguished in neutrophils, including primary or azurophilic granules which contain neutrophil myeloperoxidase (MPO) and many hydrolytic enzymes such as β-glucuronidase (Borregaard 1997). There are three peroxidase-negative granules which are classified as secondary (specific) granules, tertiary (gelatinase) granules, and secretory vesicles. The release of these different granules follows a strict kinetic hierarchy in which secretory vesicles containing adhesion molecules and receptors such as the FPR1 receptor are released promptly after activation. Gelatinase granule release follows whereas specific and primary granule releases occur at a much slower rate. Neutrophils can discharge the contents of the granules both into a phagosome containing engulfed particles of bacteria or to the external environment when activated by soluble stimuli such as fMLF (Borregaard 1997). fMLF-induced activation of degranulation downstream of FPR requires 10–50 times higher concentration of the agonist but the cells were committed to full degranulation abilities after only 10 s of receptor-agonist interaction (Korchak et al. 1984). The FPR1-mediated signaling pathway leading to degranulation involves the secondary messengers PLCβ and PI3K. PLCβ leads to the activation of diacylglycerol and release of Ca^{2+} from intracellular stores, both of which have been shown to modulate the activation of PKC. The role of PKC in granule release has been shown to be both Ca^{2+} dependent in the case of primary granules, whereas secretory and specific granule contents are released in a Ca^{2+}-independent manner. Pharmacological characterization of the signaling pathway leading to degranulation has implicated additional kinases, PI3K, p38 MAPK, and ▶ Src-family kinases such as Fgr and Hck (Ye et al. 2009). PI3K, which controls the phosphoinositide

population of PIP2 and PIP3, is involved in granule release by regulating the actin cytoskeleton. Tyrosine kinases such as the above-mentioned Src-family kinases Fgr and Hck are required for adhesion-dependent degranulation and are speculated to initiate actin cytoskeletal rearrangements leading to granule mobilization to the plasma membrane. In addition, the small GTPases Rac and Rho and their respective GDP dissociation inhibitors (GDIs) and guanine nucleotide exchange factors (GEFs) are directly involved in the signaling pathway that leads to granule release, due to their effect on the actin cytoskeleton (Bokoch 1995). Proper docking of the vesicles in neutrophils is one of the final steps of granule release after fMLF activation and requires a set of exocytosis machinery proteins. Activation of the cytoskeletal contractile components is followed by phosphorylation of the soluble N-ethylmaleimide-sensitive factor-attachment protein (SNAP) and receptor proteins (SNAREs). Many of the classic, neural-type SNARE proteins such as syntaxin 1, VAMP-1, and SNAP-25 are not detected in granulocytes but homologs such as syntaxin 4 and VAMP-2 have been found in granulocytes. Other homologs have been found in leukocytes, one being SNAP-23 which is the homolog of SNAP-25. At resting state, the Munc-18 family of proteins that serve as binding partners for targeting membrane SNAREs (t-SNAREs) assumes a closed conformation that prevents the SNARE complex from forming. Phosphorylation of these proteins by kinases such as PKC can induce dissociation of Munc18 and syntaxins and therefore facilitates vesicular fusion with the plasma membrane. Specific evidence in a mast cell line, RBL, and human neutrophils indicates that Munc 18–3, SNAP-23, and syntaxins 2, 4, and 6 are phosporylated after fMLF stimulation. Further evidence identified the cGMP-dependent kinase PKG-1 and PI3K are both involved in phosphorylating Munc18-3, SNAP-23, and syntaxins 2 and 4 and the subsequent granule release. Further studies will be necessary to link direct phosphorylation by kinases downstream of fMLF signaling pathway and regulation of the SNARE proteins involved in vesicular fusion for granule release.

Superoxide Generation. Superoxide production is initiated in neutrophils when the oxidase accepts an electron from reduced nicotinamide adenine dinucleotide phosphate (NADPH) and donates it to molecular oxygen, generating O_2^- in the phagosome or to the extracellular environment in cases of soluble stimuli such as fMLF. The O_2^- that is generated can be converted to cytotoxic products such as hydrogen peroxide by superoxide dismutase. The hydrogen peroxide can then be converted to the most potent bactericidal product, hypochlorous acid (HOCl), by the granular enzyme MPO. fMLF activation of superoxide generation in neutrophils requires a number of different proteins, and regulation of these proteins, as well as the coupling of responses to granulation, produces the appropriate amount of microbicidal response without resulting in injury to surrounding tissue. fMLF activation of FPR1 has been shown to require higher concentrations of the agonist than necessary for functions such as chemotaxis and degranulation. The mechanism underlying different concentration requirement of fMLF in activating these functions have not been fully appreciated; however, it is plausible that it helps to prevent tissue injury from migrating neutrophils. It could implicate that additional signaling pathways are required due to different receptor occupancy. Unlike degranulation that showed commitment to full granule release after finite receptor occupancy, O_2^- generation was shown to require continuous occupation of the receptor to initiate and maintain full superoxide response and generation (Korchak et al. 1984; Boxer et al. 1979).

Activation of the signaling pathway to stimulate O_2^- production downstream of FPR1 involves a number of additional proteins that are not necessary for chemotaxis and degranulation. The production of O_2^- is dependent on the translocation and activation of membrane and cytosolic components forming a fully active complex. In the resting state, the membrane components $gp91^{phox}$ and $p22^{phox}$ create the stable membrane complex cytochrome b_{558}. The cytosolic components of the NADPH oxidase, $p47^{phox}$, $p67^{phox}$, $p40^{phox}$, and the small GTPase Rac are physically separate from the membrane components and require phosphorylation and translocation to the membrane to assemble the functioning complex. $P47^{phox}$ contains an N-terminal phox homology (PX) domain that targets $p47^{phox}$ to the membrane to interact with the membrane component $p22^{phox}$ and PIP2. Phosophorylation of $p47^{phox}$ is required before translocation to change the conformation and expose the PX domain for the membrane. Evidence has been shown for a number of kinases to phosphorylate $p47^{phox}$. Several PKC isoforms, including α, β, δ, and ζ have been implicated in $p47^{phox}$ phosphorylation (Ye et al. 2009). With

regard to fMLF-specific activation of $p47^{phox}$ and subsequent superoxide production, the PKCδ isoform has been implicated and shown to directly phosphorylate the autoinhibitory region of $p47^{phox}$ (Babior et al. 2002). Additional kinases, including AKT and the MAPKs, ERK and p38 have been shown to phosphorylate $p47^{phox}$ such as the SH3 domain and the C-terminal proline-rich domain. The $p67^{phox}$ protein is a larger protein that interacts with almost all proteins involved in the NADPH complex. Its N-terminal tetratricopeptide repeat domains (TPR) interact with activated Rac. Phosphorylation of $p67^{phox}$ in its activation domain enhances binding of the protein to the $gp91^{phox}$ membrane component of the oxidase. Additional interaction with both $p47^{phox}$ and $p40^{phox}$ proteins allows for full activation and regulation of the oxidase system. $P40^{phox}$ has been indicated as a regulatory protein in the NADPH oxidase complex, specifically through its association with 67^{phox} in the resting state. Both basal phosphorylation and subsequent phosphorylation of $p40^{phox}$ by a PKC isoform after stimulation with fMLF have been suggested for its involvement in both regulation and activation. Rac is a cytosolic component of the NADPH oxidase complex essential for activation (Abo et al. 1991). Rac2 binds directly to $p67^{phox}$ at the membrane but does not bind $p40^{phox}$ or $p47^{phox}$. The activation of Rac involves guanine nucleotide exchange factors that exchange the inactive GDP for GTP. A Rac GEF, ▶ P-Rex1, is activated by PIP3 and Gβγ downstream of FPR1 stimulation, and therefore generates active GTP bound Rac. Additional GEFs, such as Vav1, have also been shown to play a role in fMLF-induced activation of NADPH oxidase (Welch et al. 2002).

Regulation of FPR1

Activation of FPR1 is tightly regulated through mechanisms including phosphorylation, desensitization, and internalization, which are necessary for the regulation of the levels of G protein activation and subsequent expansion of the signal through secondary messengers. The first step in FPR1 desensitization is the rapid phosphorylation of the C-terminal tail which is both time- and agonist-concentration dependent. Phosphorylation of FPR1 is PKC independent unlike other GPCR chemoattractant receptors such as the C5a receptor. The C-terminal tail of FPR1 contains a total of 11 serine and threonine residues, which are arranged in two domains characteristic of G protein receptor kinase (GRK) phosphorylation sites. GRK2 has been shown as a primary kinase in phosphorylating FPR1, whereas other GRKSs have minimal (GRK3) or no effect (GRK5,6) on the receptor (Prossnitz 1997). The phosphorylation of the clusters of serine and threonine residues modulates the affinity of the receptor to both β-arrestins and agonists. The affinity of FPR1 for β-arrestins is controlled by the phosphorylation level on the C-terminal tail of the receptor, allowing β-arrestin to form a high affinity complex and sterically inhibit Gαi protein coupling. Desensitization of FPR1 also uncouples it from G proteins independently of β-arrestin, indicating that phosphorylation of the receptor alone is sufficient in uncoupling the receptor from G protein–mediated signaling cascade. In addition to uncoupling receptors from their respective G proteins, β-arrestins have also been shown to colocalize with FPR1 during internalization of the receptor through an endocytic pathway. There are a number of reviews that address desensitization and internalization of GPCRs with details of the involvement of GRKs and β-arrestins (Ye et al. 2009; Prossnitz and Ye 1997; Rabiet et al. 2007; Migeotte et al. 2006).

Diversity of Formyl Peptide Receptor Family Ligand Binding and Downstream Effects

Although this review focuses on the downstream signaling and functional response of FPR1 activation after fMLF stimulation, it is important to note that different members of the family, such as FPR2, can mediate response through an entirely separate system or pathway. One notable difference is in the primary response, calcium mobilization, after receptor activation. The cyclic adenosine 5′-diphosphate ribose (cADPR) is a known regulator of calcium signaling. It is synthesized by CD38 ADP ribosyl cyclase and regulates intracellular calcium release from the ryanodine receptor–gated stores (Migeotte et al. 2006). Human FPR2 has been shown to be dependent on the presence of cyclic ADP-ribose for intracellular calcium release, whereas FPR1 calcium release is independent of this specific calcium metabolite. There is some evidence that FPR2 can couple to the Gq family of G proteins, which could lead to differential downstream effects for the calcium signaling. In addition to calcium mobilization, there is evidence for different endocytic machinery involved in FPR1 and FPR2 signaling. The classical GPCR internalization pathway involving β-arrestin, dynamin, and clathrin, is absent in FPR1 internalization. However, FPR2 undergoes

clathrin-mediated and dynamin-dependent endocytosis and has also been shown to require at least one β-arrestin for internalization. Another interesting phenomenon is the diversity in ligand binding between FPR1 and FPR2. These two receptors share 68% sequence identity, yet they bind the same agonists, fMLF, with drastically different affinity (Rabiet et al. 2005). It is surprising that FPR2 can bind a wider range and more structural diverse group of agonists than FPR1, including the eicosanoid lipoxin A4. These agonists can induce similar signaling pathways as described above; however, many can also trigger divergent signaling pathways with different functional outcomes (Ye et al. 2009).

Summary

FPR1 is a "classic" chemoattractant receptor characterized with its ability to mediate strong neutrophil activation of a full set of bactericidal functions, and functionally couple to the Gαi family of G proteins. FPR1 is one of the first cloned and well-characterized leukocyte chemoattractant receptors, and is often used as a model for studies of G protein–mediated signaling pathways in leukocytes. Although a tremendous amount of work has been completed on the formyl peptide receptor family, many questions still remain. These include the diverse ligand-binding properties of the FPR family receptors, the ability to mediate both pro-inflammatory and anti-inflammatory activities, and the physiological functions of these receptors when bound to bacterial formyl peptides compared to endogenous ligands. Studies have begun in recent years for the characterization of mouse FPR family receptors, which may result in genetic models for a better understanding of the signaling properties of this family of G protein–coupled chemoattractant receptors.

FKHR (forkhead in rhabdomyosarcoma)

Historical Background

FoxO1 (NCBI Accession:NM002015) belongs to the forkhead box O family that is characterized by a highly conserved DNA binding motif, known as forkhead box or winged helix domain (Accili and Arden 2004). FoxO1 is initially described by Galili et al. (1993) as the product of the t(2;13)(q35;q14) translocation associated with alveolar rhabdomyosarcoma, a cancer of connective tissue that usually develops in children. FoxO1 is also known as forkhead in rhabdomyosarcoma (FKHR). Subsequent investigation characterizes FoxO1 as a key nuclear factor that mediates the inhibitory effect of insulin or insulin-like growth factor 1 (IGF-1) on the expression of genes, whose functions are instrumental for cell growth, differentiation, and metabolism in mammals (Accili and Arden 2004). FoxO1 orthologues dFoxO in Drosophila melanogaster and DAF16 in *C. elegans* contribute to the regulation of longevity (Hwangbo et al. 2004; Lee et al. 2003).

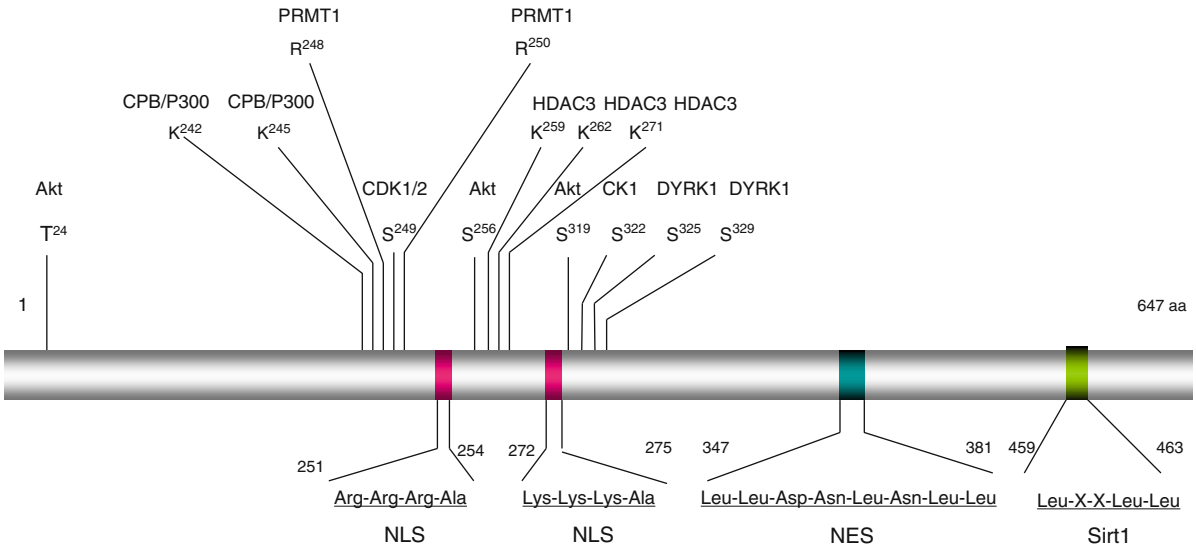
FoxO1 and Insulin Action

FoxO1 is a target of protein kinase B (PKB, also known as Akt) and serum/glucocorticoid-induced kinase (SGK), whose activities are tightly controlled by insulin or IGF-1. Insulin or IGF-1 exerts its inhibitory effect on gene expression via a highly conserved sequence (TG/ATTTT/G), termed insulin response element (IRE) in target promoters (Accili and Arden 2004). In the absence of insulin, FoxO1 resides in the nucleus and binds as a trans-activator to the IRE DNA motif, enhancing promoter activity. In response to insulin, FoxO1 is phosphorylated at three highly conserved phosphorylation sites (Thr24, Ser256, and Ser319) via the PI3K-dependent pathway, resulting in its nuclear exclusion and inhibition of target gene expression (Accili and Arden 2004) (Fig. 1). Three additional phosphorylation sites (S322, S325, and S329) are identified and their phosphorylation by CK1 (casein kinase 1) and DYRK1A (dual-specificity tyrosine-phosphorylated and regulated kinase 1A) seems to accelerate FoxO1 nuclear exclusion (Accili and Arden 2004). The three mammalian homologues of FoxO1, namely, FoxO3, FoxO4, and FoxO6, play redundant and complementary functions in cell survival, differentiation, and metabolism. Except for FoxO6, all members of the FoxO family undergo insulin-dependent phosphorylation and nuclear exclusion. Failure in phosphorylation of FoxO1 results in its permanent nuclear localization and constitutive transactivation of gene expression (Accili and Arden 2004).

Insulin (or IGF-1) inhibition of FoxO1 activity can occur without necessarily altering FoxO1 subcellular redistribution, but this inhibition depends on the ability of FoxO1 to undergo insulin-dependent phosphorylation (Accili and Arden 2004). Phosphorylation distorts FoxO1 DNA binding domain, preventing its cognate binding to target promoters. Consistent with this notion is the presence of both Thr24 and Ser256 phosphorylation sites in its DNA binding domain (Accili and Arden 2004). However, phosphorylation of *C. elegans* ortholog DAF-16 does not affect its DNA binding activity (Accili and Arden 2004). Instead, DAF-16 phosphorylation promotes its association with the multifunctional factor 14-3-3, perturbing DAF-16 binding to target DNA. Likewise, FoxO1 is capable of interacting with 14-3-3 via two consensus sites for 14-3-3 binding (Thr24 and Ser253) (Accili and Arden 2004). A prevailing notion is that 14-3-3 in complex with FoxO1 masks its DNA binding motif and disables its binding to target promoters. In the cytoplasm, 14-3-3 serves as an anchor to sequester FoxO1, precluding its reentry into the nucleus (Accili and Arden 2004).

FoxO1 and Glucose Metabolism

FoxO1 plays a pivotal role in mediating insulin action on gluconeogenesis, a metabolic pathway that



FoxO1, Fig. 1 Schematic depiction of FoxO1 protein. FoxO1 comprises two structural domains, the amino DNA binding and carboxyl trans-activation domains. Localized in the DNA binding domain are two highly conserved basic nuclear localization signals (*NLS*). The first NLS (^{251}Arg–Arg–Arg–Ala^{254}) has been shown to mediate FoxO1 nuclear import, but the function of the second NLS (^{272}Lys–Lys–Lys–Ala^{275}) remains to be determined. The predicted leucine-rich nuclear export signal (*NES*) is located within 374–381 amino acid residues. This region is thought to be associated with nuclear export factors Ran-GTP and Crm-1, promoting FoxO1 nuclear export. A conserved Sirt1 binding site (^{459}Leu-X–X-Leu–Leu^{463}) is located in the carboxyl domain. FoxO1 has six well-characterized phosphorylation sites, three of which (T24, S256, and S319) are phosphorylated in the PI3K-dependent pathway by Akt/PKB and SGK, two of which (S322 and S325) are phosphorylated by casein kinase 1 (CK1) and one site (S329) is phosphorylated by the dual-specificity tyrosine-phosphorylated and regulated kinase (*DYRK*). The acetylation and deacetylation sites are marked along their respective enzymes (CPB/P300 and HDAC3). In addition, FoxO1 contains two sites (Arg248 and Arg250) that are methylated by PRMT1

takes place mainly in liver for the generation of glucose from non-carbohydrate substrates. Gluconeogenesis is controlled by phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G6Pase). PEPCK catalyzes the conversion of oxaloacetate into phosphoenolpyruvate, the rate-limiting step of gluconeogenesis. G6Pase carries out the final step of gluconeogenesis by converting glucose-6-phosphate to glucose. FoxO1 stimulates PEPCK and G6Pase expression via selective binding to the IRE motif in the PEPCK and G6Pase promoters, promoting gluconeogenesis. This effect is enhanced by glucagon and inhibited by insulin (Accili and Arden 2004). FoxO1 gain-of-function is associated with augmented hepatic gluconeogenesis, contributing to fasting hyperglycemia in mice (Matsumoto et al. 2007; Qu et al. 2006). FoxO1 loss-of-function is associated with diminished hepatic gluconeogenesis, resulting in reduced fasting blood glucose levels in mice (Altomonte et al. 2003).

FoxO1-dependent regulation of gluconeogenesis provides an acute mechanism for the liver to adjust the rate of glucose production. In response to postprandial insulin release, hepatic gluconeogenic activity is suppressed to limit glucose production and prevent excessive postprandial blood glucose excursion. In response to fasting, hepatic gluconeogenesis is stimulated, resulting in increased glucose output from liver (Accili and Arden 2004). Such a reciprocal mechanism of hepatic insulin action is crucial for rapid adaptation of liver to metabolic shift between fed and fasting states to maintain blood glucose levels within the physiological range. Consistent with its action in gluconeogenesis, FoxO1 activity in liver is enhanced in response to fasting and is inhibited in fed states (Qu et al. 2006).

FoxO1 and Lipid Metabolism

The role of FoxO1 in lipid metabolism culminates in its ability to mediate insulin action on hepatic expression of microsomal triglyceride transfer protein (MTP)

and apolipoprotein C-III (ApoC-III), two rate-limiting steps in triglyceride metabolism. MTP (MW, 88 kDa) is a molecular chaperone that is responsible for transporting lipid droplets to nascent apolipoprotein B (apoB) for very low-density lipoprotein (VLDL) production in liver (Kamagate et al. 2008). ApoC-III functions as an inhibitor of lipoprotein lipase (LPL) and hepatic lipase (HL), key enzymes in the hydrolysis of triglyceride in VLDL and chylomicrons (Altomonte et al. 2004). MTP deficiency is associated with abnormal production of triglyceride-rich particles, resulting in abetalipoproteinemia or Bassen-Kornzweig syndrome, a rare autosomal recessive disorder in humans (Berriot-Varoqueaux et al. 2000). Elevated ApoC-III levels are associated with impaired clearance of TG-rich particles, leading to the accumulation of TG-rich lipoprotein remnants in plasma (Altomonte et al. 2004). FoxO1 is shown to mediate insulin-dependent regulation of both MTP and ApoC-III production in liver (Altomonte et al. 2004). This effect coincides with the ability of FoxO1 to bind to the IRE motif within both MTP and ApoC-III promoters (Altomonte et al. 2004).

These findings provide important mechanistic insights into the pathophysiology of hypertriglyceridemia, the most common lipid disorder that is characterized by increased production of very low-density lipoprotein (VLDL) and/or decreased clearance of TG-rich particles (VLDL and chylomicrons). Unbridled FoxO1 activity, resulting from insulin resistance, promotes hepatic MTP and ApoC-III overproduction, contributing to increased secretion of VLDL from the liver and decreased clearance of triglyceride-rich particles in plasma. These data have spurred the idea of targeting FoxO1 for improving triglyceride metabolism and ameliorating hypertriglyceridemia in insulin resistant subjects with diabetic dyslipidemia.

FoxO1 and Nonalcoholic Fatty Liver Disease

Qu et al. (2006) show that elevated FoxO1 production in liver is associated with increased intrahepatic fat infiltration. Similar findings are reported by Valenti et al. (2008), who detect an enhanced FoxO1 activity along with increased fat deposition in the liver of patients with nonalcoholic fatty liver disease (NAFLD). To dissect the underlying mechanism, Zhang et al. (2006) show that hepatic lipogenic genes including SREBP-1c, FAS, and ACC are upregulated in transgenic mice expressing a constitutively active FoxO1 allele. These findings are reproduced by two independent studies showing that adenovirus-mediated FoxO1 production results in augmented lipogenesis with concomitant fat accumulation in the liver (Qu et al. 2006; Matsumoto et al. 2006). It appears that unchecked FoxO1 activity contributes to the upregulation of lipogenic gene expression, accounting in part for the development of NAFLD under insulin resistant conditions.

To understand the underlying mechanism, two independent studies show that FoxO1 gain-of-function, resulting from adenovirus-mediated FoxO1 production or transgenic overexpression of its constitutively active allele, is associated with impaired insulin action in liver, accompanied by inappropriately increased hepatic glucose production (Accili and Arden 2004). FoxO1 loss-of-function, caused by hepatic expression of its dominant-negative allele or antisense oligonucleotide-mediated FoxO1 knockdown in liver, is associated with improved insulin action and blood glucose profiles in insulin resistant obese mice (Altomonte et al. 2003). FoxO1 haploinsufficiency protects mice from developing high fat diet-induced insulin resistance and rescues the diabetic phenotype in insulin receptor substrate 2 (IRS2)-deficient diabetic mice (Accili and Arden 2004). Liver-specific FoxO1 knockout results in near normalization of metabolic disorders in insulin resistant mice with both IRS1 and IRS2 depletion in liver (Dong et al. 2008). These results support the notion that FoxO1 is a counter-regulator of insulin signaling in liver, suggesting that aberrant FoxO1 production is deleterious to hepatic insulin signaling, contributing to abnormal metabolism in diabetes.

Insulin Regulation of FoxO1 Activity

FoxO1 is subject to insulin inhibition. Insulin inhibits FoxO1 activity by stimulating its phosphorylation and promoting its trafficking from the nucleus to cytoplasm. Loss of insulin inhibition, due to insulin deficiency or insulin resistance, results in unbridled FoxO1 activity, contributing to the dual pathogenesis of fasting hyperglycemia and hyperlipidemia in diabetes (Matsumoto et al. 2006). Insulin-dependent regulation

of FoxO1 activity provides an acute mechanism for suppressing hepatic glucose and triglyceride production after meals. This mechanism is critical for maintaining blood glucose and lipid levels within the physiological range. Apart from its acute regulation by insulin, FoxO1 is regulated at multiple levels. At the transcriptional level, FoxO1 mRNA expression is induced in response to fasting, correlating with its enhanced activity in augmenting hepatic gluconeogenesis (Qu et al. 2006).

FoxO1 Feedback Regulation

FoxO1 activity is subject to feedback regulation. FoxO1 stimulates the expression of its upstream effector gene encoding insulin receptor (IR), which in turn activates insulin signaling and inhibits FoxO1 activity. To understand the underlying physiology, Kamagate et al. (2010) show that hepatic FoxO1 activity is subject to feedback regulation in an IR- and IRS2-dependent manner. Unchecked FoxO1 activity, resulting from molecular defects in the FoxO1 feedback loop, is deleterious to hepatic metabolism, culminating in unrestrained glycogen breakdown and excessive ER stress in liver. ER is the principal organelle for biosynthesis of proteins and steroids, and VLDL assembly. Perturbation of ER homeostasis such as accumulation of misfolded proteins or altered glycosylation triggers adaptive ER stress (Hotamisligil 2010). Unresolved ER stress results in apoptosis and causes insulin resistance (Hotamisligil 2010). FoxO1 feedback loop is thought to serve as a safeguarding mechanism for keeping FoxO1 activity in check to avert hepatic glycogen depletion and ER stress.

Non-insulin-dependent Regulation of FoxO1 Activity

Aside from its regulation by insulin (or IGF-1), FoxO1 activity is regulated by other signaling molecules, such as cyclin-dependent kinases (CDKs). CDK1 catalyzes FoxO1 phosphorylation at Ser249. This effect disrupts FoxO1 association with 14-3-3 proteins, promoting FoxO1 nuclear retention and augmenting FoxO1-dependent transcription, leading to cellular apoptosis (Yuan et al. 2008). In contrast, CDK2-mediated phosphorylation of FoxO1 at Ser249 promotes its cytoplasmic localization, resulting in inhibition of FoxO1 transcriptional activity (Huang et al. 2006). This effect favors cell survival in response to DNA damage. Further studies are warranted for clarifying the mechanism underlying the opposite effects of CDK1 and CDK2 on FoxO1 activity.

FoxO1 also undergoes phosphorylation by extracellular signal regulated kinase (ERK) and p38, two members of the Mitogen-activated protein kinase (MAPK) family in endothelial cells (Asada et al. 2007). MAPK-mediated phosphorylation of FoxO1 enhances its transcriptional activity in stimulating vascular endothelial growth factor receptor 2 (VEGFR2) in modulating angiogenesis (Asada et al. 2007).

FoxO1 Acetylation and Deacetylation

FoxO1 activity is modulated by acetylation via cAMP response element-binding (CREB)-binding protein (CBP) and/or p300 factor. FoxO1 is acetylated by the intrinsic acetyltransferase activity of p300, resulting in its enhanced trans-activation activity (Perrot and Rechler 2005). In contrast, FoxO1 acetylation at the basic residues (Lys-242, Lys-245, and Lys-262) attenuates FoxO1 activity by inhibiting its ability to bind target DNA (Matsuzaki et al. 2005). Acetylation of FoxO1 at these three residues by CBP appears to enhance its phosphorylation at Ser-253 by Akt/PKB, resulting in inhibition of FoxO1 activity (Matsuzaki et al. 2005). These data reflect diverse effects of acetylation on FoxO1 transcriptional activity.

FoxO proteins are substrates of SIRT1, the mammalian ortholog of the yeast Sir2 deacetylase (Motta et al. 2004). Deacetylation of FoxO proteins modulates their trans-activation activities, which has been viewed as an important mechanism for cells to defend against oxidative stress. FoxO1 contains a consensus site (459-LXXLL-463) within its carboxyl trans-activation domain that is responsible for SIRT1 binding. Mutations in the LXXLL motif (L462A and L463A) disrupt FoxO1 binding to SIRT1 and abolish SIRT1-mediated deacetylation (Nakae et al. 2006).

FoxO1 is also subject to deacetylation by the Class IIa histone deacetylases (HDACs) (Mihaylova et al. 2011). In response to glucagon, HDACs are dephosphorylated and translocated to the nucleus, where HDACs recruits HDAC3 for deacetylating FoxO1 in hepatocytes. This effect enhances FoxO1 activity in promoting hepatic gluconeogenesis during fasting.

FoxO1 Ubiquitination and Degradation

FoxO1, when phosphorylated in response to insulin or IGF-1, is targeted for ubiquitination and proteolytic degradation (Matsuzaki et al. 2003). Efficient ubiquitination depends upon both phosphorylation and cytoplasmic retention. Likewise, FoxO3 undergoes proteosome-mediated degradation in response to Akt signaling. To gain insight into the molecular basis of ubiquitin-mediated FoxO1 degradation, studies show that MDM2 serves as an E3 ligase to promote FoxO1 and FoxO4 ubiquitination (Fu et al. 2009). COP1 also possess E3 ligase activity to stimulate cytosolic FoxO1 ubiquitination and degradation (Kato et al. 2008). FoxO1 ubiquitination serves as a distinct posttranslational mechanism by which insulin (IGF-1) inhibits FoxO1 activity in cells.

FoxO1 Dephosphorylation and Reverse Translocation

Not all phosphorylated FoxO1 proteins are destined for proteosome-mediated degradation in the cytoplasm. There is evidence that cytosolic FoxO1 proteins undergo Sirt1-dependent deacetylation, resulting in FoxO1 reverse translocation to the nucleus in cultured hepatocytes in response to oxidative stress (Accili and Arden 2004). Sirt1 activation promotes FoxO1 nuclear retention and enhances its activity in resveratrol-treated cells. Yan et al. (2008) show that FoxO1 is a substrate of protein phosphatase 2A (PP2A), which dephosphorylates FoxO1 and promotes FoxO1 nuclear localization in cultured lymphoid FL5.12 cells. Inhibition of PP2A protects FoxO1 from dephosphorylation and perturbs FoxO1 nuclear localization (Yan et al. 2008). FoxO1 dephosphorylation and reverse translocation may serve as a fine-tuning mechanism for recycling cytosolic FoxO1 and promoting its reentry to the nucleus for function.

FoxO1 Methylation

FoxO1 methylation constitutes a new paradigm for posttranslational modification of FoxO1 activity. Yamagate et al. (2008) show that FoxO1 is methylated by the protein arginine methyltransferase 1 (PRMT1), a ubiquitous enzyme that catalyzes methylation of terminal nitrogens of guanidinium side chains at arginine residues of target proteins. As PRMT1 methylates FoxO1 at Arg248 and Arg250 within a consensus motif for Akt phosphorylation, the resulting methylation interferes with Akt-mediated phosphorylation of FoxO1 at Ser253. As a result, FoxO1 is confined in the nucleus, accounting for enhanced transcriptional activity. Arginine methylation seems to serve as an antagonistic mechanism for counterbalancing Akt/PKB-mediated phosphorylation of target proteins.

FoxO1 O-Linked Glycosylation

O-linked glycosylation is an enzymatic process by which sugar moieties are added to serine and threonine residues by O-N-acetylglucosamine (O-GlcNAc) transferase. As this action takes place on serines or threonines, residues that are targeted for phosphorylation by serine/threonine kinases, O-linked glycosylation consequently interferes with phosphorylation, resulting in alterations in stability, folding or subcellular distribution of target proteins. There is evidence that FoxO1 undergoes O-linked glycosylation in cultured hepatocytes at high glucose levels. O-linked glycosylation of FoxO1 enhances its transcriptional activity in cultured cells (Housley et al. 2008). These data help explain why FoxO1 activity is enhanced in the liver under hyperglycemic conditions, presaging that inhibiting O-linked glycosylation would reduce FoxO1 activity and alleviate hyperglycemia in diabetes.

Summary

Characterization of FoxO1 signaling has provided important insights into the mechanism by which insulin (or IGF-1) regulates the expression of target genes in cell growth, differentiation, metabolism, oxidative stress, and aging. Ubiquitously expressed, FoxO1 plays important roles in different organs. Due to space limitation, this article focuses on reviewing research progress made in the liver toward delineating the PI3K-Akt-FoxO1 cascade in glucose and lipid metabolism. Insulin signaling through FoxO1 is instrumental for adjusting the rate of hepatic glucose and triglyceride production in response to nutritional cues. FoxO1 is subject to insulin inhibition in liver. Unchecked FoxO1 activity, resulting from insulin

resistance, promotes unrestrained hepatic glucose and triglyceride production. This effect contributes to the dual pathogenesis of hyperglycemia and hypertriglyceridemia. The available preclinical studies support the notion of inhibiting FoxO1 for improving glucose and lipid metabolism in diabetes.

FPR

► Formyl Peptide Receptor

FPR2

▶ FPR2/ALX

FPR2/ALX

Karen Nolan and Catherine Godson
UCD Diabetes Research Centre, UCD Conway Institute, School of Medicine and Medical Sciences, University College Dublin, Dublin, Ireland

Synonyms

ALX; ALXR; FMLP-related receptor II (FMLP-R-II); FMLPX; FPR2; FPR2A; FPRH1; FPRH2; FPRL1; HM63; LXA4R; Receptor related to FPR (RFP)

Historical Background

The FPR2/ALX receptor is a member of the formyl peptide receptor (FPR) superfamily which in humans also includes formyl peptide receptor 1 (FPR1) and formyl peptide receptor 3 (FPR3). Recent interest in this specific receptor reflects its intriguing anti-inflammatory and proresolving bioactions in contrast to other FPR family members (Serhan 2007; Maderna et al. 2010). FPR2/ALX was identified as a specific receptor for lipoxin A_4 (LXA_4) in 1992 (Fiore et al. 1992). Using radiolabeled [11,12-^{3}H]LXA_4 and human polymorphonuclear leukocytes (PMNs) in which LXA_4-mediated action had previously been identified, specific stereoselective binding with a Kd of approximately 0.5 nM was demonstrated. Modulation of [11,12-^{3}H]LXA_4 binding by guanosine analogs indicated that this binding site was a G-protein-coupled receptor (GPCR). Screening of orphan receptors in differentiated HL-60 cells, which displayed specific LXA_4 binding, was carried out in parallel and it identified a GPCR with high affinity for and selective binding by [11,12-^{3}H](6R)-LXA_4. Leukotriene B_4 (LTB_4), lipoxin B_4 (LXB_4), (6S)-LXA_4, or 11-trans-LXA_4 did not compete with LXA_4 for binding of this orphan receptor when expressed in CHO cells, indicating specificity for LXA_4. LXA_4 stimulated GTPase activity and promoted the release of esterified arachidonate in this model system. A pertussis toxin sensitive response further supported the hypothesis that the cDNA encoded a GPCR. The receptor cDNA sequence was found to be ~70% homologous to FPR1 and was thus named formyl peptide receptor-like1 (FPRL1) (for more detail refer to Chiang et al. 2006; Ye et al. 2009). It has also been referred to by a number of other names in the literature (see synonyms). In accordance with the International Union of Basic and Clinical Pharmacology (IUPHAR) nomenclature 2009 (Ye et al. 2009), this receptor is referred as FPR2/ALX in this entry. FPR2/ALX was subsequently identified and cloned in several cell types including monocytes, T cells, synovial fibroblasts, and intestinal epithelial and renal mesangial cells. The gene encoding FPR2/ALX is located at 19q13.3 and is a single copy gene with an intronless open reading frame (for more detail refer to Chiang et al. 2006; Ye et al. 2009). FPR2/ALX is now known to bind endogenous and exogenous proteins and lipid ligands eliciting distinct proinflammatory or anti-inflammatory responses indicating that FPR2/ALX can thus serve as a stereoselective multirecognition receptor in immune responses (Maderna et al. 2010).

FPR2/ALX Expression, Structure, and Agonists

FPR2/ALX is expressed in cells of diverse lineage: myeloid, epithelial, and mesenchymal. Upregulation of FPR2/ALX by proinflammatory cytokines (e.g., tumor necrosis factor-α [▶ TNF-α]) suggests the regulation of the receptor under inflammatory conditions. Additionally, upregulation of FPR2/ALX expression by anti-inflammatory glucocorticoid-stimulated signaling in human PMNs and monocytes as well as murine dermal tissues is thought to contribute to their potent anti-inflammatory effects (Perretti and D'Acquisto 2009).

FPR2/ALX is a 351 amino acid protein, the overall homology between human, mouse, and rat FPR2/ALX is 74% at nucleotide and 65% at the amino acid sequence level. One hundred percent homology across

these species is found in the second intracellular loop, 97% homology in the sixth transmembrane domain (TMD), followed by the second, third, and seventh TMD as well as the first extracellular loop (87–89%). ChemR23 is a GPCR which like FPR2/ALX binds both peptide and lipid ligands and is implicated in anti-inflammatory signal transduction. ChemR23 shares 36.4% overall homology with FPR2/ALX amino acid sequence. It has been suggested that highly conserved domains within the second intracellular loop and the seventh TMD which share 75% and 69.5% identity with FPR2/ALX, respectively, may contribute to their anti-inflammatory and proresolving properties. Such conservation between species and among similar receptors suggests these regions of the receptor play an essential role in ligand recognition and functional G-protein coupling. Studies using chimeric receptors show that the seventh TMD and its adjacent regions are essential for LXA_4 recognition. Ser-236, Ser-237, and Tyr-302 are essential for LXA_4-stimulated FPR2/ALX signaling and a role for conserved glycosylation sites present on Asn-4 and Asn-179 are important for peptide binding (for more detail refer to Chiang et al. 2006). The ability of FPR2/ALX to interact with ligands of diverse structural and chemical nature (i.e., lipid, peptide, protein) is thought to be related to certain properties within its binding pocket, which is large enough to accommodate ligands like the protein Annexin A1 (AnxA1) (~40 kDa), yet flexible enough to contact the smaller peptide ligands like the synthetic proinflammatory peptide WKYMVm. Hydrophobic interactions and possibly multiple ligand-binding sites may also facilitate interaction with both peptide and lipid agonists (for more detail refer to Ye et al. 2009). FPR2/ALX agonists elicit either proinflammatory or anti-inflammatory responses depending on the ligand and cell type. The bacterial peptide *N*-formyl-methionine-leucine-phenylalanine (fMLF) is one of the smallest and most potent formyl peptides and one of the first identified chemotactic peptides. Although FPR2/ALX shows low affinity for fMLF (Kd = 430 nM) compared to FPR1 (Kd = 1 nM), it does show high affinity for mitochondrial derived formyl peptides as well as several *Listeria monocytogenes*–derived formyl peptides (for more detail refer to Ye et al. 2009). It is hypothesized that during inflammation, impaired mitochondrial function results in *N*-formyl peptide secretion which attracts inflammatory cells to the site of tissue damage (Godson et al. 2000). In vitro studies show that a number of mitochondrial *N*-formylated peptides are agonists at FPR2/ALX. Some of these naturally produced peptides interact with FPR2/ALX in the nanomolar to subnanomolar range. FPR2/ALX also shows affinity for nonformylated peptides such as major histocompatibility complex (MHC)–binding peptide, a potent necrotactic peptide derived from mitochondrial NADH dehydrogenase subunit 1, which competes with $[^3H]LXA_4$ for FPR2/ALX binding and stimulates PMN chemotaxis (Chiang et al. 2000).

A number of FPR2/ALX ligands have antimicrobial properties and are stored in human neutorphil granules. LL-37 is expressed by leukocytes and epithelial cells and secreted into wounds and onto the airway surface where it attracts monocytes, neutrophils, and T lymphocytes through FPR2/ALX activation (for more detail refer to Ye et al. 2009). LL-37-stimulated release of proinflammatory LTB_4 from PMNs is inhibited by LXA_4 (Wan et al. 2011). Temporin A, a frog-derived antimicrobial peptide also acts through FPR2/ALX, stimulating monocyte, macrophage, and neutrophil migration. Nonformylated peptides from *Helicobacter pylori* attract monocytes and basophils to the gastric mucosa and those from human immunodeficiency virus-1 (HIV-1) activate phagocytic leukocytes through their agonistic activity at FPR2/ALX (for more detail refer to Ye et al. 2009). Furthermore, FPR2/ALX has been shown to recognize phenol-soluble modulin produced by strains of highly pathogenic *Staphylococcus aureus* and to initiate a proinflammatory neutrophil response (Rautenberg et al. 2011).

Host-derived peptides signaling through FPR2/ALX have been associated with inflammatory and amyloidogenic diseases. Serum amyloid A (SAA) is an acute-phase protein best known for its role in the pathogenesis of inflammatory arthritis. SAA serum concentrations increase dramatically in response to infection, trauma, and other physiological stress and it acts through FPR2/ALX to promote chemotaxis of monocytes, neutrophils, mast cells, and T lymphocytes to the wounded area. SAA is also known to induce matrix metalloproteinase expression in fibroblast-like synoviocytes and monocytes and this activity is mimicked by the proinflammatory peptide and FPR2/ALX agonist WKYMVm (for more detail refer to Ye et al. 2009). $A\beta_{42}$ the 42 amino acid peptide cleavage

product of the β-amyloid peptide, is implicated in the pathology of Alzheimer's disease. FPR2/ALX mediates $A\beta_{42}$-stimulated activation and accumulation of monocytic phagocytes as well as facilitating $A\beta_{42}$ uptake, thus contributing to fibrillar formation (Cui et al. 2002). Humanin is an endogenous neuroprotective peptide which displays increased potency at FPR2/ALX when *N*-formylated. Humanin may competitively inhibit $A\beta_{42}$ at FPR2/ALX. Other proinflammatory FPR2/ALX ligands include truncated chemotactic peptides (e.g., CKβ8-1), a urokinase-type plasminogen activator receptor fragment and prion protein (Ye et al. 2009).

FPR2/ALX ligands which display anti-inflammatory properties are of particular interest. AnxA1 is a glucocorticoid-inducible protein and FPR2/ALX agonist which is expressed by a wide range of immune cells and tissues. Following cellular activation, AnxA1 is mobilized to the cell surface and secreted, where it colocalizes with FPR2/ALX. AnxA1 and AnxA1 peptide derivatives have been shown to inhibit neutrophil adhesion and transmigration through endothelial barriers both in vitro and in vivo. Additionally, increased secretion of the anti-inflammatory cytokine, interleukin-10 (IL-10), in response to AnxA1 exposure has been described (Perretti and D'Acquisto 2009). Endogenous AnxA1 and peptide derivatives are released from apoptotic cells and act on macrophages to promote efferocytosis of apoptotic leukocytes (Scannell et al. 2007). Interestingly, it has been shown that LXA_4 and Antiflammin-2, the FPR2/ALX peptide agonist, which corresponds to the region 246–254 of AnxA1, also provoke FPR2/ALX-dependent mobilization of AnxA1 to the plasma membrane of PMNs (Brancaleone et al. 2011).

LXA_4 was the first identified endogenous ligand described for FPR2/ALX. Unlike the diverse array of peptide ligands for FPR2/ALX discussed so far, lipoxins (LXs) are arachidonate-derived lipid mediators. LXs are generated in vivo within an inflammatory milieu where they possess anti-inflammatory activity as well as the ability to promote the resolution of inflammation. LXA_4 displays multilevel control of processes relevant in acute inflammation via specific and selective actions on multiple cell types through specific receptors (Serhan 2007). Well-established effects of LXA_4 include limiting of leukocyte infiltration, inhibition of neutrophil and eosinophil activation, stimulation of efferocytosis of apoptotic leukocytes by macrophages as well as stimulation of genes which promote inflammatory resolution (reviewed in Maderna and Godson 2009). In vitro studies have shown that LXA_4 inhibits production of proinflammatory cytokines in synovial fibroblasts and intestinal and bronchial epithelial cells (for more detail refer to Ye et al. 2009). Furthermore, LXA_4 stimulates the expression of anti-inflammatory IL-10 in endothelial cells (Baker et al. 2009). More recently, LXA_4 has been shown to have antifibrotic activity in experimental models of lung and kidney fibrosis as will be discussed later (Rodgers et al. 2005; Wu et al. 2006; Martins et al. 2009; Borgeson et al. 2011).

Aspirin-triggered lipoxins (ATLs) such as 15-epi-LXA_4 are generated by the activity of aspirin-acetylated cyclooxygenase-2 (COX-2) and 5-lipoxygenase (5-LO). 15-epi-LXA_4 displays similar activity to native LXA_4 and acts with higher affinity for and potency at FPR2/ALX. Given the rapid metabolic degradation of native LXA_4, several generations of analogs have been synthesized. These include a new class of chemically stable LX analogs featuring replacement of the tetraene unit of native LXA_4 with a substituted benzo-fused ring. These benzo-LXs have also been shown to have potent anti-inflammatory properties that are likely to be mediated through FPR2/ALX (O'Sullivan et al. 2007; Sun et al. 2009).

Recent investigations using mice deficient in the murine homologue of FPR2/ALX have provided important insights into this receptor. In experimental models the animals showed exaggerated inflammatory responses to arthrogenic stimuli (Dufton et al. 2010). Bone marrow–derived macrophages from these mice were unable to phagocytose apoptotic PMNs in response to stimulation with LXA_4 or Ac2-26 (Maderna et al. 2010). These data highlight the role of FPR2/ALX as an anti-inflammatory and proresolution receptor in the context of LXA_4 or AnxA1 stimulation. It is now appreciated that the murine FPR2/ALX homologues targeted in these models may also have deleted Fpr3.

Resolvin D1 (RvD1), like LXA_4, is generated during the resolution phase of inflammation and also displays potent and stereoselective anti-inflammatory actions. Using [^{3}H-RvD1], FPR2/ALX was identified as one of two specific RvD1 recognition sites. RvD1 increased macrophage phagocytosis of apoptotic PMNs and its ability to do so was enhanced by overexpression of FPR2/ALX

and GPR32, the orphan receptor identified to bind RvD1 (Krishnamoorthy et al. 2010).

The potential of computational platform design to identify novel, potent FPR2/ALX agonists with anti-inflammatory and cardioprotective effects has been demonstrated using inflamed air pouch and myocardial ischemia-reperfusion-injury (IRI) in rodent models (Hecht et al. 2009).

Antagonists of the formyl peptide receptor family include t-Boc which was developed by replacing the *N*-formyl group of fMLF with a tertiary butyloxy-carbonyl. Similar antagonists include Boc1 and Boc2 which act at high micromolar concentrations to partially inhibit FPR2/ALX. Selective antagonists for FPR2/ALX like WRWWWW have been identified through screening hexapeptide libraries for the ability to inhibit binding of a synthetic peptide agonist, WKYMVm to FPR2/ALX (for more detail refer to Ye et al. 2009) and as described above FPR2/ALX knockout mice have been developed for in vivo studies (Dufton et al. 2010).

FPR2/ALX Signal Transduction

FPR2/ALX is phosphorylated in response to ligand activation, but as of yet little is known about the kinase(s) involved in the process. Lipid rafts are known to play an important role in receptor coupling to G-proteins and FPR2/ALX signaling is sensitive to cholesterol depletion in PMNs. Although the current understanding of the downstream signaling following FPR2/ALX activation remains incomplete, it does appear that the nature of signaling elicited is dependent on the ligand concentration and cell type in which FPR2/ALX is activated (for more detail refer to Chiang et al. 2006; Ye et al. 2009).

Proinflammatory responses mediated by FPR2/ALX include the activation of nuclear factor-κB (► NF-κB) by SAA in human neutrophils resulting in interleukin-8 (IL-8) secretion (He et al. 2003). SAA induces neutrophil Ca^{2+} mobilization and activation of ERK1/2 and p38. SAA also promotes the survival of neutrophils by delaying apoptosis. The underlying mechanism is thought to involve SAA activation of ERK1/2 and Akt which in turn leads to downstream phosphorylation events which regulate apoptosis (El Kebir et al. 2008).

The signaling pathways involved in the anti-inflammatory and proresolving effects of FPR2/ALX agonists are of great interest. LXA_4 and ATLs suppress the expression of neutrophil and endothelial adhesion molecules and thus attenuate adhesion and the production of proinflammatory cytokines through modulation of MAPK signaling, superoxide generation, and ► NF-κB activity (Filep et al. 2005). LXA_4 stimulates the non-phlogistic uptake of apoptotic PMNs by monocyte-derived macrophages (Godson et al. 2000; Mitchell et al. 2002) by a process coupled to Rho- and Rac-dependent cytoskeletal rearrangement (Maderna et al. 2002). In human enterocytes, ATL analogs downregulate *Salmonella typhimurium*–induced gene expression (Gewirtz et al. 1998). A subset of these genes are known to be regulated by the transcription factor ► NF-κB through a FPR2-/ALX-dependent mechanism (for more detail refer to Chiang et al. 2006). LXA_4 and ATLs attenuate nuclear accumulation of ► NF-κB and AP-1 transcription factors in human leukocytes thus inhibiting LPS-induced IL-8 secretion. Mesangial cell proliferation is a feature of glomerular inflammation and LXA_4 inhibits LTD_4-stimulated mesangial proliferation (McMahon et al. 2000). The underlying mechanisms involve LXA_4's inhibition of LTD_4-stimulated platelet-derived growth factor (PDGF) receptor transactivation (McMahon et al. 2002). LXA_4 and Ac2-26 attenuated PDGFRβ phosphorylation but did not alter the receptor tyrosine kinase activity, suggesting the involvement of protein tyrosine phosphatases. Using cells stably transfected with FRP2/ALX, transient transfection with PDGFRβ and stimulation with PDGF-BB resulted in a decrease in PDGFRβ phosphorylation compared to control cells. These data confirmed that the reduced phosphorylation was FPR2/ALX dependent. LXA_4 was shown to promote SHP-2-mediated dephosphorylation of PDGFRβ. Site-directed mutagenesis of the cytoplasmic domain of PDGFRβ indicated the importance of the binding site of the p85 subunit of ► PI3K in LXA_4-mediated transinactivation of the receptor (Mitchell et al. 2007). LXA_4 has also been shown to inhibit epidermal growth factor (EGF) receptor and vascular endothelial growth factor (VEGF) receptor 2 activation (Baker et al. 2009). These studies highlighted the complex cross talk between GPCRs and receptor tyrosine kinases in an inflammatory milieu and suggested a protective role for LXA_4 in renal inflammation and

fibrosis in which activation of the PDGFRβ is known to play a pathological role (Mitchell et al. 2007). Additionally LXA_4 inhibits TNF-α induced mesangial cell proliferation (Wu et al. 2005).

The best characterized mechanism of FPR2/ALX internalization is described following stimulation with a synthetic proinflammatory peptide agonist WKYMVm and results in lipid raft–dependent, clathrin-mediated FPR2/ALX endocytosis. However it has recently been shown that when stimulated with anti-inflammatory ligands, FPR2/ALX colocalizes with caveolin-1 and flotillin-1 but not clathrin and that internalization of FPR2/ALX is required for LXA_4 and Ac2-26 stimulated macrophage phagocytic activity and is dependent on PKC (for more detail refer to Ye et al. 2009; Maderna et al. 2010).

FPR2/ALX: Anti-inflammatory, Proresolution, and Therapeutic Potential

As outlined, FPR2/ALX agonists have been shown to modulate specific actions of cells involved in immune-inflammatory responses and thus FPR2/ALX has been proposed as a target for therapeutic intervention. Several experimental models of disease further support this idea.

Transgenic mice with myeloid-selective expression of human FPR2/ALX (generated by DNA injection of 3.8 kb transgene consisting of full-length human FPR2/ALX cDNA driven by a fragment of human CD11b promoter) were challenged via dermal ear skin with proinflammatory LTB_4 and prostaglandin E_2 (PGE_2). The FPR2/ALX transgenic mice showed a significant reduction in neutrophil infiltration compared to nontransgenic littermate controls. In a model of zymosan-induced peritonitis, transgenic mice exhibited a reduced level of neutrophil infiltration and increased sensitivity to i.v. administration of 15-epi-LXA_4 (Devchand et al. 2003).

The potential of LXA_4 as a therapeutic mediator has been demonstrated in numerous animal models including a variety of renal injury models, inflammatory skin conditions, inflammatory intestinal disorders, lung injury, and asthma. Of particular interest in the context of Alzheimer's disease, LXA_4 has been shown to attenuate $A\beta_{42}$-induced expression of proinflammatory cytokines, interleukin-1β (IL-1β) and ▶ TNFα, to inhibit the degradation of IκBα and the translocation of ▶ NF-κB p65 subunit into the nucleus in the cortex and hippocampus of mice (Wu et al. 2011). An orally stable LX analog ZK-192 has been shown to have antiinflammatory activity in vivo (Guilford et al. 2004). The chronic perpetuation of an inflammatory response can result in fibrosis and eventual organ failure. The antifibrotic actions of LXA_4 and a synthetic-LX analog have been demonstrated in a murine model of early renal fibrosis. LXs attenuated collagen deposition and renal apoptosis and shifted the inflammatory cytokine milieu toward resolution by inhibiting ▶ TNF-α and IFN-γ expression, while stimulating proresolving IL-10. LXs attenuated unilateral ureteric obstruction–induced activation of ▶ MAP kinases, Akt, and Smads in injured kidneys. Further analysis suggests that renal fibroblast responses to TGF-β_1 may be among the targets of LXA_4 in this context (Borgeson et al. 2011). Furthermore, the antifibrotic activity of an ATL analog has been demonstrated in bleomycin-induced lung injury (Martins et al. 2009).

In murine models of IRI, FPR2/ALX ligands have been shown to have protective effects. Hundred microgram of Ac2-26, 30 min prior to renal artery clamping was shown to be effective at preventing loss of glomerular filtration rate and decreases in urinary osmolarity as well as protecting against the development of acute tubular necrosis, preventing neutrophil extravasation, and attenuating macrophage infiltration as well as affording structural protection against IRI. In vitro ischemia-reperfusion studies using isolated proximal tubules from control mice with no inflammatory cell influence showed that Ac2-26 protected against IRI. It has been proposed that this indicates that the protective effects are directly related to the intracellular actions of this peptide in tubular epithelial cells and suggest an important role for AnxA1 in renal epithelial cell defense against IRI (Facio et al. 2011). Analogous to findings with Ac2-26, a synthetic analog of 15-epi-LXA_4, 15-epi-16-(para-fluorophenoxy)-LXA_4-methyl ester was shown to be protective against murine renal IRI (Leonard et al. 2002).

Compound 43, a nitrosylated pyrazolone derivative, was identified as a FPR2/ALX agonist in a high-throughput compound library screen. It was found to inhibit PMN migration and to have good solubility characteristics and bioavailability following i.v.

administration to rats. In a murine model of prostaglandin E_2 and LTB_4 induced ear inflammation, oral administration of Compound 43 (50 mg/kg) 1 h before induction of inflammation afforded protection from edema which was comparable to established therapy (i.e., dexamethasone,1 mg/kg i.v.) (Burli et al. 2006).

Together, these in vivo studies using a number of molecules known to be FPR2/ALX agonists make a convincing argument for targeting this receptor for therapeutic purposes in a diverse range of inflammatory conditions. The development of stable and potent FPR2/ALX agonists makes it an even more attractive target. Recent developments have shown that human PMN-derived microparticles contain precursors for proresolving lipid mediator biosynthesis and display anti-inflammatory properties via FPR2/ALX. Using microparticle scaffolds, nanoparticles containing aspirin-triggered RvD1 or a stable analog of LXA_4, *o*-[9,12]-benzo-ω6-epi-LXA_4 have been developed. These enriched nanoparticles dramatically reduce PMN influx in murine zymosan–induced peritonitis, accelerate keratinocyte wound healing, and protect against inflammation in the temporomandibular joint (Norling et al. 2011).

Summary

Since its identification in 1992, FPR2/ALX has been shown to be a receptor with the ability to interact with a diverse array of ligands and to transduce signals which elicit completely contrasting physiological responses, which are either proinflammatory or anti-inflammatory in nature. Precise mechanisms through which differential responses are mediated remain incompletely understood. Yet this promiscuous receptor continues to attract research interest as a possible therapeutic target. Future studies will reveal the true potential of FPR2/ALX in anti-inflammatory and proresolving circuits where its modulation may help restore tissue homeostasis and prevent fibrosis, the common, progressive pathologic feature of numerous inflammatory conditions.

Historical Background

Dynamic reorganization of the actin cytoskeleton is essential for many cellular activities, such as cell shape changes, cell migration, cell adhesion, and cytokinesis. The Rho family small GTP-binding proteins (G proteins), including Cdc42, Rac, and Rho, regulate these actin cytoskeleton-dependent cellular activities (Takai et al. 2001; Hall 2005). In fibroblasts such as NIH 3T3 and Swiss 3T3 cells, Cdc42 regulates the formation of filopodia; Rac regulates the formation of lamellipodia and ruffles; and Rho regulates the formation of stress fibers and focal adhesions. Cdc42 and Rac activate the Arp2/3 complex through their respective target proteins, Wiskott-Aldrich syndrome protein (WASP)/neural (N-) WASP and WASP-family verprolin-homologous protein (WAVE) (Takenawa and Suetsugu 2007). The Arp2/3 complex interacts with the sides of preexisting actin filaments (F-actin) to promote actin polymerization and generate a branched F-actin network. Rho promotes actin polymerization through two distinct targets, p160 and mDia (Hall 2005). In addition to these actin cytoskeleton-dependent activities, the Rho family small G proteins regulate other cellular activities, such as the c-Jun N-terminal kinase (JNK) and p38 mitogen-activated protein kinase (p38 MAPK) cascade, an NADPH oxidase enzyme complex and the transcription factor ▶ NF-κB (Hall 2005).

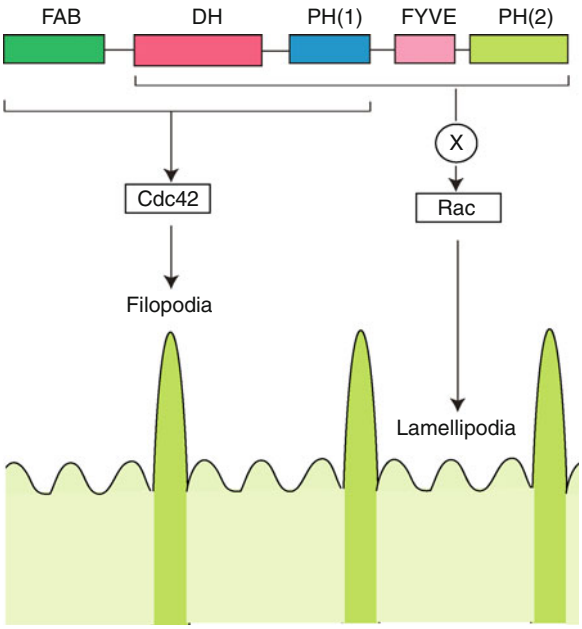
The Rho family members cycle between the GDP-bound inactive and GTP-bound active forms (Takai et al. 2001; Hall 2005). This cycling is tightly controlled by three types of regulators: guanine nucleotide exchange factors (GEFs) that stimulate conversion from the GDP-bound form to the GTP-bound form; GDP dissociation inhibitors that inhibit this reaction; and GTPase activating proteins that stimulate conversion from the GTP-bound form to the GDP-bound form. Most GEFs for the Rho family members share two conserved domains: a Dbl homology (DH) domain of about 250 amino acids, for which the Dbl oncogene product is the prototype, and a pleckstrin homology (PH) domain of about 100 amino acids. Many GEFs for the Rho family members were originally identified as oncogenes (Takai et al. 2001; Hall 2005), but FGD1, which encodes a GEF specific to Cdc42, was discovered by positional cloning to be the gene responsible for faciogenital dysplasia (FGDY) (Pasteris et al. 1994). FGD1 homologues were subsequently identified: FGD2, FGD3, FGD5, and FGD6 were identified by genetic searches; in contrast, frabin/FGD4 was identified by protein purification as an F-actin-binding protein (Obaishi et al. 1998; Nakanishi and Takai 2008).

Molecular Structure, Tissue Distribution, and Splicing Variants

Frabin/FGD4 possesses a domain organization similar to those of FGD1, FGD2, FGD3, FGD5, and FGD6, and these molecules constitute a family of GEFs; however, each FGD has a unique N-terminal region (Nakanishi and Takai 2008). Frabin has an F-actin-binding (FAB) domain at the N-terminal region (Fig. 1). Following the FAB domain, a DH domain, a first PH domain adjacent to the DH domain, a FYVE domain, and a second PH domain are located in order from the N-terminus to the C-terminus. The FAB domain binds along the sides of F-actin (Obaishi et al. 1998). Full-length frabin causes F-actin to associate into bundles, while the FAB domain alone does not show the bundling activity in a cell-free assay system. It is likely that frabin forms an oligomer with multiple FAB domains, and thereby shows F-actin-bundling activity.

DH domains encode a principal GEF catalytic unit and are required to stimulate GDP release from the Rho family small G proteins (Takai et al. 2001; Hall 2005). PH domains not only serve to target cellular membranes by binding to phosphoinositides, but also participate in the binding of small G proteins to facilitate guanine nucleotide exchange reactions (Rossman et al. 2002; Lemmon 2004). The amino acid sequence of the DH domain and the first PH domain of frabin shows significant homology to those of FGD1, FGD2, FGD3, FGD5, and FGD6 (Nakanishi and Takai 2008). A fragment of frabin containing the DH domain and the first PH domain stimulates the guanine nucleotide exchange reaction of Cdc42 in a cell-free assay system (Umikawa et al. 1999). This GEF activity is specific to Cdc42. The frabin fragment does not show the GEF activity toward Rho or Rac.

FYVE domains have been found in many proteins involved in membrane trafficking and phosphoinositide metabolism, and have been shown to specifically interact with one of phosphoinositides, phosphatidylinositol 3-phosphate (PI3P) (Kutateladze 2006). PI3P is found on the limiting membrane domain of early endosomes. However, frabin as well as FGD1 possesses an atypical FYVE domain, which recognizes not only PI3P but also another phosphoinositide, phosphatidylinositol 5-phosphate (PI5P) (Sankaran et al. 2001). PI5P is proposed to be present on late endosomes and at the plasma membrane (Lecompte et al. 2008). It is, therefore, likely that the two PH and FYVE domains of frabin serve to target to specific membrane domains or structures by binding to phosphoinositides.



Frabin, Fig. 1 Domain organization and roles of the domains. Frabin consists of an FAB domain, a DH domain, a first PH [PH(1)] domain, an FYVE domain, and a second PH [PH(2)] domain from the N-terminus and to the C-terminus. The N-terminal region of frabin containing the FAB domain, the DH domain, and the first PH domain induces the formation of filopodia through the direct activation of Cdc42. The C-terminal region of frabin containing the DH domain, the first PH domain, the FYVE domain and the second PH domain induces the formation of lamellipodia through the indirect activation of Rac

Rat frabin is expressed in all the tissues, including heart, brain, spleen, lung, liver, skeletal muscle, kidney, and testis (Umikawa et al. 1999). In cultured rat hippocampal neurons, frabin is highly concentrated at filopodia in growth cones. Mouse frabin has two smaller splicing variants (Ikeda et al. 2001a). The original biggest, middle, and smallest variants are named frabin-α, -β and -γ, respectively. Frabin-β lacks the second PH domain, whereas frabin-γ lacks the FYVE domain and the second PH domain. These three splicing variants are expressed in all the tissues, but their expression levels differ among tissues. In this entry, unless otherwise indicated, frabin represents the α form. Human frabin has other splicing variants, one of which is deprived of the FAB domain (Delague et al. 2007). The splicing variants of frabin induce partly

different morphological changes, suggesting that the variants may have different physiological functions (Ikeda et al. 2001a).

Role of Domains in Cellular Activities

In fibroblasts, exogenous expression of full-length frabin induces the formation of filopodia and the activation of JNK through the activation of Cdc42 (Obaishi et al. 1998; Umikawa et al. 1999; Ono et al. 2000). The DH domain and the first PH domain are sufficient for the activation of Cdc42 in a cell-free assay system, but these two domains alone do not induce the formation of filopodia or the activation of JNK in fibroblasts (Obaishi et al. 1998; Umikawa et al. 1999). The FAB domain is additionally required for the formation of filopodia, suggesting that the association of frabin with the actin cytoskeleton is necessary for the formation of filopodia (Fig. 1). The FAB domain is recruited to the constitutively active mutant (CA) of Cdc42-formed filopodia, but not to Rho CA-formed stress fibers (Kim et al. 2002). Furthermore, co-expression of this domain inhibits the formation of filopodia induced by full-length frabin. It is likely that the FAB domain competes with full-length frabin for the association with a specific actin structure (s), and thereby inhibits the formation of filopodia.

Expression of frabin induces the formation of not only filopodia, but also lamellipodia, in fibroblasts (Ono et al. 2000) (Fig. 1). This morphological change is inhibited by a dominant-negative mutant (DN) of Rac, indicating that the formation of lamellipodia is mediated by the activation of Rac. The FYVE domain and the second PH domain, in addition to the DH domain and the first PH domain, are necessary for the formation of lamellipodia and the activation of JNK, suggesting that the association of frabin with membranes is required for these activities (Umikawa et al. 1999; Ono et al. 2000) (Fig. 1). Expression of the fragment containing the mutated DH, first PH, FYVE, and second PH domains inhibits the formation of membrane ruffles induced by full-length frabin; however, expression of shorter fragments, such as the FYVE domain alone, does not result in this inhibitory action. The mutated DH domain is constructed to lack the GEF activity. It is, therefore, likely that this fragment, containing the DH, first PH, FYVE, and second PH domains, competes with full-length frabin for the association with a specific membrane structure(s). The highly ordered structure of this fragment may be required for its interaction with the specific membrane structure(s), because shorter fragments, such as the FYVE domain alone, do not show a DN effect.

In epithelial cells, such as MDCK cells, frabin induces the formation of microspikes at the basal area of the lateral membrane through the activation of both Cdc42 and Rac, although Cdc42 CA alone, Rac CA alone, or both do not induce the formation of microspikes (Yasuda et al. 2000). However, microspikes are formed when Cdc42 CA is co-expressed with a fragment of frabin minimally including the FAB domain and a mutated DH domain, which lacks the GEF activity (Ikeda et al. 2001b). These data suggest that the region containing the FAB and DH domains directly reorganizes the actin cytoskeleton in a Cdc42-independent manner, and that both the Cdc42-GEF and F-actin-modulating activities of frabin are required for the generation of microspikes in MDCK cells.

Possible Mode of Action in Morphological Changes

A model for the mode of action of frabin in the formation of filopodia and lamellipodia is proposed as follows: initially, frabin is targeted to a preexisting specific actin structure through the FAB domain. Once recruited, frabin reorganizes the actin cytoskeleton through the action of its N-terminal region, including the FAB domain and the DH domain, in a Cdc42-independent manner. In addition, frabin activates Cdc42 through the DH domain and the first PH domain in the vicinity of the actin structure(s), resulting in the WASP/N-WASP-induced generation of branched F-actin. The F-actin-bundling activity of frabin may contribute to the formation of bundled F-actin in filopodia. Furthermore, Cdc42 stimulates actin polymerization via mDia2 (Hall 2005). The cooperation of Cdc42-independent and Cdc42-dependent actin reorganization finally induces the formation of filopodia. This newly formed actin structure further recruits frabin in a positive feedback cycle to lengthen the filopodia. Frabin is also recruited to a specific membrane structure(s) through the region including the DH domain, the first PH domain, the FYVE domain, and the second PH domain (Kim et al. 2002). Frabin activates Rac in the vicinity of

membrane structure(s), resulting in the WAVE-induced generation of branched F-actin. WAVE furthermore induces outward membrane protrusion at the plasma membrane (Takenawa and Suetsugu 2007). The synergistic reorganization of the actin cytoskeleton and the plasma membrane finally induces the formation of lamellipodia.

Involvement in Human Diseases

Many pathogen microbes, including viruses, bacteria, and parasites, utilize the host-cell actin cytoskeleton for multiple actions, such as attachment, entry into cells, and movement within and between cells (Gruenheid and Finlay 2003). *Cryptosporidium parvum*, an intracellular parasite, is one of the most commonly reported enteric pathogens worldwide. Frabin was shown to mediate the cellular invasion of this parasite (Chen et al. 2004). *C. parvum* recruits ▶ phosphoinositide 3-kinase to the host cell–parasite interface, an event that then results in the recruitment of frabin, leading to the activation of Cdc42 and subsequent host-cell actin reorganization during cellular invasion.

Mutations in human frabin have been identified to be responsible for the Charcot–Marie–Tooth (CMT) disorder Type 4H (Delague et al. 2007; Stendel et al. 2007). CMT disorders are clinically and genetically heterogeneous hereditary motor and sensory neuropathies characterized by muscle weakness and wasting, foot and hand deformities, and electrophysiological changes. The CMT4H subtype is an autosomal recessive demyelinating form of CMT disorder. Patients show early disease onset, but slowly progressive sensorimotor neuropathy. Nerve biopsy specimens display a severe loss of myelinated fibers, thinly myelinated axons, and outfolding of myelin sheaths. These data indicate that frabin plays an important role in the proper myelination of the peripheral nervous system.

Summary

Frabin/FGD4, together with at least FGD1, FGD2, FGD3, FGD5, and FGD6, is a member of a family of Cdc42-specific GEFs. Frabin consist of FAB, DH, first PH, FYVE, and second PH domains, in order, from the N-terminus to the C-terminus. Frabin associates with specific actin and membrane structures and activates Cdc42 and Rac in the vicinity of these structures, resulting in the reorganization of the actin cytoskeleton coupled with membrane dynamics. Thus, it has been shown how frabin induces cell shape changes. However, important questions still remain to be solved: (1) how external stimuli and intracellular signals induce the activation of frabin; (2) the physiological significance of a variety of splicing variants; (3) how frabin induces the activation of Rac; and (4) how frabin regulates myelination. Solving these questions will lead to a better understanding of the modes of action and activation of frabin.

FRS2

Noriko Gotoh
Institute of Medical Science, The University of Tokyo, Minato-ku, Tokyo, Japan

Synonyms

FRS2 family members: FRS2α; FRS2β; FRS3; suc 1-associated neurotrophic factor target (SNT-1); suc 1-associated neurotrophic factor target (SNT-2)

Historical Background

FRS2 stands for fibroblast growth factor (FGF) receptor substrate 2. The FGF receptor substrate 1 is phospholipase (PLC) γ, which was identified as the first substrate of FGF receptor tyrosine kinases (Gotoh et al. 2004). Historically, SNT was identified as a protein that is tyrosine phosphorylated in response to nerve growth factor (NGF) or ▶ FGF in PC12 cells and can bind to $p13^{suc1}$, a yeast cyclin–dependent kinase binding protein, immobilized on agarose (Rabin et al. 1993). It was reported that there is a good correlation between the tyrosine phosphorylation of SNT and differentiation of PC12 cells. Then FRS2 was purified and cloned as a novel protein that is tyrosine phosphorylated in NIH3T3 cells in response to FGF (Kouhara et al. 1997). It turned out to be the same protein as SNT. Another protein that has homology with FRS2 was found in one of the expression sequence tag (EST) fragments. After the full-length cDNA of this protein was cloned, it was named as FRS2β and the original FRS2 was renamed as FRS2α {Gotoh, 2004 #1}. Other groups also identified this protein and named it SNT-2 or FRS3 (Xu et al. 1998; McDougall et al. 2001).

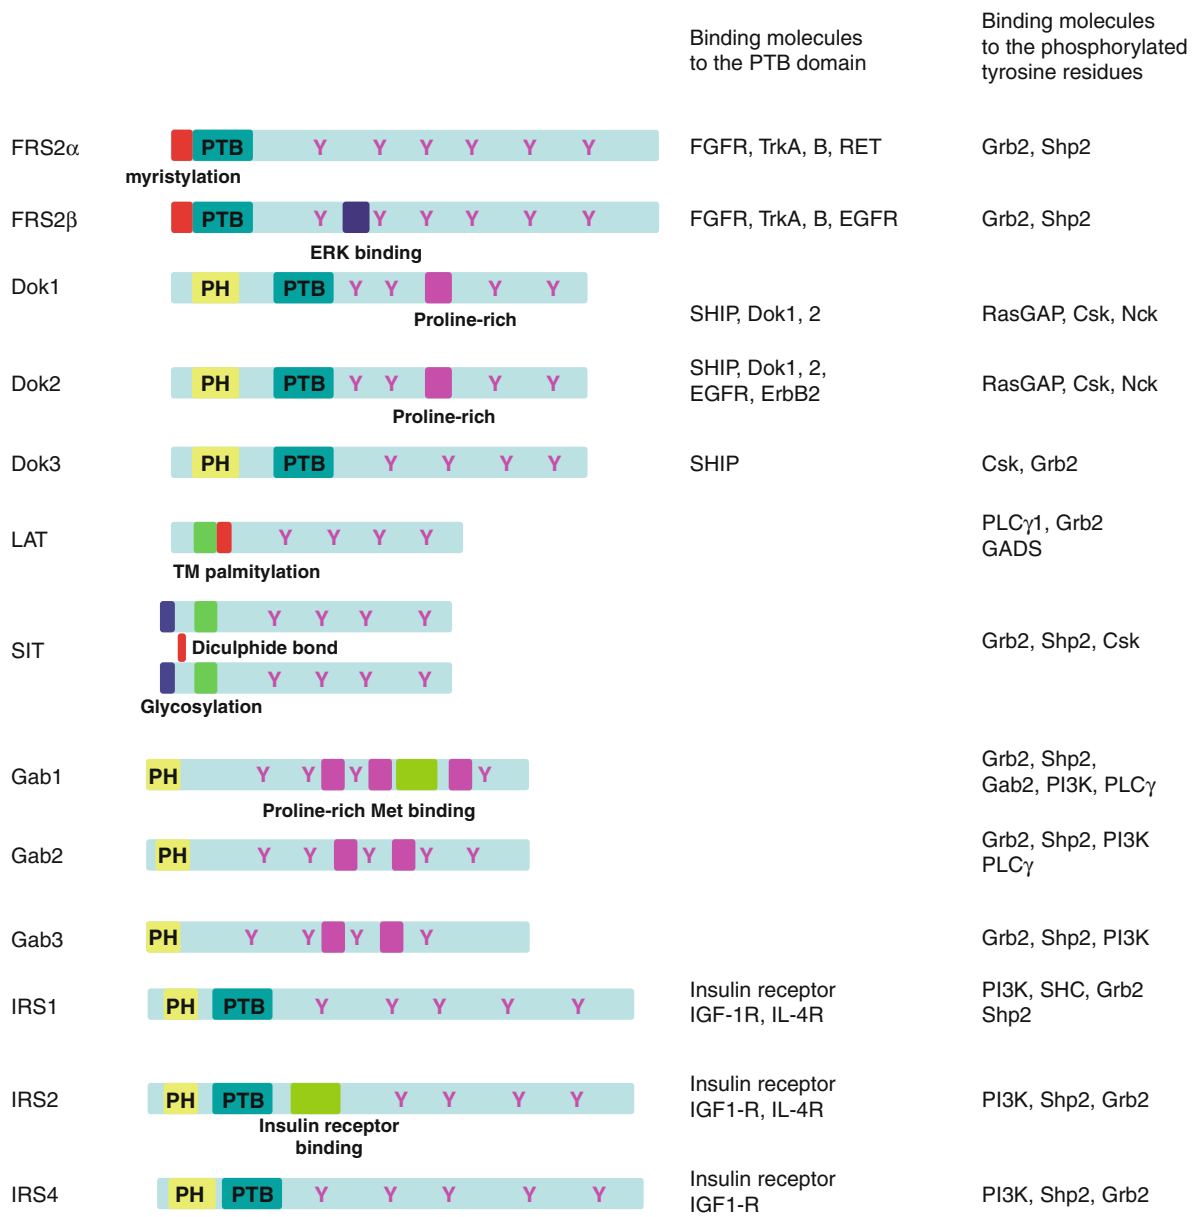
FRS2 Family Proteins Belong to a Group of Membrane-Linked Docking/Adaptor Proteins (MLDP)

Signal transduction pathways through receptor tyrosine kinases (RTKs) play pivotal roles in a number of aspects of physiological and pathological biology including cancer (Lemmon and Schlessinger 2010). Ample amounts of evidence indicate that proteins lacking catalytic activity, so-called scaffolding adaptor proteins, relay many key events of signal transduction from upstream components such as receptors to downstream elements (Pawson 2007). The scaffolding adaptor proteins that are upstream of RTK signal transduction are classified into two groups. One is comprised of docking proteins that have multiple tyrosine phosphorylation sites to dock downstream signaling proteins. They also often have other domains to bind other molecules. This group includes FRS2-, a new SH2-containing sequence (Shc), Grb2-associated binder (Gab)-, insulin receptor substrate (IRS)-, downstream of kinase (Dok)-family proteins-, and transmembrane adaptor proteins (TRAP). Several proteins in this group are subdivided into a group of membrane-linked docking protein (MLDP) (Fig. 1) (Gotoh and Tsuchida 2008). MLDP is localized in the lipid component of plasma membrane, since the protein contains membrane-anchor domain of a stretch of hydrophobic amino acid residues, pleckstrin homology (PH) domain, or transmembrane domain at or close to N-terminus. The other is comprised of adaptor proteins in a narrow sense. They have only SH3 or/and SH2 domains to bind signaling proteins. This group includes Grb2, Crk, and Nck.

Some of the scaffolding adaptor proteins have phosphotyrosine binding (PTB) domain or Src homology (SH)2 domain to bind specific residues containing a tyrosine residue that becomes phosphorylated by activated RTKs or other tyrosine kinases. All the scaffolding adaptor proteins act in the specification and/or amplification of the signal transduction pathway. Since these scaffolding proteins were first discovered almost two decades ago, signal transduction pathways have emerged as a very complex network. FRS2 proteins are typical scaffolding adaptor proteins.

Domain Structure of FRS2 Proteins

FRS2α and FRS2β are similar in structure. Both proteins contain amino acid residues MGSCCS, a consensus myristylation sequence (MGXXXS/T), at the N-terminus for binding to lipids in the membrane structure, including plasma membrane, constitutively (Fig. 2). Each has a PTB domain and multiple tyrosine phosphorylation sites at the C-terminus. FRS2α has six tyrosine phosphorylation sites and FRS2β has five. The PTB domains are highly homologous and 72% of

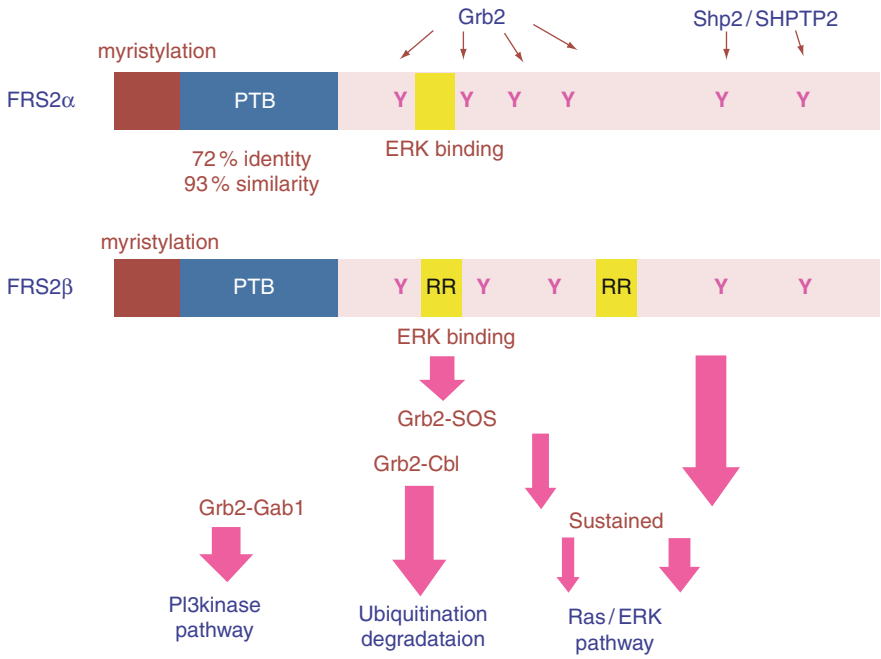


FRS2, Fig. 1 Model of signaling through membrane-linked docking protein (MLDP). Schematic structure of several members of MLDPs. The phosphotyrosine binding domain (PTB) binds to phosphrylated tyrosine residues on receptors or signaling proteins. The pleckstrin homology (PH) domain binds to phospholipids such as phosphatidyl inositol (PI)-3 phosphate. The proline-rich domains are important for binding to SH3 containing proteins such as Src family tyrosine kinases or Grb2. Y designates potential tyrosine (Y) phosphorylation sites. The ERK binding domain in FRS2β, Met binding domain in Gab1, or insulin receptor binding domain in IRS2 contains a unique sequence for binding to ERK, Met or insuling receptor

amino acids are identical. The residues surrounding each tyrosine phosphorylation site are similar but more than ten amino acids from the sites there is no similarity. Both proteins have binding sites for ERK; arginine residues (R) are critical for ERK binding to FRS2β.

Molecular Functions of FRS2α

FRS2α proteins act as docking proteins downstream in certain types of RTKs, including FGF receptors (FGFR)s, neurotrophin receptors (TrkA, TrkB, TrkC), Eph (EphA4), RET, and ALK (Gotoh 2008). In particular, emerging evidence indicates that FRS2α



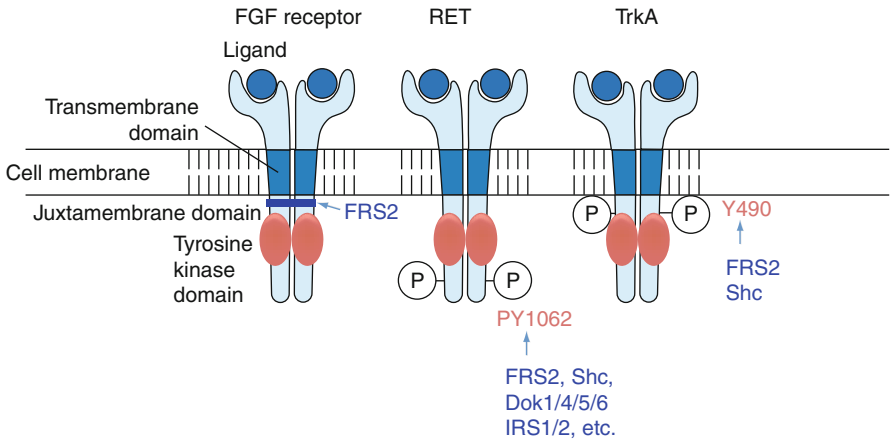
FRS2, Fig. 2 Schematic structures of FRS2 family proteins. The PTB domains of FRS2α and FRS2β have 72% identity and 93% similarity in amino acids. Tyrosine-phosphorylated Grb2 binding sites activate Ras/ERK, ubiquination/degradation, and PI-3 kinase pathways. Tyrosine-phosphorylated Shp2 binding sites activate Ras/ERK pathway stronger than the Grb2 binding site. Arginine residues (R) in the ERK binding domain of FRS2β are essetinal for binding to ERK

acts as a central mediator for intracellular signaling in response to FGF, as described in detail below. FRS2α proteins bind to these RTKs via the PTB domain and become phosphorylated on tyrosine residues upon activation of these RTKs. In contrast, FRS2α proteins are not good substrates for other RTKs, insulin receptors, platelet-derived growth factor receptors, epidermal growth factor receptors (EGFR), and so on. Selectivity, in that FRS2α proteins choose only some tyrosine kinases for phosphorylation, is characteristic of this protein family.

The PTB domain is able to bind to specific peptides with or without tyrosine-phosphorylated residues. FRS2 proteins bind to non-phosphorylated peptides at the juxtamembrane domain of the FGFR via their PTB domains independently on ligand binding and receptor activation (Fig. 3). In contrast, binding between the PTB domain of FRS2α, TrkA and TrkB, or RET is mediated by tyrosine-phosphorylated peptides that have NPXY motif (X is any amino acid reside and Y is phosphorylated) in the receptors and is dependent on activation of the RTKs.

Molecular functions of FRS2α are well studied in FGF signaling (Fig. 2) (Lemmon and Schlessinger 2010; Gotoh 2008; Eswarakumar et al. 2005). When FGFR is activated, FRS2α becomes tyrosine phosphorylated and creates two specific binding sites for Shp2, the SH2-containing tyrosine phosphatase, and four binding sites for the SH2 domain of Grb2. Several proteins are constitutively bound via two SH3 domains of Grb2: SOS, Cbl and Gab1. SOS is a guanine nucleotide exchange factor for Ras, and FRS2α-mediated recruitment of Grb2-SOS induces activation of the Ras/extracellular signal-regulated kinase (ERK) pathway. Cbl functions as an E3 ubiquitin ligase and the ternary complex FRS2α-Grb2-Cbl results in ubiquitination and degradation of FRS2α and its receptors. This is one of the negative feedback mechanisms of FGF signaling. The ternary complex FRS2α-Grb2-▶ Gab1 enables tyrosine phosphorylation of Gab1 followed by recruitment of phosphatidyl inositol (PI)-3 kinase and activation of a cell survival pathway. SOS binds to the N-terminal SH3 domain of Grb2, Gab1 binds to the C-terminal SH3 domain of Grb2, and Cbl binds to both N- and C-terminal SH3 domains of Grb2. Thus, FRS2α assembles both positive and negative signaling proteins to mediate a balanced signal transduction through Grb2. The FRS2α-Shp2 complex induces tyrosine phosphorylation of Shp2 followed by strong activation of ERK in response to FGF. Tyrosine-phosphorylated Shp2 activates its own tyrosine phosphatase, resulting in strong activation of the Ras/ERK pathway in numerous cell contexts. The Grb2-binding sites of FRS2α activate ERK at more moderate levels.

Signaling pathways activated through Trks and RET downstream of FRS2α upon activation of these



FRS2, Fig. 3 Binding sites of FRS2 proteins in RTKs. FRS2 binds to unphosphorylated peptides in the juxamembrane domain of FGF receptor. It binds to tyrosine-phosphorylated peptides in RET and TrkA and the binding sites are shared with those of other PTB domain-containing signaling proteins

RTKs appear to be similar to FGF signaling. Tyrosine phosphorylation of FRS2α is also induced by the activation of EphA4. FGFRs and EphA4 form complex proteins by direct interactions between the juxtamembrane domain of FGFRs and the N-terminal portion of the tyrosine kinase domain of EphA4. Activation of EphA4 leads to the activation of FGFRs and tyrosine phosphorylation of FRS2α.

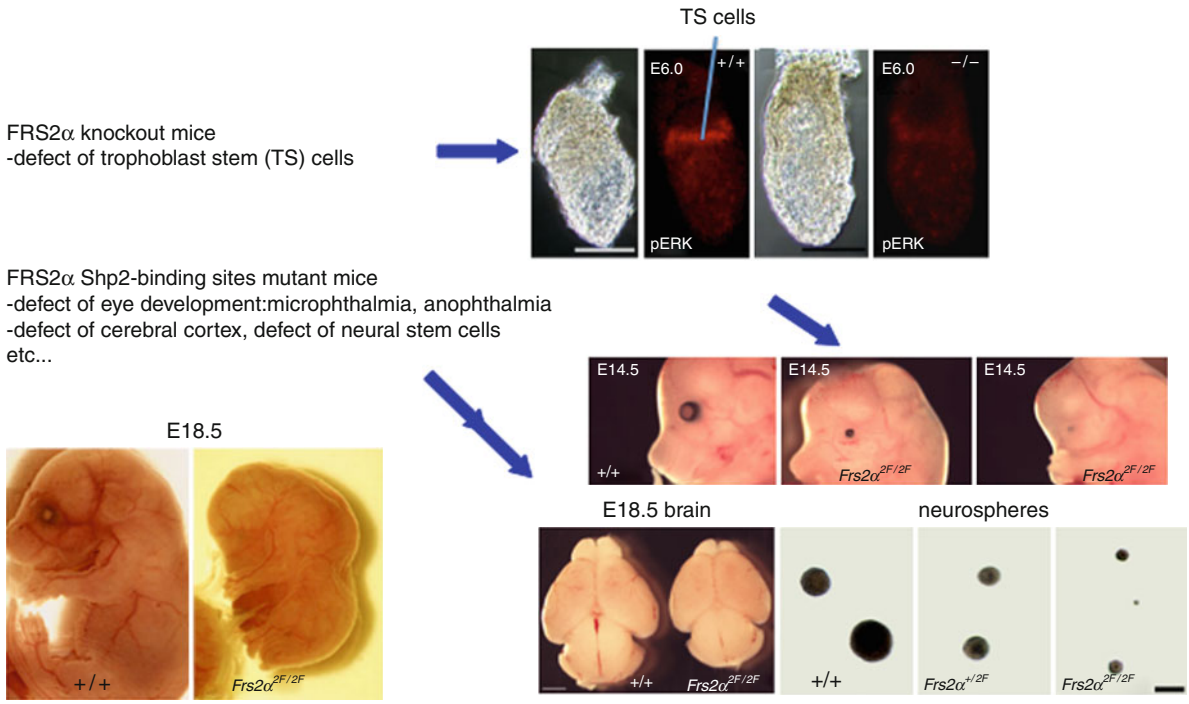
FRS2α is phosphorylated by ERK at multiple threonine residues in response to a variety of ligands, FGF, insulin, EGF, and PDGF. These include extracellular stimuli that do not induce tyrosine phosphorylation of FRS2α. There are eight canonical ERK phosphorylation sites (PXTP motif) in FRS2α. In addition, activated ERK binds to threonine phosphorylated FRS2α (Fig. 2). Thus there is an ERK-mediated negative feedback mechanism for the control of signaling pathways that are dependent on FRS2α.

Physiological Roles of FRS2α

The expression of *Frs2α* can be detected at embryonic day (E) 5.5 in mouse embryos and is expressed ubiquitously during development. FRS2α play critical roles for a variety of FGF-induced developmental processes and maintenance of tissue type–specific stem cells that are dependent on FGF. Several *Frs2α* mutant mice were generated: *Frs2α*-knockout mice and two knock-in mice that express a mutant form of FRS2α whose tyrosine residues of Grb2 ($Frs2\alpha^{4F}$ mutant)- or Shp2 ($Frs2\alpha^{2F}$ mutant)-binding sites are replaced with phenylalanine (Fig. 4) (Gotoh 2008). Embryos of the *Frs2α*-knockout mouse have defects in the FGF4-dependent maintenance of trophoblast stem cells and show developmental retardation, resulting in embryonic lethality by E8 (Gotoh et al. 2005; Murohashi et al. 2010). $Frs2\alpha^{2F/2F}$ mice display multiple developmental defects and show perinatal death, though $Frs2\alpha^{4F/4F}$ mice can survive as adults and show no gross morphological defects except an eyelid developmental defects. Embryos of $Frs2\alpha^{2F/2F}$ mice lack carotid body, have defective eye development, and show anophthalmia (no eyes) or microphthalmia (small eyes). Neural progenitor cells of $Frs2\alpha^{2F/2F}$ mice show reduced proliferation in response to FGF stimulation. FRS2α is also essential for self-renewing activity of neural stem/progenitor cells (NSPCs) in response to FGF (Sato et al. 2010). Specific ablations of *Frs2α* in the prostate epithelium inhibit prostatic branching morphogenesis and growth (Zhang et al. 2008).

Molecular Functions of FRS2β

FRS2β binds to a few RTKs including FGFR, Trk, and ALK through the PTB domain and becomes phosphorylated on tyrosine residue, similar to FRS2α. Like FRS2α, Grb2 and Shp2 are recruited to phosphorylated tyrosine residues on FRS2β upon activation of RTKs, leading to the activation of ERK (Fig. 2). FRS2β also binds to EGFR family members, including EGFR and ErbB2, constitutively with its PTB domain regardless of the absence or presence of ligands (Fig. 5).



FRS2, Fig. 4 FRS2α is a central mediator in FGF signaling in vivo. *Frs2α* null mouse embryos showed early embryonic lethality due to a failure of maintenance of trophoblast stem (TS) cells. TS cells are dependent on FGF4 and localized in extraembryonic ectoderm (ExE). The wild type ExE is positive in pERK staining but it is weak in the mutant. The *Frs2α* $^{2F/2F}$ mice have a variety of developmental defects and some of them are reasonably explained by failure of FGF signaling

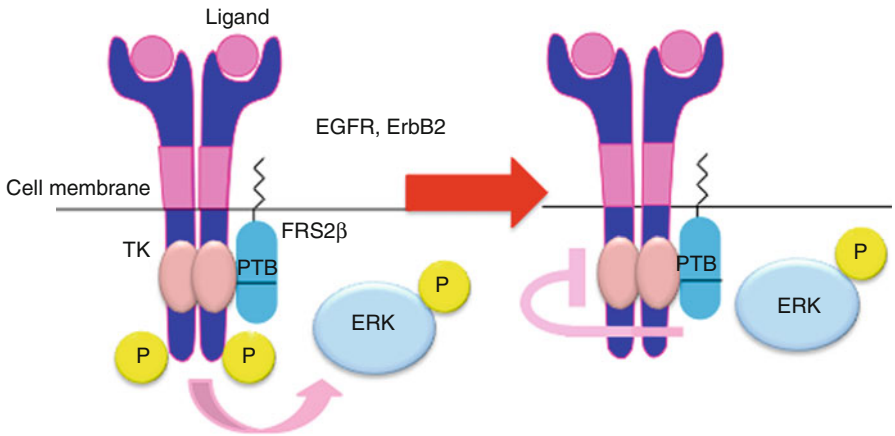
However, FRS2β is not phosphorylated by EGFR RTK in this case. Instead, FRS2β inhibits the activity of EGFR. Expression of FRS2β inhibits EGF-induced autophosphorylation of EGFR, and also decreases activation of its downstream signaling proteins. The binding between FRS2β and phosphorylated ERK is important for inhibition of EGFR signaling. This forms a negative feedback loop after the activation of ERK downstream of the activated EGFR, or to maintain the EGFR in an inactive state after the activation of ERK by other stimuli. Therefore, it appears that FRS2β is a unique scaffolding adaptor that serves as both a negative and a positive regulator for receptor species–dependent RTK signaling (Iejima et al. 2010).

Physiological Roles of FRS2β

In contrast to the rather ubiquitous expression pattern of *Frs2α*, *Frs2β* is expressed only in a limited number of tissues, including central nervous systems (CNS) and other epithelial tissues, such as lung epithelial cells and the gastrointestinal tract (Gotoh et al. 2004; Minegishi et al. 2009). Though both *Frs2α* and *Frs2β* are expressed in CNS, the expression pattern of these genes tends to be mutually exclusive. For example, though *Frs2α* is strongly expressed in the ventricular zone of mesencephalon, expression of *Frs2β* is weak there. The distinct expression patterns of *Frs2α* and *Frs2β* suggest the possibility that they have different physiological roles. In contrast to the well-known functions of FRS2α, the functions of FRS2β have long been unclear.

Relevance of FRS2 Proteins to Cancer

It is known that FGF ligands and their recepors are overexpressed in a variety of cancers, including of the breast, stomach, prostate, pancreas, bladder, and colon (Sato and Gotoh 2009). Activating mutations in FGFR3 are observed frequently in bladder and cervical carcinoma and in some cases of multiple myeloma, while activating mutations in FGFR2 are found in gastric carcinoma. Further, several types of fusion proteins involving FGFR1 caused by chromosomal translocation are found in hematologic malignancies. Given that aberrant FGF signaling is important in tumorigenesis based on all these reports, it is reasonable to predict that FRS2 proteins are also involved in tumorigenesis.



FRS2, Fig. 5 FRS2β constitutively binds to EGFR family members. Activated EGFR family members activate the ERK pathway. The activated ERK binds to FRS2β and inhibits the EGFR signalling

Somatic rearrangements of the TrkA gene are detected in a fraction of papillary thyroid carcinomas and produce chimeric proteins. All of them contain a portion of TrkA, including tyrosine kinase domain. The resultant thyroid Trk oncoproteins activate FRS2α and FRS2β. Gene rearrangements leading to fusion of the kinase domain of RET with heterologous proteins containing dimerization motifs result in constitutively activated RET proteins. Such fusion proteins are expressed in some cases of papillary thyroid carcinoma. Germ line point mutation in RET results in inherited multiple endocrine neoplasm types 2A and 2B and familial medullary thyroid carcinoma. FRS2α is tyrosine phosphorylated by ligand-stimulated and constitutively activated oncogenic forms of RET, leading to activation of ERK. The NPM-ALK oncoprotein activates FRS2α and FRS2β and transforms NIH3T3 cells.

Expression of FRS2β suppresses EGF-induced cell transformation and proliferation. High expression levels of *FRS2β* significantly correlate with good prognosis of non-small lung cancer patients (Iejima et al. 2010). These findings suggest that FRS2β is suppressive for tumorigenesis in which aberrant EGF signaling is involved.

Summary

There are two members – FRS2α and FRS2β – in the FRS2 family of docking/scaffolding adaptor proteins. These proteins function downstream of certain kinds of RTKs that are important for tumorigenesis, including the FGFR, Trk, RET, and ALK. Activation of these RTKs allows FRS2 proteins to become phosphorylated of tyrosine residues and then bind to Grb2 and Shp2, a SH2 domain-containing adaptor and a tyrosine phosphatase, respectively. Subsequently, Shp2 activates a Ras/ERK pathway and Grb2 activates a Ras/ERK, PI-3 kinase, and ubiquitination/degradation pathways by binding to SOS, Gab1, and Cbl via the SH3 domains of Grb2. FRS2α acts as a central mediator in FGF signaling. FRS2α mutant mice exhibit a variety of defects in developmental processes and in maintenance of tissue type–specific stem cells, such as trophoblast stem cells and neural stem cells; many of them are due to defects in FGF signaling. Although FRS2β binds to EGFR family RTKs, including EGFR and ErbB2, it does not become tyrosine phosphorylated. Instead, it inhibits EGF signaling, resulting in inhibition of EGF-induced cell proliferation and cell transformation. FRS2β may have a tumor suppressive role for non-small cell lung cancer.

Historical Background

Drosophila frizzled (Dfz1) was originally identified as a causative gene for a mutant with disoriented cuticular hairs, and then was cloned and characterized as a seven-transmembrane-type protein similar to G protein-coupled receptors (GPCRs) (Vinson and Adler 1987; Lagerström and Schiöth 2008).

The phenotype of *Dfz1* mutant was aberrant polarization of epithelial cells within the epithelial plane, or dysregulation of planar cell polarity (PCP). *Drosophila* mutants of *dishevelled*, *Van Gogh (strabismus)*, *prickle*, *diego*, and *starry night (flamingo)* show phenotypes similar to *Dfz1* mutant. Dfz1, Dishevelled, Van Gogh (strabismus), prickle, diego, and starry night are characterized as core PCP components (Katoh 2005; Wang 2009; Wu and Mlodzik 2009).

Drosophila frizzled-2 (Dfz2) was cloned and characterized as a seven-transmembrane-type receptor for secreted glycoprotein Wingless, which is involved in the patterning of embryonic segments and their adult derivatives (Bhanot et al. 1996; Zhang and Carthew 1998). Genetic interaction experiments revealed that Dfz2, Wingless, Dishevelled, and Armadillo belong to the WNT group of segment polarity components.

FZD1 (Frizzled-1), FZD2 (Frizzled-2), FZD3 (Frizzled-3), FZD4 (Frizzled-4), FZD5 (Frizzled-5 or Hfz5), FZD6 (Frizzled-6 or Hfz6), FZD7 (Frizzled-7), FZD8 (Frizzled-8), FZD9 (Frizzled-9), and FZD10 (Frizzled-10) constitute the human Frizzled family of atypical GPCRs functioning as WNT receptors (Zhao et al. 1995; Wang et al. 1996; Koike et al. 1999; Katoh 2007).

Structural Features of Frizzled Receptors

Frizzled family members share the conserved domain architecture consisting of N-terminal extracellular cysteine-rich domain (Frizzled-like CRD), seven transmembrane domains, and cytoplasmic K-T-X-X-X-W motif. Frizzled-like CRD is a WNT-binding domain, which is conserved among Frizzled family members (Wang et al. 1996), secreted-type WNT antagonist SFRPs (Elston and Clifton-Bligh 2010), ROR family of WNT co-receptors (Green et al. 2008), and single transmembrane-type Frizzled-related protein (MFRP) (Katoh 2001). The K-T-X-X-X-W motif in the C-terminal cytoplasmic region is a binding motif for the PDZ domain of Dishevelled family of scaffold proteins (Wong et al. 2003).

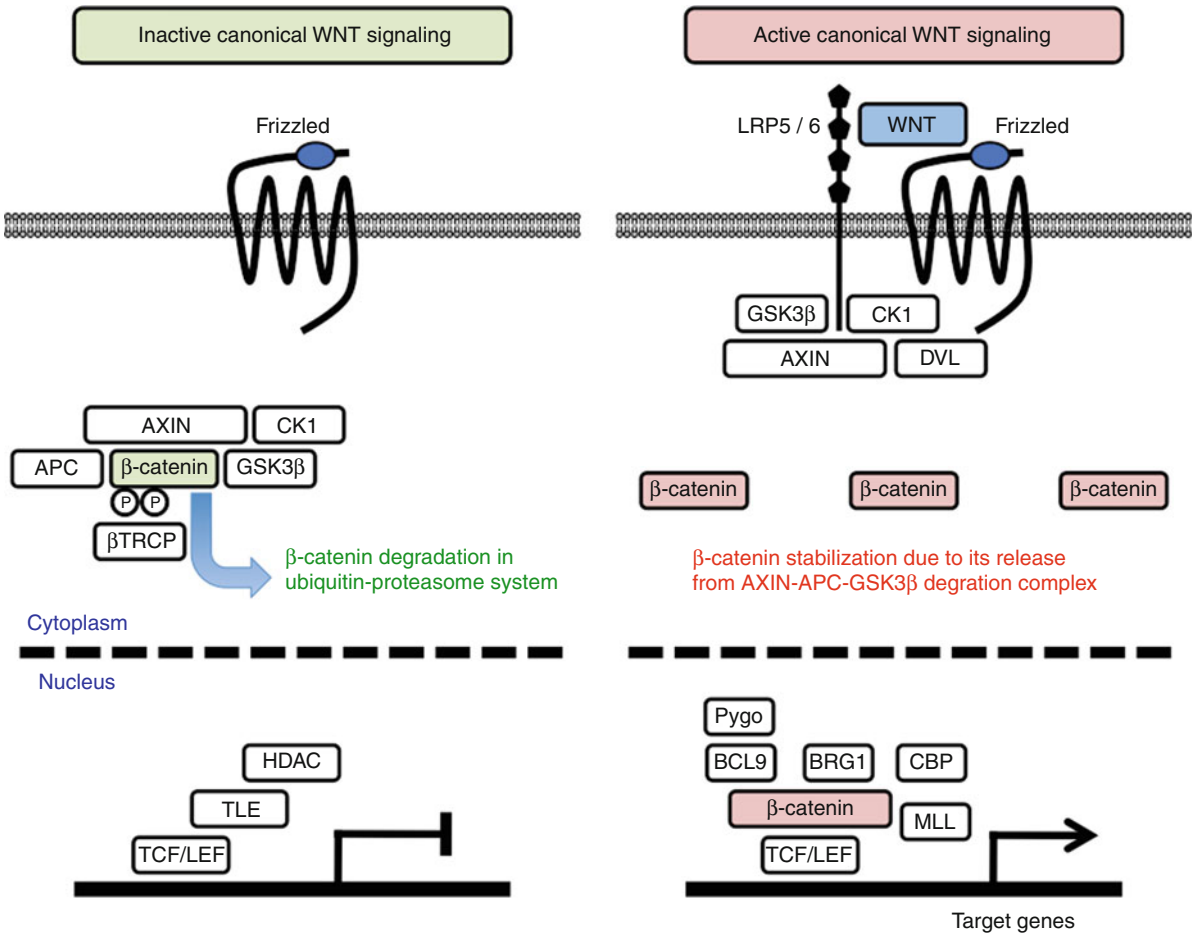
Context-Dependent WNT Signaling Through Frizzled Receptors

Frizzled receptors transduce WNT signals via cytoplasmic Dishevelled family members to β-catenin-dependent TCF/LEF transactivation cascade (Barker and Clevers 2006) and β-catenin-independent RhoA-ROCK, RhoB-Rab4, Rac-JNK, and aPKC signaling cascades (Chien et al. 2009). Frizzled receptors also transduce WNT signals via phospholipase C (PLC) to β-catenin-independent MAP3K7-NLK, Calcineurin-NFAT, and DAG-PKC signaling cascades (Chien et al. 2009). Canonical WNT signaling cascade is defined as the β-catenin-dependent TCF/LEF branch, whereas noncanonical WNT signaling cascades as a variety of β-catenin-independent branches. WNT signals are transduced to canonical and noncanonical signaling cascades in a context-dependent manner based on the combination of WNT ligands, Frizzled receptors, other co-receptors, and WNT antagonists (Swain et al. 2005; Mikels and Nusse 2006; Katoh and Katoh 2007).

Canonical WNT Signaling Cascade

In the absence of canonical WNT signals, β-catenin forms a ternary complex with AXIN and APC to undergo CK1-mediated priming phosphorylation at Ser 45 and GSK3β-mediated subsequent phosphorylation at Thr 41, Ser 37, and Ser 33 (Fig. 1). Phosphorylated β-catenin is recognized by F-box proteins βTRCP1 or βTRCP2 to be poly-ubiquitinated by an E3 ubiquitin ligase complex for its degradation in the proteasome system (Frescas and Pagano 2008).

In the presence of canonical WNT signals, Frizzled-Dishevelled complex is indirectly associated with LRP5/6 co-receptor via extracellular WNT ligand (Fig. 1). Dishevelled recruits AXIN based on DIX-DIX hetero-dimerization, and then AXIN directly binds to LRP5/6, which results in the assembly of canonical WNT signalosome consisting of WNT ligand, Frizzled-Dishevelled complex, and LRP5/6-AXIN complex (Fig. 1). Due to its release from the AXIN-APC degradation complex, β-catenin is stabilized for nuclear accumulation and subsequent association with TCF/LEF family of HMG-box transcription factors. Because nuclear β-catenin is also associated with BCL9-PYGO co-activator complex, SWI/SNF-related chromatin regulator BRG1, histone acetyl transferase CBP/p300, TRRAP, and histone methyltransferase MLL, stabilized β-catenin induces transcriptional activation of TCF/LEF target genes



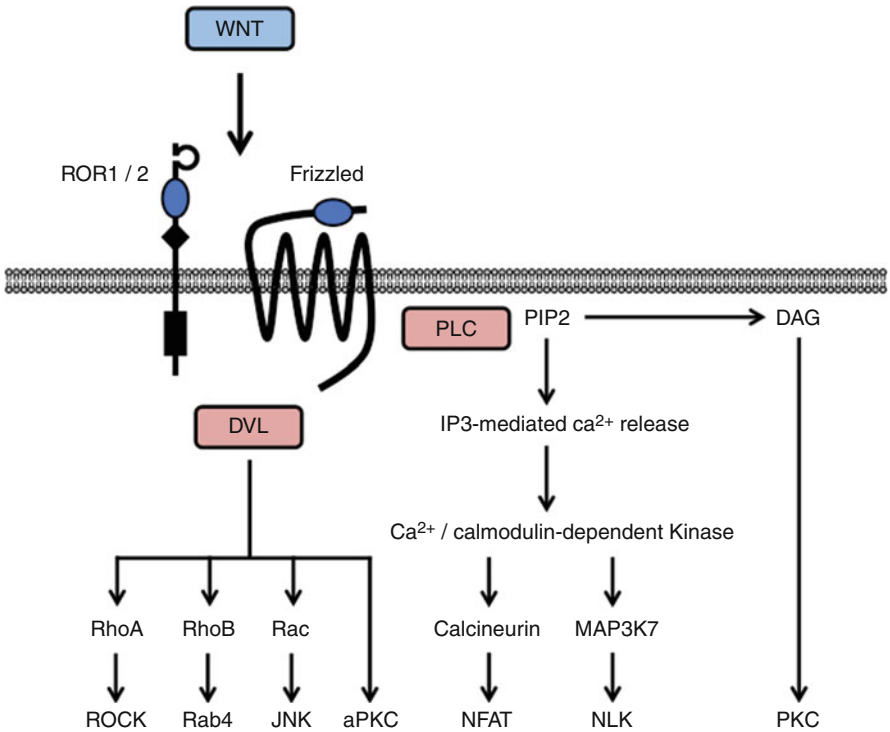
FZD (Frizzled), Fig. 1 Canonical WNT signaling cascade. Canonical WNT signals are transduced through Frizzled to the TCF/LEF transactivation cascade in a β-catenin-dependent manner. (*Left*) In the absence of canonical WNT signals, β-catenin is phosphorylated by CK1 and GSK3β in the AXIN-APC degradation complex. Phosphorylated β-catenin is poly-ubiquitinated by an E3 ubiquitin ligase complex for its degradation in the proteasome system. (*Right*) In the presence of canonical WNT signals, assembly of canonical WNT signalosome consisting of WNT ligand, Frizzled-Dishevelled complex, and LRP5/6-AXIN complex leads to the release of β-catenin from the AXIN-APC degradation complex. Stabilized β-catenin is translocated to the nucleus for the subsequent association with TCF/LEF transcription factors. Because nuclear β-catenin is also associated with multiple co-activators, stabilized β-catenin induces transcriptional activation of TCF/LEF target genes such as *FZD7, LEF1, DKK1, AXIN2, βTRCP1, MYC*, and *CCND1*

(Fig. 1). *FZD7, LEF1, DKK1, AXIN2, βTRCP1, MYC*, and *CCND1* are representative target genes of the canonical WNT signaling cascade (Barker and Clevers 2006; Katoh and Katoh 2007). FZD7 and LEF1 are involved in positive-feedback regulation, whereas DKK1, AXIN2, βTRCP1 in negative-feedback regulation. Because MYC and CCND1 induce cell-cycle progression, canonical WNT signals promote self-renewal of stem cells and proliferation of progenitor or transit-amplifying cells in physiological and pathological situations.

Noncanonical WNT Signaling Cascades

Noncanonical WNT signals are transduced to a variety of signaling cascades, including RhoA-ROCK, RhoB-Rab4, Rac-JNK, aPKC, MAP3K7-NLK, Calcineurin-NFAT, and DAG-PKC branches (Fig. 2).

Noncanonical WNT signals are transduced to RhoA-ROCK, RhoB-Rab4, Rac-JNK, and aPKC signaling cascades in a Dishevelled-dependent and β-catenin-independent manner. Dishevelled-dependent RhoA-ROCK and Rac-JNK signaling branches are involved



FZD (Frizzled),
Fig. 2 Noncanonical WNT signaling cascades. Noncanonical WNT signals are transduced through Frizzled receptors to a variety of downstream cascades in a β-catenin-independent manner. Dishevelled mediates noncanonical WNT signaling to RhoA-ROCK, RhoB-Rab4, Rac-JNK, and aPKC branches, whereas phospholipase C (PLC) mediates noncanonical WNT signaling to MAP3K7-NLK, Calcineurin-NFAT, and DAG-PKC branches

in PCP or polarized cell movements. DAAM1 and DAAM2 are Formin family proteins regulating the actin-filament dynamics, such as nucleation, elongation, and barbed-end capping. DAAM proteins are tethered in the cytoplasm based on intramolecular interaction in the absence of noncanonical WNT signals, while DAAM proteins are recruited to the membranous Frizzled-Dishevelled complex based on intermolecular interaction between DAAM and Dishevelled in the presence of noncanonical WNT signals. Because DAAM in the Frizzled-Dishevelled complex preferentially interacts with GTP-bound RhoA, noncanonical WNT signals activate the RhoA-ROCK signaling cascade via Dishevelled and DAAM to regulate actin remodeling during fetal morphogenesis and tumor invasion (Katoh 2005; Wang 2009; Chien et al. 2009).

Noncanonical WNT signals activate PLC for the catalysis of phosphatidylinositol diphosphate (PIP2) to inositol triphosphate (IP3) and DAG, because Frizzled receptors are GPCR superfamily members (Lagerström and Schiöth 2008; Chien et al. 2009). IP3 triggers Ca^{2+} release from endoplasmic reticulum for the activation of MAP3K7-NLK and Calcineurin-NFAT signaling cascades, while DAG induces PKC activation. MAP3K7 is a mitogen-activated protein kinase kinase kinase (MAP3K), which phosphorylates NLK, IKK, MAP2K3 (MEK3), and MAP2K6 (MEK6). Noncanonical WNT signals induces PLC-mediated Ca^{2+} release for the MAP3K7 activation, which leads to phosphorylation and subsequent activation of NLK. NLK then phosphorylates TCF/LEF to inhibit the transcriptional activation of the canonical WNT signaling cascade. Therefore, noncanonical WNT signaling to the MAP3K7-NLK branch switches off the canonical WNT signaling cascade.

Pathophysiology of Frizzled Family Members

FZD3 and *FZD6* genes are human orthologs of *Dfz1*, which is involved in PCP (Katoh 2005). Double knockout mice for *Fzd3* and *Fzd6* show PCP phenotypes characterized by neural tube closure defect (NTD) and disoriented sensory hair cells of inner ear (Wang 2009), whereas single nucleotide polymorphisms (SNPs) of human *FZD3* or *FZD6* were not associated with NTD in a case-control study, including 338 cases of NTD infants and 338 non-malformed infants (Wen et al. 2010).

FZD4 gene at human chromosome 11q14.2 is mutated in autosomal-dominant familial exudative vitreoretinopathy (FEVR) and sporadic exudative vitreoretinopathy featured by variable clinical manifestations, such as retinal exudates, retinal neovascularization, retinal detachment, vitreous hemorrhage, and total blindness (Kirikoshi et al. 1999; Kondo et al. 2003).

FZD7 is expressed in blastocyst, undifferentiated embryonic stem (ES) cells, ES-derived endodermal progenitors, ES-derived neural progenitors, fetal cochlea, adult gastrointestinal tract, and regenerating liver. *FZD7* expression on mesenchymal stem cells is downregulated during osteogenesis. *FZD7* is upregulated in gastric cancer, esophageal cancer, colorectal cancer, and liver cancer. *FZD7* is one of the target genes of the canonical WNT signaling cascade as mentioned above. FZD7 transduces WNT3, WNT6, or WNT8B signals to the canonical WNT signaling cascade, and also WNT11 or WNT5A signals to the noncanonical WNT signaling cascades. FZD7 orchestrates cellular proliferation, epithelialization, migration, and tissue movement in a context-dependent manner during embryogenesis, adult-tissue homeostasis, and carcinogenesis (Sagara et al. 1998; Vincan and Barker 2008).

FZD9 gene at human chromosome 7q11.23 was initially cloned and characterized as one of genes within the region commonly deleted in patients with Williams syndrome, which is a neurodevelopmental disorder with dysmorphic facial features, cardiovascular disease, mild mental retardation, and a unique cognitive profile; however, because *FZD9* gene is not always deleted in patients with Williams syndrome, it is believed that *FZD9* is not responsible for the major features of the Williams syndrome (Botta et al. 1999).

FZD10 gene at human chromosome 12q24.33 was cloned and characterized as the last member of the Frizzled family (Koike et al. 1999). *FZD10* is upregulated in several types of human cancer, such as cervical cancer, glioblastoma, colorectal cancer, and synovial sarcoma (Koike et al. 1999; Nagayama et al. 2005). Anti-FZD10 polyclonal antibody effectively mediates antibody-dependent cell-mediated cytotoxicity (ADCC) against synovial sarcoma cells in nude mice xenograft model (Nagayama et al. 2005), and phase I study of anti-FZD10 monoclonal antibody conjugated with radioisotope started for its clinical application.

Summary

Frizzled family members are atypical GPCRs functioning as WNT receptors. Canonical WNT signals are transduced through Frizzled to the TCF/LEF transactivation cascade in a β-catenin-dependent manner to upregulate target genes, such as *FZD7, LEF1, DKK1, AXIN2, βTRCP1, MYC*, and *CCND1*. Noncanonical WNT signals are transduced through Frizzled to a variety of downstream cascades in a β-catenin-independent manner. Dishevelled-mediated noncanonical WNT signaling to RhoA-ROCK and Rac-JNK signaling cascades are involved in PCP and cellular migration during embryonic morphogenesis and tumor invasion, whereas PLC-mediated noncanonical WNT signaling to MAP3K7-NLK signaling cascade is involved in the inhibition of the canonical WNT signaling cascade. Because WNT-Frizzled signaling cascades play key roles in a variety of cellular processes during embryogenesis, adult-tissue homeostasis, and carcinogenesis, Frizzled receptors are utilized as stem-cell markers in the field of regenerative medicine, and also as therapeutic targets in the field of clinical oncology.

Historical Background

Gα12, along with the closely related Gα13, is a member of the G12 subfamily of heterotrimeric guanine nucleotide-binding protein α-subunits (G proteins). These proteins are activated by GDP-GTP exchange, which is triggered by external stimulation of heptahelical G protein coupled receptors (GPCRs) and causes the Gα to dissociate from the βγ dimer of the heterotrimeric complex and serve as an active signaling moiety until inactivated by its intrinsic GTPase activity. Proteins of the G12 subfamily are posttranslationally modified by palmitoylation, facilitating their localization at the inner face of the plasma membrane. Gα12 was discovered in a PCR-based screen of a mouse cDNA library, utilizing oligonucleotides derived from conserved sequences within known Gα subunits of the ▶ Gs and Gi subfamilies (Strathmann and Simon 1991). Independent of these studies, a genetic screen for female sterile mutations in the fruit fly yielded a mutant form of the gene *concertina*, which encoded a protein harboring ~54% amino acid identity with the murine Gα12 (Parks and Wieschaus 1991). Furthermore, the *concertina* gene product was found to be necessary for proper gastrulation during embryogenesis. Northern blotting and immunoblot analyses revealed the presence of Gα12 in essentially all mammalian tissues (Radhika and Dhanasekaran 2001). The potential role of Gα12 in cell growth and tumorigenesis was discovered when Chan et al. (1993) generated a combined cDNA library from Ewing's sarcoma and synovial tumor-derived cell lines and performed a screen for cDNAs that induced aberrant growth in cultured fibroblasts. The cDNA with highest transforming potency in these

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,

assays was revealed to encode human Gα12, and subsequent studies of mutationally activated (GTPase-deficient) Gα12 revealed its acute oncogenic potential in several cell types (Radhika and Dhanasekaran 2001).

The first purification of Gα12 was performed by Kozasa and Gilman (1995), who utilized baculovirus vectors to overexpress Gα12 along with mammalian heterotrimeric β and γ subunits in cultured *Spodoptera frugiperda* cells. Hexa-histidine tagging of the recombinant γ subunit enabled capture of the heterotrimer on nickel resin, and activation of Gα12 by AlF_4^- triggered its elution from the immobilized G protein βγ dimer. Although this approach did not yield levels of Gα12 necessary for crystallographic studies, it allowed the first biochemical characterization of this 43-kDa protein and revealed striking differences from the well-studied ▶ Gs and Gi subfamilies in its slow rate of nucleotide exchange, exceptionally slow rate of GTP hydrolysis, and lack of ADP-ribosylation by cholera toxin or pertussis toxin (Kozasa and Gilman 1995). Follow-up studies showed Gα12 to have the unusual property among Gα subunits as a substrate for phosphorylation by protein kinase C. In similar fashion to Gαz of the Gi subfamily, phosphorylation of Gα12 inhibited its binding to the βγ dimer, suggesting a role of this covalent modification in prolonging the activated, monomeric state of Gα12. Several years later, a chimeric Gα12 harboring the N-terminal 28 amino acids of the Gi subfamily member $Gαi_1$ was purified in sufficient quantity to allow crystallographic analysis of Gα12 in its activated conformation (Kreutz et al. 2006).

The downstream mechanisms of Gα12-mediated signaling remained unknown until the small G protein Rho was found to mediate Gα12-driven cytoskeletal changes, specifically the formation of stress fibers and assembly of focal adhesion complexes (Buhl et al. 1995). These findings led to a wide range of downstream processes that required activation of Rho by Gα12 or Gα13, and helped lead investigators to the first direct downstream binding partners of the Gα12 subfamily, a subset of Rho-specific guanine nucleotide exchange factors, or RhoGEFs (Kozasa et al. 1998). In addition to linking Gα12 to Rho, these effector proteins were shown to act as GTPase activating proteins (GAP) for the G12 subfamily, a finding of particular significance given the slow GTP hydrolysis rate of purified Gα12. However, it has become increasingly evident that Gα12 stimulates pathways in addition to a RhoGEF-Rho axis, as nearly 20 non-receptor proteins have been reported as interactors with Gα12 specifically or with both G12 subfamily members (Kelly et al. 2007).

Role of Gα12 in Cell Growth, Apoptosis, and Oncogenic Transformation

Human Gα12 was discovered as a potential transforming oncogene in a soft tissue sarcoma-derived cDNA library, and comparison to several cDNAs isolated from non-cancerous mammary epithelial cells verified this Gα12 clone as the wild-type form. Significantly, this revealed Gα12 as the only heterotrimeric Gα protein among the four subfamilies – ▶ Gs, Gi, Gq, and G12 – to harbor transforming ability as an overexpressed but not mutationally activated protein. Gα12-induced transformation is serum-dependent; however, introduction of activating point mutations, analogous to those discovered in Gαs isolated from pituitary and thyroid tumors, allow Gα12 to drive cellular transformation in the absence of serum (Radhika and Dhanasekaran 2001). The mechanisms of Gα12-induced growth activation and cellular transformation are not fully understood; however, several signaling pathways have been implicated in these responses, particularly pathways harboring mitogen-activated protein kinases (MAPK) and small G proteins of the Rho and Ras families. One of the first downstream signaling proteins reported to be activated by Gα12 signaling was the c-Jun-N-terminal kinase (JNK), which plays a role in stress responses and apoptotic signaling but also has been linked to cell proliferation and tumorigenesis. Subsequent studies revealed several transcriptional responses downstream of Gα12; constitutively active Gα12 stimulated AP-1-mediated gene expression via a mechanism sensitive to dominant-negative Ras, and also activated several primary response genes through stimulation of serum response factor (SRF). Gα12 was also shown to mediate a signaling pathway in which extracellular thrombin stimulation triggered AP-1 activation (Sah et al. 2000). Also, activated Gα12 was found to stimulate G_1-to-S phase progression in a manner dependent on Ras, Rho and Rac. Furthermore, acylation of Gα12 plays an important role in its growth signaling; mutation of a native palmitoylation target Cys in Gα12 to Ser abolished the transforming ability of the protein in cultured NIH3T3 fibroblasts. Introduction of a residue allowing myristoylation of Gα12 near its N-terminus rescued transforming ability in this Cys-to-Ser mutant,

suggesting that membrane tethering of Gα12 is essential to its function in cell growth and transformation (Kelly et al. 2007).

It is apparent that Rho activation is a critical aspect of the mechanism through which Gα12 stimulates cell proliferative pathways. Gα12 stimulation of JNK and SRF are blocked by Rho inhibition, and Gα12-mediated transformation of cultured fibroblasts requires Rho signaling to SRF (Radhika and Dhanasekaran 2001). Gα12-mediated responses disrupted by expression of a dominant-negative RhoGEF include stimulation of ▶ phospholipase D activity and angiotensin-triggered activation of JNK and p38 MAPK. However, mutationally activated Rho lacks the potency of activated Gα12 in triggering cellular transformation, supporting a model in which Gα12 engages additional, Rho-independent pathways in order to activate growth and tumorigenesis (Suzuki et al. 2009). For example, Gα12 interaction with the ▶ cadherin cytoplasmic domain triggers dissociation of the transcriptional co-activator ▶ β-catenin from ▶ cadherin, and in specific cell types up-regulates the expression of several ▶ β-catenin target genes. Gα12 binding to axin, a protein required for regulated degradation of ▶ β-catenin, provides an additional point at which Gα12 potentially regulates ▶ β-catenin-mediated pathways (Kelly et al. 2007). In addition, a dominant-negative Rac inhibited Gα12-induced transformation in cultured cells, and Gα12 activation of JNK was blocked by dominant-negative forms of Rac, Ras, and MAP kinase kinase kinase 1 (MEKK1), although these effects were specific to certain cell types. Furthermore, Gα12-mediated stimulation of ERK5, a MAPK harboring an extended C-terminal region, was unaffected by Rho inhibition. Finally, the proline-rich tyrosine kinase PYK2 has been implicated in Gα12-mediated mitogenic signaling; a kinase-deficient PYK2 mutant blocked stimulation of SRF by constitutively active Gα12 (Radhika and Dhanasekaran 2001; Kelly et al. 2007). Several effects of Gα12 on growth signaling appear cell type specific; for example, constitutively active Gα12 weakly stimulated extracellular signal-regulated kinase (ERK) in NIH3T3 fibroblasts, but in a separate study utilizing COS-7 fibroblasts, Gα12 inhibited ERK while simultaneously stimulating JNK. Also, Gα12 inhibited p38 MAPK signaling and stimulated JNK in NIH3T3 cells, whereas in neonatal rat cardiomyocytes, Gα12 stimulated p38 MAPK along with JNK (Radhika and Dhanasekaran 2001).

Evidence is mounting that Gα12-mediated pathways regulate cell growth by interfacing with pathways driven by receptor tyrosine kinases, or by stimulating autocrine loops that promote cell proliferation. Specific inhibitors of the platelet-derived growth factor (PDGF) receptor and the protein tyrosine kinase JAK3 blunted the ability of constitutively active Gα12 to stimulate cell proliferation in the absence of serum. Dominant-negative variants of the PDGF receptor and ▶ STAT3 hindered Gα12 in triggering focus formation in NIH3T3 cells (Kelly et al. 2007). Also, Gα12 stimulated expression of cyclooxygenase-2 (COX-2), and specific inhibitors of COX-2 blocked Gα12-mediated activation of DNA synthesis. Taken in the context of a previous finding that Gα12 stimulates ▶ phospholipase A_2 to catalyze arachidonic acid release from cell membranes, an event predicted to up-regulate prostaglandin biosynthesis, these results suggest multiple points at which Gα12 may regulate prostaglandin signaling in cell growth and transformation (Radhika and Dhanasekaran 2001). In addition to its complex roles in growth signaling, Gα12 can activate programmed cell death pathways through JNK. Activated Gα12 was shown to induce apoptosis in COS-7 fibroblasts through two separate pathways that converge on JNK activation, one via MEKK1 and the other via apoptosis signal-regulating kinase. More recently, Gα12 was found to stimulate apoptosis through a pathway dependent on PP2A, leading to degradation of the anti-apoptotic protein ▶ Bcl-2 (Juneja and Casey 2009). Other studies revealed the polycystic kidney disease–related protein polycystin-1 as a negative regulator of the apoptotic signaling generated by expression of constitutively active Gα12, or by thrombin stimulation, in human embryonic kidney cells (Yu et al. 2011). Stimulation of JNK by Gα12 was recently implicated in yet another cellular response: the transcription factor ▶ Nrf2, a protein activated by oxidative stress, was stimulated through a Gα13-dependent pathway but negatively balanced by Gα12. Additional findings showed ▶ Nrf2 to be up-regulated in the absence of Gα12, due to reduced JNK-dependent proteolysis of ▶ Nrf2 (Cho et al. 2007).

Role of Gα12 in Cell Polarity, Adhesion, Migration, and Invasion

Two early lines of investigation implicated Gα12 and its homologs as regulators of cell shape change. In fruit flies homozygous for a mutation in the

concertina gene, apical constriction of cells was severely disrupted during the ventral furrow formation stage that initiates gastrulation (Parks and Wieschaus 1991). Subsequently, expression of a constitutively active mammalian Gα12 in cultured cells was found to trigger formation of actin stress fibers, as well as assembly of focal adhesion complexes (Buhl et al. 1995). These discoveries led to Gα12 being implicated in mechanisms regulating cell polarity, which is an essential aspect of proper cytoskeletal rearrangement and directed migration. Gα12 was found to regulate actin-mediated protrusions, as well as reorientation of the microtubule-organizing center toward the leading edge of the cell (Juneja and Casey 2009). Activated Gα12 also triggered neurite retraction and cell rounding in cultured PC12 and 1321N1 cell lines (Sah et al. 2000), and signaling through the ▶ sphingosine-1-phosphate receptor was shown to stimulate stress fiber formation in a Gα12-dependent manner (Riobo and Manning 2005). Also, expression of constitutively active Gα12 in human embryonic kidney cells stimulated phosphorylation of the focal adhesion proteins paxillin, focal adhesion kinase, and p130 Crk-associated substrate (▶ p130 CAS), although studies in Madin-Darby canine kidney epithelial cells revealed Gα12 to inhibit phosphorylation of paxillin and focal adhesion kinase (Radhika and Dhanasekaran 2001; Kong et al. 2009).

Many cytoskeletal effects of Gα12 are Rho-dependent. The first reports of Gα12 triggering the generation of stress fibers and focal adhesions revealed these events as sensitive to *Clostridium botulinum* C3 exoenzyme, a specific inhibitor of Rho (Buhl et al. 1995). Guanine nucleotide exchange on Rho, activated by a Gα12-stimulated RhoGEF, results in downstream activation of the Rho target proteins Rho kinase (ROCK) and ▶ myosin II. These Rho effectors mediate contraction of the trailing edge of the cell, a critical step in migration. Gα12 stimulation of this pathway was shown to mediate polarity of neutrophils and contraction at the back and sides of the cell during migration (Xu et al. 2003). In cultured neonatal cardiomyocytes, either Rho inhibition or expression of a peptide mimicking the C-terminal 55 amino acids of Gα12 blocked α-adrenergic receptor-induced hypertrophic responses, including cytoskeletal rearrangements (Kelly et al. 2007). Also, stimulation of cell migration by lysophosphatidic acid (LPA) was hindered by inhibitors of Rho or ROCK. The downstream effects of Gα12 signaling on the cytoskeleton are complex; for instance, thrombin was found to stimulate endothelial cell permeability through a Gα12-Rho axis, with ROCK mediating cytoskeletal rearrangements and protein kinase C-related kinase mediating the remodeling of focal adhesions (Gavard and Gutkind 2008). Although Rho signaling is crucial in Gα12-mediated cytoskeletal changes and migration, it is apparent that other downstream targets of Gα12 are involved in these events. Constitutively active Gα12 was demonstrated to overcome epithelial cadherin (▶ E-cadherin)-mediated blockage of breast cancer cell migration in wound-filling assays, and this effect of Gα12 was insensitive to a specific inhibitor of ROCK (Kelly et al. 2007). Glycogen synthase kinase-3 (GSK3) is involved in neurite retraction induced by LPA, and Gα12 and the closely related Gα13 were found to up-regulate GSK3 activity. Interestingly, the effect of Gα12, but not Gα13, was refractory to C3 exoenzyme, suggesting a Rho-independent mechanism specific to Gα12. Constitutively active Gα12 also stimulated invasiveness of several breast cancer and prostate cancer cell lines through an artificial extracellular matrix (Kelly et al. 2006, 2007).

Gα12 has been revealed as a regulator of cell adhesion. Following the discovery of Gα12 interaction with several members of the ▶ cadherin superfamily of cell-cell adhesion glycoproteins, this binding event was found to disrupt ▶ cadherin association with ▶ β-catenin, allowing the latter protein to accumulate in the cytoplasm and nucleus of colon carcinoma cells and drive transcriptional activation of key cell proliferative genes (Kelly et al. 2007). Gα12-▶ cadherin interaction was also shown to negatively regulate the cell-cell adhesive function of E-cadherin, as well as overcome ▶ cadherin-induced inhibition of breast cancer cell migration. Gα12 may regulate cell adhesion through other downstream proteins. Its interaction with p120 catenin, a protein implicated in stabilizing ▶ cadherin at the plasma membrane, increases the affinity of p120 catenin for E-cadherin; furthermore, Gα12 modulates the ability of p120 catenin to bind and negatively regulate Rho. In addition, Gα12 may regulate cell adhesion through interaction with an additional ▶ cadherin-associated protein, αSNAP, that has been shown to stabilize ▶ cadherin at the cell surface and regulate endothelial barrier function (Kelly et al. 2007). In addition to its role in regulating cell-cell adhesion mechanisms, Gα12 has been

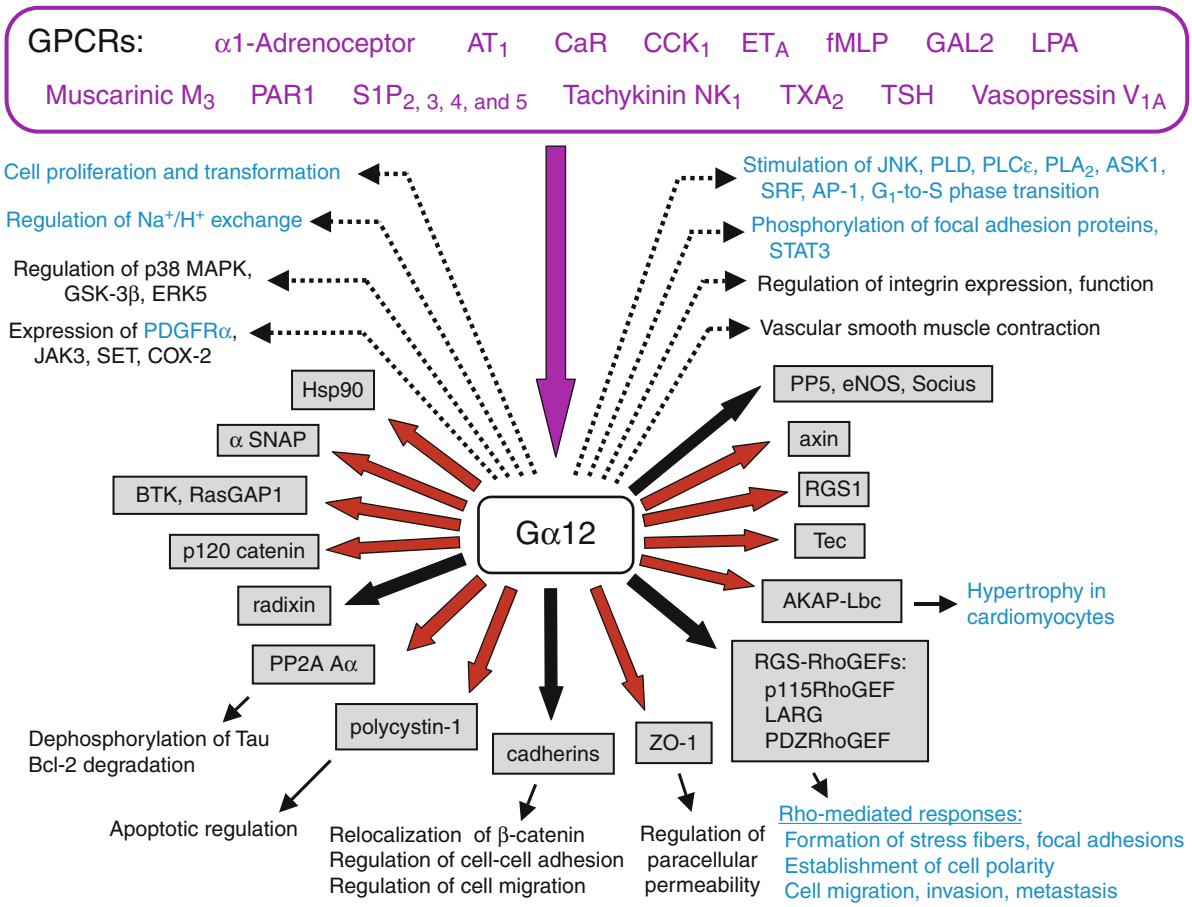
implicated as a modulator of cell-substrate interaction. Attachment of Madin-Darby canine kidney cells to laminin-5 was negatively regulated by Gα12-mediated transcriptional inhibition of the α6 integrin gene, which encodes a protein that adheres specifically to the laminin-5 substrate. Gα12 was also reported to negatively regulate epithelial cell attachment and migration on collagen-I, via inhibition of α2β1 integrin through an "inside-out" signaling pathway that requires Gα12, Rho, and ▶ Src, but apparently does not involve transcriptional regulation of integrins (Kong et al. 2009).

Receptors and Effectors Coupled to Gα12

A diverse group of cell surface, heptahelical G protein coupled receptors (GPCRs) have been reported as activators of Gα12. For several of these GPCRs, it is not clear whether coupling to Gα12, Gα13, or both proteins occurs (see below), but a number of GPCRs have been demonstrated to bind and/or activate Gα12 directly (Fig. 1). Most of these receptors have also been found to stimulate Gα13. Receptors were implicated as Gα12-coupled by experiments employing either a dominant-negative Gα12 mutant, a blocking peptide matching the Gα12 C-terminus, [^{32}P]GTP-azidoanilide photolabeling or [^{35}S]GTPγS binding to detect guanine nucleotide exchange on Gα12, or microinjection of antibodies to bind and inactivate Gα12 (Riobo and Manning 2005). In addition, the Ca^{++}-sensing receptor was shown to co-immunoprecipitate with Gα12 in lysates of breast cancer cells (Huang et al. 2009). These putative Gα12-coupled receptors bind a wide range of extracellular molecules, including peptides, phospholipid-derived ligands, and other chemical messages (Fig. 1). Also found to couple to Gα12 is the protease-activated receptor PAR1, which is activated by cleavage within its extracellular N-terminal region catalyzed by thrombin (Riobo and Manning 2005). For several GPCRs not shown in Fig. 1, signaling is blocked by expression of a dominant-negative RhoGEF, which binds the activated forms of Gα12 and Gα13 and, therefore, does not distinguish between these G12 subfamily members. These GPCRs include the chemokine receptor CXCR4, the orphan receptor GPR56, and the muscarinic M1, lysophosphatidylcholine G2A, and Smoothened receptors (Riobo and Manning 2005; Dorsam and Gutkind 2007; Juneja and Casey 2009). Domain-exchange mutants within the G12 subfamily may shed light on specific receptor-Gα couplings. A recent study utilizing Gα12 and Gα13 chimeras with interchanged N-terminal regions suggested thrombin-induced signaling as preferentially Gα12-mediated, whereas LPA-generated signaling appeared to utilize Gα13 rather than Gα12 (Suzuki et al. 2009).

Several Gα12-coupled receptors have independently been linked to cell proliferation and cancerous progression. PAR1 is overexpressed in advanced breast and prostate cancers, and appears to contribute to metastatic invasion. Also, the LPA receptor appears involved in an autocrine signaling mechanism that promotes the growth of ovarian cancer cells, whereas endothelin receptors have been implicated in metastatic progression in prostate tumors. The ▶ sphingosine-1-phosphate receptor, which couples to Gα12, has been shown to induce proliferation and migration in vascular smooth muscle cells (Juneja and Casey 2009). Also, loss of physiological regulation of the ▶ Sonic hedgehog-stimulated receptor Smoothened has been linked to basal cell carcinomas. The receptor CXCR4, which binds exclusively to stromal cell–derived factor 1, is particularly interesting due to its aberrantly high expression in several metastatic cancers (Dorsam and Gutkind 2007); however, direct coupling of this receptor to Gα12 remains to be demonstrated. Because essentially all of these receptors couple to heterotrimeric G proteins outside the G12 subfamily, it remains to be determined whether the interface between Gα12 and specific receptors will provide a viable target for cancer drug development.

After the discovery of Gα12 (see Historical Background), nearly a decade elapsed before the first direct effector of Gα12 was identified: the Rho-stimulatory guanine nucleotide exchange factor p115RhoGEF. This protein bound to Gα12 and Gα13 and accelerated GTP hydrolysis on both proteins (Kozasa et al. 1998). During the next several years, yeast two-hybrid screening and other approaches yielded a structurally and functionally diverse collection of Gα12-interacting proteins. Some of these are targets for both Gα12 and Gα13, while others appear selective for Gα12 within the G12 subfamily. As illustrated in Fig. 1, the former group includes leukemia-associated RhoGEF (LARG), p115RhoGEF and PDZ-RhoGEF, several ▶ cadherins, the actin-binding protein radixin of the ezrin/radixin/moesin family, protein phosphatase-5, endothelial nitric oxide synthase, and Socius, whereas the Gα12-specific interactors include heat shock protein-90, the scaffolding subunit of the protein



G Protein Alpha 12, Fig. 1 Receptors, effectors, and signaling responses mediated by Gα12. G protein coupled receptors (GPCRs) demonstrated to couple to Gα12 are enclosed by a rounded rectangle at top. Effector proteins that directly interact with Gα12 are indicated by *shaded boxes*. *Thick black arrows* indicate binding to both Gα12 and Gα13, and *thick red arrows* indicate binding that appears selective for Gα12. *Non-boxed text* and *dashed lines/arrows* indicate downstream cellular responses demonstrated to be mediated by Gα12, and *solid, thin lines/arrows* indicate responses for which the effector protein immediately upstream of the *arrow* has been implicated. *Lighter* text indicates downstream responses shown to be dependent on Rho activation. Abbreviations for GPCRs are as follows: *AT* angiotensin, *CCK* cholecystokinin, *ET* endothelin, *fMLP* formyl peptide, *GAL* galanin, *LPA* lysophosphatidic acid, *PAR* protease-activated receptor, *S1P* sphingosine-1-phosphate, *TXA_2* thromboxane A_2, *TSH* thyroid-stimulating hormone. Abbreviations for effector proteins and downstream responses are as follows: *AKAP* A-kinase anchoring protein, *ASK* apoptosis signal-regulating kinase, *BTK* Bruton's tyrosine kinase, *COX* cyclooxygenase, *eNOS* endothelial nitric oxide synthase, *ERK* extracellular signal-regulated kinase, *GEF* guanine nucleotide exchange factor, *GSK* glycogen synthase kinase, *Hsp* heat shock protein, *JAK* Janus kinase, *JNK* c-Jun N-terminal kinase, *LARG* leukemia-associated RhoGEF, *PDGFR* platelet-derived growth factor receptor, *PDZ* PSD-95/Dlg/ZO-1, *PL* phospholipase, *PP* protein phosphatase, *RGS* regulator of G protein signaling, *SET* leukemia associated protein SET, *SNAP* soluble NSF-associated protein, *SRF* serum response factor, *STAT* signal transducer and activator of transcription, *ZO* zonula occludens

phosphatase-2A (PP2A) holoenzyme, non-receptor tyrosine kinases (Tec, Bmx, Bruton's tyrosine kinase), potential regulators of ▶ cadherin stabilization (p120 catenin and αSNAP) the tight junctional protein zonula occludens-1, proteins harboring a regulator of G protein signaling domain (axin and RGS1), the polycystic kidney disease–related protein polycystin-1, and the Rho-stimulatory A-kinase-anchoring protein AKAP-Lbc (Kelly et al. 2007; Yu et al. 2011). Efforts are ongoing to connect specific Gα12-target interactions to known Gα12-mediated signaling responses. The pathways in which RhoGEF

interaction drives Rho-mediated signaling are the best characterized, although the specific roles of Gα12 and Gα13 in these pathways are not resolved. Likewise, the effects of Gα12 and Gα13 on cadherin-mediated cell biology remain to be determined. Regulation of cell polarity and migration by Gα12 has been shown to involve LARG, which associates with pericentrin and localizes to the microtubule-organizing center (Juneja and Casey 2009). Gα12 interaction with zonula occludens-1 has been linked to regulation of paracellular permeability, and AKAP-Lbc appears to mediate Gα12 signaling leading to hypertrophy in cardiomyocytes (Appert-Collin et al. 2007). Gα12 interaction with the scaffolding subunit of PP2A revealed a potential role of Gα12 as a regulatory subunit in the PP2A holoenzyme, and implicated the Gα12-PP2A signaling axis in regulation of Tau phosphorylation in neural cells (Juneja and Casey 2009). Furthermore, the discovery of Bruton's tyrosine kinase, a protein involved in B-lymphocyte maturation, as a Gα12 target suggests a role for Gα12 in signaling pathways that govern this process (Worzfeld et al. 2008).

It remains to be determined whether subgroups of these Gα12-binding partners participate in common signaling pathways, or compete for interaction with Gα12. Also, for some Gα12 targets it is not clear whether the protein serves as a direct effector of Gα12 activation (i.e., interacts exclusively with GTP-bound Gα12 to propagate a signal). At least one protein, the scaffolding subunit of PP2A, has been reported to bind Gα12 in both its active and inactive (GDP-bound) conformation (Kelly et al. 2007). Also, the region of polycystin-1 mapped as interacting with Gα12 harbors a motif found in a number of GPCRs (Yu et al. 2011). It is possible that some Gα12-interacting proteins do not serve as classical downstream effectors, but instead play other roles such as facilitating Gα12 binding to effectors, specifying Gα12 coupling to receptors, regulating the intracellular location of Gα12, participating in non-receptor activation of guanine nucleotide exchange, or other, unknown functions.

Role of Gα12 at the Organismal Level: Development and Morphogenesis

Although many investigations of Gα12 have focused on its function at the single-cell level (e.g., signaling mechanisms, structural aspects of interaction with effector proteins, transcriptional responses), a number of studies have examined its role in larger-scale physiological events such as morphogenesis, organ system development, and embryogenesis. The first such studies revealed the role of the *Drosophila* Gα12 homolog Concertina in formation of the posterior midgut and ventral furrows during gastrulation (Parks and Wieschaus 1991). In studies of the roundworm *Caenorhabditis elegans*, RNA interference targeting the Gα12 homolog Gpa-12 caused an egg-laying defect, was embryonic lethal in most of these offspring, and caused locomotion and sensory defects in the few survivors. RNA interference of CeRhoGEF, a homolog of the G12-coupled mammalian RhoGEFs, phenocopied the Gpa-12-impaired roundworms to a lesser degree, suggesting that the Gα12-RhoGEF-Rho axis is an ancient signaling pathway. However, the greater severity of Gpa-12 knockdown than Ce-RhoGEF knockdown, along with Gpa-12 expression in several cell types lacking expression of Ce-RhoGEF, suggest the presence of other, Rho-independent Gpa-12-driven effector pathways in *C. elegans* (Suzuki et al. 2009). Initial studies of Gα12 knockout mice were less than encouraging; these mice appeared normal while mice engineered to lack the G12 subfamily member Gα13 died at embryonic day 9.5 with severe defects in angiogenesis. However, it has become apparent that Gα12 function is not completely eclipsed by Gα13 during embryogenesis. In mice haploinsufficient for Gα13, at least one allele of Gα12 was required to avoid embryonic lethality, and mice lacking both Gα12 and Gα13 died at least 1 day earlier in embryogenesis than Gα13 ($^{-/-}$) mice (Worzfeld et al. 2008). In more recent studies, approaches such as conditional gene inactivation and expression of dominant-negative proteins have revealed novel roles for Gα12; for example, knockout of Gα12 and Gα13 in neurons and glial cells resulted in over-migration of cortical neurons in certain brain subregions, suggesting Gα12 as a negative regulator of this migratory stage. A similar outcome was observed in marginal zone B-lymphocytes lacking Gα12 and Gα13, and in neutrophils harboring dominant-negative versions of these G12 subfamily proteins; these cells showed an increase in random migration that disrupted the ability of B-lymphocytes to settle properly in the marginal zone of the spleen. Also, Gα12 was shown to mediate migration of neural progenitor cells in response to stimulation of the orphan receptor GPR56

(Juneja and Casey 2009). In addition, Gα12 has been implicated in vascular smooth muscle contraction; studies in mice harboring conditional Gα12/Gα13 knockout in smooth muscle cells revealed Gα12 activation as necessary for the increased vascular tone that underlies salt-induced hypertension, but not basal vascular tone (Worzfeld et al. 2008). Finally, in studies examining the role of Gα12 in cancer progression, a dominant-negative, G12-specific RhoGEF hindered metastatic invasion of breast cancer cells implanted in the mammary fat pad of athymic mice. In contrast to the extensive results in cultured fibroblasts (see Role of Gα12 in Cell Growth, Apoptosis, and Oncogenic Transformation), Gα12 did not stimulate proliferation of these implanted cells (Kelly et al. 2006). These results suggest that the differential effects of Gα12 on proliferation versus migration/invasion are cell type specific, and that aberrant Gα12 signaling in some tumors may be most important during the progression of aberrantly dividing cells to a metastatic, invasive state.

Gα12 is essential for embryonic development in zebrafish, as suppression of Gα12 function was shown to disrupt convergence and extension during gastrulation. This effect of Gα12 requires signaling through a RhoGEF-Rho pathway; however, Gα12 also appears to act through other downstream effectors. Epiboly is a stage of embryogenesis in which the blastoderm spreads over the yolk cell, and involves the coordinated shape changes and movements of several cell populations. Interaction between Gα12 and the cytoplasmic domain of E-cadherin has been demonstrated as a critical step during epiboly in zebrafish, and gastrulae with disrupted Gα12 signaling phenocopy E-cadherin mutants, displaying aberrant movement and dissociation of several cell types. Gα12 signaling during epiboly appears to occur via two distinct mechanisms: a Rho-independent down-regulation of E-cadherin adhesive function and a Rho-dependent reorganization of the actin cytoskeleton (Lin et al. 2009).

Summary

This entry describes the molecules, cellular responses, and organismal processes regulated by Gα12, but it must be noted that many of these signaling functions of Gα12 overlap with functions of its G12 subfamily counterpart, Gα13. However, many properties of Gα12, particularly in terms of downstream target proteins, appear to be exclusive to Gα12 or show differential regulation by Gα12 and Gα13. For example, one of the earliest signaling responses reported for the G12 subfamily was stimulation of Na^+/H^+ ion exchange via the integral plasma membrane NHE proteins. This occurred through a protein kinase C-dependent pathway for Gα12, whereas activation of Na^+/H^+ exchange by Gα13 did not require protein kinase C. Furthermore, the ubiquitous Na^+/H^+ exchanger NHE1 was stimulated by Gα13 but, surprisingly, was inhibited by Gα12 (Lin et al. 1996). In *Drosophila* and *C. elegans*, the G12 subfamily is comprised of a single protein that harbors roughly equal similarity to the two mammalian members; for example, Concertina shares approximately 54% identity with Gα12 and Gα13. Therefore, many questions in the field of Gα12 signaling concern the respective signaling properties and biological roles of the two mammalian G12 α-subunits, as well as the evolutionary advantages afforded by the gene duplication and divergence that yielded these similar yet distinct signaling proteins.

The G12 subfamily has several interesting distinctions among heterotrimeric G proteins. First, it regulates an unusually wide variety of cellular processes that have potential to become aberrant in cancers (e.g., cell migration, growth, polarity, cell-cell adhesion, and cell-substrate adhesion). Second, the α-subunits of the G12 subfamily appear to be unique among G protein α-subunits in their ability to transform cells as an overexpressed rather than constitutively GTP-bound form. Therefore, it is possible that aberrantly high production or impaired turnover of Gα12 is sufficient to exert oncogenic effects in cells. Third, Gα12 interacts with a more diverse group of target proteins than any other Gα subunit. These discoveries have revealed intriguing possibilities for cellular events in which Gα12 plays a role; however, this diversity of downstream targets has created a maze of potential signaling mechanisms and possible regulatory relationships between different Gα12 effector proteins. Furthermore, cross-talk with other signaling pathways must be considered; for example, the G protein Gαq has been shown to stimulate Rho via activation of a recently discovered guanine nucleotide exchange factor, p63RhoGEF (Suzuki et al. 2009). Toward the goal of a comprehensive understanding of Gα12 signaling, it will be important to elucidate the structural features of Gα12 that mediate specific

target protein interactions. Mutational analyses of Gα12 have revealed amino acid determinants of its binding to several proteins, including RhoGEFs, polycystin-1, and the scaffolding subunit of PP2A (Kelly et al. 2007; Yu et al. 2011). A crystallographic analysis of Gα12 in complex with a downstream target protein has yet to be reported. However, it is promising that crystal structures have been published of recombinant Gα13 bound to the RGS domain of RhoGEFs (Suzuki et al. 2009). Similar structural studies of Gα12 may reveal subtle differences in the mechanisms through which Gα12 and Gα13 engage their respective effector proteins.

Although evidence is compelling that Gα12 can induce oncogenic transformation of cells, as well as initiate progression of existing cancer cells toward metastasis, it is important to note that human tumor samples harboring activating mutations in Gα12 have yet to be reported. Studies in breast and prostate cancer cell lines suggest that overexpression of Gα12 may suffice as a transforming agent in the absence of a GTPase-impaired mutant of Gα12 (Kelly et al. 2006). Also, recent results in a small cell lung carcinoma line showed RNA interference of Gα12 to block cell proliferation in culture and in a mouse xenograft model (Grzelinski et al. 2010). Clearly, a broad analysis of tumor samples from breast, prostate, lung, and other tissues will be valuable in assessing the significance of Gα12 in the pathology of specific human cancer types. Also, because of the mounting evidence that aberrantly high levels of Gα12 may drive cancerous growth and/or invasion, studies that examine factors regulating Gα12 gene expression, transcript stability (e.g., microRNAs), and protein turnover may be increasingly vital to understanding the role of Gα12 in cancer progression. Furthermore, continued efforts to identify the key Gα12 target proteins and pathways that mediate its growth, migratory, and invasive effects should aid the development of reagents for manipulating Gα12-mediated signaling as a treatment for cancers and other diseases.

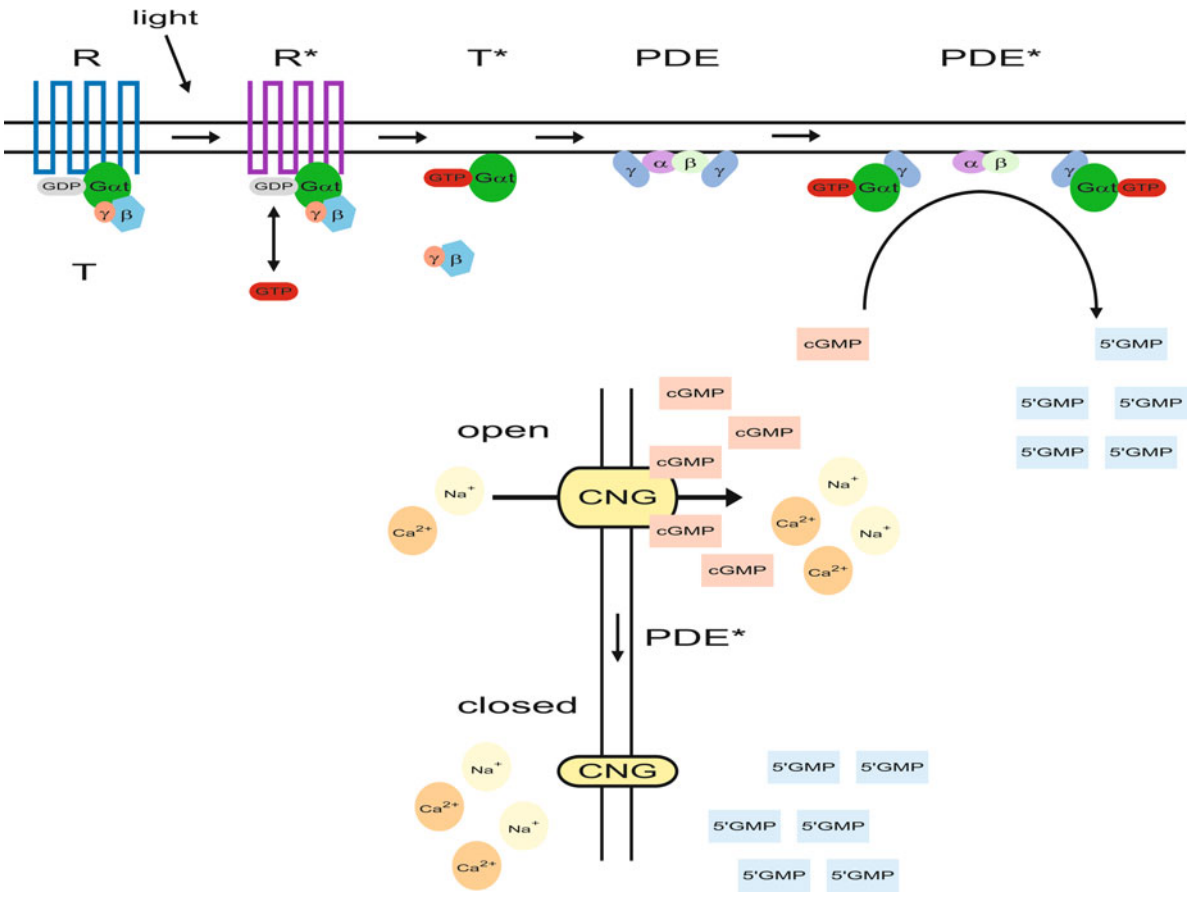
Historical Background

G protein alpha transducin was purified from bovine retinal extracts more than three decades ago. The discovery of transducin was the culmination of a series of findings that started in the mid-1970s (see Bourne 2006 for a recent review), beginning with the identification of the effector molecule cGMP phosphodiesterase (Bitensky et al. 1975). Shortly afterward, the presence of light-induced GTPase activity in rod outer segment extracts was described (Wheeler and Bitensky 1977). In 1978, activation of cGMP phosphodiesterase was shown to require activated rhodopsin and the presence of GTP (Yee and Liebman 1978). In 1979, a soluble guanine nucleotide binding protein with light-activated GTP–GDP exchange was purified (Godchaux and Zimmerman 1979). However, only two components, the α and β subunits, of the heterotrimeric G protein transducin were described. In 1981, the full heterotrimeric G protein was purified in Lubert Stryer's group, and they named it "transducin." Using purified transducin and rhodopsin, Fung et al. were able to demonstrate light-dependent binding and hydrolysis of GTP (Fung et al. 1981). These pioneered discoveries were later augmented by human and mouse genetics along with suction-electrode recordings to elucidate the role of transducin in phototransduction. However, many questions remain unresolved.

Role of Transducin in Phototransduction

In the absence of light, photoreceptors maintain a high concentration of intracellular cGMP. The dark cGMP level is sufficient to keep up to 10% of cyclic nucleotide-gated (CNG) channels on the plasma membrane open to allow an inward "dark current" of sodium and calcium ions to depolarize outer segment membranes to a resting voltage of approximately −35 mV. At this depolarized state, photoreceptors tonically release glutamate at their synaptic terminals. When light is introduced, a cascade of events involving transducin and collectively called phototransduction is activated, which leads to photoreceptor hyperpolarization and cessation of the tonic glutamate release.

The rod phototransduction cascade involves the G-protein-coupled receptor (GPCR) rhodopsin (R), the heterotrimeric G protein transducin (Tαβγ), and the effector cGMP phosphodiesterase ($PDE\alpha\beta\gamma_2$). In the dark, R is in an inactive conformation comprised of an apoprotein opsin and a covalently attached chromophore 11-*cis*-retinal. Light isomerizes the 11-*cis*-retinal to all-*trans*-retinal, which induces conformational changes of rhodopsin leading to an



G Protein Alpha Transducin, Fig. 1 Rod phototransduction cascade. Refer to the text for a description of the rod phototransduction cascade. An asterisk (*) denotes the activated state of a molecule

activated form called Metarhodopsin II (R^*). As shown in Fig. 1, rhodopsin (R) is coupled to the heterotrimeric G protein transducin (T); after light is introduced, rhodopsin is activated (R^*) to catalyze the exchange of GDP on Gαt for GTP. The GTP bound Gαt is the activated form (T^*) of G protein transducin. The activated transducin α subunit (T^*) dissociates from its Gβγ subunits and interacts with the PDEγ subunit, preventing it from inhibiting the catalytically active PDEαβ subunits. With PDEγ inhibition removed, PDEαβ (PDE^*) hydrolyzes cGMP into 5′GMP, which leads to a decline in intracellular cGMP concentration. This results in the closure of cyclic nucleotide-gated (CNG) cation channels and a decreased Na^+ and Ca^{2+} influx, which leads to membrane hyperpolarization. Cone phototransduction is similar to rod phototransduction; however, cones have a distinct set of signaling molecules with presumably similar functions (see Table 1).

Transducin Activation

The exchange of GTP for GDP on the α subunit of transducin, catalyzed by light-activated rhodopsin, constitutes the first amplification step in the phototransduction cascade. Transducin has a fairly fast guanine nucleotide exchange rate at approximately 1,000/s (Vuong et al. 1984). During its effective lifetime, R^* may activate multiple transducin molecules. The estimated rate of transducin activation by a single R^* has been reported in the range of 10–3,000/s (Fu and Yau 2007). In mouse rods, the activation rate of transducin by R* is reported to be ~240/s (Fu and Yau 2007). Rods have a large pool of transducin molecules and this characteristic has partly been attributed to the ability of rods to sense a single photon of light. The activation rate of rod transducin is approximately tenfold higher than cone transducin by cone pigment, which also contributes to rod's higher sensitivity to

G Protein Alpha Transducin, Table 1 Distinct phototransduction molecules in mouse rods and cones

Phototransduction molecule	In rods	In cones

[a]Mouse cones do not contain red-sensitive opsin (*Opn1lw*), which is present in primate cones

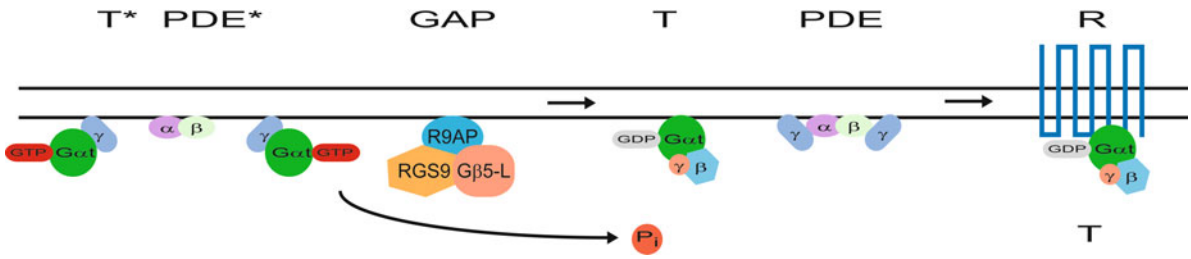
light (Luo et al. 2008). The effector cGMP phosphodiesterase (PDE) is a tetrameric membrane-associated protein consisting of two active and highly similar catalytic subunits αβ and two identical inhibitory γ subunits. The interaction of T^* with PDEγ removes the inhibitory PDEγ from the two catalytic PDEαβ subunits. Since there are two PDEγ subunits in the tetrameric PDEαβγ_2, two activated T^* molecules are required to achieve full PDE activation.

Transducin Deactivation

Deactivation of T^* requires its intrinsic GTPase activity to hydrolyze the bound GTP to GDP. When GTP is hydrolyzed by T^*, conformational changes in T^* lead to the release of PDEγ, which reassociates with and inhibits PDEαβ catalytic subunits. The rate at which GTP is hydrolyzed by T* determines the rate at which PDE^* is deactivated. As seen in Fig. 2, Regulator of G protein signaling 9 (RGS9-1) with the signature 120 amino acid RGS domain forms the so-called transducin GTPase accelerating protein (GAP) complex along with Gβ5-L and ▶ RGS9 anchoring protein (R9AP). The GAP complex binds T^* when it is bound to PDEγ to accelerate GTP hydrolysis (Keresztes et al. 2004; Krispel et al. 2003). Therefore, T^* will not be prematurely deactivated before it associates with PDEγ. The members of the transducin (GAP) complex, RGS9-1, Gβ5-L, and R9AP, are obligate protein partners. Knockout mice lacking any of these proteins, all result in a common phenotype: a delay in the recovery phase of the phototransduction cascade (Chen et al. 2000; Keresztes et al. 2004; Krispel et al. 2003). In photoreceptors, the rate-limiting step of rod recovery is determined by the level of the transducin GAP complex (Krispel et al. 2006). The GAP level is then determined by the R9AP expression level. In mice with different degrees of R9AP overexpression, which have corresponding overexpression of the entire transducin GAP complex, rod recovery can be accelerated to approach an asymptote with a time constant of ~70 ms. This suggests that when GAP concentration is significantly elevated, rod recovery is rate-limited not by transducin deactivation but by a different reaction(s) (Krispel et al. 2006).

Light-Dependent Redistribution of Transducin

In darkness, transducin is localized to the outer segment (OS) of rod photoreceptors. After prolonged light exposure, transducin can redistribute throughout the photoreceptor (Slepak and Hurley 2008). Interestingly, the Gβγ subunits also redistribute, but follow a different time course. Upon return to darkness, both Gαt and Gβγ return to the rod OS. Two lipid modifications are present in heterotrimeric rod transducin: Gαt is N-acylated and Gγ is S-prenylated on the C-terminus with a farnesyl group. A mutant form of Gαt (Q200L) that lacks the intrinsic GTPase activity was developed. The Q200L Gαt is constitutively bound to GTP and maintained in the active state (T*), and thus cannot reassociate with Gβγ. The Q200L Gαt is unable to stay localized to the rod OS in darkness, suggesting that reassociation with Gβγ was necessary for localization to the rod OS (Artemyev 2008; Slepak and Hurley 2008). Interestingly, cone transducin does not redistribute in response to light. One reason for this difference is the fact that Gβγ in cones has a stronger affinity for cone transducin even in the activated form. When a transgenic mouse was developed replacing rod transducin with cone transducin, the transgenic cone transducin in rods redistributed in a light-dependent manner (Chen et al. 2010). This suggests that it is not the proteins, but rather the cells that are responsible for the lack of transducin redistribution in cones. However, a recent paper by Lobanova et al. demonstrates that intense



G Protein Alpha Transducin, Fig. 2 Recovery phase of the rod phototransduction cascade. The intrinsic GTPase activity of Gαt is accelerated by the transducin GAP complex composed of RGS9-1, Gβ5-L, and R9AP. Hydrolysis of GTP to GDP on Gαt releases PDEγ to reassociate with PDEαβ. Gαt-GDP returns to heterotrimeric form by binding to its Gβγ and then recouples to rhodopsin (R). An asterisk (*) denotes the activated state of the molecule

light exposure for a prolonged period of time can cause cone transducin to redistribute in cones. This entry further shows that increasing cone sensitivity by ectopically expressing rhodopsin also moves cone transducin out of the outer segment in a light-dependent manner (Lobanova et al. 2010).

Role of Transducin in Photoreceptor Sensitivity and Response Decay

Rods are more sensitive to light than cones. Since rods and cones have distinct set of transducin molecules (see Table 1), the distinct proteins found in rods versus cones may have inherent properties that contribute to differences in their responses to light. To study whether transducin has any contribution, a transgenic mouse was generated with full-length mouse cone transducin (*Gnat2*) expressed in rods (Chen et al. 2010). This transgenic mouse was mated onto the *Gnat1*−/− mouse background to produce the GNAT2C mouse line. In GNAT2C rods, where cone transducin replaces rod transducin, GNAT2 expression level is similar to that of GNAT1 in normal mouse rods. Using suction-electrode recordings, GNAT2C rods were found to be three times less sensitive than wild-type and required brighter light to produce responses of the same amplitude (Chen et al. 2010). GNAT2C rods also displayed accelerated response decay compared to wild-type. When GNAT2C mice were mated to a mouse line overexpressing transducin GAP, the response recovery was accelerated even further beyond what was achieved from the transducin substitution (Chen et al. 2010). In the *RGS9*−/− background, GNAT2C rods could still turn off twofold faster than wild-type rods (Chen et al. 2010). These results suggested that the species of Gαt may indeed play an important role in setting the response kinetics and sensitivity of rods and cones.

GNAT1-Independent Phototransduction in Rods

Researchers frequently utilize the *Gnat1*−/− mouse as a model for loss of rod phototransduction. In 2010, Allen et al. mated *Gnat1*−/−; *Cnga3*−/−, *Opn4*−/− together to generate a triple knockout (TKO) mouse line. The *Cnga3*−/− mouse has a loss of cone vision, while the *Opn4*−/− mouse lacks melanopsin, a visual pigment expressed in intrinsically light-sensitive retinal ganglion cells. The TKO mouse theoretically should not have any light response. However, when they were used as "negative" controls in electroretinography (ERG) experiments, they were found to have a reproducible flash ERG response at high stimulus intensities >0.5 log cd/m^2 (Allen et al. 2010). Spectral analysis suggests that the light responses of TKO mice are mediated by rhodopsin. Since GNAT2 is known to couple to rhodopsin (Chen et al. 2010), *Gnat1*−/− was mated to a spontaneous mutant *Gnat2*^{cpfl3} mice, which have progressive loss of cone vision. The results from *Gnat1*−/−, *Gnat2*^{cpfl3} mice showed that the ERG response was reduced, but not eliminated. Consistent with their findings: the original characterization of the *Gnat1*−/− mouse by Calvert et al. showed that one (out of 213 examined) *Gnat1*−/− rod was found to have robust light responses similarly mediated by rhodopsin (Calvert et al. 2000). Allen et al. speculated that some ERG responses in TKO mice are mediated by GNAT2 (Allen et al. 2010). In an era in which genetics and technology are rampantly expanding the edge of scientific knowledge, the presence of robust

light responses in TKO mice exemplifies the opportunities that exist in the vision research field, where scientific dogma can be frequently challenged to reveal underappreciated intricacy and beauty of the visual system that are yet to be fully comprehended.

Summary

The critical role of $G\alpha t_1$ in the phototransduction cascade has been elucidated in rods, while the role of $G\alpha t_2$ in cone phototransduction is less understood. Custom-made transgenic animals, such as the GNAT2C mouse, should be useful to further dissect the difference of rod and cone phototransduction.

G Protein Beta

► G Protein Beta/Gamma

G Protein Beta/Gamma

Denis J. Dupré[1] and Terence E. Hébert[2]
[1]Department of Pharmacology, Dalhousie University, Nova Scotia, Canada
[2]Department of Pharmacology and Therapeutics, McGill University, Montréal, Québec, Canada

Synonyms

G beta; G gamma; G protein beta; G protein gamma; Gb; Gnb; Gng; Guanine nucleotide binding protein;

Guanine nucleotide binding protein, beta; Guanine nucleotide binding protein, beta polypeptide; Guanine nucleotide binding protein (G protein), gamma; Guanine nucleotide binding protein, gamma

Isoforms

Five different isoforms of Gbeta have been identified, numbered 1 to 5. Ggamma isoforms are numbered from 1 to 5 and 7 to 13.

G protein beta5 can also be known as Flailer, Flail, Flr, Hug.

G protein gamma2 is also known as G protein gamma6.

Historical Background

G protein β and γ subunits were first discovered as components of G proteins over 30 years ago. Since then, their role has evolved significantly from simple inhibitors of ► G protein α subunits to independent signaling regulators modulating a number of different cellular effectors. Although several isoforms of Gα were cloned in the early 1980s, it was not until 1986 that the transducin Gβ subunit was cloned (Fong et al. 1986). The following year, a second Gβ subunit was identified and the count rapidly increased to five different genes. Gβ1-4 shared 82–92% identity, while Gβ5 shared only 51–53% identity with the other four isoforms. As was the case for Gα and Gβ, the first Gγ subunit to be cloned was also from transducin (Hurley et al. 1984). The Gγ subunits are more structurally diverse than the Gβ subunits; 12 nonallelic mammalian Gγ genes encode proteins of between 68 and 75 amino acids that share between 27% and 76% sequence homology. If divided into subfamilies, the sequence similarities among family members are much greater. For example, Gγ1, Gγ11, and Gγ13 share 62–73% homology. Gγ subunits undergo several posttranslational modifications including isoprenylation of an invariant cysteine residue in a conserved CAAX motif at the carboxyl end of the protein which have been demonstrated to be important for membrane localization of Gβγ. Most Gγ subunits have a leucine at the carboxyl terminus which directs addition of a geranylgeranyl group, while some (Gγ1, Gγ8, Gγ11, and Gγ13) have a serine which permits addition of a farnesyl group. Gγ subunits form tight (essentially non-dissociable) complexes with Gβ, and confer structural diversity and functional diversity to the Gβγ signaling complex. Although Gβγ is made up of two polypeptides, Gβ and Gγ, it essentially exists as a single protein as they do not dissociate in the absence of denaturing agents. The high resolution structure of the Gβγ subunit was first elucidated in the context of the G protein heterotrimer (Lambright et al. 1996). Subsequently, the structure of the Gβγ dimer alone was solved (Sondek et al. 1996). The Gβ subunit is folded into four stranded β-sheets forming each of the seven blades of the prototypical circular β-propeller. The circular structure is held closed by a molecular "Velcro snap" in the seventh blade of the propeller. The first 57–70 amino acids N-terminal to the β-propeller form an α-helical domain, which is tightly associated with the Gγ subunit in a coiled-coil interaction.

Five different Gβ subunits and 12 different Gβγ subunits genes have been identified in the human and mouse genomes. The different subunits can pair to form unique $G\beta_x\gamma_x$ combinations, which contribute to the functional diversity of Gβγ signaling. Interpretation of phenotypes resulting from knockout of individual Gβγ subunits has failed to provide a clear picture of the role of each subunit, as Gβγ subunits participate in multiple, integrated functional interactions with receptors, Gα subunits, and effectors. Surprisingly, knockout of the Gβ1 subunit, despite its homology with Gβ2-4, was embryonic lethal (Okae and Iwakura). This suggests that the different Gβ subunits are developmentally regulated. This has been demonstrated directly for Gβ3 subunits in cardiomyocytes (Rybin and Steinberg 2008). Nevertheless, there is evidence suggesting that specific Gβγ subtypes interact with particular G protein-coupled receptors (GPCR). Genetic deletion of specific Gγ subunits in mice results in specific phenotypes. For example, deletion of Gγ7 resulted in distinct behavioral changes associated with loss of cAMP production in the striatum, while deletion of Gγ3 induced changes in metabolism resulting in resistance to a high fat diet (Schwindinger et al. 2003).

If all Gβ subunits interact and randomly form dimers with all Gγ subunits, there would be 60 possible combinations in total. Most can form pairs in vitro but some exceptions have been reported. For example, Gβ1 can combine with all known Gγ subunits, while

Gβ2 was shown to be more selective, associating with Gγ2, but not Gγ1. The region of Gγ defining the specificity of interaction with Gβ subunits has been localized to a 14-amino acid segment located toward the middle of the molecule (Spring and Neer 1994). Gβ5 is clearly an outlier with respect to sequence and its capacity to interact with Gγ. While Gβ5 can interact with some Gγ subunits, it appears to be weakly bound and the complex can be separated under non-denaturing conditions. Biochemical studies demonstrated that RGS7 formed stable complexes with Gβ5, but not other Gβ subunits (Cabrera et al. 1998) and was co-purified as a tight complex, while no Gγ subunit was found to co-purify or form stable complexes with Gβ5 (Witherow et al. 2000). Another study examining Gβ5 complex formation with different potential partners showed that Gβ5 slightly prefers Gγ2 relative to RGS7, suggesting that in native tissues, Gγ2 could potentially assemble with Gβ5 unless there is a tight regulation of this interaction by molecular chaperones (Yost et al. 2007).

While functional Gα subunits can be synthesized in almost any expression system, Gβγ synthesis seems more tightly regulated. This is not simply owing to differential posttranslational modification as both Gα and Gγ subunits are modified by the addition of lipid moieties that facilitate their association with lipid bilayers. For example, Gβγ can be synthesized in vitro in rabbit reticulocyte lysates. However, either cotranslationally or by subsequent attempts at assembly in vitro, formation of functional Gβγ dimers is inefficient; only 30–50% of the synthesized Gβ and Gγ subunits can form functional Gβγ dimers. Interestingly, Gβ subunits can be synthesized separately from Gγ subunits in rabbit reticulocytes and wheat germ extract, but these will not interact efficiently with Gγ subunits. By contrast, Gγ subunits can be synthesized in rabbit reticulocyte lysates, wheat germ extracts, and bacteria, and will efficiently associate with Gβ subunits. This specificity suggests that molecular chaperones are necessary for the proper folding of Gβ and subsequent assembly into a Gβγ dimer. Recent studies have indicated that there are preferential associations of such chaperone candidates for different Gβγ subunits in living cells. Members of the phosducin family were originally proposed to act as inhibitors of G protein signaling via sequestration of the Gβγ subunits from Gα and effector molecules. Phosducin-like proteins (PhLP 1–3) have been shown to serve as co-chaperones with the cytosolic chaperonin complex (CCT) to assist in folding a variety of nascent proteins (Martin-Benito et al. 2004; Lukov et al. 2006). CCT is an essential chaperone required for protein folding in the cytosol of eukaryotic cells. Among the known substrates of CCT are Gα and multiple proteins with β-propeller WD40 structures similar to Gβ. PhLP acts as a co-chaperone by binding above the CCT cavity and occluding the cavity to stabilize folding processes until native protein formation occurs. PhLP1 may act as a co-chaperone for the folding of the Gβ subunit until Gβγ reaches its native stable state. This idea is consistent with observations that when PhLP1 is deleted in *Dictyostelium*, Gβ does not colocalize with Gγ at the plasma membrane but is expressed in the cytosol, as if the Gγ interaction was inhibited. To facilitate Gβγ dimer formation, PhLP1 must be phosphorylated on serine residues by ▶ casein kinase 2 (CK2). A mutant of PhLP1 that cannot be phosphorylated (S18–20A) inhibits both Gβ release from CCT and subsequent Gβγ assembly. The mechanism for Gβ release from CCT may involve steric repulsion, thereby triggering release of a PhLP1-Gβ complex intermediate. Here, Gβγ subunits are not yet in their native form because the intermediate complex of PhLP1-Gβ does not contain Gγ subunits (Dupre et al. 2009; Lukov et al. 2006; Willardson and Howlett 2007).

Interestingly, Gγ was not found to interact with CCT either directly or in a complex with Gβ. A separate chaperone has also been identified for Gγ subunits. Dopamine receptor interacting protein 78 (DRiP78) is an ER membrane–bound HSP40 co-chaperone that regulates receptor transport to the plasma membrane of GPCRs such as β_2-adrenergic (β_2AR), dopamine D1, M2 muscarinic cholinergic, and angiotensin II AT1 receptors (Bermak et al. 2001; Leclerc et al. 2002; Dupre et al. 2007). Gγ subunits and DRiP78 initially colocalize in the ER, presumably facing the cytosolic compartment where they can interact with Gβ. It was suggested that DRiP78 maintains the stability of nascent Gγ in the absence of its heterotrimeric partners. Furthermore, DRiP78 interacts directly with PhLP1, suggesting that PhLP-Gβ complex might interact with DRiP78-Gγ complex, thus participating in the assembly of the native Gβγ dimer. DRiP78 acts as a co-chaperone for Gβγ assembly, protecting Gγ from degradation until both subunits can be assembled into their native form (Dupre et al. 2009).

Role in G Protein Coupled Receptor Assembly, Organization, and Signaling

Receptors, G proteins, effectors, as well as several scaffolding/chaperone proteins are observed as multimeric complexes at the plasma membrane. Some studies have suggested that several of these signaling partners can form complexes before receptor activation by agonist, that is, they are pre-associated complexes. A rather confusing picture regarding the trafficking of individual components of GPCR signaling complexes has appeared in recent years. While it is clear that receptor oligomers themselves are assembled in the endoplasmic reticulum, the site of the assembly of the rest of the core signaling components was still unclear. Constitutive trafficking of some GPCR-regulated effectors, such as adenylyl cyclase isoforms or various ion channels, demonstrates that components of these signaling pathways can make their way to the membrane independently of the receptor or G protein. However, there is now significant evidence that like GPCR oligomers, these complexes are also formed early in their maturation steps. A number of studies have also demonstrated that receptors can directly interact with Gβγ subunits as well as Gα subunits (Wu et al. 1998; Wu et al. 2000; Mahon et al. 2006) and that many of these proteins interact initially in the endoplasmic reticulum (ER), including receptor dimers, receptor and Gβγ subunits, and effectors such as Kir3 channels and ▶ adenylyl cyclase with nascent Gβγ (Dupre et al. 2006; Rebois et al. 2006). If these complexes are preformed during protein biosynthesis and maturation, they would need to be trafficked inside the cell as a complex and not necessarily as individual proteins (Fig. 1). It is clear that both GPCRs and their effector molecules interact with G protein subunits before targeting to the plasma membrane. It has been suggested that Gβγ subunits might play an organizing role for assembly of GPCR-based signaling complexes as they interact with all of the relevant components, receptor, Gα, and effectors before any of them reach their destination. A potential mechanism may rely on early interactions with G protein subunits which may regulate assembly of receptor signaling complexes in the ER as when Gβγ function is inhibited by using a membrane-localized GRK2ct construct, Kir3.1/Gβγ complex formation in the ER can be blocked. Although still in its infancy, it seems that current research points toward an important role of Gβγ in signaling complex organizations.

G Protein βγ Regulation of Effectors

Early reconstitution studies with receptors and purified G proteins indicate that Gβγ is required for GPCR-induced nucleotide exchange. While some studies suggested Gβγ was necessary for the targeting of Gα subunits to the receptor, others have suggested that Gβγ might not only promote coupling, but also organize the structure of the Gα subunit so it is a substrate for GPCRs. Gβγ subunits can also regulate a wide range of effectors. Although various Gβγ binding motifs within effectors have been identified, no single consensus sequence or structure has been identified. However, energetic hot spots have been identified on the surface of Gβγ which allow several types of chemical interactions (ionic, hydrophobic), with multiple structural and chemical motifs at a single binding site (DeLano 2002; Fairbrother et al. 1998; Ma et al. 2001; Scott et al. 2001). Two general mechanisms for Gβγ-dependent regulation of effectors were proposed, according to the localization of the effector. In the case of cytosolic proteins like PLCβ2 or GRK2, whose substrates are membrane-bound, a potential mechanism for activation is via membrane-bound Gβγ recruitment to the effector. Membrane-embedded targets like Kir3 channels and adenylyl cyclase would be regulated via conformational changes. Some examples of different Gβγ effectors are given in Table 1, and a brief overview of the mechanisms used to regulate some effectors is presented here.

Gβγ is known to regulate several ion channels, such as Kir3 (inward rectifier G protein-gated K^+ channel) and voltage-gated calcium channels. The model of activation of membrane-bound channels such as Kir3 suggests that Gβγ binding to an intracellular cytosolic domain of the channel strengthens interactions between PIP_2 and the channel, which alters the structure at the mouth of the conductance pore to increase channel activity. PLCβ activation by Gβγ relies on the alteration of its enzymatic activity either through conformational alteration of the active isoforms or modulation of the orientation of PLC with respect to membrane surface (Romoser et al. 1996; Runnels et al. 1996). Evidence for the alteration of enzymatic activity comes from studies showing that fragments of PLCβ2 could compete for the PLCβ2 activation by Gβγ in transfected cells. Two overlapping fragments from the catalytic Y domain of PLC blocked activation by Gβγ or a Gαi coupled C5A receptor, but not Gαq

coupled α_1-adrenergic receptor (Kuang et al. 1996). A triple substitution (E574, L575, K576) in the PLCβ2 catalytic domain disrupted direct binding of Gβγ to PLCβ2, strongly suggesting that the region involved in the activation of PLCβ2 is also mediating the interaction (Bonacci et al. 2005; Sankaran et al. 1998). Supporting the notion that a pleckstrin homology (PH) domain is involved is the observation that the isolated PH domain from PLCβ2 interacts with Gβγ on membrane surfaces and splicing of the PH domain to PLCδ confers the ability for PLCδ to be activated by Gβγ (Wang et al. 2000). Further biochemical and structural analysis will be required to determine the exact mechanism involved in the process.

Gβγ will not only regulate classic GPCR signaling effectors, but also seems to be involved in vesicular traffic. Heterotrimeric G proteins are associated with intracellular membrane compartments. For example, it was shown that purified Gβγ subunits inhibited the export of a marker protein from the endoplasmic

reticulum (Schwaninger et al. 1992). Although the exact mechanisms are still unclear, both Gαs and Gβγ interact with the small GTPase ARF (Colombo et al. 1995), important for vesicular trafficking. Also, the association of ARF and β-COP with Golgi membranes is sensitive to a number of reagents that modulate heterotrimeric G protein function (Donaldson et al. 1991; Ktistakis et al. 1992). Interestingly, ARF might be an exception in the small GTPases family, as Rab, Ras, Rho, and their relatives did not display binding capacity to Gβγ subunits. The Ras exchange factor ▶ $CDC25^{Mm}$ or $p140^{Ras\text{-}GRF}$ could become constitutively activated following co-expression with Gβ1γ2 or Gβ1γ5, classifying it as a Gβγ-sensitive pathway.

Receptor-Independent Signaling by G Protein βγ

The classical view holds that GPCR signaling was mediated solely via activation of G proteins and their downstream effectors. However, an emerging area of research is non-receptor and nucleotide exchange-independent mechanisms for G protein activation (Luttrell 2005). Some of the mechanisms used to activate Gβγ involve binding to Gα, leading to the release of free Gβγ. Other proteins have been found to directly activate Gβγ via a direct interaction; however, the mechanisms remain poorly understood. Below is a sampling of these events.

Several activators of G protein signaling (AGS) have been identified to date. Group I AGS proteins are guanine nucleotide exchange factors that promote receptor-independent G protein activation by facilitating GDP dissociation from, and thus GTP binding to, Gα subunits. Group II AGS proteins (also called GPR or GoLoco proteins), in contrast, *inhibit* GDP dissociation, but may promote Gβγ signaling by altering the association between Gα and Gβγ. Group III AGS proteins differ from the others in that they do not appear to bind appreciably to Gα subunits but rather they produce their effects by binding directly to Gβγ. This interaction could promote dissociation of the heterotrimer subunits or simply compete for interaction with Gα. AGS2, a light chain component of the dynein motor in the cytoplasm may also be a direct Gβγ effector important for the modulation of neurite outgrowth and other processes required dynamic modulation of the cytoskeleton (Sachdev et al. 2007). Another study indicated that AGS9, a Group III AGS protein, modulated signaling events via interactions with an intact G protein heterotrimer, and may in fact form a signaling complex with the G protein heterotrimer and one of the classic Gβγ effectors, PLCβ (Yuan et al. 2007). However the exact function of the Group III AGS proteins remains unclear. Gβ1 can be phosphorylated on histidine 266 by histidine kinase and this high energy phosphate can be transferred to Gα-GDP, yielding Gα-GTP, by nucleoside diphosphate kinase B (NDPK B) (Wieland 2007). This may represent a mechanism for heterotrimeric G protein activation which does require a GPCR per se. In rat cardiomyocytes, Gβ1 H266L, a mutant which cannot be phosphorylated by histidine kinase showed reduced cAMP stimulation and reduced levels of cardiac contractility and decreased phosphorylation of phospholamban on serine 16 following receptor stimulation by agonist (Hippe et al. 2007).

G Protein βγ as a Target for Therapeutic Development

The diversity of physiological Gβγ functions in the cell suggests that their specific manipulation might be of significant therapeutic interest. Although the blockade of Gβγ in cells is a highly promising target, selective manipulation would be required. Indeed, the type of compound that would be preferred would be a small molecule capable of binding to Gβγ and affecting particular downstream signaling events, without affecting other vital functions of the heterotrimeric G protein (Gαβγ) and GPCR activation. Interestingly, some molecules have been found to act in such way. For example, the carboxy terminus of GRK2 (GRK2ct) (Koch et al. 1995) was used in cardiac cells to demonstrate the therapeutic potential of targeting Gβγ in cardiac function and failure. During heart failure, a loss of β-adrenergic receptor (βAR)-dependent expression is observed, where it has been shown that receptor desensitization following GRK2 phosphorylation of the receptor is occurs. GRK2 is controlled by Gβγ which, following GPCR activation, recruits GRK2 to the receptor leading to receptor phosphorylation. GRK2ct blocks this recruitment and permits continuation of receptor function, as demonstrated in transgenic cardiac overexpression

of GRK2ct in mice where cardiac performances were improved following β-adrenergic receptor stimulation. Another study demonstrated in cardiomyocytes isolated from human biopsies that expression of GRK2ct could significantly improve contractile function (Williams et al. 2004).

Peptides with the capacity to bind directly to Gβγ as observed for the SIRK/SIGK peptides. Although these peptides were shown to block Gβγ-dependent PLCβ2 and PI3Kγ activation in vitro, while they had no effect on the inhibition of ▶ adenylate cyclase, demonstrating selectivity for inhibition of some Gβγ targets. Cell-permeable versions of the peptides predicted to inhibit G protein signaling demonstrated rapid, efficient, and potent activation of the ERK/MAPK pathway, while a Gβ mutant (W332A), unable to bind the peptide showed significantly inhibited SIRK-dependent ERK activation (Malik et al. 2005).

These molecules could represent potentially specific Gβγ targets in inflammation, as well as drug addiction. Although one major therapeutic target, chemokines and their receptors physiology is extremely complex, due to their natural tendency for redundancy and the multitude of chemokines and receptors that can be expressed in a single cell. These considerations make it difficult to convincingly identify the factors responsible for inflammatory diseases such as arthritis. Gβγ regulates some downstream effectors such as PI3Kγ, which was shown to be involved in the regulation of neutrophil migration in response to chemoattractants and inhibition of inflammation. In this system, inhibition of PI3Kγ would bypass the inhibited interactions between Gβγ and targets that are critical for chemoattractant-dependent directed migration or reactive oxygen species production by neutrophils or other monocytes (Lehmann et al. 2008). For example, M119 blocked membrane translocation of ▶ P-Rex, a PIP_3- and Gβγ-regulated Rac2 exchange factor, in neutrophils. This action could result from direct blockade of P-Rex binding to Gβγ in addition to blocking PIP_3 production by ▶ PI 3-kinase (Lehmann et al. 2008; Zhao et al. 2007). In vivo validation of small molecules targeting Gβγ has been shown in studies of opioid-dependent nociception (Mathews et al. 2008). M119, when injected intracerebroventricularly in mice, could cause tenfold and sevenfold increases in the potencies of morphine and the μ-opioid receptor peptide DAMGO, respectively, while having little or no effect on the κ- or δ-opioid receptor dependent analgesic pathways. M119 also inhibited μ-opioid receptor dependent activation of PLC, and systemic administration of M119 resulted in a fourfold shift increase in potency of systemically administered morphine. A recent study showed that inhibition of Gβγ signaling with small molecules based on these peptides (M119) was protective in heart failure models (Casey et al.). These results suggest that small organic compounds that specifically regulate Gβγ signaling could have important therapeutic applications in several diseases.

Summary

Gβγ are important modulators of cellular function, highly implicated in G protein signaling, and possibly the scaffolding of receptors with their signaling partners. Despite years of investigation, the selectivity of assembly of the different subunits and the specific function of all these pairs is still poorly understood. It is likely that in the near future, new properties, mechanisms of action and functions will emerge which might provide us with a better understanding of the role of this key component in signal transduction. Given the large potential for therapeutic strategies targeting Gβγ, understanding how these proteins work in physiological systems will likely provide answers as to how we can manipulate them to develop novel therapeutic approaches to several diseases.

Historical Background: Discovery of G Protein α i as the Inhibitor of Hormone-Stimulated Adenylyl Cyclase Activity

During the discovery purification that identified G protein (alpha) s (Gαs) as the ▶ adenylyl cyclase activator, Gilman and colleagues noted a 41 kDa contaminating protein (now known as G protein alpha i (Gαi)) that persisted into the final stages of the Gsαβγ heterotrimer purification. Hormonal activation *and* inhibition of ▶ adenylyl cyclase were known at the time to be GTP-dependent. The 41 kDa protein was found to be an ADP-ribosylation substrate of *Bordetella pertussis* toxin (PTX). Importantly, PTX was known to block hormonal inhibition of ▶ adenylyl cyclase activity. Activity-based purification of the inhibitor (G protein i) from rabbit liver correlated with PTX-catalyzed ADP-ribosylation of the 41 kDa (Gαi) substrate. The purified G protein i heterotrimer consisted of the 41 kDa GTP binding α subunit, the 35 kDa Gβ subunit, and a later recognized 8–10 kDa Gγ

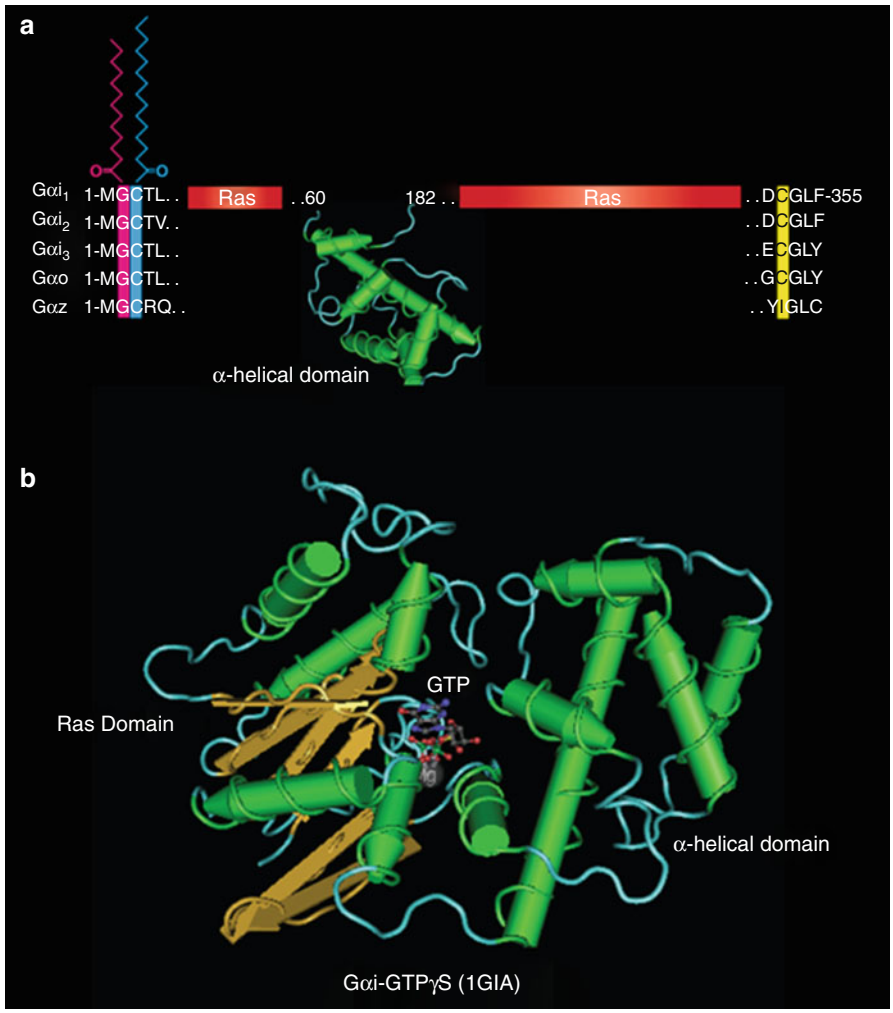
subunit. When reconstituted into cellular membranes pretreated with PTX, purified G protein i heterotrimer restored the ability of hormone and GTP to inhibit ▶ adenylyl cyclase activity (for review and a comprehensive historical account of primary references, see Gilman (1995)). Subsequent molecular cloning endeavors collectively identified three closely related G protein αi genes that encode the $G\alpha i_1$ (NP_002060), $G\alpha i_2$ (NP_002061), and $G\alpha i_3$ (or in some current databases, GαK) (NP_006487) proteins (Didsbury and Snyderman 1987; Jones and Reed 1987; Suki et al. 1987). Gαo was discovered by purification of an "other" G protein substrate of PTX from bovine brain and is estimated to constitute a substantial percentage (~1%) of total brain membrane protein (Neer et al. 1984; Sternweis and Robishaw 1984). Two alternatively spliced Gαo gene products encode two nearly identical proteins, $G\alpha o_A$ (or $G\alpha o_1$) (NP_066268) and $G\alpha o_B$ (or $G\alpha o_2$) (NP_620073). Later, peptide antisera raised against translated Gαz cDNA sequences were used to purify Gαz from bovine brain (Casey et al. 1990). Unlike all other Gαi-class G proteins, Gαz (NP_002064) does not contain the specific cysteine residue located in the fourth position from the carboxyl terminus that is the site of *Pertussis* toxin-catalyzed ADP-ribosylation Fig. 1. G protein α T (Transducin), and G protein α Gust (Gustducin) are tissue-specific G protein αi-class family members in the visual transduction and tastant sensing pathways, respectively, and are the subjects of a separate essay. The Gαi G protein subfamily comprises the largest number of individual members and constitutes the bulk of expressed G proteins in most tissue types.

Gi Biosynthesis

Gi heterotrimers follow a similar biosynthetic route as most G proteins, but aspects of Gαi-class subunit biosynthesis include unique processing. Gα subunits are translated on free cytosolic ribosomes and the initiator methionine is cleaved. The resultant amino terminal Gαi/o/z glycine residue becomes myristoylated. *N*-myristoyl transferase catalyzes the covalent attachment of a 14-carbon myristate chain to the glycine amino group during protein translation (Mumby et al. 1990). The nascent, myristoylated Gαi chain is folded by action of the cytosolic chaperone complex (CCT), as documented for Gαi family member G protein α Transducin (Farr et al. 1997). A new role for Gα non-receptor ▶ Ric-8 guanine nucleotide exchange factors (GEFs) showed that Ric-8A may aid Gαi folding with the CCT, or function after folding is mostly complete to promote the initial membrane association of nascent Gαi/o subunits. In *Ric-8A*$^{-/-}$ cells, Gαi (and also Gαq and Gα12/13) subunits exhibit membrane targeting defects and were subjected to rapid turnover (Gabay et al. 2011). Gαi binds to Gβγ on the endoplasmic reticulum membrane to form the nascent Gi heterotrimer, which is requisite for trafficking of the intact heterotrimer to the plasma membrane. Posttranslational Gαi/o/z palmitoylation at cysteine 3 is also required for G protein plasma membrane targeting (Fig. 1a). ER or Golgi-enriched DHHC palmitoyl transferases are likely responsible. The actual G protein heterotrimer trafficking mechanism has not been elucidated, but may involve a diffusive or membrane sampling type of mechanism until plasma membrane residence is achieved. Once G protein heterotrimers reach the inner leaflet of the plasma membrane, they are considered mature and sufficient to transduce signals from G protein coupled receptors (GPCRs). Plasma membrane residence is not static and Gαi/o and Gβγ subunits undergo agonist-dependent and -independent translocation to (and from) other cellular residences, including the Golgi during a process that may intersect a dynamic palmitoylation and depalmitoylation cycle (for comprehensive reviews of G protein trafficking mechanisms and accounts of primary references therein, see Chisari et al. (2007), Marrari et al. (2007), Saini et al. (2009)).

Gαi Structure and G Protein Catalytic Mechanism

Gαi/o/z subunits share primary structural features common to all heterotrimeric G protein α subunits. Each contain a core Ras small GTP-binding protein homology domain consisting of Gαi amino terminal amino acids ~1–60, interrupted by a region of ~120 amino acids, followed by the carboxyl-terminal ~175 amino acids that complete the Ras homology domain. The intervening region has high α-helical content and is commonly referred to as the Gα subunit α-helical domain. It is not found in small GTP binding proteins (Fig. 1a). Guanine nucleotide and its Mg^{+2} cofactor bind the Ras domain and are sandwiched between the



G Protein α i/o/z, Fig. 1 (**a**) Members of the Gα(i) family comprise a conserved Ras small GTP binding domain containing a ~120 amino acid insertion termed the α-helical domain. The initiator methionine is cleaved from all Gαi species leaving an amino-terminal glycine 2 residue that becomes irreversibly *N*-myristoylated (14 carbon chain) (shown in *magenta*). The sulfhydryl group of Cysteine 3 is reversibly palmitoylated (16 carbon chain) (shown in *light blue*). The fourth residue from the carboxyl-terminus is the site of *Pertussis* toxin-catalyzed ADP-ribsolyation of all Gαi species (cysteine) except Gαz (isoleucine) (highlighted in *yellow*). (**b**) Rendering of the structure of $G\alpha i_1$ bound to Mg^{+2} and GTPγS. GTPγS is bound in the guanine nucleotide-binding pocket located between the Ras and α-helical domains. Pivoting and/or rotation about the two loop/hinge regions that connect the two domains is thought to be the mechanism by which guanine nucleotide exchange occurs. The $G\alpha i_1$-GTPγS structure was obtained from RCSB PDB (www.pdb.org) of PDB ID: 1GIA (Coleman et al. 1994) and modified using the Cn3D v.4.3 macromolecular structure viewer software available from the NCBI

Ras and α-helical domains. Like other Gα subunits, the Gαi carboxyl terminal residues constitute one region responsible for the specificity of G protein-receptor coupling.

G protein catalytic mechanisms have been elucidated biochemically and structurally, predominantly using $G\alpha i_1$, as well as Gαs and Gαq as the prominent model G proteins (for review and primary references therein, see Elliott (2008), Gilman (1987), Sprang (1997)). The G protein catalytic cycle consists of three primary steps, GDP release (intrinsic $G\alpha i_1$ rate: ~0.02–0.05 min^{-1}), subsequent GTP binding to the open, nucleotide-free Gαi subunit (predicted to be very fast), and subsequent GTP hydrolysis ($G\alpha i_1$ rate ~3 min^{-1}). As is evident, GDP release is rate limiting to the steps of Gαi activation and single turnover and

steady-state hydrolysis of GTP. GPCRs act as guanine nucleotide exchange factors (GEFs) for Gi heterotrimers and accelerate the GDP release rate such that it may no longer be the slowest step in the G protein catalytic cycle. In many activated-GPCR signaling contexts, the intrinsic Gαi GTP hydrolysis rate becomes limiting, underscoring the relevancy of the action of RGS GTPase activating proteins. RGS proteins bind to Gαi (and Gαq and Gα12/13-class) subunits and accelerate the GTP hydrolysis rate to keep pace with the rate of GPCR-stimulated GDP release (and apparent GTP binding) (Berman and Gilman 1998). The mechanism of *Pertussis* toxin inhibition of Gi is to ADP-ribosylate Gαi subunits. This renders Gi heterotrimers as non-substrates for GPCR-mediated activation.

The X-ray crystal structures of various forms of Gαi helped reveal the important features of G protein function and catalysis, and demonstrated the changes in the G protein Ras domain switch regions that occur during the transition from the GDP-bound to GTP-bound state. The conformational differences between these two states enable the G protein to interact with different sets of protein binding partners. G protein structures and mechanisms of action are reviewed in exquisite detail by Sprang (1997). Many structures of G proteins were produced using Gαi subunits as the model G protein and prominent examples include the following structures with PDB ID numbers: RCSB PDB (www.pdb.org): $G\alpha i_1$-GTPγS (1GIA) (Fig. 1b) (Coleman et al. 1994), $G\alpha i_1$-GDP-AlF_4^- (1GFI) (Coleman et al. 1994), $G\alpha i_1$-GDP (1GDD) (Mixon et al. 1995), $G\alpha i_1$-GDP:Gβγ (1GP2) (Wall et al. 1995), Gαi/αT chimera:Gβγ (1GOT) (Lambright et al. 1996), and $G\alpha i_1$-GDP-AlF_4^-:RGS4 (1AGR) (Tesmer et al. 1997).

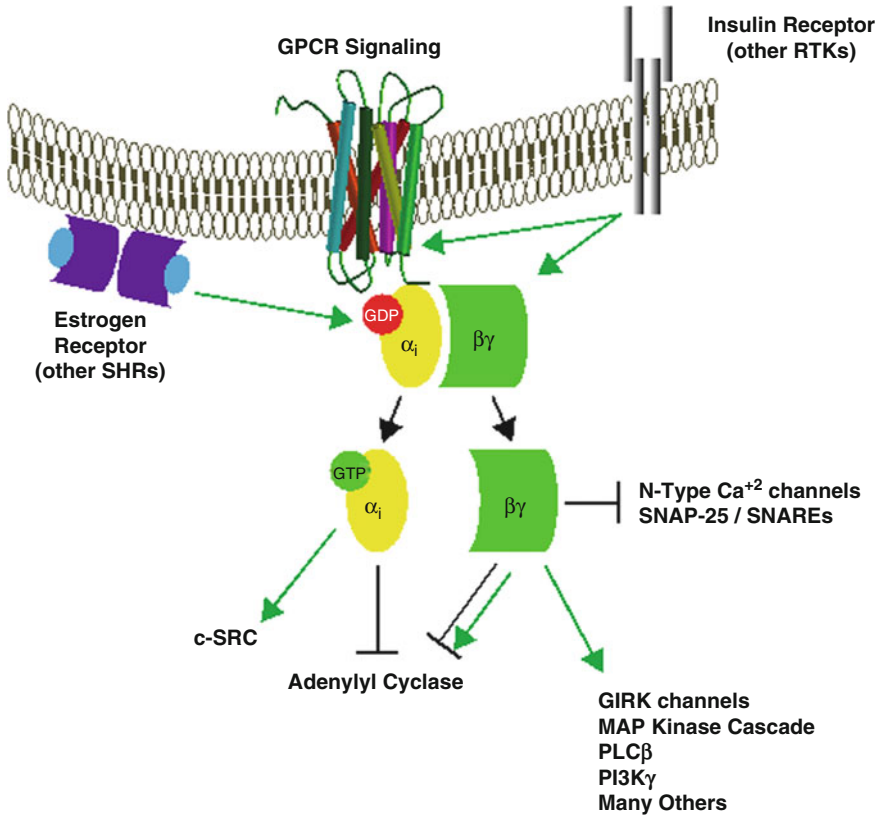
GPCR-Regulated Gi Signaling

GPCR regulation of Gi heterotrimer activation and downstream signaling pathways can broadly be grouped into two classes: effector enzyme targets regulated directly by Gαi/o/z-GTP and those regulated by Gβγ subunits released from Gi-class heterotrimers (Fig. 2).

Gαi-GTP targets – Agonist-stimulated GPCRs coupled to Gi-class heterotrimers produce Gαi-GTP and Gβγ. Gαi/z-GTP interacts directly with ▶ adenylyl cyclase (AC) isoforms I, V, and VI to inhibit catalytic production of the soluble second messenger cAMP. In comparison to Gαi, Gαo has reduced ability to inhibit adenylyl cyclase I. Gαs-GTP is the G protein stimulator of all membrane-bound ▶ adenylyl cyclase isoforms. The Gαi-GTP interaction site of AC is distinct from the Gαs-GTP binding site. Combined mutagenesis, biochemical, and kinetic modeling studies show that the opposed allosteric action of these G proteins may occur in simultaneous fashion (Chen-Goodspeed et al. 2005; Dessauer et al. 1998; Taussig et al. 1994). Gβγ liberated from Gi heterotrimers also influences AC activities in an AC isoform-dependent manner (activation or inhibition depending on isoform). The activities of Gβγ and the small molecule AC activator, forskolin are synergistic to the action of Gα-GTP (for comprehensive reviews and accounts of primary references therein, see Sadana and Dessauer (2009), Sunahara et al. (1996), Taussig and Gilman (1995)).

Free Gαi subunits bisect tyrosine kinase signaling pathways in ways that are unique from Gβγ (Gi) regulation. In vitro ▶ c-SRC tyrosine kinase activity was activated directly by purified Gαi-GTPγS (and Gαs-GTPγS), and ▶ c-SRC-dependent phosphorylation of cellular substrates appeared to be enhanced by co-expression of (activated) GTPase-deficient Gαi or Gαs (Ma et al. 2000). Reciprocally, ▶ c-SRC can phosphorylate Gαi and Gαs on tyrosine residues to alter adrenergic receptor coupling to the phosphorylated G proteins (Hausdorff et al. 1992). There are multiple modes of pathway integration and crosstalk between Gi and SRC or other tyrosine kinases (Natarajan and Berk 2006). Gαi and Gβγ subunits liberated from Gi heterotrimers have both redundant and opposed contextual effects toward tyrosine kinase signaling outputs.

Gi-dependent Gβγ targets – The majority of cellular responses to GPCR-induced Gi heterotrimer activation are arguably manifested by Gβγ. One explanation of why Gβγ dimers released from Gαi-GTP elicit signaling responses that other Gα/GPCR species do not is that Gi-class heterotrimers constitute the majority of expressed G proteins in many tissues. The "dose" of Gβγ produced from Gi heterotrimers may be above a particular response threshold for a given effector enzyme. This threshold may not be attainable by release of Gβγ from lower expressed G protein heterotrimer subtypes (Gq, ▶ Gs, G12/13). Regulated subcellular localization and



G Protein α i/o/z, Fig. 2 *Major Gαi signaling pathways and mechanisms of Gαi regulation*. G protein coupled receptor (GPCR) activation of Gi heterotrimers results in the exchange of GDP for GTP bound to the Gαi subunit. Gαi-GTP and Gβγ are dissociated or altered in conformation such that they functionally interact with downstream effector enzymes. Gαi-GTP inhibits the enzymatic activity of its major target, adenylyl cyclase and appears to functionally activate c-SRC kinase activity through direct binding. Gβγ subunits interact with a variety of effector targets. Major Gβγ effector targets are shown, but the list is not exclusive in this figure. Crosstalk from other receptor signaling systems regulates the activity of Gi. Estrogen receptors and other steroid-hormone-receptors (SHRs) regulate Gαi and Gβγ signaling pathways using a mechanism that might not include Gαi guanine nucleotide exchange (Kumar et al. 2007). The insulin receptor and other receptor tyrosine kinases (RTKs) exhibit extensive cross-talk with GPCR systems that regulate Gi heterotrimers, and in some cases are found in protein-protein complexes containing Gi subunits (Natarajan and Berk 2006; Kreuzer et al. 2004). The action of many SHR and RTK agonists to activate Gi signaling is sensitive to *Pertussis* toxin

scaffolding of G proteins and effectors also contributes to the specificity of Gi-mediated Gβγ signaling.

The complete list of effectors regulated by Gβγ subunits is expansive and beyond the scope of this Gαi topical essay (for comprehensive reviews of Gβγ signaling and the roles of Gi, see Clapham and Neer (1997), Smrcka (2008)). In brief, Gi-derived Gβγ activates the mitogen-activated protein kinase (MAPK) signaling cascade. Extracellular regulated kinases (ERKs) and downstream kinases are phosphorylated in response to cell treatment with agonists that stimulate Gi-coupled receptors (Gutkind 2000). Phospholipase Cβ (PLCβ) enzyme activity is co-modulated by Gαq-GTP and Gβγ subunits released from Gi heterotrimers to mediate phosphatidylinositol 3,4-bisphosphate (PIP_2) hydrolysis (Exton 1994). The produced inositol trisphosphate (IP_3) binds IP_3 receptors to activate Ca^{+2} release from intracellular stores. Gβγ directly regulates the activities of many ion channels. Two prominent examples are activation of G protein inwardly rectifying potassium (GIRK) channels that regulate cellular K^+ influx, and inhibition of N-type Ca^{+2} channels that convert neuronal action potentials to neurotransmitter release through cellular

Ca^{+2} influx (Nathan 1997; Tedford and Zamponi 2006). Gi heterotrimer activation potentiates signaling through the phosphatidyl-inositol-3 kinase (PI3Kγ) and protein kinase B/Akt signaling pathways. The 110 kDa PI3Kγcatalytic subunit is a direct effector of Gβγ (Stephens et al. 1994).

Gi-Family Regulation of Vesicle-Mediated Protein Transport

Gi family members impart multiple modes of regulation toward intracellular trafficking and secretory processes by influencing vesicle budding, priming, and fusion events. $G\alpha i_3$ overexpression or PTX treatment disrupted protein trafficking through the secretory pathway (Stow et al. 1991). The heterotrimeric G-protein activators AlF_4^-, mastoparan and related peptides, and compound 48/80 inhibited ER to Golgi transport (Beckers and Balch 1989; Schwaninger et al. 1992). PTX treatment also blocked vesicle budding from the trans-Golgi (Barr et al. 1991), and studies in model organisms revealed that Gαi/o proteins were important regulators of exocytosis (Ch'ng et al. 2008; Hajdu-Cronin et al. 1999; Miller et al. 1999; Lackner et al. 1999; Vashlishan et al. 2008).

One of the most well-studied trafficking pathways influenced by Gi family members is the regulation of insulin secretion by pancreatic β cells. Knowledge of PTX enhancement of glucose-stimulated insulin secretion (GSIS) predated the actual discovery of Gαi by at least a decade. PTX is known as islet activating protein (IAP) (Katada and Ui 1979, 1981a) and PTX treatment enhanced GSIS whether administered systemically or directly to primary cultures of pancreatic islets or β cell lines (Katada and Ui 1979, 1981a, b; Gulbenkian and Schobert 1968; Szentivanyi et al. 1963; Tabachnick and Gulbenkian 1969; Yajima et al. 1978). Subsequent reports showed that insulin secretion was inhibited by hormones that are Gi/o-coupled (reviewed in Sharp 1996). Consistent with these findings, selective ectopic expression of PTX in pancreatic β cells induced basal hyperinsulinemia and enhanced GSIS and glucose tolerance (Regard et al. 2007).

The specific Gαi family subunit(s) responsible for regulating insulin secretion has not been determined since the PTX effects would implicate $G\alpha i_1$, $G\alpha i_2$, or $G\alpha i_3$ and/or $G\alpha_o$. In fact, the regulation by Gαi family members appears to be redundant in part, as individual roles for Gαi, Gαo, and PTX-insensitive Gαz have been described. In the case of $G\alpha i_2$, chemically-induced diabetic rodent models exhibited decreased $G\alpha i_2$ expression in liver (Gawler et al. 1987) and adipose tissue (Baculikova et al. 2008), and antisense-mediated loss of $G\alpha i_2$ expression in liver and white adipose tissue lead to the development of insulin resistance (Moxham and Malbon 1996). Manipulation of the activation state of $G\alpha i_2$ in mice, either by conditional expression of GTPase-deficient $G\alpha i_2$-Q205L or homozygous knock-in of $G\alpha i_2$-G184S RGS-insensitive alleles (suggesting a prolonged time of $G\alpha i_2$ in the activated, GTP-bound state) resulted in enhanced glucose tolerance (Chen et al. 1997) or mice that were lean, resistant to high-fat diet-induced diabetes and had increased insulin sensitivity (Huang et al. 2008). These data suggest a key role for $G\alpha i_2$ in insulin secretion and signal regulation.

$G\alpha_o$ also participates in the regulation of insulin secretion by inhibiting secretory vesicle docking. A mouse with a conditional null $G\alpha_o$ allele in pancreatic islet cells had improved glucose tolerance and the effect of PTX to enhance insulin secretion was blocked, which led the authors to conclude that $G\alpha_o$ is the primary target of the PTX effect on insulin secretion (Zhao et al. 2010a). It was subsequently demonstrated that the $G\alpha o_B$ isoform was responsible for this effect (Wang et al. 2011).

Although most aspects of hormonal regulation of insulin secretion are PTX-sensitive, this is not always the case. Kimple and colleagues demonstrated that PGE1 inhibition of GSIS was insensitive to PTX and that this effect was blocked in a pancreatic β-cell line with reduced Gαz expression (Kimple et al. 2005). The same authors also demonstrated that Gαz-null mice are hyperinsulinemic and have increased glucose tolerance (Kimple et al. 2008). Collectively, Gαz appears to have an important role in hormonal regulation of insulin secretion apart from the roles ascribed to the PTX-sensitive Gαi and Gαo regulation.

Gi-family regulation of insulin vesicle secretion is manifested by liberated Gβγ subunits and shares a conserved mechanism with Gi regulation of neurotransmitter release. Gβγ subunits inhibit neurotransmitter release (Blackmer et al. 2005, 2001; Gerachshenko et al. 2005) by binding directly to the SNARE complex component SNAP-25 to disrupt synaptic vesicle fusion (Blackmer et al. 2005; Gerachshenko et al. 2005). SNARE complexes and

intracellular calcium levels similarly regulate insulin-containing secretory vesicle fusion and therefore insulin release from pancreatic β cells (Wang and Thurmond 2009). The secretory-promoting effects of elevated Ca^{+2} are blocked by noradrenaline, implicating Gi-family heterotrimers. Noradrenaline-inhibited insulin secretion was also blocked by Gβ antibodies, a Gβγ-activating peptide mSIRK, or *Botulinum A* toxin which cleaves the Gβγ binding site from the SNAP-25 carboxyl terminus (Zhao et al. 2010b). These results show that Gβγ released from Gi heterotrimers is the responsible G protein species that regulates secretory vesicle fusion and insulin/neurotransmitter release.

Noncanonical Gαi Signaling

As G-proteins became established as signal transducers for GPCRs at the cell surface, functional evidence suggested additional roles for Gi and Gαi in subcellular regions and contexts distinct from GPCR and classic effector signaling. Cell fractionation and immunofluorescence studies demonstrated populations of Gi proteins that did not reside on the plasma membrane, and in some cases Gαi was not always associated with Gβγ (Stow et al. 1991; Denker et al. 1996; Lin et al. 1998; Maier et al. 1995; Montmayeur and Borrelli 1994; Muller et al. 1994; Ogier-Denis et al. 1995; Pimplikar and Simons 1993; Schurmann et al. 1992; Wilson et al. 1993, 1994). Noncanonical roles for Gαi proteins include regulation of Golgi structure and function, (Jamora et al. 1999; Yamaguchi et al. 2000), signaling interactions with tyrosine kinase and steroid hormone receptors (Kreuzer et al. 2004; Kumar et al. 2007), and interactions with GPR/GoLoco proteins to regulate mitotic spindle positioning and asymmetric cell division (Yu et al. 2000; Gotta and Ahringer 2001; Parmentier et al. 2000; Schaefer et al. 2000).

Gαi Regulation of Golgi Function and Structure

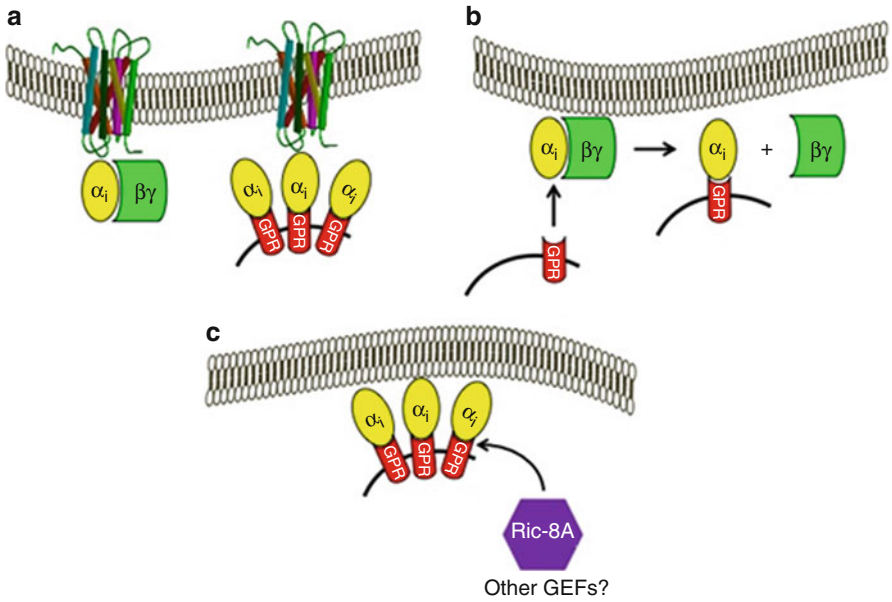
Gi-subunits, particularly Gαz and $G\alpha i_3$, are Golgi-localized (Stow et al. 1991; Wilson et al. 1993, 1994; Stow and de Almeida 1993). In addition to regulating vesicular protein transport through the Golgi, Gi/o-family proteins regulate overall Golgi structure. Chemically induced Golgi fragmentation was blocked by exogenous application of Gα subunits, including $G\alpha i_3$, to permeabilized NRK cells (Jamora et al. 1997) or by overexpression of Gαz or $G\alpha i_2$ (Yamaguchi et al. 2000). Expression of a putative dominant-negative Gαz mutant in HeLa cells disrupted Golgi structure (Nagahama et al. 2002). Golgi disruption was also observed upon overexpression of the Gαz-selective GTPase-activating protein RGSz (Nagahama et al. 2002). It will be important to determine which aspects of Gi regulation of vesicular transport and Golgi structure are related to each other (or not), and to discriminate those processes regulated through receptor-independent mechanisms and/or by Gi-coupled GPCRs.

Gαi Interactions with Steroid Hormone and Tyrosine Kinase Receptors

Gαi-GDP and Gβγ directly bind a variety of steroid hormone receptors in vitro, including estrogen receptor α (ERα). The effect of estrogen on ERα-dependent eNOS signaling and monocyte adhesion to endothelial cells was blocked by disruption of the ERα-Gαi interaction (Kumar et al. 2007). The mechanistic basis of this process awaits elucidation, but may involve a nontraditional, nucleotide-independent process of Gi heterotrimer activation by ERα. Gi heterotrimers functionally interact with a variety of tyrosine kinase receptors including the insulin receptor (IR), the epidermal growth factor receptor (EGFR), and the platelet-derived growth factor receptor (PDGFR) (Patel 2004). In most part, these functional interactions were established by demonstration that natural ligand (insulin, EGF, PDGF) effects on ▶ MAP kinase pathway activity were altered by cell pretreatment with PTX. $G\alpha i_2$ was actually shown to be recruited to the IR complex in a PTX- and guanine nucleotide-sensitive manner (Kreuzer et al. 2004). A role for Gαi proteins downstream of IR signaling was also supported by observation of PTX-sensitive antiautophagic responses to insulin in hepatocytes and insulin-sensitive localization of $G\alpha i_3$ to autophagic endomembranes (Gohla et al. 2007).

Gαi Regulation by Accessory Proteins – GPR Motif Proteins and non-receptor GEFs

Gαi family proteins are targets of many regulatory mechanisms and interacting proteins, perhaps more than any other family of Gα subunits. The identification of accessory proteins as regulatory factors included the use of protein-protein interaction screens,



G Protein α i/o/z, Fig. 3 *Schematic illustration of hypothetical modulation of alternative Gαi-mediated signaling pathways by Gαi-GPR/GoLoco modules*. (**a**) Receptor coupling to Gαiβγ (*left*) and Gαi-GPR (*right*) is hypothesized to either modulate distinct effector pathways or influence the strength, duration, or efficiency of GPCR-mediated signals. Direct interaction of Gαi-GPR complexes with GPCRs is a working hypothesis (Oner et al. 2010a, b; Vellano et al. 2011a). (**b**) Predicted influence of GPR motifs on Gαiβγ subunit interaction independent of nucleotide exchange. (**c**) Gαi-GPR complexes are substrates for receptor-independent GEFs such as Ric-8A and may be subject to a G-protein activation-deactivation cycle analogous to Gαiβγ, suggesting that the Gαi-GPR complex functions as a signaling entity that is distinct from Gαiβγ

purification of biochemical activities, forward genetic screens, and expression cloning methods (reviewed in Sato et al. 2006), also see Blumer & Lanier ESM Review of AGS Proteins). Among the Gαi-family accessory proteins identified are non-receptor GEFs (e.g., GAP-43, AGS1, ▶ Ric-8A, GIV), GAPs (e.g., RGS proteins), and guanine nucleotide dissociation inhibitors (GDIs) (e.g., proteins containing the GPR/GoLoco motif) (reviewed in Sato et al. 2006; Siderovski et al. 2005). Functional roles for each of these classes has perhaps been most clearly developed in model organisms, where the GPR-Gαi module appears to be involved in the integration of polarity cues with the orientation of the mitotic spindle during asymmetric cell division. Interestingly, a receptor-independent Gαi activation/deactivation cycle is implicated this process (Gonczy 2008; Knoblich 2010; Siderovski and Willard 2005). The discovery and overviews of each of these classes of accessory proteins are covered in depth elsewhere (Siderovski and Willard 2005; Blumer et al. 2011, 2007; Hollinger and Hepler 2002; McCudden et al. 2005; Ross and Wilkie 2000; Sato et al. 2006). The remainder of this subsection will serve to highlight recently reported key regulatory roles of these accessory proteins on Gαi/o function.

The GPR/GoLoco motif is a ~20 amino acid motif that binds Gαi/o/T-GDP independent of Gβγ and is found in at least seven mammalian proteins to date (Blumer et al. 2011). The GPR/GoLoco motif from RGS14 was cocrystallized with $G\alpha i_1$-GDP, revealing contacts along the switch II/α3 helix as well as the nucleotide binding pocket of $G\alpha i_1$ where an invariant Arg residue found in all GPR/GoLoco motifs directly contacts the α and β phosphates of GDP to inhibit its release (Kimple et al. 2002). By influencing Gαi–Gβγ subunit interactions independent of nucleotide exchange, GPR motifs may impart particular, system-dependent effects on Gβγ-sensitive pathways in some systems (Kinoshita-Kawada et al. 2004; Nadella et al. 2010; Regner et al. 2011; Sanada and Tsai 2005; Wiser et al. 2006) but not others (Webb et al. 2005). The GPR motif binding to Gαi-GDP is thus somewhat analogous to that of Gβγ subunits and recent evidence suggests

that Gαi-GPR complexes may actually interface with GPCRs (Oner et al. 2010a, b; Vellano et al. 2011a). Unlike the 1:1 stoichiometry of Gα:Gβγ, proteins with multiple GPR motifs bind more than one Gαi subunit simultaneously (Adhikari and Sprang 2003; Bernard et al. 2001; Kimple et al. 2004), which may have broad implications for signal processing through Gαi/o family subunits. Although the GPR-Gαi interaction can be regulated by GPCR activation (Oner et al. 2010a, b; Vellano et al. 2011a) and non-receptor GEFs (Garcia-Marcos et al. 2011; Tall and Gilman 2005; Thomas et al. 2008; Vellano et al. 2011b), the regulatory mechanisms controlling the GPR-Gαi cassette and the precise subcellular locations of GPR and Gαi interactions are not yet fully defined (Fig. 3).

The Gαi-GPR module is also a substrate for ▶ Ric-8A-catalyzed nucleotide exchange in a manner that may be analogous to GPCR-mediated regulation of Gαiβγ heterotrimers (Tall and Gilman 2005; Thomas et al. 2008; Vellano et al. 2011b). A non-GPCR-mediated Gαi-GPR activation (by Ric-8) and deactivation (by *C. elegans* RGS7) cycle and has been proposed to be the means by which the Gαi protein switch regulates mitotic spindle positioning processes during asymmetric cell division (Afshar et al. 2004; Couwenbergs et al. 2004; Hess et al. 2004; Wilkie and Kinch 2005). The non-receptor GEF, GIV/Girdin also appears to act on GPR-Gαi complexes in the regulation of autophagy (Garcia-Marcos et al. 2011).

Summary

The Gαi-class is one of four subfamilies of G protein α subunits. The Gαi subfamily has the largest number of individual members, and in most cases constitutes the bulk of expressed G protein α subunits in a given tissue or cell type. Gαi was discovered as a key component in the hormonal inhibition of ▶ adenylyl cyclase. GPCR signals that are transduced through Gi heterotrimers are propagated directly by the activated Gαi-GTP subunit, but most Gi signaling arguably stems from the Gβγ subunits of Gi heterotrimers. New roles for Gαi subunits have emerged more recently, in which Gαi acts independently of Gβγ. Gαi interaction with GPR/Goloco domain-containing proteins provides a means to regulate distinct signaling pathways including intracellular events that do not always occur at the cell periphery.

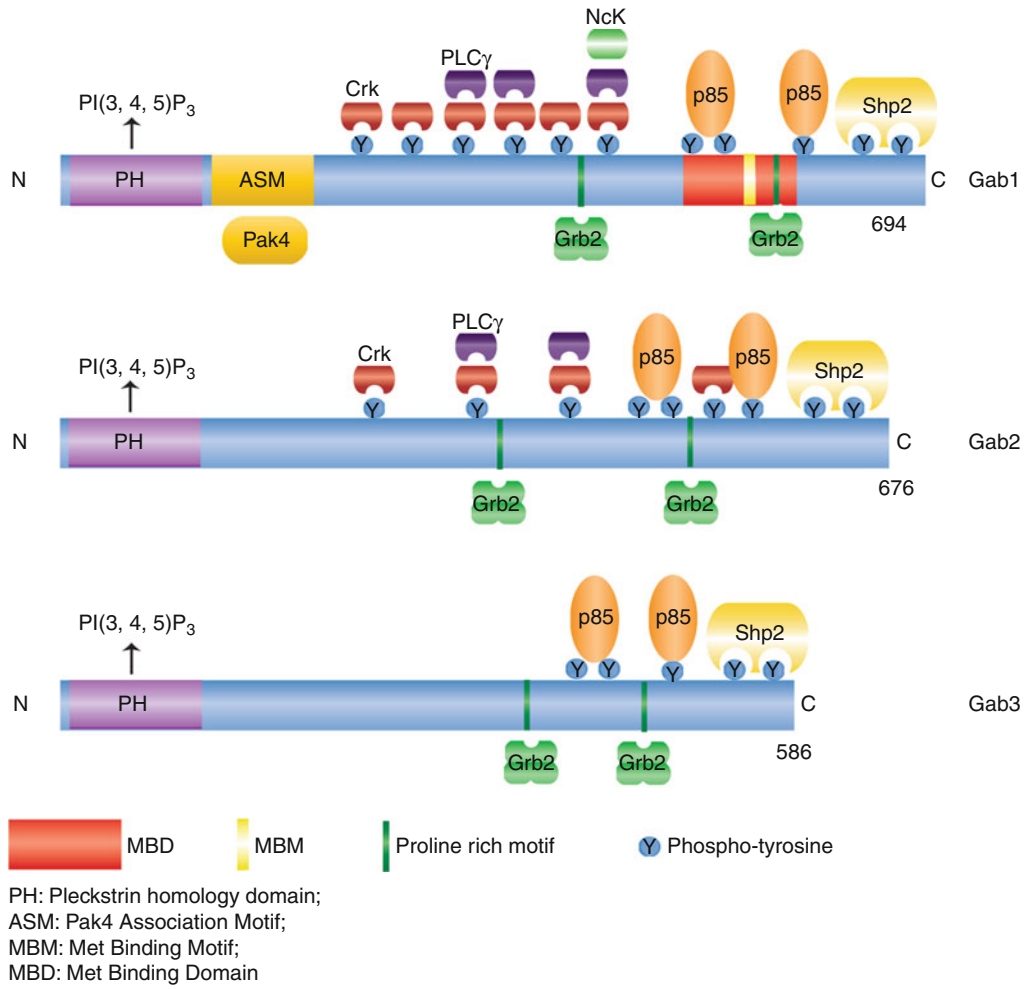
Historical Background

Gab proteins are scaffold proteins that are related to the insulin receptor substrates (IRS1/2/3), the fibroblast growth factor (▶ FGF) receptor substrate 2 (FRS2-α/β), the downstream of kinase (Dok), and the linker of T cell (▶ LAT). These proteins lack intrinsic enzymatic activity. Upon their recruitment to activated growth factor and cytokine receptors, they become tyrosine phosphorylated, providing binding sites for multiple proteins involved in signal transduction. By virtue of their ability to assemble multiprotein complexes, they act to modulate, amplify, and diversify the signals downstream from receptors (Pawson and Scott 1997; Schlessinger and Lemmon 2003).

The Gab family comprises three mammalian members, Gab1, Gab2, Gab3 (Fig. 1), the *Drosophila melanogaster* DOS (daughter of sevenless), and the *Caenorhabditis elegans* SOC-1. Gab1 was first identified in a screen for Grb2 binding proteins and was found to be a substrate for the EGF, TrkA, and insulin receptor tyrosine kinases (RTK). Gab1 was also independently identified as a hepatocyte growth factor (HGF) RTK, Met, interacting protein in a yeast two-hybrid screen (Birchmeier et al. 2003; Peschard and Park 2007). Gab2 was discovered as a phosphoprotein interacting with the Shp2 phosphatase (Gu and Neel 2003), and Gab3 was isolated based on its sequence similarity with Gab1 (Liu and Rohrschneider 2002). In addition, a fourth paralogue, Gab4, has been predicted based on sequence analysis (Wohrle et al. 2009). Although Gab family proteins are only moderately conserved at the level of the amino acid sequence, the domains and key sites for recruitment of signaling proteins downstream of activated receptors are highly conserved between Gab1 and Gab2 (Fig. 1).

Genetic and cell biology analyses have demonstrated that Gab proteins are crucial in RTK signaling and biology. *dos* and *soc-1* were found to be essential for RTK signaling in the developing fly and worm. *Gab1* null mice are embryonic lethal and show impaired migration of muscle precursor cells and muscle development, thinner placenta, impaired diaphragm formation, reduced liver size, defective heart development, skin problems, open eyelids, and liver regeneration defects (Schaeper et al. 2007). These phenotypes predominantly mimic *Hgf* null *and Met* null mice, but also include additional defects observed in *Pdgf* and *Egf* null mice, demonstrating the important role played by Gab1 in transduction of signals from these growth factor signals during development. In the adult, Gab1 regulates glucose uptake in the liver, bone homeostasis, and differentiation of myocytes and B cells.



Gab1, Fig. 1 Domain structure of the Gab family of scaffold proteins. Schematic representation of the mammalian Gab1, 2, and 3 proteins. Gab proteins all share a conserved N-terminal PH domain involved in phospholipid binding. In Gab1, tyrosine phosphorylation creates binding sites for signaling molecules including Crk, Nck, PLCγ, p85, and Shp2. Proline rich regions mediate the interaction with the SH3 domain of Grb2. The Met Binding Domain (MBD), which includes the Met Binding Motif (MBM), mediates the direct recruitment of Gab1 to the Met receptor

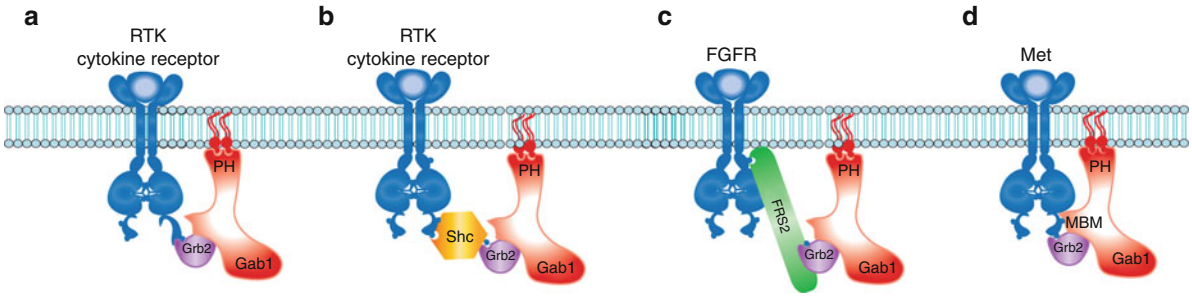
Despite having similar overall structure and signaling capacity, *Gab2* null mice are viable, have a normal life span, yet show severe defects in mast cell lineages (Gu and Neel 2003), whereas *Gab3* null mice have no apparent phenotype. The marked differences in knockout phenotypes suggest that despite high similarity in their domain structure organization, Gab proteins play different roles in RTK signaling during development in mammals.

This entry will focus on the Gab1 protein, its role in signal transduction, and its implication in development and cancer initiation and progression.

Gab1 in Signal Transduction

Membrane Targeting

Following receptor activation, Gab1 translocates from the cytosol to the plasma membrane. At least three mechanisms regulate this translocation (Fig. 2). Gab1 is indirectly recruited to cell surface receptors by the small adaptor Grb2 (Peschard and Park 2007). All mammalian Gab proteins contain a canonical PXXP motif and an atypical PXXXR motif responsible for the recruitment of the C-terminal SH3 domain of Grb2. The SH2 domain of Grb2 can interact with



Gab1, Fig. 2 Mode of Gab1 recruitment to activated receptors. Gab1 is recruited to activated receptors via different mechanisms. (**a**) The SH2 domain of the Grb2 adaptor binds to a consensus tyrosine phosphorylated motif YVNV. Gab1 is recruited to this complex by interaction with the SH3 domain of Grb2. (**b**) and (**c**) Through a ternary complex, where Grb2 couples Gab1 to the Shc adaptor or FRS2 scaffolds via its SH2 domain. In this model, a Gab1/Grb2 complex binds the Shc/Receptor or FRS2/FGFR complex. (**d**) Gab1 is recruited by a dual mechanism to the Met receptor. The MBM of Gab1 directly binds Met and requires tyrosine phosphorylation of Met. Gab1 is also indirectly recruited to Met by the Grb2 adaptor

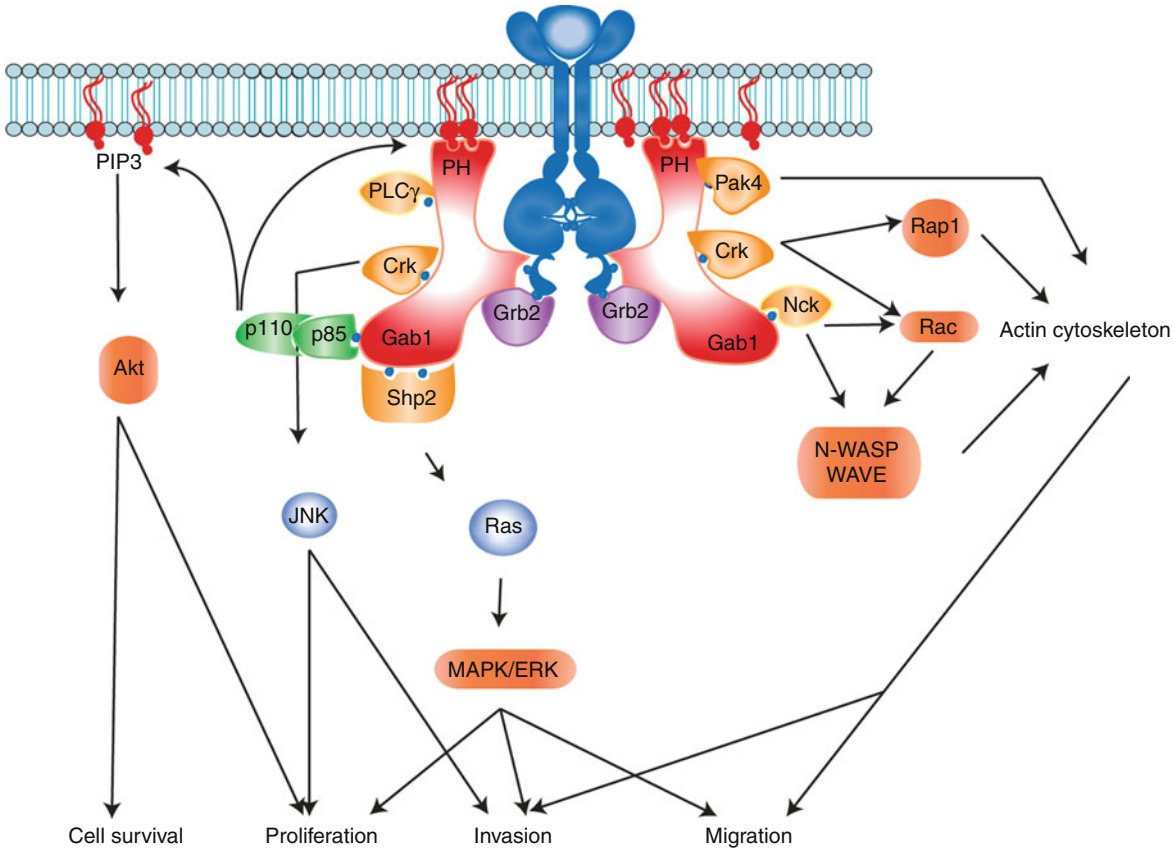
a phosphotyrosine motif (YVNV) on activated receptors, thus creating a bridge between the receptor and Gab proteins. Alternatively, following activation of the FGF receptor, the FRS2α and β scaffolds are phosphorylated on 5 Grb2 binding sites and mediates the recruitment of a Grb2–Gab1 complex to the FGFR. This ternary complex plays an important role in ▶ PI3K activation downstream of an ▶ FGF signal (Eswarakumar et al. 2005). Similarly, Gab1 is recruited to cytokine and immune receptors through a Shc–Grb2–Gab1 complex.

In addition to the indirect recruitment via Grb2, Gab1 is also directly recruited to the Met receptor. This direct interaction is mediated by the Met Binding Motif (MBM) on Gab1 and requires the activated kinase domain of Met (Birchmeier et al. 2003; Peschard and Park 2007). The Gab1 MBM does not resemble classical SH2 or PTB domains and is not conserved in other members of the Gab family. The direct recruitment of Gab1 correlates with sustained phosphorylation of Gab1, Erk and Akt downstream from Met, and is required for the invasive morphogenic program induced by HGF (Peschard and Park 2007).

The N-terminal region of all Gab proteins contains a conserved, phosphoinositide-binding, pleckstrin homology (PH) domain that is important for both membrane targeting and protein function. The PH domain of Gab1 predominantly binds phosphoinositol-3,4,5-phosphate ($PI_{3,4,5}P3$), which is required for its translocation from the cytoplasm to the cell cortex, lamellipodia, membrane ruffles, and cell–cell junctions in sheets of epithelial cells in response to receptor activation (Peschard and Park 2007). Gab1 mutants unable to bind $PI_{3,4,5}P3$ or lacking the PH domain are poorly phosphorylated and defective in transducing signals and biological responses downstream from the EGF and Met RTKs (Peschard and Park 2007; Rodrigues et al. 2000). This is overcome by targeting Gab1 to the plasma membrane using a ▶ Src myristoylation sequence (Peschard and Park 2007), highlighting the importance of membrane localization for Gab1 signaling.

Tyrosine Phosphorylation

Gab1 is a key intermediate required for biological responses downstream of RTKs, cytokine and immune receptors, including cell proliferation, cell survival, cell migration, and epithelial morphogenesis (Fig. 3). Tyrosine phosphorylation of Gab1 on specific tyrosine residues is a fundamental mechanism for Gab1-mediated signal transduction. This phosphorylation is a consequence of the recruitment of Gab1 to activated growth factor, cytokine, and immune receptors. Met, EGFR, PDGFR, VEGFR2, c-Kit, IGF1R, TrkA, RET, Insulin-R, EPO-R, TPO-R, gp130, IL-3-R, INFα/γ-R, and T and B cell receptors all induce tyrosine phosphorylation of Gab1 following activation (Liu and Rohrschneider 2002; Nishida and Hirano 2003; Sarmay et al. 2006). Whereas RTKs can directly phosphorylate Gab1, other types of receptor use JAK or Src family kinases. Tyrosine phosphorylation of Gab1 provides docking sites for SH2 domain containing molecules, leading to the recruitment of enzymes (Shp2, PLCγ) or adaptor molecules (Crk, Nck, p85). In the following section, we describe the signaling pathways activated downstream of Gab1.



Gab1, Fig. 3 Gab1 signaling. Gab1 regulates cell survival by activating the PI3K/Akt pathway through the recruitment of p85. Shp2 binding to Gab1 activates the Ras/MAPK pathway to regulate cell proliferation, invasion, and migration. The recruitment of Crk, Pak4, and Nck to Gab1 regulates actin cytoskeleton remodeling, membrane dynamics, and cell migration

Gab1 Signaling

Shp2 and MAPK Activation (pY627, 659)

Gab1 binds to the phosphatase Shp2 in response to multiple growth factors and cytokines including EGF, insulin, FGF, PDGF, or HGF (Gu and Neel 2003; Liu and Rohrschneider 2002; Wohrle et al. 2009). Recruitment of Shp2 SH2 domains leads to the activation of Shp2 enzymatic activity and is required for full activation of the MAPK pathway by the EGFR (Birchmeier et al. 2003; Peschard and Park 2007). Knockin mice expressing a Gab1ΔShp2 mutant are embryonic lethal and display impaired migration of muscle progenitor cells to the limb buds and placental defects, a phenotype similar to *Gab1*, *Met* and *Hgf* null animals (Schaeper et al. 2007), highlighting the importance of the Gab1–Shp2 interaction during development. Different models for the function of the Gab–Shp2 complex in Ras signaling have been proposed; however, the exact mechanisms of this regulation still need to be defined. One model supported by data from *D. melanogaster* proposes that recruitment of $p120^{Ras\text{-}GAP}$ on tyrosines 307 and 317 of Gab1 promotes the return of Ras to its inactive, GDP-bound state. Shp2 recruitment to Gab1 promotes dephosphorylation of these $p120^{Ras\text{-}GAP}$ sites thus decreasing the negative regulation of Ras, resulting in sustained activation (Gu and Neel 2003; Wohrle et al. 2009).

p85 and PI3K Signaling (pY 447, 472, 589)

Gab1 plays a crucial role in the activation and amplification of PI3K signaling downstream of RTKs and cytokine receptors. The majority of RTK-dependent PI3K activity is associated with Gab1 and depends on its ability to recruit the p85 regulatory subunit of PI3K through three YXXM motifs that include tyrosines 447, 472, and 589. Gab1-dependent PI3K activation

is critical for cell survival and proliferation through the Akt pathway in many biological contexts. This is particularly important for RTKs that are unable to directly recruit p85, including EGFR, VEGFR-2, and FGFR. The ability of Gab1 to activate the PI3K pathway is also required for actin remodeling and formation of membrane ruffles, cell migration, and tubulogenesis downstream from several RTKs. This possibly occurs through generation of $PI_{3,4,5}P3$-rich membranes following localized Gab1-dependent PI3K activation and subsequent activation of guanine exchange factors (GEFs) for the Rac GTPase. A Gab1-p85 interaction is required for cell scatter and epithelial morphogenesis induced by HGF (Peschard and Park 2007), to induce Rac activation and lamellipodia formation downstream of the Ret RTK (Maeda et al. 2004), and for the formation of HGF-induced circular dorsal ruffles (Abella et al. 2010). During development, Gab1/p85 interaction is also required for keratinocyte migration as well as EGF-induced eyelid closure (Schaeper et al. 2007).

Crk (pY242, 259, 307, 317, 373, 406)

The interaction between Gab1 and Crk relies on six YxxP motifs in Gab1 and the SH2 domain of Crk. The Gab1–Crk interaction controls cytoskeleton rearrangement, cell motility, adhesion, morphology and polarity downstream of RTKs, antigen and cytokine receptors. These biological outcomes possibly depend on the ability of Crk to regulate the activation of the small GTPases Rac and Rap1 via the recruitment of the Rac GEF Dock180 and the Rap1 GEF C3G to their SH3 domains (Peschard and Park 2007).

Gab1 overexpression also enhances HGF- and EGF-induced JNK activation. Downstream of Met, this effect is abrogated by co-expression of a dominant negative Crk mutant, suggesting that Met activates JNK through a Gab1–Crk complex. In addition, Gab1–Crk signaling to JNK is correlated with anchorage independent growth, and MMP-1 secretion, supporting a role for Gab1–Crk signaling in cell transformation and invasion (Lamorte et al. 2000).

PLCγ (pY307, 373, 406)

Structure-function analysis identified that the SH2 domain of PLCγ was recruited to three of the Crk binding sites (pY307, 373, 406). These studies have proposed a requirement for the Gab1–PLCγ interaction for branching morphogenesis in response to HGF/Met signaling (Birchmeier et al. 2003) and for endothelial cell migration (Laramee et al. 2007) downstream from the VEGFR-2.

Nck (pY406)

Nck1 SH2 domain directly interacts with tyrosine 406 on Gab1 downstream from Met, EGF, and PDGF RTKs activation. This interaction is required for induction of dorsal ruffles downstream of EGF, PDGF, and Met RTKs, and for Met-dependent Rac activation and for epithelial morphogenesis in MDCK cells and provides a mechanism through which Gab1 binding to RTKs can signal to the actin cytoskeleton (Abella et al. 2010). Although these biological outcomes were originally attributed to Crk and/or PLCγ, which also bind Gab1 on tyrosine 406, it is now important to assess the relative contribution of each signaling molecule to these biological processes.

Pak4 (ASM, aa. 116–234)

In addition to proteins containing SH2 domains, the P21-activated serine/threonine kinase 4 (Pak4) is recruited to Gab1 downstream from the Met RTK. This interaction has been mapped to amino acids 116 to 234 of Gab1 (Fig. 1) and requires phosphorylation. If this association is direct, however, remains to be addressed. Pak4 association with Gab1 is required for HGF-induced epithelial cell dispersion, migration, and invasive growth, likely through the ability of Pak4 to phosphorylate cofilin and promote remodeling of the actin cytoskeleton (Paliouras et al. 2009).

Feedback Loops Regulating Gab1 Signaling

Cross Talk Between PI3K and Shp2

The most important arms of Gab1 signaling network are the Shp2/MAPK arm and the PI3K/Akt arm. Activation of these pathways can influence each other through negative and positive feedback loops. As described earlier, Gab1 is a substrate for the Shp2 phosphatase. Recruitment of Shp2 to Gab1 leads to the dephosphorylation of the p85 binding sites on Gab1, which attenuates PI3K signaling.

Activation of PI3K potentiates activation of the MAPK pathway by increasing Shp2 recruitment to Gab1. p85 binding to Gab1 leads to an increase in local $PI_{3,4,5}P3$ formation, resulting in increased Gab1 membrane targeting and tyrosine phosphorylation. Downstream of EGFR, VEGFR, and EPO-R, a Gab1Δp85 mutant has a reduced ability to activate

the MAPK pathway due to a decreased ability to recruit Shp2 (Liu and Rohrschneider 2002; Nishida and Hirano 2003; Wohrle et al. 2009). These data indicate the existence of Gab1-dependent cross talk between the PI3K and MAPK signaling pathways.

Serine/Threonine Phosphorylation

Growth factor and cytokine stimulation induces a decrease in the mobility of Gab1 on an SDS PAGE that is attributed to increased serine and threonine phosphorylation. The biological role of this Ser/Thr phosphorylation depends on the cell type and receptor activated. Insulin and EGF stimulation induces Erk-dependent phosphorylation of Gab1 on Ser454, Ser581, Ser597, and Thr476, which are located in the vicinity of the p85 binding sites. This Ser/Thr phosphorylation correlates with reduced Tyr phosphorylation and attenuated PI3K signaling. In contrast, Met activation induces Erk-dependent phosphorylation of Thr476 and is associated with an increase in PI3K signaling (Wohrle et al. 2009). In melanocytes, however, HGF induces a PKCβII-dependent Ser/Thr phosphorylation of Gab1 associated with attenuated PI3K activation, as well as a decrease in cell migration and invasion (Oka et al. 2008). Furthermore, MAPK-dependent phosphorylation of Ser551 positively regulates the function of the PH domain of Gab1 in response to IL-6, and therefore enhances its recruitment to the plasma membrane (Wohrle et al. 2009). Taken together, these data suggest that Gab1 Tyr and Ser/Thr phosphorylation can influence each other by creating feedback loops allowing fine-tuned responses by modulating protein–protein interactions and subcellular localization.

Gab1 in Cancer

Even though Gab1 is essential in embryonic development, it has not been strongly linked to specific disease. Disease-linked phenotypes due to germline mutations in *GAB1* may not be visible because Gab1 is essential during development. Somatic mutations of *GAB1* have been described in cancers; however, their significance for tumorigenesis remains to be addressed. Nevertheless, in vitro and in vivo data have identified a role for Gab1 protein in cellular transformation and cancer progression in various systems due its critical role in RTK signaling. Expression of a mutant EGFR unable to efficiently phosphorylate Gab1 delays the onset of ErbB2-driven mammary tumor in mouse model (Gillgrass et al. 2003). In addition, expression of a Gab1 mutant uncoupled from Shp2, and Shp2 knock down impairs invasion and migration of Met overexpressing colorectal cancer cells in matrigel and prevents tumor formation when these cells are subcutaneously injected into nude mice (Seiden-Long et al. 2008). Furthermore, recent studies demonstrated that Gab1 plays a role in resistance to EGFR tyrosine kinase inhibitors induced by HGF and Met in NSCLC patients and cell lines by promoting cell survival (Turke et al. 2010).

In contrast to Gab1, Gab2 is often over-expressed in breast, ovarian, gastric, and skin cancer. In breast epithelial cell lines, over-expression of Gab2 cooperates with ErbB2 over-expression to promote cell survival and proliferation (Gu and Neel 2003; Wohrle et al. 2009). The differences between the roles of Gab1 and Gab2 in tumor initiation and progression may reflect that despite having similar signaling capacity, these two proteins have nonredundant functions as supported by the different phenotypes observed in the respective knockout mice. Alternatively, it may reflect the genetic instability of the *GAB2* locus located on chromosome 11q14.1 that is often amplified in human cancers.

Summary

The Gab1 scaffold protein is a critical node in signaling networks initiated by RTKs, cytokine and immune receptors. Recruitment of signaling molecules to Gab1 leads to two different outcomes. First, activation of PI3K/Akt, Shp2/MAPK, and JNK pathways engages a transcriptional program regulating cell survival, proliferation, morphogenesis, and invasion. Second, the recent discoveries that Pak4, Nck, and Crk are recruited to Gab1 downstream of RTKs indicate that Gab1 is a crucial scaffold for the regulation of the actin cytoskeleton and cell motility.

It is becoming evident that the role of Gab1 in signal transduction is more complex and dynamic than the classic definition of adaptor molecules. Recent data demonstrated that Gab1 does not only amplify and diversify receptor signals, but spatially organizes these signals in microdomains such as dorsal ruffles (Abella et al. 2010).

Gab1 associates with numerous receptors, binds many different downstream signaling molecules, and shows dynamic relocalization upon stimulation. Gab1 therefore likely engages in complexes of different composition and localization over time. In the future, it will be important to dissect the spatial and temporal regulation of these signaling complexes.

Historical Background

Grb2-associated binder 2, Gab2, belongs to the Gab/DOS family of scaffolding adaptors that include mammalian ▶ Gab1, Gab3, *Drosophila Daughter of Sevenless* (DOS), and *Caenorhabditis elegans Suppressor of Clear* 1 (SOC1) (Gu and Neel 2003; Wohrle et al. 2009). Gab1, the first identified member of this family of adaptors, was discovered in search of protein ligands for Grb2 SH3 domain (Holgado-Madruga et al. 1996). DOS was identified as a potential substrate for Corkscrew (Csw), the *Drosophila* ortholog of the SH2 domain containing protein tyrosine phosphatase 2 (Shp2) (Herbst et al. 1996). Gab2, the third member

identified in this family, was initially cloned as a binding protein and substrate of Shp2 (Gu et al. 1998). Gab2 gene is located on human chromosome 11q14.1. Two other groups later cloned Gab2 by searching DNA database for protein with sequence homology to Gab1 (Nishida et al. 1999; Zhao et al. 1999). SOC1 was uncovered in a screen for suppressors of hyperactive signaling from Egl-15, an FGF receptor ortholog (Schutzman et al. 2001). Gab3 was identified by sequence similarity to Gab1 and Gab2 (Wolf et al. 2002). Gab1 and Gab2 are expressed ubiquitously. However, Gab2 is expressed at relatively higher level in myeloid cells and low in lymphoid tissues and fibroblasts (Gu et al. 1998). Gab3 also has a widespread expression pattern, although it is highly expressed in lymphoid tissue (Wolf et al. 2002). GenBank database also contains a human cDNA clone (Acession Number AB076978), termed Gab4. However, it is unclear how this "Gab4" cDNA sequence information was obtained. Although mRNAs for parts of the "Gab4" cDNA are found as ESTs in testis specifically, no report has shown that the full-length "Gab4" protein is expressed 10 years after the sequence was deposited into the GenBank. Thus, it is unclear whether this "Gab4" clone represents a *bona fide* Gab protein.

Gab2 Domain Structures

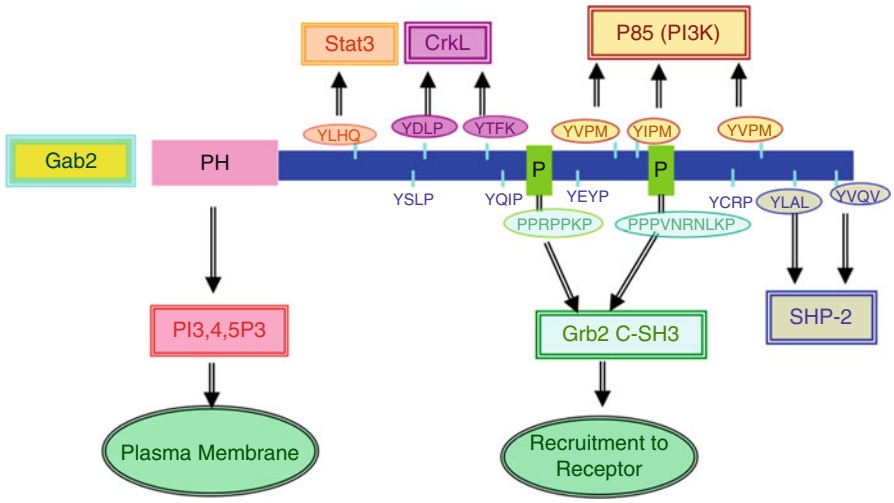
Gab2 and its family members have a similar topology although the overall amino acid sequence identity among the Gab/DOS family members is about 20–40%. Gab2 contains an N-terminal pleckstrin homology (PH) domain (~120 aa) and the C-terminal portion of the molecule (Fig. 1). Gab2 PH domain has the highest sequence identity with the PH domains of the other Gab/DOS family members except the SOC1 PH domain, ranging from ~45% to 80% (Gu et al. 1998; Wohrle et al. 2009). The main function of the Gab2 PH domain is to preferentially bind phosphatidylinositol (*3,4,5*)-trisphosphate (PI3,4,5P3), the lipid product of ▶ phosphoinositide 3-kinase (PI3K) (Yu et al. 2006a). Although the C-terminal portion of Gab2 does not have significant sequence homology to other Gab/DOS members, it contains multiple conserved tyrosine phosphorylation and serine/threonine phosphorylation sites, and proline-rich sequences. Tyrosyl phosphorylation in Gab2 results in the recruitment of various SH2 domain-containing signaling molecules including Shp2 and p85 (the regulatory subunit of PI3K) and activation of key cell signaling pathways (Figs. 1 and 2). Serine/threonine phosphorylation negatively modulates Gab2 interactions with SH2 domain-containing signaling molecules (Gu and Neel 2003; Wohrle et al. 2009). Gab2 contains two proline-rich motifs that are required for binding to the Grb2 C-SH3 domain (Lock et al. 2000). However, these two proline-rich motifs do not conform to the typical SH3 domain ligand (i.e., PXXP) that is mainly involved in hydrophobic interaction with the SH3 domain. Both of the Gab2 SH3-domain binding sites contain the atypical SH3 domain-binding motif, RXXK (Fig. 1), which engages electrostatic interaction with the Grb2 C-SH3 domain (Harkiolaki et al. 2009). All of these structural features play important roles in mediating Gab2 function in cell signaling.

Gab2 in Cell Signaling

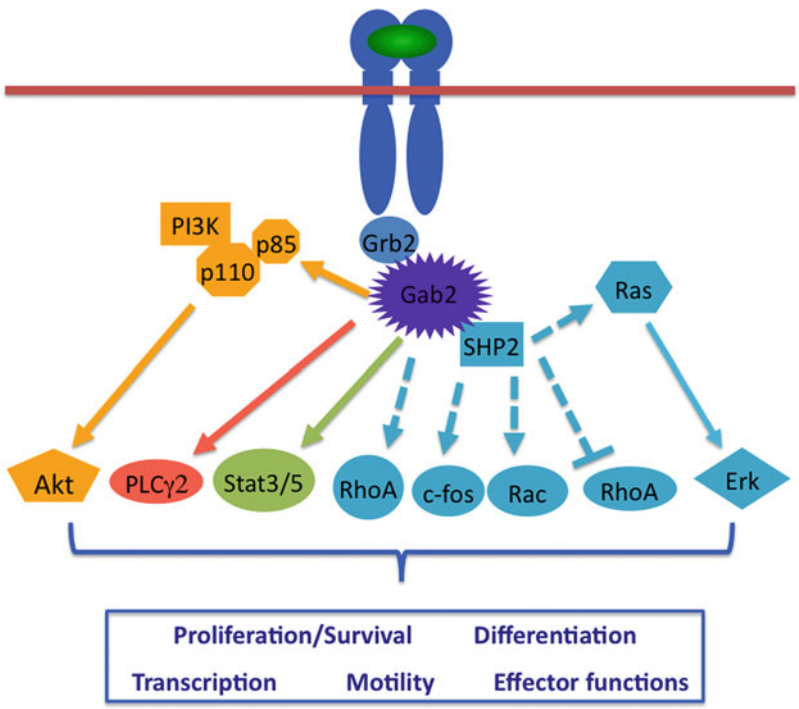
Gab2 functions to mediate the activation of critical cell signaling pathways by multiple cell surface receptors for growth factors, cytokines, antigens, and immunoglobulins (Fig. 2). The current model is that upon receptor activation, Gab2 is recruited to the activated receptor, becomes tyrosyl phosphorylated, binds SH2 domain-containing signaling molecules, and activates key downstream signaling pathways. Gab2-activated signaling events can be turned off at least by serine and threonine phosphorylation in Gab2 (Gu and Neel 2003; Wohrle et al. 2009).

Gab2 Recruitment to the Receptor

Gab2 is recruited to the activated receptors through other signaling intermediates because Gab2 does not contain modular domain that can directly interact with the receptor. The main route of Gab2-receptor interaction is mediated through Grb2. Grb2 has one SH2 domain flanked by two SH3 domains. The two RXXK motifs in Gab2 (Harkiolaki et al. 2009) lead to constitutive interaction of Gab2 with the Grb2 C-SH3 domain (Lock et al. 2000). The Grb2 SH2 domain mediates the targeting of the Grb2-Gab2 complex to the activated receptor (i.e., Flt3-ITD) or upstream activator (i.e., BCR-ABL) that contains



Gab2, Fig. 1 Schematic structure of Gab2. Gab2 has an N-terminal pleckstrin homolog (*PH*) domain that binds preferentially *PI3,4,5P3*, and the C-terminal half of the molecule containing multiple tyrosine phosphorylation sites (YXXX) that recruit different SH2 domain-containing signaling proteins including Shp2, p85, Stat3, and CrkL, and two proline-rich motifs (*P*) that bind Grb2 C-SH3 domain. The specific interactions between Gab2 and its ligands are color-coded. For details, see text



Gab2, Fig. 2 Signaling pathways regulated by Gab2. Gab2 activates the Ras/Erk pathway, via its ability to bind to and activate the SH2 domain-containing protein tyrosine phosphatase Shp2, and the PI3K/Akt pathway, by virtue of its ability to bind the p85 regulatory subunit of PI3K, thereby activating the associated p110 catalytic subunit. Studies also reveal that Gab2 can activate other signaling pathways such as members of RhoGTPase family, Stat3/5, PLCγ2, and immediate early gene transcription. All of these pathways play important roles in regulating the growth, differentiation, migration, and effector functions of different cell types. *Dashed lines* mean that the detailed mechanisms are still lacking. For details, see text

Grb2-SH2 domain binding sites (YXNX) (Masson et al. 2009; Sattler et al. 2002). However, in cell signaling initiated by receptors for IL3/IL5/GM-CSF/IL2 and FcεRI that lacks direct Grb2 binding to their cytoplasmic tails, another adapter protein Shc, brings the Grb2-Gab2 complex to these receptors that contain binding sites for the Shc PTB or SH2 domain (Gu et al. 2000; Yu et al. 2006a). Shc also has three Grb2-SH2 binding sites which, when phosphorylated, recruit the Grb2-Gab2 complex to the receptor (Gu and Neel 2003). A Gab2 mutant with the two RXXK mutated cannot be tyrosyl phosphorylated efficiently and is impaired in its ability to mediate receptor signaling (Brummer et al. 2006; Yu et al. 2006a).

The PH domain provides another route for Gab2 recruitment. PI3,4,5P3 produced by the receptor-activated ▶ PI3K recruits Gab2 via its PH domain to the subcellular compartment where the activated receptor is located. The importance of Grb2 C-SH3 binding sites and PH domain in mediating Gab2 recruitment and functions depends on the receptor involved. The Grb2 C-SH3 binding sites play a dominant role in Gab2 function in EGFR and Flt3 signaling (Brummer et al. 2006; Masson et al. 2009) whereas in the FcγR-induced signaling response, the PH domain exerts a major role (Yu et al. 2006a). However, both Grb2 C-SH3 binding sites and PH domain contribute to Gab2 action in FcεRI-induced signaling (Yu et al. 2006a).

Protein Tyrosine Kinases That Phosphorylate Gab2

Upon recruited to the activated receptors or receptor signaling complexes, Gab2 undergoes tyrosyl phosphorylation in a receptor-dependent manner. Although it is likely that receptor tyrosine kinase may directly phosphorylate on certain tyrosine residues in Gab2 (Lee and States 2000), this scenario has not been carefully examined. JAK2, the receptor-associated protein tyrosine kinase, plays an essential role in cytokine receptor signaling. However, JAK2 is not required for the G-CSF-induced Gab2 tyrosyl phosphorylation (Zhu et al. 2004). Instead, most of the studies show that the cytoplasmic tyrosine kinases are responsible for Gab2 tyrosine phosphorylation. In T cell antigen receptor (TCR) signaling, ▶ ZAP-70 forms a complex with Gab2 and phosphorylates it (Yamasaki et al. 2001). Syk is required for Gab2 tyrosyl phosphorylation and is associated with Gab2 upon FcεRI activation (Yu et al. 2006a). Members of ▶ Src Family protein tyrosine Kinase (SFK) such as Src and Lyn are also responsible for Gab2 tyrosyl phosphorylation upon activation of CSF1R (Lee and States 2000) and G-CSFR (Zhu et al. 2004).

Signaling Pathways Activated by Gab2

Tyrosyl-phosphorylated Gab2 can activate multiple downstream signaling pathways by recruiting SH2 domain-containing signaling proteins. The major Gab2-induced signaling pathways include Shp2 and ▶ PI3K (Fig. 2). Recent studies also reveal additional signaling pathways activated by Gab2.

Role in Shp2 pathway. Gab2 contains two tyrosine motifs VDYXXV/L (where X = any amino acid) (Fig. 1), when phosphorylated, which that bind Shp2. Shp2 has low basal activity due to allosteric inhibition of its PTP domain by the N-terminal SH2 domain. Upon binding to tyrosyl-phosphorylated Gab2, the basal inhibition is relieved, resulting in strong activation of Shp2 (Neel et al. 2003). Vertebrates express another SH2 domain containing PTP, Shp1. The SH2 domains of Shp1 and Shp2 recognize similar phosphorylated tyrosine containing motifs. However, the interaction between the tyrosyl-phosphorylated Gab2 and Shp1 has not been observed. It is not well understood why Gab2 binds preferentially to Shp2. Nevertheless, this deferential binding ability helps explain the distinct biological functions of Shp1 and Shp2 (Neel et al. 2003).

Gab2, acting via Shp2, is required for full activation of Erk downstream of many receptors. Expression of a Gab2 mutant with Y->F in the VDYXXV/L motifs impairs Erk activation in response to CSF-1 (Liu et al. 2001), IL2 (Arnaud et al. 2004b), and EGF stimulation (Brummer et al. 2006) as well as under three-dimensional culture condition (Bentires-Alj et al. 2006). In addition, SCF-induced full activation of Ras and Erk requires Gab2 interaction with Shp2 (Yu et al. 2006b), indicating that Gab2/Shp2 contribute to the efficient Erk activation at the level of Ras. Gab2/Shp2 complexes may serve as "amplifiers" of initial Ras/Erk pathway activation (Gu and Neel 2003).

Gab2/Shp2 complexes also have additional signaling roles besides activation of the Ras/Erk pathway. Expression of Gab2 mutants that cannot bind Shp2 fails to activate IL3-induced immediate early gene (i.e., fos) transcription without affecting Erk activation (Gu et al. 1998). The Gab2/Shp2 complex appears to activate the Rac-JNK pathway in response

to SCF in mast cells (Yu et al. 2006b). Gab2 via Shp2 promotes migration and invasion of mammary epithelial cells by recruiting p190RhoGAP and inhibiting RhoA activation (Abreu et al. 2011).

Role in PI3K pathway. Gab2 has three potential binding sites (YXXM) for the SH2 domain of p85. By binding p85, Gab2 mediates the activation of the ▶ PI3K pathway for receptors that lack the p85 binding sites. For example, Gab2 is implicated in PI3K activation from the receptor for IL-3/GM-CSF (Gu et al. 2000), EGFR (Kong et al. 2000), FcγR (Gu et al. 2003), and FcεRI (Gu et al. 2001). Gab2 also recruits PI3K in response to stimulation of receptor systems, such as the TCR (Nishida et al. 1999; Pratt et al. 2000) and BCR (Nishida et al. 1999), in which co-receptors recruit PI3K. In these systems, Gab2/p85 probably serves to amplify receptor-evoked PI3K activity. Gab2-induced activation of PI3K can have different signaling effects depending on the cell type. Recruitment of PI3K to Gab2 is critical for FcεRI-induced degranulation of mast cell (Gu et al. 2001). In contrast, Gab2/PI3K complexes inhibit TCR-induced IL2 production (Pratt et al. 2000; Yamasaki et al. 2001).

Role in other signaling pathways. Gab2 has been implicated in the activation of the Stat pathway. Gab2 has been shown in complexes with Stat5 (Nyga et al. 2005). However, it is still unclear how Stat5 interacts with Gab2 and whether Gab2 is required for Stat5 activation. It appears that the constitutively activated mutant of Stat5 via interaction with Gab2 activates the PI3K-Akt and Erk pathways in BaF3 cells (Nyga et al. 2005). A recent study also reveals that Stat3 interacts with the phosphorylated tyrosine residue in $_{195}$YLHQ motif of Gab2. Gab2 is required for Stat3 activation, which is important for Gab2-dependent transformation of primary hematopoietic cells by Stk/Ron in response to Friend virus infection (Ni et al. 2007). Gab2 association with PLCγ2 has been observed in osteoclasts upon RANK activation (Mao et al. 2006). It appears that PLCγ2 acts as an adaptor mediating Gab2 tyrosyl phosphorylation (Mao et al. 2006). Gab2 contributes to efficient activation of ▶ NF-κB induced by RANKL (Wada et al. 2005). However, it is unknown whether PLCγ2 association with Gab2 is required for RANK signaling. Although Gab2 via Shp2 can inhibit RhoA activation in mammary epithelial cells, a report shows that Gab2 activates RhoA, which is important for microtubule-dependent granule transport to plasma membrane in mast cells. It is unclear how Gab2 activates RhoA in mast cells, which is likely independent of Shp2 (Nishida et al. 2005). Yeast two-hybrid screens have identified CrkL (Crouin et al. 2001) that can bind Gab2. The functional significance of this interaction remains unclear.

Turning Off Gab2 Signaling Activity

Gab2 activates cell signaling pathways through phosphotyrosine interaction with SH2 domains. One way to terminate Gab2-initiating signaling is to dephosphorylate tyrosine residues in Gab2 by protein tyrosine phosphatases. Although Gab2 was identified as potential substrate for Shp2 (Gu et al. 2000), the functional consequence of Gab2 dephosphorylation by Shp2 is still unclear. Recent studies reveal that serine and threonine phosphorylation of Gab2 function as negative feedback mechanism to inhibit Gab2 signaling activities. Phosphorylation of three amino acid residues contributes to negative regulation of Gab2 tyrosyl phosphorylation and Gab2-involved responses. Ser159, phosphorylated by Akt, is involved in reducing Gab2 tyrosyl phosphorylation by ErbB2 (Lynch and Daly 2002). Gab2 Ser210 and Thr391, phosphorylated partially by Akt or an Akt-dependent kinase, recruit 14-3-3 protein, which reduces tyrosyl phosphorylation of Gab2 and Gab2-initiated signaling responses (Brummer et al. 2008). In addition, Ser623 phosphorylation by Erk results in reduced Gab2 association with Shp-2 and Erk activation induced by IL2 (Arnaud et al. 2004a). However, the mechanism by which Ser/Thr phosphorylation inhibits Gab2 signaling is still not well understood.

Biological Functions

Gab2 mainly plays positive roles in regulating cell proliferation, survival, differentiation, and migration in a cell type-specific manner. While Gab2 activation of PI3K contributes to proliferation of hematopoietic cells (Gu et al. 2000), and hepatocytes (Kong et al. 2000), Gab2 via Shp-2 is required for the proliferation of mammary epithelial cells in three-dimensional culture (Bentires-Alj et al. 2006) and mast cells (Yu et al. 2006b). Likewise, while Gab2 activation of PI3K plays a critical role in differentiation and survival of neuronal cells (Mao and Lee 2005), Gab2 via association with Shp-2 and

activation of Erk promotes differentiation of macrophages (Liu et al. 2001) and myeloid cells (Dorsey et al. 2002). In addition, Gab2 expression also contributes to cell migration in different cell types (Horst et al. 2009; Meng et al. 2005). Despite its major role as a positive signal transducer in regulating cell responses, some studies also suggest that Gab2 plays a negative role in cell signaling. Gab2 mediates the suppression of TCR-evoked IL2 gene expression in T lymphocytes (Pratt et al. 2000; Yamasaki et al. 2001).

Studies using mice with targeted disruption of the Gab2 gene (Gab2−/−) help elucidate the functions of Gab2 in vivo. Gab2 is not required for the normal development of mice since Gab2−/− mice are viable and healthy (Gu et al. 2001; Nishida et al. 2002). However, detailed analyses of the Gab2−/− mice reveal that Gab2 expression is required for the growth and functions of a variety of hematopoietic cells. Gab2−/− mast cells are defective in FcεRI-evoked degranulation and cytokine gene expression (Gu et al. 2001), which contributes to the impaired allergy response of the Gab2−/− mice (Gu et al. 2001). In addition, mast cell development is comprised in Gab2−/− mice due to impaired c-Kit-evoked signaling of Gab2−/− mast cells (Nishida et al. 2002; Yu et al. 2006b). Although differentiation of the Gab2−/− macrophage seems to be normal, FcγR-induced phagocytosis is diminished in Gab2−/− macrophages (Gu et al. 2003). Eosinophil number in the peripheral blood from Gab2−/− mice is also significantly reduced (Gu and Neel 2003). Gab2−/− mice also display mild osteopetrosis and decreased bone resorption due to defective RANK-evoked signaling in Gab2−/− osteoclasts and osteoclast differentiation from Gab2−/− progenitor cells (Wada et al. 2005). Hematopoietic stem cells from Gab2−/− mice show reduced survival and self-renewal capability (Zhang et al. 2007). Further studies of mutant mice that lack the expression of both Gab1 and Gab2 in cardiomyocytes uncover a role of Gab2 in contributing to the normal cardiac function in adult mice through mediating neuregulin1/ErbB signaling (Nakaoka et al. 2007).

Gab2 in Cancer and Alzheimer's Disease

Gab2 has been implicated in different types of cancers including solid tumors and leukemia. Gab2 protein overexpression has been reported in breast cancer cells and breast tumors (Bentires-Alj et al. 2006; Daly et al. 2002) and melanoma (Horst et al. 2009). In breast tumors, Gab2 overexpression is associated with early stage of breast cancer (Fleuren et al. 2010). Gab2 gene amplification is at least one mechanism contributing to Gab2 protein overexpression in breast cancer (Bentires-Alj et al. 2006) and melanoma (Horst et al. 2009). Gab2 overexpression is associated with metastatic melanoma (Horst et al. 2009). Studies by manipulating the expression of Gab2 in cell lines and mice indicate that Gab2 expression alone or in combination with other oncogenes promote breast tumor cell growth (Bentires-Alj et al. 2006; Brummer et al. 2006), migration, invasion, and metastasis in vitro and in mice (Bentires-Alj et al. 2006; Ke et al. 2007). Gab2-regulated Shp2-Erk pathway contributes to the proliferation, invasion, and metastasis of breast cancer cells (Bentires-Alj et al. 2006; Ke et al. 2007). In contrast, Gab2-regulated PI3K pathway promotes migration, invasion, and metastasis of melanoma cells (Horst et al. 2009). Although Gab2 protein overexpression or gene amplification has been reported in gastric carcinomas (Lee et al. 2007), acute myeloid leukemia (Zatkova et al. 2006), and ovarian cancer (Brown et al. 2008), the functional roles of Gab2 in these cancers remain unexplored.

Besides Gab2 overexpression, endogenous level of Gab2 plays critical roles in leukemogenesis induced by BCR-ABL and juvenile myelomonocytic leukemia (JMML)-associated Shp2 mutants. BCR-ABL is the causative oncogene for chronic myelogenous leukemia (CML). Gab2 via Grb2 interacts with BCR-ABL through Y177 (a Grb2 SH2 domain binding site) and mediates BCR-ABL-evoked PI3K-Akt and Erk activation, and oncogenic transformation of myeloid progenitor cells (Sattler et al. 2002). Importantly, Gab2 is required for BCR-ABL-induced CML-like disease in mice (Gu and Neel 2003). Further supporting a role for Gab2 in CML, a recent study shows that Gab2 protein expression is significantly enhanced in bone marrow samples of CML patients with accelerated phase and blast crisis diseases (Aumann et al. 2011). About 35% of JMML has somatic Shp2 mutations. Transplantation of wild type, not Gab2−/−, bone marrow progenitor cells transduced with retroviruses expressing the JMML-associated Shp2 mutants induces JMML-like disease in mice, indicating that Gab2 is required for leukemogenesis induced by these Shp2 mutants (Mohi et al. 2005). Lastly, only Gab2, not Gab1, mediates

oncogenic transformation of fibroblasts by the V-Sea oncogene (Ischenko et al. 2003) and induction of erytholeukemia by the Stk receptor tyrosine kinase in response to Friend virus infection (Teal et al. 2006).

A recent study using genome-wide association analysis reveals that several Gab2 polymorphic alleles can increase the risk of Alzheimer's disease (AD) onset in patients carrying the APOE epsilon4 allele (Reiman et al. 2007). Subsequent studies by more than ten different groups indicate that the association of Gab2 polymorphic alleles with increase AD onset depends on patient cohorts, with about half of those studies supporting Gab2 polymorphic allele as a risk factor for AD in APOE epsilon4 carriers whereas roughly the other half of the studies fail to demonstrate significant association of Gab2 polymorphic allele with increased risk of AD. It is not understood how the polymorphic alleles of Gab2 contribute to Alzheimer disease onset. These polymorphic alleles are located in the intron regions of Gab2 gene. They are more likely to change the expression of Gab2, not the protein structure of Gab2. Knockdown of Gab2 expression by siRNA increases ▶ GSK-3 and Tau phosphorylation in neuronal cell culture, suggesting that polymorphic alleles of Gab2 may involve in Alzheimer disease onset by modulating Tau phosphorylation (Reiman et al. 2007). Future study by changing the expression level of Gab2 in the brain of mouse model of AD should help clarify the role of Gab2 in AD.

Summary

Since the discovery of Gab2 13 years ago, results from molecular, biochemical, cellular, and genetic studies have revealed Gab2 as a critical regulator of multiple important cell signaling pathways including PI3K-Akt and Shp2-Ras-Erk. One important question needs to be addressed is how Gab2 via Shp2 regulates the activation of the Ras-Erk pathway. In addition, it will also be important to understand the detailed mechanism of the negative regulation on Gab2 signaling by serine/threonine phosphorylation. Gab2 overexpression or expression is functionally implicated in various diseases including cancer, allergy, and Alzheimer's. Because Gab2 belongs to the so-called undruggable target, it will be a challenge to find agents or small molecule inhibitors that can decrease Gab2 expression or blocking Gab2 activation of downstream signaling pathways. However, with the new technological advances in the drug discovery field, drugging Gab2 should provide potential new therapeutics for treating human diseases with minimal side effects since mice lacking Gab2 expression are generally healthy.

GABA$_A$ Receptor

Mikko Uusi-Oukari
Department of Pharmacology, Drug Development and Therapeutics, Institute of Biomedicine, University of Turku, Turku, Finland

Synonyms

γ-Aminobutyric acid type A receptor; γ-Aminobutyrate$_A$ receptor

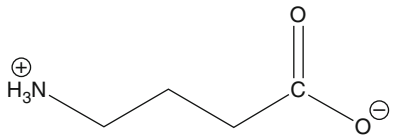
Historical Background

γ-Aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the mammalian brain, where it was first discovered in 1950. It is a small zwitterionic γ-amino acid with molecular weight of 103 g/mol (Fig. 1). Such a hydrophilic molecule cannot cross the blood brain barrier. It is produced in the brain by decarboxylation of L-glutamate by the enzyme glutamic acid decarboxylase (GAD). GABA was recognized as an inhibitory transmitter in 1967. It interacts with two types of receptors: ionotropic GABA$_A$ receptors (GABA$_A$Rs) that are fast-acting ligand-gated chloride channels, and metabotropic GABA$_B$ receptors that are coupled indirectly via G Proteins to either Ca^{2+} or K^+ channels to produce slow and prolonged inhibitory responses. The first GABA$_A$R subunits were cloned in 1987. Since then, molecular biological, electrophysiological, and pharmacological studies have revealed the highly heterogeneous nature of GABA$_A$Rs (Olsen and Sieghart 2008; Froestl 2011).

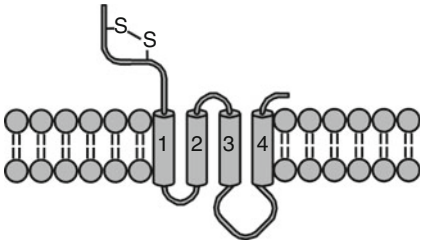
Structure of GABA$_A$ Receptors

GABA$_A$Rs belong to Cys-loop superfamily of ligand-gated ion channels. In addition, the Cys-loop receptor superfamily comprises the Nicotinic Acetylcholine Receptors, the Glycine Receptors, the 5-Hydroxytryptamine$_3$ Receptor, and Zinc-Activated Cation Channel. The subunits of Cys-loop receptors share a common primary structure consisting of large extracellular domain with a "signature" disulfide, four transmembrane segments (TM), and a large variable cytoplasmic domain (cytoplasmic loop) between TM3 and TM4 (Fig. 2). The secondary and three-dimensional structures of the subunits and the quaternary pentameric assembly of the subunits are also well conserved within the superfamily.

Mammalian GABA$_A$Rs are assembled from 19 subunits that belong in 8 subunit classes according to sequence similarity: α1–α6, β1–β3, γ1–γ3, δ, ε, π, θ, and ρ1–ρ3 (Olsen and Sieghart 2008). Each subunit is encoded by a homologous but separate gene. The subunits produce heteropentameric receptor complexes (Fig. 3). Most GABA$_A$Rs consist of α, β, and γ subunits with a subunit stoichiometry of 2α:2β:1γ (Olsen and Sieghart 2008). The γ2 subunit is the γ isoform

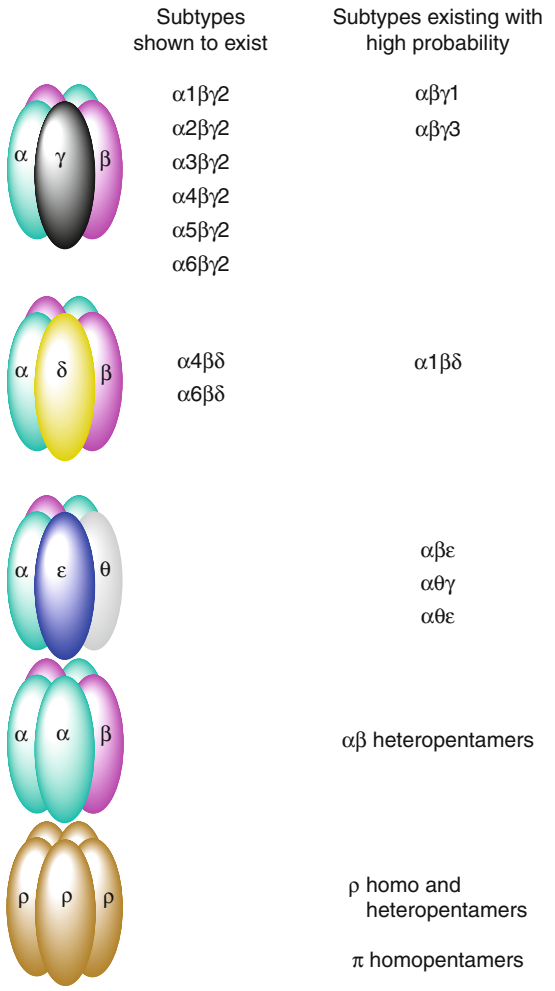


GABA$_A$ Receptor, Fig. 1 γ-Aminobutyric acid (GABA) is the principal inhibitory neurotransmitter in the mammalian brain



GABA$_A$ Receptor, Fig. 2 Secondary structure of a GABA$_A$ receptor subunit. The subunit consists of a large extracellular domain containing the signature disulfide loop, four transmembrane domains, and a large intracellular domain between TM3 and TM4

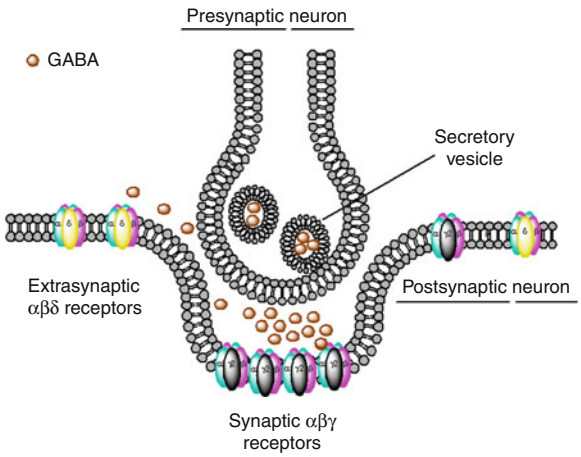
present in more than 90% of receptors. Thus, 75–80% of GABA$_A$Rs contain γ2 (Whiting 2003). γ2 subunit in the receptor complex confers sensitivity to benzodiazepines. The αβγ receptor subtypes clearly identified in the brain thus far consist of each α subunit isoform in combination with β and γ2 subunits (Fig. 3). The α1 is the most abundant α subunit; it is present in most brain regions and its expression colocalizes with those of β2 and γ2. Thus, the α1β2γ2 receptor subtype comprises 40–50% of brain GABA$_A$Rs (Olsen and Sieghart 2008). Subunits α4 and α6 combine with β and δ subunits to form α4βδ and α6β2δ receptor subtypes that are localized extrasynaptically (Fig. 4). Receptor subtypes existing with high probability include αβγ receptors containing either the γ1 or γ3 subunit; receptors containing only α and β subunits (αβ); and αβγ or αβδ receptors containing two different α or β variants (Olsen and Sieghart 2008). Rho subunits form homomeric and heteromeric ρ pentamers. Epsilon and θ are believed to combine with other classes of GABA$_A$R subunits to form receptors, but the native receptor combinations are currently not known. The π subunit is expressed outside CNS and forms homo-oligomeric complexes (Fig. 3) (Olsen and Sieghart 2008; Uusi-Oukari and Korpi 2010).



GABA$_A$ Receptor, Fig. 3 GABA$_A$ receptor subunits combine to form various GABA$_A$ receptor subtypes. A part of the combinations has been shown to exist in native brain, while the presence of other combinations have been deduced from similarities between the subunits in mRNA expression patterns and in immunochemical experiments showing similar localization of the subunits

Regulation of GABA$_A$ Receptor Expression

The large number of GABA$_A$R genes and the various types of neurons and glial cells in the brain with different patterns of subunit expression suggest a complex system regulating their transcription (Laurie et al. 1992a; Wisden et al. 1992; Olsen and Sieghart 2008). Major changes occur during development in the subunit expression patterns (Laurie et al. 1992b). Changes in receptor subunit expression also take place in adult brain. The changes are often suggested



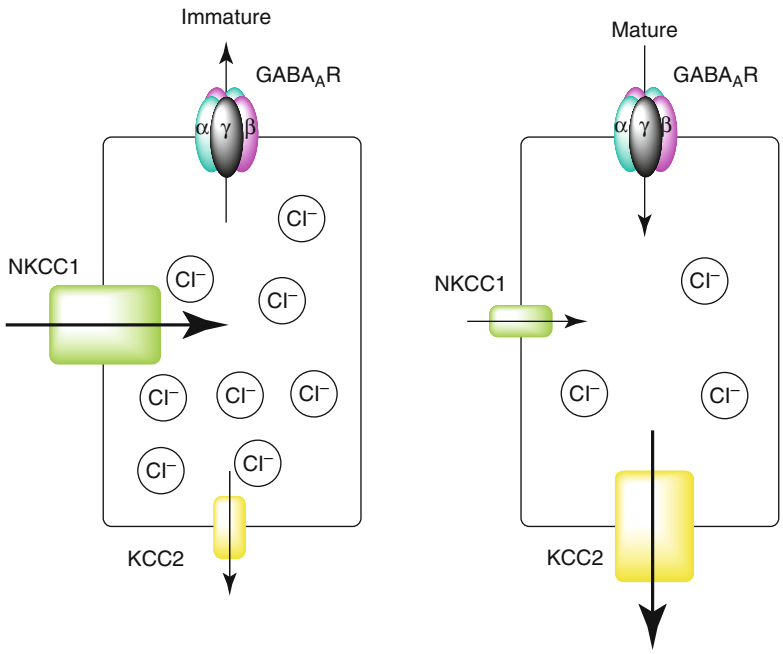
GABA$_A$ Receptor, Fig. 4 Synaptic GABA$_A$ receptors form synaptic clusters in the postsynaptic membrane. Extrasynaptic receptors are localized in extrasynaptic parts of the cell membrane. Synaptic receptors are activated by high concentration of presynaptically released GABA, while extrasynaptic receptors are activated by ambient GABA present in the interstitial space

to reflect changes in neuronal activity. Activity-dependent signaling pathways modulate the function of both transcriptional activators and repressors, but the transcription factors responsible for the developmental and brain region/cell-specific expression of GABA$_A$R subunits are presently unknown. Calcium is a crucial second messenger in the transduction of synaptic activity into gene expression, and it is involved in the mechanisms of GABA$_A$R up- and downregulation (Gault and Siegel 1998; Lyons et al. 2001). Some mechanisms regulating α1 mRNA transcription have been revealed recently. The transcription factor cAMP Response Element Binding Protein (CREB) is induced in response to stimulation with neurotransmitters, neuromodulators, and neurotrophic factors. Activation of Protein Kinase C (PKC) in primary rat neocortical cultures increases transcription of α1 mRNA via phosphorylation of CREB that is bound to the *GABRA1* promoter (Hu et al. 2008). In contrast, activation of Protein Kinase A (PKA) represses α1 mRNA transcription via Inducible cAMP Early Repressor (ICER) that forms inactive heterodimers with CREB (Hu et al. 2008). Brain-Derived Neurotrophic Factor (BDNF) decreases α1 transcription via activation of the Janus Kinase/► Signal Transducer and Activator of Transcription (STAT) pathway (Lund et al., 2008). BDNF-dependent phosphorylation of STAT3 induces the synthesis of ICER that binds with phosphorylated CREB at the *GABRA1* promoter CRE site, thereby repressing transcription (Lund et al. 2008). BDNF has been shown to regulate transcription and cell surface expression of many GABA$_A$R subunits, the effects being brain region- and subunit-specific (Uusi-Oukari and Korpi 2010).

Cell surface expression of GABA$_A$Rs includes various interacting proteins affecting receptor cell surface expression and postsynaptic accumulation. Heterodimers of α and β subunits are initially formed in a process involving interaction with endoplasmic reticulum (ER) – associated chaperones calnexin and binding immunoglobulin protein (BiP). Heteropentameric GABA$_A$Rs assembled in the ER are stabilized with ubiquitin-like protein Plic-1 that interacts with α and β subunits and facilitates the exit of assembled receptors from ER to the Golgi. GABA$_A$R γ2 subunit is palmitoylated at cytoplasmic cysteine residues by the Golgi resident palmitoyltransferase GODZ, thus promoting translocation of receptors through the Golgi apparatus to the plasma membranes and to synapses. BIG2, a GTP exchange factor (GEF) is implicated in facilitating exit of GABA$_A$Rs by interacting with β subunits. Translocation of GABA$_A$Rs to the cell surface is further facilitated by several proteins including GABARAP (interacts with GABA$_A$R γ subunits), *N*-ethylmaleimide-sensitive factor (NSF), and glutamate receptor interacting protein (GRIP). Postsynaptic clustering of GABA$_A$R subtypes α2βγ2 and α3βγ2 is facilitated by interaction of α2 and α3 subunits with gephyrin, a multifunctional protein that serves as a subsynaptic scaffold organizing the spatial distribution of receptors and other proteins in inhibitory postsynaptic membranes. The interaction of α1-3βγ2 GABA$_A$Rs with the postsynaptic cytoskeleton is regulated by the activity-dependent and calcineurin-regulated phosphorylation state of γ2 subunit. Transmembrane domain 4 and intracellular domain of the γ2 subunit have been shown to be necessary for recruiting gephyrin to the synapse. The role of gephyrin is to stabilize clustered GABA$_A$Rs at the cell surface (Luscher et al. 2011; Vithlani et al. 2011).

GABA$_A$ergic Signaling Is Developmentally Shifted from Depolarizing (Excitatory) to Hyperpolarizing (Inhibitory)

In prenatal and early postnatal stage of the development, the intracellular Cl^- concentration ($[Cl^-]_i$) of immature



GABA$_A$ Receptor, Fig. 5 In immature neurons the $[Cl^-]_i$ is higher than that in extracellular space. The chloride efflux via GABA$_A$ receptors along chloride concentration gradient results in depolarization of the cell membrane. In mature neurons the $[Cl^-]_i$ is lower than $[Cl^-]$ in extracellular space. Thus, chloride influx via GABA$_A$ receptors along chloride concentration gradient results in hyperpolarization of the cell membrane. High intracellular $[Cl^-]_i$ in immature neurons is due to high and low expression levels of NKCC1 and KCC2 transporters, respectively. In mature neurons, the expression levels of NKCC1 and KCC2 are opposite to that in immature cells resulting in low $[Cl^-]_i$

neurons is higher than that of the extracellular space. This is due to high expression of the cation-chloride cotransporter NKCC1 that accumulates Cl^- inside the cells by an energy-dependent transport process (Fig. 5). Thus, GABA$_A$R activation at an early stage of development results in Cl^- efflux via the receptor-associated anion channel and in subsequent depolarization of the cell membrane. Excitatory GABA$_A$R activity regulates neuronal proliferation, migration, differentiation, and neuronal network formation and remodeling. The depolarizing activity of GABA activates Voltage-Dependent Ca^{2+} Channels, relieves Mg^{2+} blockade of *N*-Methyl-D-Aspartate Receptors (NMDAR), and can lead to generation of action potentials (Ben-Ari et al. 2007).

During brain development, GABA signaling is established before glutamatergic transmission, suggesting that GABA is the principal excitatory transmitter during early development. GABA$_A$Rs are expressed well before synapses are formed. GABA is released at an early developmental stage and acts as a trophic factor to modulate several essential developmental processes including neuronal proliferation, migration, differentiation, synapse formation, neuronal growth, and network construction. This early intercellular communication is based on diffusion and distal paracrinic actions that contrasts with the local fast communication provided by synaptic currents. GABA tonically reduces the speed of cell migration via GABA$_A$R activation. Astrocytes may generate a microenvironment that controls the degree of GABA$_A$R activation and the migration of neuronal precursors (Ben-Ari et al. 2007).

Proliferation of neocortical progenitors in ventricular and subventricular zones of the developing cortex is downregulated by GABA$_A$R activation that leads to depolarization of plasma membrane and increase in intracellular Ca^{2+}. The interneuronal precursors synthesize and release GABA, and express GABA$_A$Rs to respond to the secreted GABA. Cortical entry of tangentially migrating interneuronal precursors arriving from the medial ganglionic eminence is enhanced

by GABA and GABA$_A$Rs. This enhanced motility of interneurons is dependent on GABA$_A$R-mediated depolarization and downstream activation of L-type calcium channels. However, soon after interneurons enter the cortex, their spontaneous calcium oscillations and their migration terminate. This is due to an increase in the expression of KCC2 transporter which reduces the $[Cl^-]_i$ and terminates depolarizing activity of GABA$_A$Rs (Jovanovic and Thomson 2011).

Developmental changes in GABA signaling are determined by the progressive negative shift in E_{GABA} that in turn reflects the developmental reduction of intracellular $[Cl^-]_i$. KCC2 is the principal transporter for Cl^- extrusion from neurons. KCC2 extrudes K^+ and Cl^- using the electrochemical gradient for K^+. Cl^- extrusion is weak in immature neurons and increases with neuronal maturation. The KCC2 is strongly expressed in mature neurons (while the expression of NKCC1 is strongly downregulated), thus underlying the developmental changes in Cl^- extrusion. K^+-Cl^- cotransport also contributes to the low $[Cl^-]_i$ in mature neurons. Developmental expression of KCC2 is pivotal for development of hyperpolarizing GABA$_A$R-mediated inhibition (Ben-Ari et al. 2007).

Synaptic (Phasic) and Extrasynaptic (Tonic) GABA$_A$ Receptor-Mediated Inhibition

The receptor subtypes α1-3βγ2 form clusters in synapses. They are activated with a very high local concentration of presynaptically released GABA. A large number of clustered synaptic receptors are activated very quickly and their desensitization is also fast. In contrast to α1-3βγ2 combinations that are clustered in synapses, α5βγ2 receptor subtype is predominantly clustered extrasynaptically by interaction with phospho-activated radixin, which links these receptors to submembrane microfilaments (Luscher et al. 2011). Part of αβγ2 receptors are freely moving in extrasynaptic portion of plasma membrane. In addition to α4βδ and α6βδ receptors that are localized exclusively extrasynaptically, part of each αβγ2 receptor subtypes contribute, in addition to αβδ receptors, to the production of the continuous tonic inhibition (Fig. 4). α4/6βδ receptors are particularly suited for tonic activity, because they possess high affinity for GABA and are thus activated by the ambient GABA leaking out from synapses or released extrasynaptically. In addition, α4/6βδ receptors desensitize very slowly, therefore being tonically active (Luscher et al. 2011; Belelli et al. 2009).

Summary

In addition to production of receptor subtype-selective drugs with minimal adverse effects, one of the major challenges in GABA$_A$R research is to resolve the signaling molecules and pathways responsible for developmental and brain region/cell-specific regulation of GABA$_A$R subunit and receptor subtype expression. The work is already in progress and new challenges are arising from the progression.

Gadd45 Family Members

Gadd45a: Gadd45α; DDIT1 (DNA-damage inducible transcript 1)
Gadd45b: Gadd45β; Myd1118
Gadd45g: Gad45γ; Cytokine responsive 6 (CR6)

Historical Background

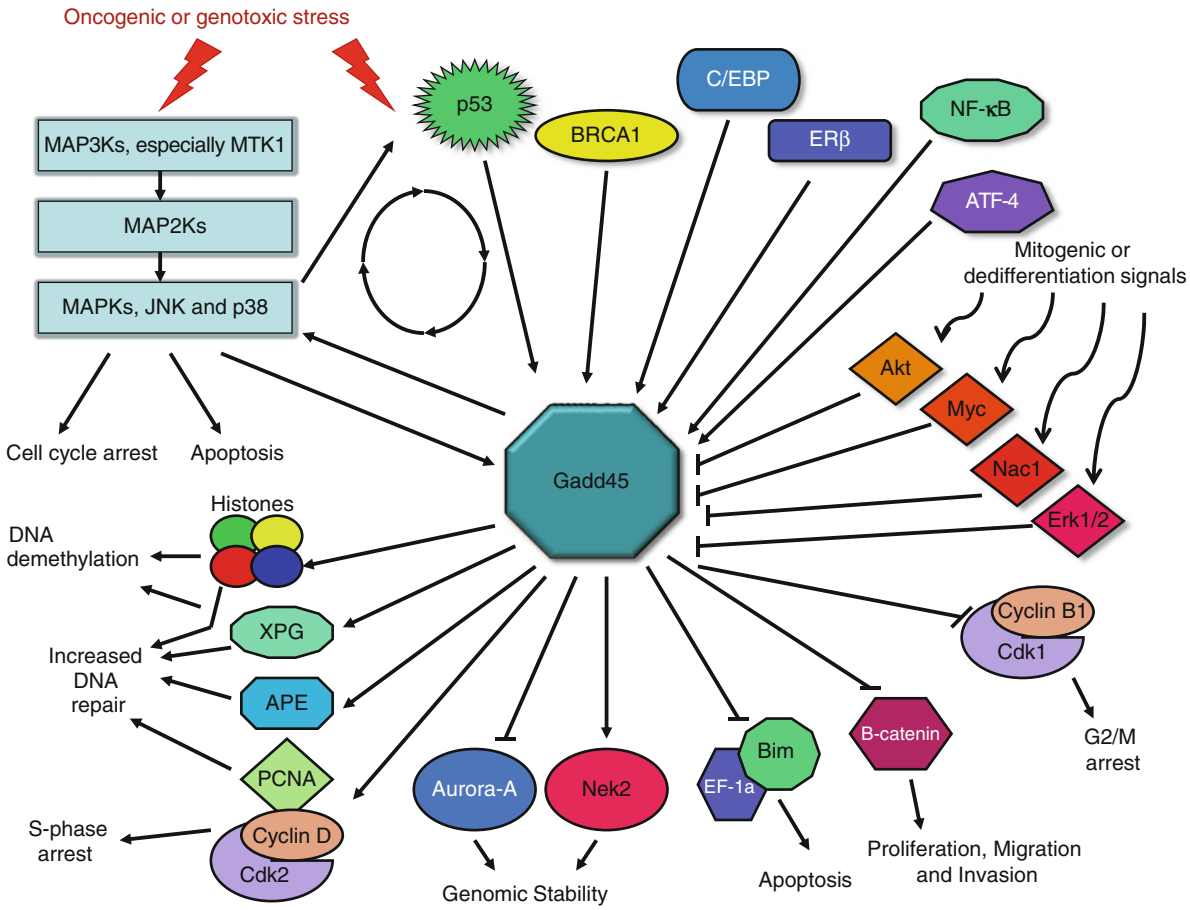
The *Gadd* genes were first cloned from Chinese hamster ovarian cells in 1988 as a subset of transcripts that were consistently upregulated after exposure to ultraviolet (UV) radiation and in many cases to other DNA-damaging agents, including methyl methane sulfonate (MMS), hydrogen peroxide, and *N*-acetoxy-2-acetylaminofluorene (Fornace et al. 1988). They were also found to be induced by other growth cessation signals, such as medium depletion or hydroxyurea. This class of transcripts was termed *Gadd*, for *g*rowth *a*rrest and *D*NA *d*amage inducible. The Gadd45 protein, now referred to as Gadd45a, was peculiar among the radiation-response genes in that it could be induced in an ATM-dependent and protein kinase C-independent manner after exposure of human cells to ionizing radiation (IR) and this induction was subsequently found to be ▶p53-regulated; indeed, Gadd45 was the first stress gene discovered that was transcriptionally regulated by p53 (Hollander and Fornace 2002).

There are three Gadd45 proteins, encoded by three different genes: Gadd45a, Gadd45b, and Gadd45g. Gadd45b was originally cloned as a gene expressed after terminal differentiation and growth arrest of M1D + myeloid precursor cells induced by IL-6. Gadd45g was similarly originally cloned as an early IL-2 response gene in T cells. These three proteins are highly conserved among metazoa, although insects have only a single *GADD45* gene, which is more similar to Gadd45g, indicating this may be the ancestral gene. They are all small (18 kDa), highly negatively charged (in the top two percentile of proteins in the ratio of negative charge to amino acids) and localize to the nucleus (Cretu et al. 2009). Gadd45a is the most well-characterized isoform and will be the focus of this entry; the other two members will be covered briefly.

Regulation of Gadd45

A myriad of factors regulate *Gadd45a* expression in the cell at the transcriptional, posttranscriptional, and posttranslational levels, frequently in response to genotoxic stress; these are illustrated in Fig. 1 and also in Table 1. *Gadd45* is one of the very few genes that has been shown to be consistently upregulated after IR, across numerous conventional and gene expression profiling studies in p53 wild-type cells (Snyder and Morgan 2004). Although ubiquitously expressed, basal *Gadd45* expression is very low, but its expression varies through the cell cycle, with levels highest during G_1 phase and lowest during S-phase (Kearsey et al. 1995).

A well-characterized mechanism of induction of Gadd45a expression is binding of p53 to a conserved site within the third intron of the *Gadd45a* gene, stimulating its transcription. This binding is induced by



Gadd45, Fig. 1 Schematic representation of representative upstream regulators of Gadd45 and its downstream inducers. *Arrows* indicate positive regulation while *blocked lines* indicate negative regulation. This figure is by no means a complete list of all of Gadd45's regulators and inducers

genotoxic stress but has been found to be necessary only in the case of IR exposure and not in the Gadd45a response to UV radiation or MMS, although loss of p53 does attenuate subsequent Gadd45a induction. WT1, a transcription factor that is mutated in various tumors and congenital defects, can also induce *Gadd45* transcription in a p53-dependent manner but in the absence of direct p53-DNA binding in response to nonionizing radiation (Gao et al. 2009).

A number of other tumor suppressor genes induce Gadd45a expression. BRCA1 induces Gadd45a expression indirectly by interacting with the transcription factors Oct-1 and NF-YA. The CCAAT/enhancer-binding protein-α (C/EBPα) activates Gadd45 expression, and other members of the C/EBP family can induce Gadd45g expression as well (Gao et al. 2009).

Mitogen-activated protein kinase (MAPK) signaling, via c-Jun N-terminal Kinases (JNK) and p38 kinases, induces expression of Gadd45a. Specifically, they activate c-Jun, which, similar to p53, binds to the third intron of *Gadd45a* and activates its transcription. However, it is of interest that transient ERK signaling induces Gadd45a expression while sustained expression has been shown to repress it (Gao et al. 2009); this Gadd45a induction may be due to transient activation of the other MAPK pathways through cross talk. ▶ Estrogen receptor β (ERβ) can bind to the promoter of Gadd45a in a ligand-independent manner and recruits c-Jun and NCOA2 to stimulate transcription and subsequent G_2/M arrest (Paruthiyil et al. 2011).

The mammalian forkhead family transcription factor FoxO3A also directly binds to the *Gadd45a* promoter and induces its transcription. The activating

Gadd45, Table 1 *Upstream regulators*. While by no means comprehensive, this table lists the regulators of Gadd45 and whether they positively (P) or negatively (N) affect a particular Gadd45 protein's expression. *Green* letters indicate a direct transcriptional activation or repression while *orange* characters indicate an indirect, upstream protein-protein interaction. *Red* indicates posttranscriptional regulation

	Gadd45a	Gadd45b	Gaddg

Foxo3a	P	–	–
Pregnane X receptor	–	P	–

transcription factor-4 (ATF-4) plays a central role in cellular stress responses and induces *Gadd45a* transcription in response to arsenite exposure, leucine deprivation, inhibition of the proteasome, and endoplasmic reticulum stress; however, only after arsenite exposure or proteasome inhibition did Gadd45a protein levels rise, showing that there is a sophisticated regulation of Gadd45a that responds differentially to various cellular stressors (Gao et al. 2009).

Transcriptional repression also takes place. The proto-oncogenes c-▶ Myc and Akt repress *Gadd45a* expression (Gao et al. 2009), highlighting the role of Gadd45a in arresting cell growth. Akt inhibition of Gadd45a is most likely through Akt-mediated FoxO3a inactivation.

Gadd45a is also regulated at the posttranscriptional level. In unstressed cells, AUF1 destabilized *Gadd45a* mRNA and TIAR1 hindered its translation, potently inhibiting expression of the Gadd45a protein. After exposure of cells to MMS or UV radiation, these proteins quickly dissociated from *Gadd45a* mRNA through an unknown mechanism and allowed robust expression of the protein. Conversely, the mRNA stabilizing protein, nucleolin, bound *Gadd45a* mRNA after cellular stimulation with arsenic chloride or inhibition of NF-κB and potently increased both mRNA and protein levels (Lal and Gorospe 2006). It was also recently discovered that MAP2Ks upstream of p38 can phosphorylate three proteins involved in RNA regulation, hnRNPA0, TIAR, and PARN, stabilizing *Gadd45a* mRNA (Reinhardt et al. 2010).

▶ NF-κB activation of Egr-1 leads to direct Egr-1-mediated transcriptional activation of Gadd45a. The NF-κB-activating kinases, IKKα and IKKβ, are also able to induce Gadd45 expression through a NF-κB-independent mechanism. The p65 (RelA) subunit of NF-κB binds directly to three κB elements in the promoter of Gadd45b and activates its transcription. However, NF-κB also inhibits Gadd45a expression through activation of c-Myc and downregulation of nucleolin. Therefore, NF-κB's differential regulation of Gadd45a may contribute to the observed pro- and anti-oncogenic actions of NF-κB, although the mechanisms governing this switch are not well understood (Yang et al. 2009).

The final level of Gadd45a regulation is at the posttranslational level. Arsenite stimulation of cells induces the formation of an IκB-kinase-β (IKKβ)/NF-κB p50 subunit complex that decreases ubiquitinated Gadd45a levels and its subsequent proteasomal degradation (Yang et al. 2009).

Gadd45b- and Gadd45g-specific mechanisms of transcriptional regulation also exist. The p65 (RelA) subunit of NF-κB binds directly to three κB elements in the promoter of Gadd45b and activates its transcription (Yang et al. 2009). Nucleus accumbens-1 (Nac1) is a transcription factor that is associated with embryonic stem cell self-renewal and pluripotency; it is also found to be upregulated in several cancer types, and particularly chemoresistant, recurring ovarian carcinomas. Nac1-mediated downregulation of Gadd45g was found to contribute to paclitaxel resistance in ovarian cancer cells (Jinawath et al. 2009).

The Effects and Consequences of Gadd45a Expression

As can be expected from a protein that is predominantly induced after genotoxic and many other

Gadd45, Table 2 *Downstream effectors*. While by no means comprehensive, this table lists the downstream effectors of Gadd45

Downstream effectors			
PCNA	DNA repair and demethylation; S-phase arrest	DNA repair and demethylation	S-phase arrest
Cdk1	G2/M arrest	G2/M arrest	G2/M arrest
APE	Stimulates DNA base excision repair	–	–
Aurora-A protein kinase	Maintenance of genomic stability	–	–
Nek2	Maintenance of genomic stability	–	–
p38	Cell cycle arrest, apoptosis, negative regulation of T-cell activation, full activation of innate immune cells, induction of senescence	Cell cycle arrest, apoptosis (or survival?), negative regulation of T-cell activation, full activation of innate and adaptive immune cells	Cell cycle arrest, apoptosis, negative regulation of T-cell activation, full activation of innate and adaptive immune cells
JNK	Cell cycle arrest and apoptosis	Cell cycle arrest and apoptosis	Cell cycle arrest and apoptosis
EF-1a	Release of Bim, apoptosis	–	–
Apc	Destruction of b-catenin	–	–
β-catenin	Inhibition of its pro-invasion program, increased b-catenin plasma membrane localization and cell-cell adhesion	–	–
p21	Negative regulation of p21 in keratinocytes, allowing NER	Positive regulation in senescing chondrocytes	Interacts but outcome unknown
XPG	Stimulates DNA nucleotide excision repair; perhaps mediates DNA demethylation		

stresses, the most well-characterized functions of Gadd45a are to induce growth arrest and stimulate DNA repair. Although few direct biochemical mechanisms have been shown for Gadd45a, it has been repeatedly found to form complexes with other proteins and even chromatin. Thus, it seems likely that the ability to both facilitate protein-protein interactions and sequester proteins may be important; these interactions and their subsequent effects are also illustrated in Fig. 1 as well as in Table 2 for select proteins.

Gadd45a plays a role in both S-phase and G_2/M arrest (Smith et al. 1994) (Hollander and Fornace 2002); it can displace proliferating cell nuclear antigen (PCNA) from the cyclin D1 complex, possibly inhibiting DNA replication during S-phase (Smith et al. 1994). Likewise, Gadd45a can also bind cyclin-dependent kinase 1 (Cdk1), most likely preventing its association with cyclin B1, inhibiting Cdk1 activity and arresting the cell at the G_2/M checkpoint (Hollander and Fornace 2002).

Gadd45a has the ability to stimulate DNA repair, seemingly through its ability to interact with PCNA and DNA repair complexes. In vitro and cell culture assays have shown that recombinant Gadd45a can stimulate nucleotide excision repair (NER) (Smith et al. 1994; Tran et al. 2002), while loss of Gadd45a expression in ex vivo assays of lymphoblasts resulted in a substantially reduced NER ability (Gao et al. 2009). More recently, Gadd45a deficiency was linked with reduced base excision repair (BER), cytoplasmic localization of apurinic endonuclease (APE), a key enzyme in the BER pathway, and decreased APE interaction with PCNA, as well as delayed removal of apurinic sites. Gadd45a's capability to interact with acetylated or UV radiation-exposed (which leads to histone acetylation) mononucleosomes and increase DNA accessibility locally may facilitate its stimulation of DNA repair (Ma et al. 2009).

Gadd45a works by multiple mechanisms to maintain genomic stability throughout mitosis. Mouse embryonic fibroblasts (MEFs) and mice with a Gadd45a$^{-/-}$ genotype were much more likely to exhibit centrosome amplification and incomplete chromosomal condensation during mitosis. This would result in defective chromosomal segregation, likely leading to the chromosomal and chromatid aberrations often seen in this genotype (Hollander and Fornace 2002), which is quite similar to the p53$^{-/-}$ phenotype. Gadd45a physically associates with Aurora-A protein kinase, the deregulated expression of which similarly

produces centrosome abnormality, and strongly inhibits its activity. Conversely, Gadd45a and Brca1 are both required for the full, physiological transcriptional upregulation of Nek2, the proper concentration of which has been found to be essential for timely centrosome separation (Gao et al. 2009).

Gadd45a has been repeatedly associated with apoptotic induction after genotoxic stress. Its level rises notably in apoptotic mammalian cells and inhibition of Gadd45a expression reduces apoptosis in response to DNA damage. The p38 and c-Jun N-terminal kinases (JNKs) mediate most of Gadd45a's proapoptotic effects. These two MAPKs act to induce cell cycle arrest and the apoptotic response. All three Gadd45 proteins were found to be able to bind the N-terminus of MTK1, a mitogen-activated protein kinase kinase kinase (MAP3K) that exclusively activates p38 and JNK signaling, inducing a conformational change that resulted in its autophosphorylation, activation, and a strong apoptotic response. Gadd45a activation of p38 and JNK signaling, which are upstream activators of Gadd45a (as well as of p53, which also induces Gadd45a expression), forms the basis for a positive feedback loop to raise the levels of these tumor suppressive signaling molecules in the event of genotoxic stress and unresolved DNA damage; this positive feedback loop is illustrated in Fig. 1. Furthermore, Gadd45a expression is necessary for sustained p38 and JNK signaling and consequent growth arrest or apoptosis in keratinocytes after UV radiation exposure (Gao et al. 2009).

Gadd45a also effects its pro-apoptosis program through interaction with the cytoskeleton. Elongation factor 1α (EF-1α) is a microtubule-severing protein that binds, bundles, and promotes microtubule assembly, playing a key role in cytoskeletal stability. Induction of Gadd45a expression leads to interaction of Gadd45a with EF-1α and inhibits its bundling of microtubules, destabilizing the cytoskeleton. This causes release of Bim, a ▶ Bcl-2 family pro-apoptotic protein, from microtubule-associated complexes and allows its translocation to the mitochondria, releasing cytochrome c into the cytoplasm and initiating apoptosis (Gao et al. 2009).

Gadd45a inhibits tumor cell invasion and migration induced by high levels of ▶ β-catenin. After UV radiation induction, Gadd45a stimulates p38 promotion of dephosphorylation of glycogen synthase kinase 3β (GSK3β), activating the adenomatous polyposis coli (APC) destruction complex, which increases β-catenin phosphorylation and degradation. Similarly, Gadd45a increases p38 positive regulation of both nuclear translocation of APC, an important step in degradation of β-catenin, and plasma membrane localization of β-catenin, preventing activation of its pro-invasion transcriptional program, and increasing its interaction with Caveolin-1, strengthening cell-cell adhesion (Gao et al. 2009).

Gadd45a interacts with tumor suppressor cyclin-dependent kinase inhibitor 1a (encoded by *CDKN1A*), also known as $p21^{Cip1/Waf1}$. The exact nature of this interaction and the outcome remain unclear, however. The two proteins compete for interaction with PCNA and Gadd45a seems to negatively regulate CDKN1A expression in keratinocytes, allowing NER repair after UV radiation exposure (Gao et al. 2009).

Deficiency of Gadd45a was found to sensitize cells to cisplatin and UV radiation, implying subtleties to the proapoptotic effects of this protein or more likely reduced DNA repair in the absence of Gadd45a. In hematopoietic cells exposed to UV radiation, Gadd45a was involved in a NF-κB-p38 survival pathway (Cretu et al. 2009). Additionally, Gadd45a protects neurons from apoptotic cell death after withdrawal of nerve growth factor in spinal cord ligation (Lin et al. 2011). The first two examples may be explained as Gadd45a enhancing survival by mitigating the effects of genotoxic stress, e.g., arresting cell replication and stimulating DNA repair. However, the last example is clearer evidence for a pro-survival function of Gadd45a and for dramatic tissue specificity in Gadd45a action.

Oncogene-induced senescence (Bulavin et al. 2003) and establishment of the senescent phenotype in response to DNA damage requires Gadd45a expression (Passos et al. 2010). In both cases, Gadd45 signaling through p38 was essential for induction of this phenotype and also for full transactivation of p53, the activity of which was shown elsewhere to be essential for entry of cells into a senescent state. In senescent human fibroblast cells, p53 preferentially occupied the promoters of Gadd45 and p21 and this was associated with a unique combination of phosphorylated p53 sites (Gao et al. 2009). Therefore, the positive feedback loop between Gadd45, p38, and p53 is essential for induction and maintenance of the senescent phenotype after oncogenic overexpression or high DNA damage

in fibroblasts and keratinocytes, and most likely in other cell types as well.

Immunologically, Gadd45a is a negative regulator of T-cell activation and proliferation. Gadd45a-deficient mice, particularly females, develop a lupus-like syndrome with high titers of anti-DNA and –histone antibodies (Lu 2006). Surprisingly, T cells from Gadd45$^{-/-}$ mice showed constitutive p38 activation, which functions via an alternative pathway to stimulate T-cell activation, and recombinant Gadd45a inhibited p38 in isolated Gadd45$^{-/-}$ T cells (Salvador et al. 2005). Despite this heightened T-cell activity, Th1 differentiation in Gadd45$^{-/-}$ mice is impaired due to reduced expression of IL-12 and CD40 co-stimulatory molecule by dendritic cells (Jirmanova et al. 2007).

Finally, there is accumulating evidence that a NER or BER-like process is involved in removal of DNA methylation, an epigenetic marker associated with repression of transcriptional initiation. Acetylation is a requisite step for DNA demethylation, as is general RNA transcription (indicating that transcription of additional factors not normally present at high levels, such as Gadd45, is necessary). Gadd45a is able to interact directly with the four core histones and increase DNase accessibility to DNA with hyperacetylated mononucleosomes in vitro, perhaps allowing access of demethylation/DNA repair complexes to DNA in the cell. In vivo studies showed significant specificity of Gadd45b-mediated DNA demethylation and Gadd45a- and Gadd45b-null mice displayed conserved global genomic methylation patterns, indicating that Gadd45 is more likely to be involved in demethylation and transcriptional activation of specific genes. A role for Gadd45 in DNA demethylation was not observed in two studies, but a number of recent reports do emphasize the highly cell-type and context-specific nature of this mechanism; this fact, together with differing experimental conditions, may explain the observed discrepancies (Ma et al. 2009). Recently, TATA-binding protein-associated factor 12 (TAF12) was found to recruit Gadd45a and the nucleotide excision repair complex to the promoter of ribosomal DNA and induce its transcription in a demethylation-dependent manner (Schmitz et al. 2009). The Gadd45 protein interacts directly with various nuclear hormone receptors, including constitutive active/androstane receptor (CAR) (Yamamoto et al. 2010), RXR α, RAR α, ER α, PPAR α, PPAR β, and PPARγ2, perhaps mediating or facilitating transcriptional initiation of their target genes (Ma et al. 2009). Gadd45a- and Gadd45b-mediated DNA demethylation has also been found to be necessary for full expression of epidermal differentiation-inducing genes during calcium-induced differentiation of epidermal stem cells (Sen et al. 2010). Lastly, Gadd45a is significantly overexpressed in CD4+ T cells from systemic lupus erythematous patients and mediates demethylation, with subsequent increased transcription, of the promoter regions of CD11a and CD70, both of which contribute to autoimmunity and therefore progression or maintenance of the disease (Li et al. 2010), despite the role of Gadd45a in T cells as a negative regulator.

Gadd45b and Gadd45g

The other two Gadd45 proteins are less well characterized compared to Gadd45a. Gadd45g is clearly defined as a pro-apoptotic, cell cycle arrest–inducing protein, similar to Gadd45a, and Gadd45b as well to a lesser extent, although there is some controversy surrounding it. Gadd45b and Gadd45g also inhibit Cdk1 activity and play a role in S and G_2/M checkpoints. Gadd45b and Gadd45g activate MTK1 in order to trigger JNK signaling (Yang et al. 2009). Both Gadd45b and Gadd45g interact with p21$^{Cip1/Waf1}$; Gadd45b does positively regulate its expression in senescing chondrocytes but the outcome of this interaction is otherwise unclear in other tissues and contexts (Gao et al. 2009). Gadd45b facilitates p38-mediated retinoblastoma tumor suppressor protein (Rb) activation by enhancing their interaction after Fas stimulation in murine hepatocytes (Cho et al. 2010). It also mediates TGF-induced apoptosis in murine hepatic cells in a p38- and Smad-dependent manner and both Gadd45b and Gadd45g overexpression induced apoptosis in HeLa cells. Gadd45g has been associated with neuronal cell death and Gadd45b with the apoptotic response in neural ischemia (Cretu et al. 2009). Gadd45g levels were found to be significantly lower in anaplastic thyroid cancer cells compared to primary cultured thyrocytes and its reintroduction by viral expression significantly inhibited proliferation (Yang et al. 2009).

However, the role of Gadd45b in apoptosis and cell growth arrest has been controversial. Gadd45b has also

been found to mediate ▶ TNFα-induced NF-κB suppression of JNK-induced apoptosis by binding directly to MKK7 and inhibiting its catalytic activity. It also suppresses JNK signaling in hematopoietic cells in response to UV treatment (although this was later challenged) (Yang et al. 2009). Similarly, stimulation of CAR induces it to interact with Gadd45b and cause Gadd45b-mediated repression of both JNK signaling and subsequent cell death in mouse hepatocytes (Yamamoto et al. 2010). The role for Gadd45b in TGFβ-mediated apoptosis has been shown with a genetic approach in Gadd45b-/- mouse hepatocytes where this Gadd45 protein was required for p38 activation (Yoo et al. 2003). Gadd45b promoted liver regeneration in vivo (Papa et al. 2008) and was protective of retinal ganglion cells in the response to different neuronal injuries, such as oxidative stress, and TNFα and glutamate cytotoxicity (Liu et al. 2009).

Contrary to Gadd45a, Gadd45b and Gadd45g potentiate p38 signaling in Th1 and CD8+ cytotoxic T cells, which is necessary for full effector function, but, similar to Gadd45a, are negative regulators of T-cell activation and proliferation (Lu 2006; Ju et al. 2009). Additionally, Gadd45b is necessary for full expression of the Th1 lineage-inducing proteins, T-bet and Eomes (Ju et al. 2009); thus, the Gadd45 family members seem to synergistically work together to promote full maturation and function of Th1 and CD8+ cells, but they also prevent inappropriate overexpression, except under certain pathological conditions.

Finally, Gadd45b has been found to be required for specific DNA demethylation of factors critical for activity-induced adult neurogenesis (Ma et al. 2009). Thus, there appears to be a wide variety of roles for these two proteins and further characterization is necessary to determine the extent of their roles in cellular biology.

The Gadd45-Null Phenotype

Gadd45a-knockout mice display genomic instability in a significant proportion of cells, immunological deficiencies, low levels of fetal exencephaly and, despite wild-type basal levels of carcinogenesis, treatment of Gadd45a$^{-/-}$ mice with carcinogens such as dimethylbenzanthracene or IR results in increased rates of tumorigenesis with a shorter latency period (Hollander and Fornace 2002; Lu 2006). This indicates that Gadd45a is more important in stress signaling and is the response to DNA damage than constitutive suppression of carcinogenesis. Although most mouse models using a genetic approach indicate tumor suppressor features for Gadd45a, a recent report showed that it can function as a promoter or suppressor of mammary cancer dependent on the oncogenic stress. It's tumor promoting activity seems to be an extension of Gadd45a's ability to repress beta-catenin activity, the negative regulation of which is normally associated with tumor suppression. However, this appears to have tumorigenic consequences in a Myc-driven breast cancer mouse model (Tront et al. 2010).

Additionally, although in vitro studies have implicated Gadd45a in a large number of different signaling pathways, in vivo studies seem to show that the most important downstream effector of Gadd45a signaling is the p38 MAP kinase. Mouse models of Gadd45a deficiency show that Gadd45a-dependent protection against UV irradiation-induced skin tumors requires functional p38 (Hildesheim et al. 2002) and abolition of either Gadd45a or p38 activity resulted in compromised negative regulation of β-catenin via the adenomatous polyposis coli destruction complex (Gao et al. 2009). Notably, p53-signaling in the sunburn response has been shown to require Gadd45a for effective p38 activation which then signals to p53 (Hildesheim et al. 2002). The tissue-specific Gadd45a regulation of p38 signaling in dendritic and T cells is discussed above and highlights the importance of p38 as a target of Gadd45. Although the genomic instability exhibited by Gadd45a$^{-/-}$ mice may be due to additional mechanisms, much of the observed phenotype seem to be mostly due to altered p38 signaling.

Involvement of Gadd45 in Cancer

Gadd45 has been implicated in a number of studies of cancer. Gadd45a deficiency in mice resulted in increased rates of IR- or dimethylbenzanthracene-induced tumors with a shorter latency period, as discussed above. Deletion of Gadd45a in an XPC$^{-/-}$ mouse model of lung cancer led to an increase in lung tumor malignancy, and allelic deletion of Gadd45a is associated with multiple tumor types including lung (Hollander et al. 2005). The Gadd45a promoter is methylated in a majority of breast cancers and a significant fraction of prostate cancers, while the

Gadd45b promoter was likewise hypermethylated in several human hepatocellular carcinomas, in both cases with subsequent downregulation of expression. Sustained ERK1/2 signaling in an acute myeloid leukemia model cell line was found to downregulate Gadd45a, the reintroduction of expression of which induced S-phase arrest and apoptosis (Cretu et al. 2009). Mechanistically, simultaneous overexpression of H-ras and knockout of Gadd45a were sufficient to transform cells, indicating that Gadd45a knockout may serve as one of the "two hits" in oncogenic transformation (Bulavin et al. 2003).

Despite the apparent tumor suppressor role of Gadd45, it also appears to offer malignant cells survival advantages, in line with its roles in cell growth arrest and DNA repair and beyond. In one study, point mutations were found in exon 4 of the *Gadd45a* gene in 14% of studied pancreatic cancer samples and Gadd45a expression in p53-positive tumors was significantly associated with a lower patient survival rate. Gadd45a induction was also found to protect melanoma cells from UV radiation–induced death. Lack of Gadd45a induction in cervical carcinomas correlated significantly with a good clinical response to radiotherapy (Gao et al. 2009). Additionally, despite decreased FOXO3A transcriptional activity, Gadd45a expression was found to be upregulated in thyroid cancers (Karger et al. 2009). The pregnane X receptor can activate Gadd45b/p38 MAPK signaling to induce change of morphology and migration in a hepatocellular carcinoma cell line (Kodama and Negishi 2011). However, given the higher reported rate of promoter hypermethylation or upregulation of Gadd45 transcription-repressing proteins, multiple Gadd45 functions may be important such that alteration of a single function may be insufficient to induce or intensify the tumor phenotype.

Gadd45g is also deficient in several tumors. Its promoter region was found to be hypermethylated and its transcription repressed in a significant number of non-small cell lung cancers (Na et al. 2010), lymphomas, nasopharyngeal carcinomas, cervical carcinomas, esophageal carcinomas, pituitary adenomas (Yang et al. 2009), and gastric, colorectal, and pancreatic cancers (Zhang et al. 2010); however, genetic mutation and inactivation was very rare. Exogenous reintroduction of Gadd45g resulted in G_2/M arrest in a number of tumor cell lines, including prostate carcinoma and pituitary adenoma (Yang et al. 2009).

Summary

In summary, the Gadd45 proteins are mostly characterized as classical tumor suppressors that induce cell cycle arrest and apoptosis in response to DNA damage or oncogenic stimuli. Moreover, they play important roles in a range of other physiological processes, including DNA demethylation and repair, maintenance of genomic stability through mitosis and immunological regulation and activation, although the details and exact mechanisms of Gadd45 involvement in these are still under investigation. Equally intriguing is the accumulating evidence, after initial negative findings, for a role for Gadd45 in both suppressing and promoting cancer. Gadd45 occupies a key role as a hub between different signaling pathways, which no doubt contributes to the difficulty elucidating its function and the contradictory reports; this is in addition to significant tissue specificity in its expression and downstream effectors. That its overexpression has been linked to cancer cell survival, chemoresistance, and migration marks it as a possibly valuable therapeutic target. However, given its tumor suppressor and pleiotropic aspects, research mindful of the difficulties inherent in analyzing a key signaling molecule involved in multiple processes would be necessary to determine the most efficacious manner of exploiting it for clinical benefit.

Synonyms

Galanin receptor; GALNR; GalR; GAL-R

Historical Background

Galanin is a 29 amino acids (30 amino acids in human) long neuroendocrine peptide, originally isolated from porcine upper intestine in 1983 (Tatemoto et al. 1983). Subsequently, galanin was found to be expressed widely in brain and peripheral tissues. Galanin triggers cellular responses by binding to specific galanin receptors, and then the signals are transduced into intracellular effectors via G proteins. So far, there are three receptors (GalR1, GalR2, GalR3) were cloned (Branchek et al. 2000), and all of them are G-protein-coupled receptors (GPCR). The three receptors have substantial difference in their functional coupling and subsequent signaling activities, which contributes to the diversity of possible physiological effects of galanin. Galanin receptors can be found throughout the peripheral and central nervous systems (CNS) and the endocrine system, and they can regulate numerous physiological process such as sleeping regulation, feeding, nociception, nerve regeneration, learning and memory, neuroendocrine release, and gut secretion and contractility. However, the specific function of each subtype of galanin receptor remains to be fully elucidated, although great progress is being made in recent studies which newly available subtype selective agonists and antagonists and transgenic mouse models were established (Lu et al. 2008).

Agonists and Antagonists

Molecular cloning of galanin receptor subtypes has allowed design and screening for receptor subtype-specific agonists and antagonists in order to study the molecular basis of galanin actions and to develop potential therapeutic compounds. Selective galanin agonists are anticonvulsant, while antagonists produce antidepressant and anxiolytic effects in animals (Lu et al. 2005), so either agonist or antagonist ligands for the galanin receptors may be potentially therapeutic compounds in humans.

Agonists

Galanin: Human galanin is a 30 amino acids long, non-C-terminally amidated peptide, while galanin from all the other species is 29 amino acids long, C-terminally amidated (Tatemoto et al. 1983). Endogenous galanin is a high-affinity agonist for all three galanin receptors, GalR1, GalR2, and GalR3. The N-terminal 14 amino acids of galanin are fully conserved between different species (Lu et al. 2005). Deletion of first 16 amino acids of galanin causes the complete loss of its affinity for galanin receptors, suggesting the N-terminal 16 amino acids of galanin are critical for receptor binding.

Galanin 1–15 fragment: Galanin (1–15) have been shown to be highly efficacious galanin receptor agonists in vitro and in vivo, but with slightly different pharmacological profiles from that of galanin in the dorsal hippocampus.

Galmic and Galnon: As two small rationally designed galanin receptor agonists, both compounds have been synthesized using a tripeptidomimetic scaffold (galnon) and an oxazole scaffold (Galmic) (Saar et al. 2002). They are systemically active and substantially more resistant to degradation than the endogenous agonist galanin, making it possible to examine galanin receptor roles by systemic application intraperitoneally. The drawbacks of galnon and galmic are that they are low affinity (micromolar affinities), nonreceptor subtype selective, and interacting with other pharmacologically important targets.

Galanin 2–11 fragment: It was also called AR-M1896. Galanin (2–11) has been introduced as a GalR2 selective agonist. However, it also binds to GalR3 receptors with an affinity that is similar to that for GalR2, which has higher than for GalR1 receptors. Its effects have been demonstrated in the spinal cord and locus coerules.

Galanin-like peptide (GALP): GALP is a 60 amino acids long endogenously occurring peptide, which shares amino acid sequence homology with galanin (1–13) in position 9–21. GALP is a high-affinity agonist for both GalR1 and GalR2 receptors with slight preference for GalR2 over GalR1 (18-fold), but not GalR3.

Antagonists

M15, M32, M35, M40, and C7 peptides: They are synthesized chimeric high-affinity ligands, consisting of mammalian galanin (1–13) conjugated to other bioactive molecules. They act as antagonists by mediating a decrease in cyclic AMP production.

Spirocoumaranon (Sch 202596): It is fungal metabolite, belonging to non-peptide galanin receptor ligand. This compound was reported to act as an inhibitor on human GalR1. In addition, Sch 202596 is a low-affinity compound with additional problems precluding their further optimization.

3-[(3,4-dichlorophenyl)imino]-1-(6-methoxy-3-pyridinyl)-1,3-dihydro-2Hindol-2-one: The synthesized compound has 15 nM affinity for GalR3 and shows receptor subtype selectivity and low affinity to other pharmacological targets.

The Distribution of the Three Galanin Receptors, GalR1, GalR2, and GalR3

The first known galanin receptor GalR1 was isolated from the human Bowes melanoma cell in 1994 (Habert-Ortoli et al. 1994). GalR1 was subsequently cloned from rat and mouse. Human GalR1 contains 349 amino acids, and the gene has been mapped to chromosome 18q23. GalR1 mRNA is widely expressed in the mammalian CNS, including brain and spinal cord, as well as in the gut and pancreas-derived cells such as RIN-4b. GalR2 and GalR3 were first cloned from rat hypothalamus in 1997 (Howard et al. 1997). Human GalR2 receptor contains 387 amion acids and has been mapped to chromosome 17q25.3. Unlike GalR1, GalR2 is widely distributed in almost all tissues, including in the hypothalamus, hippocampus, amygdala, and pyriform cortex, as well as in the dentate gyrus, mammillary nuclei and cerebellar cortex, and peripheral tissues such as the vas deferens, prostate, uterus, ovary, stomach, large intestine. GalR3 mRNA is relatively abundant in peripheral tissues, but expression in the CNS is more limited, been largely confined to the hypothalamus and the midbrain and hindbrain. The GalR3 is the least abundantly expressed of the galanin receptor subtypes.

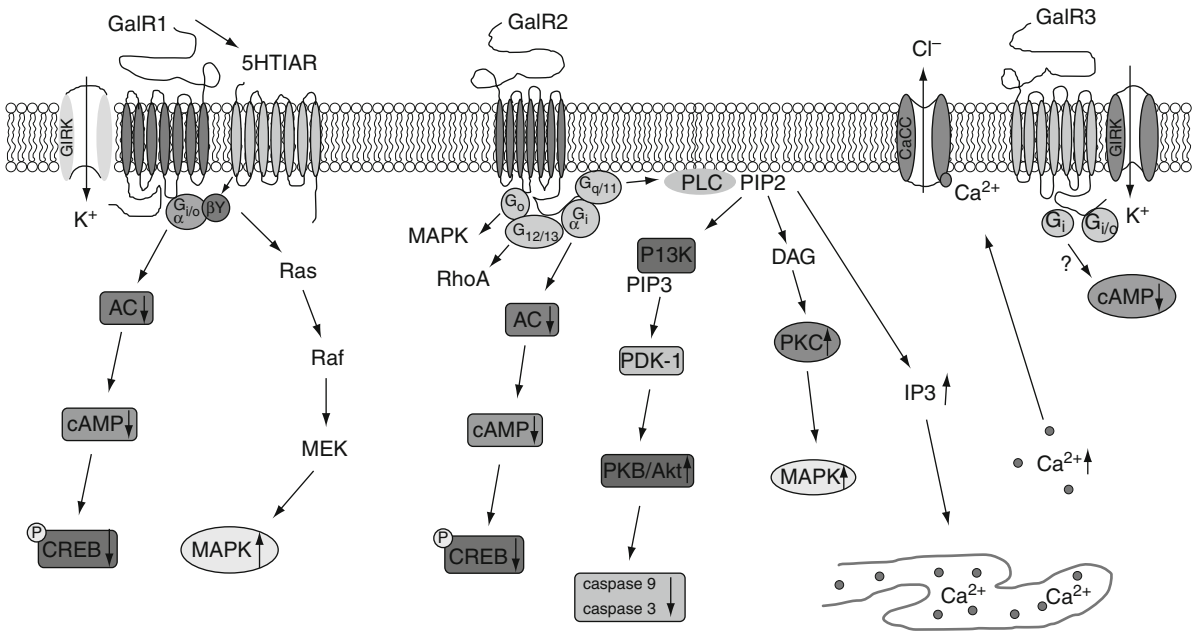
In areas of the mouse brain involved in drug addiction, including the ventral tegmental area (VTA), substantia nigra (SN), nucleus accumbens (NA), and locus coeruleus (LC), all three galanin receptors were found, with the most highly expressed of GalR1 protein in the VTA, NA, and SN, suggesting that GalR1 may play a predominant role in galanin-mediated regulation of dopamine neurotransmission. GalR1 and GalR3 protein levels are high in the LC, indicating that these isoforms may be important for galanin-mediated regulation of noradrenergic transmission during opiate withdrawal.

In the areas of gastrointestinal tract, GalR1 and GalR2 mRNAs were detected in all segments with the highest levels in the large intestine and stomach, respectively. GalR3 mRNA levels were quite low and mostly confined to the colon. The differential distribution of GalRs supports the hypothesis that the complex effects of galanin in the gastrointestinal tract result from the activation of multiple receptor subtypes (Anselmi et al. 2005).

Galanin Receptor Signaling

The galanin receptors are GPCR; therefore, cells devoted to the binding of galanin share common signal transduction components triggered by G proteins. Generally, the first step is that ligands interact with their specific galanin receptors on the membrane. Then the signal pathway mediated by the G protein is activated that initiates intracellular signal cascades. However, the three subtypes of the galanin receptors have differences in their functional coupling and subsequent signaling activities (Fig. 1, Lang et al. 2007).

GalR1 is coupled to the G_i proteins and therefore capable of inhibiting the intracellular cAMP signaling pathway upon ligand binding. It has demonstrated that rat or human GalR1 expressed in transfected cell lines inhibits forskolin-stimulated cAMP production in a pertussis toxin (PTX)-sensitive manner. GalR1 is specifically upregulated in the locus coeruleus



GALR, Galanin Receptor, Fig. 1 Signaling pathways of galanin receptor subtypes. *AC* adenylate cyclase, *CaCC* Ca^{2+}-dependent chloride channel, *cAMP* 3′,5′-cyclic adenosine monophosphate, *(p)CREB* (phosphorylated) cAMP response element-binding protein, *DAG* diacylglycerol, *IP3* inositol triphosphate, *MEK* mitogen-induced extracellular kinase, *PDK-1* phosphoinosotide-dependent protein kinase 1, *PIP2* phosphatidylinositol bisphosphate, *PIP3* phosphatidylinositol trisphosphate, *PI3K* phosphatidylinositol 3-kinase, *PKB* protein kinase B, *PLC* phospholipase C, *5HT1AR* 5-hydroxtryptamine-1A receptor, *GIRK* G protein-coupled inwardly rectifying potassium channel (Adapted from Lang et al. (2007))

(LC)-like Cath, a cell line in a cyclic AMP-dependent manner. GalR1 protein and mRNA levels are also upregulated in the LC of galanin knockout mice. Also, GalR1 activates G proteins via $G_{\beta\gamma}$-subunits. Activation of GalR1 expressed in squamous carcinoma cells induces a marked and prolonged ERK1/2 activation, in this case via $G_{\alpha i}$-subunits, leading to induction of the cell cycle arrest and suppresses proliferation in a p53-independent manner. In addition, galanin binding to GalR1 led to receptor internalization in the transfected Chinese hamster ovary (CHO) cells, which may be a mechanism for regulating the endogenous signaling cascade in native cells. Recently, Borroto-Escuela et al. (2010) have examined the possible existence of GalR1-5HT1AR (5-hydroxtryptamine-1A receptor) heteromers, indicating the existence of GalR1-5HT1A receptor–receptor interactions in the discrete brain regions. This would give rise to explore possible novel therapeutic strategies for treatment of depression by targeting the GalR1-5HT1A heteromers.

GalR2 can be coupled to different classes of G proteins, initiating two second-messenger signal cascades: the cyclic adenosine monophosphate (cAMP) and phosphoinositide signals, which are two parallel streams of intracellular events. In the pathway of phosphoinositide signal, phospholipase C (PLC) is activated. Thus, inositol phosphate hydrolysis is increased, mediating the release of Ca^{2+} into the cytoplasm and opening Ca^{2+}-dependent chloride channels. In this case, GalR2 may act through $G_{q/11}$-type G proteins since the intracellular effects are not affected by PTX. In addition, it is suggested that neuronal survival enhanced by galanin is mediated by the AKT signaling pathway leading to suppression of caspase-3 and caspase-9 activity. In the pathway of cAMP signal, the forskolin-stimulated cAMP production was inhibited in CHO cells transfected with rat GalR2 and HEK-293 cells transfected with human GalR2 after galanin stimulation, and the G_i-type G proteins were suggested to be used. Furthermore, both GalR1 and GalR2 activations inhibit cyclic AMP-responsive element-binding (CREB) protein. However, there are somewhat controversial points on this pathway. It is also supported that GalR2 is coupled to

a G_o-type G-protein, activating MAPK in a PKC-dependent fashion or to a $G_{12/13}$-type G-protein, activating RhoA.

GalR3 appears to couple to a $G_{i/o}$-type G-protein to stimulate the activation of an inward K^+ current. In addition, a G_i-type G-protein was also reported to be involved in GalR3 signaling. However, the detail signaling pathways mediated by GalR3 are still poorly understood. New molecular tools, such as application of subtype-specific antisense reagents and gene knockout approaches, will clarify our understanding of the role of galanin receptor subtypes in galaninergic signaling.

Effects of GalRs in NS

Galanin and its receptors are widely expressed in the CNS and peripheral nervous system (PNS), indicating the numerous physiological effects of GalRs. The three galanin receptors have been found to be involved in the control of feeding, alcohol intake, seizure threshold, cognitive performance, and mood and pain threshold (Mitsukawa et al. 2008).

Learning and Memory

The effects of galanin participating in the learning and memory have been shown in many studies. It is generally accepted that the ability to perform learning and memory tasks will be impaired if too much galanin in the hippocampus or lateral ventricles of rats. This effect can be blocked by GalR2 antagonist M40. However, we should also be aware that the results have some controversy. In some recent testing of a GalR2-KO strain (Lang et al. 2007), the mutant mice were not significantly different to wild-type littermates on the cognition tests (Ogren et al. 1996). This suggests that GalR2 may be not centrally involved in learning and memory. But it cannot rule out the possibility that galanin levels have not reached sufficient levels during the behavioral tasks, or compensatory developmental changes in the other galanin receptors (Ogren et al. 1996). Further experiments should be able to address these possibilities.

Mood Regulation and Alcohol Intake

Galanin was found to be coexpressed with noradrenaline in the noradrenergic neurons in the locus coeruleus (LC) and with serotonin in the serotonergic neurons in the dorsal raphe nucleus (DRN) (Lu et al. 2005). The overactivity of the LC noradrenergic neurons leads to suppression of the firing of the DRN serotonergic neurons, thus causing depression. It was suggested by Lu et al. (2005) that GalR2 agonists, like blockers of serotonin (SSRIs), may be effective in the treatment of major depression. Also, GalR3 antagonists have anti-depressant-like activity. The GalR3 subtype selective antagonists had been synthesized, and they were confirmed to be active in some anxiety or acute antidepressant models. In addition, GalR3 has been shown a significant association with alcoholism, but there was no effect of GalR1 or GalR2 haplotypes on alcoholism risk. Thus, Mitsukawa et al. (2008) indicated that development of galanin receptor antagonists, in particular GalR3 antagonists, might be a breakthrough in the addiction relevant field.

Feeding

It is reported that galanin had the ability to induce food intake strongly (Leibowitz 2005). The choice of food preference – if protein, carbohydrates, and fat are available – is fat first and carbohydrate second. It also suggested that the food preference was caused by activating the process of ingestion rather than controlling satiety feeling. Although all three galanin receptor subtypes are present in brain regions important for galanin-stimulated feeding, it is indicated that the rat feeding response was attributed to either GalR1 or an unidentified GalR rather than to GalR2 and GalR3. Furthermore, the studies on GalR1 null mutation carrying mice showed that GalR1 mediated the important effects that are required for glycemic control and body weight control (Zorrilla et al. 2007).

Pain

Galanin and its three receptors are expressed in both sensory and spinal cord interneurons. Also, nerve injury such as axotomy can lead to a rapid high-level expression of galanin in the sensory ganglia. The expression profiles of galanin and the three receptors indicate that they may play a key gatekeeper role in pain signaling (Wiesenfeld-Hallin and Xu 2001). Galanin has double-eged function in many pain models. It can both act as inhibitory or excitatory mediator, depending on the circumstance such as the nature of stimulus of the nociceptive (thermal, mechanical, chemical), the acute or chronic state, and the concentration of galanin available to act on the nociceptive afferent nerves. It is suggested that low galanin doses can escalate and high doses suppress

pain. The GalR2-mediated depolarizing effects may contribute to pain sensation, while GalR1-mediated hyperpolarization of the sensory and interneurons are responsible for the analgesic effect. Therefore, GalR1 agonists may be the potential candidates for systemic or intrathecal use in pain therapy.

Neuronal Injury

The expression of galanin is strongly increased in mRNA or protein levels after neuronal injury, suggesting a trophic role for galanin. Indeed, galanin acts as a survival- and growth-promoting factor for different types of neurons in the peripheral and central nervous system. For example, the decrease of galanin level was observed in many damage models of different brain region, including the cut or extrusion of motor and sensory neurons, traverse of central nerve, focal cerebral ischemia. Also, GalR2 was suggested to be related to the survival of hippocampal neuron and injured brain (O'Meara et al. 2000). It is reported that the selective GalR2 peptide agonist AR-M1896 counteracts a number of morphological alterations induced by glutamate toxicity in neuronal hippocampal cells.

Anxiety

Galanin and receptors were found to be expressed in brain areas relevant to emotional behavior, such as the amygdala and the BNST (the bed nucleus of the stria terminalis). Its coexistence with noradrenaline (NE) and serotonin in relevant neural pathways were also discovered. Thus, the roles of galanin and its receptors in animal models of anxiety were concerned. Behavioral studies of both GalR1- and GalR2-KO mouse strains suggested a role for galanin in regulating anxiety-related behaviors. In addition, it is reported that galanin express the activity of anti-anxiety via GalR1 under the relatively high pressure. Also, there are other experiments indicated that GalR2 and GalR3 have been involved in the process of anti-anxiety. However, the concrete process concerning the three receptors has to be further research.

Effects of Galanin and GalRs for Many Pathological Diseases

Epilepsy

During the past decade, the growing evidences have been suggesting that galanin is in fact a powerful inhibitor of seizure activity. In the hippocampus, galanin inhibits both acetylcholine release and postsynaptic cholinergic functions. It was reported that both acetylcholine release and postsynaptic effects of pilocarpine and acetylcholine were increased in GalR1 null mutation mouse, thus promoting seizures (Fetissov et al. 2003). The duration of epilepticus can be significantly shortened by the pretreatment of galanin, but this effect can be reversible by the injection of a GalR1 antagonist, M35. Moreover, M35 alone promotes the establishment of seizures and prolongs their duration. Collectively, galanin can affect the maintenance phase of seizures possibly via GalR1. Pharmacological application of galanin agonists should be a potently useful antiepileptic.

Alzheimer's Disease

Alzheimer's disease is characterized by the progressive degeneration of the cholinergic/galaninergic neurons and the cognitive function losing gradually. Learning and cognitive performance of rodents were shown to be impaired after intrahippocampal- or intracerebroventricularly (i.c.v)-injected galanin (Rustay et al. 2005). This is in line with the overexpression of galanin in Alzheimer's disease. Also, the expression of galanin receptor was found to be higher in Alzheimer's disease afflicted brains. GalR1 antagonists, as a cognitive enhancer, might help the treatment of the Alzheimer's disease since they would disinhibit the release of acetylcholine. In addition, GalR2 agonists were suggested to run roles in neuroprotection and neurogenesis. Thus, GalR2 agonists are also expected to be useful to cognitive disorders of neurodegenerative etiology.

Tumors

The expressions of galanin and galanin receptors have been detected in several tumors such as pancreatic, hypothalamic, and pituitary tumors; small cell lung carcinoma; and colon cancer isolates (Mitsukawa et al. 2008), which prompts that galanin can be involved in many tumor pathophysiological process. For example, galanin has mitogenic effects on human pancreatic cancer cells and stimulated the proliferation and prolactin secretion of rat pituitary tumor cells in vitro. Therefore, galanin and galanin receptor expressions are becoming increasingly used markers for certain tumors. In head and neck squamous cell carcinoma (HNSCC), signal mechanism has also been studied, which GalR1 and GalR2 were revealed to act as tumor suppressors in a p53-independent manner.

GalR1 or GalR2 induces cell cycle arrest and suppresses proliferation in HNSCC, and GalR2 can also induce apoptosis (Kanazawa et al. 2010). Indeed, galanin has been clinically used in pancreatic tumor therapy.

Diabetes

Galanin has been detected in pancreatic islet cells in several species. There are a large number of galanin-like immunoreactive (galanin-LI) cells in both the peripheral and central regions of the islet of Langerhans of normal rat pancreas, but the galanin-LI cells are significantly less in diabetic ones. In addition, the concentration of insulin in humans was shown to be suppressed after galanin injection. Therefore, the positive correlation of galanin with diabetes is expected. It was suggested that the specific mechanism for galanin effect was involved in GalR1 since the GalR1 agonist M40 can suppress glucose-stimulated insulin release. GalR3 was also reported to be involved in this process.

The Evolution of GalR

To obtain insights into the evolution of GalRs, Liu et al. (2010) have searched the genomes of the deuterostomes by extensive BLAST survey and phylogenetic analyzes. Typical GalR1 and GalR2 genes were found from fish to human; however, GalR3 were only found in some mammalian. Interestingly, two GalR1 genes were found in fish, including *F. rubripes*, *T. nigroviridis*, and *D. rerio*, and two GalR2 genes were presence in *G. gallus*. These indicate that the GalR1 and GalR2 gene duplication events occurred in fish and chick, respectively. GalR2 and GalR3 share similar genomic structures, which most of them are composed of two exons and one intron. However, most of GalR1 are composed of three extrons and two introns. Typical GalR genes were not detected in the genomic databases of invertebrate deutserotomes, including *S. purpuratus*, *C. intestinalis*, and amphioxus, but three GalR1/Alstr homologs and two GalR1/Gpr151 homologs in amphioxus, two GalR1/Gpr151 homologs in sea squirt, and one GalR1/Gpr151 homolog in sea urchin were identified. It is highly possible that the GalR genes in vertebrates may evolve from the homologous genes of GalR1/Alstr/Gpr151 in invertebrate deuterostomes. Also, GalR3 genes may be the products of GalR2 duplication during evolution, while GalR2 genes may evolve from GalR1.

Summary

The widely distribution of galanin and GalRs in the CNS and in the PNS and various organs demonstrates that the galanin and GalRs play key roles in numerous physiological functions such as seizure, learning, nociception, nerve regeneration, food intake, and reproduction. However, there is controversy concerning some certain physiological functions of galanin and GalR, such as learning and memory, anxiety behavior modulation. With more galanin receptor knockout mice are got, the biological effects mediated by activation of distinct galanin receptor subtypes in various organ systems would be more clear. The search for agonists and antagonists of specific GalRs will promote the research and application of GalRs in the drug target.

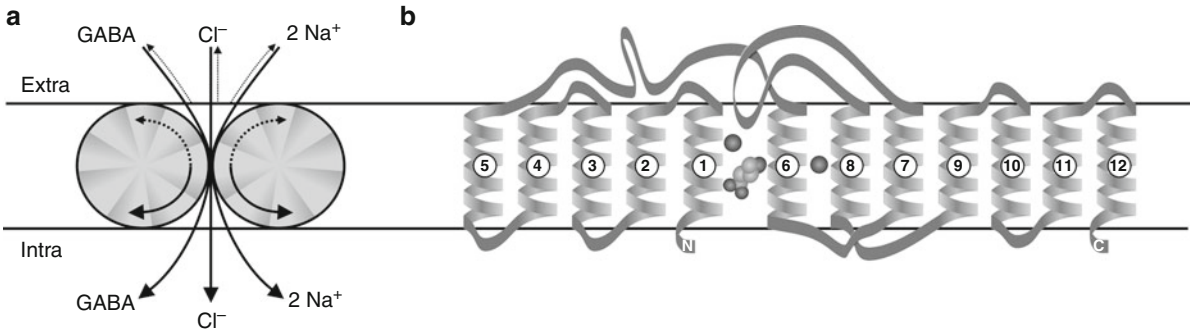
Historical Background

The amino acid γ-amino butyric acid (GABA) is the main inhibitory neurotransmitter in the adult brain. The actions of GABA are mediated via two distinct classes of receptors: ionotropic ($GABA_A$ and $GABA_c$) and metabotropic ($GABA_B$) receptors (Farrant and Kaila 2007). For adequate synaptic transmission, the released GABA has to be rapidly sequestered from the synaptic cleft by high affinity GABA transporters. Experiments performed in neuronal and astroglial cell cultures in the 1970s revealed that a number of GABA analogues selectivity inhibited GABA uptake in one or the other culture type. Based on these results, it was concluded that neurons and astrocytes express distinct GABA transporters (Krogsgaard-Larsen et al. 1987). Molecular biological techniques revealed that most probably four distinct GABA transporters exist (Borden 1996).

Properties and Subtypes of GABA Transporters

GABA transporters (GATs) belong to the superfamily of solute carriers and the class of Na^+-Cl^--dependent neurotransmitter transporters (Nelson 1998). All GATs described so far mediate the symport of 1 molecule GABA with 1 Cl^- ion and 2 Na^+ ions (Fig. 1a).



GAT (GABA Transporters), Fig. 1 Transport properties and topology of GABA-transporters. (**a**) Schematic diagram illustrating that GATs mediate the symport of 1 molecule GABA with 1 Cl^- and 2 Na^+ ions. Although the transport direction is inward directed under most physiological conditions (*bold arrows*), the direction of GABA transport can be reversed under various physiological and pathophysiological conditions (*dashed arrows*). (**b**) Proposed membrane topology of Na^+-Cl^--dependent transporters according to Yamashita et al. (2005). GABA transporters contain presumably 12 transmembrane helices. GABA and one Na^+ ion (*gray circle*) were probably bound to transmembrane helices 1 and 6, while the second Na^+ ion interacts with transmembrane helices 6 and 8. All binding sites were located in a central pocket formed by the transmembrane helices and 1, 6, 8, and 10 and part of the extracellular loop 4 (between TMH 7 and 8)

GATs share great homology to other classes of the Na^+-Cl^--dependent neurotransmitter transporters, like glycine-, dopamine-, serotonin-, or choline-transporters, but are structurally and functionally distinct from excitatory amino acid transporters (EAAT1-5) and vesicular neurotransmitter transporters (e.g., VGAT, VGluT1-3, VAChT) (Masson et al. 1999). Like other Na^+-Cl^--dependent transporters, GATs contain presumably 12 transmembrane helices (Fig. 1b). The GABA and the Na^+ binding sites are located on the transmembrane helices 1, 6, and 8, which together with the transmembrane helix 10 and part of the extracellular loop 4 form a central cavity with alternating contact to the extra- and intracellular compartment (Yamashita et al. 2005).

Four different GATs have been identified in rodents and humans so far (Borden 1996). These four GATs have different GABA affinities, distinct pharmacological profiles and show a specific cellular distribution. There are two nomenclatures for GABA transporters. In the rat/human nomenclature GABA transporters are called GAT-1, betaine/GABA transporter-1 (BGT-1), GAT-2, and GAT-3 (Borden et al. 1992). In the mouse nomenclature GATs are called GAT1, GAT2, GAT3, and GAT4 (without hyphen, Liu et al. 1993). They were encoded by the genes SLC6A1 (for GAT-1) and SLC6A11-13 (for GAT-3, BGT-1, and GAT-2, respectively). In this review the rat/human nomenclature will be used.

GAT-1 was the first GABA transporter to be cloned. Data obtained in different expression system (Xenopus oocytes, COS-7 cells, etc.) revealed that GAT-1 has an IC50 of 5–30 μM and is Na^+ and Cl^- dependent. The expression of GAT-1 mRNA is restricted to the central nervous system, where it was found to be present in all brain regions examined. Immunohistochemical studies showed that all GABAergic neurons (as identified by the expression of GAD67) express GAT-1. In addition, some non-GABAergic neurons and glial cells (for instance, Bergmann glial cells in the cerebellum) also express GAT-1. GAT-1 immunoreactivity is almost exclusively associated with punctate structures resembling axon terminals and fibers. These observations indicate that GAT-1 is a preferentially neuronal GABA transporter and is predominantly synaptically located, suggesting that the main physiological function of GAT-1 is the fast removal of GABA from the synaptic cleft, i.e., termination of GABAergic transmission, and the recycling of GABA to the presynaptic terminal.

GAT-2 shows about 52% amino acid identity with GAT-1. GAT-2 has an IC50 of 17 μM and is also Na^+ and Cl^- dependent. GAT-2 mRNA is present both in the central nervous system and in a number of nonneural tissues such as kidney, liver, or hearth. Although GAT-2 immunoreactivity was mainly detected in the leptomeninges (pia and arachnoid) surrounding the brain, GAT-2 staining was also

observed in some neuronal and glial cells. Because GAT-2 positive punctae are mainly localized to glial limitans and outline blood vessels, GAT-2 may regulate GABA levels in the cerebrospinal fluid, thereby regulating GABAergic transmission indirectly.

GAT-3 displays 52% amino acid identity with GAT-1 and 67% amino acid identity with GAT-2. GAT-3 has an IC50 of 33 μM and is also Na^+ and Cl^- dependent. The expression of GAT-3 mRNA is restricted to the central nervous system. Immunohistochemical studies show that GAT-3 is predominantly expressed in astrocytes. Moreover, GAT-3 is preferentially located in distal astrocytic processes including perivascular end-feet. GAT-3 positive punctae are adjacent to axon terminals making both symmetrical and asymmetrical synapses. These observations suggest that the main physiological function of GAT-3 is a removal of GABA that escaped from the synaptic cleft, i.e., prevention of synaptic crosstalk.

BGT-1 was firstly identified in kidney, where it mediates the accumulation of the osmolyte betaine in renal medullary epithelial cells to make them resistant to hypertonicity. Since this transporter is able to utilize also GABA as substrate, it was termed BGT-1 (for Betaine/GABA transporter). Surprisingly, BGT-1 has a higher affinity for GABA ($IC_{50} = 42$ μM) than for betaine ($IC_{50} = 400$ μM). This is, however, in line with BGT-1 function in the kidney because the concentration of betaine in plasma is about 180 μM, while GABA concentration in plasma is <1 μM. BGT-1 shows 68% and 65% degrees of identity with GAT-2 and GAT-3. BGT-1 was also expressed in the CNS, most probably on astrocytes, where it contributes to the regulation of extrasynaptic GABA levels (Clausen et al. 2006).

Despite these evident differences in the cellular and subcellular localization of GATs in the adult CNS, the situation seems to be less clear in the immature brain, where a substantial abundance of GAT-1 in astrocytes and of GAT-3 in neurons was reported (Conti et al. 2004). In rodent neocortex, GAT-1 expression is rather low at birth and reaches adult levels approximately by the end of third postnatal week (Conti et al. 2004). In contrast, GAT-2 and GAT-3 expression is relatively high at birth and reaches the adult levels the first and second first postnatal weeks, respectively (Conti et al. 2004).

Stoichiometry and Kinetics of GABA Transporters

GATs mediate the symport of one uncharged GABA molecule, two positively charged Na^+ ions, and one negatively charged Cl^- ion, thus generating an electrogenic transport process (Attwell et al. 1993). Therefore, the thermodynamic equilibrium provides a reversal potential for GABA transport (Richerson and Wu 2003):

$$E_m = \frac{RT}{(2z_{Na} + z_{Cl})F} \times \ln\left(\frac{[GABA]_i}{[GABA]_a} \times \left(\frac{[Na^+]_o}{[Na^+]_i}\right)^2 \times \frac{[Cl^-]_o}{[Cl^-]_i}\right)$$

For neuronal cells, the concentrations of molecules involved in GABA transport can be found in the literature: $[Na^+]_i = 15$ mM, $[Cl^-]_i = 7$ mM, $[GABA]_i = 2$ mM, $[Na^+]_o = 150$ mM, $[Cl^-]_i = 135$ mM, $[GABA]_i = 0.1$ μM. Surprisingly, these values predict the reversal potential for GABA transport of about −60 mV, i.e., unexpectedly close to the resting potential (Attwell et al. 1993; Richerson and Wu 2003). Only if membrane potential is more negative than reversal potential, GABA transporters will operate in the inward direction, i.e., will take up GABA. But when membrane potential is more positive than the reversal potential, which can, e.g., occur during excitatory synaptic transmission, GABA transporters will operate in the reverse mode and will release GABA. Moreover, elevations of either $[Na^+]_i$ (for instance, as consequence of AMPA/NMDA receptor activation) or $[Cl^-]_i$ (for instance, as consequence of $GABA_A$ receptor activation) will increase the reversal potential of GABA transport, therefore favoring its switch to reversed mode. This suggests that synaptic activity can modulate GAT-mediated uptake/release and thus extracellular GABA levels. However, such a synaptic modulation is only possible if GATs are fast enough to follow these dynamic processes. Although GATs expressed in Xenopus oocytes demonstrated rather slow kinetics (one cycle per about 100 ms), recent data indicate that the turnover rate is faster than previously believed, taking about 10 ms per translocation at 37°C. Moreover, recent study in both artificial expression system and

in hippocampal neurons showed that GAT-1 is fast enough to be reversed during an action potential (Wu et al. 2007).

Modulation of GABA Transport

In addition to the modulation via membrane voltage and intracellular ions, functional modulation of GATs occurs through a variety of second messengers such as kinases, arachidonic acid, and pH (Beckman and Quick 1998). These factors may act directly on the transporter protein or by modulating the interaction with other proteins. Interestingly, not only GAT kinetics is regulated but also the number of GATs expressed on the surface. GATs could be internalized and reinserted into the plasma membrane within minutes and, moreover, GAT-1 trafficking resembles the cycling of neurotransmitter-filled synaptic vesicles (Deken et al. 2003). Such redistribution of GAT-1 protein between the plasma membrane and the cytoplasm is regulated by different G-protein coupled receptors via protein kinase C (PKC). PKC activation leads to GAT-1 internalization, while PKC inhibition increases the surface expression of GAT-1 (Beckman et al. 1999). The surface expression of GAT-1 is also dependent on the availability of its substrate. GAT-1 stimulation by GABA or other transported substrates increases GAT-1 surface expression, whereas GAT-1 inhibitors that are not substrates induce GAT-1 internalization. Thus, the number of GAT-1 on the cell surface and/or synapse is fine-tuned by GABA itself (Bernstein and Quick 1999).

GABA Transporters in Diseases

A variety of reports suggest an essential function of GATs in the etiology of neuronal diseases. There is a strong link between GAT function and epilepsy, although the functional implications of GAT in epilepsy are far from being completely understood. During epileptic activity, the enhanced neuronal activity promotes the reversal of GATs and thus a nonvesicular GABA release that can dampen neuronal excitation. Enhanced GAT-1 expression increases the susceptibility for epileptic seizures, most probably by reducing extracellular GABA levels and shortening GABA availability in the synaptic cleft. Accordingly, inhibition of GATs attenuates epileptic seizures; therefore, GAT inhibitors are used for antiepileptic medication. In addition, alterations in the expression of GATs, in particular of GAT-1, have been reported in epileptic animals, where an up- and downregulation of different GATs has been described. The alteration in the GAT expression levels may either serve to enhance nonvesicular GABA release under epileptic conditions, thus contributing to homeostatic inhibition, but can also aggravate seizures. In any way, these complex alterations in epileptic tissue complicate a pharmacological interaction with GATs (Allen et al. 2004; Conti et al. 2004). A downregulation of GAT-1 has also been shown in schizophrenic patients (Schleimer et al. 2004).

A beneficial effect of GATs has been suggested for brain ischemia. Under ischemic condition, the GATs reversed due to a massive increase in the intracellular Na^+ concentration under this condition, with lead to the nonsynaptic release of GABA. Although this increased GABA concentration may promote a neuroprotective effect, it can also contribute to cell swelling, thus aggravating excitotoxic insults. Recent reports indicate that this GABA release occurred mainly via neuronal GAT-1, while glial GAT-3 does not contribute. In this respect, it is also interesting that ischemic conditions stimulate the synthesis of GABA, thus additionally increasing the driving force for reversed GABA transport (Allen et al. 2004).

Summary

GABA transporters belong to the family of Na^+-Cl^--dependent neurotransmitter transporters and mediate the electrogenic symport of 1 molecule GABA with 1 Cl^- and 2 Na^+ ions. Due to its transport stochiometry, the regular inward transport direction can be easily reversed under various physiological and pathophysiological conditions, thereby mediating nonvesicular GABA release. Four different GATs have been described so far: GAT-1 is mainly expressed in GABAergic neurons of all brain regions and mediates the fast removal of GABA from the synaptic cleft. GAT-2 is expressed in neuronal and nonneuronal tissues and may regulate GABA levels in the cerebrospinal fluid. GAT-3 expression was restricted to the central nervous system where it was described predominantly in

astrocytes. GAT-3 is most probably involved in the regulation of GABA at extrasynaptic sites. The betaine/GABA transporter BGT-1 was expressed in nonneuronal and neuronal tissues. In the kidney, it mediates the accumulation of the osmolyte betaine.

Synonyms

GATA-binding protein 3

Historical Background

Cellular fate during development, differentiation, and function is tightly regulated and orchestrated in

a hierarchical fashion by transcriptional activators and repressors. GATA-3 is one such master regulator of cellular fate, which was identified in 1990 along with two other GATA family members and was found to be abundantly expressed in T lymphocytes and the brain (Yamamoto et al. 1990). GATA-3 was first described as a transcription factor that interacts with the TCR-α gene enhancer (Ho et al. 1991). It belongs to the GATA family of transcription factors that are conserved proteins containing one or two C2-C2-type zinc fingers and a highly conserved C4 zinc finger that recognizes a consensus DNA sequence A/TGATAA/G from which the name of the family originated (Hosoya et al. 2010). The mammalian GATA family of transcription factors consists of six members: GATA-binding protein 1 (GATA-1)–GATA-6. These proteins are highly homologous, conserved among species, have distinctive tissue-specific expression patterns, and play essential roles during vertebrate development. Based on their profile of tissue-specific expression, the GATA proteins can be classified as hematopoietic (GATA-1–GATA-3) or non-hematopoietic (GATA-4–GATA-6) (Hosoya et al. 2010). In contrast to GATA-1 and GATA-2 that are primarily expressed in hematopoietic cells, or GATA-4, -5, and -6 whose expression is restricted to mesoderm- and endoderm-derived tissues, such as the heart, liver, and intestines, GATA-3 is present in both hematopoietic (e.g., T cells) and non-hematopoietic tissues.

Similar to other GATA proteins, GATA-3 contains a distinct amino-terminal region that contains two trans-activation domains followed by two highly conserved zinc-finger domains in which the C-terminal finger and the immediately adjacent conserved basic region together constitute the DNA-binding domain (Hosoya et al. 2010). The laboratory of Engel was the first to clone the GATA-3 gene and further dissected important biochemical properties of the GATA-3 protein (George et al. 1994). The entire coding region of the murine GATA-3 locus is approximately 23-kilo base pairs. The gene is composed of six exons. Exon 1 is untranslated and exon 2 contains the initiation codon for murine GATA-3. The amino and carboxy zinc fingers are encoded by exons 4 and 5, respectively. Exon 6 comprises the 3′ untranslated region and the polyadenylation signal (George et al. 1994). For GATA-3 to regulate gene expression, it must translocate from the cytoplasm into the nucleus to access its target genes. GATA-3 contains a classical nuclear import signal, and is transported into the nucleus by importin-α. The affinity of GATA-3 to importin-α is regulated by phosphorylation, which is mediated by p38 mitogen-activated protein kinase (MAPK) (Maneechotesuwan et al. 2007). The GATA-3 protein is unstable with a short half-life (1 h) in developing Th2 cells. GATA-3 is ubiquitinated in vitro and in vivo and degraded by the 26s proteasome pathway. The deletion of the ubiquitination sites lends stability to the protein.

GATA-3 is the main GATA family member that is expressed in immune cells and can be easily detected in developing and mature T cells, natural killer (NK) cells, and CD1-restricted natural killer T (NKT) cells. Beyond the immune system, GATA-3 is expressed in many embryonic and adult tissues, including the adrenal glands, kidneys, central nervous system, inner ear, hair follicles, skin and breast tissue (mammary glands), and important functions for GATA-3 in several of these tissues have been shown in knockout and conditional knockout mouse models (Hosoya et al. 2010). In immune cells, GATA-3 is best known to function as a master regulator of T-helper-2 (Th2) cell differentiation (Zhang et al. 1997, 1999; Zheng and Flavell 1997). However, in recent years, GATA-3 has been found to have additional crucial functions in early T cell commitment, β-selection, and CD4+ T cell development (Hosoya et al. 2010).

GATA-3 is a critical regulator in both mouse and human development. The expression pattern of *GATA-3* during embryonic development, at least at the tissue level, is highly conserved among different vertebrates (George et al. 1994). In human embryos, *GATA-3* expression can be detected from the beginning of the fourth week of gestation (Debacker et al. 1999). From then on, *GATA-3* transcripts are observed in various developing embryonic and fetal tissues, including the developing kidney, the parathyroids, and the inner ear. GATA-3 null embryos die between E11 and E12 due to internal bleeding, and display growth retardation, deformities in the brain and spinal cord, and gross aberrations in fetal liver hematopoiesis, suggesting that this gene is important in the development of various systems (Pandolfi et al. 1995). Haploinsufficiency of GATA-3 results in Barakat syndrome in humans, characterized by familial hypoparathyroidism, sensorineural deafness, and renal dysplasia (also known as HDR syndrome), and can be caused by mutations in GATA-3 that render it physically or functionally

inactive. Interestingly, mutations that abrogate the DNA-binding ability of GATA-3 are also found in human breast cancer specimens.

GATA-3: Essential for T Cell Development and Th2 Differentiation

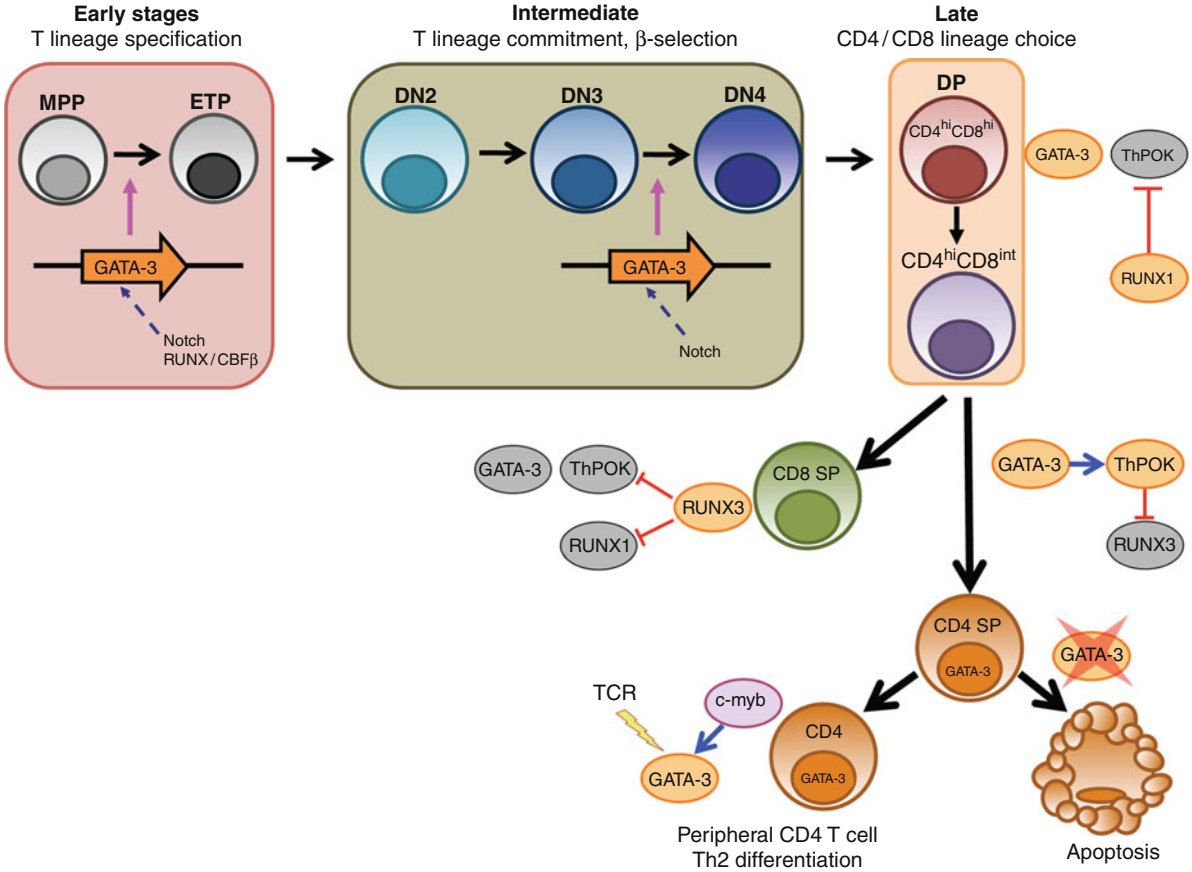
GATA-3 is one of the first genes that are transcriptionally activated in hematopoiesis as early as hematopoietic stem cells (HSCs) stage (Debacker et al. 1999). GATA-3 mRNA is also expressed in the multipotent progenitors (MPPs) and at the pre-pro-B cell stage in the bone marrow. Its involvement during early stages of thymopoiesis was first proposed in 1996 and poorer Thy1+ cell development was shown in fetal thymus organ culture following the introduction of antisense oligonucleotide to GATA-3 (Hattori et al. 1996). More definite information about the expression and role of GATA-3 in early stages of lymphopoiesis was provided by studies using various GATA-3 mutant mice. Collectively, these studies suggest that the major role of GATA-3 in thymopoiesis is to regulate the cellular differentiation of thymic stromal progenitors (TSPs) to ETPs, and in turn, downstream T cell development stages as well. Most likely the underlying mechanism does not involve cellular survival or proliferation although more conclusive investigations are required to support or dismiss the proposed hypothesis (Hosoya et al. 2010). Overexpression strategies, used to explore the role of GATA-3 in thymopoiesis also demonstrated that the expression level of GATA-3 decides the fate of lineage differentiation from early progenitors (Hosoya et al. 2010). It appears that a regulated low expression level of GATA-3 in pre-thymic progenitors is required to initiate thymopoiesis and induce T cell development.

Similar to early stages of thymopoiesis, GATA-3 has been shown to contribute to intermediate stages, especially the DN2-DN3-DN4 transition, of T cell development (Hosoya et al. 2010). Conditional ablation of GATA-3 in DN2-DN3 thymocytes was shown to result in abnormal accumulation of DN3 cells and reduced frequency of DN4 and later stages of T cells. On further analysis of the DN3 and DN4 thymocytes, it was observed that even though DN3 thymocytes from the GATA-$3^{flox/flox}$ Lck cre mice expressed rearranged Tcrβ gene, the intracellular expression of TCR β protein in DN4 cells was reduced as compared to that in the wild type. Also the frequency of Annexin V + apoptotic cells was higher in mutant mice as compared to control mice, suggesting that deficiency of GATA-3 affected DN3-DN4 transition and results in poorer expression of pre-TCR complex on DN4 thymocytes causing their elimination by apoptosis. GATA-3 has been also shown to be expressed in γδ T cells but its function and necessity in thymic γδ T cells is unknown (Hosoya et al. 2010). After β-selection, GATA-3 expression has been shown to be repressed and then later re-induced between early DP and late DP stages that continues to be expressed through CD4 SP stage, while decreasing in CD8 SP T cells (Hosoya et al. 2010). Figure 1 illustrates the central role of GATA-3 in T cell development.

Role of GATA-3 in the Development and Function of Other Hematopoietic Cells

In addition to T cells, GATA-3 is also expressed in other hematopoietic cell lineages such as natural killer (NK) cells and CD1-restricted natural killer T (NKT) cells (Hosoya et al. 2010). Recent studies have proposed a potential role for GATA-3 in development, maturation, and function of invariant NKT (iNKT) cells. These cells are a unique subset of T cells expressing Vα14Jα18 (mouse) or Vα24Jα18 (human) T cell receptors, which often dimerize with Vβ8, Vβ7, or Vβ2. Similar to the conventional α/β T cells, iNKT cells also originate from thymic DP cells but they are positively selected by CD1d molecules. Subsequent to successful positive selection, iNKT cells differentiate into either CD4+ or CD4-CD8- mature iNKT cells that constitute approximately 5% of the peripheral T cell pool (Kinjo and Kronenberg 2005). Following antigen encounter, this unique T cell subset has been shown to rapidly produce large amounts of various Th1 and Th2 cytokines including IFN-γ, IL-4, and IL-13, a phenomenon called cytokine storm. Over the years, multiple studies have demonstrated that iNKT cells play a crucial immunomodulatory role not only against infections, but are also involved in autoimmunity, allergy, and cancer.

As in the case of α/β T cells, the role of GATA-3 in iNKT cell development, differentiation, and function was also studied by either loss-of-function approach or by enforced expression of GATA-3 in the system. Mice in which *GATA-3* was deleted using *Cd4*-Cre were found to have near normal numbers of thymic



GATA-3 (GATA Binding Protein 3), Fig. 1 Role of GATA-3 in various stages of T cell development. GATA-3 is expressed at different stages (early, intermediate, and late) of T cell lymphopoiesis and regulates various cell fate decisions involving T lineage commitment and development. In the thymus, GATA-3 (induced by transcription factors like Notch and RUNX/CBFβ) plays a crucial role in cellular differentiation of MPPs to ETPs, DN3-DN4 transition, and β-selection. It also regulates CD4 versus CD8 lineage choice following positive selection. The commitment of $CD4^{hi}CD8^{int}$ cells to the CD4 SP lineage requires the expression of T-helper-inducing POZ/Kruppel-like factor (ThPOK), whereas commitment to the CD8 SP lineage requires the expression of runt-related transcription factor (RUNX). In $CD4^{hi}CD8^{int}$ cells, Runx1 contributes to Thpok repression. In CD4-differentiating cells, Runx1-mediated Thpok repression is relieved and further promoted by GATA-3. Thpok prevents Runx3 upregulation and CD8 differentiation. In CD8-differentiating cells, Thpok repression is maintained, presumably through Runx3. GATA-3 also regulates additional developmental events required for CD4 cell differentiation and further maturation of committed CD4 SP thymocytes

iNKT cells, but interestingly the majority of these were CD4-CD8- with a selective loss of CD4 iNKT cells which was similar to the loss of conventional CD4+ T cell in the absence of GATA-3 (Hosoya et al. 2010). Unlike in the thymus, there was a sixfold reduction of iNKT cells in peripheral lymphoid organs such as the spleen and almost complete lack in the liver suggestive of apoptosis of iNKT cells that did not develop or mature properly in the absence of GATA-3 indicated by failure to upregulate CD69 expression subsequent to their thymic egress. Lastly, GATA-3-deficient iNKT cells failed to respond to the NKT cell agonist α-galactosylceramide in vivo and mount a cytokine storm. This unresponsiveness is possibly due to defects in TCR signal transduction and was probably upstream of protein kinase C and calcium influx. This is because GATA-3-deficient iNKT cells were still capable of producing IFN-γ but not Th2 cytokines like IL-4, IL-5, or IL-13 that suggests that GATA-3 has a similar role in iNKT cells as in conventional T cells.

GATA-3 and Th2 Differentiation

The role of GATA-3 as a key transcription factor that is essential for Th2 differentiation is without doubt the most studied function of this protein. The role of this transcription factor as a master regulator of Th2 differentiation was independently codiscovered in the laboratories of Ray and Flavell (Zhang et al. 1997; Zheng and Flavell 1997). However, the initial clue for the involvement of GATA-3 in Th2 differentiation was provided by a prior study by Ray and colleagues that identified GATA-3 binding to the IL-5 promoter that was crucial for cyclic AMP-induced expression of the cytokine gene in T cells (Siegel et al. 1995). Subsequently, using Th1 or Th2 cells generated from naive $CD4^+$ T cells and representational differential analysis (RDA), the role of GATA-3 in Th2 differentiation was established (Zhang et al. 1997; Zheng and Flavell 1997). Although GATA-3 was identified as a key factor for Th2 development, a careful analysis of regulation of the individual Th2 cytokine genes showed that unlike the IL-5 promoter, the IL-4 promoter, which lacked high affinity GATA-binding sites, was not directly regulated by GATA-3 (Zhang et al. 1998). Furthermore, in Th2 cells, antisense GATA-3 RNA inhibited IL-5 but not IL-4 promoter activation (Zhang et al. 1998). If GATA-3 was only responsible for IL-5 activation, how could it be a master Th2 regulator? Rao and colleagues showed that a distal enhancer in the IL-4 gene binds GATA-3 to induce its expression (Agarwal et al. 2000). In light of this study, it was not surprising when conditional deletion of GATA-3 from CD4 T cells resulted in global suppression of all Th2 cytokines that included IL-4, IL-5, and IL-13 (Zhu et al. 2004). Furthermore, deletion of GATA-3 resulted in Th1 differentiation without the requirement for IL-12 and IFN-γ and inhibition of GATA-3 in differentiated Th2 cells caused a dramatic decrease in IL-5 and IL-13 expression although IL-4 expression was better preserved possibly due to the ability of other factors such as c-Maf that can directly regulate IL-4 but not IL-5 or IL-13 promoter activity (Zhu et al. 2004). These data taken together reiterated the dominant role of GATA-3 in Th2 differentiation. The expression of GATA-3 is significantly upregulated in human cells that express Th2 cytokine genes (Nakamura et al. 1999). Inhibiting its expression using siRNA strategy compromised Th2 differentiation and similar data was obtained in individuals with the loss of one functional GATA-3 allele.

One of the important attributes of GATA-3 that makes it a dominant Th2 transcription factor is its ability to autoactivate itself. This property of GATA-3 was a serendipitous finding in the laboratory of Murphy when they were investigating the mechanism underlying the ability of GATA-3 to promote Th2 differentiation in a STAT6-independent fashion (Ouyang et al. 2000). These investigators found that activation of naïve CD4 + T cells results in upregulation of endogenous GATA-3 expression, which was also evident in IL-4/STAT6-deficient T cells indicating that this property was not dependent on the initial secretion of IL-4 (Ouyang et al. 2000). Thus the maintenance and amplification of the Th2 loop is efficiently promoted by autoactivation of endogenous GATA-3 expression. p38 MAPK was shown to be important for cAMP-mediated phosphorylation of GATA-3 that promotes Th2 cytokine gene expression (Chen et al. 2000). Interestingly, corticosteroids, which are commonly used to treat allergic diseases, have a potent inhibitory effect on GATA-3 in T cells by competing for importin-α, and by inducing the expression of a p38 MAPK inhibitor (Maneechotesuwan et al. 2009).

GATA-3 in the Context of Other T Cell Transcription Factors

The induction and sustenance of a Th2 response is an intricately orchestrated process involving the concerted inhibition of select transcription factors while promoting others.

NF-κB is required for GATA-3 expression in differentiating Th2 cells. ▶ Nuclear factor kappa B (NF-κB) is a transcription factor involved in TCR-induced activation signals in peripheral T cells. Mice lacking the p50 subunit of NF-κB showed impaired GATA-3 induction that blunted Th2 responses (Das et al. 2001). This defect was specific to Th2 cells since p50-deficient mice showed normal T-bet expression and secretion of the Th1 cytokine, IFN-γ. Importantly, this defect was restricted to the initial differentiation of Th2 cells, and inhibition of p50 activity in differentiated Th2 cells did not affect GATA-3 expression or secretion of Th2 cytokines (Das et al. 2001).

STAT5 and GATA-3 synergize to promote Th2 phenotype. Naïve T cells require IL-2 for their differentiation and maintenance. IL-2 utilizes ▶ STAT5a and

▶ STAT5b for downstream signaling. Naïve T cells from STAT5a knockout mice are handicapped in their ability to differentiate into Th2 cells. In fact the constitutive expression of STAT5a in naïve T cells can induce the differentiation of Th2 cells even in the absence of IL-2 (Zhu et al. 2003). Furthermore, low TCR stimulation causes early IL-4 production, which is dependent on IL-2-mediated STAT5 signaling and also GATA-3. However, the early expression of GATA-3 can be achieved in an IL-4-independent fashion and is linked to autoactivation of GATA-3 expression (Ouyang et al. 2000). Also, neutralization of IL-2 cripples this early burst of IL-4 cytokine without compromising GATA-3 expression. Importantly, while the induction of a Th2 response has been shown to be dependent on both IL-2/STAT5 and GATA-3, these pathways operate independent of each other. GATA-3 is not considered to be downstream of IL-2 since the addition of IL-2 to in vitro culture can be delayed by 2 days without affecting the frequency of IL-4 producers. From these observations it became obvious that even if GATA-3 and STAT5 operate via independent pathways, these molecules synergize to promote Th2 responses. In fact, this hypothesis was proven correct in experiments in which forced expression of GATA-3 and STAT5 in naïve T cells or in Th1 cells induced a higher frequency of IL-4 producers when compared to cells expressing either factor alone (Zhu et al. 2006). While emphasizing the role of IL-2 in promoting Th2 responses it is also important to discuss the cooperation between GATA-3 and growth factor independent-1 (Gfi-1), which was initially cloned from an IL-2-independent cell line. The expression of this transcription factor is induced by IL-4 signaling in activated T cells and is dependent on STAT6. Deletion of Gfi-1 was shown to cause reduced expression of GATA-3 and IL-4. The few cells expressing GATA-3 in Gfi-1-deficient T cells were found to be unable to upregulate GATA-3 expression even with IL-2 supplementation. Conversely, forced expression of Gfi-1 in cells expressing high levels of GATA-3 resulted in a proliferative advantage of these cells. In summary, Gfi-1 is able to amplify the proliferation of high GATA-3-expressing CD4 T cells in response to IL-2 (Zhu et al. 2006). Taken together, these studies showed that Gfi-1, STAT5, and GATA-3 form the triad of Th2-promoting factors.

Notch and GATA-3. Notch signaling has been implicated in Th2 differentiation by directly regulating GATA-3 expression (Amsen et al. 2007) although more studies are needed to determine the importance of this regulation in vivo.

GATA-3 dominates STAT6 in Th2 induction. STAT6 is closely associated with Th2 responses and IL-13 and IL-4 trigger the phosphorylation of STAT6. Also, the kinetics of GATA-3 expression parallels STAT6 activation. The polarization of STAT6-deficient T cells under in vitro conditions does lead to the production of Th2 cytokines although less than that in WT cells, but more than in WT cells skewed under Th1 condition (Ouyang et al. 2000). Interestingly, analysis of DNaseI hypersensitivity sites in STAT6-deficient T cells reconstituted with GATA-3 reveals a pattern similar to that seen in WT cells, indicating that the chromatin remodeling fingerprint of a Th2 response is independent of STAT6 (Ouyang et al. 2000). Also, data from CTLA-4/STAT6 double knockout mice clearly show that in the absence of inhibitory signals, GATA-3 expression is sufficient to drive the differentiation of Th2 cells, illustrating the transcriptional dominance of GATA-3 in this process (Bour-Jordan et al. 2003). Although studies document evidence of STAT6-independent mechanisms of GATA-3 induction, the consensus is that STAT6 ensures optimal GATA-3 expression.

GATA-3 suppresses Th1 induction via STAT4. GATA-3 actively represses IL-12 and IFN-γ signaling both of which are critical for Th1 differentiation, implying a possible negative function of GATA-3 in Th1 development. Retroviral expression of GATA-3 during Th1 development results in the induction of Th2 phenotype with high levels of IL-4, IL-5, and IL-13 (Ferber et al. 1999). It was further revealed that the promotion of the Th2 phenotype could not simply be attributed to the high level of Th2 cytokines since the same results could be recapitulated in T cells deficient in both IL-4 and STAT6 and programmed toward a Th1 phenotype. GATA-3-mediated inhibition of Th1 differentiation is remarkable only when GATA-3 is introduced as early as day 1 in the Th1 differentiation program. If this "early development window" is missed then the effect of IL-12-mediated STAT4 signaling becomes dominant and expression of GATA-3 in committed Th1 cells results only in a modest decrease in IFN-γ and does not promote IL-4 production (Usui et al. 2003). Surprisingly, unlike in CD4 T cells, in NK cells, GATA-3 appears to be required for the production of IFN-γ (Samson et al. 2003). While there is no direct evidence that GATA-3

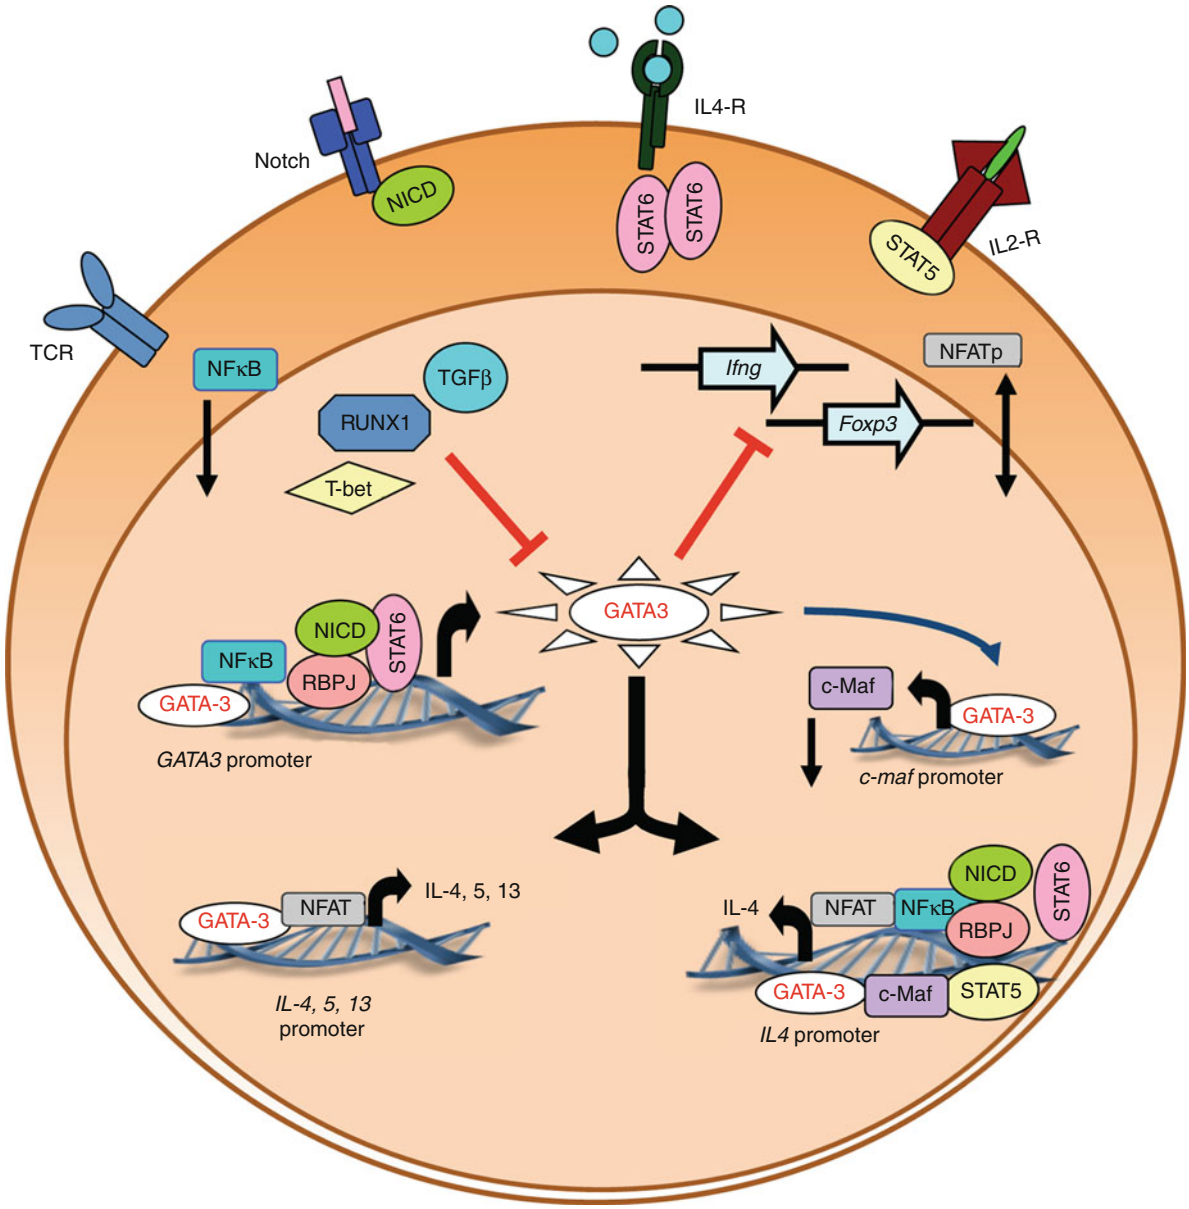
represses the promoter activity of IFN-γ, GATA-3 represses IL-12R β2 mRNA expression, thereby preventing IL-12 signaling during the early Th1 developmental window (Ouyang et al. 1998). Also GATA-3 expression significantly blunts ▶ STAT4 phosphorylation and promotes Th2 response. The mechanism behind GATA-3-mediated STAT4 suppression is unknown, but clearly the suppression of STAT4 phosphorylation is not mediated through effects on T-bet (Usui et al. 2003).

GATA-3 and NFAT1 bind to an enhancer region in the IL-4 gene. The NFAT family of transcription factors is activated by receptors involved in calcium mobilization, and their activation is blocked by cyclosporin A (CsA) and FK506. Rao and colleagues identified an enhancer region in the 3′ end of the IL-4 gene, designated V_A, and showed that both NFAT and GATA-3 bind to this enhancer region suggesting an active cooperation between these transcription factors in enhancing the expression of IL-4 (Agarwal et al. 2000).

GATA-3 derepresses RUNX3 silencing of IL-4. RUNX (runt-related transcription factor) proteins dictate important T cell lineage choices and consist of three family members, RUNX1, 2, and 3. These proteins have unique DNA-binding subunits that complex with the non-DNA-binding subunit core-binding factor β. It has been recently shown that RUNX3 can bind to a silencer region in the IL-4 gene and repress expression of the IL-4 gene (Naoe et al. 2007). Interestingly, the expression of RUNX3 is similar in Th1 and Th2 cells, which suggests that another molecule is responsible for derepressing the suppressive effect mediated by RUNX3. In fact, forced overexpression of GATA-3 in Th1 cells results in the dissociation of RUNX3 from the IL-4 silencer region (Naoe et al. 2007). It is interesting to note how GATA-3 promotes IL-4 secretion without directly influencing its promoter activity.

T-bet represses GATA-3 activity. T-bet, also called TBX21, is a member of the T-box gene family and its role in Th1 commitment was discovered by the Glimcher laboratory shortly after the role of GATA-3 in Th2 development was identified (Szabo et al. 2000). With the discovery of T-bet and GATA-3 it seemed highly probable that cross-regulation between Th1 and Th2 cells might underlie some form of antagonism between these two master regulators. The first clue to T-bet-mediated suppression of GATA-3 came from T-bet knockout mice, which expressed high levels of endogenous GATA-3 (Finotto et al. 2002). Also, retroviral expression of T-bet in developed Th2 cells not only promoted IFN-γ production, but also suppressed IL-4 and IL-5 production (Usui et al. 2006). This effect was found to be partly independent of STAT4. Furthermore, T-bet-deficient CD4 T cells produced IFN-γ if endogenous GATA-3 was suppressed that derepressed GATA-3-mediated inhibition of STAT4 lifted (Finotto et al. 2002; Usui et al. 2006). The possibility of T-bet directly inhibiting GATA-3 was formally explored by Glimcher and colleagues (Hwang et al. 2005). It was shown that the phosphorylation of T-bet occurs as early as day 2 during Th1 skewing and is mediated by IL-2 inducible T cell kinase ITK, which results in the tyrosine phosphorylation of T-bet at position 525 (Hwang et al. 2005). Mutation of this tyrosine residue prevented the physical association between GATA-3 and T-bet. In fact, T-bet was shown to physically interact with the N-terminal region of GATA-3 once it was phosphorylated and this sequestration of GATA-3 by T-bet prevented its binding to the IL-5 promoter. Thus an important function of T-bet is repression of GATA-3 binding to its target (Hwang et al. 2005).

GATA-3 and Tregs. Regulatory T cells (Tregs) promote tolerance and these cells express the transcription factor FOXP3, which is required for their suppressive activity. Interestingly, GATA-3 seems to be an important molecular switch which inhibits the expression of FOXP3 by directly binding to its promoter (Mantel et al. 2007). This repression is delicately balanced by the availability of IL-4. Low concentration of IL-4, which is not sufficient to induce robust expression of GATA-3, is important for triggering the expression of FOXP3 resulting in the conversion of naïve CD4 T cells into regulatory T cells. On the other hand, high concentration of IL-4 rapidly promotes GATA-3 expression, which in turn represses induction of FOXP3 (Mantel et al. 2007). Interestingly, there seems to be an innate mechanism, which predisposes cells expressing low levels of FOXP3 to convert into GATA-3-expressing Th2 cells (Wang et al. 2010). These data collectively show that the balance between tolerance and allergic inflammation mediated by Th2 cells is extremely fine-tuned in which GATA-3 plays an important regulatory role. The roles of multiple transcription factors with respect to GATA-3 function and their influence on Th2 differentiation are shown in Fig. 2.



GATA-3 (GATA Binding Protein 3), Fig. 2 GATA-3 in Th2 cell differentiation. GATA-3 is essential for Th2 differentiation. Shown are various other transcription factors that are involved in transcriptional regulation of Th2 cytokine genes along with GATA-3. GATA-3 also autoactivates its own expression and blocks Th1 development

GATA-3 and Disease

GATA-3 and Asthma. Asthma is a pathological condition associated with an overzealous Th2 response in response to innocuous antigens resulting in mucus production and eosinophilic infiltration. Studies have documented that asthmatics have a higher percentage of $CD4^+$ T cells producing IL-4, IL-5, and IL-13 which are secreted in the airways of patients with asthma (Walker et al. 1992; Robinson et al. 1992). The association of elevated Th2 responses and asthma underscores an important role for GATA-3 in the disease process. In fact, GATA-3 mRNA expression is significantly increased in the airways of asthmatic subjects compared with that in normal control subjects and positively correlates with IL-5 expression (Nakamura et al. 1999).

Mice expressing a dominant negative mutant of GATA-3 demonstrate reduced inflammation, low IgE levels and blunted eosinophilia (Zhang et al. 1999). Similarly, delivering antisense GATA-3 reduced airway inflammation (Finotto et al. 2001). The dominant effect of GATA-3 in driving an asthmatic response is further evident from studies analyzing the repressive effects mediated by other transcription molecules on GATA-3. For example, mice deficient in ROG display enhanced airway hyperresponsiveness and inflammation in response to Th2-specific antigenic stimulation (Hirahara et al. 2008). T-bet-deficient mice demonstrate spontaneous induction of asthma even in the absence of immunological challenge with enhanced eosinophilia and airway hyperresponsiveness (Finotto et al. 2002).

GATA-3 and breast cancer. In recent years, a dominant role for GATA-3 in development of mammary cells has come to light. Deletion of GATA-3 driven by K14-Cre resulted in the failure to develop mammary placodes. GATA-3 has been shown to have a dominant function in controlling the development of luminal cells in the mammary gland and the maintenance of the differentiated phenotype of the luminal cells in the adult mammary gland. More recently, bioinformatic analysis of breast cancer specimens revealed loss of expression of GATA-3 in poorly differentiated and highly metastatic tumors (Chou et al. 2010).

Summary

Since its cloning 20 years ago, a treasure trove of information on GATA-3 has been unearthed that encompasses its divergent role in the development and function of both hematopoietic and non-hematopoietic cells. Undoubtedly, it is best known as the master regulator of Th2 cell differentiation, which implicates it in allergic diseases such as asthma. Rather unexpectedly, GATA-3 plays a regulatory role in a completely different setting, which is the luminal cell that is essential for mammary gland development. Low GATA-3 expression has been associated with poor prognosis in breast cancer and is being considered as a better prognostic marker than the estrogen receptor status of the tumors. Clearly, GATA-3 casts a wide net and identification of its partners in different cell types in homeostasis and in disease may provide new opportunities for therapeutic intervention of immune- and nonimmune-mediated diseases.

Historical Background

The primary processes of vertebrate visual excitation are located in the rod and cone photoreceptor cells of the retina. Illumination of the rod and cone cells

GCAP (Guanylate Cyclase–Activating Protein), Fig. 1 Domain topography of a GCAP molecule highlighting the four EF-hand Ca^{2+}-binding motifs and the myristoyl group at the amino terminus

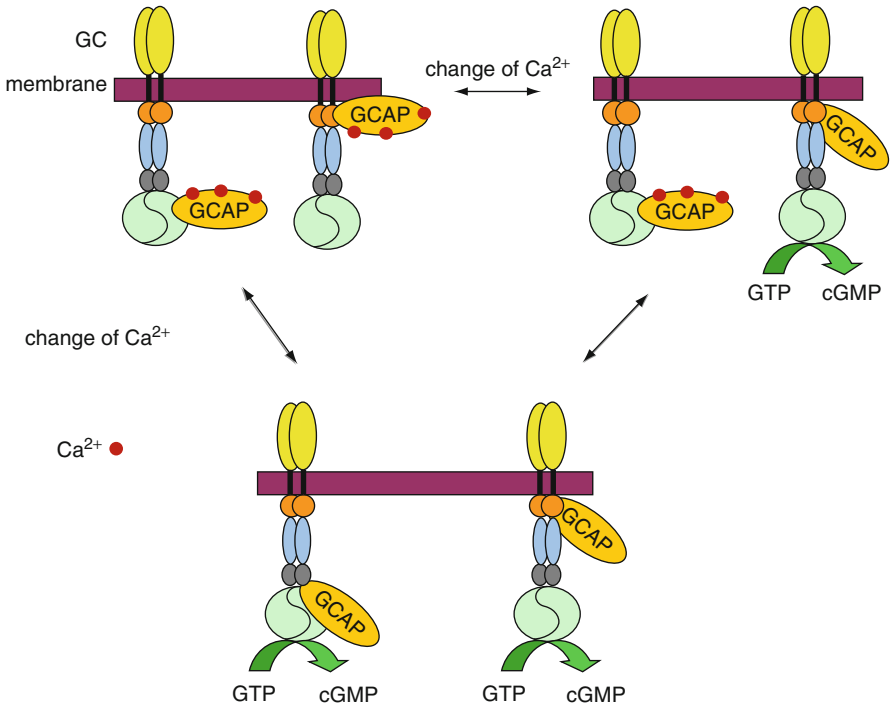
triggers a biochemical cascade leading to hyperpolarization of the cell. This conversion of a light signal into an electrical signal is called phototransduction, and in the 1970s the concept of an intracellular second messenger mediating this process was developed. Two competing hypotheses were intensively discussed, the "calcium hypothesis" and the "cGMP hypothesis" to reconcile different lines of experimental results. With the identification of a cGMP-gated cation channel (cyclic nucleotide–gated channel, CNG-channel) in the plasma membrane of rod and cone cells, the second messenger of light excitation was finally identified (for a historical overview see Luo et al. 2008). Calcium on the other hand was found to be important for the sensitivity regulation (light adaptation) of photoreceptor cells (Fain et al. 2001)and was recognized as an essential part of negative feedback loops operating in photoreceptor cells ("calcium feedback"). In the current picture of phototransduction, light is absorbed by visual pigments thereby triggering a G protein–mediated signaling cascade and leading to the hydrolysis of cGMP by a phosphodiesterase. CNG-channels are open at the high concentration of cGMP in the dark and close after removal of cGMP. Synthesis of cGMP is catalyzed by retina-specific guanylate cyclases (GCs) according to the reaction scheme GTP → cGMP + pyrophosphate (PP_i). This step is under control of a calcium feedback, low Ca^{2+}-concentrations increase and high Ca^{2+}-concentration decrease GC activity. However, this regulatory step can only be of physiological relevance, if the cytoplasmic Ca^{2+}-concentration changes over the time course of a light response. Indeed this was observed, since the cytoplasmic concentration of Ca^{2+} decreases after illumination due to the halted influx of Ca^{2+} through the CNG-channel and the continuous extrusion via a Na^+/K^+, Ca^{2+}-exchanger. Thus a decrease in cytoplasmic Ca^{2+} accelerates cGMP synthesis. While this concept was developed in the 1980s, it became clear that the Ca^{2+}-sensitive regulation of photoreceptor GC activity is mediated by a soluble Ca^{2+}-binding protein (Koch and Stryer 1988). The consequent search for this protein led to the identification of a novel class of Ca^{2+}-binding proteins, named guanylate cyclase–activating proteins (GCAPs) (Stephen et al. 2008; Dizhoor et al. 2010). Soon after their discovery and the determination of their amino acid sequence, it became apparent that GCAPs belong to the subfamily of neuronal calcium sensor (NCS) proteins, a group of EF-hand Ca^{2+}-binding proteins mainly found in neurons and sensory cells (Burgoyne 2007).

GCAP Isoforms

First discovered in mammals, GCAP isoforms have been identified in many vertebrates including human, bovine, monkey, mice, chicken, fish, and amphibians. The different isoforms are classified on the basis of their amino acid sequences and are given a number like in GCAP1, GCAP2, etc. So far mammalian rod and cone cells express two or three GCAP isoforms, which are GCAP1, GCAP2, and GCAP3, but a larger variety was found in teleost fish, where the expression of eight isoforms was predicted in pufferfish (*Fugu rubripes*) and six isoforms were described in zebrafish (*Danio rerio*) and carp (*Cyprinus carpio*). The physiological meaning of variable GCAP expression is currently under investigation (Rätscho et al. 2010).

Main Features of Protein Structure

GCAPs are small Ca^{2+}/Mg^{2+}-binding proteins of approximately 200 amino acid length with acidic and hydrophobic properties. They harbor four EF-hand Ca^{2+}-binding motifs in their primary structure, of which the first one (EF-hand1) seems to be nonfunctional based on amino acid sequence comparison with canonical EF-hand structures (Fig. 1). GCAPs are modified at the amino terminus by acyl groups mainly myristoyl (so far this has not been verified for all GCAP isoforms). In this aspect they are similar to other NCS proteins that are myristoylated at the amino terminus. However, the myristoyl group confers different functions to different NCS proteins. High-resolution structures of GCAPs (GCAP1, GCAP2, and GCAP3 either by x-ray crystal analysis or nuclear magnetic resonance) showed



GCAP (Guanylate Cyclase–Activating Protein),
Fig. 2 Mode of GC activation and regulation by GCAPs. In the dark state of the photoreceptor cell, GCAPs with three Ca^{2+} bound interact with the GC dimer. GCAP isoforms might have different interactions sites on GC as this was demonstrated for bovine GCAP1 and GCAP2. Decrease of cytoplasmic Ca^{2+} triggers conformational changes in GCAPs, but at different Ca^{2+}-concentrations for each GCAP. This leads to a sequence of activation steps and a differential mode of GC regulation (Ca^{2+}-relay model)

a general match to other known three-dimensional structures of NCS proteins (the best investigated example is ▶ recoverin, another Ca^{2+}-sensor protein operating in vision). In the Ca^{2+}-bound state GCAPs are compact proteins with the four EF-hand motifs arranged in two domains. These two domains separate the protein in an amino-terminal and a carboxy-terminal part (Stephen et al. 2008).

Tissue Distribution

Tissue distribution of GCAPs had been investigated by in situ hybridization and/or immunocytochemistry. All GCAPs show a prominent transcription and/or expression in the outer vertebrate retina, presumably in the outer and inner segments of photoreceptor cells, but GCAP-specific staining was also observed in cone somata, cell bodies, axons, axon terminals, and synaptic pedicles. A comparative study on several mammalian retinas showed a species-dependent labeling pattern for GCAP1 and GCAP2. Furthermore, for some species as human and zebrafish (but not mice) GCAP3 appeared as a cone-specific isoform of GCAP. Other teleost fish–specific isoforms like for example GCAP4, GCAP5, and GCAP7 are also cone specific (Imanishi et al. 2004; Rätscho et al. 2009; Takemoto et al. 2009).

Regulation of Guanylate Cyclase Activity

GCAPs regulate the activity of sensory GCs, in particular, the photoreceptor cell–specific forms. A triggering step of GCAP function is the light-induced decrease of the intracellular messenger cGMP and the consequent decrease of the cytoplasmic Ca^{2+}-concentration in a rod or cone cell. Since GCAPs operate as Ca^{2+}-sensors, they can detect changing concentrations of Ca^{2+} and thereby undergo a conformational change. GCAPs form a complex with the target GC in the Ca^{2+}-free and Ca^{2+}-bound state and it is assumed that the Ca^{2+}-induced conformational change is transferred to the GC by protein–protein interaction. This in turn is thought to lead to an increase of catalytic activity at the cyclase catalytic domain (Fig. 2). Binding of ATP to the intracellular kinase homology domain is known to enhance the GC activity (Koch et al. 2010). The switch of a GCAP molecule from an inhibitor to an activator state does critically depend on the binding of Ca^{2+} at submicromolar and binding of Mg^{2+} at submillimolar concentrations. In the Ca^{2+}-bound state (three Ca^{2+} bound) GCAPs suppress GC activity, in some cases below the basal level. Dissociation of Ca^{2+} from GCAP facilitates the exchange of Ca^{2+} for Mg^{2+} at two EF-hands, which is important for binding to the target GC and increase of GC activity (Dizhoor et al. 2010).

Although GCAPs have several general properties (see above) in common, they differ in many aspects particularly concerning their regulatory properties. One characteristic distinguishing feature is the different Ca^{2+}sensitivity, by which GCAP1 and GCAP2 regulate GC activity. Both proteins are present in rod and cone photoreceptor cells and overlap in their expression profile. A physiological meaning of this observation could be a so-called Ca^{2+}-relay model of GC activation (Koch 2006; Burgoyne 2007). It is based on the observations that GCAP1 and GCAP2 are present in almost equal concentrations and that they equal in total the concentration of a GC dimer in rod cells. In the dark state of the cell, when the cytoplasmic Ca^{2+}-concentration is high (Fig. 2, upper part) both GCAPs bind to a GC dimer (for simplicity every dimer is associated with one GCAP molecule). In this state, the GC activity is very low and may just maintain the cytoplasmic dark concentration of cGMP by keeping a balance with the low dark activity of the cGMP hydrolyzing *phosphodiesterase*. Illumination of rod or cone cells leads to a decrease in cGMP and consequently to a fall in Ca^{2+}. Depending on the light conditions and on the bleaching protocol, the cytoplasmic Ca^{2+}–concentration reaches an intermediate level, which transforms only GCAP1 into an activator of the GC and keeps GCAP2 still in an inactive state (Fig. 2, upper part, right side). This differential activating modus is in accordance with the observed differences in Ca^{2+}-sensitivity. Stronger illumination then causes a further decrease of intracellular Ca^{2+}, which induces the transition of GCAP2 into the activator state (Fig. 2, lower part). Changing light intensity of light flashes and background light might establish a different steady state of cytoplasmic Ca^{2+} causing a switch between different GCAP modes. By this mechanism a photoreceptor cell could expand its dynamic range of responses to Ca^{2+}.

GCAPs in Inherited Retinal Diseases

Dysfunction or progressive visual impairment leading to blindness is often associated with inherited retinal diseases. Many proteins in photoreceptor cells with key functions for cell excitation and adaptation are known to be mutated in patients suffering from these diseases. Mutations in the GCAP gene are very often located within or near the third or fourth EF-hand and correlate with diseases like autosomal dominant cone or cone-rod dystrophies (Stephen et al. 2008; Behnen et al. 2010). Disease-related GCAP1 mutants show in almost all cases an incomplete suppression of GC activity at physiological Ca^{2+}-concentration in the dark leading to a constitutive activation of the target enzyme. In turn this causes an elevated cGMP level in the cell and a distortion of the Ca^{2+}-homeostasis.

Summary

The second messenger cGMP and its fine-tuned regulation of hydrolysis and synthesis are keystones of the molecular events in phototransduction. Regulation of sensory GCs by GCAPs represents a concept of cellular signaling different from the more classical case of cGMP synthesis control via hormone binding to a receptor GC (e.g., natriuretic peptide receptor GCs). Instead GCAPs are a specialized group of neuronal Ca^{2+}-binding proteins that detect changes in cytoplasmic Ca^{2+} and control GC activity on the cytoplasmic part of the membrane-bound GC. The diversity of GCAPs in fishes, in particular in cones of the fish retina could further indicate that they are an essential part of a "Ca^{2+}-relay model" operating in cone vision under changing illumination conditions. Finally, GCAPs might participate in regulatory protein–protein interactions involving other target proteins, as this has already been shown for GCAP2. The variety of GCAPs found in teleost fishes could also hint to a wider diversity of GCAP target molecules.

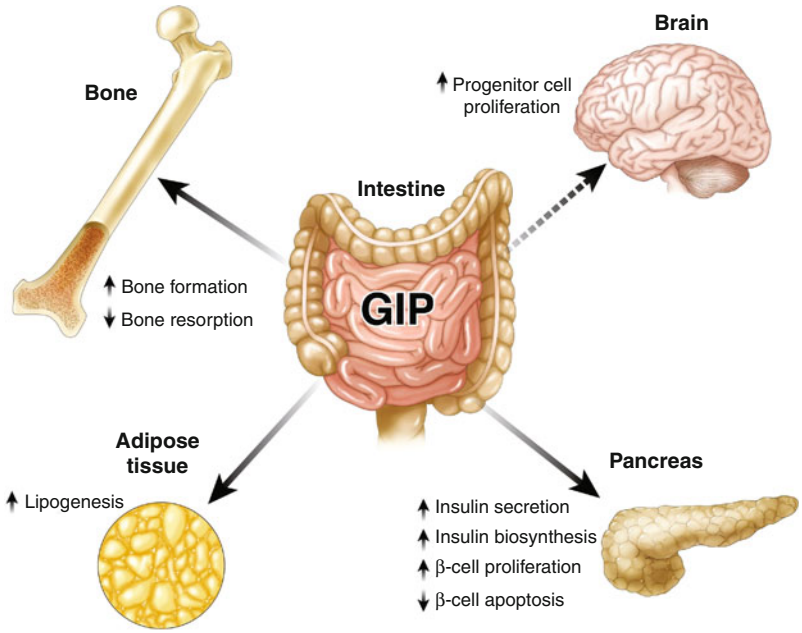
Gastric inhibitory polypeptide receptor

Historical Background

Way back in 1900, duodenal mucous extract was shown to inhibit gastric acid secretion. It was in 1930 that Kosaka and Lim observed that intravenous



Glucose-Dependent Insulinotropic Polypeptide Receptor (*GIPR*), Fig. 1 GIP actions in peripheral tissues (Reproduced with permission from Elsevier-L no. 2731900143478)

infusion of intestinal extracts led to inhibition of gastric acid secretion and gastric emptying; the term "enterogastrone" was subsequently floated (Kosaka and Lim 1930; Meier et al. 2002). Brown and coworkers purified this extract to homogeneity and reported the amino acid sequence of this newly found hormone naming it as "Gastric Inhibitory Polypeptide" (GIP) since the latter also inhibited gastric acid secretion. In parallel, Moore and coworkers had for the first time (1906) found antidiabetogenic effect of duodenal mucous membrane extract (Moore 1906). The development of immunoassay for insulin in 1960 revealed that the duodenal extract stimulated secretion of insulin from pancreas in humans. It was also observed that orally administered glucose instigated higher insulin secretion as compared to glucose administered intravenously. This established a hormonal link between intestine and pancreas which was later termed as enteroinsular axis. Subsequent experimentation led to the finding that two peptides (commonly termed as incretins) were released from intestine upon oral food intake that led to the increased insulin secretion from the pancreas. Interestingly, one of the peptides was found to be same as GIP and since it was involved in glucose-mediated insulin secretion, it was renamed by Brown and Pederson as glucose-dependent insulinotropic polypeptide (GIP) maintaining the same acronym; the other peptide being termed as glucagon like polypeptide-1(GLP-1). The insulinotropic effect on pancreatic islet β-cells was then recognized to be the principal physiologic action of GIP. Together with glucagon-like peptide-1, GIP is largely responsible for the secretion of insulin postprandially. In the course of trying to elucidate the molecular mechanism of insulin secretion and GIP effect, functionally relevant and high affinity-binding sites for GIP as GIP receptors were identified on the surface of hamster β-cells by radioisotopic assay using ^{125}I-labeled GIP (Amiranoff et al. 1984, 1985, 1986). Subsequently, the expression of the mRNA for GIP receptor was observed in pancreatic cells followed by its cloning, functional expression, sequencing, and chromosomal localization (Takeda et al. 1987; Gremlich et al. 1995; Yamada et al. 1995).

Physiological Actions of GIP

GIP is known to exert myriad of physiological effects on tissues such as pancreas, central nervous system, bone, adipose tissue, stomach, and liver (Fig. 1). In the pancreas, it potentiates the glucose-dependent insulin secretion from the β-cells. It also positively influences insulin biosynthesis and increases β-cell survival

(Drucker 2006). In the CNS, it enhances the proliferation of hippocampal progenitor cells and enhances sensorimotor coordination and memory recognition. In adipose tissue, it increases the deposition of fat via increased synthesis of lipoprotein lipase, stimulates fatty acids synthesis and re-esterification, enhances incorporation of fatty acid into triglycerides and reduction of lipolysis. It increases the density of bone and enhances new bone formation. It is also shown to exert an inhibitory effect on gastric acid secretion and upregulates intestinal hexose transport. In the liver, it reduces the glucagon-stimulated hepatic glucose production. By and large, the physiological effects of GIP are exerted via the receptor that is a G-protein coupled receptor (namely, GIPR).

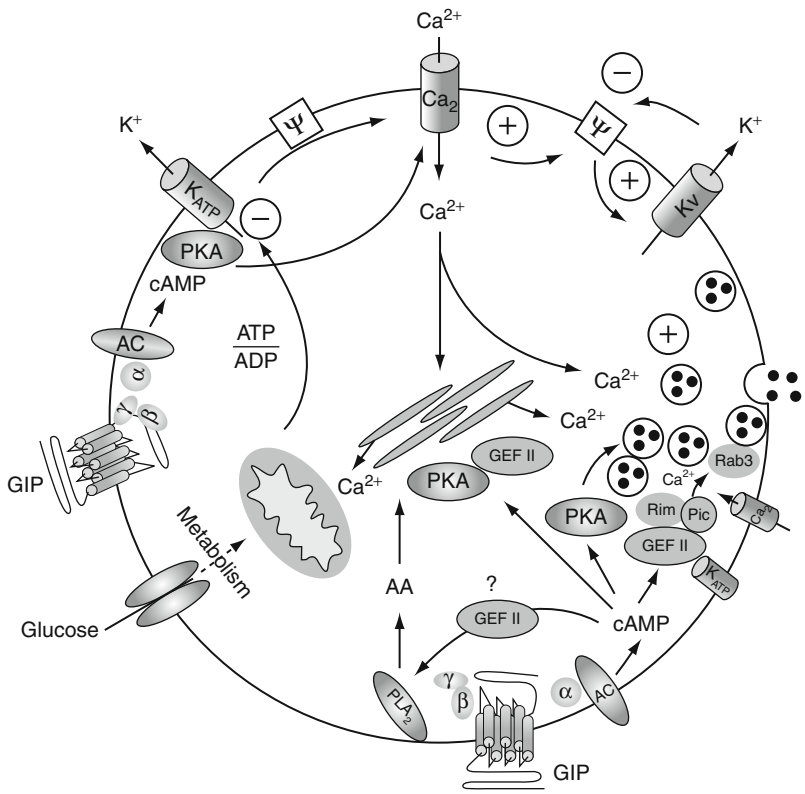
Glucose-Dependent Insulinotropic Polypeptide Receptor (GIPR)

The human GIPR (hGIPR) is a 466 amino acid, seven transmembrane (heptahelical) receptor belonging to class B of the G-protein-coupled receptor (GPCR) family. It is a glycoprotein, well conserved across all mammalian cells. However, GIP receptors have not been identified in non-mammalian species to date. The gene encoding hGIPR is located on chromosome 19q13.3 and comprises of 14 exons and 12 introns (Gremlich et al. 1995). GIPR is abundantly expressed on the surface of the β-cells of the pancreas and those of the adipose tissue, bone, and nerves. It is also known as a secretin receptor since it belongs to the same family that contains secretin, glucagon, glucagon-like peptide-1 (GLP-1), vasoactive intestinal polypeptide (VIP), growth-hormone-releasing hormone (GHRH), and pituitary adenylate cyclase-activating polypeptide (PACAP). It is involved in the transmission of vital secretory and mitogenic signals to the inside of the cell and activates the intracellular signal transduction pathways (discussed later). GIPR is activated by the binding of GIP, secreted by the K-cells of the duodenum. GIP comes into blood circulation in response to nutrient (fatty acid, glucose) absorption in proportionate amount and is involved in the secretion of insulin from the β-cells of pancreas and thus it is known to be glucose dependent. The insulinotropic action of the peptide is known as incretin effect and due to this GIP-GIPR has immense antidiabetogenic potential (Gault et al. 2003; Ranganath 2008).

Structural Organization and Dynamics of GIP–GIPR Interaction

Like any GPCR, the GIPR assembly on the cell membrane has five domains – the extracellular N-terminus domain (residues 22–138), intracellular C-terminus domain (residues 399–466), seven transmembrane domains (TM) (TM1 residues139–161, TM2 residues 170–189, TM3 residues 218–242, TM4 residues 255–278, TM5 residues 294–319, TM6 residues 342–362, TM7 378–398), three extracellular loops (ECl) (ECl1 residues 190–217, ECl2 residues 279–293, ECl3 residues 363–377) and three intracellular loops (ICl) (ICl1 residues 162–169, ICl2 residues 243–254, ICl3 residues 320–341). The transmembrane domains are linked to each other by intracellular loops on the inside of the cell and by the extracellular loops on the outside. The C-terminus of the receptor is coupled to a heterotrimeric GTP-binding protein also called G-protein, which is made up of three subunits Gα, Gβ, and Gγ. The Gα subunit harbors a catalytic site for binding GTP and in an inactive state of the receptor it is bound to GDP. Upon activation by the receptor, GTP displaces GDP at the Gα subunit, thereby activating it. The GβGγ dimer dissociates from the trimeric form and Gα activates its membrane bound effector, adenylyl cyclase, causing a cascade of reactions in the downstream signaling pathway (Baggio and Drucker 2007; McIntosh et al. 2009).

According to the receptoral dynamics suggested by Hoare, the N-terminus of the receptor is responsible for high affinity binding to the C-terminus of GIP (Hoare 2005). Once bound, the N-terminus of GIP is projected onto the extracellular loops of GIPR for its activation. Upon activation, the signal is transmitted within the cell through one of the transmembrane domains to the intracellular C-terminus domain. A recently solved crystal structure (Parthier et al. 2007) of GIP bound to the extracellular N-terminus domain reveals the N-terminus domain of the receptor as a α-helical structure spanning amino acids Ala32 to Ala52 and the two antiparallel β sheets (β1a: Ser64 to Phe65; β1b: Cys70 to Trp71; β2a: Ala78 to Ser83; β2b: Phe98 to Cys103) and two short helices at the C–terminus end (His91 to Val94 and Thr116 to Cys118). There are three disulfide bonds, a typical characteristic of family B GPCR, these are between the N-terminus and the first β sheet (Cys46 and Cys70), between the two β sheets (Cys61 and Cys103) and



Glucose-Dependent Insulinotropic Polypeptide Receptor (*GIPR*),

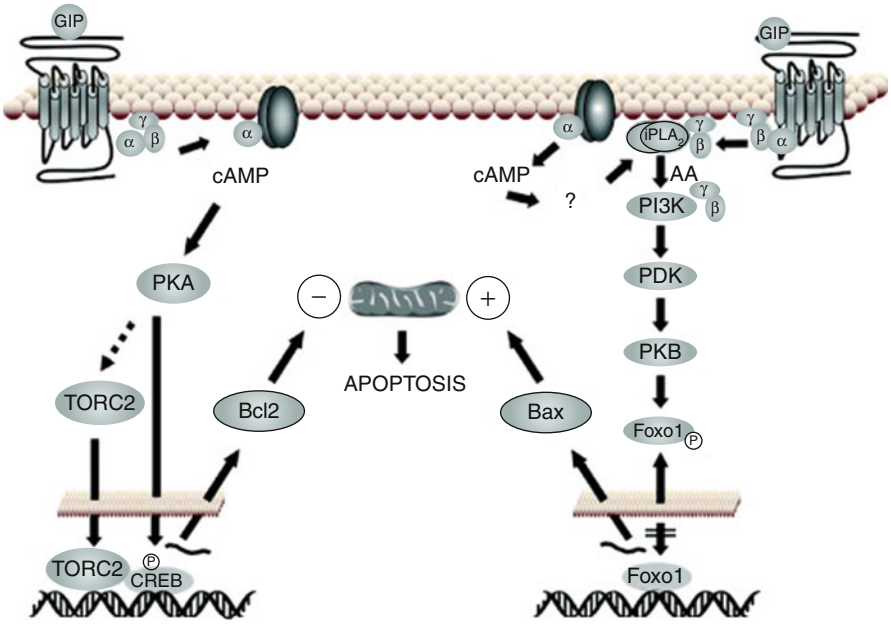
between Cys84 and Cys118. GIP is also seen to be composed of an α helix that spans Phe6 to Ala28. The helix is partly amphipathic in nature between Gln20 and Ala28 with all the hydrophobic amino acids (Phe22, Val23, Leu26, and Leu27) aligned on one side and projected towards the N-terminus domain of the receptor; this suggests that the interaction between GIP and its receptor is primarily hydrophobic in nature. Apart from hydrophobic interactions, hydrogen bonding also occurs between the peptide and the receptor domain.

The Signal Transduction Pathways of GIP-GIPR

Insulin Secretory Pathway

Insulin secretion is primarily mediated by signals originating from two sources – one by glucose and the other by incretins (Fig. 2). When the postprandial blood glucose concentration increases, it is taken up into the pancreatic cells via Glut2 uniporter. Inside the cell, glucose undergoes glycolysis and mitochondrial oxidation by Krebs cycle, thus generating ATP. This leads to an increase in the ATP/ADP ratio and closure of the K^+ (K_{ATP}) channel. As a result, depolarization of the cell membrane occurs, leading to opening of the voltage-gated calcium channel with an influx of Ca^{2+} inside the cells. The increased cytoplasmic Ca^{2+} mobilizes the vesicle-containing insulin to the surface of the cell membrane; exocytosis of its content releases insulin. GIPR is shown to have a potentiating effect on the insulin secretion. Upon activation, it stimulates the ▶ adenylyl cyclase enzyme via G-protein and catalyzes the formation of cAMP. The resultant increase in cAMP further activates the protein kinase A (PKA)-dependent as well as protein kinase A (PKA)-independent pathways (Baggio and Drucker 2007; McIntosh et al. 2009). The PKA-dependent pathway involves GIPR-mediated activation of PKA which phosphorylates a number of downstream proteins including Glut2, K^+ (K_{ATP}) channel and the voltage-gated Ca^{2+} channel leading to exocytosis of insulin from the secretory vesicles. On the other hand, the PKA-independent pathway involves cAMP-specific guanine nucleotide exchange factor (GEF) II also



Glucose-Dependent Insulinotropic Polypeptide Receptor (*GIPR*),

known as Epac, which under inactive state is associated with Kir6.2. The increased cAMP produced due to GIPR stimulation dissociates the GEFII from Kir6.2, which leads to calcium-dependent dimerization of Rim2 and Piccolo. This in turn interacts with Rab3 leading to exocytosis of insulin granules and release of insulin.

GIPR is also known to stimulate insulin secretion by another pathway which leads to increased arachidonic acid production through Group VIA islet Ca^{2+}-independent phospholipase A_2 (iPLA$_2$).

β-Cell Growth and Survival Pathways

Apart from insulin secretion, GIPR signaling is also known to play a vital role in β-cell survival and proliferation. The dominant negative mutant of human GIPR in β-cells generated by transgenic method showed a diminished islet size and the development of diabetes in mice (McIntosh et al. 2009). Also, mice with the receptor knockout failed to respond to a high fat diet with hyperinsulinemia. This suggests the role of GIP signaling in regulation of β-cell mass in insulin resistance. GIPR serves as a mitogenic and anti-apoptotic factor for β-cells by pleiotropic activation of several interlinked pathways involving PKA/▶ CREB, MAPK, and PI3-kinase (Fig. 3). The major effectors of these pathways are kinases, enzymes that require ATP for their functioning; hence linked to glucose metabolism and Ca^{2+} signaling.

- The PKA/▶ CREB pathway involves activation of PKA by GIPR signaling and inhibition of phosphorylation of the cytoplasmic enzyme adenosine mono phosphate kinase (AMPK), which is responsible for phosphorylation of TORC2. TORC2 is a coactivator of the nuclear regulating factor ▶ CREB, present inside the nucleus. Under the reduced state of phosphorylation, the nuclear localization of TORC2 increases and within the nucleus it interacts with phospho-▶ CREB. The union of the TORC2-phospho-▶ CREB binds to the CRE-1 element of the Bcl-2 promoter and upregulates the expression of the downstream *Bcl-2* gene. The Bcl-2 protein so formed prevents the apoptosis of β-cells (Kim et al. 2008).
- The growth and cell survival effect of GIPR signaling also occurs via a PKA-independent mechanism. GIPR activation stimulates phosphatidylinositol 3-kinase (PI3K), which activates the downstream protein kinase B (▶ PKB) by phosphorylation. The so activated ▶ PKB in turn phosphorylates various components of the apoptotic machinery such as caspase 9, Bad, glycogen synthase kinase 3B, and a member of the forkhead/winged helix/Foxo family response element (FHRE) in β-cells and downregulates *Bax* gene. The product of the *Bax* gene plays an important role as a mediator of apoptotic cell death (Kim et al. 2005).

- GIPR is also known to exert a mitogenic effect on β-cells by activating the mitogen-activated protein kinase (MAPK) or the extracellular signal-regulated kinase1/2 (▶ MEK1/2 – ERK1/2) modules and the PI3K/▶ PKB pathway. The ▶ MEK1/2 and ERK1/2 are activated by phosphorylation and they in turn phosphorylate downstream substrates of ERK1/2, ▶ p38MAPK and ▶ PKB. This further inactivates caspase-3 and DNA fragmentation and prevents apoptosis (Trumper et al. 2002).

GIPR has a potential influence on increased insulin biosynthesis as well. The rat insulinoma cell line showed increased expression of insulin mRNA upon treatment with GIP. Once the action is accomplished, GIPR signaling is terminated rapidly by physiological cleavage of GIP by a dipeptidyl peptidase-IV (DPP-IV) enzyme at the N-terminus (McIntosh et al. 2009).

GIPR and Antidiabetic Drug Design

Since the emergence of the incretin concept, there has been increasing efforts directed toward designing novel antidiabetic drugs. The structure of the N-terminus domain of the receptor in complex with the peptide has been solved and the key amino acids involved in this interaction are known; this knowledge can help in designing GIPR agonists. There have been attempts to enhance the action of incretins on the receptor by designing peptide analogs that are resistant to DPP-IV and small molecules that are inhibitors of the enzyme. The design of incretin receptor agonists is in the state of infancy and so far no small molecule has been developed that can activate the GIPR. However, several peptide analogs resistant to DPP-IV and inhibitors of DPP-IV have been introduced into therapeutics (Green and Flatt 2007).

Summary

GIPR has emerged as a major signaling molecule on the enteroinsular axis with a key role in glucose homeostasis. As a GPCR, it is predominantly expressed on the surface of β-cells of islets of pancreas, adipose tissue, central nervous system, bone, and to some extent in stomach and liver cells. Along with glucose, it is known to potentiate insulin secretion from pancreas, increase insulin biosynthesis, and enhance β-cell survival by exerting mitogenic effects. It is also known to increase fat deposition in adipose tissue, enhance memory recognition in CNS, and inhibit gastric acid secretion in stomach. The past two decades of research have exhaustively delineated various pathways involved in GIPR signaling in pancreas with PI3K, PKA, ▶ PKB, and MAPK being major ones. Due to its role in insulin secretion, GIPR has become an attractive target for studying its role in pathophysiology underlying diabetes and for designing novel antidiabetics. Though GIPR agonists are yet to see the light of the day, inhibitors of DPP-IV, which enhance the action of GIP and prolong GIPR signaling, have been successfully designed and put to practice.

Synonyms

Ionotropic glutamate receptors (AMPA, kainate and NMDA receptors); Metabotropic glutamate receptors

Nomenclature of Glutamate Receptor Proteins

International Union of Basic and Clinical Pharmacology (IUPHAR) recommended and previous nomenclatures of glutamate receptor proteins

1. Ionotropic glutamate receptors (Collingridge et al. 2009)
   - AMPA receptor subunits GluA1-4 (previously: GluR1-4; GluRA-D; GLU_{A1-4})
   - Kainate receptor subunits GluK1-5 (previously: GluR5-7, KA-1/2; EAA3-5, EAA1/2; GLU_{K5-7}, $GLU_{K1/2}$)
   - NMDA receptor subunits GluN1, GluN2A-D, GluN3A-B (previously: NR1, NR2A-D, NR3A/B; GLU_{N1}, GLU_{N2A-D}, $GLU_{N3A/B}$)
   - δ receptor subunits GluD1-2 (previously: GluRδ1/2)
2. Metabotropic glutamate receptors (Nicoletti et al. 2011)
   - mGlu1-8 (previously: mGluR1-8)

Historical Background

The excitatory neurotransmitter role of L-glutamate gradually emerged in the 1950s–1960s. Early studies

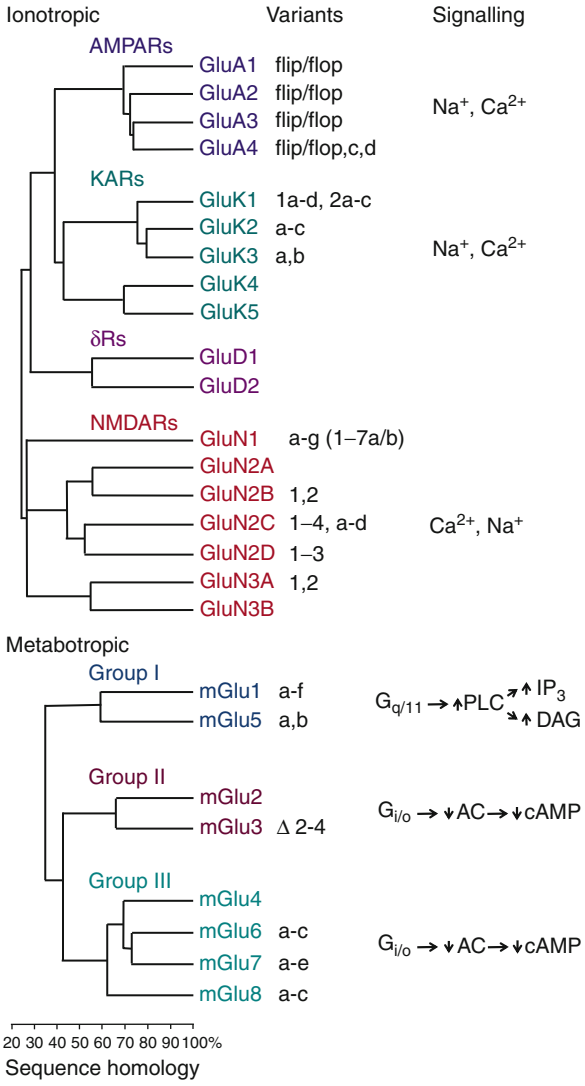
indicated that L-glutamate: (1) was present in high concentrations throughout the mammalian central nervous system (CNS), (2) produced convulsions, and (3) excited single neurons (reviewed in Lodge 2009). The development of increasingly specific pharmacological tools during the 1970s started to reveal considerable functional diversity. The family of glutamate-activated cation channels (ionotropic glutamate receptors [iGluRs]) was classified into three major pharmacological subfamilies, defined by their most selective agonists: α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA), kainate, and *N*-methyl-D-aspartate (NMDA) receptors (Dingledine et al. 1999; Lodge 2009). In the mid-1980s, evidence began to appear of the existence of another glutamate receptor (GluR) group termed metabotropic GluRs (mGluRs) that are directly coupled to second-messenger systems via GTP-binding proteins (Conn and Pin 1997; Nicoletti et al. 2011). However, iGluR and mGluR proteins remained elusive until the late 1980s. The application of the newly emerging expression cloning approach led to a breakthrough and provided the original sequence information for the first iGluR subunits GluA1 and GluN1 (Lodge 2009). The first member of the family of mGluRs (mGlu1a) was also discovered by expression cloning (Nicoletti et al. 2011). Successive cloning by sequence homology led to the identification of additional iGluR subunits, mGluR isoforms, and their splice variants (Dingledine et al. 1999; Niswender and Conn 2010). Receptor localization studies in the 1990s–2000s, together with the development of a range of transgenic animals and more selective pharmacological tools, started to reveal the mechanisms of glutamatergic signaling in the CNS. The availability of X-ray crystal structures, molecular modeling and site-directed mutagenesis studies provided much improved understanding of the molecular organization of iGluRs (Traynelis et al. 2010) and mGluRs (Nicoletti et al. 2011). A very diverse range of receptor phosphorylation–dephosphorylation events, protein–protein interactions, and receptor trafficking have been identified as important regulators of GluR function and synaptic plasticity (Collingridge et al. 2004; Henley et al. 2011).

Key Features of the Glutamate Receptor Family

The amino acid L-glutamate is the predominant neurotransmitter of the vast majority of excitatory synapses in the mammalian CNS. This ubiquitous neurotransmitter acts via the activation of a number of ionotropic (ligand-gated ion channels) and metabotropic (G-protein-coupled) GluRs. These receptors are involved in nearly all aspects of nervous system development and function including many forms of synaptic plasticity such as long-term potentiation (LTP) and long-term depression (LTD), mechanisms that are involved in learning and memory (Collingridge et al. 2004). GluRs are also involved in a very wide range of neurological and psychiatric disorders including chronic neurodegenerative conditions (Lau and Tymianski 2010). They are thus also potential targets for therapies for CNS disorders.

Ionotropic Glutamate Receptors

The related subunit proteins of glutamate-gated ion channels (iGluRs) are encoded by 18 genes in mammals. Based on their sequence homology, electrophysiological properties, and pharmacological selectivity they are subdivided into four subtypes: AMPA, kainate, NMDA, and δ receptors (Fig. 1). While the role of δ receptor subunits is unclear and they seem to be incapable of forming receptors that can be activated by any known agonists, properties of other iGluRs are extensively studied. All iGluRs share a common basic structure, which differs from other ligand-gate ion channels. iGluRs are formed from the tetrameric assembly of homologous subunits around a central ion pore (Dingledine et al. 1999; Traynelis et al. 2010). The membrane topology of the iGluR subunits consists of a large extracellular N-terminal domain and four hydrophobic membrane-associated domains (M1-4; Fig. 2a). M2 is a re-entrant loop in the phospholipid bilayer and represents the channel pore-forming region (Dingledine et al. 1999). Each subunit carries its own ligand-binding site, which consists of residues that are distributed throughout both the distal N-terminal domain (called S1) and the extracellular loop between M3 and M4 (called S2; Fig. 2a; Dingledine et al. 1999). The S1S2 ligand-binding domain regions of some of the iGluR subunits have been isolated and crystalized with and without bound ligands (Traynelis et al. 2010). X-ray analysis of these proteins and protein-ligand complexes elucidated fine molecular details of the binding site, and the conformational changes of different agonists and

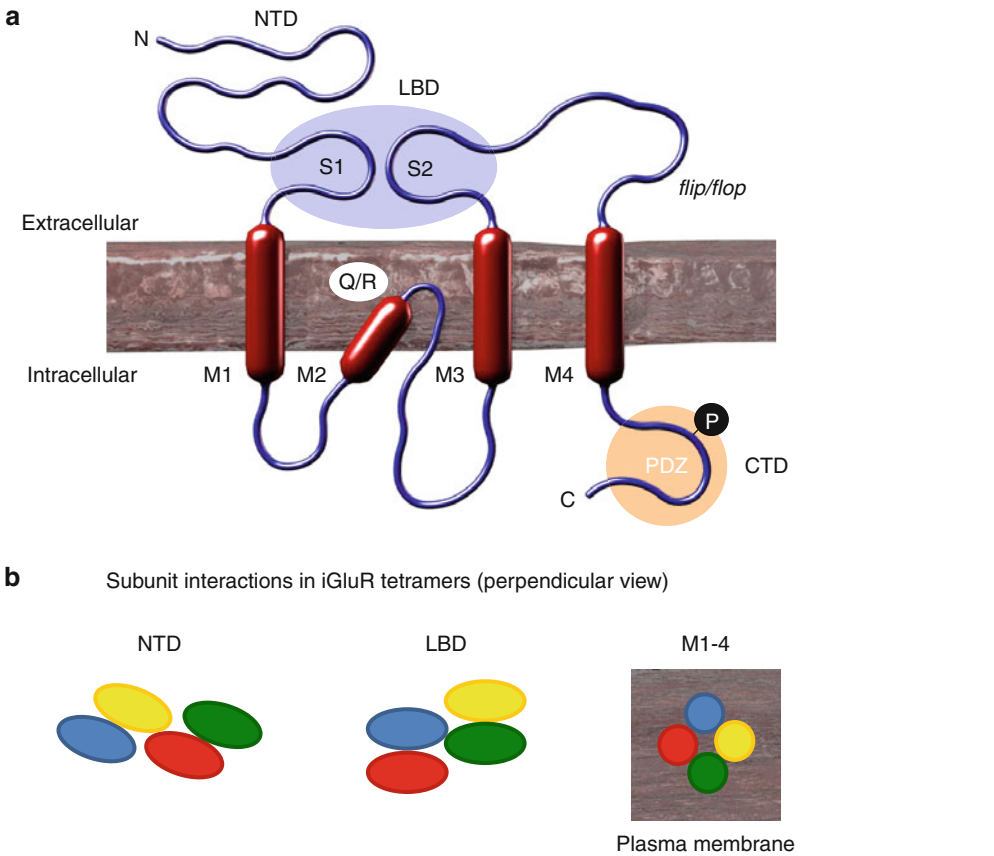


Glutamate Receptors, Fig. 1 IUPHAR recommended nomenclature, classification and sequence homology dendrograms of iGluR and mGluR proteins. The known splice variants and main signaling mechanisms are indicated next to the code name of the GluR proteins

antagonists induce to open or block the ion channels or modulate the manifestation of their activity (Traynelis et al. 2010). Recent crystallographic studies have provided the first detailed structure of the antagonist-bound tetrameric GluA2 AMPARs (Sobolevsky et al. 2009), which started to reveal complex subunit domain interactions within iGluRs (Fig. 2b). Oligomerization of iGluR subunits plays a major role in their surface expression (Greger et al. 2007). Nonfunctional receptors are retained intracellularly, suggesting that glutamate binding and associated conformational changes are prerequisites for the forward trafficking of intracellular KARs following multimeric assembly (Fleck 2006). Functional and immunolocalization studies indicate that segregated populations of iGluRs are localized at diverse subcellular compartments (Molnár 2008). All members of the iGluR family bind to a variety of intracellular and transmembrane proteins (Traynelis et al. 2010). These interactions allow local signaling to proceed, providing the possibility of spatial and temporal specificity to receptor regulation.

AMPA receptors (AMPARs) mediate fast synaptic transmission in the CNS and they are key components of the modifiable synaptic response. AMPARs are formed by co-assembly of the GluA1-4 subunits (Fig. 1), each of which can form functional homomeric receptors, although most native AMPARs contain both the GluA2 subunit and either GluA1, GluA3, or GluA4 (Dingledine et al. 1999). All AMPAR subunits exist as two splice variants termed *flip* and *flop*. The alternatively spliced region is in the extracellular loop (S2) adjacent to the last transmembrane domain (M4; Fig. 2a). The *flip* splice variants of GluA1-4 desensitize more slowly and to a lesser extent than the *flop* variants, which can influence the amplitude of the total AMPAR current (Dingledine et al. 1999). The C-terminal domain of AMPAR subunits also undergo alternative splicing to yield short and long forms of the intracellular domain (Dingledine et al. 1999). GluA2 undergoes editing in the M2 channel pore-forming region at the functionally significant Q/R site (Isaac et al. 2007; Fig. 2a). The GluA2 subunit in the edited form is responsible for the Ca^{2+} impermeability of AMPARs (Isaac et al. 2007).

AMPARs are highly mobile proteins that undergo constitutive and activity-dependent translocation to, and removal from, synapses (Henley et al. 2011). Increases in synaptic AMPAR function through changes in their number, subunit composition, and/or properties result in the long-term potentiation (LTP) of synaptic efficacy. Conversely, removal of synaptic AMPARs provides a mechanism for long-term depression (LTD) (Collingridge et al. 2004; Molnár 2008). Several functionally important phosphorylation sites have been identified in the C-terminal domains of AMPAR subunits (Molnár 2008). The effects of these phosphorylation/dephosphorylation events together



Glutamate Receptors, Fig. 2 (**a**) Schematic representation of iGluR subunit membrane topology. iGluR subunits composed of two extracellular domains: the N-terminal domain (NTD) and the ligand-binding domain (LBD) formed by the S1 and S2 segments. Unlike other ligand-gated ion channels (e.g., nicotinic acetylcholine receptors, $GABA_A$ receptors), iGluRs contain three transmembrane domains (M1, M3, and M4). A membrane re-entrant loop (M2) forms the pore of the channel in iGluRs and contains the Q/R editing site in GluA2, GluK1, and GluK2 subunits. The intracellular C-terminal domain (CTD) contains phosphorylation sites and binds to intracellular proteins. See text for details. Schematic image was provided by Dr. Andrew Doherty. (**b**) Assembled iGluR subunits have an overall twofold symmetry perpendicular to the membrane plane; the extracellular N-terminal domains (NTDs) and ligand-binding domains (LBDs) are organized as dimmers of dimmers, and the ion channel forming membrane-associated domains (M1-4) exhibit a fourfold symmetry (Sobolevsky et al. 2009)

with protein–protein interactions (e.g., α-actinin, AP2, GRIP, GRIP2, IQGAP1, mLIN-10, NSF, PICK1, PSD95, RIL, SAP97, Shank3, syntenin, TARPs, 4.1; Traynelis et al. 2010) are crucial in functional changes, localization and trafficking of these receptors so that they can fulfill their roles in synaptic transmission and plasticity (Collingridge et al. 2004; Molnár 2008; Henley et al. 2011).

Kainate receptors (KARs) are key players in the modulation of neuronal-network activity throughout the CNS (Lerma 2003). While other iGluRs (AMPA and NMDA receptors) mainly operate at postsynaptic sites, KARs are located at both presynaptic and postsynaptic sites where they modulate neurotransmitter release or mediate excitatory neurotransmission, respectively (Lerma 2003; Jane et al. 2009). KARs are also involved in neuronal differentiation, synaptic plasticity, epileptogenesis, chronic pain, neurodegeneration, and neuronal cell death (Jane et al. 2009). Some of the functions of KARs involve metabotropic action through coupling with a G-protein, which does not require an ionotropic action.

For instance, KARs regulate neuronal excitability by inhibition of Ca^{2+}-dependent K^+ channels (Rodríguez-Moreno and Sihra 2007).

Molecular cloning has identified five KAR subunits, named GluK1-5 (Fig. 1; Lerma 2003). KAR subunits are subdivided into low-affinity (GluK1-3) and high-affinity (GluK4/5) kainate-binding subunits (Jane et al. 2009). Electrophysiological and biochemical analysis of recombinant KARs indicate that functional KAR channels are formed by both homomeric and heteromeric expression of GluK1-3 subunits. In contrast, the GluK4 and GluK5 subunits do not form functional homomeric channels, but they co-assemble with the GluK1-3 subunits (Jane et al. 2009). The diversity of KARs is increased by the existence of splice variants for GluK1 (1a-d, 2a-c), GluK2 (a-c), and GluK3 (a,b) subunits (Fig. 1; Jane et al. 2009). GluK1 and GluK2 are subject to mRNA editing at the functionally significant Q/R site in the channel pore forming domain (Fig. 2a). Q/R editing of GluK1 and GluK2 subunits reduces Ca^{2+}-permeability of KARs (Lerma 2003).

Studies with recombinant receptors in cell lines and cultured neurons have started to define rules for the trafficking of KARs to the plasma membrane. The relative level of their surface expression depends on subunit composition, alternative splicing of their C-terminal domains, and editing of the Q/R site in the pore forming M2 domain. Some subunits (GluK2a and GluK3a) contain a forward trafficking motif, whereas others (GluK1a, GluK1b, GluK2b, GluK3b, and GluK5) are retained in the endoplasmic reticulum due to retention signals (Jane et al. 2009).

KAR subunits and splice variants show great divergence in their C-terminal cytoplasmic domain, which has been identified as a region of interaction with a number of protein partners (Traynelis et al. 2010). Many KAR-interacting proteins have been identified (e.g., actifilin, calmodulin, CASK, COPI, cortactin, dynamin-1, dynamitin, G-α(q/11), GRIP/GRIP2, NETO1/2, NSF, PICK1, profiling, PSD95, SAP97, SAP102, SNAP25, spectrin, SUMO, syntenin, VILIP1/3, 14-3-3). Some of these proteins have been implicated in trafficking, synaptic localization and modulation of the properties of KARs (Traynelis et al. 2010).

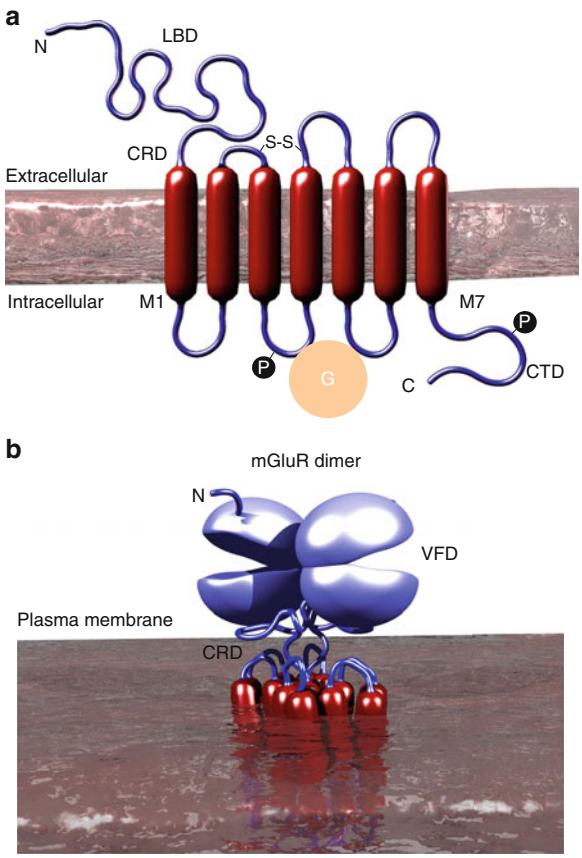
NMDA receptors (NMDARs) function as modulators of synaptic response and coincidence detectors. At resting membrane potentials, NMDARs are inactive. This is due to a voltage-dependent block of the channel pore by Mg^{2+}, preventing ion flows through it. Sustained activation of AMPARs by, for instance, a train of impulses arriving at a presynaptic terminal, depolarizes the postsynaptic cell, releasing the channel inhibition and thus allowing NMDAR activation. In addition to Na^+ and K^+, NMDARs are also permeable to Ca^{2+}. Thus, NMDAR activation leads to a Ca^{2+} influx into the postsynaptic cells, a signal that is instrumental in the activation of a number of signaling cascades. Depending on the pattern of synaptic plasticity, NMDARs are responsible for a wide range of postsynaptic functions, including LTP and LTD (Collingridge et al. 2004). Excessive activation of NMDARs leads to pathological processes (e.g., excitotoxic injury) in a number of acute and chronic neurological disorders (Lau and Tymianski 2010).

NMDARs are obligate heterotetramers formed from assemblies of GluN1 subunits with GluN2A-D and GluN3A/B (Fig. 1). In addition, GluN3A can assemble with GluN1 (without other GluN2 subunits) to form excitatory, Ca^{2+}-impermeant glycine receptors. Eight possible variations of the GluN1 subunit arise by alternative splicing of a single gene transcript. The insertion of one splice cassette at the N-terminal region of GluN1 and the deletion of two independent consecutive splice variants at the C terminus have been identified. Therefore, a large number of different NMDARs with differing functional and pharmacological properties exist in different parts of the brain or at different stages in development (Molnár 2008). Unusually for the iGluR, L-glutamate is not the only agonist for the NMDAR. Glycine, another amino acid, is a co-agonist and both transmitters must bind in order for the receptor to function. The binding sites for glutamate and glycine are found on different subunits – glycine binds to the GluN1 subunit while glutamate binds to the GluN2 subunit. This is one reason why both subunit types are required to generate a fully functioning receptor. The GluN2B subunit also possesses a binding site for polyamines, regulatory molecules that modulate the functioning of NMDARs. Like other iGluRs, NMDARs also interact with a wide range of cytoskeletal, scaffolding and signaling proteins (e.g., α-actin-2, AP2, calmodulin, CaMKII, CARPI, COPII, GPS2, LIN7, MAP1S, PACSIN1, plectin, PSD95, RACK1, SALM1, SAP97, SAP102, S-SCAM; Traynelis et al. 2010).

Metabotropic Glutamate Receptors

mGluRs play important roles in regulating the activity of many synapses in the CNS. These receptors activate a multitude of signaling pathways; therefore, they are involved in a wide number of physiological and pathological processes: modulation of slow excitatory and inhibitory responses; the regulation of Ca^{2+}, K^{+}, and nonselective cation channels; the inhibition and facilitation of transmitter release; the induction of LTP/LTD; the formation of various types of memory; the regulation of iGluR trafficking; modification of NMDAR-mediated synaptic transmission; the regulation of neuronal development; and signaling between neurons and glial cells (Ferraguti and Shigemoto 2006; Gladding et al. 2009; Niswender and Conn 2010). mGluRs are also implicated in various diseases such as epilepsy, anxiety and stress disorders, depression, schizophrenia, fragile X mental retardation, Parkinson's disease, chronic pain, drug addiction, hypoxic brain damage, and excitotoxic neuronal death (Nicoletti et al. 2011).

The seven transmembrane-domain proteins mGluRs (Fig. 3) are coupled to heterotrimeric GTP-binding proteins which link the receptors to downstream signaling pathways (Conn and Pin 1997; Nicoletti et al. 2011). The family of mGluRs comprises eight different subtypes (mGlu1-8 receptors; Fig. 1) classified into three groups on the basis of sequence similarities, pharmacological properties, and intracellular signal transduction mechanisms (Conn and Pin 1997; Niswender and Conn 2010). Group I includes mGlu1 and mGlu5 receptors, which couple to G_q and activate phospholipase C (PLC). In group II (mGlu2, mGlu3) and group III (mGlu4, mGlu6, mGlu7, and mGlu8) receptors couple to G_i/G_o and inhibit ▶ adenylyl cyclise (AC) (Niswender and Conn 2010). Many of these receptors (mGlu1, mGlu3, mGlu5-8) exist as various isoforms with different intracellular C-termini generated by alternative splicing (Fig. 1; Ferraguti and Shigemoto 2006; Niswender and Conn 2010). The large N-terminal domain of the mGluRs contains the ligand-binding site, which is formed by two-hinged globular domains – the so-called Venus fly trap domain (Fig. 3a, b; Nicoletti et al. 2011). Binding of glutamate causes the two domains to close, providing the structural change in the transmembrane domains that triggers intracellular G-protein activation. mGluRs



Glutamate Receptors, Fig. 3 Schematic representation of mGluR membrane topology (**a**) and diagram of the mGluR dimer (**b**). mGluRs contain large extracellular domains called the Venus flytrap domains (VFDs), which bind L-glutamate and other ligands. The cysteine-rich domain (CRD) links the VFD to the seven transmembrane domains (M1-7). The intracellular C-terminal domain (CTD) is often subject to alternative splicing to generate different C-terminal tails. The open state of the VFD is the inactive state and can be stabilized by antagonists. Schematic images were provided by Dr. Andrew Doherty

form dimers stabilized by an inter-subunit disulfide bond (Fig. 3b). Only mGluR subtypes coupled to the same G-protein can form heterodimers (Nicoletti et al. 2011). The binding of a single agonist per dimer is sufficient for receptor activation (Nicoletti et al. 2011). mGluRs are expressed by neurons and glia, where they locate in the proximity of the synaptic cleft. In neurons, mGlu1/5 are mostly localized postsynaptically, mGlu4/7/8 at the presynapse, while mGlu2/3 do not show any preference. mGlu6 is only expressed in retinal

bipolar cells postsynaptic to photoreceptors (Ferraguti and Shigemoto 2006). Proteins interacting with mGluRs include: 4.1 G, adenosine receptor A1, $Ca_v2.1$, Ca^{2+}-sensing receptor, calmodulin, caveolin-1/-2β, $GABA_{B1}$ receptor, filamin-A, G-protein βγ, GRIP, GRK2, ▶ homer, optineurin, pias1, PICK1, PKA, PKC, PP1γ1, PP2α, siah-1A, syntenin, tamalin, α/β-tubulin (Enz 2006).

Summary

While iGluRs are responsible for fast synaptic transmission, mGluRs modulate slow synaptic transmission through intracellular second messengers. Both iGluRs and mGluRs are critically important signaling molecules for normal brain function. They transduce the vast majority of excitatory neurotransmission and regulate the strength of both excitatory and inhibitory transmission in the CNS via complex interactions. Glutamatergic systems are dysfunctional in most neuropathologies, and aberrant receptor function appears to have causative roles in many neurological disorders. In addition to neurons, iGluRs and mGluRs have been identified in nonneuronal cells where they are involved in a broad range of signaling processes (Julio-Pieper et al. 2011). The full functional significance of these nonneuronal GluRs remains to be established. A confound in the study of GluRs has been the lack of congruence between the properties of recombinant receptors expressed in heterologous systems and those of native receptors studied in the brain tissue. This mismatch suggests that heterologously expressed receptors lack modulatory components that can influence essential properties. The discovery of auxiliary subunits for iGluRs (e.g., TARPS, NETO1/2; Traynelis et al. 2010), dimerization of mGluRs (Niswender and Conn 2010), various interaction partners (Enz 2006; Traynelis et al. 2010), phosphorylation/dephosphorylation (Molnár 2008), and other covalent modifications of GluRs has started to provide answers for many of these discrepancies. A better understanding of the specific functions and molecular interactions of native GluR subtypes and the development of more subtype/subunit-specific pharmacological tools are needed for future breakthroughs in the treatment of several neurological and psychiatric disorders.

Glutathione-*S*-Transferases: As Signaling Molecules

Thyaga Raju Kedam, Pallavi Chittoor and Divya Kurumala
Department of Biochemistry, Sri Venkateswara University College of Sciences, Tirupati, AP, India

Synonyms

GST; Gsto 1

Historical Background

The Glutathione-*s*-transferases exist as cytosolic, mitochondrial, and microsomal can participate in signal transduction by not phosphorylating any factor that is directly involved in cell growth and death. This signal transduction is considered to be a new way of implication in cell metabolic pathways due to the influence of external, such as xenobiotics and UV radiation, and internal, such as oxidative stress, free radicals, etc., agents. The GST binding assay studies revealed that they participate in the inhibition of various proteins, for example, phosphoproteins, AP-1, JNK, etc., in the systems to regulate cell mechanisms during cell synthesis.

Biomembranes and Signal Transduction

A biomembrane is an enclosing or separating membrane that acts as a selective barrier, within or around a cell. It consists of a lipid bilayer with embedded proteins that may constitute close to 50% of membrane content (Mark Latash 2007). It has a selective permeable structure, which is essential for effective separation of a cell or organelle from its surroundings. Biomembrane has certain mechanical or elastic properties. These membranes contain receptors on their surface and receive signals from various influences. During this process an extracellular signaling molecule activates a membrane receptor that in turn alters intracellular molecules creating a response (Silverthorn 2006) called signal trasduction. In signal transduction, the chemical signal binds to the outer portion of the transmembrane receptor, changing its shape and conveying another signal inside the cell. Some chemical messengers, like testosterone, can pass through the cell membrane, and bind directly to receptors in the cytoplasm or nucleus. Sometimes these chemicals can have cascade of amplified signals, so a small signal can result in a large response (Reece and Campbell 2002). Eventually, the signal creates a change in the cell, either in the expression of the DNA in the nucleus or in the activity of enzymes in the cytoplasm. These processes can take milliseconds (for ion flux), minutes (for protein and lipid mediated kinase cascades), hours, or days (for gene expression). In 1980, Martin Rodbell examined the effects of glucagon on a rat's hepatocyte membrane receptor and noted that guanosine triphosphate disassociated glucagon from this receptor, and stimulated the G-protein, which heavily influenced the cell's metabolism. Thus, he deduced that the G-protein was a transducer to accept glucagon molecules and affect the cell (Rodbell 1980). For this, he shared the 1994 Nobel Prize in Physiology/Medicine with Alfred G. Gilman. The current understanding of signal transduction processes reflects contributions made by Rodbell and many other research groups throughout the years.

Signal transduction involves the binding of extracellular signaling molecules, and intracellular signaling cascades can be started through cell–substratum interactions (Beato et al. 1996). Most of the chemicals have receptors within the cytoplasm and act by stimulating the binding of their receptors to the promoter region of their responsive genes (Hammes 2003). Examples of signaling molecules include the hormone melatonin (Sugden et al. 2004), the neurotransmitter acetylcholine (Kistler et al. 1982), the cytokine interferon γ (Schroder et al. 2004), environmental stimuli, and certain microbial molecules. All of these may be independent of signal transduction stimulation by other molecules, as is the case for the

toll-like receptor. It may occur with help from stimulatory molecules located at the cell surface of other cells, as with T-cell receptor signaling. Single-celled organisms may respond to environmental stimuli through the activation of signal transduction pathways. For example, slime molds secrete cyclic adenosine monophosphate upon starvation, stimulating individual cells in the immediate environment to aggregate (Hanna et al. 1984), and yeast cells use mating factors to determine the mating types of other cells and participate in sexual reproduction (Sprague 1991).

Receptors

Receptors can be roughly divided into two major classes: extracellular receptors and intracellular receptors.

Extracellular receptors are integral transmembrane proteins and make up most receptors. They span the plasma membrane of the cell, with one part of the receptor on the outside of the cell and the other on the inside. Signal transduction occurs as a result of a ligand binding to the outside; the molecule does not pass through the membrane. This binding stimulates a series of events inside the cell; different types of receptor stimulate different responses and receptors typically respond to only the binding of a specific ligand. Upon binding, the ligand induces a change in the chemical confirmation of the inside part of the receptor. These result in either the activation of an enzyme in the receptor or the exposure of a binding site for other intracellular signaling proteins within the cell, eventually propagating the signal through the cytoplasm.

Intracellular receptors include nuclear receptors and cytoplasmic receptors, and are soluble proteins localized within the nucleoplasm or the cytoplasm, respectively. The typical ligands for nuclear receptors are lipophilic hormones, with steroid hormones (e.g., testosterone, progesterone, and cortisol) and derivatives of vitamin A and D among them. To reach its receptor and initiate signal transduction, the hormone must pass through the plasma membrane, usually by passive diffusion. The nuclear receptors are ligand-activated transcription activators; on binding with the ligand (the hormone), the ligands will pass through the nuclear membrane into the nucleus and enable the transcription of a certain gene and, thus, the production of a protein. Intracellular signal transduction is by and large carried out by second messenger molecules.

Ca^{2+} concentration is usually maintained at a very low level in the cytosol by sequestration in the smooth endoplasmic reticulum and the mitochondria. The Ca^{2+} release from endoplasmic reticulum into the cytosol results in the binding of the released Ca^{2+} to signal proteins, which is then activated. Ca^{2+} is used in a multitude of processes, among them muscle contraction, release of neurotransmitter from nerve endings, vision in retina cells, proliferation, secretion, cytoskeleton management, cell migration, gene expression, and metabolism. The three main pathways that lead to Ca^{2+} activation are:

1. G-protein-regulated pathways
2. Pathways regulated by receptor-tyrosine kinases
3. Ligand- or current-regulated ion channels

There are two different ways by which Ca^{2+} can regulate proteins:

1. A direct recognition of Ca^{2+} by the protein
2. Binding of Ca^{2+} in the active site of an enzyme

One of the best-studied interactions of Ca^{2+} with a protein is the regulation of calmodulin by Ca^{2+}. Calmodulin itself can regulate other proteins, or be part of a larger protein (e.g., phosphorylase kinase). The Ca^{2+}–calmodulin complex plays an important role in proliferation, mitosis, and neural signal transduction. The response of cells to extracellular stimuli is in part mediated by a number of intracellular kinase and phosphatase enzymes (Hunter 1995). The mitogen-activated protein (MAP) kinases are members of discrete signaling cascades, which are focal points for diverse extracellular stimuli, and function to regulate fundamental cellular processes. Four distinct subgroups within the MAP kinase family have been described. These include (1) extracellular signal-regulated kinases (ERKs), (2) c-jun N-terminal or stress-activated protein kinases (JNK/SAPK), (3) ERK5/big MAP kinase 1 (BMK1), and (4) the p38 group of protein kinases. The JNK group of protein kinases is activated in response to a number of cellular stresses, including high osmolarity and oxidation (Ip and Davis 1998). The ERK5/BMK1 MAP kinase signaling pathway regulates serum-induced early gene expression (Kato et al. 1997). The p38 group kinases have been found to be involved in inflammation, cell growth, cell differentiation, the cell cycle, and cell death (New and Han 1998).

The JNK Signal Transduction Pathway

The c-Jun NH_2-terminal kinase (JNK) is a member of an evolutionarily conserved subfamily of mitogen-activated protein (MAP) kinases. Recent studies have led to progress toward understanding the physiological function of the JNK signaling pathway. Mitogen-activated protein (MAP) kinase signaling pathways relay, amplify, and integrate signals from a diverse range of extracellular stimuli, thereby controlling the genomic and physiological response of a cell to changes in the environment. In mammalian systems, these responses include cellular proliferation, differentiation, development, the inflammatory response, and apoptosis. The c-Jun NH_2-terminal kinase (JNK) represents one subgroup of MAP kinases that is activated primarily by cytokines and exposure to environmental stress. A major target of the JNK signaling pathway is the activation of the AP-1 (Activator protein-1) transcription factor that is mediated, in part, by the phosphorylation of c-Jun and related molecules. The JNK proteins are encoded by three genes such as *JNK1*, *JNK2*, and *JNK3*. Recent mutation study on mice has revealed that the JNK proteins are required for cell viability; however, they are required for cellular physiology.

Two protein kinases that activate JNK have been identified (▶ MKK4 and MKK7). During embryo development the modification of MKK4 alone causes death to hepatic cells but MKK7 is necessary for embryo viability (Davis 2000). Disruption of either MKK4 or MKK7 was found to cause partial defects in stress-stimulated JNK activation (e.g., ultraviolet light). In contrast, disruption of both genes prevented JNK activation by these stimuli (Tournier et al. 2001). Interestingly, MKK4 and MKK7 preferentially phosphorylate JNK on Tyr and Thr, respectively (Lawler et al. 1998) and both protein kinases are activated in response to environmental stress (Davis 2000). As dual phosphorylation of JNK on Tyr and Thr is required for full activation, it is likely that MKK4 and MKK7 cooperate to activate JNK in response to environmental stress. However, the roles of MKK4 and MKK7 are different in cells stimulated with cytokines. Treatment of cells with tumor necrosis factor (TNF) causes activation of MKK7, but not MKK4. Gene-knockout studies demonstrate that MKK7 is essential for TNF-stimulated JNK activation and that MKK4-deficiency causes some reduction in JNK activation (Tournier et al. 2001). Together, these data indicate that TNF stimulates MKK7 activity, that JNK activation is triggered by MKK7, and that the basal activity of MKK4 is required for full activation of JNK in response to TNF. In yeast, four groups of potential scaffold proteins that may coordinate JNK signaling modules have been reported: CrkII; filamin; β-arrestin; and JIP (JNK interacting protein). This can occur due to binary complex formation of JNK proteins. In Drosophila, the JNK signaling pathway is required for the morphogenetic process of dorsal closure (Davis 2000) with the help of the TGF-β family member Decapentaplegic (Dpp)-initiated elongation and migration of dorsal epithelial cells during dorsal closure.

The JNK signaling pathway has been implicated in many pathological conditions, including cancer, stroke, heart disease, and inflammatory diseases (Davis 2000). Drugs that inhibit JNK signaling may, therefore, be therapeutically beneficial. Furthermore, such drugs will facilitate research on JNK function. In addition, the JNK pathway participates in activating transcription factor 2, ELK-1, and the SAP-1a transcription factor, and JNK may influence p53 and NF-κB pathways (Beuckmann et al. 2000). Extracellular signals such as growth factors, transforming oncoproteins, and UV irradiation stimulate phosphorylation of c-Jun at ser-63/73 and activate c-Jun-dependent transcription. The binding of JNK to the N-terminal region of c-Jun permits substrate phosphorylation. This pathway has also been shown to be important in the control of cell survival and death pathways by the induction of apoptosis.

The p38 Signal Transduction Pathway

The p38 signaling transduction pathway, a Mitogen-activated protein (MAP) kinase pathway, plays an essential role in regulating many cellular processes including inflammation, cell differentiation, and cell growth and death. Activation of p38 often through extracellular stimuli, such as bacterial pathogens and cytokines, mediates signal transduction into the nucleus to turn on the responsive genes. p38 also transduces signals to other cellular components to execute different cellular responses.

Protein p38α (or simply p38) was first isolated as 38 kDa protein, which has specificity to phosphorylate

tyrosine in response to LPS stimulation (Han et al. 1994). Three p38 homologues of alpha, p38β, p38γ (or ERK6, SAPK3), and p38 δ (or SAPK4) are cloned in mammals. The p38α and p38β genes are ubiquitously expressed. However, p38γ and δ are differentially expressed in different tissues. p38γ is predominantly expressed in skeletal muscle (Lechner et al. 1996), and p38δ is enriched in lung, kidney, testis, pancreas, and small intestine. p38γ expression was reported to be induced during muscle differentiation and p38β expression was shown to be developmentally regulated (Lechner et al. 1996). An upregulation of the expression of p38 isoforms was observed in the inflammatory cell lineages. Sequence comparisons revealed that each p38 isoform has more than 60% identity within this group, but only 40–45% to the other MAP kinase family members.

p38 homologues have been identified and cloned in both low and high eukaryotic species, including fly, frog, and yeast. Their role has been implicated in osmoregulation, responses to extracellular stress stimuli, and cell cycle events. Mammalian p38δ are also activated by environmental stresses. Since mammalian p38 was identified in studies designed to understand signaling pathways during inflammation (Han et al. 1994), extensive data of p38 regulation have been developed in immune systems. p38 activation has been observed in inflammatory responses, as in LPS-treated macrophages (Han et al. 1994), TNF-stimulated endothelial cells, IL-17-stimulated chondrocytes, IL-18-stimulated U1 monocytic cell line, human platelets stimulated with thrombin, and chemotactic peptide *N*-formyl-methionyl-leucyl-phenylalanine (fMLP)-treated or phorbol myristate acetate (PMA)-treated human neutrophils.

MAP kinase–activated protein kinase 2 (MAPKAPK2 or M2) was the first identified p38α substrate. Subsequently, a closely related protein kinase, M3 (or 3pk), was also found to be a substrate of p38α. Moreover, activated M2 and 3 phosphorylate various substrates including small heat shock protein 27 (HSP27), lymphocyte-specific protein 1 (LSP1), cAMP response element-binding protein (CREB), ATF1, and tyrosine hydroxylase. The expression of many cytokines, transcription factors, and cell surface receptors was found to be coordinated by p38. The activation of the p38 pathway plays an essential role in: (1) Production of proinflammatory cytokines such as IL-1b, TNF-a, and IL-6; (2) induction of enzymes such as COX-2, which controls connective tissue remodeling in pathological condition; (3) expression of an intracellular enzyme such as iNOS, which regulates oxidation; and (4) induction of adherent proteins such as VCAM-1 and many other inflammatory-related molecules. In addition to these, the p38 pathway plays a regulatory role in the proliferation and differentiation of cells of the immune system.

Protein Kinase C (PKC)

Protein kinase C was originally identified as a serine/threonine kinase that was maximally active in the presence of diacylglycerols (DAG) and calcium ion. It is now known that there are at least ten proteins of the PKC family. Each of these enzymes exhibits specific patterns of tissue expression and activation by lipid and calcium. PKCs are involved in the signal transduction pathways initiated by certain hormones, growth factors, and neurotransmitters. The phosphorylation of various proteins, by PKC, can lead to either increased or decreased activity. Of particular importance is the phosphorylation of the EGF receptor by PKC, which downregulates the tyrosine kinase activity of the receptor. This effectively limits the length of the cellular responses initiated through the EGF receptor.

Glutathione-*S*-Transferase

Glutathione transferases (EC 2.5.1.18; GSTs) are members of a multigene family of isoenzymes ubiquitously expressed in most living organisms. GSTs are a family of Phase II detoxification enzymes that catalyze the conjugation of glutathione (GSH) to a wide variety of xenobiotics. This detoxification ability plays a role in cellular protection from environmental and oxidative stress, yet is also implicated in cellular resistance to drugs. Advances in the molecular biology of the GSTs over the past several years have revealed a broader role for these enzymes. Indeed, GSTs have been found to be involved in the biosynthesis and metabolism of prostaglandins (Beuckmann et al. 2000), steroids, and leukotrienes; in the management of toxic products of lipid oxidation and *S*-glutathiolated proteins generated by oxidative stress (Ruxana Begum and Kedam 2010); and in the acquisition of resistance to chemotherapeutic agents (Tew 1994).

The GST proteins are also extensively involved in the control of ►ROS species, which can cause

oxidative stress. Excess free radicals are formed in many ways, for example, trauma, medications, metabolism of lipids, etc., and can create a potentially dangerous and unstable cellular environment, linked to pathology of tissue damage, degenerative diseases such as Parkinson's, and accelerated aging. Steroid hormone synthesis has also been linked to GST activity, where GST catalysis is in part responsible for progesterone and testosterone synthesis. Membrane bound GSH transferases (mitochondrial) are more active and specific for leukotriene synthesis.

Three major families of GST proteins are: (1) cytosolic, (2) mitochondrial, and (3) microsomal (also referred to as membrane-associated proteins in eicosanoid and glutathione (MAPEG)), of which the cytosolic GSTs constitute the largest family (Hayes et al. 2005). On the basis of amino acid sequence similarities, substrate specificity, and immunological cross-reactivity, seven classes of cytosolic GSTs have been identified in mammals (Board et al. 2000). These classes are designated by the names of the Greek letters α (*alpha*), μ (*mu*), π (*pi*), σ (*sigma*), θ (*theta*), ω (*omega*), and ζ (*zeta*), and abbreviated in Roman capitals A, M, P, S, T, O, and Z. The mammalian GSTs, such as cytosolic, mitochondrial, and microsomal forms, each of which displays distinct catalytic as well as non-catalytic binding properties are given below:

Cytosolic	Soluble, predominantly found in the cytosol of hepatocytes. Highly polymorphic
Mitochondrial	Soluble
Microsomal	Come to be known as "MAPEG" – membrane-associated proteins in eicosanoid and glutathione metabolism. GST1-3. These enzymes form part of a larger super family of small membrane proteins, additional members being leukotriene C_4 synthase and 5-lipoxygenase-activating protein. Largely involved in eicosanoid synthesis. Six identified to date

Cytosolic and mitochondrial forms are soluble enzymes sharing similarities in 3D structure, but share no resemblance with microsomal forms. Cytosolic GSTs, the most studied of the GSTs, were originally defined based on their substrate/inhibitor specificity.

Most GST classes show a high degree of polymorphism and include several subunits. Each subunit with 199–244 amino acids in length, and 22–29 kDa mass, contains a catalytically independent active site that consists of a GSH-binding site ("G-site") in the amino-terminal domain and a site that binds the hydrophobic substrate ("H-site") in the carboxy-terminal domain. More than a dozen cytosolic GST subunits have been identified in humans. As the functional enzymes are dimeric, and those of α and μ classes, in addition to homodimers, can also form heterodimers, the number of isoenzymes that can be generated from these subunits is significantly larger. The isoenzymes are named according to their class and subunit composition, with each subunit designated by an Arabic numeral (e.g., GSTA1-2 denotes the enzyme composed of subunits 1 and 2 of α class). Expression of the different classes of GSTs varies among tissues and with developmental stage. For example, α-class GSTs are predominantly expressed in liver, testis, and kidney and their expression levels are similar in both adult and fetal tissues. In contrast, GSTπ (GSTP1-1), originally isolated from placenta, is found mainly in brain, lung, and heart; its expression in liver decreases during embryonic development, becoming very low in adult tissue and expressed on phenobarbitol treatment in hepatocyte of rat.

Alpha Class

The GSTα isoform is mainly expressed in the liver and is encoded by a gene cluster localized on chromosome 6p12. This cluster contains five genes encoding proteins belonging to GSTA1–A5. Human tissues widely express transcripts for GSTA1, A2 and A4, whereas expression of GSTA3 is rare and GSTA5 has yet to be detected in human tissues. Epidemiological results show that aberrant expression of GSTα has been linked to an increased risk in colorectal cancer, ovarian cancer, and clear cell renal cell carcinoma. The GSTA1 gene contains seven exons and is ~12 kb in length. A genetic polymorphism of GSTA1 is characterized by two alleles, GSTA1*A and GSTA1*B. These alleles differ in promoter regions based on three linked single nucleotide substitutions at positions −567, −69, and −52. Specifically, the −52 substitution has been shown to increase promoter activity in GSTA1*A, thus making it predominantly expressed. Coles et al. (2001) previously showed a correlation between GSTA1*B expression and an increased risk of colorectal cancer. However, as with many such published accounts, other groups have recently reported conflicting evidence

finding no association between GST expression and susceptibility to colorectal cancer. GSTA2 has not been extensively studied, but it is known to have several variants (GSTA2*A–E). The catalytic properties of GSTA2 variants A–D do not seem to differ; however, the novel variant GSTA2E shows reduced rates of catalysis when compared to A–D. This may be due to substitution of the highly conserved Pro residue. GSTA3 is selectively expressed in steroidogenic tissues and plays a role in steroid hormone biosynthesis. Three GSTA3 transcripts have been identified and found exclusively in African populations. Polymorphisms in GSTA3 may affect steroidogenesis through altered protein levels or function, and it has recently been hypothesized that alterations in genes involved in steroidogenesis and sex steroid metabolism could potentiate risk factors for the development of ovarian cancer.

Omega Class

The Omega class of GSTs contains two functional members, GSTO1 and GSTO2, and a pseudogene (GSTO3p). Based on two defining features, the Omega class is both structurally and functionally distinct from other eukaryotic GSTs (Townsend et al. 2003). This protein on X-ray crystallography shows a unique 19-residue N-terminus extension that forms a structural unit quite unlike any found in other classes. At present, its function remains undefined (Board et al. 2000) and known substrates of other GSTs are not catalyzed by GSTO.

GSTO1 is a single gene located on chromosome 10 that codes for GSTO1 proteins expressed abundantly in the liver, macrophages, glial and endocrine cells. To date, four polymorphisms have been identified, GSTO1*A–D. Among the Australian, African, and Chinese populations, GSTO1*A was the most prevalent haplotype with a frequency ranging from 0.6 to 0.9, whereas GSTO1*B*A was the least common, with a frequency of 0.01–0.05. GSTO1*A demonstrated a GSH-dependent reduction of dehydroascorbate, a function characteristic of glutaredoxins rather than GSTs (Board et al. 2000). This allele was first described as the human monomethylarsenic acid reductase, (MMA [V]), and is the rate-limiting enzyme of inorganic arsenic metabolism. GSTO2, while separated from GSTO1 by 7.5 KB on chromosome 10, shares 64% amino-acid identity. GSTO2, like GSTO1, is ubiquitously expressed and shares GSH-dependent dehydroascorbate reductase activity. However, GSTO2 has a high catalytic activity toward CDNB, and its over expression induced apoptosis, suggesting a possible role in cell signaling (Wang et al. 2005). This is the first report made on cell signaling by GSTs.

Zeta Class

The Zeta class (GSTZ1) is a single 10.9 KB gene located on chromosome 14 that codes for a 29-kDa protein. GSTZ1 was independently characterized as maleylacetoacetate isomerase (MAAI) and plays a putative isomerase role in the catabolic pathway of phenylalanine and tyrosine in addition to the GSH-dependent transformation of α-halogenated acids. GSTZ1 is preferentially expressed in hepatocytes and renal proximal tubule cells where phenylalanine and tyrosine are catabolized.

GSTZ1-deficient mice have an elevated urinary excretion of FAA (Free amino acid) and were subject to renal injury following phenylalanine and tyrosine overload. Four families have been identified that lack GSTZ1 members that were died within the first year of life. Whereas the clinical data for GSTZ1 are insufficient to deduce a role for GSTZ1 in inherited genetic disease, it is plausible that a perturbation in GSTZ1-mediated tyrosine metabolism is contributory to the described pathology. Whether this tyrosine undergoes signal mechanism is not known.

Mu Class

Five GST isoforms belonging to the mu class (GSTM1–5) have been described. A gene cluster located on chromosome 1 encodes for GSTM1–5. The GSTM1 gene contains four different alleles allowing for several M1 class polymorphisms. GSTM1*A and M1*B are functionally identical and differ at K173N amino-acid substitution (McLellan et al. 1997). The presence of the GSTM1*A allele has been associated with a decreased risk of bladder cancer with the implication that detoxification of possible bladder-specific carcinogens may occur in these individuals. In addition McLellan et al. (1997) described a rapid enzyme activity phenotype in Saudi Arabian individuals attributed to a tandem M1 gene duplication resulting in two functional M1 genes. It was inferred that this rapid detoxification phenotype could have an increased protective effect against carcinogens.

Loss of GSTM enzyme function is ascribed to a homozygous deletion of this gene resulting in the GSTM1*0 allele. It has been suggested that the

mutation is a result of an unequal crossing-over of the M1 and M2 loci which are in close physical proximity and share 99% nucleotide sequence identity. The frequency of GTSM1*0 individuals is approximately 67% in Australians, 50% in Caucasians, and 22% in Nigerians. The GSTM null phenotype is associated with an increased risk of the lung, colon, and bladder cancer and has also been associated with response rates to some chemotherapy. Cytosolic prostaglandin E was purified from the human brain and characterized as GSTM2 (Beuckmann et al. 2000). The GSTM2*B allele has been shown to catalyze the conjugation of GSH to aminochrome, a redox cycling product of dopamine. Products formed during the redox cycling of catecholamines (such as dopamine) contribute to the processes involved in neurodegenerative diseases such as Parkinson's disease and schizophrenia; therefore, GSTM2*B may play a cytoprotective role in neurodegeneration.

The GSTM3 locus contains two alleles, A and B. The GSTM3*B allele has a three base pair deletion in intron 6 that introduces a recognition motif for the transcription factor YY1. GSTM3*A and *B are expressed in the brain; yet, there appears to be no direct relationship between GSTM3 expression and the incidence of astrocytomas. The GSTM3*AA genotype is associated with an increased risk for laryngeal squamous cell carcinoma, whereas GSTM3*BB was putatively protective. In addition, GSTM3*AA was shown to occur more frequently in patients with multiple cutaneous basal cell carcinoma than GSTM3*BB. The roles of GST M-4 and GST M-5 were not known.

Theta Class

The Theta class of GSTs consists of two different subfamilies: GSTT1 and GSTT2. Genes encoding both proteins are colocalized on chromosome 22 and are separated by 50 kb. Polymorphisms exist between these two and within both genes including a null phenotype (GSTT1*0) that exhibits decreased catalytic activity and has been associated with an increased risk of cancers of the head, neck, and oral cavity (Strange and Fryer 1999).

GST Pi

The GST Pi class is encoded by a single gene spanning approximately 3 kb and located on chromosome 11. In this group, four active, functionally different polymorphisms (GSTP1*A–D) have been identified. The GSTP1 genotype has been associated with differences in chemotherapeutic response and cancer susceptibility and is over expressed in a wide variety of tumors including ovarian, NSCLC, breast, colon, pancreas, and lymphoma (Tew 1994). Although it is well established that GSTπ is over expressed in a wide variety of solid tumors, prostate cancer is the only example in which the absence or reduced expression of GSTπ is associated with tumor incidence. GSTπ is widely expressed in normal prostate tissue; however, its presence is undetectable in malignant cells. Studies examining the absence of GSTπ in human prostate cancer show that hypermethylation of the GSTπ regulatory region is the most common somatic alteration identified. This alteration results in the loss of GSTπ expression and is proposed to occur during pathogenesis of the disease. Recently, a methyl-CpG binding domain protein has been identified that mediates hypermethylation of the GSTπ regulatory region. These findings provide a possible target for restoration of GSTπ activity. So the expression of GST proteins is independent on the concentration of each class GST protein in any tissue. GST expression (and/or activity) of specific isoforms is lost in some individuals with allelic variation.

Recently, Dang et al. (2005) examined the effect of GSTP1 on the survival and proliferation of human colon cancer cells. GSTP1 wild type and deficient colon cancer cells were grown under serum deprivation and low-density seeding conditions, and cellular apoptosis, oxidative stress, and kinase signaling were examined. Lack of GSTP1 expression resulted in an increase in cellular oxidative stress and resulted in apoptosis when cells were cultured under growth-limiting conditions. In addition, the presence of GSTP1 was essential for the mediation of MAPK kinase and ERK kinase signaling. GSTP1 plays a critical role in protection from cell cycle arrest and oxidative stress under growth-limiting conditions.

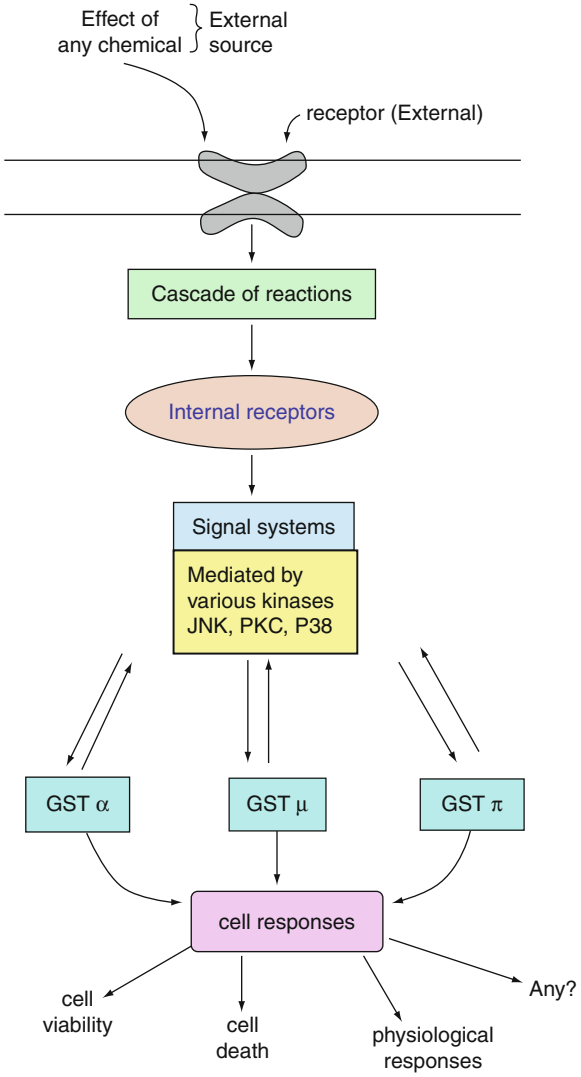
GSTs as Signaling Molecule

GSTs comprise a multigene family, of which GSTp is the most prevalent and ubiquitous non-hepatic isozyme. Recently, GSTs have also been shown to act as modulators of signal transduction pathways that

control cell proliferation and cell death. Because of their cytoprotective role and their involvement in the development of resistance to anticancer agents, GSTs have become attractive drug targets. Among cellular functions attributed to GSTs is ligand binding and xenobiotic detoxification (Tew 1994). Reduced glutathione (GSH) binds to the "G" site of GSTp (and other GST isozymes) and plays an important role in detoxification of reactive oxygen species (ROS) and the maintenance of the cellular redox state. Among factors implicated in regulating JNK activity are ROS and altered redox potential. ROS have also been associated with regulation of other signaling cascades, for example, certain isozymes of protein kinase C and mitogen-activated protein kinase. The addition of exogenous oxidants or antioxidants has been found to influence the activation of MAPK/JNK.

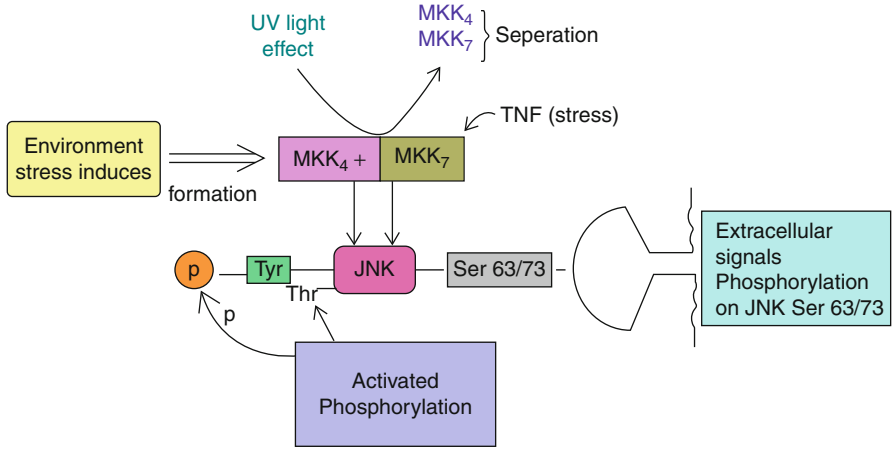
It has been speculated that the absence or decreased expression of GSTπ results in a reduced detoxification of possible carcinogens that may be causal to malignant transformation and disease progression. In addition, the GST-mediated conjugation of GSH to a number of anticancer drug substrates has long been linked to anticancer drug resistance in a variety of tumors. A disparity of this is that GSTπ has a weak affinity for the majority of anticancer drugs, although its increased expression is highly correlated with multidrug resistance. From this it can be inferred that the capacity of GSTs to regulate kinase-dependent proliferation pathways, especially in the case of GSTπ, may be of more consequence than its catalytic properties alone.

GSTs play a regulatory role in cellular signaling by forming protein–protein interactions with critical kinases involved in controlling stress response, apoptosis, and proliferation. The ligand-binding capacity of GST results in the negative regulation of signaling pathways through sequestration of signaling kinases. The first example of GST-mediated kinase regulation is the characterization of GSTπ as a Jun kinase (JNK) inhibitor (Adler et al. 1999). JNK has been implicated in proapoptotic signaling and may be required for the induced cytotoxicity of a variety of chemotherapy agents. Phosphorylation of c-Jun activates JNK resulting in subsequent activation of downstream effectors. In non-stressed cells, low JNK1 catalytic activity is orchestrated and maintained through its sequestration within the protein complex that includes at least GSTπ and JNK (Adler et al. 1999). However,



Glutathione-S-Transferases: As Signaling Molecules, Fig. 1 GSTs as signaling molecules model made from the work of Adler et al. 1999

under conditions of oxidative or chemical stress, a dissociation of the GSTπ–JNK complex occurs releasing GSTπ for oligomerization, and activation of released JNK allows for the subsequent induction of apoptosis (Fig. 1). The high levels of GSTπ in many tumors may be a consequence of an acquired dependence on the protein. Because of the proliferative nature of tumor cells, many kinase pathways are deregulated, and as a consequence, tumor cells may attempt to compensate by enhancing expression of GSTπ in an attempt to control kinase activity.



Glutathione-S-Transferases: As Signaling Molecules, Fig. 2 JNK phosphorylation based on the work of Dorion et al. 2002

Under non-stressed conditions, GSTπ inhibits JNK phosphorylation by sequestering JNK/c-Jun. Exposure to anticancer drugs or oxidative stress can alter the redox potential of the cell resulting in the oligomerization of GSTπ and the dissociation of the GSTπ–JNK complex. JNK can then become phosphorylated and subsequently activate downstream kinases and transcription factors. In some cases, transient or low exposure to stress can induce cell proliferation. During prolonged or high exposure, apoptosis can be induced.

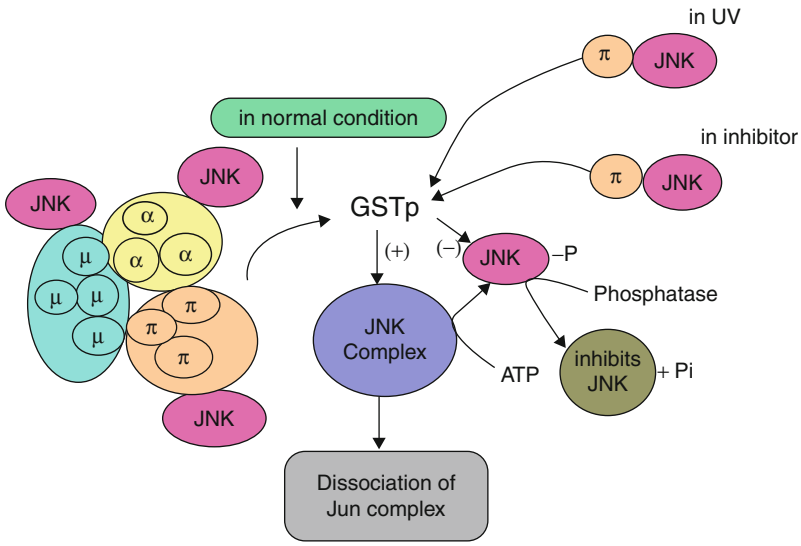
Another example of GST-mediated kinase regulation is evidence that GSTM1 binds to and inhibits the activity of ASK1 (apoptosis signal-regulating kinase). ASK1 is an MAP kinase that activates the JNK and p38 pathways leading to cytokine- and stress-induced apoptosis. ASK1 is activated in response to oxidative stress and heat shock. Under normal conditions, ASK1 exhibits low activity because of its sequestration via GSTM1. This protein–protein interaction forms a GSTM1–ASK1 complex, which is dissociated under stressful conditions leading to the release and activation of ASK1 (Fig. 2) (Dorion et al. 2002).

This mechanism is similar to the one proposed for GSTπ–JNK. In conditions, such as oxidative stress or heat shock, GSTM1 oligomerizes allowing for the release of ASK1 and subsequent induction of apoptosis (Dorion et al. 2002). GSTM1 plays a regulatory role in the heat shock–sensing pathway, while thioredoxin plays a regulatory role in the oxidative stress–sensing pathway that leads to p38 activation. Impaired clinical response to therapy in a variety of tumor types has been associated with an altered expression of GSTM1. Thus, any enzymatic influence GSTM1 plays in anticancer drug resistance is only further augmented by its role in kinase regulation.

GSTμ and thioredoxin (Trx) can act as inhibitors of ASK1. Stresses such as heat shock or reactive oxygen species can result in the release of ASK1 from the GSTμ–ASK1 or TRX–ASK1 complex (respectively). ASK1 oligomerizes and is activated through autophosphorylation, which in turn activates downstream kinases such as ▶ MKK4/MKK7, MKK3/MKK6, JNK, and p38. The fate of the cell (either proliferation or apoptosis) is dependent upon the time/concentration exposure to the stress.

Forced expression of GSTM1 blocked ASK1 oligomerization and repressed ASK1-dependent apoptotic cell death. GST-mediated regulation of the kinase pathways adds a new dimension to their known role in metabolism and cellular homeostasis.

In addition to acting as a negative regulator of kinase activation, GSTπ has also been shown to play a necessary role in the glutathionylation of 1-cys peroxiredoxin (1-cysPrx). Oxidation of the catalytic cysteine of 1-cysPrx has been associated with its loss of peroxidase activity. Recently, it was shown that heterodimerization of 1-cysPrx with GSTπ mediates the glutathionylation of the previously oxidized cysteine thus restoring its peroxidase activity. From this study, it was concluded that the glutathionylation and subsequent GSH-mediated reduction of 1-cysPrx requires heterodimerization with GSTπ. This provides the first example in which GSTπ functions in the glutathionylation of oxidized cysteine residues.



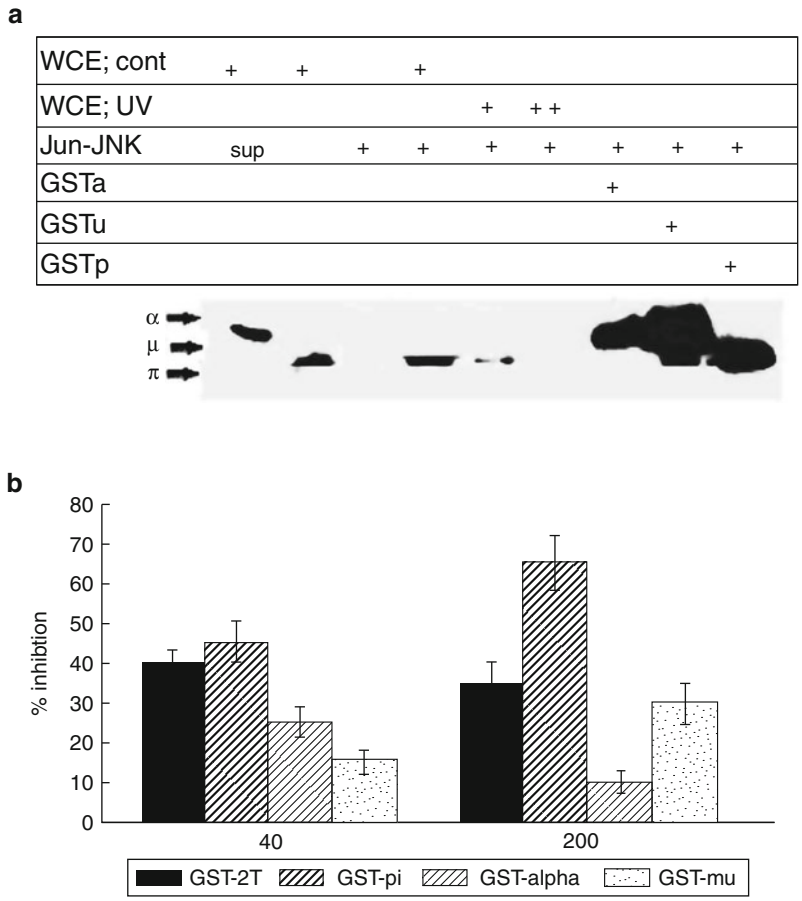
Glutathione-*S*-Transferases: As Signaling Molecules, Fig. 3 Mechanism of GSTp on JNK complex (+ effect; − no effect). (**a**) GSTp as a JNK inhibitor. GSTp was added at the indicated concentrations (micrograms) to the preformed Jun–JNK complex and the level of Jun phosphorylation was measured by means of autoradiography (Courtesy from Ishibashi group 1992). (**b**) To measure the effect of GSTp on JNK phosphorylation, JNK was immunoprecipitated from UV-treated cells and incubated with GSTp followed by Western blot with antibodies to phospho-JNK. (**c**) As a positive control, JNK from UV-treated cells was incubated with no protein, dual specificity phosphatase (Ishibashi et al. 1992), or GSTp before carrying out immunoblot analysis with antibodies to phospho-JNK. Quantification via densitometer scanning revealed 35% inhibition of JNK phosphorylation by PP, whereas GSTp did not elicit such inhibition. (**d**) The immunoblot study has revealed that the c-Jun phosphorylation level after incubation with the inhibitor for the indicated time periods (minutes) cannot be altered by the GSTp protein. So from a, b, c, and d it is known that GSTp has role but phosphorylation of JNK is mediated by other kinases

In addition, Townsend et al. (2003) have found that cells deficient in GSTP1-1 and/or GSTP2-2 have a reduced capacity to respond to oxidative or nitrosative stress by enacting glutathionylation of a select group of target proteins. These findings imply that GSTπ may play a direct role in control of post-translational glutathionylation reactions.

To determine whether GSTp affected the degree of JNK or Jun phosphorylation, increasing concentrations of GSTp (purified form) were added to preformed Jun–JNK complex, which contained the phosphorylated form of JNK, obtained from UV-treated cells. GSTp decreased JNK phosphorylation of c-Jun in a dose-dependent manner (within a range of 0.05–1 mg), but it did not decrease the number of phosphate groups on JNK, as revealed by immunoblots with phospho-JNK antibodies. Dual activity protein phosphatase (Ishibashi et al. 1992) was used as a positive control in these reactions.

To determine whether GSTp affects the number of phospho groups on c-Jun, cellular extracts from normally growing cells were incubated with preformed Jun–JNK complex for the indicated periods of time before or after the phosphorylation step with [g-32P] ATP. The extent of c-Jun phosphorylation was not altered when cell extracts were added after the phosphorylation reaction. This observation suggested that GSTp did not reduce the number of phospho groups on c-Jun (Fig. 3).

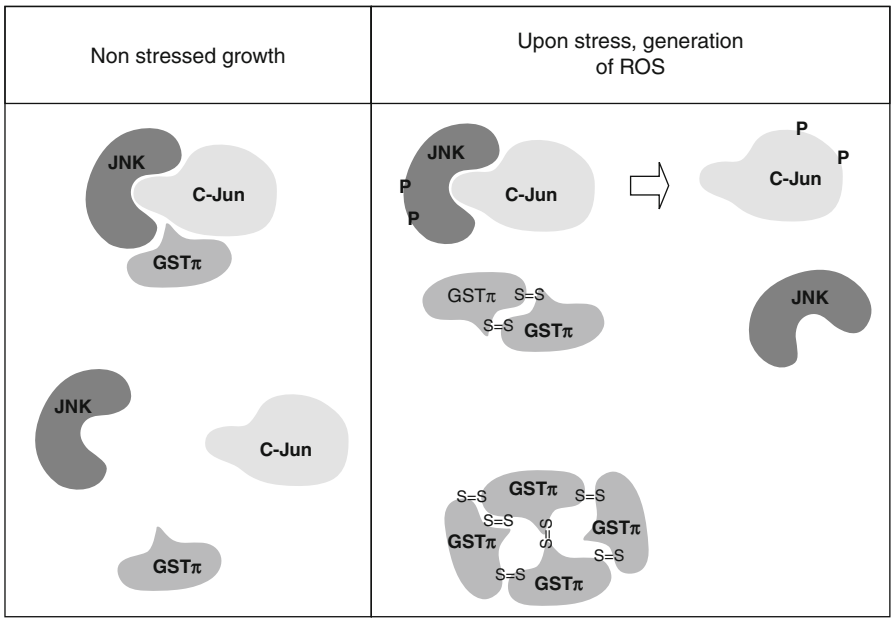
Later incubation of whole-cell extract prepared from unstressed mouse fibroblasts with the his Jun–JNK complex identified GSTp as the associated protein. A marked decrease in this association was found in proteins prepared after UV irradiation. In addition to GSTp, isozymes of the GSTα and GSTμ families were also capable of associating with the Jun–JNK complex in vitro. GSTp exhibited greater JNK inhibitory activity than did GSTμ, which was more potent than GSTα (Fig. 3b). Bacterially expressed GST (GST-2T) also mediated JNK inhibition. This excludes the possibility that the inhibitor activity was dependent on any putative GST-associated cellular component (Fig. 4a).



Glutathione-*S*-Transferases: As Signaling Molecules, Fig. 4 (**a**) GSTp associates with Jun–JNK in vitro. The preformed Jun–JNK complex was incubated with whole-cell extract (10 mg) prepared before (WCE cont) or after (WCE UV) UV irradiation or with purified forms of GST isozymes (Ciaccio et al. 1991), as indicated. Following extensive washes, complex-bound and non-bound (absorbed on Jun–JNK; sup) material was analyzed on immunoblots with polyclonal antibodies that recognize multiple forms of GST (Ramgamaltha and Tew 1991). *Arrows* point to the identified forms of GSTp. (**b**) Effect of different GST isozymes on JNK activity. Preformed his Jun–JNK was incubated with the indicated forms of GST (α, α; μ, μ; p, p; 2T, bacterially produced form of GST) purified as described in Materials and methods before the addition of [g-32P]ATP. Autoradiography demonstrates the degree of c-Jun phosphorylation in the presence of various GSTs

Ciaccio et al. study, as conducted above, has revealed that GSTp in different forms can associate with JNK proteins and in the presence of inhibitor α, μ and π GSTs are associated more as indicated by antibody interaction studies (Fig. 4a).

Changes in ROS affect GST oligomerization and its association with, and inhibition of, JNK were next assessed whether modulation of the cellular redox potential would affect JNK inhibition by GSTp. Further they monitored the GST–JNK complex in vivo by means of immunoprecipitation followed by immunoblot analysis. Exposure of mouse fibroblast cells to either UV or H_2O_2 reduced the amount of the JNK–GSTp complex and increased JNK activity, whereas pretreating cells with the free radical scavengers *N*-acetylcysteine (NAC) or the ethyl-ester of glutathione (eeGSH) prevented JNK dissociation from GSTp and maintained GSTp inhibitory activity. GST–JNK–Jun association is inversely correlated with JNK activity. Only the monomeric form of GSTp was capable of mediating efficient inhibition of JNK phosphorylation of c-Jun. GSTp inhibition of JNK is due primarily to their association, which is released upon the conversion of GSTp from a monomer to a dimer form.



Glutathione-*S*-Transferases: As Signaling Molecules,
Fig. 5 Modification of GST proteins on their association and dissociation upon binding with various proteins (Courtesy from Tew 1994)

Since JNK efficiently targets the ubiquitination of its nonphosphorylated associated proteins c-Jun, ATF2, and p53, we determined the possible effects of GSTp on ubiquitination of JNK substrates in this reaction. Under non-stress growth conditions, c-Jun exhibits a short half-life, which is prolonged upon phosphorylation by JNK (Musti et al. 1997). Transfection of GSTp cDNA into 3T3 mouse fibroblasts increased the level of c-Jun ubiquitination in vivo. Since the level of ubiquitinated Jun is inversely correlated with its degree of phosphorylation (Musti et al. 1997), the increase in ubiquitinated c-Jun is an expected result of the GSTp inhibition of basal JNK activity, which reduces the number of c-Jun molecules that undergo phosphorylation. The noticeable increase in ubiquitinated c-Jun molecules provides an example of the physiological significance of JNK inhibition under normal growth conditions.

Model of GST inhibition on JNK signaling, based on Tew's (1994) findings, is proposed as follows (Fig. 5): under non-stressed conditions, GSTp can be free or part of a complex with Jun–JNK. Upon stress, in which ROS are formed, GSTp forms dimers and larger aggregates which cannot accommodate Jun–JNK, thus enabling JNK phosphorylation of c-Jun, which as a result is a stable and active transcription factor.

The link between GSTs and the MAP kinase pathway provides a rationale as to why many of the selecting drugs are neither subject to conjugation with GSH, nor substrates for GSTs (Tew 1994). Many anticancer agents induce apoptosis via activation of the MAP kinase pathway, specifically via JNK and p38 (Davis 2000). Elevated levels of GST are associated with increased resistance to apoptosis initiated by a variety of stimuli (Cumming et al. 2001).

Aberrant cellular signaling is also a hallmark of the malignant phenotype, and thus high levels of GSTπ in many tumors may be either a cause or effect of the transformation process. The pathology of prostate cancer strongly supports these conclusions. Hypermethylation of the GSTπ regulatory region is the most common somatic alteration identified in human prostate cancer (Lin et al. 2001). This alteration results in the loss of GSTπ expression, and is proposed to occur during pathogenesis of the disease. Recently, a methyl-CpG-binding domain (MBD) protein that mediates hypermethylation of the GSTπ regulatory region has been identified. These findings provide a possible target for restoration of GSTπ activity. GST expression and/or activity of specific isoforms are lost in some individuals with allelic variation. Although it has been speculated that reduced detoxification of possible carcinogens may be causal to malignant transformation and disease progression, a more plausible link may be through an altered capacity to regulate kinase-dependent proliferation pathways.

As GST isozymes (in particular GSTπ) are frequently upregulated in many solid tumors and lymphomas, prodrugs activated by GST-mediated catalysis

have become a viable drug design concept. Additionally, the regulatory properties of GSTπ in kinase cascades have provided a translational opportunity to target GSTs in myeloproliferative pathways, with the consequent clinical testing of new agents in myelodysplastic syndrome.

Conclusion

The first GST described was originally identified as "ligandin" due to its ability to interact covalently and noncovalently with various compounds that are not substrates for enzymatic activity, including steroids, thyroid hormones, bile acid, bilirubin, and heme (Danielson and Mannervik 1985). While the ligand-binding function remains unclear, sequestering molecules may serve a regulatory role, preventing cytotoxic ligands from interacting with their targets. Supporting this conclusion, recent studies have demonstrated a regulatory role for the π and μ classes of GSTs in the mitogen-activated protein (MAP) kinase pathway that participates in cellular survival and death signaling.

Synonyms

Adenomatous polyposis coli; APC; Casein kinase-I; CK-I; EMT; Epithelial to mesenchymal transition; GSK-3; Glycogen synthase; GS; Phosphoinositide 3-kinase; PI3K; PKB; Protein kinase B/Akt

Historical Background

Glycogen synthase kinase-3 (GSK-3) is a highly conserved protein-serine/threonine kinase that was first isolated from skeletal muscle in 1980 as one of five enzymes capable of phosphorylating glycogen synthase (Embi et al. 1980). In resting tissues, GSK-3 phosphorylation inhibits glycogen synthase, the rate-limiting enzyme of glycogen synthesis. In subsequent work, insulin was found to cause inactivation of GSK-3 (via induction of PKB/Akt) and this relieves the suppression of glycogen synthase, leading to enhanced glucose conversion into glycogen in response to insulin. In mammals GSK-3 is encoded by two genes that generate highly related proteins termed GSK-3α and GSK-3β that have molecular masses of 51 and 46 kDa, respectively. In brain, the *GSK-3β* gene is alternatively spliced to generate a version with a 13 amino acid insert termed GSK-3β2. In addition to its initial role in glycogen metabolism, GSK-3 has since been demonstrated to regulate many cellular processes by suppressing substrates and to be regulated itself by several upstream pathways. As exemplified by insulin, extracellular signal-dependent control of GSK-3 then relieves its blockade and allows targets to become active. Hence, this protein kinase acts as a regulatory switch that throttles the flux through numerous signaling pathways initiated by diverse stimuli (reviewed in: Forde and Dale 2007; Doble and Woodgett 2007). Deregulation of GSK-3 has been implicated in the development of cancer, diabetes, Alzheimer's disease, schizophrenia, and bipolar disorder. Indeed, GSK-3 is a validated target of lithium, which is frequently prescribed to patients with bipolar disorder (Klein and Melton 1996). Given its involvement in many pathophysiological processes, GSK-3 is a tempting therapeutic target and several pharmaceutical companies have active GSK-3 inhibitor discovery programs. However, its proclivity for involvement in multiple pathways also raises issues of selectivity. It is therefore imperative to assess the full spectrum of GSK-3 cell functions to predict clinical efficacy and avoid surprises.

Signaling Pathways Involving GSK-3

▶ *Phosphoinositide 3-kinase* (▶ *PI3K*): The first pathway biochemically shown to directly regulate GSK-3 activity was ▶ phosphoinositide 3-kinase (▶ PI3K). This pathway is induced by a wide variety of stimuli, including insulin and polypeptide mitogens. Activating mutations in ▶ PI3K are frequently observed in human cancers and inactivation of ▶ PTEN, the lipid phosphatase that reverses the action of ▶ PI3K, is also found, albeit less commonly, in tumors (and is responsible for the cancer predispositions of Cowden's disease). ▶ PI3K activation of PKB/Akt leads to phosphorylation of GSK-3α and β at serine 21 and 9, respectively, leading to their partial inactivation. Although rarely mutated in human cancers, PKB/Akt was first identified as an oncogene. Cancer-associated ▶ PI3K mutations have also been linked to activation

of serum and glucocorticoid-activated kinase 3 (SGK3), which also phosphorylates GSK-3. ▶ p38 mitogen-activated protein kinase (p38 MAPK) can also inactivate GSK-3β via phosphorylation of Ser389 and Thr390 and this mode of regulation has been observed in neurons and thymocytes (Thornton et al. 2008).

Cyclic AMP: This second messenger is induced primarily in response to seven-transmembrane pass receptors that signal through G proteins that couple to ▶ adenylyl cyclase, as exemplified by the β-adrenergic/epinephrine receptors. Generated cyclic AMP binds to the regulatory subunits of cyclic AMP-dependent protein (PKA), causing dissociation from and relief of inhibition of the catalytic subunits. These phosphorylate a number of substrates, including GSK-3α and β at the same sites as PKB/Akt (Li et al. 2000). Complicating matters further, certain other protein-serine kinases such as p70 S6 kinase (S6K) are also capable of phosphorylating GSK-3 at these same sites.

Wnt: The canonical Wnt pathway acts primarily by raising cytoplasmic levels of β-catenin that then translocates to the nucleus to regulate gene expression in concert with LEF/TCF DNA-binding proteins. In unstimulated cells, cytoplasmic β-catenin levels are kept very low via phosphorylation by GSK-3 at three residues that target the protein for ubiquitinylation by the E3 ligase, βTrCP and subsequent destruction by the 26S proteasome. A small fraction (<10%) of cellular GSK-3 (α and β) and a priming kinase (casein kinase 1; CK1) are specifically associated with a "destruction complex" that comprises the adenomatous polyposis coli (APC) tumor suppressor and the Axin scaffolding protein. This complex constantly recruits newly synthesized β-catenin and targets it for degradation. In the presence of a suitable Wnt ligand, the LRP5/6 co-receptors become phosphorylated by GSK-3 and CK1, which creates a high-affinity binding site for Axin (Zeng et al. 2005). Through a poorly understood mechanism, the destruction complex reorganizes as a consequence allowing β-catenin to escape phosphorylation and, hence, accumulate. One of the primary transcriptional targets of β-catenin is the gene for Axin2, the polypeptide product of which acts to restore the function of the destruction complex leading to only transient Wnt signaling. APC is inactivated in ~70% of colon cancers and a further 15% show mutations in the phosphorylation site region of β-catenin. Axin is also mutated in several cancers including hepatocellular carcinomas, as is β-catenin. In each of these tumors, β-catenin is no longer subject to negative control and its levels and transcriptional activity increase dramatically (20-fold or more). Inactivation of both alleles of both GSK-3 genes results in a similar effect but disruption of only 3 of the 4 GSK-3 alleles has little effect on β-catenin regulation highlighting the fact that only a small fraction of GSK-3 is associated with the destruction complex and is this relevant to Wnt signaling (Doble et al. 2007). This selective sequestration/secondment of small fractions of GSK-3 to specific compartments underlies the principle by which GSK-3 participates in several distinct signaling pathways while maintaining signal specificity.

Notch: Activation of ▶ Notch receptors via their interaction with specific Delta-like and Jagged ligands leads to ectodomain truncation of ▶ Notch by Adam-like metalloproteinases followed by juxtamembrane cleavage by a γ-secretase complex and formation of an intracellular domain fragment (▶ $Notch_{ICD}$). This signaling fragment binds to a DNA-binding protein termed CSL or RJBPκ, which transactivates genes including members of the Hes/Hey and Sonic Hedgehog (Shh) family. Activated ▶ Notch signaling in ES cells (such as induced by expression of ▶ $Notch_{ICD}$) can increase stem cell proliferation, drive neural cell fates and, in later stages of development, modulate differentiation of endothelial and epithelial cell structures as well as hematopoietic stem cell differentiation and maintenance of myogenic satellite cells (Androutsellis-Theotokis et al. 2006). Deregulated expression of ▶ Notch1 is also associated with T-cell acute lymphoblastic leukemia. Inhibition of GSK-3 leads to stabilization of ▶ $Notch_{ICD}$. Thus, GSK-3 likely acts to downregulate Notch signaling once it has been initiated.

Hedgehog: The mammalian Hedgehog pathway is initiated by three polypeptide ligands (Sonic, Desert, and Indian Hedgehog) that activate Smoothened (Smo) serpentine protein to regulate the Gli family of transcriptional activators (reviewed in Jiang and Hui 2008). Briefly, in resting cells, a transmembrane protein termed Patched inhibits Smo allowing several protein kinases including GSK-3 to phosphorylate Gli and target it for cleavage into a repressor form (Gli^R). When present, processed Hedgehog ligand binds to Patched and relieves inhibition of Smo. This consequently promotes the activation of Gli (Gli^A) through

a complex process that includes interference of Gli phosphorylation/cleavage and inactivation of a suppressor protein termed Sufu. Gli^A then induces expression of various target genes (including itself and snail). Ectopic activation of Hedgehog signaling can lead to basal cell carcinomas and medulloblastomas.

These pathways each play important, fleeting, and often temporally interdependent roles in normal development. All share the commonality of frequent deregulation in cancer via chronic activation and loss of feedback control. The fact that GSK-3 plays a fundamental role in suppressing signaling in each of these pathways is remarkable and, at the same time, rather puzzling – representing a significant potential vulnerability for loss of control without obvious rationale for burdening a single protein kinase with the responsibility of keeping multiple important pathways in check.

Regulatory Quirks of GSK-3

While the catalytic domains of GSK-3α and β products are virtually identical in their protein kinase domains (excluding the possibility of isoform-selective small molecule ATP-binding site inhibitors), they share only 36% identity in the last 76 C-terminal residues (Woodgett 1990). GSK-3α also has a glycine-rich N-terminal extension compared to the β-isoform. In addition to mammals, the genomes of many other species such as fish, amphibians, and lizards encode genes for both isoforms, although bird genomes only contain GSK-3β and appear to have selectively lost GSK-3α (Allon et al. 2011).

Although GSK-3 phosphorylates its many substrates on serine or threonine residues, it transiently expresses tyrosine kinase activity toward itself upon initial folding (Lochhead et al. 2006). The phosphorylated tyrosine lies within the "T loop" in kinase subdomain VIII (Tyr279 for GSK-3α and Tyr216 for GSK-3β). The role of this phosphotyrosine is to allow the kinase domain to adopt an active conformation for exogenous substrates. Analysis of the crystal structure of GSK-3β revealed that unphosphorylated Tyr216 is in a conformation that interferes with substrate access whereas the phosphorylated tyrosine moves out of the path. Hence, unlike serine phosphorylation of the N-terminal region of GSK-3, tyrosine phosphorylation promotes activity. This posttranslational modification appears quite stable and unregulated. Treatment of cells with GSK-3 inhibitors causes slow loss of the phosphotyrosine at a rate consistent with its half-life. Hence, in normal conditions, the residue is phosphorylated stoichiometrically and remains so for its natural life (Lochhead et al. 2006).

GSK-3 has a strong preference for substrates that are already phosphorylated at a proximal serine/threonine lying C-terminal to the GSK-3 target residue. The so-called priming site of the substrate slots into a pocket comprising of three basic amino acids – Lys205, Arg96, and Arg180. Binding of the priming phosphate into this pocket on GSK-3 induces a conformational change, aligning the substrate for subsequent phosphorylation. Most substrates of GSK-3 demonstrate an absolute requirement for prior phosphorylation by another kinase at the "priming" residue located C-terminal to the site of subsequent phosphorylation by GSK-3 (at least 500-fold preference for the phosphorylated form). GSK-3 phosphorylates these substrates at the fourth or fifth serine or threonine residue N-terminal to the primed site (*pS/TXXXpS/T*), where the first pS/T (Ser or Thr) is the target residue, X is any amino acid (often Pro), and the last pS/T is the site for priming phosphorylation. Several protein kinases act as priming enzymes for GSK-3 substrates, including CDK-5, PAR-1, casein kinase I, ▶ casein kinase II, PKA, and PKC. In several cases, the residue initially phosphorylated by GSK-3 acts as a priming phosphate to induce phosphorylation of a second residue N-terminal to it. This leads to a series of phosphorylated residues as observed in glycogen synthase (priming kinase: ▶ casein kinase II) and β-catenin (priming kinase: casein kinase I).

Many substrates have been identified for GSK-3 to various degrees of rigor. These fall into three general categories: metabolism and regulation; structural/cytoskeletal; transcriptional regulators (Table 1). It is important to note that individual signals that regulate GSK-3 do not change the phosphorylation state of all of its targets. Rather, subsets of substrates are impacted due to local sequestration and other mechanisms.

Genetic Analysis of GSK-3 Functions

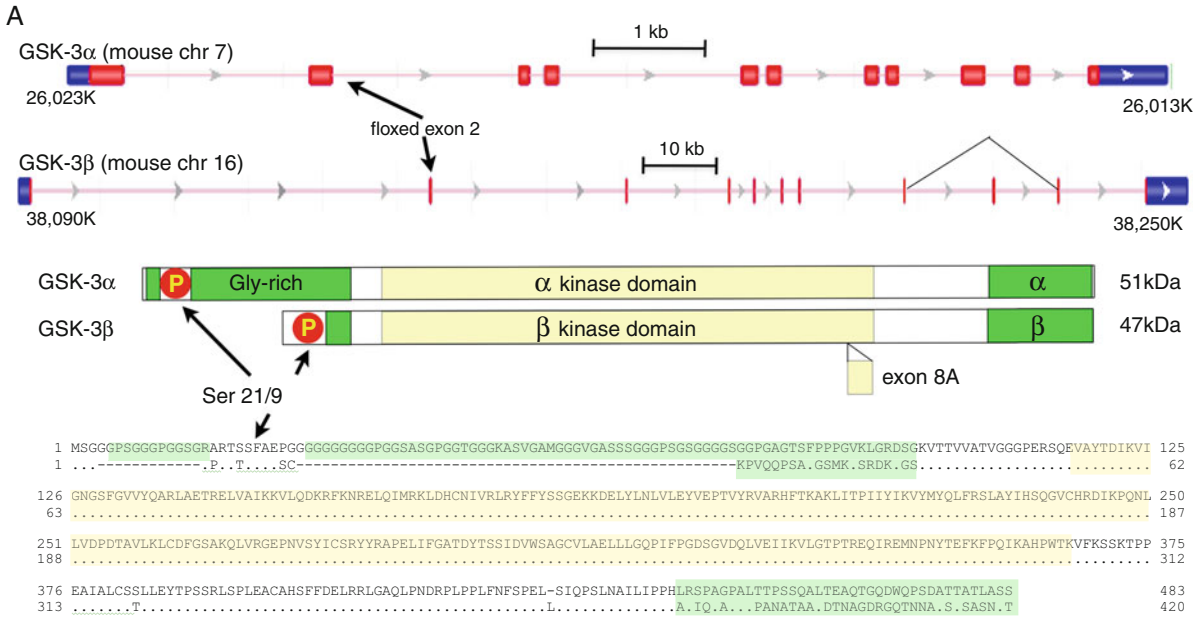
As mentioned above, mammals have two GSK-3 genes that encode two distinct proteins: GSK-33α

Glycogen Synthase Kinase-3, Table 1 GSK-3 substrates arranged into functional subgroups

Metabolism	
ATP-citrate lyase	Protein phosphatase 1
Glycogen synthase	Protein phosphatase 1 inhibitor-2
Pyruvate dehydrogenase	Acetyl CoA carboxylase
Signaling proteins	
Axin	Cyclic-AMP-dependent protein kinase – RII subunit
Adenomatous polyposis coli	Cyclin D1 and E
Cubitus interruptus/Gli	Eukaryotic initiation factor 2B
Per2	Cry2
Presenilin-1	Nucleoporin p62
p21 cdk inhibitor	Lipoprotein receptor-related protein 5/6
Insulin receptor substrate 1 and 2	Tuberous sclerosis 2
NGF receptor	Mcl-1
Structural proteins	
▶ Ncam	Collapsin response mediator proteins 2 and 4
Dynamin-like protein	Neurofilament heavy subunit
Kinesin light chain	Microtubule-associated protein 1B and 2
Ninein	Telokin (KRP) (kinase-related protein)
Tau	CLIP-associated protein 1 and 2
Paxillin	DF3/MUC1 (mucin-like glycoprotein)
Transcription factors	
β-catenin	Nuclear factor of activated T cells
Bcl3	CCAAT/enhancer-binding proteins α and β
Snail	Cyclic AMP response element-binding protein
GATA4	Microphthalmia-associated transcription factor
hypoxia-inducible factor 1	Glucocorticoid receptor
Heat shock factor-1	Bcl-2 interacting transcriptional repressor
c-▶ Myc and L-▶ Myc	SMAD1
c-Jun	▶ NF-κB (p65 and p105)
JunD	Notch
▶ P53	c-Myb

and GSK-3β (Woodgett 1990) (Fig. 1). GSK-3β is also differentially spliced in the brain to generate a minor (∼15% of total) isoform termed GSK-3β2, which contains a 13 amino acid insert within the kinase domain (exon 8A). GSK-3 orthologues have been found in all eukaryotes examined to date, including genetically tractable organisms. While structurally highly related, GSK-3α and GSK-3β are not functionally equivalent. This became obvious upon the generation of GSK-3β knockout mice (Hoeflich et al. 2000). Embryos carrying homozygous deletions of exon 2 of GSK-3β die between embryonic day 16.5 and birth due to liver degeneration caused by defects in NF-κB responses to maternal infection or (at birth) to patterning defects in the heart that preclude lung circulation of oxygenated blood. GSK-3α null animals, by contrast, are viable and demonstrate that GSK-3β can substitute for α but not vice versa (MacAulay et al. 2007). GSK-3α mutant mice do exhibit a variety of phenotypes including insulin sensitization and behavioral abnormalities. Conditional alleles of GSK-3α and β have also been generated. The first analysis of these animals involved rat insulin promoter-driven Cre that expresses the recombinase only in β-islet cells. These animals only lacked GSK-3β in the β-cells and had normal insulin responses. However, β-islet cell inactivation of GSK-3β rescued insulin resistance of insulin receptor substrate-2 mutant animals as well as insulin resistance caused by haploinsufficiency of the insulin receptor itself. Although the GSK-3α global knockout mice were insulin-sensitized, this effect was largely restricted to the liver, which exhibited significantly higher efficiency in glycogen deposition and was also dependent on strain background. Since GSK-3β null animals are inviable, floxed GSK-3β animals with either albumin-Cre or myosin light chain kinase-Cre have been generated to inactivate the gene in liver or skeletal muscle, respectively. These mice revealed inverse effects to the GSK-3α mutants, such that knocking out GSK-3β in the liver had no impact, whereas the animals lacking the enzyme in skeletal muscle were insulin-sensitized. These unanticipated results demonstrated that not only are the two isoforms of GSK-3 nonredundant, they also have tissue-specific roles.

An allelic series of embryonic stem cells have been engineered that are deficient in the various alleles of GSK-3α and GSK-3β. GSK-3 nullizygous ES cells proliferate normally but were highly refractive to differentiation cues and maintained expression of the pluripotency-associated transcription factors nanog and oct-4 even when grown as embryoid bodies in the absence of LIF (Doble et al. 2007). Likewise,



Glycogen Synthase Kinase-3, Fig. 1 *Structural architecture of GSK-3 genes and proteins*. Panel **A**. Chromosomal organization of mouse *GSK-3* genes. Coding exons are *red*, noncoding exons *blue*. The exon flanked by LoxP sites (exon2) is indicated. In the *middle* is a schematic topology of the two protein isoforms. *Pale yellow boxes* indicate the kinase domain, *green boxes* indicate the unconserved regions. The PKB/Akt phosphorylation site (Ser21/Ser9 in GSK-3α/β respectively) is shown by a *red-circled* "P." Below this are protein sequence alignments of mouse GSK-3α and GSK-3β, color-coded as above

treatment of mouse or human ES cells with GSK-3 inhibitors maintains pluripotency (Sato et al. 2004). GSK-3 therefore plays a critical role in supporting the capacity of embryonic stem cells to differentiate and, in its absence, these cells are effectively locked in a "ground state" (Ying et al. 2008).

Consequences of total inactivation of GSK-3: The block to differentiation in ES cells upon inactivation of GSK-3 is recapitulated upon genetic inactivation of the kinase in more differentiated or lineage-committed cells. For example, expression of Cre recombinase in presumptive neuronal precursor cells (via nestin-Cre) causes greatly enhanced neuronal precursor populations (as marked by Sox2) at the expense of differentiated neurons (Kim et al. 2009). These animals died at birth. Activation of the Wnt, ▶ Notch, Hedgehog, and PI-3K pathways downstream of GSK-3 was observed in the nullizygous neurons. Treatment of primary neuronal cultures with inhibitors (dominant-negative TCF4, γ-secretase inhibitor, cyclopamine and wortmannin, respectively) to these individual pathways revealed partial dependence on each for proliferation, with only a combination of the inhibitors achieving full suppression. This study also noted a loss of polarized cell division in dividing neurons in the subventricular zone, a process that is required for efficient stratification of the neuronal layers, suggesting an important role for GSK-3 in regulating spindle pole orientation. Similar suppression of differentiation to that observed in ES cells and neuronal precursors has been observed in other cell types and tissues in which all alleles of GSK-3 has been selectively genetically inactivated (Woodgett lab, Unpublished observations).

GSK-3 and Cancer Etiology

These animal models each share a similar property: differentiation is inhibited and there is expansion of precursor populations. These findings have implications for in vitro expansion of adult stem/progenitor cells in regenerative medicine but also provide insight into the early stages of tumor development. GSK-3 has been implicated in cancer at various levels, primarily as a tumor suppressor. Its inhibitory role in the major

signaling pathways described above that are most commonly activated in human cancers is well documented. However, the kinase has also been positively linked to pancreatic cancer and regulation of Snail, a transcription factor key to epithelial to mesenchymal transitions (EMT), a process associated with metastasis. A splice mutant of GSK-3β has recently been identified in a population of leukemic stem cells derived from blast crisis chronic myelogenous leukemia (CML) (Abrahamsson et al. 2009). Reintroduction of wild-type GSK-3β into the CML cells reduced engraftment efficiency suggesting a role in promoting stem cell expansion. By contrast, GSK-3 was found to play a tumor-promoting role in MLL-driven leukemias where its inhibition led to regression of the leukemic cells through destabilization of the CDK inhibitor, p27Kip1. In addition, inhibition of GSK-3 has been reported to induce glioma apoptosis through inhibition of ▶ NF-κB and to enhance sorafenib-stimulated apoptosis in melanoma cell lines. Hence, GSK-3's role in cancer progression remains to be properly elucidated.

Summary

GSK-3 is clearly an unusual protein kinase. It has an inhibitory influence in multiple signaling pathways that are critical for normal development as well as in metabolic control. Its high activity in "resting" tissue suggests its role is generally and suppressive. Signals must relieve the inhibitory action of GSK-3 and there are several means to achieve this including phosphorylation and sequestration. There are many inhibitors of GSK-3, a number of which are potent and relatively specific. Of note, these inhibitors do not discriminate between the isoforms or subcellular fractions. Chemical inhibition of GSK-3 is therefore a blunt tool for investigating the functions of the kinase. It is also recognized that the consequences of GSK-3 inhibition depend on the degree to which activity is suppressed. For example, mice lacking a single GSK-3 allele (equivalent to 25% inhibition) have clearly measurable behavioral phenotypes whereas almost complete inhibition by drugs is required to induce β-catenin stabilization. Lastly, research into this protein kinase has largely focused on the GSK-3β isoform. A search of PubMed identifies over 1300 articles with GSK-3β in the title but only 66 for GSK-3α. This is in spite of the fact that the two isoforms are largely, although not completely, redundant and no available small molecule inhibitors are selective to either isoform. Hence, much of the literature is overly focused on GSK-3β and many data are erroneously attributed to effects of GSK-3β without consideration of the role of GSK-3α. This "β bias" is both unnecessary and unfortunate in that much of the data pertain equally to the less appreciated isoform which likely pulls as much weight in cellular regulation as its sibling.

Historical Background

G-protein-coupled receptors constitute the largest and most diverse family of integral membrane proteins and are involved in a wide variety of physiological functions. Some of these functions include mediating responses to hormones, neurotransmitters, odorants and light, and regulation of the immune system and inflammation (Yousefi et al. 2001; Lattin et al. 2008; Weis and Kobilka 2008; Gloriam et al. 2009). GPR84 belongs to the rhodopsin subfamily of G- protein-coupled receptors and was first discovered during a comprehensive search of available expressed sequence tags (EST; Wittenberger et al. 2001). Since its discovery, *GPR84* has been found in many human tissues, in mouse spleen and liver, and in embryonic *Xenopus laevis* tissues (Wittenberger et al. 2001; Perry et al. 2010). This receptor was considered an orphan receptor until late 2006, when it was discovered that GPR84 functions as a receptor for medium-chain free fatty acids (FFAs, Wang et al. 2006).

Structure and Activation of GPR84

GPR84 is an integral membrane protein that consists of an extracellular amino terminus, seven transmembrane domains, and a cytoplasmic carboxy terminus (Fig. 1). The transmembrane domains contain the most sequence conservation among the rhodopsin family and are characterized by a stretch of 25–35 consecutive residues that are believed to represent seven alpha helices. Each alpha helix is arranged in the plasma membrane in a counterclockwise orientation and groups together to form a heptahelical bundle, which is considered the receptor (Fredriksson et al. 2003). Another signature element specific to GPR84 is the (D/G/S)RY motif in the second cytoplasmic domain. In human, mouse, and rat, this is represented as GRY, while in *Xenopus* it is represented as SRY (Fig. 1). The final characteristic element contained in the last transmembrane domain is the NPXXY motif, which is represented as NPVLY in human, mouse, and rat, and NPILY in *Xenopus* (Perry et al. 2010).

The arrangement of the transmembrane domains creates a ligand-binding pocket or receptor that is important for signaling events. Activation of this

receptor occurs when the ligand binds, resulting in an interaction of the cytoplasmic part of the receptor with the heterotrimeric G protein (Weis and Kobilka 2008). The cellular response to the extracellular signal is mediated through second messenger cascades and this attenuation of GPCR signaling can be achieved by phosphorylation of the receptor. This results either in a conformational change affecting G protein binding or by reduced cell surface expression (Gainetdinov et al. 2004; Prossnitz 2004).

Identification of the ligands that activate GPCRs has been ongoing and many receptors still remain classified as orphan receptors. However, a library of biochemical intermediates was used to identify the ligands capable of activating GPR84 (Wang et al. 2006). This study identified medium-chain free fatty acids (FFAs) with carbon lengths of 9–14 as activators of GPR84. The most potent agonists of GPR84 were found to be capric acid, undecanoic acid, lauric acid, and the small molecule, diindolylmethane. Since diindolylmethane activates GPR84 with much greater potency, it has been used to investigate the effect of GPR84 activation on cytokine secretion (Wang et al. 2006). Interestingly, GPR84 is not activated by short-chain FFAs or by long-chain saturated and unsaturated FFAs.

Role in Immune Response

Several studies have emerged that have given some insight into the role of GPR84 during immune response in humans and mice. During a screen of human peripheral blood neutrophils, the *EX33* gene (later named GPR84) was found and identified as a novel G-protein-coupled receptor (Yousefi et al. 2001). Since movement of neutrophils into inflamed tissues is mediated by chemokines that regulate signaling through GPCRs (Adams and Lloyd 1997), it was of particular interest to determine whether EX33 was involved in this type of signaling mechanism. Additionally, identification of chemoattractants and their receptors has implications in the treatment of inflammatory diseases. Experiments were conducted to test *EX33* expression and revealed its presence in a variety of human cells and tissues (bone marrow, lung, colon, placenta). Abundant expression was noted in neutrophils and eosinophils in comparison with significantly lower levels in other cell types. This study was of particular interest because it presented the first evidence that EX33 was regulated by agonist-dependent mechanisms. In experiments where neutrophils were stimulated with granulocyte-macrophage colony-stimulating factor (GM-CSF; an inflammatory

cytokine), lower levels of EX33 proteins were detected, as compared to unstimulated neutrophils. In addition to its accepted involvement in neutrophil activation, the data suggests that GM-CSF might also be involved in the hindrance of neutrophils at the site of inflammation by downregulation of cell surface receptors (Yousefi et al. 2001).

A recent study to examine the biological function of GPR84 in mice utilized GPR84 knockout animals (Venkataraman and Kuo 2005). The proliferation rates of T and B cells were found to be similar in wild-type animals versus GPR84 knockout mice and though GPR84 is not necessary to modulate T and B cell proliferation, the absence of GPR84 in $CD4^+$ T cells results in the increased production of IL-4 by anti-CD3-activated cells. Additionally, when T cells were cultured in the appropriate stimuli, differentiation into Th1 or Th2 effector populations occurred. Those Th2 effector cells cultured from GPR84-deficient mice consistently secreted higher levels of IL-4, IL-5, and IL-13 in comparison to wild-type animals. Early cytokine signaling mechanisms are poorly understood, yet it can be suggested that hyper-Th2 cytokine production in GPR84-deficient mice can be correlated with their ability to synthesize more IL-4 protein during initial stimulation under Th2 differentiation conditions.

The inflammatory response of GPR84 was also noted in microglia (macrophage population of the brain) of mice analyzed after lipopolysaccharide (LPS)-induced endotoxemia (Bouchard et al. 2007). GPR84 is strongly expressed here and also in peripheral monocytic cells of the spleen. Additional evidence reveals that GPR84 is also expressed in clusters near blood vessels in microglia with induced experimental autoimmune encephalomyelitis (EAE) and the abundance of labeled clusters increases with the severity of the disease. Endogenous or exogenous inflammatory stimuli are capable of inducing *GPR84* gene transcription in the microglia. Soluble mediators such as TNF and IL-1 mediate the effect of LPS on GPR84 expression in the brain, although other mediators have yet to be discovered (Bouchard et al. 2007). The higher levels in microglia and populations of peripheral macrophages suggest that GPR84 may play a predominant role in populations of macrophages. Additional research has revealed that GPR84 is restricted to bone-marrow macrophage (BMM) and microglia in an unstimulated state (Lattin et al. 2008). However, upon stimulation with LPS, GPR84 is significantly upregulated in BMM and thioglycollate-elicited peritoneal macrophages (TEPMs), consistent with the previously mentioned study. These recent studies reveal a role for GPR84 in neuroinflammation and may present a useful tool in tracking macrophage populations.

Role in Fatty Acid Metabolism

In the presence of G protein G_{qi9}, both human and murine GPR84 are activated by medium-chain FFAs, suggesting that signaling occurs through the pertussis-sensitive $G_{i/o}$ pathway. GPR84 does not signal through the G_s-mediated pathway and is unlikely to signal through the G_q pathway.

Medium-chain FFAs were also shown to amplify LPS-stimulated production of IL-12 p40 directly through GPR84 (Wang et al. 2006). In the presence of naturally occurring medium-chain FFAs (capric acid, undecanoic acid, lauric acid) or in the presence of the small molecule agonist, diindolylmethane, an increase was observed in the secretion of IL-12 p40 subunit from LPS-stimulated RAW264.7 cells. IL-12 p40 is a proinflammatory cytokine responsible for the eradication of pathogens. This cytokine induces and maintains T helper 1 (Th1) responses and inhibits T helper 2 (Th2) responses (Scott 1993; Hsieh et al. 1993; Kopf et al. 1994). Consistent with these results is the increased production of Th2 cytokines in GPR84-deficient T cells (Venkataraman and Kuo 2005). Combined, these studies emphasize a role for GPR84 as a leukocyte-specific receptor for medium-chain FFAs.

Role in Development

Recent studies have focused on GPR84s role in immune response and so far little is known about its role during development. One study showed that GPR84 expression is also important for proper morphogenesis of the eye in the frog, *Xenopus laevis* (Perry et al. 2010). RT-PCR analysis of various embryonic stages of *Xenopus* shows that *GPR84* mRNA is present beginning at gastrulation through larval stages and more specifically in the retina, lens, and larval cornea epithelium. Previous mouse and human studies have not noted expression in the eye; however, these specific tissues do not appear to have been examined

(Yousefi et al. 2001; Venkataraman and Kuo 2005; Wang et al. 2006; Bouchard et al. 2007; Lattin et al. 2008).

GPR84 MO-mediated knockdown experiments revealed a role for GPR84 specifically in lens and retina morphogenesis (Perry et al. 2010). Significantly reduced lenses formed, but did not display secondary fiber cells and had defects in the lens epithelium. The retina was also significantly impacted, showing signs of improper differentiation of various neural retinal layers. Cell proliferation and apoptosis assays also show that GPR84 knockdown tissues not only display a higher number of proliferating cells, but also a higher number of apoptotic cells. Previous studies (Ohnuma et al. 2002; Casarosa et al. 2003) have demonstrated that the proper development of cells depends on the delicate balance of cell proliferation and fate determination. Impairing a cell's ability to exit the cell cycle can have significant implications in terms of the ultimate cell fate. It is possible that GPR84 could be a negative regulator of cell proliferation in the retina and lens, where suppressing proliferation at specific time points may be important for differentiation of the neural retina, lens, and cornea.

Summary

GPR84 is a transmembrane receptor originally identified through an EST search. Various medium-chain FFAs act as ligands to activate and induce a conformational change in the receptor. Interaction between the intracellular portion of the receptor and heterotrimeric G proteins results in activation of second messenger cascades and effector proteins. Mediation of cell signaling occurs through phosphorylation of GPR84 and results in lower binding efficiencies or reduced cell surface expression. Further analysis to determine the conformation of the active and inactive receptor will yield a better understanding of this signaling mechanism. *GPR84* expression has been noted to be higher in neutrophils and eosinophils. Inflammatory stimuli are able to induce GPR84 transcription in microglia and in clusters near blood vessels of microglia, and can be mediated by TNF and IL-1. GPR84-deficient mice result in $CD4^+$ T cells that produce higher levels of IL-4 and culturing those T cells produces Th2 effector cells that secrete higher levels of IL-4, IL-5, and IL-13. Increased secretion of IL-12 p40 occurs in LPS-stimulated RAW264.7 cells in the presence of medium-chain FFAs or diindolylmethane. *GPR84* expression is also important for proper eye development in *Xenopus*. Knockdown of *GPR84* expression results in defective lens formation, an improperly differentiated neural retina, higher proliferation rates, and an increase in cells undergoing apoptosis. Overall, GPR84 plays an important role in development, free fatty acid metabolism, and immune system regulation. Further understanding of the GPR84 signaling cascade may lead to promising therapies/drugs for the treatment of both metabolic and autoimmune diseases.

G-Protein α_q (Gene Name: GNAQ)

Björn H. Falkenburger
Department of Neurology, RWTH University Medical Center, Aachen, Germany

Historical Background

Hormone receptors elicit cellular responses most often not directly, but through diffusible second messengers. In the early 1970s it was found that second messenger synthesis requires guanosine triphosphate (GTP). Yet, GTP binds neither to hormone receptors nor to enzyme effectors. Instead, GTP binds to GTP-sensitive transducers (see Gilman 1987). These G-proteins are heterotrimers of α, β, and γ subunits. The first Gα subunits to be identified were $G\alpha_s$ and transducin. $G\alpha_s$ triggers the formation of cAMP. Transducin mediates the effects of rhodopsin. Signaling by $G\alpha_s$ was found sensitive to pertussis toxin. Signaling by $G\alpha_i$, which inhibits cAMP formation, was found sensitive to cholera toxin. Formation of the second messengers inositol trisphosphate (IP_3) and diacylglycerol (DAG) by phospholipase C (PLC) was neither affected by pertussis toxin nor by cholera toxin. Therefore, a third class of Gα subunits was proposed. In 1990 Strathmann and Simon cloned murine Gα subunits that lack the sites modified by pertussis and cholera toxin. They termed them $G\alpha_q$ and suggested that they mediate signaling to PLC (Strathmann and Simon 1990).

Gene and Protein

The official gene symbol for $G\alpha_q$ in *Homo sapiens* and other mammals is GNAQ (guanine nucleotide-binding protein alpha q). GNAQ is the prototypical member of a G-protein family formed by GNAQ, GNA11, GNA14, and GNA15. As for the related $G\alpha_i$ family, the genomic organization is such that two $G\alpha_q$ genes are located in sequence, likely the result of tandem duplication (Wilkie et al. 1992). GNAQ is located on chromosome 9q21 together with GNA14. A very similar pseudogene is at 2q14.3–q21 (Dong et al. 1995).

The tertiary structure of $G\alpha_q$ has been solved (e.g., Nishimura et al. 2010). It is (reversibly) palmitoylated at *N*-terminal cysteins (C9, C10, Tsutsumi et al. 2009). The GTPase domain of $G\alpha_q$ is similar to the small, monomeric GTPase Ras. While not all combinations between Gβ and Gγ isoforms are possible, any of these Gβγ dimmers can in principle form a heterotrimer with $G\alpha_q$. The heterotrimeric G-protein $\alpha_q\beta\gamma$ is termed G_q after the α subunit.

Medical Relevance

Plasma membrane receptors signaling through G_q include the following G-protein coupled (GPCR) or seven-transmembrane domain (7TM) receptors: α_1 adrenoreceptor, M_1, M_3, M_5 muscarinic receptors, several P2Y purinergic (ATP, UTP) receptors, 5-HT_2 serotonin, B_2 bradykinin, H_1 histamine, GPR55 cannabinoid, PAR_2 trypsin, and group I metabotropic ► glutamate receptors. A close homologue of G_q mediates light perception in drosophila photoreceptors. Downstream responses include a rise in cytosolic calcium, which induces the secretion of hormones and neurotransmitters and the contraction of smooth muscles in vasculature and eye. Many of the GPCR activated by G_q are important drug targets. For instance, α_1 receptors mediate the actions of blood pressure–lowering drugs

and drugs treating benign prostatic hyperplasia, M_1 receptors mediate the effects of cholinergic drugs treating Alzheimer's disease, and H1 receptors are targeted by drugs treating allergies.

Mutations in GNAQ (and GNA11) have been associated with cancers, in particular uveal melanoma (Van Raamsdonk et al. 2009). $G\alpha_q$-deficient mice show cerebella ataxia and defective platelet activation (Offermanns 2001).

Overview of the G-Protein Cycle

In the classical view, $G\alpha_q$ has GDP bound at rest and forms a heterotrimer with $G\beta\gamma$ subunits. Activation of a G_q-coupled receptor (by ligand binding or other means) will lead to binding of G_q to the receptor and promote nucleotide exchange at $G\alpha_q$, i.e., the unbinding of GDP and the binding of GTP. $G\alpha_q$-GTP then dissociates from the receptor and from $G\beta\gamma$. This free $G\alpha_q$-GTP is the active form of $G\alpha_q$. It binds to effectors, most importantly isoforms of phospholipase C β (PLCβ). PLCβ hydrolyze the membrane phospholipid phosphatidylinositol (4,5)-bisphosphate (PIP_2), forming the cytosolic second messenger inositol trisphosphate (IP_3) and the lipid diacylglycerol (DAG). In some cases, PLC activation depletes PIP_2. IP_3 releases calcium from intracellular stores; DAG activates protein kinase C (PKC); PIP_2 is an activator for many plasma membrane proteins. The endogenous GTPase activity of $G\alpha_q$ hydrolyzes GTP to GDP. This ends the activation of $G\alpha_q$. $G\alpha_q$-GDP then binds again to $G\beta\gamma$. If the receptor is still active, it can bind G_q again, catalyze nucleotide exchange, and induce another round of $G\alpha_q$ activity.

A More Detailed Description of the G-Protein Cycle

This section considers the individual steps of the G-protein cycle in more detail. Receptor activation evokes a conformational change in the receptor. This conformational changes occurs relatively fast (<100 ms in M_1R, Jensen et al. 2009). The affinity of the activated receptor for G_q is higher than the affinity of inactive receptor, leading to net binding of G-proteins to the receptor. For M_1R, G-protein binding takes about 200 ms. Because of the law of mass action, the speed of binding may depend on the local density of G-proteins in the vicinity of the receptor (Falkenburger et al. 2010).

Some investigators suggest, that heterotrimeric G_q is preassembled with G_q-coupled receptors. Whether – and to which extent – this is the case has remained controversial (discussed, e.g., in Hein and Bünemann 2009 and Falkenburger et al. 2010). Likely there is some finite affinity, and the fraction of receptors that have G_q bound at rest depends on the local density of G_q molecules in the vicinity of the receptor. A related question is whether an inactive receptor can catalyze nucleotide exchange, i.e., whether the receptor is "precoupled" to G_q. Some effects of the M_1R antagonist atropine can be interpreted in this way, but the extent of precoupling is certainly smaller than in adrenoreceptors. Finally, there is some recent evidence that different ligands may stabilize the receptor in different conformations, favoring binding of certain downstream partners over others and thus biasing signaling through one of several alternative pathways.

The active receptor acts as a GEF (guanine exchange factor) for $G\alpha_q$, speeding up the exchange of GDP to GTP. The rate-limiting step of nucleotide exchange is the unbinding of GDP from $G\alpha_q$. This step is what is accelerated when G_q is bound to activated receptor (Ross 2008). Without GAP (GTPase activating protein), the endogenous GTPase activity of $G\alpha_q$ is very slow (time constant of 30 s, Falkenburger et al. 2010), leaving $G\alpha_q$ (and $G\beta\gamma$) active for a fairly long time. Some effectors, including PLCβ, act as GAPs and accelerate the GTPase activity of $G\alpha_q$, speeding up recovery. Other GAPs for $G\alpha_q$ include RGS proteins (regulators of G-protein signaling) and the $G\alpha_q$ effector p115RhoGEFe (Ross and Wilkie 2000).

If PLCβ would only accelerate GTPase activity, it would turn off the molecule that activates it and PLCβ activation should be transient. However, this is not what was observed experimentally. PLCβ can be continually active for minutes. One possibility is that PLCβ also acts as GEF and accelerates nucleotide exchange (see Falkenburger et al. 2010). A different explanation is "kinetic scaffolding" (see Ross 2008), meaning that the GTPase activity of $G\alpha_q$ bound to PLCβ is so fast that GTP is hydrolyzed even before $G\alpha_q$-GTP has had a chance to dissociate from the receptor. The receptor (a GEF) then catalyzes again

nucleotide exchange and $G\alpha_q$ is kept at the receptor until the latter is no longer active. In both cases, fast GTPase activity is balanced by fast nucleotide exchange and $G\alpha_q$ bound to PLCβ is kept active by a rapid cycle of nucleotide exchange and GTP hydrolysis. The purpose of such seemingly futile GTP consumption is to allow rapid signaling. Without the GAP/GEF effect, responses would persist and blur into one another.

Spatial Aspects

The classical view holds that upon nucleotide exchange, G_q dissociates into $G\alpha_q$ and Gβγ. And indeed, some G-proteins do physically dissociate (Lambert 2008). Some Gβγ subunits even translocate to intracellular membranes upon activation while $G\alpha_q$ stays at the plasma membrane (Saini et al. 2009). However, for some G-proteins, activation results in a *decreased* distance between the Gα and Gβ subunits, which is inconsistent with subunit dissociation. Here, nucleotide exchange may merely result in a conformational rearrangement without physical dissociation (see Lohse et al. 2008). A related question is whether $G\alpha_q$ can stay bound to the receptor while binding and activating PLC. For $G\alpha_q$, an *increase* in the average distance to Gβ was observed upon activation along with a *decrease* in the distance to PLCβ (Jensen et al. 2009). This is consistent with the classical view. Nonetheless, effectors can be activated without dissociation of $G\alpha_q$ and Gβγ (Yuan et al. 2007). In addition to the mentioned activation-induced translocation of G-protein subunits, recent evidence suggests a continuous shuttling of G-protein heterotrimers between the plasma membrane and intracellular membrane compartments at rest (Saini et al. 2009).

Summary

$G\alpha_q$ mediates signaling from ubiquitous G_q-coupled plasma membrane receptors to PLCβ. Since its identification, considerable progress has been made in understanding kinetics and functioning of the GDP/GTP cycle. Further work is expected to decipher in more detail the spatial aspects of $G\alpha_q$ signaling, i.e., whether signaling molecules are preassembled in a large complex and information is transmitted mainly through conformational changes, or whether G-proteins indeed dissociate upon activation and translocate to associate with effectors.

Because many different receptors couple to G_q, a second challenge will be to better understand to what extent – and by which mechanisms – signaling from these different receptors can be kept separate within a single cell. For example, M_1 muscarinic receptors do elicit a calcium response in superior cervical ganglion cells, whereas bradykinin receptors do not (see Delmas et al. 2004).

Finally, it has become clear that $G\alpha_q$ can signal through other pathways than PLC. $G\alpha_q$ can activate Rho family GTPases through p115RhoGEFe, which activates RhoA by favoring nucleotide exchange there (Rojas et al. 2007). In addition, $G\alpha_q$ can bind to and activate Bruton's tyrosine kinase (Ma and Huang 1998), and possibly further kinases. Conversely, some Gβγ dimers can also activate isoforms of PLCβ, suggesting that not all effects of Gq are mediated by $G\alpha_q$. Therefore, even 20 years after cloning $G\alpha_q$ it can still be difficult to determine which molecules mediate a signaling event that is unaffected by pertussis and cholera toxins.

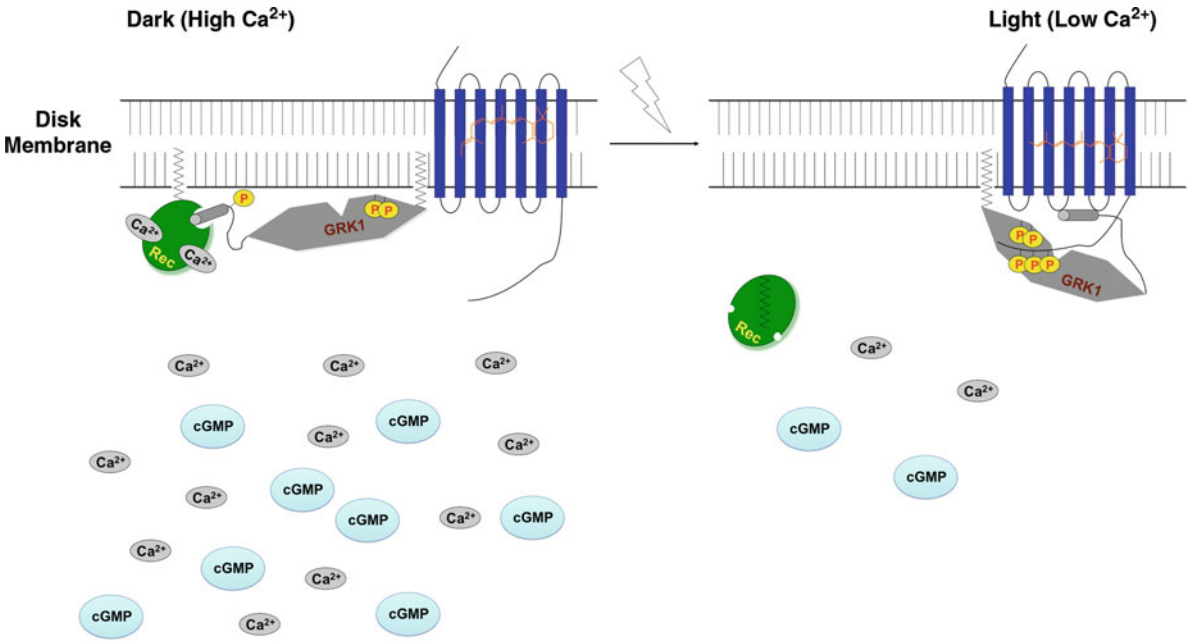
Historical Background

The activity of G-protein-coupled receptor kinase 1 (GRK1) was first observed in the light-dependent phosphorylation of rhodopsin in rod outer segment (ROS). As GRK1 was unstable during biochemical manipulations, isolating it in sufficient quantity and quality was proven to be difficult over a period of 30 years (Maeda et al. 2003). The GRK1 gene was cloned in the early 1990s (Lorenz et al. 1991), and many findings regarding its roles in phototransduction recovery, light and dark adaptation, and stationary night blindness of human Oguchi disease took place in the following decade (Chen et al. 1999; Lyubarsky et al. 2000; Khani et al. 1998; Cideciyan et al. 1998). GRK1 is posttranslationally modified by isoprenylation and phosphorylation, and its catalytic activity can be regulated by other proteins such as recoverin (Chen et al. 1995) and protein kinase A (Horner et al. 2005). It is now firmly established that GRK1 is essential for deactivation of activated visual pigments in rod and cone photoresponses. GRK1 crystal structure has recently become available (Singh et al. 2008). The most recent discoveries and unsolved questions on GRK1 are summarized here.

Introduction

G-protein-coupled receptors (GPCR) with heptahelical transmembrane domains are the largest group of integral proteins enabling a cell to sense its outside environment by coupling to heterotrimeric G-proteins.



G-Protein-Coupled Receptor Kinase 1 (GRK1), Fig. 1 Current understanding of GRK1 function in photoreceptors

A wide range of physiological processes such as senses, hormonal actions, and neurotransmission employ GPCRs. The deactivation of GPCR signaling requires phosphorylation of C-terminal Serine and/or Threonine residues and this is catalyzed by G-protein-coupled receptor kinases (GRKs). Following GPCR phosphorylation, the interaction with G-protein is weakened and the affinity for arrestin is heightened. The binding of arrestin to phosphorylated receptors prevents coupling to G-proteins. In many cells, arrestin binding initiates receptor endocytosis to prolong and enhance desensitization (Dorn 2009). Keeping GPCR activity at bay by this simple but elegant deactivation mechanism is important, as loss-of-function mutations in GRKs have led to a variety of pathologic conditions. There are seven members in the GRK family that can be further subdivided into three groups: GRK1-like, GRK2-like, and GRK4-like. GRK1-like group consists of GRK1 and GRK7, which are expressed specifically in retinal photoreceptors. GRK2-like group contains GRK2 and GRK3, which are ubiquitously expressed. GRK4-like group is comprised of GRK4, GRK5, and GRK6. GRK4 expression is restricted to kidney, cerebellum, and testis, while GRK5 and GRK6 are expressed ubiquitously. All GRKs share a central kinase domain of approximately 270 amino acids, typical to that of other Ser/Thr kinases. The N-terminus of GRKs contains an RGS homology (RH) domain, which is found in regulators of G-protein signaling (RGS) proteins (Ribas et al. 2007; Dorn 2009). The RH domain of GRK1 and GRK2 has ~20–25% homology to that of the R7 subgroup of RGS proteins (data not shown). The physiological function of GRK1 RH domain remains unclear. The C-terminal regions of GRKs are most dissimilar with varying sizes and different protein motifs that contribute to the diversity of GRKs. GRK2 is critical in cardiac physiology, as its inactivation leads to cardiac abnormality and embryonic lethality in mice (Dorn 2009). GRK1 and GRK2 are the most extensively studied GRK members. GRK1 is required for visual pigment deactivation in rod and cone (Chen et al. 1999; Lyubarsky et al. 2000). Because of its unique expression pattern in retinal photoreceptors, knowledge stemming from studying GRK1 (Fig. 1) has contributed much to our understanding of GRK function in general.

In retinal rod, the phototransduction cascade is initiated when 11-cis-retinal, covalently linked to a Lysine residue in rhodopsin, is photoisomerized to all-trans-retinal. This induces a series of conformational changes in rhodopsin, leading to an active

conformation called Metarhodopsin II (R*), which is capable of catalyzing the exchange of GTP for GDP on the α subunit of heterotrimeric G-protein transducin ($G_{\alpha t}$). The GTP-bound transducin α subunit ($G_{\alpha t}$-GTP) activates phosphodiesterase 6 (Pde6) and results in rapid reduction of cGMP level and the closure of cGMP-gated (CNG) channels located on ROS plasma membranes. The reduction of cation influx leads to membrane hyperpolarization and a transient cessation of glutamate release at synaptic terminal. To reset a rod to detect additional photons, all active molecules during phototransduction, including R*, must be deactivated in a timely fashion. For R*, this is mediated by a two-step process, the first of which is phosphorylation of up to six Ser/Thr residues at the C-terminal tail by GRK1. Phosphorylated-R* is then recognized and bound by arrestin, preventing further receptor/G-protein coupling and allowing R* to decay (Chen 2005). More than a decade ago, a close relative of GRK1, called GRK7, was cloned from mammalian species (Weiss et al. 1998) and was subsequently suggested to be a cone opsin kinase. While GRK1 is expressed in both rod and cone, GRK7 is expressed only in cone and not in rod for human (Chen et al. 2001; Weiss et al. 2001). In species such as pigs and dogs, their cones only express GRK7. In rodents, GRK7 is absent and both rods and cones rely on GRK1 for receptor deactivation. Studying the differences between GRK1 and GRK7 has provided insights into the structure/function relationship of GRKs and the pathological mechanism of human Oguchi disease.

Role of GRK1 in Phototransduction, Oguchi Disease, and Light-Dependent Degeneration

Photoreceptors without GRK1 need longer time to dark adapt. In $GRK1^{-/-}$ photoreceptors, receptor deactivation is so slow that it becomes the slowest step that dominates the overall recovery phase of rod and cone phototransduction (Chen et al. 1999; Lyubarsky et al. 2000). Inactivating one copy of GRK1 also causes a noticeable delay in rod recovery, suggesting that GRK1 level may be critical in setting the duration of rod's photoresponses. However, while loss-of-function approach demonstrates the importance of GRK1 in rod recovery, it lacks the power to reveal whether R* phosphorylation dominate the recovery time course under normal conditions. Using a gain-of-function approach, Krispel et al. generated several transgenic mouse lines with varying levels (up to fourfold) of GRK1 and found in them that rods showed no statistically significant acceleration of recovery. Using a similar approach where the ternary GTPase accelerating protein (GAP) complex of R9AP/Gβ5-L/RGS9-1 is overexpressed, the recovery can be dramatically sped up. Together, this indicates that transducin deactivation is the overall rate-determining step in normal rod (Krispel et al. 2006). With transducin turn-off identified as the slowest step, is rhodopsin deactivation mediated by GRK1 the second slowest step in recovery? One strategy to identify the second rate-limiting step is to sufficiently speed up transducin GTP-hydrolysis until the second step becomes the slowest step. Another strategy is to use rods with much less GRK1 (Chen et al. 2010), whereas rod recovery was found to be faster than $GRK1^{-/-}$ but slower than that in normal rods. Under such condition the presence of background light was found to speed up rod recovery. Interestingly, the effect of background light depends on recoverin, a calcium-dependent GRK1 regulator (see below).

Photoreceptor degenerates in the presence of light delivered at high intensity or for a prolonged period (Hao et al. 2002). Genetic manipulation in mouse in recent years has identified several proteins that protect photoreceptors from light damage and GRK1 is one of them (Chen et al. 1999). Photoreceptor lacking arrestin also degenerates under intense light exposure. In double knockout ($GRK1^{-/-}$/$Arrestin^{-/-}$) mice, photoreceptors become extremely sensitive to light damage, which can occur as short as 1 min of light exposure (Choi et al. 2001; Hao et al. 2002; Krishnan et al. 2008). The susceptibility to light damage in $GRK1^{-/-}$, $Arrestin^{-/-}$, and double knockout photoreceptors presumably arises from the prolonged activation of rhodopsin. The degeneration in these animal models has been shown to activate both transducin-dependent and transducin-independent pathways to cause cell death (Hao et al. 2002; Fan et al. 2010). In the presence of bright light, photoreceptor without transducin still degenerates in a pathway that signals through activated rhodopsin. In contrast, the degeneration seen in $GRK1^{-/-}$ and $Arrestin^{-/-}$ photoreceptors under dim light condition is mediated by constant transducin activation. By mating these animals with $GNAT1^{-/-}$, the degeneration under dim light can be prevented (Hao et al. 2002). These evidences showcase the protective

properties of GRK1 and arrestin in rods against light damage by timely rhodopsin deactivation.

Since the loss of GRK1 leads to prolonged rhodopsin lifetime and cell death, can increasing GRK1 protect photoreceptor against degeneration? In a recent study by Whitcomb et al., BAC transgenic technique was used to overexpress GRK1 in rod photoreceptor to approximately threefold (GRK1+). Correspondingly, rhodopsin phosphorylation is also increased in GRK1 + rods. Retinal morphology in GRK1+ animals is similar to WT under regular illumination. However, when the animals are exposed to intense light (10,000 lux) for 12 h, GRK1+ photoreceptors display faster degeneration (Whitcomb et al. 2010). These data are contrary to what one may expect because GRK1 overexpression does not provide protection against light-induced degeneration, instead, hyperphosphorylation of rhodopsin may accelerate an unknown signaling event that leads to cell death. GRK1 concentration apparently needs to be maintained optimally within photoreceptors as an increase or loss of GRK1 can accelerate light-induced photoreceptor degeneration. While retinal degeneration has been described in many mouse strains in which they become useful models of human macular degeneration and retinitis pigmentosa, the cellular mechanisms that trigger apoptosis have been less understood. Future studies are needed to determine the signaling pathway(s) leading from rhodopsin light absorption to photoreceptor cell death to shed light into these dark and debilitating human conditions.

It is evident from animal studies that the loss of GRK1 results in severe defects in photoreceptors. Similarly, mutations in GRK1 and arrestin genes have been found in human patients with Oguichi disease, a rare form of stationary night blindness (Yamamoto et al. 1997). Color vision in Oguchi patients is typically normal, which indicates that cone function is unaffected. ERG analyses of Oguchi patients demonstrate severe delay in scotopic recovery and elevated rod thresholds, while their photopic responses are by and largely unaffected (Carr and Gouras 1965; Cideciyan et al. 1998; Zhang et al. 2005). Various GRK1 mutations have been identified and are listed in Table 1. Ectopically expressing GRK1 with Oguchi mutations (V380D, Ser536 (4-bp del), and exon 5 deletion) in COS7 cells has demonstrated a reduced ability to phosphorylate R* (Cideciyan et al. 1998; Khani et al. 1998). However, these mutations may also destabilize GRK1 in photoreceptors and this remains to be tested. As losing kinase activity or protein expression lead to defective rhodopsin phosphorylation and a prolonged dark adaptation time in Oguchi disease patients, one interesting discrepancy is worth noting here. Mouse without GRK1 has severe recovery defects in both cone and rod, while cones of most Oguchi disease patients appear spared. This is because of the expression of GRK7 (Maeda et al. 2003) in human cones. It is also interesting to note that cone ERG responses are diminished in patients with P391H GRK1 mutation, suggesting that this particular mutation may have a dominant effect in these cones affecting both GRK1 and GRK7 (Hayashi et al. 2007). The possibility that the photoreceptors with P391H mutation suffer some degree of degeneration leading to the cone defect remains, as shown in GRK1$^{-/-}$ mouse photoreceptors. The clinical presentation of Oguchi patients seems indistinguishable across the different mutations, although the molecular consequences of these mutations to GRK1 may be different.

Structure/Function of GRK1

Crystal structures of GRK1 have been solved to provide structure and function insights (Singh et al. 2008). Recent studies have further revealed the molecular interaction between GRK1 and recoverin, its calcium-dependent regulator. The NMR structure of the first 25 amino acid of GRK1 (RK25) in complex with Ca^{+2}-bound recoverin is solved. Residues 4–16 of RK25 form an amphipathic α-helix, where the hydrophobic surface interacts with a conserved groove lined with hydrophobic residues in recoverin. This N-terminal groove of recoverin, comprised of nine hydrophobic residues conserved across other neuronal calcium sensors, is implicated in target recognition (Ames et al. 2006). This N-terminal groove is exposed through the Ca^{2+}-myristoyl switch to allow recoverin binding to GRK1. The residues in GRK1 responsible for binding recoverin are V9, V10, A11, A14, and F15, which form a network of hydrophobic interactions to confer a K_d of 1.4 μM with recoverin. In addition, the N-terminal residues of GRK1 are required for rhodopsin binding (Higgins et al. 2006). Taken together, the binding of recoverin to GRK1 at the N-terminal domain prevents GRK1 from association to rhodopsin when Ca^{2+} level is high. As the calcium level drops in

photoreceptors upon illumination, the myristoyl group on recoverin is sequestered within the hydrophobic groove, resulting in dissociation of recoverin from GRK1 and allowing GRK1–rhodopsin interaction.

Several crystal structures of a truncated GRK1 were reported in various distinct conformations to demonstrate the key elements important for activity and interaction with R* (Singh et al. 2008). The kinase domain is similar to a typical Ser/Thr kinase (AGC Kinase), which contains a large (residues 181–268) and small (residues 269–454) kinase lobe and a C-terminal kinase extension. The active site is formed within a cleft between the large and small kinase lobe and complex with two Mg^{2+} and the nucleotide, ATP or ADP. At the active site, the surface of the large lobe is lined with basic residues to bind with rhodopsin's C-terminal peptides. The small lobe contains the phosphate-binding loop (P-loop) to interact with the triphosphate of ATP. However, the P-loop (Gly-rich B1-B2 turn) in GRK1 is observed to shift away from the nucleotide-binding site when compared to GRK2 and GRK6 and resembles more closely to the structure in Protein Kinase A without any bound nucleotide (Apo-PKA). In the apo-GRK1 structure, the kinase domain adopts a more flexible conformation as compared to nucleotide-bound GRK1. It is hypothesized

that the kinase domain adopts a rigid conformation upon nucleotide binding and become fully closed and active upon binding to R* at the second and third cytoplasmic loops.

Residues 455–511 form the C-terminal kinase extension domain in GRK1 and contain three regions: the C-terminal (large) lobe tether (residues 455–471), an active site tether (AST, residues 472–480), and an N-terminal (small) lobe tether (residues 498–511). The N-terminal and C-terminal lobe tethers have been previously described, while AST has not, due to its sequence variability among GRKs and AGC kinases. GRK1's AST can only be observed in the nucleotide-bound structure and becomes disorder in the apo-kinase, similar to the one in PKA. GRK1 AST includes the "tail loop" (Asp472-Tyr477), which packs closely to the active site, and is predicted to participate in substrate stabilization. The AST is connected to the N-terminal lobe tether through residues 481–489, which contains the autophosphorylation sites (Ser488/Thr489). The phosphorylation status of the two residues is unclear in the structure, although they are phosphorylated in mass spectrometric analysis in the presence of ATP (Singh et al. 2008). It is speculated that the autophosphorylation may participate in electrostatic interaction with Arg222 and Lys221 to stabilize the kinase domain.

The N-terminal structure of the truncated GRK1 is visible in one of the six crystals (form I, PDB 3C4W). The N-terminus (up to residue 32) forms extensive contacts with the RH domain and some with the kinase domain. Two novel phosphorylation sites at Ser5 and Thr8 are identified, but only Ser5 is phosphorylated in native bovine GRK1. Whether phosphorylation of these sites affects GRK1 activity during phototransduction remains to be determined. Interestingly, the N-terminal structure determined by crystallography is different from the RK25 amphipathic helix determined by NMR that complex with Ca^{2+}-recoverin. Recently, a more ordered GRK6 structure revealed the N-terminal region as a helix that interacted with the C-terminal kinase extension (C-tail) to stabilize the large and small kinase lobe and adopt a near-active conformation (Boguth et al. 2009). A set of residues from the small lobe (Arg190), N-terminal helix (Ala8, Asn9, Leu12, and Leu13), and C-tail (Ile472 and Lys475) forms a network of hydrophobic interactions and hydrogen bonds to stabilize the kinase. As these residues are highly conserved in GRK1, it is likely a similar intramolecular network is required for GRK1 to become activated. It is also possible that the amphipathic helix formation of GRK1 requires the presence of recoverin, the GPCR, or other cofactors. Further study is required to resolve the structure and interaction of N-terminus with other regions during GRK1 activation.

The RH domain of GRK1 is made up of nine α-helices that are typical of the RGS domain, with two additional GRK-specific helices. Other than serving as a GAP for transducin, the RH domain may have a role in GRK1 dimerization, but both speculations await experimental confirmation.

Regulations of GRK1 Activity

Several molecules have been identified to regulate GRK1 function in photoreceptors. As demonstrated through biochemical and structural analysis, recoverin interacts with GRK1 and negatively regulates GRK1 in a light-dependent manner (Fig. 1). In the dark, high level of cGMP opens the CNG channel on the plasma membrane and maintains a high Ca^{2+} concentration in the OS. The high Ca^{2+} level induces exposure of the myristoyl group of recoverin and allows it to translocate to OS. At the disk membrane, recoverin inhibits GRK1 activity through interactions of the N-terminal domains. As light stimulation leads to a drop in calcium concentration, the myristoyl group of recoverin becomes embedded within the protein and recoverin loses its ability to associate with the membrane and perhaps diffuses out of OS (Strissel et al. 2005). Without calcium, the inhibition of GRK1 is relieved to allow R* phosphorylation. While studies have shown that recoverin myristoylation is not required for its inhibition on GRK1, it does enhance the cooperative effect of recoverin on GRK1 (Chen et al. 1995). In mouse photoreceptors lacking recoverin, the recovery is faster compared to wild-type rods (Makino et al. 2004). To further test whether recoverin influences R* lifetime through regulating GRK1, Chen et al. underexpressed GRK1 to make rhodopsin deactivation the slowest step in rod recovery. Under such a condition, the presence of background light accelerates rod recovery but this effect disappears when recoverin is removed from photoreceptors. In the absence of recoverin, the inhibitory control on GRK1 is removed and rhodopsin phosphorylation occurs faster (Chen et al. 2010). Thus recoverin is indeed a negative regulator of GRK1 in photoreceptors.

In addition to recoverin regulation, PKA has also been found to phosphorylate and negatively regulate GRK1 (Horner et al. 2005). In vitro, GRK1 is phosphorylated at Ser21 when incubated with the catalytic subunit of PKA or PKA-holoenzyme stimulated with cAMP. Furthermore, urea-stripped ROS incubated with GRK1 and PKA has a 50% decrease in rhodopsin phosphorylation. The importance of Ser21 phosphorylation is seen with the phospho-mimetic mutation (S21E) of GRK1, which has decreased activity toward rhodopsin. In contrast, S21A GRK1 is resistant to PKA inhibition and constitutively phosphorylates rhodopsin. These evidences suggest a role of PKA in phosphorylating and regulating GRK1 in photoreceptor. Under high Ca^{2+} influx in the dark, calmodulin is activated and stimulates cAMP synthesis in photoreceptor. High cAMP level activates PKA to stimulate its phosphorylation on GRK1 at Ser21. Since the N-terminal residues of GRK1 are important in rhodopsin interaction, the phosphorylation at Ser21 introduces a charge residue and obstructs receptor-kinase recognition. Future studies are required to test PKA's action on GRK1 activity in vivo and its modulation on phototransduction.

One of the posttranslational modifications on GRK1 is isoprenylation, which is the covalent attachment of an isoprenoid group to a C-terminal cysteine residue. The modification allows the protein to associate with and function at the membrane. Isoprenylation occurs at the CaaX box motif (C, cysteine; a, any aliphatic residue; X, the residue that determines the type of isoprenoid group attached) (McTaggart 2006). The very C-terminus of GRK1 contains a CaaX box motif (C^{558}VLS) to promote isoprenylation (Inglese et al. 1992). The last three residues are proteolytic removed and a farnesyl group (15 carbon unit) is covalently linked to cysteine through a thioester bond. A methyl group is then added to complete the reaction events. In COS7 cells, GRK1 isoprenylation is abolished by the C558S mutation, and the protein loses its ability to associate with the plasma membrane. In addition, GRK1 without isoprenylation has reduced (~25%) R* phosphorylation activity, indicating that GRK1 isoprenylation is needed for full activity by anchoring the kinase to the disk membrane. It is unclear whether GRK1 isoprenylation and membrane association affects the intrinsic kinase activity, which can be examined by measuring the degree of autophosphorylation of the C558S GRK1 mutant. By changing the terminal serine to leucine at position 561 (Ser561Leu), the farnesylation of GRK1 can be changed to geranylgeranylation (20 carbon unit). When incubating geranylgeranylated GRK1 with urea-stripped ROS extract, the kinase is found to constitutively anchor to the disk membrane independent of light condition, whereas farnesylated GRK1 only localizes to membrane in the presence of light. Activated rhodopsin may serve as a docking site for farnesylated GRK1 to associate to the disk membrane, whereas geranylgeranylated GRK1 is self-sufficient to anchor to the membrane.

Similar to other kinases, GRK1 is found to be autophosphorylated at two residues, Ser488 and Thr489, at the C-terminus. Over the years, experiments studying GRK1 have used the autophosphorylation status as a method to assess the intrinsic kinase activity and compare it to the kinase's capability to phosphorylate R* (Horner et al. 2005; Higgins et al. 2006). To test the effect of autophosphorylation on GRK1, a synthetic peptide that corresponds to the autophosphorylation region is incubated with purified GRK1. The peptide did not affect GRK1's ability to phosphorylate rhodopsin as the kinase has low activity toward it. This suggests that the autophosphorylation domain in GRK1 does not serve as an autoinhibitory domain, which makes GRK1 unique among the protein kinases. Unphosphorylated GRK1 (Ser488 and Thr489 to alanines) have been shown to preferentially phosphorylate Ser338 on R*, whereas regular GRK1 phosphorylates Ser338 and Ser343. It is speculated that autophosphorylation influences the affinity and enhances the dissociation of GRK1 from phosphorylated rhodopsin to allow arrestin binding, but its exact physiological role remains to be elucidated.

Summary

As the kinase responsible for light-dependent rhodopsin phosphorylation, GRK1 is essential for timely R* deactivation during phototransduction recovery. The regulation of GRK1 through posttranslational modification (phosphorylation and isoprenylation) and other signaling molecules (PKA and recoverin) are important as slowing it down can change the rate-limiting step in rod recovery. Understanding the structure–function relationship of GRK1 is not complete and requires the crystal structure of a full length and active kinase preparation. As already demonstrated in several studies, changes in GRK1

level can have significant consequences in phototransduction recovery and may lead to sensitivity to light damage. More studies are needed to reveal the signaling events leading to photoreceptor degeneration in the absence of GRK1 and additional roles GRK1 may play in photoreceptors.

Historical Background

Grp94 is the endoplasmic reticulum (ER) paralog of heat shock protein (Hsp) 90. This chaperone/stress protein was identified together with the other members of the family of glucose-regulated proteins because its levels significantly increased after treatment of mammalian cells with culture medium lacking glucose. Subsequent evidence showed that other ER stressors, such as calcium depletion, inhibition of glycosylation, and reducing agents, similarly affected Grp94 protein levels, making it one of the hallmarks of ER stress response (Lee 1987). Grp94 protein levels increase also after exposure to low-doses of endotoxin, hypoxia, and mild ischemia and in most tumors (Srivastava 2006; Glembotski 2008). The last feature, which is accomplished by Grp94 binding of tumor-specific peptides, explains the other widely used synonyms gp96 and TRA1 (Srivastava 2006).

The apparent Mr of Grp94 is around 94–100 kDa in most Vertebrate species and is the product of a single gene. Whereas Grp94 orthologs are detected in Metazoans, plants enclosed, no corresponding gene or protein has been so far identified in yeast and other monocellular eukaryotes, except for *Leishmania* (Eletto et al. 2010). The protein shows multiple Mr isoforms depending on the variable degree of glycosylation and on the presence of Ser/Thr- or Tyr-phosphorylation (Frasson et al. 2009 and references within). Whereas the functional significance of glycosylation remains still obscure, Ser/Thr-phosphorylation by Golgi casein kinase and Tyr-phosphorylation by Fyn Src-kinase are

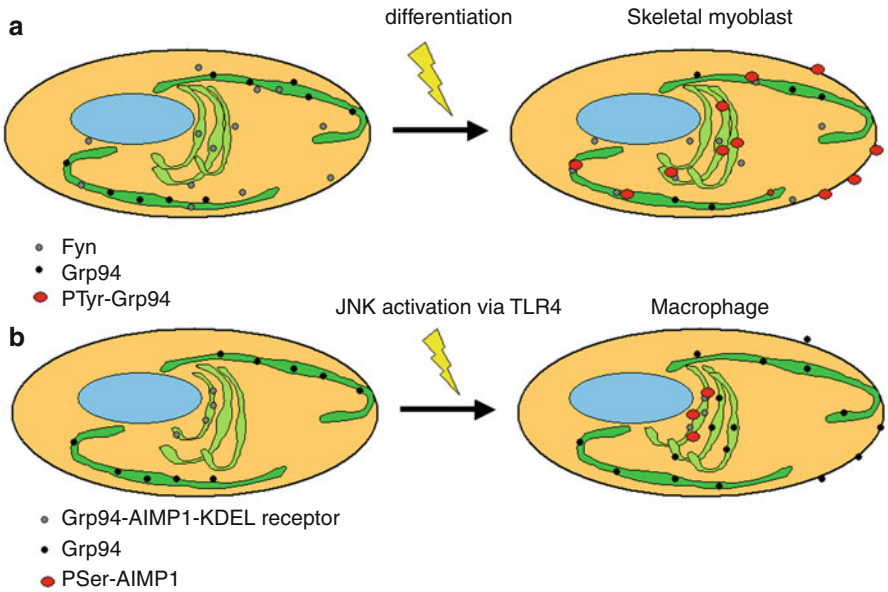
At variance with Hsp90, whose conformation is changed to a catalytically active one by nucleotide binding, Grp94 ground-state conformation is apparently not affected

involved in Grp94 subcellular localization. Detailed analyses of Grp94 distribution in adult mammalian tissues and primary cells indicate relatively low expression levels of mRNA and protein in most tissues, except for lung bronchial epithelium, pancreatic islets, kidney tubular cells, and dendritic cells (Mao et al. 2010).

Structurally, Grp94 contains four domains (Eletto et al. 2010 and Fig. 1a). The N-terminal (N) domain contains a nucleotide binding site, a peptide binding site, unmapped sites responsible for interaction with dendritic cells during antigen presentation (Jockheck-Clark et al. 2010), the binding site for the co-chaperone Murine canopy 3 (CNPY3, Liu et al. 2010), and a putative transmembrane domain (Frasson et al. 2009 and references within). The second domain, as in Hsp90, is a charged linker between the N and middle (M) domains, but it is longer in Grp94 and functionally important for binding of both nucleotide and calcium. The M-domain contains residues involved in ATP hydrolysis after interaction with the N-terminal domain, and the C-terminal domain mediates the dimerization of Grp94 and ER localization via the C-terminal KDEL peptide. Grp94 displays a "twisted V" conformation as crystal structure (Fig. 1b), whereas in solution it has an extended, "chair-like" conformation, which shifts toward less extended, more closed conformations after nucleotide binding (Eletto et al. 2010).

Like other ER chaperones, such as Grp78 and calreticulin, Grp94 is a putative low affinity-high capacity Ca^{2+}-binding protein. Grp94 binds about 16–28 moles Ca^{2+} per mole protein with a few high affinity (Kd 1–5 μM) binding sites and the rest, lower affinity sites (Kd ~600 μM). Thus, Grp94 may bind about 4 moles of calcium/mole of protein in the presence of 1 mmol/L calcium, namely the range of free calcium concentration considered to be present within the ER (Eletto et al. 2010).

ER localization of Grp94 is regulated, like other ER chaperones, through the C-terminal KDEL sequence. The KDEL sequence is recognized by a specific receptor, which is mainly localized in the cis-Golgi. Dimers-oligomers of Grp94 interacting with the aminoacyl-tRNA synthetase-interacting multifunctional protein 1 (AIMP1; previously known as p43) bind to the receptor and lead to its oligomerization and rapid transport out of cis-Golgi (Kim et al. 2010). The KDEL receptor-Grp94 complex returns to the ER, where it dissociates, thus freeing the receptor for further cycling of transport. In addition to the ER, Grp94 is detected at the cell surface of several tumors and of immature cells



Grp94 (HSP90B1), Fig. 2 Signals responsible for Grp94 cell-surface localization. (**a**) Differentiation of skeletal myoblasts induced by low serum culture medium activates an ER-resident Fyn, which interacts with and Tyr-phosphorylates Grp94, promoting its migration to the Golgi compartment and the cell surface. (**b**) Exposure of circulating or spleen macrophages to bacterial lipopolysaccharide activates TLR4 and JNK-mediated AIMP1 phosphorylation, which dissociates Grp94-KDEL receptor complex and favor Grp94 export to the cell surface

(Srivastava 2006; Gorza and Vitadello 2000). Two signaling pathways responsible for Grp94 exit outside the ER have been so far identified (Fig. 2): (1) in differentiating myoblasts, the Tyr phosphorylation of Grp94 by Fyn Src-kinase is required for the chaperone translocation to Golgi and cell surface (Frasson et al. 2009) and (2) in LPS-stimulated monocytes and splenocytes, the Ser-phosphorylation of AIMP1 by c-Jun N-terminal kinase (JNK) releases the binding of the protein from Grp94 and the interaction with the KDEL receptor (Kim et al. 2010).

Another distinctive feature of Grp94 is the transmembrane configuration, which apparently involves a minor proportion of molecules and coexists in the ER compartment with the luminal configuration (Frasson et al. 2009 and references within). The precise mechanism of anchorage of Grp94 molecules to the cell surface is presently unknown; however, data suggest that it occurs through noncovalent, nonionic binding with other proteins (Srivastava 2006).

Physiological Functions

Protein Chaperone

Grp94 exists as a homodimer or higher-order oligomer. Although it has been shown to bind to some nascent ER proteins, Grp94 participates to the second major ER chaperone system, which operates, in addition and/or in alternative to the lectin system, on unfolded regions of proteins containing hydrophobic residues and is involved in folding and assembly of multimeric proteins, whose first and most studied example is the immunoglobulin heavy chain (Ma and Hendershot 2004). A large ER-localized multi-protein complex is initiated by the ER chaperone Grp78 that recognizes protein hydrophobic residues and recruits Grp94 and other molecular chaperones, among which are protein-disulfide isomerase, cyclophilin B, Grp170. As revealed by studies performed using chemical cross-linking, the complex forms also in the absence of protein synthesis (Ma and Hendershot 2004). The mechanism through which Grp94 exerts its chaperone function is still obscure, due to controversial evidence concerning ATPase activity, to the lack of co-chaperones and the paucity of client proteins. Conservation of amino acids involved in ATP binding and hydrolysis between Hsp90 and Grp94 would suggest a similar mechanism of nucleotide utilization. Grp94 binds adenosine nucleotides in vitro and mutations of either the ATP binding site, or the putative catalytic one, hamper chaperone activity in vivo (Randow and Seed 2001). However, structure analysis methods, including x-ray crystallography, mass spectrometry, and optical techniques showed that the ATP and ADP-bound forms of Grp94 are equivalent, that is,

they display identical twisted "V"-shape conformation with closed C domains and open N domains in opposing orientation (Eletto et al. 2010; Fig. 1b). Therefore, ATP binding is not sufficient to drive Grp94 into a hydrolytically productive conformation: the open N domain and the relaxed N–M orientation leave the catalytic residues too distant from the gamma-phosphate of the ATP, at variance with Hsp90 and other proteins of the GHKL ATPase/kinase superfamily, whose ATPase activity results from the contact of residues localized in both the N and M domains with the bound nucleotide. As argued by the structural analysis, co-chaperone(s) would be required by Grp94 to promote ATP hydrolysis by rotating the catalytic loop, and to regulate binding and release of client proteins. The ER resident protein CNPY3 has been recently identified as the first Grp94 co-chaperone, specifically involved in TLR folding (Liu et al. 2010). CNPY3 binds Grp94 close to the ATP pocket and in competition with nucleotides, suggesting that it regulates the folding of conformational intermediates without nucleotides, as shown for some Hsp90 co-chaperones (Eletto et al. 2010; Liu et al. 2010). Indeed, the same single point mutation at the highly conserved amino acid 103 (E103A) of Grp94, which was found to abolish ATPase activity and insulin-like growth factor (IGF) folding (Eletto et al. 2010), hampered the interaction with CNPY3 (Liu et al. 2010) and folding of Toll-like receptors (TLR) (Randow and Seed 2001), but it did not affect the folding of other client proteins, such as integrins (Randow and Seed 2001). At present, no recognition moiety has been identified for Grp94. Its small population of client proteins does not display common features other than the presence of disulfide bonds, and, in the case of integrins and TLR, shows selectivity even among family members (Table 1 and McLaughlin and Vandenbroeck 2011).

An unexpected role for Grp94 has been described in the ER quality control, that is, in targeting misfolded proteins to ER-associated degradation (ERAD). Misfolded and demannosylated protein substrates are bound by OS-9, a ER lumenal lectin, which associates with Grp94 in order to present substrates to the ubiquitination and dislocation apparatus. The role of Grp94 is presumably to facilitate or mediate substrate recognition, since degradation of mutated glycosylated proteins is impaired in Grp94-depleted cells (Eletto et al. 2010).

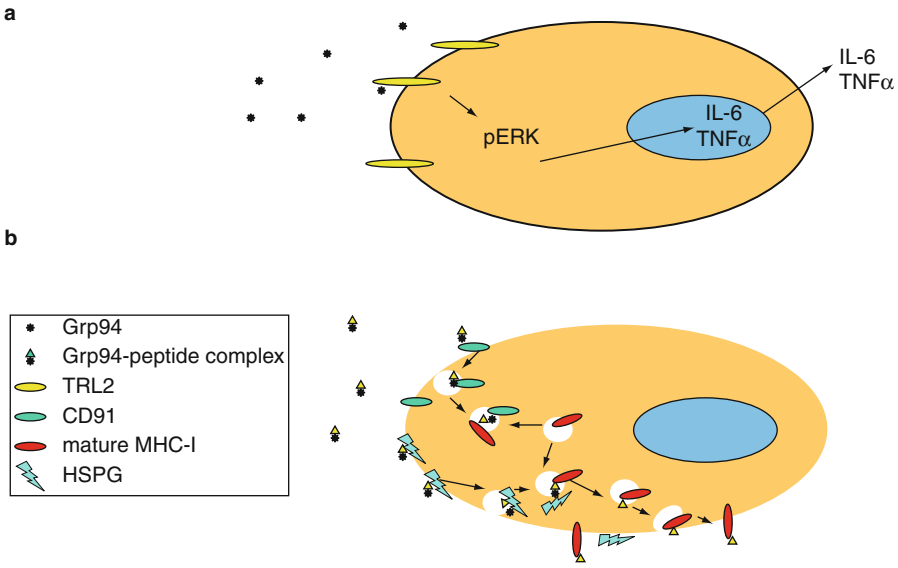
Immune Regulator

Grp94 is involved in both innate and adaptive immune responses.

In addition to play a key role in the folding of several TLR, Grp94 was proposed to activate professional antigen-presenting cells (pAPC) by interacting with TLR2 and ▶ TLR4. Contaminating endotoxin, either derived from recombinant Grp94 preparations or released even at very low levels from commensal flora, appears to have confounded the interpretation of these studies. However, after stringently controlling the level of endotoxin contamination and evaluating the inhibition of the Grp94 interaction by means of specific antibodies, a recent study demonstrated that this chaperone activates human macrophages primarily through TLR2 and induced both IL-6 and TNF-α release (Huang et al. 2009) (Fig. 3a). Some activation occurs through TLR4, concerning only IL-6 production. Besides, Grp94 appears to regulate the pathway activated by the TLR2 receptor downstream the mitogen extracellular kinase (▶ MEK)-ERK1/2. In kidney tubular cells, this chaperone binds and maintains in active conformation the serine-threonine protein phosphatase 5 (PP5), a negative modulator of ▶ Raf-1 (Mkaddem et al. 2009).

In addition to initiate the innate immune responses by interacting with TLR2 and TLR4, Grp94 contributes to the adaptive one. Several in vitro studies demonstrated that the N-terminal and charged linker domains of Grp94 comprise



Grp94 (HSP90B1), Fig. 3 Schematic representations of the pathways activated by exposure of pAPCs to Grp94 in innate and adaptive immune responses. (**a**) Interaction of soluble Grp94 with TLR2 induces IL-6 and TNF-α secretion in human macrophages through ERK1/2 pathway activation. (**b**) Peptides complexed to Grp94 are internalized by pAPCs after either receptor-mediated or fluid-phase endocytosis, and loaded onto mature MHC class I molecules in a post-ER compartment. HSPG: heparan sulfate proteoglycan

a peptide-binding domain, which is inhibited when small molecules such as radicicol, geldanamycin and NECA occupy the nucleotide pocket at the opposite site (Eletto et al. 2010). Although it is presently debated whether Grp94-peptide binding is physiologically relevant in vivo, it is fully recognized that Grp94 can direct the associated peptides into the Major Histocompatibility Complex (MHC) class I cross-presentation pathway of pAPCs (Srivastava 2006; Jockheck-Clark et al. 2010). Peptides bound to Grp94 are internalized by pAPCs by endocytosis and trafficked to a post-ER endosomal compartment, where they are processed and loaded onto mature MHC class I molecules (Fig. 3b). The mechanism of endocytic uptake of the Grp94-peptide complex remains controversial. A large body of evidence indicates the requirement of receptor-mediated internalization, via the low-density lipoprotein receptor-related protein 1 (▶ CD91) and/or the scavenger receptors, whereas recent results obtained in pAPC, engineered to knockdown or knockout CD91 expression, support a prominent role of the pathway of nonspecific fluid-phase uptake (Jockheck-Clark et al. 2010). In any case, the interaction of Grp94-peptide complex with pAPC elicits proinflammatory cytokine secretion and MHC class I/II up-regulation, leading to subsequent priming and activation of peptide-specific CD8+ T lymphocytes.

Calcium Binding Protein

Although each Grp94 molecule can bind between 16 and 28 Ca^{2+}, only one high affinity calcium-binding site has been mapped with certainty in the N-terminal portion of Grp94, in the charged linker domain (Eletto et al. 2010). In vitro studies showed that Ca^{2+} binding at this site stimulates Grp94 peptide binding. Due to its relative abundancy in the ER, Grp94 is expected to provide about 30 μM of Ca^{2+} storage capacity. This property, which is shared with other ER chaperones, like Grp78 and calreticulin, might imply the participation of Grp94 to the maintenance of calcium homeostasis. In addition to protein folding, ER is deputed to the storage and utilization of calcium. Release and uptake of calcium by the ER is involved in many signaling pathways and physiological responses, like protein secretion and muscle contraction. Depletion of calcium from the stores induces an ER stress response. Besides, alterations in ER free calcium concentration strongly influence cell survival. If the ER has less free calcium to release upon stress, then cytosolic calcium levels will not rise to the critical levels needed for triggering deleterious downstream effectors. Therefore, the increased expression of ER chaperones with calcium-binding properties should protect cells by decreasing the amount of releasable calcium. Such a hypothesis finds support from several studies showing that Grp94 overexpression counteracts the increase in intracellular Ca^{2+} evoked by exposure

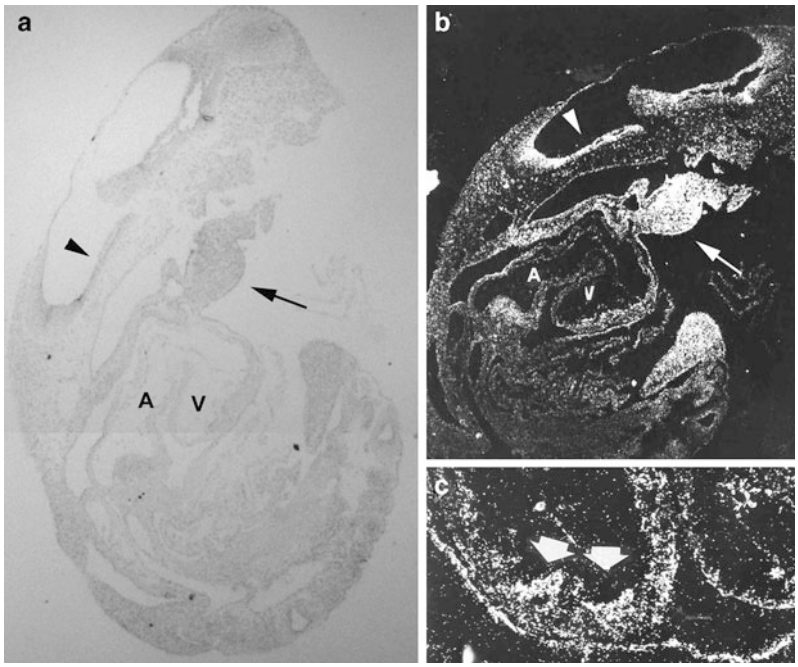
either to calcium ionophore or to oxidants, whereas cells engineered to decrease Grp94 expression appear unable to cope with it (Pizzo et al. 2010 and references within). Passive calcium release from the stores, induced in myogenic cells by means of sarcoendoplasmic calcium ATPase (SERCA) inhibition, showed that cellular levels of Grp94 inversely correlate to the rise in intracellular Ca^{2+} (Pizzo et al. 2010). This body of evidence points toward a role for Grp94 in preserving cell viability, when challenged by perturbations of Ca^{2+} homeostasis, suggesting that Grp94 may modify intracellular Ca^{2+} content, probably by interaction with calcium cycling proteins.

Physiological Function in Embryonic Development

Consistently with the observation that Grp94 is absent from most unicellular organisms, knockdown of Grp94 in different cell culture systems shows that low basal expression levels of the protein are sufficient to support cell growth and proliferation (Eletto et al. 2010). Similarly, two Grp94 gene mutations causing knocking out of the protein (the *Shepherd* mutation in *A. thaliana* and the frameshifts terminating Grp94 prematurely in the pre-B lymphocyte 70Z/3 cell line) are not cell-lethal, but rather affect selected processes. Although these data suggest that Grp94 does not appear to be essential for growth of individual mammalian cells in culture, survival of $grp94^{-/-}$ embryonic stem cells (ES) is strictly dependent from the presence of serum and IGFs. In addition, a parallel independent study showed that $grp94^{-/-}$ ES cells display an increased, compensatory, expression of ER chaperones, whereas in the presence of a 50% reduction of Grp94 levels, as it occurs in hemizygosis, there is no compensatory response (Mao et al. 2010). Furthermore, $grp94^{-/-}$ ES cells show a decreased ability to activate the XBP-1 pathway of the ER stress response. This observation reveals the involvement of Grp94 in the ER stress signaling, a function up to now mainly attributed to Grp78 (Glembotski 2008). In $grp94^{-/-}$ ES cells, the decreased expression of the ER stress-induced transcription factor XBP-1 might be due to the misfolding of the Grp94 client proteins TLR4 and TLR2, which in macrophages are known to activate the ER-stress sensor, inositol-requiring enzyme 1a (IRE 1), and its downstream target XBP-1 (Mao et al. 2010).

Conversely, Grp94 absence is responsible for the occurrence of lethal phenotypes in plants, nematodes, fruit flies, and mice (Eletto et al. 2010). In mammals, Grp94 transcripts are found in oocytes and, in 5–8.5-d embryos, protein expression is highest in the embryonic and extraembryonic ectoderm and lower in the visceral endoderm. Grp94 is also detected in mesoderm cells emerging from the primitive streak. At later stages during organogenesis (E9.5–13.5) Grp94 is expressed within the developing heart, neuroepithelium, and branchial arches (Fig. 4). Despite of the widespread and early expression of Grp94 during embryonic development, its requirement during differentiation and organogenesis differs depending on the pattern of expression and the essential function of the client proteins.

One relevant example is given by skeletal muscle progenitors, where Grp94 expression is required for differentiation and maturation (Eletto et al. 2010; Gorza and Vitadello 2000). The phenotype of $grp94^{-/-}$ mice is lethal at E7.5 and embryo bodies generated by $grp94^{-/-}$ ES cells show any type of tissue differentiation, except the formation of striated and smooth muscles. The loss of ability to give origin to muscle is due to the absolute requirement of Grp94 in folding of IGFs. When supplemented with IGF, $grp94^{-/-}$ ES cells are able to differentiate and express myogenin and contractile proteins; they can also fuse into myotube-like syncitia, although with far less efficiency of wild type ES cells. Since Grp94 depletion does not affect myoD levels, the chaperone is not required for the commitment to myogenesis. Conversely, Grp94 appears to be involved in myogenesis initiation. Few hours after switching the myogenic cell line C2C12 to differentiation medium, the protein translocates from the ER to the Golgi compartment and the cell surface, after interacting with and being Tyr-phosphorylated by the Src-kinase Fyn (Frasson et al. 2009 and Fig. 2a). It is presently unknown whether this re-localization is related to delivery of specific protein cargo; an identified relevant client is IGF-II, whose secretion and autocrine interaction with IGF-I and II receptors (IGF-R1) is required to proceed along the differentiation program. Eventually, Grp94 appears to be involved in myotube formation. Knocking down Grp94 protein levels to 40% of wild type C2C12 cells is permissive for myogenic differentiation, but not for myotube formation (Gorza and Vitadello 2000). Since IGF supplementation does not fully rescue the myotube phenotype, it is likely that



Grp94 (HSP90B1), Fig. 4 In situ hybridization analysis of Grp94 mRNA distribution in the E10 rabbit embryo. (**a**) and (**b**) show bright and dark field micrographs, respectively, of a sagittal section of the whole embryo. A and V indicate primordium of the atrial and ventricular myocardium, respectively. Strong hybridization signals are detectable at the level of branchial arches (*thin arrow*) and neuroepithelium (*arrowhead*). (**c**) The micrograph shows the myocardium of the ventricular primordium at higher magnification. *Large arrows* point to stronger hybridization signals at the level of ventricular trabeculae

other Grp94 client proteins play a relevant role at this later stage.

Another example of the tissue specificity of Grp94 involvement in tissue differentiation and maturation has been recently provided by the study of murine hematopoietic and lymphopoietic precursors after conditional knock out of Grp94 (Staron et al. 2010). Despite the essential role of the chaperone in the folding of most TLRs and integrins, only lymphopoiesis, that is, maturation of pro-B lymphocytes and development of thymocytes, is severely affected. Furthermore, this defect cannot be rescued by wild type precursors, indicating that the chaperone regulates B- and T-lymphopoiesis in a cell-intrinsic fashion.

Pathophysiological Functions

Cancer

Most neoplastic cells express high levels of chaperone/stress proteins. ER chaperones are upregulated probably because hypoxia and hypoglycemia are two characteristics of the tumor environment and inducers of the ER stress response. A direct consequence of this upregulation is the enhancement of neoplastic cell survival; an indirect one is the increase and the release of tumor-specific peptides bound to chaperones. Srivastava and coworkers first identified a series of structurally related, but distinct, Grp94 molecules associated with specific immunogenicity of chemically induced mouse sarcoma. Specific antitumor immunity, raised after purification of the Grp94-peptide complex from a highly metastatic variant of murine lung carcinoma, is mediated by $CD4^+$ and $CD8^+$ T lymphocytes and natural killer cells and suppresses tumor metastasis. Furthermore, vaccination with Grp94-peptide complexes isolated from different tumors elicits antitumor response against all the tumors (Srivastava 2006). These results, which have been confirmed experimentally by other laboratories, represent the starting point for the development of anticancer immunotherapy, which is presently tested in several clinical trials (Woods and Mulders 2009).

Grp94 is also involved in anticancer therapies aimed to disrupt Hsp90 chaperone function on several oncogenic proteins by means of molecules like geldanamycin and analogues, which inhibit ATPase activity (Fig. 1a). The effects of these molecules on Grp94 function in tumor cells are rarely investigated, although they might play a role in reducing active cell surface levels of transmembrane receptors implicated in cancer, such as the receptor for the epidermal growth factor (EGF receptor) and, most importantly, the release of IGFs (McLaughlin and Vandenbroeck 2011).

Autoimmune Diseases

Only immature cells and some neoplastic ones express Grp94 molecules at the cell surface. Spontaneous systemic lupus erythematosus-like autoimmune phenotype was experimentally obtained by inducing persistent expression of cell surface Grp94, via transgenic overexpression of an obligatory transmembrane form of Grp94 (Liu et al. 2006) or knock out of AIMP1, which allows the interaction of Grp94 with the KDEL receptor (Kim et al. 2010). A subsequent study excluded the direct role of the enforced cell surface expression of Grp94 demonstrating that disease phenotype occurs secondary to the concomitant increased expression of TLR4 and the enhanced sensitivity of the receptors to low levels of endotoxin released by the commensal flora (Liu et al. 2006). On the other hand, the inhibition of Grp94 localization to the surface of $AIMP^{-/-}$ cells, achieved by restoring KDEL receptor uptake, appeared efficient in ameliorating the disease phenotype (Kim et al. 2010). Despite these controversial findings, the participation of this chaperone in the pathogenesis of autoimmune diseases has been recently demonstrated for rheumatoid arthritis. Released Grp94 is increased in synovial fluid from the joints of human rheumatoid arthritis patients, where it interacts with the extracellular domains of both TLR2 and TLR4, promoting the self-perpetuating activation of synovial macrophages (Huang et al. 2009).

A major nonimmune role in the pathogenesis of autoimmune myositis is played by the ER stress response accompanying transgenic MHC class I upregulation in mouse skeletal muscle fibers and leading to NF-kB activation and increased expression of ER chaperones. Extensive analysis of patients' biopsies revealed that Grp94 overexpression was restricted to regenerating myofibers, which recapitulating muscle differentiation overexpressed also MHC class I molecules and other autoantigens (Vitadello et al. 2010). In this context, the immunomodulatory and pro-inflammatory effects of Grp94 upregulation appear to play a secondary role, bound to muscle regenerative events, which, however, may stimulate further the immune response.

Nevertheless, Grp94 involvement in the inflammatory and the adaptive immune response represents an interesting therapeutical target for autoimmune disorders. Grp94 chaperone activity on client proteins, such as TLRs and the p40 subunit of the interleukin 12 family of cytokines (IL-12), might be inhibited by radicicol and geldanamycin derivatives, which have been shown to reduce inflammatory markers and capillary leakage and modulate IL-12 family secretion levels (McLaughlin and Vandenbroeck 2011).

Ischemia-Reperfusion

Ischemia-reperfusion represents a strong inducer of the ER stress response. Several studies have been performed in the brain, where the activation of the ER stress response upregulates ER chaperone expression and is protective. Such an issue is far more relevant for mammalian cardiomyocytes, where control of intracellular calcium concentration $[Ca^{2+}]_i$ becomes critical during ischemia. Although evidence obtained in vitro and in vivo confirmed the activation of the ER stress response in ischemic-reperfused cardiomyocytes, it is less clear what function the ER stress response serves in the cardiac context. Several studies show that ER stress response contributes to ischemic damage, by inducing both apoptosis and autophagy-mediated cell death; conversely, others support the protective role of the ER stress response and of ER chaperones, among which is Grp94, in decreasing size of infarct or maintaining cardiomyocyte viability (Glembotski 2008). Such a discrepancy might depend upon the context of the study, in that protective aspects of the ER stress response predominate early after the ischemic injury, whereas pro-apoptotic features occur later. Although the mechanism through which Grp94 exerts cardioprotection remains to be determined, a body of evidence point to its role in the maintenance of calcium homeostasis. Grp94 overexpression improves myocyte survival after exposure to oxidative stress, a usual consequence of ischemia-reperfusion, because it reduces the degree of protein oxidation (Pizzo et al. 2010). Calcium dyshomeostasis is generated by and generate further oxidative stress. Grp94 overexpression, which can also be pharmacologically upregulated, appears to disrupt this pathway, by reducing the amount of releasable calcium from the stores.

Ischemia/reperfusion injury also induces an innate immune response, leading to an inflammatory reaction and tissue damage that have been attributed to engagement of TLR2 and 4. In the ischemic kidney, Grp94 contributes to the activation of ERK1/2 downstream pathway by dissociating from PP5, and thus

inactivating this negative modulator. Although multiple pathway activated by ischemia-reperfusion act upon the ERK1/2 cascade of renal tubular cells, the dissociation of Grp94 from PP5 is dependent only from TLR2 activation (Mkaddem et al. 2009).

Inhibitors and Expression Regulators

The small number of client proteins and the involvement in specific cellular events make this chaperone an interesting target to be inhibited or increased, depending of the desired outcome.

Known inhibitors of both ATP hydrolysis and peptide binding, such as radicicol, geldanamycin, and analogues, are already tested in clinical trials mostly as inhibitors of Hsp90 chaperone activity (McLaughlin and Vandenbroeck 2011). The nucleotide analog 5′-*N*-ethylcarboxamidoadenosine (NECA), a broad-spectrum adenosine A_2 receptor antagonist, which binds Grp94 and not Hsp90, is presently used only in vitro. Recently, the molecule S-methyl 2-(4,6-dimethoxypyrimidine-2-yloxy)-3-methylbutanoate (GPM1) has been shown to directly interact with hydrophobic residues of Grp94 within the dimerization domain (Fig. 1a), facilitating its oligomerization and retrograde transport to endoplasmic reticulum via the KDEL receptor. In vivo administration of this compound reduced maturation of pAPCs and activation of B and T cells, alleviating the symptoms associated to an experimental model of systemic lupus erythematosus in mice ($AIMP1^{-/-}$) (Han et al. 2010).

Although upregulation of Grp94 is achieved pharmacologically together with that one of the other ER chaperones – one example is the ER stress response induced by celecoxib, a nonsteroidal anti-inflammatory drug, and its derivatives (McLaughlin and Vandenbroeck 2011) – a more selective Grp94 involvement apparently follows the administration of curcumin (Pizzo et al. 2010). Similarly to celecoxib, also curcumin is a SERCA inhibitor and able to induce an ER stress response by depleting calcium stores. A single pulse of curcumin at low dosage selectively upregulates Grp94 expression and contains the effects of oxidative stress on protein carbonylation and cell survival, whereas the benefits of such a short curcumin treatment cannot be observed, when Grp94 is knocked down by antisense cDNA (Pizzo et al. 2010).

Summary

Grp94 is a chaperone/stress protein of the ER and is expressed only in multicellular organisms. At variance of the paralog Hsp90, Grp94 is involved in the folding of a limited population of client proteins and only one co-chaperone has been identified so far. Grp94 absolute requirement for embryonic development derives from the specific role of the client proteins played in critical contexts, like IGFs for differentiation of muscle tissues, and TLR and integrins for lymphopoiesis.

In addition to chaperone activity, Grp94 serves different functions. It binds calcium and participates, through still unknown mechanisms, to the control of intracellular calcium homeostasis. When increased, consequent to the ER stress-response, it exerts cytoprotection against different stressors, such as calcium overload and reactive oxygen species. Grp94 may change its subcellular localization, migrating to Golgi and the cell surface, depending on the cell type and the activation of signal transduction pathways involving Src-kinase or JNK. Cell surface and released Grp94 molecules act as immune regulator of both the innate and adaptive responses by allowing maturation of pAPCs. The protein interacts with TLR2 and initiates inflammation promoting IL-6 and TNF-α secretion from pAPCs. It participates to the adaptive immune response by binding peptides and being internalized in post-endoplasmic reticulum endosomal compartment of pAPCs, where the carried peptide is loaded onto mature MHC class I molecules and can recruit specific $CD4^+$ and $CD8^+$ T lymphocytes.

Although this last property suggested the use of peptide-bound Grp94 as anticancer vaccine, the other features identify this ER chaperone as an interesting target for pharmacological therapy. Hampering the chaperone activity of Grp94 or increasing the protein retention into the ER reduces the release of pro-inflammatory and immune modulatory signals. Future attempts to change selectively Grp94 protein levels would permit to vary cell resistance against lethal stresses.

Guanylyl cyclase

Historical Background

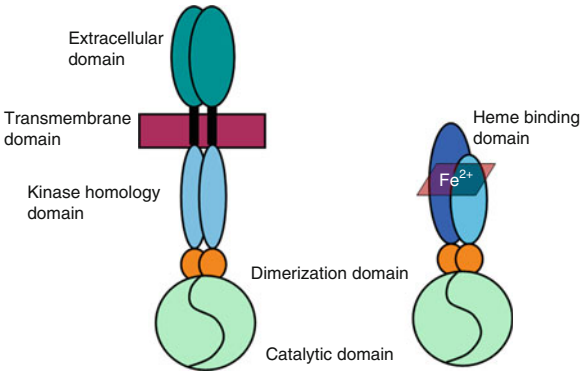
The concept of second messenger molecules in hormone signal transduction was developed in the 1950s by Earl W. Sutherland describing the cyclic nucleotide adenosine 3′, 5′-cyclic monophosphate (cAMP) as an intracellular messenger molecule. The main features of this concept are the binding of a hormone to the extracellular site of a transmembrane receptor protein which triggers an intracellular response mediated by a second messenger molecule (e.g., cAMP). Shortly after cAMP was discovered as second messenger in hormone signaling another cyclic nucleotide abbreviated cGMP (guanosine 3′, 5′-cyclic monophosphate) was first detected in rat urine (Ashman et al. 1963) and soon after was found in a variety of other tissues and biological samples. Every second messenger system requires the presence of synthesizing and degrading enzymes. For cyclic purine monophosphates these are adenylate and guanylate cyclases and specific forms of phosphodiesterases, respectively. Guanylate cyclases (GCs) catalyze the conversion of GTP to cGMP according to the reaction scheme: GTP → cGMP + pyrophosphate (PP_i). The development of suitable and effective enzymatic assays led in 1969 to several publications that report on the determination of GC activity. Consequent studies then revealed that GC activities cofractionated with soluble and particulate membrane fractions, but it was not before the mid to late 1980s that soluble and membrane-bound GCs were purified from mammalian sources to apparent homogeneity. Subsequent cloning studies in the late 1980s and early 1990s using tissue-specific cDNA libraries resulted in deduced primary structures of soluble and particulate GC isoforms. Studies on mammalian GCs were inspired by work on sea urchin sperm that is a rich source of a particulate GC and that is activated by certain peptides. In mammalians it was known already from reports in the 1970s that neuromediators like acetylcholine could regulate the cGMP level in perfused heart tissue, but the physiological pathways linking these steps remained unclear until the 1980s. Then several discoveries showed that cGMP is the second messenger of important physiological responses including smooth muscle relaxation, intestinal fluid and electrolyte homeostasis, and sensory physiology, in particular phototransduction. Several physiologically relevant molecules that regulate and/or trigger activation of GCs were identified and characterized in the last three decades. The most important so far are nitric oxide for the soluble isoforms and natriuretic peptides, paracrine intestinal hormones, and changes in cytoplasmic Ca^{2+}-levels in combination with Ca^{2+}sensor proteins for the different particulate isoforms. The identification of these regulatory molecules paved the way for integrating GC isoforms in signaling pathways or led to formulation of new signaling concepts (for historical aspects see Beavo and Brunton 2002; Kots et al. 2009; Sharma 2010).

Guanylate Cyclase Forms

Seven different forms of a membrane GC and two α- and β–subunits of the soluble form are expressed in a wide range of mammalian tissues (see under "Tissue Distribution"). They are classified on the basis of their amino acid sequences and according to their ligands or intracellular regulators (for each GC forms synonymous names are found in the literature and are given below):

Membrane-bound GCs	Soluble GCs
GC-A/ANF-RGC//NPR-A	sGC α1
GC-B/CNP-RGC/NPR-B	sGC α2
GC-C/STa-RGC	sGC β1
GC-D/ONE-GC	sGC β2
GC-E/ROS-GC1/retGC-1	
GC-F/ROS-GC2/retGC-2	
GC-G	

In addition GCs are also found in nonmammalian vertebrates like teleost fishes, in insects, nematodes, unicellular eukaryotic organisms, and bacteria (Baker and Kelly 2004; Ortiz et al. 2006; Rätscho et al. 2010).



Guanylate Cyclase, Fig. 1 Domain topography of membrane and soluble GCs

Some of these organisms express a larger variety of GCs than mammalians and are at least partially homologous to the GC forms found in mammalians.

Protein Structure and Topography

Membrane-bound and soluble GCs share some common structural features, but also differ in those protein domains that are important for their regulation by extracellular or intracellular factors (Lucas et al. 2000; Tamura et al. 2001). Figure 1 shows the main topographic features of these GC forms. Membrane (particulate) GCs are homodimers, whereas soluble GCs function as heterodimers. Both subtypes contain a cyclase catalytic domain with a high amino acid sequence homology among all GCs and significant homology to adenylate cyclases. Invariant amino acids in the catalytic domain define the substrate specificity (binding of GTP or ATP). The catalytic domain of the membrane-bound isoforms is extended by a C-terminal tail of varying length, which is not present in soluble GCs. Both subtypes also contain a dimerization domain that is N-terminal to the catalytic domain. This domain has the structural features of an amphipathic α–helix allowing forming a two-stranded α–helical coiled coil. The third large domain of the cytoplasmic part of membrane-bound GCs is the kinase homology domain that consists of approximately 250 amino acids. It shows partial amino acid sequence homology to protein tyrosine kinase receptors and harbors an ATP-binding motif that is identical or similar to the ATP-binding motif of the catalytic subdomains of protein kinases (the sequence GxGxxG that is rich in glycine is conserved in some GCs, but not in all). Particulate GCs are anchored in the membrane by a single transmembrane domain that has an amino acid sequence typical for an α-helical transmembrane region found in other membrane receptor proteins. While it is clear that this segment is important for membrane localization it is unresolved whether it also mediates transmembrane signaling. The different particulate subtypes might differ in this aspect. A short segment of amino acids called the juxtamembrane domain is sandwiched between the kinase homology and the transmembrane domain. Depending on the subtype of particulate GC this region consists of 25–100 amino acids. The more extended forms of the juxtamembrane region are found in the sensory GCs.

Instead of a kinase homology domain soluble GCs contain a heme-binding domain that is N-terminally located from the amphipathic dimerization domain (Fig. 1). The two heme-binding domains of one soluble GC heterodimer coordinate a heme prosthetic group (a porphyrin ring structure with a central ferrous ion (Fe^{2+})) that is required for the enzyme to become activated by nitric oxide (see below).

The least homology among all membrane-bound GCs is found in the extracellular domain. This large domain consists of approximately 500 amino acids and harbors the ligand-binding region, in which the ligand can be either a hormone or an odorant molecule depending on the GC subtype. Sensory GCs that are expressed in the photoreceptor cells of the vertebrate retina are an exception of this rule. No external ligand is known for the extracellular domain of these GCs and in the case of GCs expressed in rod photoreceptor cells the corresponding extracellular domain is located in the disk lumen.

Tissue Distribution

The natriuretic peptide receptor GCs GC-A and GC-B show the most diverse tissue distribution (Lucas et al. 2000; Tamura et al. 2001). GC-A is expressed in adrenal gland, pituitary gland, adipose tissue, cerebellum, aorta, heart, kidney, liver, spleen testis, colon, brain stem, retina, cochlea, ovary thymus, and others. Expression of GC-B largely overlaps with that of GC-A, but a more specific expression pattern is found for GC-C, the intestinal receptor for guanylin and uroguanylin. This GC is mainly present in the colon

and intestine, but is also found in the kidney, testis, and liver. A similar expression profile (lung, kidney, skeletal muscle, and intestine) is found for GC-G. Different from these receptor-type GCs are the sensory GCs that display a very restricted expression profile. For example, the odorant receptor GC-D is found in a subset of sensory neurons of the olfactory neuroepithelium (Sharma and Duda 2010; Zufall and Munger 2010) and the retina-specific GCs ROS-GC1 and ROS-GC2 (GC-E and GC-F) are predominantly expressed in photoreceptor cells of the vertebrate retina (Koch et al. 2010). In addition, ROS-GC1 is also found in the pineal gland.

Soluble GC forms are widely distributed and are mainly present in lung, heart, liver, kidney, cerebellum, skeletal muscle, and retina, whereby expression of the β2 isoform seems to be more restricted.

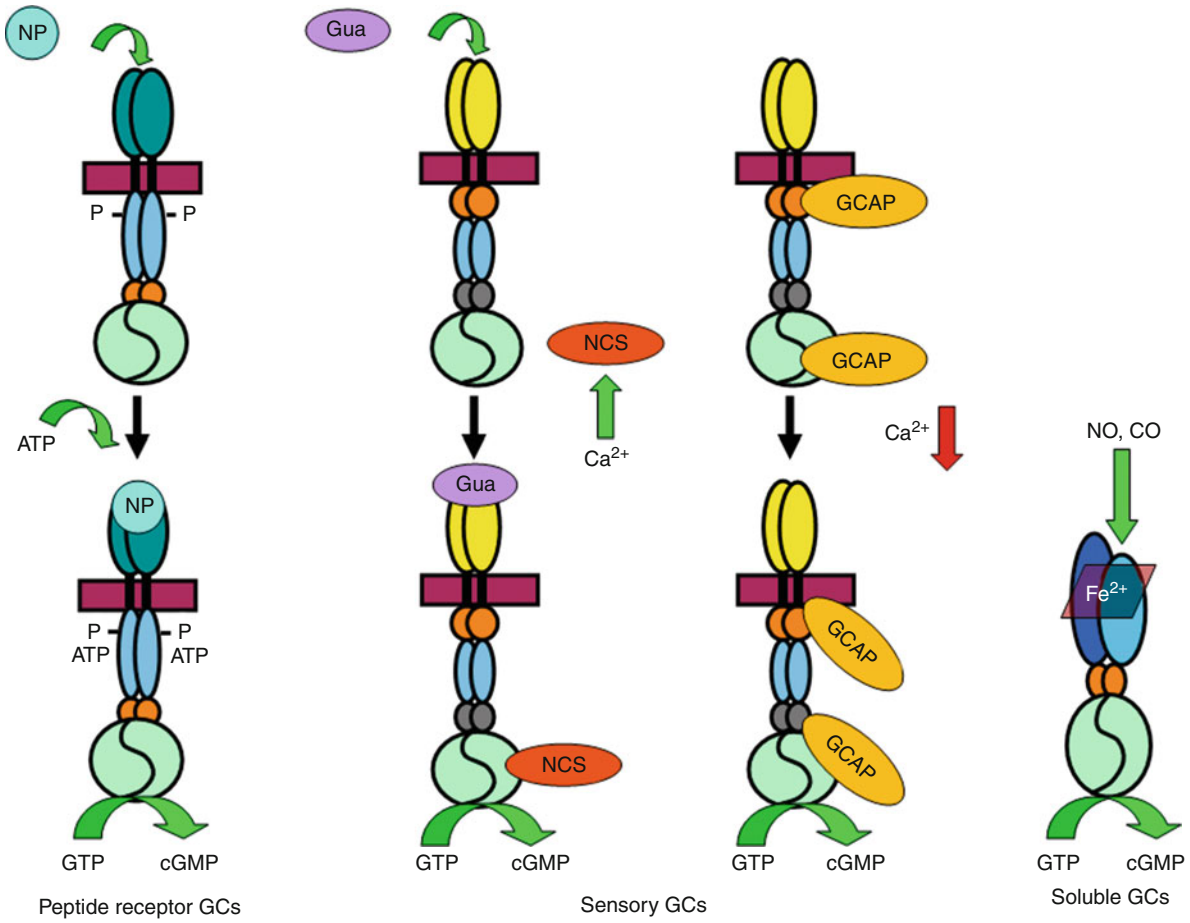
Mode of Activation and Regulation

Natriuretic peptides (NP) act on two types of membrane-bound GCs, GC-A and GC-B, and are a family of three factors (Potter et al. 2009; Martel et al. 2010). These factors are named ANP, BNP, and CNP. The active forms of these hormones/paracrine factors are between 22 and 53 amino acids long and circulate in the blood stream after posttranslational proteolytic cleavage from longer forms. ANP and BNP are secreted from cardiac myocytes and act on GC-A, CNP is secreted in the brain, chondrocytes, and epithelial cells and acts on GC-B. All peptides bind to the extracellular domain of the GC subgroup of natriuretic peptide receptors and thereby increase the guanylate cyclase activity of the receptor. The basal state of GC-A and GC-B exhibits very low GC activity, is highly phosphorylated (at serine and threonine residues), and forms homodimers. Binding of the peptide induces a conformational change enabling ATP to bind to the intracellular KHD, which is an allosteric control step for transducing the hormone signal to the cyclase catalytic domain (Fig. 2). Prolonged exposure of natriuretic peptides to the receptors leads to dephosphorylation and desensitization. Another class of peptides, guanylin and uroguanylin, are the endogenous activator of the intestinal GC-C. In addition, GC-C is specifically activated by bacterial heat-stable enterotoxins (STa) that cause severe secretory diarrhea via a cGMP-mediated signaling pathway (Lin et al. 2009). The odorant receptor GC-D is also activated by uroguanylin and guanylin as well as by natural urine stimuli and bicarbonate leading to an increase in cGMP synthesis (Zufall and Munger 2010). A further control mode is the regulation by so-called neuronal Ca^{2+}-sensor (NCS) proteins that regulate the GC activity from the cytoplasmic part of the receptor (Fig. 2). GC-D is related to the other sensory GCs (ROS-GC1 and ROS-GC2) that mainly operate in the outer segments of vertebrate photoreceptors and are regulated by intracellular NCS proteins named guanylate cyclase-activating proteins (GCAPs). Light triggers the decrease of the intracellular messenger cGMP and with a short delay the decrease of the cytoplasmic Ca^{2+}-concentration as well. Changing concentrations of Ca^{2+} are sensed by GCAPs that form a complex with the target GC and undergo a Ca^{2+}-induced conformational change. This in turn is thought to lead to an increase of catalytic activity at the cyclase catalytic domain (Fig. 2). No ligands are known for retina-specific GCs and it is unknown whether binding of a ligand to the extracellular (intradiskal) site is at all necessary. Binding of ATP to the intracellular KHD is known to enhance the GC activity (Koch et al. 2010).

Soluble GCs are activated by a fundamentally different mechanism. Gaseous molecules like NO and CO bind to the heme prosthetic group that is held between the two subunits forming the heterodimeric GC (Fig. 2). Binding of NO to the Fe^{2+} in the porphyrine ring of the heme group triggers the breakage of histidine coordinating bond and leads in consequence to a conformational change. By this mechanism the GC activity can be stimulated by about 5,000-fold (Garthwaite 2010).

Signaling Pathways and Physiological Responses Involving Guanylate Cyclases

The different GC forms are involved in complex physiological responses mirrored in the large variety of tissue. For example, the natriuretic peptide receptor GC-A is involved in regulation of blood pressure as this was demonstrated by transgenic mice lacking the receptor or the activating peptide ANP. Key steps in blood pressure regulation are vascular smooth muscle relaxation and contraction, which are under control of intracellular Ca^{2+}-spikes. In the kidney, ANP controls

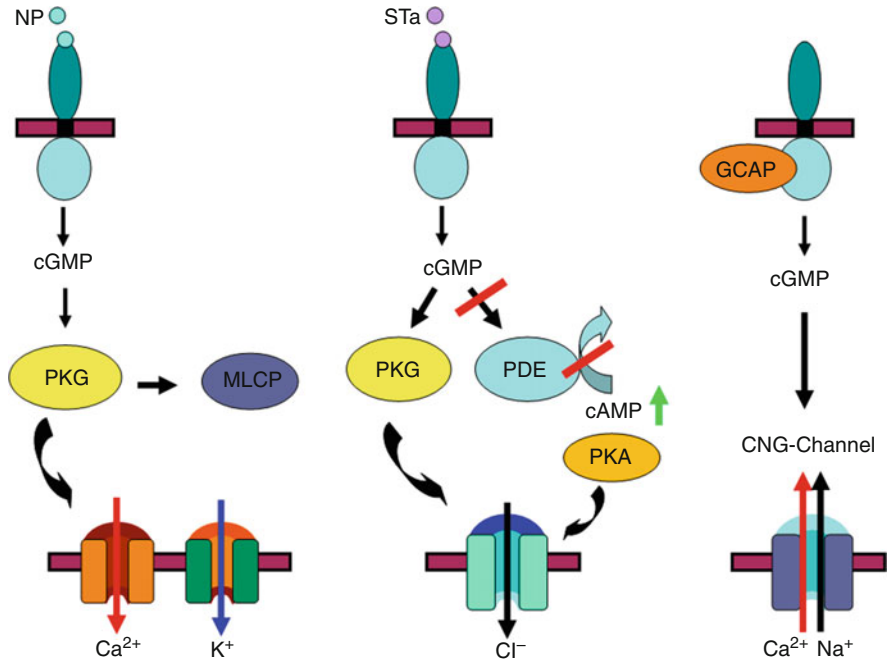


Guanylate Cyclase, Fig. 2 Modes of GC activation and regulation. Natriuretic peptides (NP) bind and thereby activate peptide receptor GCs that are phosphorylated (-P) in the basal state. The hormone signal is transferred to the catalytic domain under control of ATP. Sensory GCs are under control of Ca^{2+}-sensor proteins (NCS, GCAP) at the intracellular site. GC-D in olfactory sensory neurons is also activated by guanylin (Gua) and uroguanylin at the extracellular site, whereas no ligand appears necessary for the activation of photoreceptor GCs. GCAPs sense changes in intracellular Ca^{2+} and in turn activate photoreceptor GCs at low Ca^{2+}-concentrations. NO and CO can pass the cell membrane and stimulate soluble GCs

the fluid and electrolyte secretion by an increase of the glomerular filtration rate. These responses are triggered by an elevation of the intracellular cGMP level (Lucas et al. 2000; Tamura et al. 2001; Martel et al. 2010). Three main intracellular targets of cGMP are known so far including protein kinase G (PKG), a cAMP-hydrolyzing phosphodiesterase (PDE), and cyclic nucleotide-gated (CNG) channels. In particular PKG and PDE are involved in blood pressure regulation. PKG is known to activate or inhibit Ca^{2+}-transport systems in vascular smooth muscle cells by phosphorylation. These include Ca^{2+}-activated potassium channels, Ca^{2+}-ATPases in the plasma membrane and in the sarcoplasmic reticulum, voltage-dependent Ca^{2+}-channels, and the inositol 1,4,5-triphosphate receptor. In addition PKG controls enzymes like myosin light chain phosphatase (Fig. 3).

Additional effects of cGMP that are mediated via natriuretic peptide signaling are cardiac hypertrophy and fat metabolism. The factor CNP that acts on GC-B stimulates bone growth and is involved in vascular remodeling.

The paracrine hormones guanylin and uroguanylin regulate the fluid and electrolyte homeostasis in intestinal epithelial cells by binding to the extracellular site of GC-C. A similar ligand-receptor interaction is



Guanylate Cyclase, Fig. 3 Comparison of signaling pathways involving membrane-bound GCs and synthesis of cGMP. Targets of cGMP are PKG, cAMP-specific PDE, and CNG-channels. PKG can phosphorylate and thereby regulate many targets including Ca^{2+}-transport systems, Ca^{2+}-activated K^+-channels, and myosin light chain phosphatase (MLCP). Inhibition of PDE by cGMP that is synthesized by GC-C in intestine can lead to an increase of cAMP and activation of PKA, in particular during toxin (STa)-induced activation of GC-C. Both kinases (PKG and PKA) phosphorylate the CFTR and thereby increase its chloride-permeability. CNG-channels in photoreceptor cells bind directly to cGMP leading to an opening of the channel and an influx of Na^+ and Ca^{2+} into the cell

observed with bacterial enterotoxins leading also to an increase of intracellular cGMP. The latter is a major cause of secretory diarrheal disease. Elevated levels of cGMP activate PKG type II, but can also inhibit a cAMP-specific PDE leading to an increase in cAMP levels and in consequence to an activation of protein kinase A (PKA). PKGII and PKA then phosphorylate and thereby activate the cystic fibrosis transmembrane regulator (CFTR) a chloride-ion channel in the intestinal brush border membrane (Fig. 3).

Sensory GCs are predominantly expressed in sensory cell types and are part of signaling pathways that have CNG-channels instead of PKGs as main downstream targets of cGMP. Among them GC-D is a receptor GC that can be activated by the ligand peptides guanylin and uroguanylin (see above). GC-D is present in a subpopulation of olfactory sensory neurons and not part of the predominant cAMP-signaling pathway in most olfactory sensory neurons. Intracellular signaling of GC-D is linked to Ca^{2+}-signaling pathways as well, since Ca^{2+}-binding proteins of the NCS protein subfamily were shown to regulate GC activity by binding to intracellular regions of GC-D. These NCS proteins are GCAP1, neurocalcin-δ, frequenin, and ▶ hippocalcin. The biological role of GC-D has been discussed in the context of chemosensory detection of the metabolic status (Sharma and Duda 2010; Zufall and Munger 2010).

Vision in vertebrate photoreceptor cells involves membrane-bound GCs that are regulated by intracellular Ca^{2+}-binding proteins named GCAPs. No extracellular ligands are known so far. Mammalian rod and cone cells harbor two of these GCs named ROS-GC1 and ROS-GC2 or GC-E and GC-F, respectively. They synthesize the intracellular messenger of visual excitation, cGMP, thereby keeping the CNG-channels open to allow influx of Na^+ and Ca^{2+} from the extracellular medium in the dark adapted state of the cell. GCAPs are an important regulatory part of an intracellular feedback loop, since they activate ROS-GCs

at low Ca^{2+}-concentration and inhibit them at higher Ca^{2+}-concentration leading to resynthesis of cGMP after illumination, when the cytoplasmic Ca^{2+}-concentration has dropped (Fig. 3). ROS-GCs are key components of signal transduction in rod and cone cells by controlling the second messenger level. Thereby they are important for the cell's recovery to the dark state after illumination and its adaptational properties (Koch et al. 2010).

Soluble GCs are the target of the versatile messenger molecule NO that is synthesized by nitric oxide synthase isoforms. NO is, for example, mediating smooth muscle relaxation and is involved in the central and peripheral nervous system and in the immune response of macrophages. NO can act on other targets than soluble GCs, but increase of cGMP production by NO leads in general to activation of PKG and subsequent phosphorylation of PKG targets.

Summary

The second messenger cGMP and its synthesizing enzymes (membrane and soluble GCs) have become essential parts of different signaling pathways that mediate important physiological functions. These include, for example, blood pressure regulation, kidney and smooth muscle function, olfaction, and vision. Components of the corresponding signaling pathways have been characterized at the molecular level and the physiological impact of GCs has been investigated by a combination of biochemical, genetic, and physiological studies. For these systems a deeper mechanistic understanding at the structural level has also partially been achieved. Elucidating the structure-function relationships of GCs and their regulatory components will also guide future directions of pharmaceutical and therapeutical inventions, since several diseases correlate with dysfunctions of GC signaling systems. These include, for example, hypertension, different forms of retinal degeneration, and colorectal cancer. Another challenge is to dissect other signaling pathways, in which cGMP has been implicated, but information on a participating GC in these pathways is missing. Examples are other sensory cell systems (e.g., sensing of tastants, heat, and pain) or the Wnt-frizzled signaling pathway in early embryonic development (Wang and Malbon 2004). Finally, some nonmammalian organisms express a larger variety of GC forms than mammalians. It will be a promising task to investigate the properties and the operation principles of these GC forms in an environmental and evolutionary context.

Historical Background

Guanylyl cyclase C (GC-C) is the target for a family of heat-stable enterotoxins (ST) produced by enterotoxigenic *Escherichia coli* (ETEC), *Vibrio cholera* non-01, and *Yersinia enterocolitica*. Stable toxin-mediated diarrheas are observed frequently in infants and contribute significantly to incidences of Travelers' Diarrhea. Early studies demonstrated that the effects of ST were mediated by increases in intracellular cGMP levels in intestinal cells, and the receptor for ST was almost exclusively expressed in the apical microvillar compartment of the intestinal brush-border epithelia (De Jonge 1975; Schulz et al. 1990). Subsequently, the receptor for ST peptides was identified as a member of the membrane-associated guanylyl cyclase family, and binding of ST to GC-C led to activation of the receptor, resulting in the production and accumulation of cGMP in enterocytes (Schulz et al. 1990). Effectors of cGMP in intestinal cells include protein kinase G (PKG), cyclic nucleotide gated ion channels (CNG), and the cystic fibrosis transmembrane conductance regulator (CFTR), which regulate net fluid and ion efflux into the intestinal lumen manifesting as watery diarrhea in humans and farm animals (Basu et al. 2010).

Peptide Ligands

ST peptides are low molecular weight peptides that differ slightly in their amino acid composition, but have a cysteine rich core with a conserved disulfide bonding pattern essential for the heat stability and biological activity of these peptides (Gariepy et al. 1987). Nearly a decade after the isolation of bacterial ST peptides, a peptide that increased cGMP levels in T84 human colon carcinoma cells was purified from the extracts of rat jejunum and named guanylin. This was soon followed by the isolation of a related peptide, uroguanylin. These endogenous ligands as well as ST peptides are synthesized as precursor proteins which have little or no intrinsic biological activity until cleaved by converting enzymes that release the active peptides for interaction with GC-C (Forte 2004). Guanylin and uroguanylin are less potent in stimulating chloride secretion in comparison with ST peptides, since the affinity of guanylin and uroguanylin for GC-C is lower than that of ST. Uroguanylin is effective in stimulating cGMP production in cells at a pH of ~5.5, whereas guanylin has a reduced efficacy at an acidic pH, and is active at an alkaline pH. This is because acidic pH markedly decreases the affinity of guanylin binding to GC-C but enhances that of uroguanylin. The presence of both guanylin and uroguanylin in the gastrointestinal tract allows for effective control of cGMP-mediated regulation of salt and water transport over a broad pH range that is encountered in the extracellular fluid of the intestinal tract (Hamra et al. 1997). Recently a novel peptide agonist has been developed for GC-C (Busby et al. 2010).

Domain Organization of GC-C

The mRNA of GC-C is translated to a polypeptide of 1,073 amino acids, which adopts the multidomain architecture similar to that seen in other receptor guanylyl cyclases. The N-terminal signal sequence of 23 amino acid residues undergoes proteolysis on transit to the endoplasmic reticulum, generating a mature polypeptide of 1,050 amino acids with a theoretical molecular mass of 120 kDa. From the N to the C terminus of GC-C, an extracellular ligand binding domain (ECD)

is followed by a single transmembrane helix, and an intracellular domain consisting of juxtamembrane, kinase-homology (KHD), linker, guanylyl cyclase (GCD), and the C-terminal tail (CTD) domains. The minimal catalytic unit required for the guanylyl cyclase activity of GC-C is a homodimer, although higher order oligomers have been reported and may be the physiologically relevant forms. As with all guanylyl cyclases, the active site is thought to lie at the interface of the two guanylyl cyclase domains of the homodimer. Other than the intestinal tract, GC-C is also expressed at lower levels in various extra-intestinal tissues such as the kidney, seminiferous tubules of the testis, perinatal liver, brain, and epididymis (Basu et al. 2010).

The ECD of GC-C shows low sequence similarity to the ECDs of other receptor guanylyl cyclases, reflecting the differences in the ligands that bind each individual receptor. GC-C binds ST peptides with a high affinity (Kd $\sim$ 0.1 nM) and guanylin (Kd $\sim$ 10 nM) and uroguanylin (Kd $\sim$ 1 nM) with lower affinity. The ECD of GC-C shows N-linked glycosylation resulting in 130 kDa and 145 kDa forms of the receptor. The 145 kDa form contains sialic acid and galactose residues and is present on the plasma membrane, whereas the 130 kDa form contains high mannose structures and is primarily resident in the endoplasmic reticulum. The 130 kDa is the precursor for the 145 kDa form, and though both differentially glycosylated forms bind ST with equal affinity, cGMP production in the presence of ligands is seen only with the 145 kDa form (Ghanekar et al. 2004).

GC-C harbors a domain of approximately 250 residues between the juxtamembrane and the guanylyl cyclase domains, which shares a significant homology to protein tyrosine kinases, and is called the KHD. The crucial position of the KHD in receptor guanylyl cyclases suggests that it transduces the signal of ligand binding from the ECD to the guanylyl cyclase domain. This is supported by the fact that complete and partial deletions of the KHD in GC-C led to inactivation of the receptor. A sequence alignment of the KHD of GC-C with tyrosine and serine-threonine kinases reveals that the highly conserved HRD motif present in active protein kinases is replaced with a HGR motif in the KHD of GC-C. The absence of the catalytic aspartate residue predicts that the KHD of GC-C is a pseudokinase (Rudner et al. 1995).

A $\sim$70 amino acid region connecting the KHD and the guanylyl cyclase domain is referred to as the linker region. A recent bioinformatic analysis has suggested that the linker region in receptor GCs serves as a signaling helix, which could regulate the activities of these receptors, and adopt a coiled-coil structure. Mutational analysis of the linker region has demonstrated its importance in repressing the guanylyl cyclase activity of GC-C in the absence of ligand and permitting ligand-mediated activation of the cyclase domain (Saha et al. 2009).

The primary structure of the guanylyl cyclase domain is highly conserved in both receptor and soluble GCs and is similar to the catalytic domain of adenylyl cyclases. Guanylyl cyclases belong to the Class III nucleotide cyclase family. Homodimeric receptor GCs could have two active sites, and the allostery seen in biochemical assays suggests that there are indeed two substrate binding sites per dimer of enzyme (Parkinson et al. 1994). Recent crystal structures of the guanylyl cyclases Cya2 from cyanobacterium *Synechocystis* PCC6803 and CYG12 from the green algae *Chlamydomonas reinhardtii* reveal the presence of a head-to-tail homodimer with the two monomers in a wreath-like arrangement.

GC-C and the retinal GCs (GC-E and GC-F) possess a short C-terminal domain (CTD) of approximately 60 residues. It has been suggested that the CTD may be involved in interaction of receptor GCs with the cytoskeleton. Deletion of the CTD in GC-C led to a loss of ligand-mediated activation of the receptor. The CTD contains a unique region of 11 highly conserved amino acids, which acts as an apical sorting signal (Hodson et al. 2006).

Regulation

One of the hallmarks of any signaling system is the intricate and diverse modes of regulation that it is subjected to, and GC-C is no exception.

Transcriptional regulation. GC-C mRNA is encoded by the gene GUCY2C present at the locus 12p12 in *Homo sapiens* and contains 27 exons. The regulatory region lies $\sim$ 2 kb upstream of the gene and has binding sites for caudal type homeobox gene-2 (Cdx2), hepatocyte nuclear factor 4 (HNF4), GATA-4, glucocorticoid receptor, and nuclear factor-IL6 (NF-IL6). HNF4, Cdx2, and GATA-4 are expressed in the intestine, and Cdx2 and HNF4 are responsible for the predominant expression of GC-C in the intestine as well as in cell-lines derived from colorectal carcinoma tissue such as Caco2 and T84. Protein

kinase C (PKC) has been shown to transcriptionally regulate expression of GC-C. Activation of PKC by phorbol esters such as phorbol 12-myristate 13-acetate (PMA) led to a down regulation of GC-C mRNA levels in T84 cells (Roy et al. 2001).

Desensitization. Refractoriness to prolonged exposure of cells to ligands of GC-C, in terms of cGMP production, has been observed. In Caco2 cells, selective removal of the 145 kDa form from the surface of the receptor is seen on extended treatment with ST (Ghanekar et al. 2003). Increased activity of the cGMP-binding, cGMP-specific phosphodiesterase, PDE5, was found to contribute to cellular refractoriness in T84 cells, reducing the levels of cGMP in the cell (Bakre et al. 2000). Exposure of HEK293 cells stably expressing GC-C to ST for prolonged periods did not result in desensitization, indicating that cell-specific mechanisms contribute to cellular refractoriness.

Inactivation of GC-C occurs in vitro on ST incubation prior to addition of MgGTP as the substrate for the guanylyl cyclase assays. Inactivation of GC-C was alleviated in the presence of ATP, indicating a role for ATP (and perhaps the KHD) in regulation of GC-C activity (Gazzano et al. 1991).

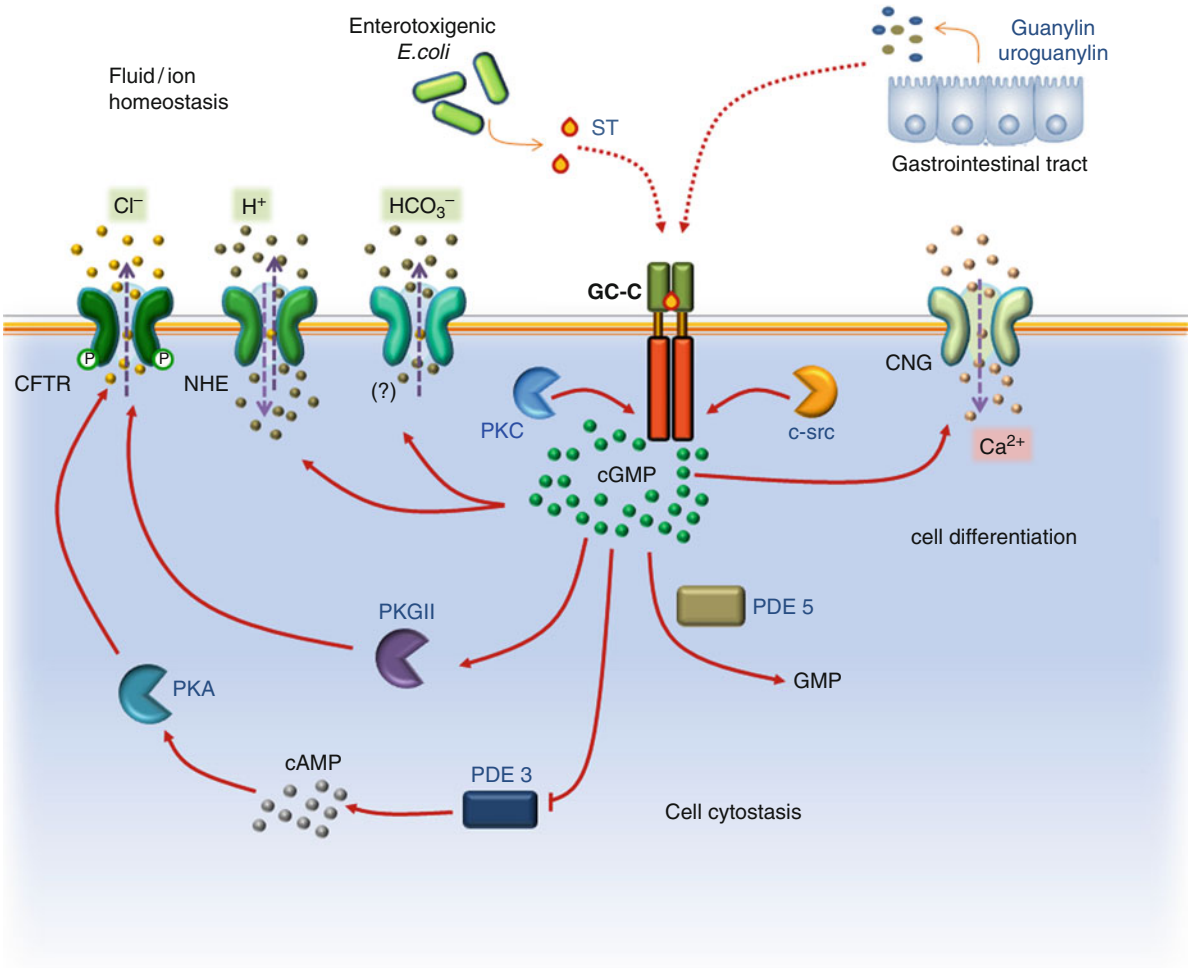
Phosphorylation. PKC phosphorylates GC-C on Ser1029 in the CTD of GC-C and enhances ST-mediated GC-C activation in terms of increased cGMP production (Wada et al. 1996). This is in contrast to the role of PKC in transcriptional down-regulation of GC-C. Phosphorylation at tyrosine residues has not been reported in any receptor GC except GC-C. The GC-C intracellular domain was tyrosine phosphorylated when expressed in *E. coli* cells harboring the tyrosine kinase Elk (EphB1). Recent data shows that GC-C is a substrate for inhibitory phosphorylation by c-src, resulting in reduced ligand-mediated cGMP production. The tyrosine at position 820 gets phosphorylated, and this generates a docking site for the c-src SH2 domain leading to interaction and further activation of ▶ c-src. Therefore, GC-C could be involved in cross-talk with tyrosine kinases especially in colon carcinoma cells where c-src kinase expression and activity is high (Basu et al. 2009).

Allosteric regulation. ATP is able to potentiate ligand-mediated activation of GC-C and consequent cGMP production in vitro, in the presence of Mg-GTP as substrate. In contrast, ATP inhibits the cyclase activity of GC-C when Mn-GTP is used as substrate. ATP mediates its effects by binding to the KHD of GC-C and ATP hydrolysis is not required for inhibition of the guanylyl cyclase activity. Lysine 516 in the KHD of GC-C corresponds to the conserved lysine in the VAIK motif present in tyrosine kinases that is involved in coordinating the α- and β-phosphates of ATP. Mutation of Lys516 to an Alanine abolished ATP binding and the subsequent regulation of GC-C activity by the adenine nucleotide (Jaleel et al. 2006). The KHD is also the site of action for some of the 2-substituted adenine nucleotides which were found to be potent allosteric inhibitors of GC-C (Parkinson et al. 1997). Tyrphostins, known to be inhibitors of tyrosine kinases, were found to noncompetitively inhibit the activity of GC-C, by binding to the catalytic domain of GC-C, and indeed, nucleotide cyclases in general (Jaleel et al. 2004). Till date, there are no specific inhibitors of any receptor guanylyl cyclase, but it is conceivable that inhibitors directed to the individual KHDs could be more specific, since this domain is unique to receptor guanylyl cyclases and is not found in soluble guanylyl cyclases.

Downstream Signaling and Disease Phenotypes

Cyclic GMP produced by GC-C executes its cellular functions by interacting with three types of target proteins: (a) cGMP-dependent protein kinases (PKG), (b) cyclic nucleotide-gated (CNG) channels, and (c) cGMP-regulated cyclic nucleotide phosphodiesterases (Fig. 1). The endogenous peptides, guanylin, and uroguanylin are involved in the regulation of salt and water transport across the intestinal epithelia. ST peptides serve as superagonists of the receptor resulting in ST-induced watery diarrhea. GC-C knockout (KO) mice are refractory to the actions of ST that are seen in WT mice (Fig. 1).

An increase in cGMP levels can regulate ion and fluid transport in the intestine in different ways. Sodium absorption in the intestine is partly governed by the Na^+/H^+ exchanger (NHE), which absorbs NaCl in combination with the chloride/anion exchanger. Cyclic GMP is known to inhibit the NHE, thereby decreasing sodium and chloride absorption. Intestinal chloride efflux is mediated by the cystic fibrosis transmembrane conductance regulator (CFTR), which is located in the apical membrane of Cl^- secreting epithelial cells. Increase in levels of intracellular cGMP results in the activation of cGMP-dependent protein



Guanylyl Cyclase C, Fig. 1 Overview of GC-C signaling: GC-C expressed on the surface of intestinal cells is the receptor for the endogenous ligands uroguanylin and guanylin, or ST produced by enterotoxigenic *E. coli*. Ligand-mediated activation of GC-C results in the production and accumulation of intracellular cGMP. Guanylyl cyclase activity of GC-C can be potentiated by phosphorylation by protein kinase C (PKC) and inhibited by phosphorylation by c-src. Cyclic GMP activates the sodium/hydrogen exchanger (NHE) causing hydrogen ion (H^+) efflux. Bicarbonate ion (HCO_3^-) is also secreted by unidentified channels activated by cGMP. Cyclic GMP–dependent Protein Kinase (PKGII) is activated by elevated levels of cGMP. Cyclic GMP inhibits the activity of the cAMP phosphodiesterase PDE3, thereby increasing levels of cAMP in the cell which in turn activates cAMP-dependent protein kinase (PKA). PKGII and PKA phosphorylate the cystic fibrosis transmembrane conductance regulator (CFTR) leading to chloride ion (Cl^-) efflux. These processes maintain fluid-ion homeostasis in the intestine. Cyclic GMP also directly activates cyclic nucleotide gated channels (CNG) leading to Ca^{2+} influx. Signaling downstream of Ca^{2+} leads to cell differentiation and migration. GC-C signaling is terminated by hydrolysis of cGMP to 5′ GMP by the cGMP binding, cGMP-specific phosphodiesterase, PDE5

kinase II and protein kinase A, which phosphorylate CFTR thus activating the chloride channel. The reduced chloride absorption by the NHE and increased chloride secretion by the CFTR in response to cGMP are thought to be the chief mechanisms by which ST mediates its effects (Basu et al. 2010).

The intestinal epithelium undergoes homeostatic cycles of proliferation, migration, differentiation, and apoptosis. Imbalance between cell proliferation and apoptosis leads to the formation of tumors within the intestinal tract. In colon cancer, the expression of mRNAs encoding uroguanylin and guanylin is

markedly suppressed, whereas mRNA expression of GC-C is comparable in colon cancer and normal colonic mucosa. Oral administration of uroguanylin suppressed the formation and apparent progression of polyps in the $APC^{Min/+}$ mouse model of colorectal cancer. Recent reports have suggested that ST or uroguanylin treatment of T84 and Caco2 cells inhibits proliferation by delaying progression through the cell cycle. The cytostatic effects of GC-C agonists could be mimicked by 8-Br-cGMP, a cell-permeable cGMP analog, but could not be prevented by inhibitors of the known downstream effectors of elevated cGMP, such as PKG, PKA or PDE3. However, L-*cis*-diltiazem, a CNG channel inhibitor, as well as removal of extracellular Ca^{2+}, prevented ST-mediated inhibition of proliferation. This suggested that the anti-proliferative action of GC-C agonists was mediated by a cGMP signaling mechanism, which regulates Ca^{2+} influx through CNG channels. Thus, Ca^{2+} serves as the third messenger in the signaling cascade linking GC-C at the cell surface to regulation of proliferation in the nucleus.

Over a million people suffer from colon cancer in developed countries, but its incidence is relatively low in underdeveloped and developing countries. A common epidemiological characteristic of these developing nations is the prevalence of ETEC. Periodic infections with ST producing bacteria in the intestine could be therapeutic for people living in the developing nations, since the action of the ST peptides induces cell cytostasis, thus providing resistance to intestinal neoplasia (Pitari et al. 2007).

Summary

The GC-C/cGMP signaling axis is important in maintaining fluid-ion homeostasis in the intestinal tract. In addition, evidence for its anti-neoplastic role in the development of colon carcinoma is rapidly accumulating. It would be interesting in the future to look at the molecular players responsible for the cytostatic effect exerted by the ligands for GC-C. The function of GC-C expressed in extra-intestinal tissue is largely unknown but some of the key components may be common to that operative in the intestine. To elucidate these mechanisms and to evaluate their importance for the pathophysiology of an organism are important topics for future research.

Historical Background

In 1971 when Sutherland received the Nobel Prize for the discovery of the second messenger cAMP, the functions of cGMP were still a mystery, even though cGMP had been isolated from rat urine in 1963, and an enzyme that cleaved the phosphodiester bond was discovered the following year. The levels of cGMP are regulated by synthesis by guanylyl cyclases, extrusion from the cell, and/or degradation by phosphodiesterases (Kots et al. 2009). Two classes of guanylyl cyclases, one that is cytosolic (soluble) and the other that is found associated with the particulate or membrane fraction of cells could be identified. The two forms of guanylyl cyclases are composed of polypeptides of different sizes, with different biochemical properties (Kimura and Murad 1974) (Receptor membrane cyclases Fig. 1).

Soluble Guanylyl Cyclases

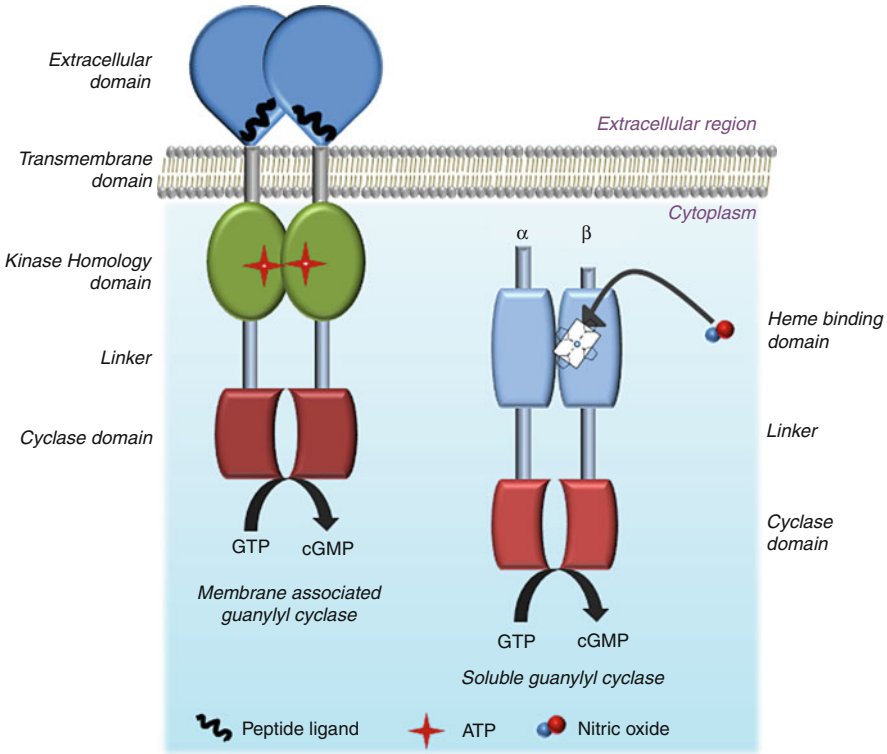
The soluble guanylyl cyclases (sGC) are heterodimers of two dissimilar subunits, alpha and beta. There are four types of alpha subunits, namely, α1, α2, α3, and $\alpha2_i$, and three types of beta subunits, namely, β1, β2, and β3. All the heterodimers are active, albeit to varying extents, except those containing $\alpha2_i$. The $\alpha2_i$ is a splice variant of α2 and provides a mechanism for regulating the activity of the α2/β1 form of sGC by acting as a dominant negative protein in cells. The crystal structure of the sGC from the green algae *Chlamydomonas reinhardtii* has been solved (Winger et al. 2008) and the structure of a human sGC has been deposited (pdb code: 2WZ1).There is also a report on the crystal structure of Cya2, a prokaryotic guanylyl cyclase from cyanobacterium *Synechocystis* PCC6803 (Rauch et al. 2008).

The sGCs are ubiquitously expressed and are responsible for smooth muscle relaxation, neurotransmission, and inhibition of platelet migration (Kots et al. 2009). Nitric oxide (NO) binds to the N-terminal heme-binding H-NOX domain. In the absence of NO, the iron atom of the heme moiety bonds with a histidine residue present in the protein, keeping the cyclase domain inactivate. NO binding to the heme moiety leads to the disruption of this interaction, altering the conformation of the enzyme, thereby resulting in its activation. Protoporphyrin IX can bind to and activate sGCs independent of heme or NO (Lucas et al. 2000). Carbon monoxide also regulates sGCs in a manner similar to that of NO, although its affinity for the enzyme is much lower than that of NO. ATP allosterically inhibits the activity of the soluble guanylyl cyclase (Derbyshire et al. 2009).

The C-terminal cyclase domains in each subunit are connected to the N-terminus by a linker region which contributes to the dimerization of sGC. Since the α-subunits of sGCs lack the critical residues required for catalytic activity, they heterodimerize with the β-subunits to give rise to a functional active site (Lucas et al. 2000; Perkins 2006).

Membrane-Associated Guanylyl Cyclases

Seven classes of membrane-associated guanylyl cyclases have been characterized. They are GC-A,



Guanylyl Cyclase Receptors, Fig. 1 Schematic of the domain organization of receptor guanylyl cyclases. Shown also is the topology of the enzymes discussed in this article either being present in the membrane of the cell or in the cytosol. Membrane-associated GCs are shown as dimers, though there is evidence that they can oligomerize in cells. Receptor GCs can exist as dimers even in the absence of their respective ligands

GC-B, ▶ GC-C, GC-D, and GC-G, and the retinal GCs, GC-E, and GC-F. All the receptor guanylyl cyclases share a common domain organization with a single-pass transmembrane region. They have an extra cellular domain (ECD), the amino acid sequence of which is poorly conserved across the different classes, thereby imparting ligand specificity. This domain is followed by a transmembrane domain and an intracellular domain (ICD). The ICD is comprised of a juxtamembrane domain followed by a regulatory kinase homology domain (KHD) which binds ATP. Following the KHD is a linker region which connects to the guanylyl cyclase domain. Ligand binding to the extracellular domains results in receptor activation and increased production of cGMP in the cell.

The Natriuretic Peptide Family Receptors

These comprise three receptors, namely, Natriuretic Peptide Receptors A, B, and C. The ligands for these receptors are natriuretic peptides – atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP).

Guanylyl Cyclase A/Natriuretic Peptide Receptor A (GC-A/NPR-A)

The mammalian cDNA encoding guanylyl cyclase A (NPR-A) was identified using the gene sequence of the sea urchin particulate guanylyl cyclase receptor as a probe to screen a cDNA library (Kots et al. 2009). NPR-A preferentially binds ANP and BNP. NPR-A is found in the heart, kidney, adrenal cortex, and vasculature.

Vasodilation and natriuresis are the most commonly studied aspects of signaling via NPR-A. GC-A prevents hypertrophy of the heart by relaxing the vascular musculature, thereby reducing the cardiac output. In kidneys, NPR-A assists in the secretion of sodium and reduction of aldosterone secretion by the adrenal cortex, thus reducing blood pressure (Martel et al. 2010).

Transcription of NPR-A is regulated by Sp1. NPR-A has been shown to downregulate its own expression by a feedback inhibition loop via a cGMP response element. Alternative splice variants of NPR-A can heterodimerize (Martel et al. 2010). The

juxtamembrane domain in NPR-A has been shown to modulate the proteolytic cleavage of the ECD, thereby regulating its activity (Huo et al. 1999). Posttranslational modifications which include glycosylation are implicated in the folding of NPR-A and its trafficking to the surface of the cells. When activated by its ligands, NPR-A is deposphorylated at serine and threonine residues in its KHD, which then attenuates the activation by the ligand, leading to desensitization and signal downregulation (Koller et al. 1993). Imbalance in circulating levels of natriuretic peptides and expression of NPR-A receptor is seen in hypertensive mice, making this receptor a potential target for gene therapy (Martel et al. 2010).

Guanylyl Cyclase B/Natriuretic Peptide Receptor B (GC-B/NPR-B)

Using the sequence of NPR-A, NPR-B was cloned from rat brain cDNA and human placenta. NPR-B is primarily located in the pituitary gland, adrenal gland, ovary, endothelium, vascular smooth muscle, and kidney (Schulz 2005). NPR-B binds CNP with highest affinity amongst the natriuretic peptides. Apart from the relaxation of the heart and lowering of blood pressure, NPR-B signaling also relaxes the smooth muscle of the oviduct, colon, and trachea. In the brain, CNP and NPR-B play a role in gonadotropin secretion. Expression of NPR-B in the ovary and testis may be responsible for development of mature ovarian follicles and regulation of sperm transport by relaxing the seminiferous tubules. NPR-B also promotes bone development and causes skeletal overgrowth on overexpression (Schulz 2005).

No cGMP response element has been identified in the NPR-B promoter (Martel et al. 2010). In NPR-B, glycosylation may play a role in ligand binding (Schulz 2005). The lack of an intact KHD in NPR-B causes stunted skeletal growth in humans, and splice variants of NPR-B lacking the KHD or intracellular domains are inactive and can act as dominant negatives, hindering bone development (Hachiya et al. 2007).

Only one other protein has been identified which binds all the natriuretic peptides, the NPR-C receptor. This receptor has no guanylyl cyclase activity as it lacks the intracellular domain. NPR-C is expressed in the heart, lung, vascular smooth muscle cells, kidney glomeruli, adrenal gland, brain cortex, and pituitary gland (Martel et al. 2010).

The primary function of the NPR-C receptor was thought to be sequestration and metabolic clearance of natriuretic peptides and it was therefore designated as the clearance receptor. The 37 amino acid long cytoplasmic tail of NPR-C has been shown to mediate inhibition of adenylyl cyclase activity on ligand binding to the receptor (Anand-Srivastava 2005).

Guanylyl Cyclase C (GC-C)

Guanylyl cyclase C (GC-C) is the third member of the family of receptor guanylyl cyclases that was identified. It was identified as the receptor for the bacterial heat-stable enterotoxin peptides produced by pathogenic strains of *Escherichia coli* (Schulz et al. 1990). GC-C is predominantly expressed in the intestinal tract.

Endogenous ligands for GC-C are guanylin and uroguanylin and have been purified from intestinal mucosa and urine. They are cysteine-rich peptides, similar to the stable toxin peptide, but, they have a 10–100-fold lower affinity for GC-C. It is believed that they regulate intestinal fluid and ion transport. Activation of GC-C, following binding of its ligands, results in increased synthesis cGMP. Accumulation of intracellular cGMP activates cyclic nucleotide-dependent protein kinases, PKA and PKG, leading to the phosphorylation of the cystic fibrosis transmembrane conductance regulator (CFTR) and increased chloride secretion through CFTR. Ion efflux leads to increased fluid secretion from the cell, resulting in a watery diarrhea. This manifests as traveler's diarrhea in adults which is self-limiting but may be fatal in infants (Basu et al. 2010).

GC-C prexists as an oligomer in the absence of ligand. GC-C is differentially glycosylated, but glycosylation may not be an essential requirement for ligand binding. GC-C is a substrate for inhibitory phosphorylation by c-src, resulting in reduced ligand-mediated cGMP production. Phosphorylation of a serine residue in the C-terminus by protein kinase C results in potentiation of ligand-stimulated activity in vivo and in vitro. Prolonged exposure of GC-C to its ligands leads to cell-specific desensitization of the receptor, by mechanisms that are not clearly understood at present. Intestine and kidney-enriched PDZ protein (IKEPP) and c-src are the only proteins to be identified that

interact with GC-C and regulate its activity (Basu et al. 2010). Ligands for GC-C have been shown to have a cytostatic effect on intestinal cells and thereby act as a barrier to tumorogenesis. A GC-C knock-out mouse has no obvious phenotype, but is resistant to stable toxin-mediated diarrhea. This raises the question of the evolutionary pressure that maintains a functional GC-C in a variety of species.

Guanylyl Cyclase D (GC-D)

The canonical olfactory signaling occurs when the cyclic nucleotide gated (CNG) ion channel are activated by cAMP in the olfactory neurons. When it was found that odorants triggered cGMP production which activated a cGMP gated ion channel, the olfactory guanylyl cyclase GC-D was identified. This gene is found to be well conserved in the rodents and canines, but is a pseudogene in a number of primate species, including the human (GC-E). A very small subset of the olfactory sensory neurons (OSN) of mice expresses GC-D, and these neurons terminate in necklace glomeruli (Zufall and Munger 2010). Non-primates detect more olfactory cues than primates, and may even detect pheromones via GC-D (Young et al. 2007). Recent reports suggest that uroguanylin and/or guanylin can activate GC-D.

GC-D can also be activated by bicarbonate ions which are produced by carbonic anhydrase specifically expressed in the GC-D subset of OSNs. The seemingly unrelated pathways appear to impinge at this point and reports have shown that rodents can be trained to avoid CO_2 concentrations as low at 0.5%. It is speculated that this is a means to detect other animals in the vicinity. There is also evidence that guanylyl cyclase activating protein (GCAP1) could also modulate a calcium-dependent activation of GC-D (Zufall and Munger 2010).

Retinal Guanylyl Cyclases: Guanylyl Cyclase E/F (GC-E/F)

In the mid-1990s, membrane-bound receptor guanylyl cyclases were identified in bovine photoreceptors. A gene encoding a particulate guanylyl cyclase was isolated from retinal cDNA based on its similarity to previously characterized GCs (Shyjan et al. 1992). This gene is referred to as retGC1 or retGC2 in humans or GC-E/GC-F in other mammals. RetGC2 is exclusively expressed in the retina while expression of retGC1 is seen in the pineal gland and retina. The mRNA of retGC1 has been detected in the olfactory bulb of fish, cochlear nerve and organ of Corti (Hunt et al. 2010).

GC-E and GC-F are important in retinal phototransduction and regulate the opening and closure of cGMP-gated ion channels. These channels are open in the dark and close on perception of light. The loss of either retGC results in compromised visual signal transduction suggesting that both retGCs are necessary for normal phototransduction.

The retGCs are orphan receptors as no ligands for the ECD have been discovered till date. These receptors are regulated by proteins which associate with their ICDs. Guanylate cyclase activating proteins (GCAPs) are always found associated with the retGCs. In resting depolarized cells, GCAPs are bound by Ca^{2+} ions which prevent activation of retGC. Upon light stimulus, the cGMP-specific phosphodiesterase, PDE6, found in photoreceptor cells is activated and degrades cGMP present in the cell, leading to closure of the CNG, thereby decreasing Ca^{2+} levels in the now hyperpolarized cell. The Ca^{2+} ions dissociate from GCAP, permitting them to activate retGC. Cyclic GMP levels are now elevated resulting in the reopening of the ion channels and reversion of the cell to a depolarized state. Despite the importance of both retGCs for visual signal transduction in mice, visual impairments studied so far in humans map only to the retGC1 locus. Recessive mutations in retGC1 are a major cause of Leber congenital amaurosis (LCA). Retinitis pigmentosa also is caused by a mutation in GC1. Other mutations in retGC1 are responsible for 35% of all rod-cone dystrophies (Hunt et al. 2010).

Guanylyl Cyclase G (GC-G)

The GC-G is an orphan receptor and transcripts have been found in mouse testis, kidney, and in the Grueneberg ganglion (Lin et al. 2008). This receptor may play a role in thermo-sensation, a process which has been shown to be via cGMP signaling in *C. elegans* (Zufall and Munger 2010).

Summary

Almost 50 years after the discovery of cGMP, its function in vision, olfaction, vasodilatation, and fluid ion homeostasis has been established. The various guanylyl cyclases have been identified and characterized but

questions still remain as to the ligands and exact functions of some of the receptors. The complex domain organization of these receptor guanylyl cyclases indicate that they may be regulated in multiple ways and be involved in cross talk with other signaling pathways, and studies along these lines will be of interest in future.

Historical Background

Since the discovery of epidermal growth factor (EGF) in 1962, a total of seven mammalian ligands that bind the EGF receptor (EGFR/ErbB1) have been identified, including transforming growth factor-α (TGFα), amphiregulin (ARG), betacellulin (BTC), epiregulin (ERG), epigen (EPG), and heparin-binding EGF-like growth factor (HB-EGF) (Harris et al. 2003). Historically, HB-EGF was the fourth growth factor to be identified among EGFR ligands. Major findings regarding HB-EGF are:

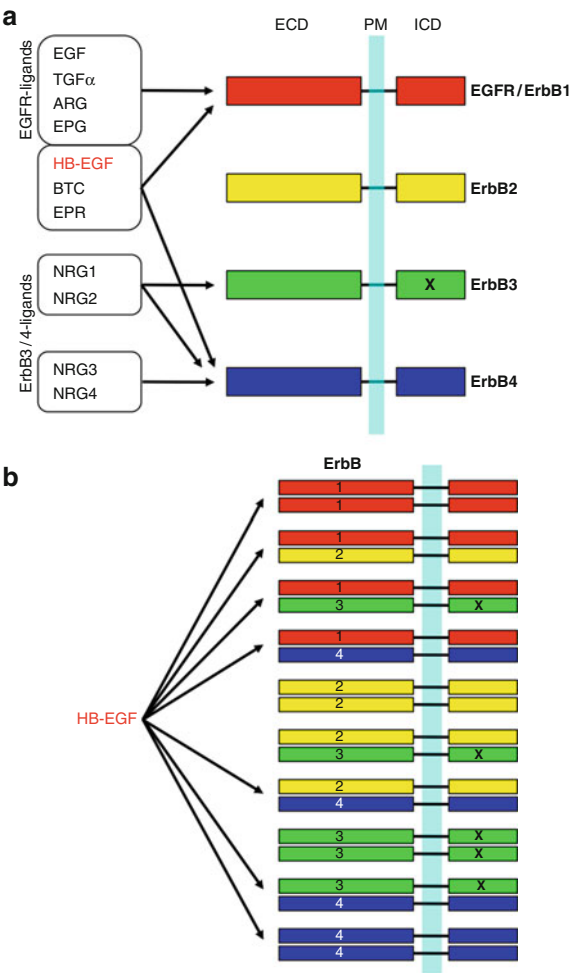
HB-EGF and ErbB Family Receptor Tyrosine Kinases

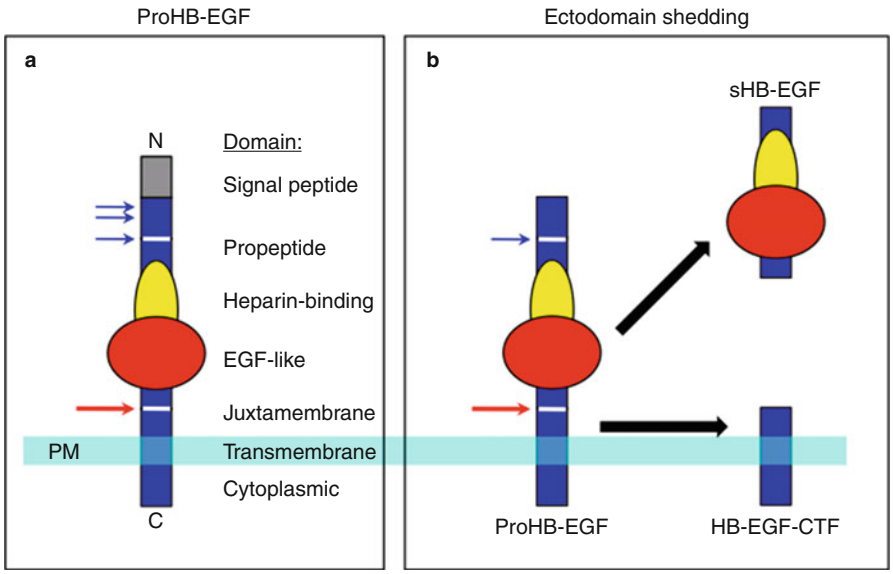
HB-EGF is a heparin-binding member of the EGFR ligands that was initially identified in the conditioned medium of human macrophage-like cells (Higashiyama et al. 1991). HB-EGF directly binds to and activates EGFR and ErbB4. The ErbB family of receptor tyrosine kinases (RTKs) consists of four receptors: EGFR/ErbB1, ErbB2, ErbB3, and ErbB4. The EGF family of growth factors binds to and activates ErbB RTKs, resulting in the formation of homo- and heterodimers, autophosphorylation of specific tyrosine residues within their cytoplasmic domains, and subsequent intracellular signaling. In vertebrates, EGF family members vary in their ability to activate distinct ErbB homo- and heterodimers, which may partly account for the differences in their bioactivities. In the case of HB-EGF, although it binds to and activates EGFR and ErbB4 directly, it can also activate ErbB2 and ErbB3 indirectly by heterodimerization (Harris et al. 2003; Mekada and Iwamoto 2008) (Fig. 1).



HB-EGF (Heparin-Binding EGF-Like Growth Factor), Fig. 1 *Binding specificity of members of the EGF ligand family to members of the ErbB receptor family*. (**a**) EGF family ligands are separated into four categories by their specificity of binding to members of the ErbB receptor family. ErbB2 has no ligand. ErbB3 is deficient in kinase activity (X). NRG, neuregulin; ECD, extracellular domain; ICD, intracellular domain; PM, plasma membrane. (**b**) ErbB homo- and heterodimier combinations activated by HB-EGF

Ectodomain Shedding

Like other EGF family members, HB-EGF is synthesized as a type I transmembrane protein (proHB-EGF), composed of a signal peptide, propeptide, heparin-binding, EGF-like, juxtamembrane, transmembrane, and cytoplasmic domains (Fig. 2). ProHB-EGF is biologically active as a juxtacrine growth factor that signals to neighboring cells in a nondiffusible manner; it also functions as the receptor for diphtheria toxin (DTR) (Naglich et al. 1992; Iwamoto et al. 1994; Iwamoto and Mekada 2000). ProHB-EGF is cleaved at its juxtamembrane domain by metalloproteinases, in a process called "ectodomain shedding." Ectodomain



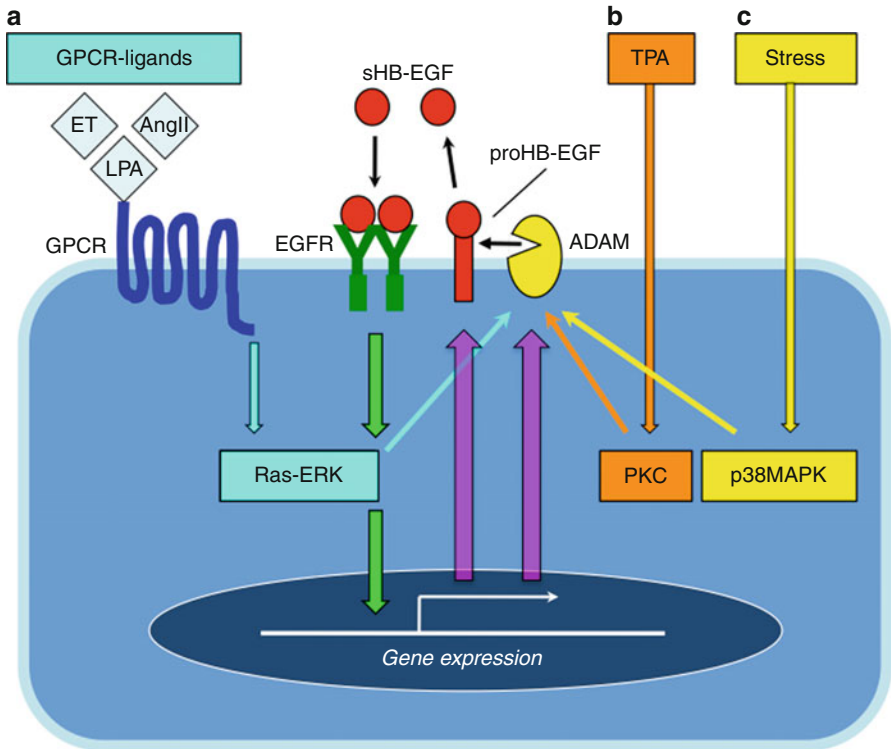
HB-EGF (Heparin-Binding EGF-Like Growth Factor), Fig. 2 *Ectodomain shedding of HB-EGF*. (**a**) Structure of proHB-EGF. The domain structure of the primary translation product of proHB-EGF is depicted. Ectodomain shedding cleaves off proHB-EGF in the juxtamembrane domain (a *large arrow*). Proteolytic cleavage also occurs at N-terminal sites (*small arrows*). MT1-MMP is involved in this cleavage. PM, plasma membrane. (**b**) Ectodomain shedding converts proHB-EGF to sHB-EGF and HB-EGF-CTF.

shedding of proHB-EGF yields a soluble ectodomain of HB-EGF (sHB-EGF) and a remnant carboxy (C)-terminal fragment (HB-EGF-CTF) (Fig. 2). sHB-EGF is a potent mitogen and chemoattractant for cells expressing its cognate ErbB receptors (Mekada and Iwamoto 2008). On the other hand, HB-EGF-CTF also functions as a signaling molecule. Subsequent to shedding, HB-EGF-CTF is phosphorylated and translocates into the nucleus, where it binds to and regulates several nuclear factors (Nanba et al. 2003; Higashiyama et al. 2008). Because proHB-EGF, sHB-EGF, and HB-EGF-CTF have distinct biological activities, ectodomain shedding is a critical process for HB-EGF proper function (Iwamoto and Mekada 2000; Higashiyama et al. 2008).

Shedding of proHB-EGF can be stimulated by various physiological and pharmacological stimuli, including G-protein-coupled receptor (GPCR) ligands and phorbol esters. Cellular stresses caused by inflammatory cytokines, reactive oxygen, and osmotic shock can also induce ectodomain shedding. These shedding stimuli activate several intracellular signaling molecules and result in the proteolytic cleavage of proHB-EGF by several metalloproteinases, including members of the ADAM family (Blobel 2005) (Fig. 3).

GPCR ligands, including lysophosphatidic acid (LPA), thrombin, angiotensin (ANG)-II, and endothelin, have been shown to stimulate EGFR tyrosine phosphorylation, in a process referred to as transactivation (Ohtsu et al. 2006). Transactivation of EGFR is a general function of GPCR signaling and is critical for the mitogenic activity of many GPCR ligands. Transactivation of EGFR is achieved by ectodomain shedding of EGFR ligands, and HB-EGF is often preferentially shed among the EGFR ligands (Prenzel et al. 1999). Ectodomain shedding of HB-EGF results in EGFR activation and subsequent Ras-ERK activation. In turn, activation of the EGFR-Ras-ERK pathway promotes further shedding of EGFR ligands. EGFR signals also induce the transcription of EGFR ligands, resulting in the repeated activation of ligand shedding and EGFR activation (Fig. 3). Thus, stimuli that induce HB-EGF shedding may trigger multiple positive feedback loops that ensure substantial EGFR activation, which potentially contributes to oncogenesis, cancer progression, and other diseases (Miyamoto et al. 2006; Mekada and Iwamoto 2008).

Dysregulation of HB-EGF shedding appears to be implicated in several diseases, including cardiovascular pathologies (cardiac hypertrophy, atherosclerosis, and pulmonary hypertension), cystic fibrosis, and various cancers. Analysis of knock-in mice, expressing transmembrane domain-truncated HB-EGF ($HB^{\Delta tm}$), revealed that dysregulated secretion of sHB-EGF induces hyperplastic tissue abnormalities, indicating that ectodomain shedding of proHB-EGF must be strictly controlled in vivo (Yamazaki et al. 2003; Mekada and Iwamoto 2008).



HB-EGF (Heparin-Binding EGF-Like Growth Factor), Fig. 3 *Molecular pathways regulating HB-EGF ectodomain shedding*. (**a**) GPCRs-Ras-ERK pathway. GPCR ligands including lysophosphatidic acid (LPA), angiotensin II (Ang II), and endothelin (ET), activate GPCR, resulting in activation of the downstream Ras-ERK pathway, which induces HB-EGF shedding. (**b**) TPA-PKC pathway. Phorbol esters, including TPA, activate protein kinase C (PKC), which induces HB-EGF shedding. (**c**) Stress-▶ p38MAPK pathway. Cellular stresses including inflammatory cytokines, reactive oxygen, and osmotic shock activate the p38MAPK pathway, which induces HB-EGF shedding. In all cases, sHB-EGF released by ectodomain shedding activates EGFR and the downstream Ras-ERK pathway, resulting in the formation of a positive feedback loop for promoting cell proliferation and migration

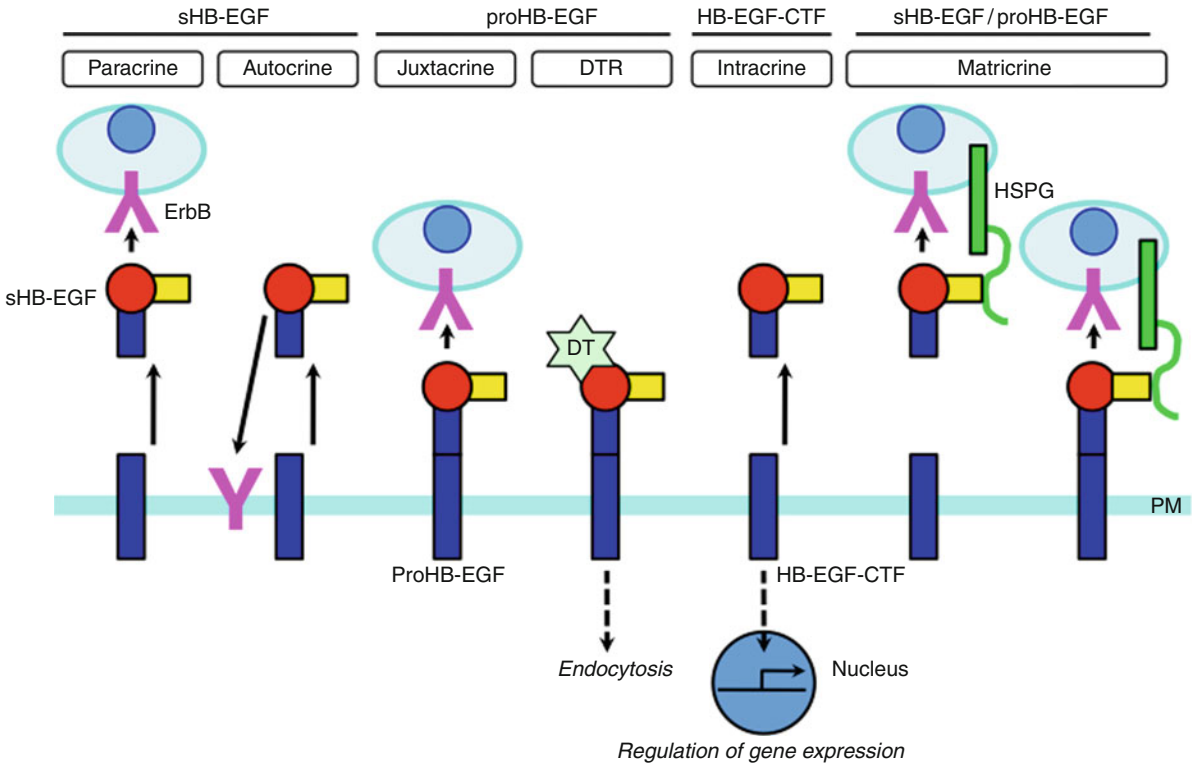
Modes of Action

Ectodomain shedding of proHB-EGF yields sHB-EGF and HB-EGF-CTF. The conversion of the molecular forms and the heparin-binding activity of HB-EGF suggest several modes of HB-EGF action (Fig. 4).

Paracrine and autocrine: Conventionally it is thought that sHB-EGF diffusively functions in a "paracrine" manner on cells expressing EGFR and/or ErbB4. Alternatively, sHB-EGF functions in an "autocrine" manner on its own cell, which also expresses EGFR and/or ErbB4. Studies of knock-in mice expressing an uncleavable mutant form (HB^{uc} mice) indicated that in vivo the major functions of HB-EGF are mediated by sHB-EGF (Yamazaki et al. 2003; Mekada and Iwamoto 2008).

Juxtacrine and DTR function: proHB-EGF functions in a "juxtacrine" manner by signaling to neighboring cells in a nondiffusible manner. Although sHB-EGF is known to be a potent mitogen, several lines of evidence from in vitro studies suggest that proHB-EGF has a distinct activity from sHB-EGF (Iwamoto and Mekada 2000). ProHB-EGF also functions as the cellular receptor for DT (DTR), mediating the entry of DT into the cytoplasm (Naglich et al. 1992; Iwamoto et al. 1994). Tetraspanin CD9 associates with proHB-EGF, which dramatically increases proHB-EGF activity as a DTR, by increasing the number of functional DTRs on the cell surface; however, the molecular mechanism underlying this process remains unclear (Iwamoto et al. 1994; Iwamoto and Mekada 2000).

Intracrine: HB-EGF-CTF has been found to be biologically active and functions in an "intracrine" manner (Nanba et al. 2003; Higashiyama et al. 2008). Subsequent to shedding, it is phosphorylated and



HB-EGF (Heparin-Binding EGF-Like Growth Factor), Fig. 4 *HB-EGF action modes.* Paracrine and autocrine by sHB-EGF: sHB-EGF acts diffusively on cells expressing EGFR and/or ErbB4 (paracrine). Alternatively, sHB-EGF acts on HB-EGF-expressing cells that also express EGFR and/or ErbB4 (autocrine). Juxtacrine and DTR function by proHB-EGF: ProHB-EGF acts by signaling to neighboring cells in a nondiffusible manner (juxtacrine). ProHB-EGF also functions as the cellular receptor for DT (DTR), mediating the entry of DT into the cytoplasm. Intracrine by HB-EGF-CTF: Subsequent to shedding, HB-EGF-CTF translocates into the nucleus, where it binds to several nuclear factors and regulates cell proliferation and apoptosis. Matricrine by sHB-EGF or proHB-EGF with HSPG: sHB-EGF interacts with HSPG as a co-receptor. ProHB-EGF also interacts with HSPGs, which up-regulates proHB-EGF activities

translocates into the nucleus, where it binds to several nuclear factors including PLZF and Bcl-6, and regulates cell proliferation and apoptosis.

Matricrine: HB-EGF has a high affinity for heparin and heparan sulfate (HS) and functions in a "matricrine" manner. Cell surface HS-proteoglycans (HSPGs) modulate various HB-EGF activities. Although the heparin-binding domain per se is not essential for HB-EGF activity, this domain suppresses the activity of the EGF-like domain and binding of heparin or HS to this domain inhibits this suppressive effect (Mekada and Iwamoto 2008). A recent study revealed that association of proHB-EGF with HSPGs promotes its localization to sites of cell–cell contact and prevents shedding (Prince et al. 2010). These studies suggested that HSPGs would be important regulators of HB-EGF activity, though the physiological significance was unclear. Recently, it has been reported that similarly to the HB-EGF-null and HB^{uc} mice, the knock-in mice that express a mutant HB-EGF, lacking heparin-binding activity ($HB^{\Delta hb}$ mice), show developmental abnormality in the cardiac valves, indicating that interaction between HB-EGF and HSPGs is essential for the physiological function of HB-EGF in this process (Iwamoto et al. 2010). Moreover, another recent study revealed that the interaction of HB-EGF with HSPGs is regulated by the processing of the N-terminal portion of HB-EGF by MT1-MMP, a membrane-bound metalloprotease (Koshikawa et al. 2010). Since the discovery of HB-EGF, it has been known that the processing of this portion of HB-EGF occurs in addition to ectodomain shedding (Fig. 2); however, its biological meaning remained unclear. N-terminal processing of HB-EGF

by MT1-MMP converts HB-EGF into a heparin-independent growth factor with enhanced mitogenic activity and thereby expression of both proteins co-stimulates tumor cell growth in vitro and in vivo. Thus, this processing might be a regulatory mechanism for the interaction of HB-EGF with HSPGs in HB-EGF-mediated processes.

Physiological Functions in Mice

Recent studies using HB-EGF-null and the mutant knock-in mice revealed that HB-EGF has critical roles in several physiological processes (summarized in Table 1) as described below (Mekada and Iwamoto 2008).

Heart muscle homeostasis: More than half of HB-EGF null mice died after birth and the survivors developed severe heart failure with grossly enlarged ventricular chambers and decreased contractility, symptoms resembling human dilated cardiomyopathy. This phenotype resembled that of mice conditionally lacking ErbB2. The data indicated that HB-EGF activation of ErbB2 and ErbB4 in cardiomyocytes is essential for normal heart function. The HB^{uc} mice showed an essentially similar phenotype, indicating that sHB-EGF functions by paracrine in this process.

Heart valve development: HB-EGF null mice also developed grossly enlarged cardiac valves. This enlargement is due to the increased proliferation of mesenchymal cells in the cardiac jelly during the later stage of cardiac valve development. This phenotype resembled that displayed by mice lacking EGFR and ADAM17, one of the sheddases for HB-EGF. The HB^{uc} mice also showed an essentially similar phenotype, indicating that sHB-EGF functions in this process. These studies proposed a model for valve development in which sHB-EGF secreted by ADAM17 from endocardial cells activates EGFR in mesenchymal cells, resulting in suppression of cell proliferation. As mentioned above, recently it has been revealed that HB-EGF must interact with HSPGs to properly function in this process (Iwamoto et al. 2010). Interestingly, although HB-EGF-null mice had abnormal heart chambers and lung alveoli, $HB^{\Delta hb/\Delta hb}$ mice did not exhibit these defects. Thus, the interaction with HSPGs is essential for HB-EGF function, especially in cardiac valve development.

Skin epidermis: Lack of HB-EGF resulted in a defect in eyelid closure in mouse embryos. Together with studies using HB^{uc}, waved-2 (a hypomorphic EGFR mutant strain), and TGFα null mice, the data indicate that sHB-EGF secreted from the tip of the leading edge of migrating epithelium activates the EGFR and ERK pathways, and that synergy with TGFα is required for the leading edge extension in epithelial sheet migration during eyelid closure. A similar mode of paracrine HB-EGF function in epithelial sheet migration underlies the skin wound healing process.

Lung development: HB-EGF is involved in distal lung development. In HB-EGF null newborns, abnormally thick saccular walls occurred accompanied by a significant increase in cell proliferation during the perinatal stage, indicating that HB-EGF suppresses distal lung cell proliferation. Together with studies using waved-2 and TGFα null mice, these findings indicate that HB-EGF has a suppressive function that contributes to decelerating distal lung cell proliferation synergistically with TGFα, through EGFR, during perinatal distal lung development.

Blastocyst implantation: HB-EGF has been suggested to be involved in the interaction between the blastocyst and the uterus during the implantation process. HB-EGF is expressed in the uterine luminal epithelium at the site of the blastocyst before the attachment reaction. Maternal HB-EGF is critical for implantation. Maternal deficiency of HB-EGF defers on-time implantation, leading to a compromised pregnancy outcome. ARG partially compensates for the loss of HB-EGF in this process.

Implications in Pathology

Recent clinical and basic studies have shed light on the relationship between the role of ectodomain shedding of the EGF family of growth factors and pathophysiology. Among EGF family, HB-EGF has been prominently studied regarding this issue (summarized in Table 2; Ohtsu et al. 2006; Miyamoto et al. 2006; Higashiyama et al. 2008).

Cardiac hypertrophy: HB-EGF shedding by a metalloproteinase ADAM12, followed by EGFR transactivation has been reported to be involved in cardiac hypertrophy. When cardiomyocytes are stimulated by GPCR-agonists, shedding of HB-EGF via

ADAM12 activation and subsequent transactivation of EGFR occur. In mice with cardiac hypertrophy, KB-R7785 (a metalloproteinase inhibitor) inhibits the shedding of HB-EGF and attenuates hypertrophic changes.

Atherosclerosis and pulmonary hypertension: Atherogenesis in the arterial wall is characterized by the formation of fibrous lesions and proliferation of neointimal smooth muscle cells (SMCs), and HB-EGF is a potent chemoattractant and mitogen for vascular SMCs. Large amounts of HB-EGF mRNA and protein are expressed in SMCs and macrophages in human atherosclerotic plaques. EGFR transactivation by sHB-EGF through ANG II-GPCR activation is required for the vascular SMC hypertrophy, and ADAM17 may be involved in this process. Remnant lipoproteins (RLPs) have also been reported as inducers of atherosclerosis, mediated by EGFR transactivation via HB-EGF shedding. Stimulation of GPCR with phenylephrine, which causes EGFR transactivation through MMP7 shedding of HB-EGF, has been suggested to be involved in the development and progression of hypertension. In spontaneously hypertensive rats (SHR), MMP levels are high at all time points. Administration of doxycycline, the only clinically approved MMP inhibitor, reduces systolic blood pressure and attenuates HB-EGF shedding in mesenteric arteries of SHR.

Cystic fibrosis: In the lungs of cystic fibrosis patients, it has been suggested that the pathway, bacterial lipoteichoic acid-GPCR-induced ADAM10 activation followed by HB-EGF shedding, and EGFR transactivation, may contribute to this pathology. Overproduction of mucus is a direct result of the activation of mucin gene expression by gram-positive bacteria. Bacterial lipoteichoic acid activates the platelet-activating factor receptor, which is a GPCR. This results in activation of ADAM10, cleavage of proHB-EGF and activation of EGFR.

Cancers: Emerging evidence has implicated dysregulation of ectodomain shedding of EGF family growth factors, especially HB-EGF, in the proliferative potential of tumor cells. It has been revealed that HB-EGF is a critical factor for ovarian cancer progression and thus suggested that HB-EGF could be a novel

targeting molecule for therapy of this cancer. Subsequently, CRM197 (a nontoxic mutant DT that neutralizes HB-EGF activity) is undergoing clinical development as an anticancer drug. Tumor progression involves the interaction of cancer cells with the cancer-surrounding stroma. A recent study, using CRM197 and humanized HB-EGF-expressing knock-in mice, has revealed that not only HB-EGF in cancer cells but also cancer stroma-derived HB-EGF contributes to tumor growth (Ichise et al. 2010).

Summary

HB-EGF is a member of the EGF family of growth factors, which binds to and activates EGFR and ErbB4. HB-EGF is synthesized first as a transmembrane proHB-EGF. Ectodomain shedding of proHB-EGF yields sHB-EGF and HB-EGF-CTF. Each form of HB-EGF has a distinct biological activity, and functions in several modes of action. Thus, ectodomain shedding is a critical process that must be strictly controlled for HB-EGF to function properly. Dysregulated shedding of HB-EGF causes severe developmental abnormalities in mice and has also been implicated in several pathologies. HSPGs are also important regulators of HB-EGF functions. Interaction with HSPGs is essential for HB-EGF function in mouse cardiac valve development. N-terminal processing of HB-EGF by MT1-MMP is a regulatory step for this interaction. HB-EGF has been implicated in several developmental, physiological, and pathological processes. Although HB-EGF has conventionally been thought of as a growth-promoting factor, especially in pathological processes including cancers, HB-EGF does not function as a growth-promoting factor, but rather as a growth-inhibitory or migration-promoting factor in developmental and physiological processes. Thus, future studies will clarify the mechanism regulating HB-EGF normal function in vivo (not as a growth-promoting factor), which will lead to novel therapeutic approaches for several HB-EGF-mediated pathologies.

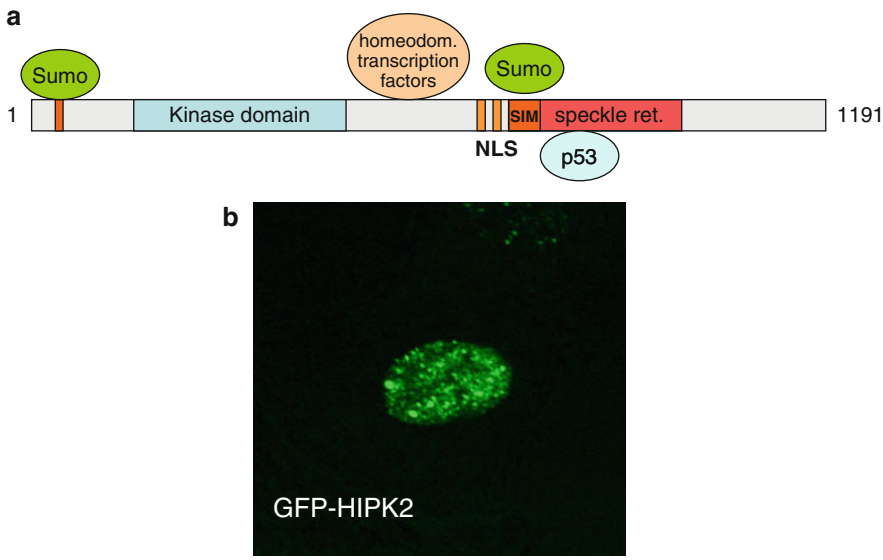
Historical Background

The homeodomain-interacting protein kinase 2 (HIPK2) was first described in 1998 as member of a novel protein kinase family (HIPK1-3) able to interact with homeodomain transcription factors of the NK-2 family and to enhance their repressor activity (Kim et al. 1998). Over the next years, it was shown that HIPK2 very likely is an autophosphorylating Ser/Thr kinase which localizes to nuclear speckles (see Fig. 1), and a number of interaction partners and putative targets such as the death receptor CD95, the corepressor Groucho, or a STAT3 peptide were identified. The HIPK2 genes were mapped to Chr. 7q32-42 in humans and to Chr. 6B in the mouse.

The findings that influenced the direction of HIPK2 research most profoundly for the next decade were published in 2002, when independent groups reported that HIPK2 is a DNA damage-responsive kinase that is partially co-recruited with the tumor suppressor ▶ p53 into PML bodies upon cytotoxic stress, most prominently by UV irradiation (D'Orazi et al. 2002; Hofmann et al. 2002). HIPK2 was shown to phosphorylate p53 on Serine 46, thereby enhancing the proapoptotic activity of the transcription factor p53 and programmed cell death. Moreover, it was shown in 2003 that HIPK2 is also able to promote p53-independent cell death by targeting the corepressor C-terminal binding protein (CtBP) for degradation, thus increasing the transcription of proapoptotic CtBP target genes. Since then, the important regulatory role of HIPK2 in determining cell fates upon genotoxic stress, but also in various developmental processes, has been elucidated in great detail.

The HIPK2 Protein

HIPK2 is a 130 kDa protein of 1191 amino acids in humans that is well conserved from flies to humans. It harbors an N-terminal kinase domain that was published to be very homologous to DYRK family kinases. It was shown that HIPK2 most probably autophosphorylates at multiple Serine/Threonine residues. Mutation of the conserved residue K221 within the ATP-binding site of the kinase domain results in an inactive kinase. HIPK2 preferentially targets Serine or Threonine residues that are followed by a Proline residue (SP/TP sites) in its substrates. Correlating with its



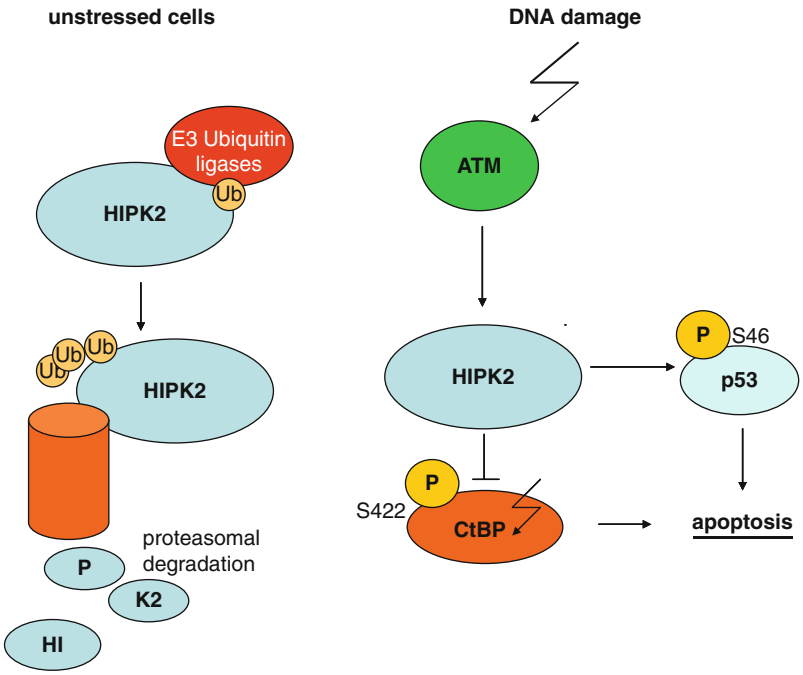
HIPK2, Fig. 1 The HIPK2 protein. (**a**) Schematic drawing of important domains and interactions of the HIPK2 protein. NLS, nuclear localization signal; SIM, SUMO interaction motif. (**b**) Nuclear speckle localization of exogenously expressed GFP-HIPK2 in U2OS cells

observed localization in nuclear substructures, it contains several C-terminal NLS sequences and a speckle retention signal. HIPK2 was also shown to be covalently SUMOylated at several sites, the principal site being K25, and to have two adjacent SUMO interaction motifs (SIMs) within the C-terminus that influence its ability to be recruited to promyelocytic leukemia (PML) nuclear bodies (de la Vega et al. 2010 and references cited therein). Recently, it has been shown that HIPK2 is an unstable protein in unstressed cells which is kept low in cells via proteasomal degradation, and the region that is responsible for this degradation has also been mapped to the C-terminus (Calzado et al. 2009a, b; Sombroek and Hofmann 2009; Winter et al. 2008). Moreover, it has been speculated that the HIPK2 C-terminus may form an auto-inhibitory loop that might block HIPK2 activity in the absence of cofactors like Han11 (Ritterhoff et al. 2010) or Axin which was reported to bind to the HIPK2 C-terminus and to enhance the kinase activity of HIPK2 towards p53.

HIPK2 and the DNA Damage Response

The role of HIPK2 in cells suffering from genotoxic stress is the best studied aspect of the functions of HIPK2 on a molecular level. As mentioned previously, HIPK2 can promote apoptosis in irreparably damaged cells by p53-dependent or p53-independent means (Fig. 2). HIPK2 protein levels are very low in unstressed cells due to efficient protein degradation via the ubiquitin/proteasome system. Several E3 ubiquitin ligases have been identified that earmark HIPK2 for degradation, namely, seven in absentia-homolog (Siah)-1 and -2, WD40 repeat/SOCS box protein 1 (WSB-1), and the p53 E3 ligase mouse double minute (MDM)2/HDM2 (reviewed in Calzado et al. 2009b and Sombroek et al. 2009).

The region within HIPK2 that is required for destabilization of HIPK2 by these proteins is located in its C-terminus, between amino acids 600 and 800 for Siah-1 and starting from amino acid 838 for MDM2. Upon DNA damage inflicted by various genotoxic stimuli like UV and ionizing irradiation or treatment with adriamycin or cisplatin, however, HIPK2 degradation is blocked, HIPK2 protein accumulates and phosphorylates its target genes. The process by which HIPK2 degradation is inhibited is best characterized for Siah-1, which is phosphorylated by the damage-activated checkpoint kinases ATM and/or ATR at Ser19, leading to the loosening of the HIPK2/Siah-1 interaction and therefore to HIPK2 stabilization. When this occurs in p53-proficient cells, HIPK2 phosphorylates p53 on Serine residue 46 (or 58 in mice) in a PML- and Sp100-dependent manner. Ser46 phosphorylation very likely causes enhanced acetylation of p53 on K382 by the HAT protein CREB-binding protein (CBP), another HIPK2 interactor, and these modifications lead to an altered promoter specificity



HIPK2, Fig. 2 HIPK2 within the DNA damage response. In unstressed cells, HIPK2 is almost completely degraded via the proteasomal pathway, whereas genotoxic stress causes HIPK2 stabilization and greatly enhanced ability of HIPK2 to promote apoptosis by phosphorylating its target proteins p53 and/or CtBP, thereby altering the promoter specificity of the p53 protein and promoting degradation of the antiapoptotic CtBP protein

of the p53 transcription factor and to the increased transcription of proapoptotic p53 target genes such as *Puma* and *Noxa*. Alternatively, HIPK2 can lead to derepression of proapoptotic genes by phosphorylating the transcriptional repressor CtBP, inducing its degradation via the proteasomal pathway. This results in upregulation of CtBP targets such as *Bax*, *Noxa*, and ▶ PTEN which then drive apoptosis in the damaged cells (for reviews, see Bitomsky and Hofmann 2009 and Puca et al. 2010). HIPK2-mediated apoptosis has also been linked to the presence of the transcriptional repressor methyl-CpG-binding protein 2 (MeCP2) (Bracaglia et al. 2009), but the underlying mechanism has not been determined. Accordingly, it has been observed that HIPK2 can act as haploinsufficient tumor suppressor in a two-stage model of skin carcinogenesis in mice. Involvement of HIPK2 in tumor suppression, however, will be discussed in more detail in a separate chapter. Likewise, the involvement of HIPK2-mediated apoptosis in normal development will be discussed later. One interesting aspect of HIPK2 regulation upon genotoxic stress is the transient stabilization that occurs after sublethal damage but does not result in Ser46 phosphorylation. The transient nature of this stabilization is probably brought about by negative feedback loops involving the Siah-1 and MDM2 ubiquitin ligases, both of which are p53 target genes which accumulate upon DNA damage. However, the functions of the transiently increased HIPK2 levels after mild stress have not been elucidated so far. Another interesting aspect of HIPK2 regulation is the question whether HIPK2 is activated in addition to its accumulation, and if so, which modification and/or interactions might be required for that. One described mechanism activating HIPK2 after damage in addition to stabilization is caspase cleavage. It was shown that HIPK2 can be cleaved after D977 and D916 in a process involving caspases 3 and 6, and that the cleaved products are more active with respect to p53 phosphorylation than corresponding uncleavable HIPK2 constructs (reviewed in Sombroek et al. 2009). Nevertheless, the issue of HIPK2 activation by other means remains subject to intense investigation.

HIPK2 in Development

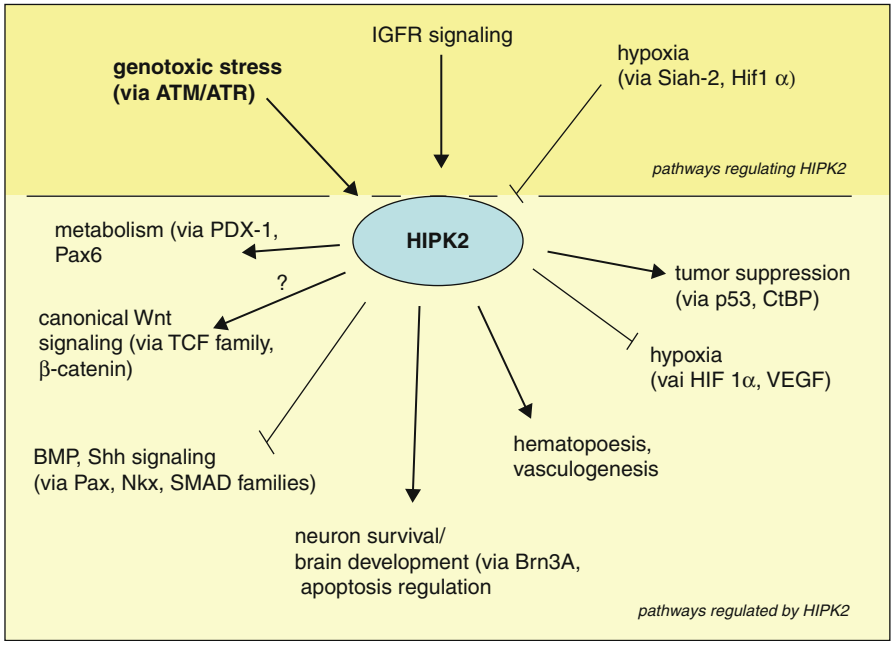
Apoptosis is an important process shaping many tissues and organs. For example, in brain development, neurons are produced in very large numbers and the excess is then eliminated by apoptosis. Indeed, it was shown that in sensory and sympathetic neurons for instance in trigeminal ganglia, HIPK2 overexpression induces massive apoptosis and thus seems to be

important for the removal of excess neurons by programmed cell death, likely by regulating the pro-survival factor Brn3a. Somewhat paradoxically, another study suggested that HIPK2 knockout actually increases apoptosis in trigeminal neurons, which would suggest an as-yet-unrecognized pro-survival function of HIPK2 (reviewed in Rinaldo et al. 2007). The phenotypes of knockout mice generated independently in different laboratories (Isono et al. 2006; Trapasso et al. 2009; Hattangadi et al. 2010; Inoue et al. 2010) suggest that there is some degree of redundancy between HIPK2 and HIPK1. Analysis of double HIPK1/2 knockout mice (Isono et al. 2006) revealed disturbed hematopoiesis, vasculogenesis, and angiogenesis in one study, and embryonic death from embryonic day 9 onward and exencephaly, eye phenotypes, and fusion of dorsal root ganglia in another study. Moreover, the latter also revealed developmental defects like the formation of ectopic ribs, indicative of disturbed Hox gene regulation, and an influence of HIPKs on the ▶ Sonic hedgehog (Shh) pathway via Pax1 and -3. MEFs from double knockout were also reported to be more resistant to UV-induced apoptosis. HIPK2 single knockouts from independent groups showed a "clasping of hindlimbs" phenotype when suspended by the tail, albeit to greatly varying percentages. One study also reported shuffling gait and other motoric abnormalities resembling a Parkinson's-like disease, and significantly enhanced apoptosis in neurons at E17.5 and P0. Another independent study (Trapasso et al. 2009) reported increased stem and progenitor cell compartments in mouse skin when HIPK2 was knocked out, suggesting that HIPK2 may restrict the proliferation of the stem and progenitor cells in the skin, maybe by interfering with the Wnt signaling pathway. Interestingly, the study reporting only 15% of "clasped hindlimbs" in their HIPK2 knockout observed a growth reduction of HIPK2-deficient animals in comparison to their littermates that was already observable at birth and persisted to adulthood, again indicating a role for HIPK2 in cell proliferation rather than cell death. However, the underlying mechanisms for a putative growth-stimulating role of HIPK2 have not been identified so far.

In *Drosophila*, knockout of the only existing HIPK gene results in defective eye formation and frequent death at the pupal or embryonal stages. *Drosophila* HIPK phosphorylates Groucho at multiple residues, resulting in upregulation of the Notch pathway (Lee et al. 2009). This connection has not (yet) been described for vertebrates. In addition, it could be shown that HIPK is required for collective programmed cell death of epithelial cells in the developing wing, similar to previously determined apoptotic factors like Dronc or Dark (Link et al. 2007).

Analyses in cell culture have yielded a set of interactors for HIPK2 that point to possible involvement of HIPK2 in several signal transduction pathways important for important developmental processes (reviewed in Rinaldo et al. 2007; Puca et al. 2010) (Fig. 3). Most prominently, the Wnt pathway has been shown to be connected to HIPK2 activity at several points. For instance, Wnt-1 induces the HIPK2- and NLK-dependent degradation of the transcription factor ▶ c-myb. Moreover, both human and *Drosophila* HIPK have been shown to interact with and phosphorylate both ▶ β-catenin and transcription factors of the Lef/TCF-family (Hikasa et al. 2010), thereby directly modulating the canonical Wnt signaling pathway, which is important for axis specification, neural tube patterning where it seems to counteract Shh signaling, and regulation of stem cell compartments. However, data concerning the interactions and effects of HIPK2 within the canonical Wnt signaling pathway appear partially contradictory and await further investigation. HIPK2 also seems to interfere with the Shh pathway at the level of its downstream homeobox transcription factors; as mentioned previously, HIPK2 likely interacts with Pax transcription factors on the one hand and the Nkx family on the other hand. Thus, HIPK2 might influence important morphogenetic processes such as motoneuron formation. HIPK2 interaction with Pax6 may also be responsible for the observed disturbances in eye formation in mice which frequently have abnormally small eyes without a lens and with incorrect lamination and cell arrangement in the retina. Furthermore, HIPK2 was recently shown to interact with the transcription factor cAMP-responsive element-binding protein (▶ CREB) (Sakamoto et al. 2010) and to increase its association with CBP, which also plays a role in neuron development and survival.

It has also been reported that HIPK2 can interact with the corepressor c-ski and with SMAD1 and thereby counteract bone morphogenetic protein (BMP) signaling, which is implicated in embryo polarity, heart and CNS development as well as bone formation.



HIPK2, Fig. 3 The HIPK2 network. The most important signals and pathways that alter HIPK2 (*upper part*) or are modulated by HIPK2 (*lower part*) that are currently known are depicted schematically

HIPK2 and HIPK1 depletion also impacts very strongly on fetal liver hematopoiesis (Hattangadi et al. 2010), preventing upregulation of many erythropoietic and heme-biosynthesis-associated genes, but the exact target(s) of the HIPK2 in this system has not been identified to date.

HIPK2 and Cancer

Given the observations that HIPK2 can induce apoptosis in both p53-proficient and p53-deficient cells upon genotoxic stress, it is highly likely that HIPK2 can act as a tumor suppressor in many tissues (Krieghoff-Henning and Hofmann 2008; Sombroek and Hofmann 2009 and references cited therein). This question has been addressed directly in mice in a skin carcinogenesis model, where deletion of only one HIPK2 allele already renders the mice more sensitive to skin cancer formation, with an even stronger phenotype in full knockouts. Thus, HIPK2 acts as haploinsufficient tumor suppressor in mouse skin. Moreover, there are a number of human tumors, such as thyroid and breast carcinoma, that show a high incidence of HIPK2 downregulation on the mRNA level. In one case each of myelodysplastic syndrome and AML, point mutations in the HIPK2 sequence were found: R868W and N958I, and these point mutants were found to localize aberrantly, affecting their ability to transactivate p53 target genes. Moreover, there is evidence for a tumor-promoting effect of the HIPK2 interactor HMGA1, which is highly overexpressed in many breast tumors and seems to recruit HIPK2 to the cytoplasm, thereby preventing its association with PML-NBs and hence p53 Ser46 phosphorylation. Interestingly, HIPK2 protein is degraded in a possibly HIF1- and Siah-2-dependent manner under hypoxic conditions, which occur very frequently in larger tumors. HIPK2 also co-localizes with the tumor suppressor PML in PML nuclear bodies, and while PML may actually stabilize HIPK2, HIPK2 was shown to phosphorylate PML IV at several residues, increasing PML SUMOylation and its ability to induce apoptosis. Finally, injection of colorectal cancer RKO cells into mice causes tumors that grow much faster if the cells are HIPK2-depleted. Moreover, depletion of HIPK2 in RKO cells leads to integrin subunit β4 upregulation (Bon et al. 2009), which is strongly associated with increased migration and metastatic potential. In breast cancer, HIPK2 nuclear positivity was reported to be inversely correlated with β4 expression. These observations all suggest that in many tumors HIPK2 is indeed inactivated, strengthening the hypothesis that HIPK2 is a tumor suppressor protein. Reports on pilocytic astrocytoma, however, indicate that HIPK2 may also be upregulated by

amplification in a subset of human tumors, although the driving factor of cancer formation in these samples may be BRAF which is located in the same region (Cin et al. 2011). In cervical cancer, HIPK2 nuclear positivity was positively correlated with tumor stage and tumor dedifferentiation, suggesting that HIPK2 may also have a growth-promoting role. However, the molecular basis of this potential role has not been determined so far.

HIPK2, Aging and Metabolism

HIPK2 may not be regulated solely by DNA damage, but also by the metabolic state of the cell. Vice versa, HIPK2 activity also appears to contribute to metabolic regulation in the presence or absence of genotoxic stress. Interestingly, it is becoming more and more obvious that metabolism, genotoxic stress, and cellular aging in particular are closely interlinked. Caloric restriction is probably extending the organismal lifespan, as shown in *C. elegans* and mice, most likely by limiting the amount of DNA-damaging reactive oxygen species (ROS).

As mentioned previously, HIPK2 plays an important regulatory role in pancreas development and function. One important HIPK2 target in this context is the Insulin Promoter Factor/Pancreatic Duodenal Homeobox 1 (IPF-1/PDX-1)-dependent upregulation of the *insulin* gene, *glut2*, *glucokinase*, etc., in the developing pancreatic epithelium and in β-cells (Boucher et al. 2009). HIPK2 seems to regulate the nucleocytoplasmic distribution of IPF-1 (An et al. 2010). HIPK2 can also regulate the *proglucagon*, *somatostatin*, and *insulin* promoters via Pax6, which also impacts on pancreas development and function. HIPK2 may also play a role in ROS metabolism, by virtue of its ability to suppress transcription of *Nox1*, encoding the catalytic subunit of a NADPH oxidase which can generate ROS (Puca et al. 2010).

Conversely, it was shown that HIPK2 is upregulated in aging neurons, which can be counteracted by caloric restriction, arguing that the presence of ROS induces HIPK2, and placing HIPK2 in the aging-associated insulin-like growth factor (IGF1)-R signaling cascade (Li et al. 2009).

A very general way in which HIPK2 regulates metabolic and other processes within the cell is its ability to recruit and/or interact with the HAT enzyme p300 and its paralog CBP, which are important co-transcription factors for a variety of transcription factors, including the CREB protein, which itself was shown to be a HIPK2 target (Sakamoto et al. 2010), and which has also been linked to lifespan extension in *C. elegans*.

Summary

Although discovered relatively recently, HIPK2 has already been shown to regulate several important processes within eukaryotic cells. The best studied function of HIPK2 is to induce programmed cell death in response to genotoxic stress, either by p53 phosphorylation at Serine residue 46 or by degrading the antiapoptotic transcriptional repressor CtBP. Furthermore, HIPK2 has been shown to act as transcriptional regulator in various transcription complexes, most prominently those formed by homeobox transcription factors. Especially with respect to the developmental functions of HIPK2, a certain degree of redundancy with the related kinase HIPK1 seems to occur, so that developmental defects are in some cases only clearly detectable when both proteins are depleted. Single and double knockout animals suggest roles for HIPK2 in brain development, hematopoiesis, pancreas development, and body patterning, in part by regulating apoptosis, but also by modulating the activity of several important signaling pathways such as canonical Wnt, TGFβ, or BMP. In part, the detailed consequences of the described interactions and phosphomodifications of the HIPK2 targets identified so far still remain to be elucidated on the organismal level.

Moreover, the prominent role of HIPK2 in the DNA damage response and first hints obtained by analyzing human tumors as well as a two-step carcinogenesis model in mice suggest that HIPK2 may act as a tumor suppressor in many tissues, and indicate that cancer patients might benefit from specific activation of HIPK2 in tumors.

BDR

Historical Background

Hippocalcin was originally cloned from a rat brain cDNA library based on the partial amino acid sequences from a calcium-binding protein of molecular mass 23,000 (P23k), which was purified during a survey of recoverin-like immunoreactivity in the brain (Kobayashi et al. 1992). During the 1990s, a number of calcium-binding proteins structurally related to hippocalcin were identified in the nervous system and named NCS (neuronal calcium sensor) proteins. There are 14 protein coding genes in the NCS family in the human genome (Burgoyne 2007; Braunewell and Klein-Szanto 2009). Hippocalcin is a highly conserved protein having an identical amino acid sequence in rat, mouse, bovine, and human genes (Kobayashi and Takamatsu 2009).

Protein Chemical Characteristics

Hippocalcin, a 23 kDa protein of 193 amino acid residues, has three functional EF-hand calcium-binding domains and an N-terminal glycine residue covalently linked to myristic acid (Kobayashi et al. 1993). Calcium binding to the EF-hands of hippocalcin induces a conformational change that results in exposure of the myristoyl group and association of hippocalcin with the cellular membranes. This process is referred to as a calcium myristoyl switch and is a prominent characteristic of some members of the NCS family including recoverin, VILIP1, VILIP2, and VILIP3 (Burgoyne 2007; Braunewell and Klein-Szanto 2009). Hippocalcin undergoes a calcium myristoyl switch in HeLa cells transfected with hippocalcin-EYFP (enhanced yellow fluorescent protein) and the maximal rate of translocation to the membrane is approximately 1 sec. Half maximal translocation occurred at approximately 300 nM free calcium with a dynamic range of calcium-sensitivity of 200–800 nM free calcium. In hippocampal neurons, spontaneous and action potential-dependent translocation of hippocalcin-YFP fluorescence were observed in different parts of neuronal processes, reaching peak translocation within 1–5 sec (Markova et al. 2008). These results suggest that hippocalcin would be able to affect interact with target proteins on membranes when free calcium levels are only slightly elevated above resting levels. N-myristoylated hippocalcin as well as an N-myristoylated hippocalcin peptide (1-14) were shown to interact with liposomes containing phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P_2) with high affinity (Kd = 50 nM) in a Ca^{2+}-dependent manner (O'Callaghan et al. 2005). Expression of hippocalcin(1-14)-ECFP (enhanced cyan fluorescent protein) partially displaced the pleckstrin homology (PH) domain of phospholipase δ1, a PtdIns(4,5)P_2-specific binding partner, from the plasma membrane in living cells. These results suggest that the interaction with PtdIns(4,5)P_2 is likely to be a physiologically significant event contributing to the targeting of hippocalcin.

Hippocalcin has been shown to interact with ▶ MLK (mixed-lineage kinase) 2, neuronal apoptosis inhibitory protein (NAIP), and the β2-adaptin subunit of the AP2 adaptor complex (Nagata et al. 1998; Lindholm et al. 2002; Palmer et al. 2005). Hippocalcin also interacts with the microsomal cytochrome b5, calmodulin (CaM)-dependent cyclic nucleotide 3′,5′-phosphodiesterase (PDE), and CAPS1, a calcium-dependent activator protein involved in secretion. However, the functional consequences of these interactions have not yet been determined (Kobayashi and Takamatsu 2009).

Distribution

Hippocalcin is expressed in various regions of the rat hippocampus, as well as other regions of the brain (Kobayashi et al. 1992; Kobayashi and Takamatsu 2009). In the hippocampus, hippocalcin mRNA and immunoreactivity are detected at high levels in the pyramidal cells of Ammon's horn and at moderate levels in the granule cells of the dentate gyrus. Hippocalcin is also found at significant levels in other regions of the brain, including the pyramidal cells of cerebral cortex layers II–VI, the caudate-putamen, taenia tecti, claustrum, olfactory tubercle, anterior olfactory nucleus and olfactory bulb, as well as in the ganglion cell layer and amacrine cell layer in the retina, and in the apical layer in the olfactory epithelium. No hippocalcin protein expression has been detected outside of the central nervous system, although expressed sequence tag (EST) sequences have been found in a few peripheral tissues (Braunewell and Klein-Szanto 2009).

In hippocampal pyramidal cells, hippocalcin is located in the cytoplasm and associated with the

plasma membrane of the cell body, dendrites and axon. The hippocalcin concentration in hippocampal pyramidal cells is estimated to be greater than 30 μM. Hippocalcin reversibly translocates from the cytosol to the plasma membrane and the trans-Golgi network of the perinuclear region in transfected HeLa cells and in hippocampal cells via the calcium myristoyl switch mechanism (O'Callaghan et al. 2003).

Physiological Functions

Roles in Neural Plasticity

The hippocampus is an important cortical region for associative learning and memory, and is especially important in the performance of spatial positioning discrimination. Hippocalcin may be involved in these functions. Hippocalcin deficient (hippocalcin$^{-/-}$) mice displayed deficits in spatial memory and working (trial-dependent) associative memory (Kobayashi et al. 2005). Hippocalcin may be involved in memory formation via regulation of extracellular signal-regulated kinase (ERK) cascade. In hippocalcin$^{-/-}$ mice, NMDA stimulation- and depolarization-induced phosphorylation of the cAMP response element binding protein (▶ CREB) was attenuated in hippocampal neurons (Kobayashi et al. 2005). Impaired CREB activation may be caused by a malfunctioning ERK cascade, since an ERK cascade inhibitor blocked stimulation-dependent CREB phosphorylation in control hippocampal slices but not in hippocalcin$^{-/-}$ mice. When the Ca^{2+}-dependent Ras/Raf/▶ MEK/ERK signaling cascade was further examined, no direct effect of hippocalcin on Raf-1 kinase or MEK kinase was observed (Noguchi et al. 2007). Hippocalcin also had no effect on the activation of Ras. However, hippocalcin$^{-/-}$ mice do display a defect in NMDA- and depolarization-induced activation of Raf-1 kinase and ERK. Therefore, hippocalcin may act on an alternative Raf-1 kinase activation pathway, such as protein kinase B (▶ PKB)/Akt or 14-3-3 protein activation of Raf-1. Notably, hippocalcin, in conjunction with the small GTPase Cdc42, led to an increase in calcium-dependent ▶ phospholipase D activation. In NIH3T3 cells, phospholipase D activation induced by overexpression of hippocalcin was dependent on upregulation of phospholipase D expression via activation of the ERK cascade (Oh et al. 2006). These results indicate that hippocalcin affects activity-dependent gene expression via regulation of ▶ MAP kinase signaling (see Fig. 1).

Moreover, hippocalcin has been implicated in hippocampal NMDA receptor-dependent long-term depression (LTD) (Palmer et al. 2005; Fig. 1). Hippocalcin binds directly to the β2-adaptin subunit of the AP2 adaptor complex, which couples clathrin to the cytosolic domains of membrane-bound proteins destined to be internalized. In hippocampal neurons, this hippocalcin-AP2 complex bound only to the GluR1 subunit of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type ▶ glutamate receptor. The calcium-dependent endocytosis of the AMPA receptor is a key event in N-methyl-D-aspartate (NMDA) receptor-dependent LTD. Expression of a mutated hippocalcin lacking all EF-hand structures in CA1 pyramidal neurons blocked synaptically evoked LTD without affecting basal AMPA receptor-mediated transmission or long-term potentiation (LTP). In addition, hippocalcin is the key intermediate between calcium influx in response to a train of action potentials and potassium channel activation, which mediates the slow after-hyperpolarization current (IsAHP) in hippocampal neurons (Tzingounis et al. 2007; Fig. 1). Brief depolarizations, which are sufficient to activate IsAHP in wild-type mice, did not elicit IsAHP in hippocalcin$^{-/-}$ mice. Introduction of hippocalcin into cultured rat hippocampal neurons led to a pronounced IsAHP, while neurons expressing a mutant hippocalcin lacking N-terminal myristoylation exhibited a small IsAHP similar to that recorded in uninfected neurons, confirming that hippocalcin gates the potassium channel that mediates IsAHP. These results demonstrate the involvement of hippocalcin in activity-dependent plasticity and memory formation.

Protection Against Neuronal Damage

Hippocalcin has been shown to have neuroprotective effects in several studies (see Fig. 2). Hippocalcin interacts with the neuronal apoptosis inhibitory protein (NAIP). Overexpression of hippocalcin alone did not substantially enhance cell survival, but co-expression of both hippocalcin and NAIP synergistically facilitates neuronal survival against calcium-induced cell death stimuli, such as ionomycin and thapsigargin. The interaction between hippocalcin and NAIP rescues neuroblastoma cells from calcium-induced cell death, but no significant effect on neuronal death induced by nerve

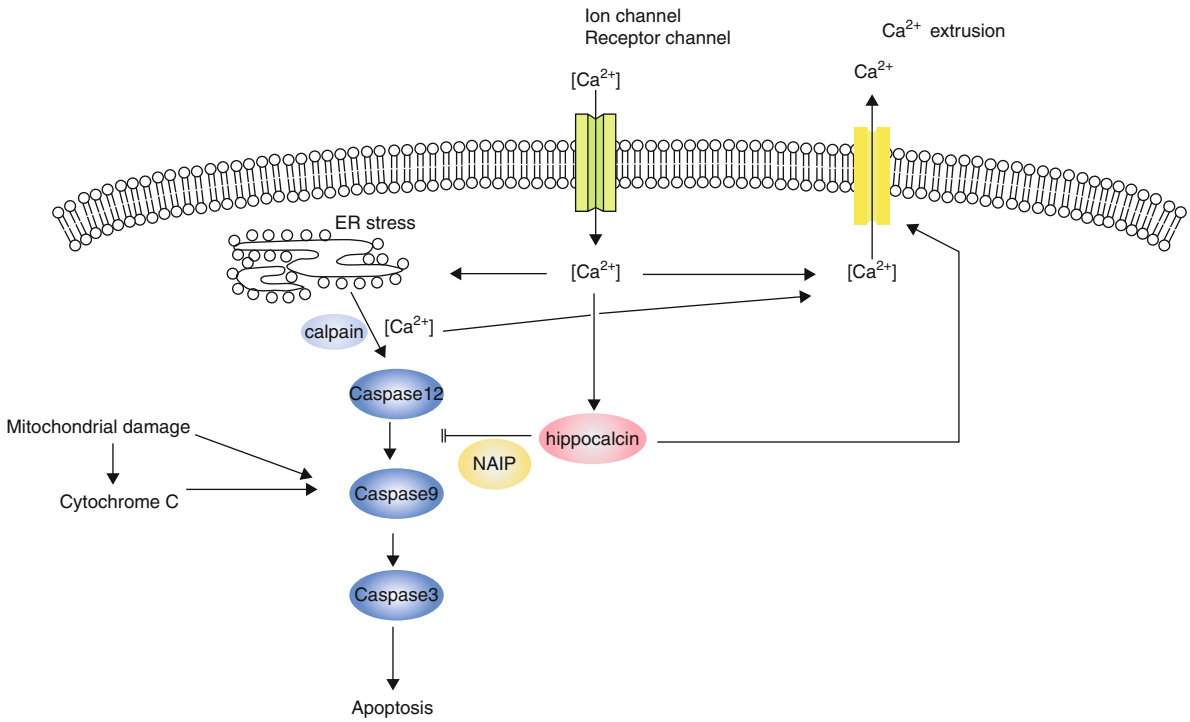
growth factor (NGF) withdrawal has been observed in sympathetic neurons (Lindholm et al. 2002). In hippocalcin$^{-/-}$ mice, systemic injection of kainic acid results in an increase in seizure-induced neuronal cell death in the CA3 field of Ammon's horn accompanied by increased caspase-3 activation (Korhonen et al. 2005). Injection of quinolinic acid, an NMDA receptor agonist, into the hippocampal CA1 region of hippocalcin$^{-/-}$ mice caused high levels of cell death in CA1 neurons (Masuo et al. 2007). Cultured hippocalcin$^{-/-}$ hippocampal neurons exhibited reduced levels of survival under basal culture conditions accompanied by an increase in caspase 12 activation, which can be caused by increased endoplasmic reticulum (ER) stress (Korhonen et al. 2005). A decrease in the survival rate of hippocalcin$^{-/-}$ hippocampal neurons was also observed independently, in a study in which the measurement of intracellular calcium in single cells revealed that calcium extrusion from hippocalcin$^{-/-}$ neurons was slower than that from wild-type neurons (Masuo et al. 2007). The involvement of hippocalcin in the upregulation of calcium extrusion was confirmed using hippocalcin-expressing COS7 cells. Thus, hippocalcin protects hippocampal neurons against various types of calcium-induced cell damage by interacting with NAIP, diminishing ER stress, and upregulating calcium extrusion (Fig. 2).

Regulation of Cyclic Nucleotide Signaling

Hippocalcin has been shown to modulate ▶ adenylyl cyclase and ▶ guanylyl cyclase activities in the olfactory epithelium where cilia of mature olfactory receptor neurons reside (see Fig. 3). In the olfactory cilia, odorant-induced activation of adenylyl cyclase and

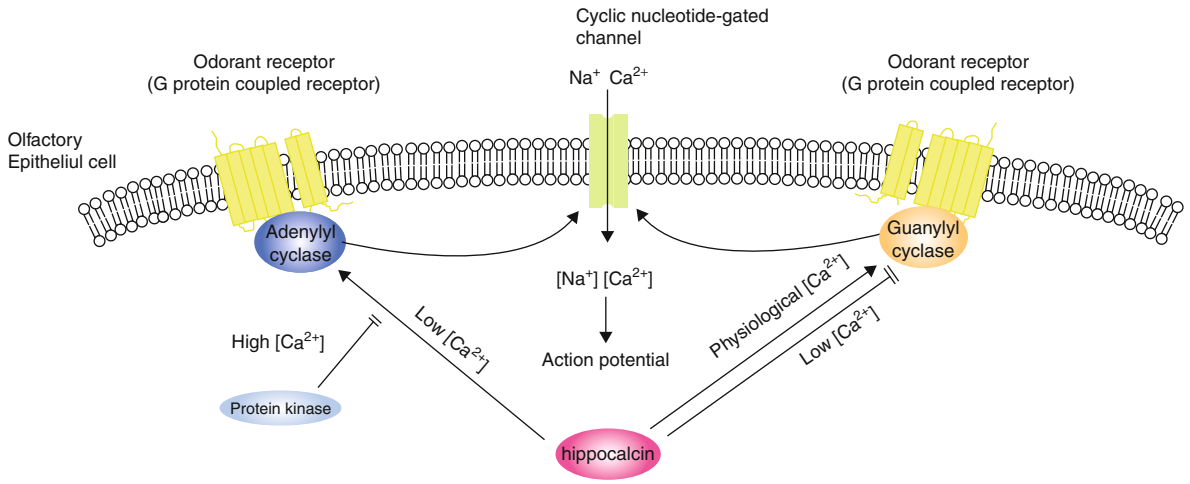


Hippocalcin, Fig. 2 Involvement of hippocalcin in the neuronal apoptosis induction pathway. *NAIP* = neuronal apoptosis inhibitory protein; *ER* = endoplasmic reticulum

guanylyl cyclase results in generation of cAMP and cGMP, respectively. As the levels of cyclic nucleotides increase, olfactory cyclic nucleotide-gated channels open to allow an influx of sodium and calcium ions, leading to the generation of an action potential. Hippocalcin increased adenylyl cyclase activity in olfactory cilia at low calcium levels and decreased adenylyl cyclase activity at high calcium levels in reconstitution system (Mammen et al. 2004). At low calcium levels, protein kinase treatment of cilia inhibited the effect of hippocalcin on adenylyl cyclase activity, whereas untreated cilia or protein phosphatase-treated cilia showed increases in hippocalcin-mediated adenylyl cyclase activity. At high calcium levels, only protein phosphatase-treated cilia showed significant increases in hippocalcin-mediated adenylyl cyclase activity. Calcium influx by odorant stimulation induces phosphorylation of adenylyl cyclase, which may reduce adenylyl cyclase activity and be involved in the mechanisms of odorant adaptation. In contrast to the effect on adenylyl cyclase, hippocalcin significantly inhibited the activity of particulate guanylyl cyclase activity within a limited range of free calcium concentrations (1–10 nM) (Mammen et al. 2004). The inhibitory effect of hippocalcin on guanylyl cyclase activity decreased as calcium levels increased. At physiological levels of calcium, hippocalcin increased guanylyl cyclase activity with an EC_{50} of 0.5 μM calcium (Krishnan et al. 2009). Studies using hippocalcin$^{-/-}$ mice demonstrated the involvement of hippocalcin in the total guanylyl cyclase-mediated signal transduction pathways to be approximately 30% (Krishnan et al. 2009). Thus, hippocalcin may be involved in the fine-tuning of stimulus detection and odor adaptation mediated by cyclic nucleotide signaling in the olfactory epithelium.

Involvement in Other MAP Kinase Cascade Signaling Pathway

Hippocalcin is involved in the mitogen-activated protein kinase (MAP kinase) pathway, including downstream gene expression (Braunewell and Klein-Szanto 2009; Kobayashi and Takamatsu 2009). In a yeast two-hybrid screen, hippocalcin was identified as a possible interacting partner of ▶ mixed-lineage kinase (MLK) 2 and MLK3 (Nagata et al. 1998; Kobayashi et al.



Hippocalcin, Fig. 3 Involvement of hippocalcin in cyclic nucleotide signaling pathways in the olfactory epithelium. *G protein* = guanine nucleotide-binding protein

unpublished data). MLKs are closely related to the MAP kinase kinase kinase (MAPKKK) family. MLK2 and MLK3 interact with the small GTPases Rac and Cdc42. MLK2 and MLK3 also interact with motor proteins of the kinesin superfamily and co-localize with the microtubule cytoskeleton, suggesting that they are involved in the regulation of cytoskeletal dynamics. MLK2 and MLK3 activate c-Jun N-terminal kinase (JNK), ERK, and p38 MAPK. The interaction of hippocalcin with MLKs is not calcium-dependent and has no influence on the kinase activity of MLKs in resting hippocalcin-transfected cells (Nagata et al. 1998). A recent report shows that hippocalcin and MLK2 are colocalized in the halo surrounding Lewy bodies in patients with Parkinson's disease (PD) (Nagao and Hayashi 2009). The fact suggests the association of both proteins with pathogenesis in PD; however, the molecular basis has not yet been determined.

Summary

Hippocalcin, a member of the NCS (neuronal calcium sensor) protein family, which is predominantly expressed in the hippocampus, is a highly conserved protein that has an identical amino acid sequence in rat, mouse, bovine, and human. Hippocalcin has three functional EF-hand calcium-binding domains and its N-terminal glycine residue is myristoylated. Hippocalcin is regulated by a calcium myristoyl switch mechanism within cells, allowing it to translocate from the cytosol to intracellular membranes of the trans-Golgi network and to the plasma membrane in response to an increase in free calcium. Hippocalcin is involved in the activity-dependent activation of the MAP kinase pathway via of ERK signaling and activation of CREB, key gene expression events mediating the long lasting synaptic plasticity underlying learning and memory. Spatial and associative learning abilities in hippocalcin-null mutant (hippocalcin$^{-/-}$) mice are impaired, as determined by the probe test, Morris water maze, and visual discrimination learning tasks. Hippocalcin is implicated in hippocampal NMDA receptor-dependent LTD via binding the β2-adaptin subunit of the AP2 adaptor complex, which mediates internalization of the GluR1 subunit of AMPA receptor. The slow after-hyperpolarization current (IsAHP), which is activated by brief depolarizations, was not elicited in hippocalcin$^{-/-}$ hippocampal neurons. This observation indicates that hippocalcin mediates potassium channel activation in response to calcium influx. Hippocalcin exhibits a protective effect against calcium-induced cell death by interacting with NAIP, diminishing ER stress, and upregulating calcium extrusion. Hippocalcin is also expressed in olfactory receptor neurons and has been found to regulate the activities of ciliary adenylyl cyclase and particulate guanylyl cyclase in a calcium-dependent manner. Thus, hippocalcin may act as a multifunctional modulator in calcium signaling pathways, such as those underlying neuronal plasticity, neuronal excitability, neuronal cell death, and olfaction.

Historical Background

AUF1, or hnRNP D (heterogeneous nuclear ribonucleoprotein D), was one of the first *trans*-acting factors identified that binds AU-rich elements (AREs) within the 3′ UTR (UTR – untranslated region) of many labile mRNAs (Brewer 1991). The importance of AREs in promoting rapid RNA turnover has been well characterized (Guhaniyogi and Brewer 2001). A mechanism was still under investigation when AUF1 was discovered. AUF1 as an ARE-binding protein (AUBP) was first identified in specific fractions of cytosol separated by sucrose gradient fractionation (Brewer 1991). Electrophoretic mobility shift assays (EMSAs) of these fractions revealed 37 and 40 kDa (kD) polypeptides that specifically bound ARE-containing *c-*►*myc* mRNA. Cell-free decay assays confirmed *c-myc* mRNA degradation occurred within the same fractions that included the ARE-binding activity. The aforementioned polypeptides, now referred to as p37 and p40, were reproducibly purified from the post-ribosomal, 130,000 × g supernatant, S130, by poly-U agarose chromatography. These polypeptides could cross-link in specific fashion to radiolabeled ARE-containing RNA substrates, including *c-fos* and GM-CSF 3′UTRs, with the same efficiency seen in the EMSAs (Brewer 1991). Cross-linking could be abolished by mutating the ARE sequence.

An antibody was generated from the poly-U agarose eluate and affinity-purified (Zhang et al. 1993). It detected p37 and p40, as well as a 45-kD polypeptide. Determination of their subcellular localization by cell fractionation and Western blot showed that p37 and p40 were present in both the nucleus and cytoplasm, while p45 was present exclusively in nuclear fractions, thereby explaining why it wasn't detected initially in the cytosolic S130 fractions.

Screening of a HeLa cDNA expression library with the affinity-purified p40 antibody allowed molecular cloning of p37, which was named AUF1 (ARE/poly (U)-binding/degradation factor 1) and later designated hnRNP D (Zhang et al. 1993; Wagner et al. 1998). Sequence analysis indicated that p37 was an RNA-binding protein distinct from hnRNP A, B, or C. Additional cDNA cloning and sequencing of genomic clones revealed that alternative splicing of the AUF1 pre-mRNA accounted for p37, p40, and p45, as well as a fourth isoform, p42 (Wagner et al. 1998).

Binding of purified AUF1 to AREs in vitro correlated with rapid decay of the transcript (DeMaria and Brewer 1996). Many short-lived cytokine mRNAs contain one or more AREs in their 3′UTR, generally consisting of repeats of overlapping AUUUA pentamers embedded within U-rich sequence (Guhaniyogi and Brewer 2001). EMSAs with cytoplasmic lysates of monocytes revealed that AUF1 bound to the ARE-containing GROα and IL-1β chemokine/cytokine mRNAs as part of a multi-subunit complex (Sirenko et al. 1997). In human monocytes, these mRNAs remain very labile until the receipt of various extracellular stimuli, whereupon the bound AUF1 and associated protein complex changes in composition, followed by transcript stabilization.

The above studies, as well as others not included in this discussion for purposes of brevity, indicate an important role for AUF1 in regulating immune responses, as many ARE-containing cytokine mRNAs undergo rapid decay until extracellular signaling pathways indicate a need for their transient stabilization. During this window of short-term stability, cytokines are produced in much greater quantities until they are down-regulated again by rapid mRNA decay. Knockdown of AUF1 in mice adversely affects survival, as the mice are unable to suppress overproduction of proinflammatory cytokines (Lu et al. 2006a). The levels of cytokine transcripts, including TNFα and IL-1β, remain constitutively high; as such, the mice die of severe endotoxic shock due to the runaway effects of cytokine production.

Characterization of AUF1 Protein Structure and Function

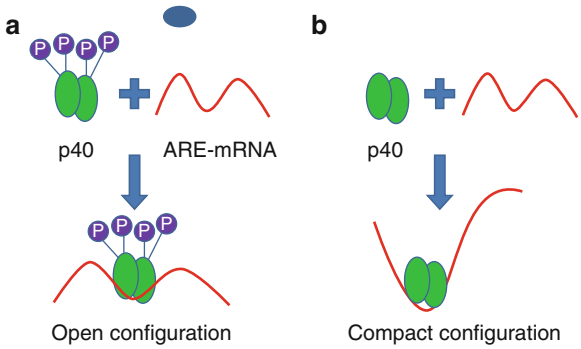
AUF1 Genomic Organization

The hnRNP D/AUF1 gene maps to human chromosome locus 4q21 and encodes four different isoforms by differential splicing of the pre-mRNA; a pseudogene lies on the X chromosome (Wagner et al. 1998; Dempsey et al. 1998). The isoforms differ in their molecular weights due to the inclusion or exclusion of specific exons in their respective mRNAs. All isoforms include a pair of RNA recognition motifs (RRMs) and a glutamine-rich region required for RNA binding and protein–protein interactions, respectively. A peptide sequence required for AUF1 dimerization in the absence of RNA is encoded by exon 1, present in all isoforms. The p40 and p45 isoforms contain an additional 19-amino acid insert encoded by exon 2 that in p40 can be phosphorylated in vitro by glycogen synthase kinase-3β and protein kinase A (Wilson et al. 2003a). The p42 and p45 isoforms have an additional 49-amino acid insert encoded by exon 7 toward the C-terminal end of the proteins, which in p45, confers protection from ubiquitination and subsequent degradation (Laroia and Schneider 2002).

Properties of AUF1 Isoforms

Differential splicing of exons 2 and 7 confers selective subcellular localization and ARE-binding affinities on the AUF1 isoforms (Zhang et al. 1993; Wagner et al. 1998). P37 and p40 are primarily found in the cytoplasm, while p42 and p45 are primarily nuclear. In terms of RNA-binding, the p37 isoform has the highest affinity for AREs, while p40 has the lowest. P42 has an affinity only slightly lower than p37, while the ARE-affinity of p45, though much lower than p37, is still much higher than p40. Altogether, the four isoforms exhibit an approximate 35-fold range of ARE-binding affinities (Wagner et al. 1998). The two isoforms with the highest binding affinity do not contain the exon 2-encoded amino acids.

The N-terminal exon 2 insert contains a pair of serines that can be reversibly phosphorylated on p40 – Ser 83 and Ser 87 (Wilson et al. 2003a,b). In vivo, the phosphates on the two serines are lost upon activation of various cell signaling pathways, correlating with an increase in ARE-mRNA stability, paralleled by changes in mRNA-protein structure (Fig. 1). In vitro studies indicate that p40 can bind to an ARE substrate as both a dimer and a tetramer (Wilson et al. 2003a). When p40 is phosphorylated, the bound RNA is held in an extended conformation versus a more compact configuration generated by the binding of unphosphorylated p40. In vivo, the extended conformation may allow easier access to the ARE by components of the cellular degradation machinery, subsequently accelerating mRNA decay.



hnRNP D (AUF1), Fig. 1 Phosphorylation of p40 induces changes in AUF1-mRNA conformation and accelerates ARE-mRNA decay. For simplicity, p40 is depicted as a dimer in the absence of other RNA-binding proteins. (**a**) When Ser 83 and Ser 87 are phosphorylated, the mRNA is held in an open conformation relative to the (**b**) more compact configuration generated by unphosphorylated bound AUF1. Note: AUF1 can also bind as tetramers to AREs in vitro. Phosphorylated p40 and an open mRNP conformation correlate with increased ARE-mRNA decay

AUF1 Can Compete with PABP in Binding to Polyadenylated Sequences

AUF1 cannot only promote mRNA decay via ARE binding, but may also function in dissociating PABP (poly-A binding protein) from transcript tails, depriving the mRNA of its 3′-end protection, and allowing digestion by deadenylases and exosomal proteins. Like PABP, AUF1 can also bind polyadenylated sequences. Affinity chromatography of Hela cytoplasmic lysates using poly(A) resin showed that the AUF1 isoforms could specifically bind the poly(A) sequence and not the control poly(C) resin (Sagliocco et al. 2006). This binding was not due to mRNA tethering, nor the amount of PABP present. Further analysis indicated endogenous AUF1 bound the poly(A) resin independently and non-consecutively of PABP, since PABP knockdown had no effect on the amount of AUF1 bound to the resin (Sagliocco et al. 2006).

In vitro, all recombinant AUF1 isoforms can associate cooperatively and sequentially in oligomeric fashion on an RNA substrate containing a poly(A) sequence 100 nucleotides long (Sagliocco et al. 2006). The presence or absence of an ARE in the substrate sequence does not affect the poly(A) binding affinity of AUF1. However, the presence of AUF1 can displace PABP on the poly (A) substrate via competitive binding in these EMSAs. Increasing AUF1 concentration reduced PABP-poly(A) complexes on the RNA substrate in a dose-dependent manner. Simultaneously, AUF1-poly(A) complexes increased. The above data indicating AUF1-PABP competition for the poly(A) tail is an additional step in regulating mRNA decay/stability.

ARE-mRNA Decay Mediated by AUF1 Is Linked to Translation Initiation Factors

AUF1 not only binds proteins at the 3′ end of the transcript like PABP, but also components of the translation initiation complex located at the 5′ end, hinting that translation also plays a role in ARE-mediated decay. Specifically, eIF4G can bind all AUF1 isoforms strongly in vitro, in the presence or absence of an ARE (Lu et al. 2006b), with p37 having the strongest affinity. Further experiments performed with truncation mutants of p37 (His-tagged) and a GST-tagged fragment of eIF4G in GST pulldown assays identified a 45-amino acid domain within the C-terminus of AUF1 necessary for eIF4G binding.

Besides binding to poly(A) sequences (see above), AUF1 can also directly bind to PABP itself in vitro (Lu et al. 2006b). The interaction can be abrogated by adding an RNA consisting of the TNFα ARE to the reaction, and to a lesser extent, by adding Hsp70, whose induction in vivo can stabilize mRNAs. In fact, AUF1 cannot interact with the ARE and PABP simultaneously in an in vitro assay. Interestingly, p37 and PABP can bind concurrently to eIF4G in the absence of an ARE. If an ARE is present, p37 detaches from PABP, leaving behind a stronger binding interaction between PABP and eIF4G. The dynamic AUF1-eIF4G-PABP complex implicates AUF1 in linking rapid mRNA decay to translation.

AUF1 Can Promote Translation of ARE-Containing mRNAs

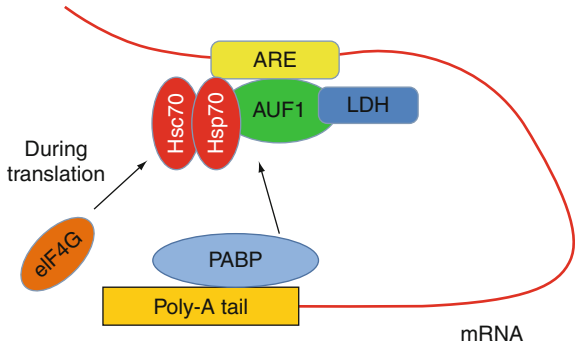
Posttranscriptional regulation of gene expression by AUF1 is not limited to accelerating mRNA decay. It can alternatively promote translation of ARE-mRNAs. For example, knocking down AUF1 expression does not affect *MYC* mRNA levels but rather reduces ▶ MYC protein levels at least threefold (Liao et al. 2007). By contrast, overexpression of the individual AUF1 isoforms, or all in combination, increases MYC protein levels by threefold or greater. As well, the presence of *MYC* mRNA on polyribosomes increases significantly upon overexpression of AUF1. Further analysis showed that the increase in *MYC* translation is dependent on the ARE. Together, these observations indicated roles for AUF1 in translational control.

The mechanism by which AUF1 promotes translation likely involves competitive binding with translational repressor/s. For example, TIAR knockdown increases *MYC* protein levels as well as the amount of AUF1 binding to the mRNA. Likewise, AUF1 knockdown increases the amount of TIAR protein bound to the transcript, resulting in reduced *MYC* translation. This reciprocal competition is ARE-dependent. However, the increase in MYC protein levels by TIAR knockdown is reversed by knocking down AUF1 simultaneously, with no effect on mRNA levels, suggesting that AUF1 can promote *MYC* translation directly and not solely by blocking TIAR binding.

AUF1 Binds to AREs as Part of a Multi-subunit Complex

AUF1 binds to ARE-containing mRNAs as part of a multi-subunit complex. As heat shock stabilizes ARE-mRNAs, it should not be surprising that AUF1 forms complexes with heat shock proteins Hsc70, Hsp70, and Hsp27 on polysomal mRNA (Laroia et al. 1999; Sinsimer et al. 2008). Hsp70 binding to AUF1 is concomitant with accumulation of stabilized ARE-mRNAs. Also, since heat shock downregulates the ubiquitin-proteosome pathway, which is necessary for AUF1-mediated mRNA decay, it is likely that ubiquitination and proteolysis of AUF1 itself is required for rapid mRNA degradation.

Other subunits of the ARE-bound protein complex include eIF4G and PABP (poly-A binding protein), which function in translation (Laroia et al. 1999). More recently, lactate dehydrogenase was identified as a protein that directly interacts with AUF1, though the significance is unclear (Pioli et al. 2002). The translation factor eIF4G is largely dissociated from the complex until heat-shock reduces its dissociation; this is accompanied by ARE-mRNA stabilization. The cross talk among subunits of the AUF1-containing



hnRNP D (AUF1), Fig. 2 Model for the regulation of ARE-mRNA decay by AUF1 and several known associating proteins. Hsp70/Hsc70, lactate dehydrogenase (LDH), PABP, and eIF4G are complexed with AUF1 to regulate ARE-mRNA decay. Some subunits may remain dissociated from the complex until needed for increased translation. eIF4G and PABP may promote a circular mRNP complex necessary for translational activation

complex of proteins and between proteins of various signaling pathways are still being elucidated, but it is apparent that ARE-mRNA decay is regulated by a complex process that is often AUF1-dependent and is affected by the rearrangements and posttranslational modifications of the ARE-bound protein complex.

Summary

AUF1 is a *trans*-acting factor that binds AU-rich elements within the 3′ UTRs of labile mRNAs. There are four isoforms generated by alternative pre-mRNA splicing: p37, p40, p42, and p45. They differ in their subcellular localizations and RNA-binding affinities, suggesting that each isoform has its own subset of target transcripts. AUF1 is needed to promote decay of many ARE-containing transcripts, not just encoding cytokines, but those encoding oncoproteins and anti-apoptotic factors as well (Lapucci et al. 2002). It does so as part of a multi-subunit, ARE-bound complex (Fig. 2). Its binding partners include Hsp70, Hsc70, Hsp27, eIF4G, PABP, lactate dehydrogenase, and other unidentified proteins. The AUF1-containing complex can also compete with RNA-binding proteins such as TIAR to control ARE-mRNA translation (Liao et al. 2007). AUF1-mediated mRNA decay is a complex process that is affected by heat shock, the ubiquitin-proteosome pathway, and posttranslational modification and/or subunit rearrangement of AUF1 and its associated proteins.

Cupidin; Vesl

Historical Background

Vesl/Homer proteins are a family of scaffolding molecules, encoded by three genes (Homer1, Homer2, and Homer3) that are abundantly expressed in a variety of tissues, including the brain, retina, cardiac muscle, skeletal muscle, smooth muscle, liver, kidneys, spleen, testis, thymus, placenta, and intestine. Their primary function is to cluster proteins and modulate their activity. Despite their system-wide expression, Homer proteins are best characterized in the brain and the central nervous system, where their primary role is to cluster and modulate the function of synaptic proteins.

Molecular Determinants of Vesl/Homer Proteins

In mammals, Vesl/Homer proteins are encoded by three genes, Homer1, Homer2, and Homer3 that give rise to at least 22 splice variants. Homer1a and Ania-3 are short isoforms encoded by the Homer1 gene (Sgambato-Faure et al. 2006; Duncan et al. 2005). Both splice variants were originally identified after induction of their expression levels following excitatory synaptic activity, including induced convulsive seizures, long-term potentiation, and ischemic injury. Interestingly, compared to other immediate early genes (IEGs) that typically encode transcription factors, Homer1a and Ania-3 are synaptic proteins that can directly modulate protein–protein interactions (Sgambato-Faure et al. 2006; Duncan et al. 2005).

Other, typically long Homer isoforms are constitutively expressed and likely fulfill different functions compared with the short IEG isoforms of Homer1 (Duncan et al. 2005).

Homer proteins contain various conserved protein/protein interaction sites. Isoforms both short and long possess an Ena/vasodilator-stimulated phosphoprotein homology-1 (EVH1) domain within the first 110 N-terminal amino acids. The EVH1 domain is evolutionarily conserved and mediates the binding of Homer to its interaction partner. Through the EVH1 domain, Homer binds receptors and channel proteins such as the metabotropic ▶ glutamate receptor (mGluR), the inositol triphosphate (IP_3R), the ▶ ryanodine receptors (RyR), and transient receptor potential canonical channels (TRPCs). Other targets of Homer include GTPases, anchoring proteins such as shank, as well as transcription factors, including nuclear factor of activated T cells (NFAT). Furthermore, the Homer EVH1 domain shares the RX_5GLGF domain found in PDZ proteins (PSD/Disks/ZO-1 [epithelial tight junction protein]), which is thought to ensure correct targeting of ion channels.

All long Homer isoforms also share a C-terminal coiled-coil (CC) domain containing two leucine zipper motifs, which mediate the multimerization between Homer monomers. It is thought that long Homer isoforms form tetrameric structures with their CC domains aligned in parallel, exposing four EVH1 domains for ligand binding (Hayashi et al. 2006).

Expression and Localization of Homer Isoforms

Homer proteins are present in many different tissues, both excitable and non-excitable. In the brain, Homer isoforms are expressed abundantly and at similar levels in cortex, hippocampus, and cerebellum. All isoforms are particularly highly expressed in cerebellar Purkinje cells. Similarly, all Homer proteins have been detected

in skeletal and smooth muscle as well as heart. In non-excitable tissues, Homer protein expression has been reported for kidney, intestine, lung, spleen, liver, thymus, ovary, and testis. The expression of Homer isoforms has been reviewed in detail by Duncan et al. (2005).

Localization studies have shown that all Homer isoforms co-localize with their binding partner Group I mGluRs in the postsynaptic density of excitatory synapses in the brain (as reviewed in Duncan et al. (2005)). Specifically, Homer proteins are predominantly localized to the soma and apical dendrites. Subcellular fractionation studies have detected all Homer isoforms in the crude nuclear pellet, synaptosomal pellet, microsomal pellet, and PSD fraction. The additional presence of Homer2a/b in the soluble and synaptic vesicle fractions suggest a role for Homer 2 in receptor trafficking.

Following ischemic injury to the retina, Homer-1c was identified as an early marker for subtle changes prior to more severe neurodegenerative events (Kaja et al. 2003).

Binding Partners of Homer Proteins

Homer proteins interact with a variety of synaptic proteins. Particularly, the interaction of Homer proteins with calcium channels and neurotransmitter receptors both at the plasma membrane and at the endoplasmic reticulum (ER) has recently attracted interest due to the possible involvement of these interactions in age-related diseases of the nervous system.

Inositol-1,4,5-trisphosphate receptors (IP_3Rs) are intracellular ER channels of which activation results in calcium release from the ER lumen to the cytosol. Homer 1 proteins directly interact with the C-terminus of the IP_3R and decrease calcium flux through the channel (Duncan et al. 2005). Interaction with Homer-1c potentiates IP_3R activation (Tanaka et al. 2006), resulting in a decrease in dendritic branching (Duncan et al. 2005; Tanaka et al. 2006). The short isoform of Homer-1a has been shown to antagonize this direct interaction, resulting in reduced IP_3R activity and a concomitant increase in dendritic branching (Duncan et al. 2005; Tanaka et al. 2006).

Similarly to IP_3Rs, ▶ ryanodine receptors (RyRs) are large endoplasmic channels that extrude calcium from the ER lumen into the cytosol. Sequence analysis of RyRs has shown a number of EVH1 binding domains and a direct interaction between Homer and RyR has been experimentally verified (reviewed in Pouliquin and Dulhunty (2009)). Binding of Homer proteins to the RyR provides for a physical tethering of the RyR to the cytoskeleton, and for RyR crosstalk with plasma membrane proteins (Duncan et al. 2005; Pouliquin and Dulhunty 2009). However, the direct effects of Homer proteins on calcium release through the RyR are subject to controversy and speculation (Duncan et al. 2005; Pouliquin and Dulhunty 2009; Westhoff et al. 2003; Hwang et al. 2003).

Group 1 metabotropic glutamate receptors (mGluRs) are plasma membrane neurotransmitter receptors, which when activated initiate a pathway resulting in calcium release through the IP_3R. Homer proteins have been found to traffic Group 1 mGluRs to the plasma membrane of neurons (Duncan et al. 2005). mGluR binding of long Homer isoforms (specifically Homer-1b and Homer-1c) creates a ready pool of mGluRs on the ER membrane. Upregulation of Homer-1a displaces the long Homer isoforms and facilitates the trafficking of mGluR to the plasma membrane (Duncan et al. 2005; Kammermeier 2008). Competition between long and short Homer isoforms hence serves as a cellular mechanism of regulating neuronal excitability in response to stress and/or injury. Recent data furthermore indicates that Homer proteins facilitate the cross talk between mGluRs and *N*-methyl-D-aspartic acid NMDA receptors (Bertaso et al. 2010), corroborating the modulatory role of Homer in excitatory glutamate signaling.

Transient receptor potential canonical (TRPC) channels are plasma membrane, nonspecific cation channels. Interestingly, TRPC channels have the requisite EVH1 sites at both the N- and C-termini to facilitate the cooperative binding of Homer proteins. Binding of the long Homer isoform inhibits the TRPC channel, where the short isoform has the opposite effect (Duncan et al. 2005). An upregulation of Homer-1a in response to depletion of ER calcium stores thus provides a mechanism for activation TRPC channels and subsequent store refilling (Duncan et al. 2005; Rychkov and Barritt 2007). Binding of Homer to polycystin-1 has implications for regulation of intracellular calcium signaling in a number of cell types and organs and has been reported for the central nervous system (Stokely et al. 2006).

As discussed previously, Homer proteins interact and link plasma membrane receptors/channels to

intracellular ER channels at neuronal synapses. In addition, Homer proteins also interact with a variety of other proteins that facilitate and/or modulate synaptic function.

The *Dynamins* form part of a superfamily of proteins that participate in membrane trafficking events following localization to cytoplasmic and membrane compartments (Reems et al. 2008). Homer-1 and Homer-2 proteins bind to Dynamin III through their EVH1 domain, whereas the physical link between Dynamin III and Homer has been reported to be involved with positioning the endocytic zone to near the PSD (Duncan et al. 2005; Lu et al. 2007). As Dynamin III also interacts with mGluR5, Homer proteins have been suggested to play a role in recruiting Dynamin III to mGluR5 at the PSD (Duncan et al. 2005).

Shank is a scaffolding protein to which Homer can bind through the EVH1 domain and C-terminal leucine zipper motifs (Duncan et al. 2005). Crystallographic analysis of the postsynaptic density revealed that Homer together with Shank binds to form a mesh-like matrix structure, where the Homer–Shank complex may provide structural support to neuronal dendritic spines and provide an assembly stage for other PSD proteins (Hayashi et al. 2009). Overexpression of Homer-1c in hippocampal neurons resulted in the synaptic localization of Shank being reduced and actin being increased (Duncan et al. 2005). Additionally, depolymerization of actin reduced synaptic localization of both Homer-1c and Shank, suggesting Homer-1c to be involved in the accumulation of synaptic F-actin (Duncan et al. 2005).

Cupidin, or Homer-2, interacts with actin cytoskeletal regulators, Cdc42 and Drebrin, in dendritic spines (Shiraishi-Yamaguchi et al. 2009). The interaction between Cupidin and activated Cdc42 has been suggested to possess a possible role in the formation of mushroom-type spines in hippocampal neurons (Shiraishi-Yamaguchi et al. 2009). Drebrin is a dendritic spine F-actin binding protein and interacts with Cupidin via the N-terminal EVH1 domain (Shiraishi-Yamaguchi et al. 2009). These interactions suggest that Cupidin may play an important role in spine morphology by scaffolding multiple dendritic spine actin regulators (Shiraishi-Yamaguchi et al. 2009).

Huntington interacting protein (Hip1) and *Hip1 protein interactor (Hippi)* form complexes and activate caspcase-8 which leads to mammalian cell death during Huntington's Disease (Sakamoto et al. 2007). Homer-1c has been shown to protect striatal neurons from hippi-hip1 induced cell death. A mutant form of Homer-1c lacking the C-terminal region failed to protect the neurons from cell death or bind to Hippi, suggesting that a direct interaction between the Homer-1c C-terminal region and Hippi is required to induce protection and concluding that a Homer-1c/Hippi complex may be an important regulator for neuronal death during Huntigton's Disease (Sakamoto et al. 2007).

Soluble N-ethyl-maleimide-sensitive attachment protein receptor (SNARE) syntaxin 13 can bind with Homer-1c, which may participate in endosomal trafficking as co-expression in COS-7 cells results in the co-localization of Homer-1c and syntaxin 13 in intracellular vesicular structures (Duncan et al. 2005).

General Mechanism

Synaptic functions of Homer proteins are to a large extent regulated by the interplay of the short Homer-1a isoform and the various long Homer proteins. Homer-1a regulates long isoforms in a dominant-negative fashion by competing with the long isoforms for Homer binding sites on Homer ligands, demonstrating the potential involvement of the inducible short Homer isoforms in the regulation of intracellular signaling and trafficking processes controlled by ubiquitously expressed long Homer isoforms. Furthermore, the general mechanism of short and long Homer proteins suggests a general stimulus-dependent mechanism using the molecular determinants of Vesl/Homer proteins to regulate intracellular signaling pathways (Duncan et al. 2005).

Summary

Homer proteins are a family of scaffolding molecules, encoded by three genes: Homer1, Homer2, and Homer3. Two short Homer1 isoforms are known (Homer1a and Ania-3) that act as IEGs and are upregulated in response to seizures, LTP, and ischemic insult; in contrast, all long Homer isoforms are constitutively expressed. The long Homer isoforms are abundantly expressed in brain, muscle, and various non-excitable tissues. Homer proteins possess an

EVH1 domain for ligand binding and interaction, and a CC domain providing for tetramerization of multiple Homer proteins into scaffolding complexes. Homer proteins physically link plasma membrane proteins (such as group I mGluRs) with intracelluar Ca^{2+} channels (such as the ▶ IP_3Rs and RyRs), and hence are critically modulating synaptic activity. The short IEG Homer1 transcripts lack a CC domain and are thought to competitively disturb this physical interaction in a response to increased synaptic activity as experienced during LTP or following seizure activity or ischemic insult (Sgambato-Faure et al. 2006; Duncan et al. 2005).

Homer proteins are important modulators of synaptic activity. However, their role in disease and in non-excitable tissues requires further investigation and could critically contribute to protective mechanisms (Duncan et al. 2010).

Acknowledgments This study was supported in part by grants EY014227 from NIH/NEI, RR022570 from NIH/NCRR and AG010485, AG022550 and AG027956 from NIH/NIA, by the Felix and Carmen Sabates Missouri Endowed Chair in Vision Research (PK). We thank Margaret, Richard, and Sara Koulen for generous support and encouragement.

HPK1

Sebastian Königsberger and Friedemann Kiefer
Department Vascular Cell Biology, Max Planck Institute for Molecular Biomedicine, Mammalian Cell Signaling Laboratory, Münster, Germany

Synonyms

Hematopoietic progenitor kinase 1; Map4k1; Mitogen-activated protein kinase kinase kinase kinase 1

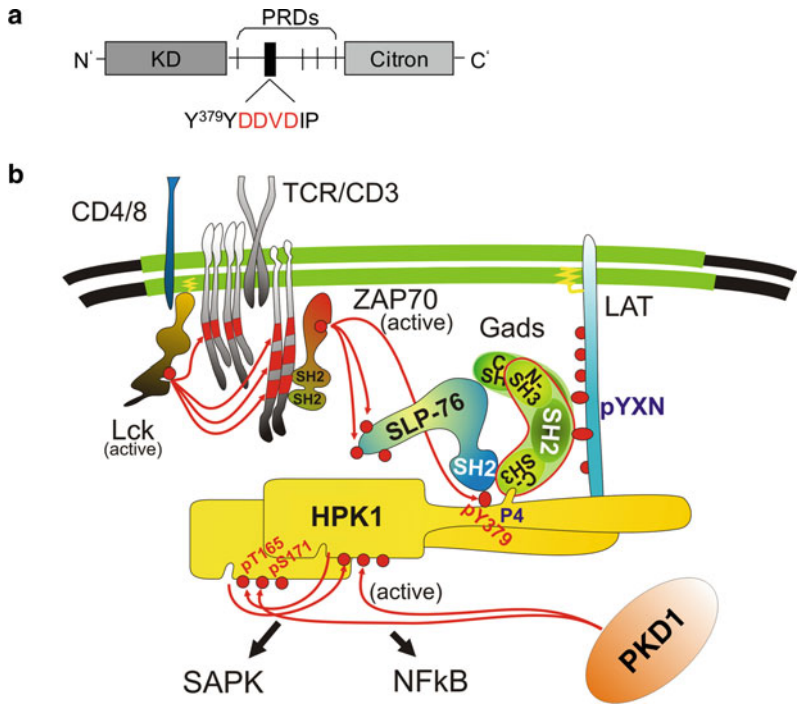
Historical Background

Since 1996, when hematopoietic progenitor kinase 1 (HPK1) was first described as an activator of the stress-activated protein kinase/c-Jun N-terminal kinase (SAPK/JNK) pathway (Kiefer et al. 1996), a range of information concerning activation, subcellular localization, putative interaction partners, and the regulatory function of HPK1 in immune cells was gathered. The initial studies showed that while HPK1 mRNA is ubiquitously detectable in embryonic tissues, expression in the adult is restricted to hematopoietic organs like thymus, bone marrow, and spleen. Protein database sequence comparison classified HPK1 as a member of the Ste20-related protein kinase family and is most closely related to the germinal center kinase (GCK), a MAP4 kinase. The structure of HPK1 comprises an N-terminal kinase domain, a central region containing proline-rich (SH3-binding) motifs and at least one tyrosine residue that serves as phosphorylation target, and a C-terminal citron homology domain of yet undefined function (Ling et al. 1999). In addition, a central caspase cleavage site alters effector properties during apoptosis induction (Arnold et al. 2001) as will be discussed in more detail in the following sections.

HPK1 Activation and Molecular Interactions

HPK1 was shown to be activated following genotoxic stress (Ito et al. 2001); growth factor stimulation via TGFβ (Zhou et al. 1999), EGF, PDGF (Ling et al. 1999), and erythropoietin (Nagata et al. 1999); prostaglanding E_2 stimulation (Sawasdikosol et al. 2003, 2007); and antigen receptor triggering (Liou et al. 2000; Liu et al. 2000; Sauer et al. 2001; Tsuji et al. 2001). In the case of BCR/TCR stimulation, HPK1 phosphorylation at Tyr^{379} in mice and Tyr^{381} in humans seems the prerequisite for further activational steps (Sauer et al. 2001; Tsuji et al. 2001). The upstream factors involved are Lck, ▶ Zap-70, ▶ LAT, and ▶ SLP-76 in T cells and Lyn, Syk, and SLP-65 in B cells (Liou et al. 2000). In addition, a detailed study by Arnold et al. revealed that Thr^{165}, Ser^{171}, and Thr^{175} located in the activation loop of the kinase are of critical importance for the optimal activation of HPK1 upon TCR stimulation (Fig. 1b). Accordingly, Lck and SLP-76 relocate HPK1 from the cytoplasm to the plasma membrane, where it follows transphosphorylation by protein kinase D1 and subsequent autophosphorylation reaches full activity. Interestingly, this study also demonstrated the recruitment of HPK1 to the interface of T-/B-cell conjugates, indicating a function at the level of immune synapse associated signaling.

To ensure proper activation, subcellular localization, and functionality, HPK1 constitutively or inducibly interacts with a range of adaptors and signaling molecules. Table 1 provides a list of reported interaction partners, the cell types in which the interaction was observed and, if determined, the HPK1-binding region responsible for the interaction. Grb2 and Grap together with Gads belong to the Grb2 family of adaptor proteins containing a SH2 domain flanked by two SH3 domains. The constitutive association of HPK1 with Gads (Grap2) was shown to be required for the synergistic activation of c-Jun and IL-2 transcription in COS-7/Jurkat T cells, whereas the binding to Grb2 in Cos1 cells was reported to link HPK1 to the EGF receptor. The finding that Grb2 family members locate HPK1 to the transmembrane adaptor LAT, led early on to the speculation that HPK1 might antagonize the recruitment of SLAP-130/▶ ADAP/Fyb, a positive regulator of IL-2 and NFAT activity. The constitutive association of HPK1 with the upstream adaptors Crk/CrkL in Jurkat T cells mediated by the proline-rich (PR) domain 2,4 – SH3 interaction was suggested to ensure synergistic activation of JNK and optimal IL-2 transcription (Ling et al. 1999; Oehrl et al. 1998). Crk family adaptor proteins are involved in a range of cell signaling pathways, including antigen receptor stimulation, integrin signaling, cell migration, and focal adhesion signal transduction, thus suggesting that HPK1 could be involved in the spatial bridging of antigen receptor signaling and integrin regulation. As already stated above, $Tyr^{379/381}$ phosphorylation of HPK1 is prerequisite for the binding to the central B- and T-cell adaptors SLP-76/65. Upon phosphorylation by Syk family protein tyrosine kinases (Syk/Zap-70), SLP76 family adaptors act as membrane proximal scaffolds enabling the coordinated activation of downstream pathways. As abrogated binding of HPK1 to mutated SLP-adaptors does not completely abolish its negative regulatory role on Erk, AP-1, and NFAT (Sauer et al. 2001), the synchronous recruitment to other adaptor molecules like Crk, Grb2, and also Nck family members might generate a complex pattern



HPK1, Fig. 1 Schematic HPK1 protein structure and inducible recruitment to the T-cell antigen receptor membrane-signaling scaffold. (**a**) The modular build of HPK1 contains an N-terminal kinase domain, a central region with proline-rich motifs involved in SH3 domain binding and several interspersed tyrosine residues, as well as a C-terminal citron homology domain. Phosphorylation of tyrosine 379 (Y^{379}) in mice is a mandatory initial step for the recruitment of HPK1 to SLP-76/65 adaptor molecules in T- and B cells; DDVD indicates the target sequence for caspase-mediated cleavage. (**b**) Upon T-cell receptor triggering, Zap-70-mediated phosphorylation of Y^{379} parallels HPK1 translocation to the membrane, auto (T165)- and transphosphorylation (S171) by PKD1, complex formation with SLP-76, LAT, and Gads, and the initiation of downstream signaling; *Gads* (Grap2), Grb2-related adaptor protein 2, *KD* kinase domain, *LAT* linker for activation of T cells, *Lck* lymphocyte-specific protein tyrosine kinase, *NFκB* nuclear factor "kappa light chain enhancer" of activated B cells; *PKD1* protein kinase D1, *PRDs* proline-rich domains, *SH3* Src-homology 3, *SLP-76/65* SH2 domain containing leukocyte protein of 76/65 kDa, *TCR* T-cell receptor, *Zap-70* zeta-chain-associated protein kinase 70 kDa

of regulation that still awaits complete resolution. As a matter of fact, HPK1 binds to the SLP-76 family adaptor Clnk with significantly higher affinity as compared to SLP-76 itself (Yu et al. 2001). Clnk can substitute for SLP-76 in immunoreceptor signaling and together with HPK1 acts synergistically on IL-2 promoter activity (Yu et al. 2001).

Abp1 (SH3P7, HIP55), a broadly expressed adaptor protein in human and mouse tissues binds HPK1 at the PR2 motif (Ensenat et al. 1999). As a member of the drebrin/Abp1 family of actin-binding proteins, Abp1 was shown to be recruited to the IS in activated T cells, where it promotes TCR downmodulation and negatively affects NFAT activation (Le Bras et al. 2004). Bam32 (DAPP1, PHISH) is an additional adaptor molecule binding to HPK1 in B cells, possibly via its N-terminal SH2 domain. It was found to be required for Rac1 activation, proper Ca^{2+} mobilization, and optimal PLCγ2 activation. Accordingly, $Bam32^{-/-}$ B cells exhibit defects in ERK, JNK, and HPK1 activity. Bam32 was also shown to colocalize with the BCR complex and clathrin to regulate BCR uptake and actin dynamics. Despite being a target for Bam32-mediated JNK activation, the relevance of HPK1 in the regulation of antigen receptor internalization and actin dynamics was not investigated so far. An interesting observation in this context was the finding by Nagata et al. that HPK1 constitutively binds to HS1, a well-established actin-regulatory protein (Uruno et al. 2003), in FD-EPO and SKT6 cells, although the functional significance of this interaction in vivo awaits further investigation. In addition to the binding of the above-mentioned adaptor molecules, HPK1 activates IKKß (Hu et al. 1999; Arnold et al. 2001) and,

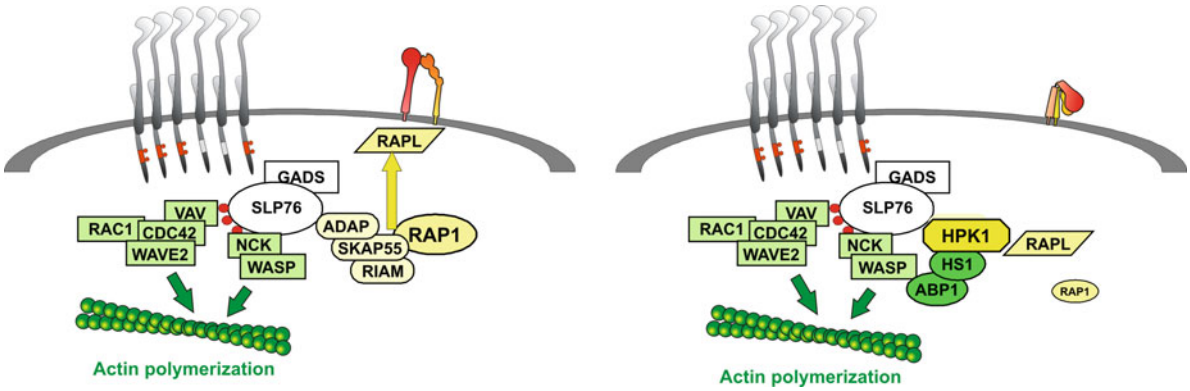
as recognized recently, phosphorylates CARMA1 (Brenner et al. 2009), which further establishes the function of the protein in NFκB regulation and apoptosis induction.

Functions in Cellular Activation and Apoptosis Induction

Already in early studies, HPK1 was shown to selectively activate the SAPK/JNK cascade via MEKK1 (Hu et al. 1996)/MLK-3 (Kiefer et al. 1996) phosphorylation, a process independent of Rac1 or Cdc42 GTPase function, which were known to feed into the SAPK/JNK pathway via PAK activation (Coso et al. 1995). Epistasis analysis established that HPK1 acts on MAP3 kinases (MEKK1, MLK-3) which in turn signal through MAP2 kinases (e.g., MKK4/7, MKK3/6) to the c-Jun N-terminal kinase (Tibbles et al. 1996; Ensenat et al. 1999; Liou et al. 2000). Besides this well-accepted function in triggering the SAPK/JNK pathway upon environmental stress, a growing list of publications shows that HPK1 is fundamentally involved in antigen receptor signaling processes.

An elegant study from di Bartolo et al. in 2007 focusing on negative regulatory components of proximal TCR signaling revealed a novel function of HPK1 in limiting/fine-tuning antigen receptor–mediated cellular activation. By phosphorylating SLP-76 at Ser^{376}, HPK1 enables the recruitment of 14-3-3 ε and ζ proteins, which limits PLCγ1 phosphorylation and IL-2 promoter activity. HPK1 was also shown to control proximal TCR signaling by limiting Vav, Lat, and PLCγ1 activation and promoting the interaction of SLP-76 with the 14-3-3 protein family member 14-3-3τ. The finding that $HPK1^{-/-}$ BMDCs show higher levels of activation markers and proinflammatory cytokines upon LPS stimulation makes them more potent in eliciting cytotoxic T-cell-mediated antitumor responses (Alzabin et al. 2010) and adds to the general view of HPK1 as a negative regulator of immunity and inflammation.

NFκB is a pleiotropic transcription factor regulating a range of genes relevant in immune and inflammatory responses. NFκB transcription factors are kept inactive in the cytoplasm by interaction with inhibitory IκB proteins. Antigen receptor stimulation triggers the activation of an IκB kinase (IKK) complex comprised of



HPK1, Fig. 2 Competition of HPK1 and ADAP for SLP-76 binding in lymphocyte inside-out integrin signaling. *Left*: Pro-adhesive interaction of the ADAP/SKAP55/RIAM module with SLP-76 leads to affinity (depicted)/avidity upregulation of β2 integrins via Rap1 recruitment and binding of the Rap1 effector RapL to the α integrin cytoplasmic tail. *Right*: HPK1 binding to SLP-76 limits integrin activation by sequestering the ADAP trimolecular complex and downstream signaling mediators; concomitant regulation of actin polymerization through the WAVE2 complex and WASP is indicated; *Cdc42* cell division cycle 42, GTP-binding protein, *Nck* noncatalytic region of tyrosine kinase adaptor protein 1, *Rac1* Ras-related C3 botulinum toxin substrate 1, *WASP* The Wiskott-Aldrich Syndrome protein, *Wave2* verprolin homology domain-containing protein 2

IKKα, β, and γ. Phosphorylation of IκB results in the cytoplasmic sequestration of IκB proteins and targeting for proteasomal degradation, while NFkB transcription factors are liberated to enter the nucleus and activate transcription. Full-length HPK1 facilitates NFκB activation in hematopoietic cell lines and primary murine $CD4^+$ T cells, while caspase-mediated cleavage at Asp^{385} within the DDVD cleavage site converts the C-terminal fragment of HPK1 into an NFκB inhibitor (Arnold et al. 2001; Schulze-Luehrmann et al. 2002). The N-terminal HPK-1 fragment, which is largely comprised of the kinase domain retains the ability to activate JNK, but is unable to bind adaptor proteins, which altogether enhances peripheral T-cell sensitivity to activation-induced cell death (AICD) (Brenner et al. 2005). This was further corroborated by a study of Brenner et al. in 2007 addressing AICD sensitivity in HPK1-C transgenic mice. In this model system, primary T- and B cells, constitutively expressing HPK1-C, were prone to CD95L-independent AICD, intimately caused by caspase-3/9 activity. In addition, HPK1 interacts with and phosphorylates the IKK-activating adaptor protein CARMA1 (caspase-recruitment domain [CARD]-containing signaling adaptor protein) at Ser^{551} upon TCR stimulation, which is a prerequisite for HPK1-dependent NFκB activation and IL-2 production (Brenner et al. 2009). Of note, HPK1 is also a target of caspase-3 during monocytic differentiation. In this context, the HPK1-N fragment confers IL-3 independent survival of mouse myeloid FDC-P1 progenitor cells and induces differentiation toward the monocytic lineage (Arnold et al. 2007). This, in contrast to the situation in lymphocytes, results in constitutive cytokine-independent signaling and prolonged cellular survival.

HPK1 as a Negative Regulator of Inside-Out Integrin Regulation

Integrins are heterodimeric cell-surface receptors mediating cell-cell and cell-extracellular matrix interactions (ECMs). Being composed of one α- and one β-subunit, integrins build up a family of at least 24 members in mammals, within which LFA-1 (lymphocyte function-associated antigen 1; $\alpha_L\beta_2$), VLA-4 (very late antigen 4; $\alpha_4\beta_1$), and $\alpha_4\beta_7$-integrins are particularly important for leukocyte function by binding cellular adhesion molecules such as ICAM-1/2, VCAM-1, MADCAM1, and the ECM component fibronectin. In the resting, low-affinity conformation, integrins are bent at the stalk region which sterically masks the ligand-binding headpiece. Upon inside-out activation through chemokines/antigen receptors and enhanced by outside-in triggering, integrins undergo a process of avidity regulation, including intracellular and extracellular conformational changes toward an open structure as well as valency changes facilitated by oligomerization.

Two recent studies by (Patzak et al. 2010) and Königsberger et al. indicated that HPK1 has a negative regulatory role in inside-out integrin activation. In addition to the hyperproliferative nature of HPK1$^{-/-}$ lymphocytes upon antigen receptor–mediated stimulation, these studies show that B and T cells lacking HPK1 exhibit a stronger basal adhesion to ICAM-1, most likely explained by an increase in the amount of the signaling active GTP-bound small GTPase Rap1 (Ras-related protein 1). Upon recruitment to SLP-76, a trimolecular complex containing ADAP (adhesion- and degranulation-promoting adaptor protein)/SKAP55 (Src kinase−associated phosphoprotein of 55 kDa)/RIAM (Rap1-GTP interacting adaptor molecule) binds the small GTPase Rap1 and thus facilitates integrin activation in T cells (Kliche et al. 2006; Menasche et al. 2007). Interestingly, HPK1 competes with ADAP for SLP-76 binding as HPK1$^{-/-}$ T cells show more SLP-76 pre-associated ADAP (Fig. 2) and this lack of ADAP localization leads to an increase in T-cell adhesion and spreading on ICAM-1. This finding adds another interesting feature to the portfolio of HPK1 functions in immune cells and opens a new field of investigation on the proteins' relevance in pathological settings of altered leukocyte adhesiveness like, for example, the involvement in the development of atherosclerosis.

Summary

Hematopoietic progenitor kinase 1 (HPK1) is a mammalian Ste20 homologue predominantly expressed in hematopoietic tissues of the adult. The protein is a specific activator of the SAPK/JNK pathway acting at the level of a MAP4 kinase and is therefore also referred to as MAP4K1. In leukocytes, HPK1 is activated by the canonical immunoreceptor signaling complexes. HPK1 interacts constitutively with SH3-containing adaptor proteins and is recruited to activated immunoreceptors upon tyrosine phosphorylation and interaction with SH2-containing adaptor proteins. In addition to the activation of the SAPK/JNK pathway, full-length HPK1 mediates T-cell receptor-proximal NF-κB activation by phosphorylating the adaptor protein CARMA1. Upon lymphocyte activation and during differentiation of monocytes, HPK1 is proteolytically processed toward a catalytic N-terminal fragment and an inhibitory C-terminal fragment (HPK1-C). This processing changes effector functions and converts HPK1 into a suppressor of NF-κB activation, which leads to sensitization of lymphocytes toward cell death. More recent insights suggest a negative regulatory function of HPK1 in lymphocyte integrin activation and hence make the kinase an interesting candidate to study in leukocyte adhesive processes.

Historical Background

Isoprenylcysteine carboxyl methyltransferase (Icmt) is the only known prenylcysteine protein-dependant methyltransferase and plays a critical role in the post-translational modification of prenylated proteins (Bergo et al. 2000). The Icmt ortholog from *Saccharomyces cerevisiae*, STE14p, was the first prenylcysteine carboxyl methyltransferase to be cloned and sequenced, and it is considered the founding member of this eukaryote protein methyltransferase family (Anderson et al. 2005). STE14p was originally recognized in a screen of mutant yeast, deficient of STE14, which rendered the yeast sterile due to their failure to methylate the mating pheromone a-factor, a protein crucial for fertility. STE14p is a 26 kDa integral membrane protein with multiple transmembrane (TM) spanning domains and is localized to the endoplasmic reticulum (ER) (Romano and Michaelis 2001). Human Icmt cDNA possess notable homology to STE14, and upon its expression in STE14-deficient yeast, the sterile phenotype is reversed (Svensson et al. 2006). Icmt orthologs such as *Schizosaccharomyces pombe* (mam4p), and *Xenopus laevis* (Xmam4p), also exhibit considerable amino acid homology with STE14p, and behave as functionally complimentary prenylcysteine carboxyl methyltransferases (Wright et al. 2009). STE14p and its orthologs lack significant amino acid conservation to other nucleotide, DNA, or protein methyltransferases, including the absence of the commonly observed consensus S-adenosylmethionine (SAM or AdoMet) binding motifs (Wright et al. 2009). The novelty and specificity of its biologic role and its unique evolutionary conservation, along with the Icmt knockout mouse being embryonic lethal, suggest that the function of Icmt is critical (Bergo et al. 2001).

CaaX/CXC Processing

Posttranslational modification of eukaryotic polypeptides is critical for proper function and localization of mature proteins. Many of these proteins are modified by a three step enzymatic process which is dictated by the succession of amino acids at the C-terminus. These proteins, termed CaaX proteins, contain a specialized carboxyl-terminal amino acid sequence that orchestrates modification of nascent proteins. Icmt is responsible for the final and only potentially reversible enzymatic step in CaaX protein processing, which involves methylation of the carboxylic acid of the

S. Choi (ed.), *Encyclopedia of Signalling Molecules*, DOI 10.1007/978-1-4419-0461-4,

protein terminal isoprenylated cysteine residue. Ras, and other critical signaling proteins, including Rho GTPases, undergo this posttranslational modification via the CaaX motif (Anderson et al. 2005).

The CaaX sequence is represented by a cysteine, followed by two residues that are typically aliphatic (aa), and finally an amino acid which dictates which of two prenyl groups will be covalently attached to the cysteine in the motif by the enzymes ▶ protein farnesyltransferase (FTase) and protein geranylgeranyltransferase type I (GGTase-I). Note there is a second class of prenylated proteins, the Rab CXC proteins, which include a CXC or CC sequence motif. CXC proteins are prenylated by protein geranylgeranyltransferase type II (GGTase-II). Icmt is capable of identifying substrates from both classes of proteins (Anderson et al. 2005). Despite the substrate prenylation specificity of the two CaaX prenyl transferases, it has been documented that alternate utilization of protein substrates does occur (Wright et al. 2009).

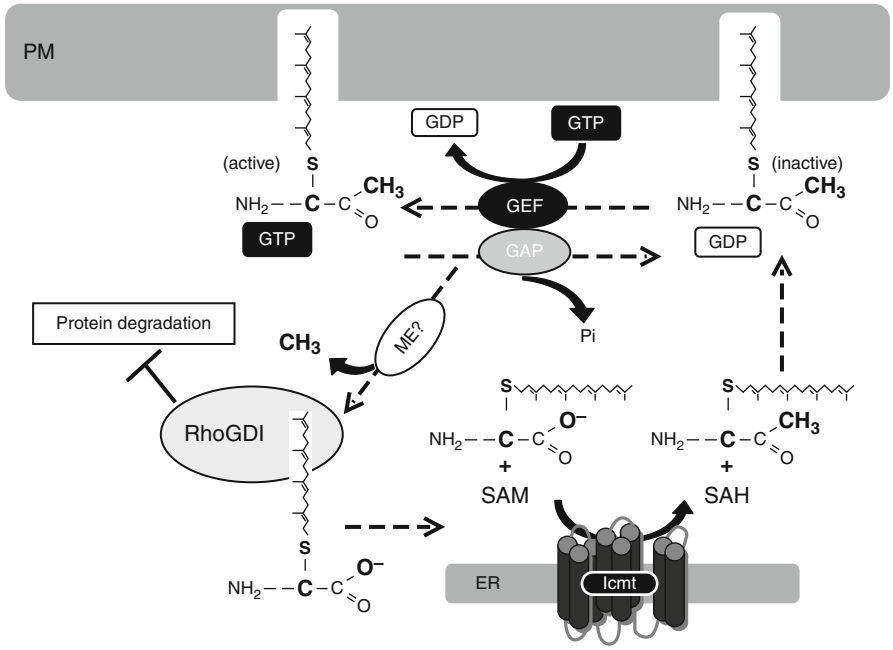
Following prenylation, the second step of CaaX protein modification involves Ras-converting enzyme I (RceI). This ER integral membrane protease cleaves the terminal three -aaX amino acid residues of the CaaX motif rendering the prenylated cysteine residue the new carboxy-terminus. Upon cleavage by RceI, CaaX proteins are specifically methylated on the alpha carboxyl group of the prenylated cysteine by Icmt. Methylation removes the negative charge from the carboxylic acid of the prenylated cysteine, and is therefore the final crucial step to modify proteins in order to increase their hydrophobicity, by leaving the protein with a terminal isoprenylcysteine methyl ester residue. The major observed effect of the isoprene lipid and methylation of the CaaX protein is a high degree of association with cell membranes.

CaaX modification is not only critical in participating in protein-membrane association, but also in protein–protein interactions as seen with Rho GDP-dissociation inhibitor (RhoGDI). RhoGDI regulates isoprenylated Rho GTPase activity and localization by its ability to avert Rho protein–membrane association via seizure of the hydrophobic carboxy-terminus portion of Rho GTPases (Cushman and Casey 2010). RhoGDI acts as an escort protein shuttling these Rho proteins in a guanine diphosphate (GDP) bound inactive state by as well as eliminating interaction with guanine exchange factors (GEFs) (Fig. 1). Rho GEFs stimulate nucleotide exchange and have decreased affinity to unmethylated Rho proteins (Papaharalambus et al. 2005). Icmt is the only potentially reversible step in the CaaX pathway, and therefore may play an important regulatory role for Rho family GTPases, such as Rac1 (Papaharalambus et al. 2005; Huizinga et al. 2008). Studies show an increase in binding of RhoGDI to the Rho GTPases, RhoA and Rac1, when Icmt is inhibited (Harrington et al. 2004; Michaelson et al. 2005). Recent evidence has provided a potential role for RhoGDI in seclusion of Rho GTPases from protein degradation pathways (Boulter et al. 2010).

Structure, Interactions, and Regulation

Icmt differs from other methyltransferases due to its unique ability to selectively bind and methylate prenylated and proteolysed CaaX proteins. Icmt also appears to be the sole enzyme responsible for methylesterification of the Rab CXC proteins (Bergo et al. 2000). Icmt is restricted to the ER, and hydropathy based topology predictions from sequence studies show STE14p likely navigates through the ER membrane with six TM segments (Wright et al. 2009). Functional evidence suggests STE14p is active as a homodimer and may even be able to further oligomerize, and the enzyme contains a GXXGXXG motif that is responsible for dimerization of several other TM proteins (Griggs et al. 2010). The human Icmt protein contains an additional N-terminal domain predicted to contain two additional TM segments for a total of eight TM segments (Wright et al. 2009). The evolution of this additional sequence grants consideration that Icmt has acquired a unique regulatory role in mammals (Wright et al. 2009).

Based on the well-characterized substrates of Icmt (farnesyl-, and geranylgeranylcysteine), synthetic prenylcysteine analogs were designed to act as efficient Icmt substrates and as classical competitive inhibitors. Establishment of an ordered sequential kinetic mechanism determined that Icmt binds first to the methyl donor SAM (Km $\sim$2μM) followed by the binding of a CaaX protein, thereby allowing methylation to occur (Baron and Casey 2004). The Icmt-catalyzed reaction leaves a newly methylated protein and S-adenosylhomocysteine (SAH or AdoHcy).



Icmt (Isoprenylcysteine Carboxyl Methyltransferase), Fig. 1 Proposed regulation of Rho GTPases by Icmt-catalyzed methylation and nucleotide dependent interactions. Depicted are the potential modified states of GTPases due to methyl, nucleotide, and RhoGDI cycling. RhoGDI functions as an escort protein by extracting unmethylated inactive GDP bound GTPases from the plasma membrane and sequestering GTPases in the cytosol away from GEFs and the protein degradation pathways. Guanine Exchange Factor (GEF): GTPase Activating Protein (GAP): Plasma Membrane (PM): Endoplasmic Reticulum (ER): Methyl Esterase (ME): Inorganic phosphate (Pi)

Currently, Icmt activity regulation appears to be mostly substrate availability dependent. The active guanine triphosphate (GTP) bound state of guanine nucleotide binding CaaX proteins, compared to the inactive GDP bound state, displays a characteristic increase in methylation proficiency (Kowluru et al. 1996). Despite apparent constitutive expression and activation in most cell types, there is evidence indicating Icmt is responsible for increased methylation of CaaX proteins as a consequence of particular ligands in specific cell types and that its expression can be regulated. Icmt is responsible for the methylation of a large number of Ras family GTPases and a variety of non-Ras signaling proteins such as the nuclear lamins, heterotrimeric G-protein gamma subunits, the prostacyclin and prostaglandin E2 receptors, and some phosphatases and kinases (Reid et al. 2004). Certain disease states such as Parkinson's disease, or physiologic conditions resulting from pharmacological treatment as seen with antifolate drugs like the dihydrofolate reductase inhibitor methotrexate, can elevate the Icmt reaction end product SAH (Winter-Vann et al. 2003). Like with many enzymes and their end products, SAH inhibits Icmt leading to cellular apoptosis and provides a partial mechanism for the therapeutic effects of drugs like methotrexate in cancer, arthritis, and psoriasis (Winter-Vann et al. 2003). Evidence supports a mechanistic role of Icmt in neuroblastoma differentiation due to a decrease in the methylation of key proteins induced by retinoic acid (Van Dessel et al. 2002). Detectable increase in methylation of CaaX and CXC proteins is observed in such cases as Cdc42 upon glucose treatment and Rap1 upon potassium treatment in beta cells (Kowluru et al. 1996).

Expression and Phenotype

Icmt is ubiquitously expressed but displays enhanced expression in testes, liver, and brain tissues, with expression of up to three splice variants being possible (Bergo et al. 2001). An alteration of Icmt expression has only been observed during mouse development, where detectable mRNA levels are observed by

postnatal day 11 and increase to reach a maximum expression by week four. The inactivation of one Icmt allele produces no apparent phenotype, whereas the deletion of Icmt locus in mice by homologous recombination results in embryonic lethality (Bergo et al. 2001). Icmt-deficient mice embryos die from anemia and cellular apoptosis at mid-gestation by day 11.5 with the primary afflicted tissue being testes, brain, and liver, with additional disruption of skeletal muscle development (Bergo et al. 2001).

Therapeutic Target

Mutations of the Ras proto-oncogene are frequent aberrancies observed in human cancer, and consequently, Ras proteins are the most studied CaaX protein. (Split the difference?) Icmt is critical for the proper plasma membrane targeting of H-, N-, and K-Ras, and localization is essential for their correct function. Icmt-deficient cells exhibit mislocation and cytoplasmic accumulation of Ras proteins (Michaelson et al. 2005). The demonstration of a reduction in K-Ras methylation being linked to slowed cell growth and attenuation of oncogenic transformation has lead to the consideration of Icmt inhibition as an attractive therapeutic target. Given the important role of oncogenic Ras protein in human tumorigenesis, it has been hypothesized that the inhibition of Icmt could be an efficacious strategy to block Ras-induced oncogenic transformation. A large effort has been undertaken in targeting FTase in CaaX processing, leading to the development of highly selective and potent FTase inhibitors, but these compounds were found to lack clinical efficacy. Icmt has been the favored alternate target due to the in-ability of Ras to promote transformation if it is unmethylated, irrespective if prenylation and proteolysis occurs (Svensson et al. 2006). Attempts to prevent Ras-induced cellular transformation by inhibiting Icmt with substrate analogs displayed limitations, due to collateral inhibition of other isoprenylated proteins and/or other methyltransferases. The necessity for a specific pharmacologic agent against Icmt led to the identification of cysmethynil, an Icmt specific inhibitor that has no observable effects on Icmt-deficient cells (Winter-Vann et al. 2005; Svensson et al. 2006). Icmt inhibition by cysmethynil results in decreased cell proliferation, and a reduction in Ras-induced oncogenic transformation (Svensson et al. 2006). Studies show the treatment of cysmethynil on human colon cancer cells results in the mislocation of Ras, a decline in anchorage-independent growth, and a reduction in the response to treatment with epidermal growth factor (EGF) (Winter-Vann et al. 2005; Svensson et al. 2006). The effects of cysmethynil are reversible upon rescue by over-expression of Icmt. Recently, evidence suggests a role for Icmt in cellular migration by impacting the function of Rho GTPases through methylation (Fig. 1). Many Rho GTPases are involved in cell migration by synchronizing changes in actin cytoskeleton from external stimuli, and therefore have implications in metastasis in oncogenic states. Cysmethynil inhibits migration in a highly metastatic breast cancer cell line, MDA-MB-231, with RhoA and Rac1 activity significantly diminished (Cushman and Casey 2009). This decrease in activity is attributed to the aforementioned observed increase in RhoGDI binding affinity to Rac and Rho; however, over-expression of Rho GTPases rescues cell migration repressed by inhibition of Icmt. The culmination of these data supports Icmt as a promising target in cancers commonly afflicted with aberrancies associated with prenylated proteins.

Summary

Icmt is a posttranslational modifying enzyme that specifically methylates prenylated proteins. Further evaluation of its structure and oligomerization state is critical for more in depth analyses of its mechanistic properties and function. Additional domain within human Icmt is still not understood despite suggestions it may play a regulatory role. The unique biologic function of methylation raises the question about the existence and regulation of a potential prenylcysteine dependant methylesterase. Addition of dynamic methylation/demethylation into RhoGDI cycling model will further characterize the impact of Icmt induced methylation in cell signaling and protein degradation. Regardless of the future outcome of Icmt inhibition as an effective cancer treatment, investigation of Icmt-catalyzed methylation of prenylated proteins is pivotal for a complete understanding of the consequences it plays in protein interactions.

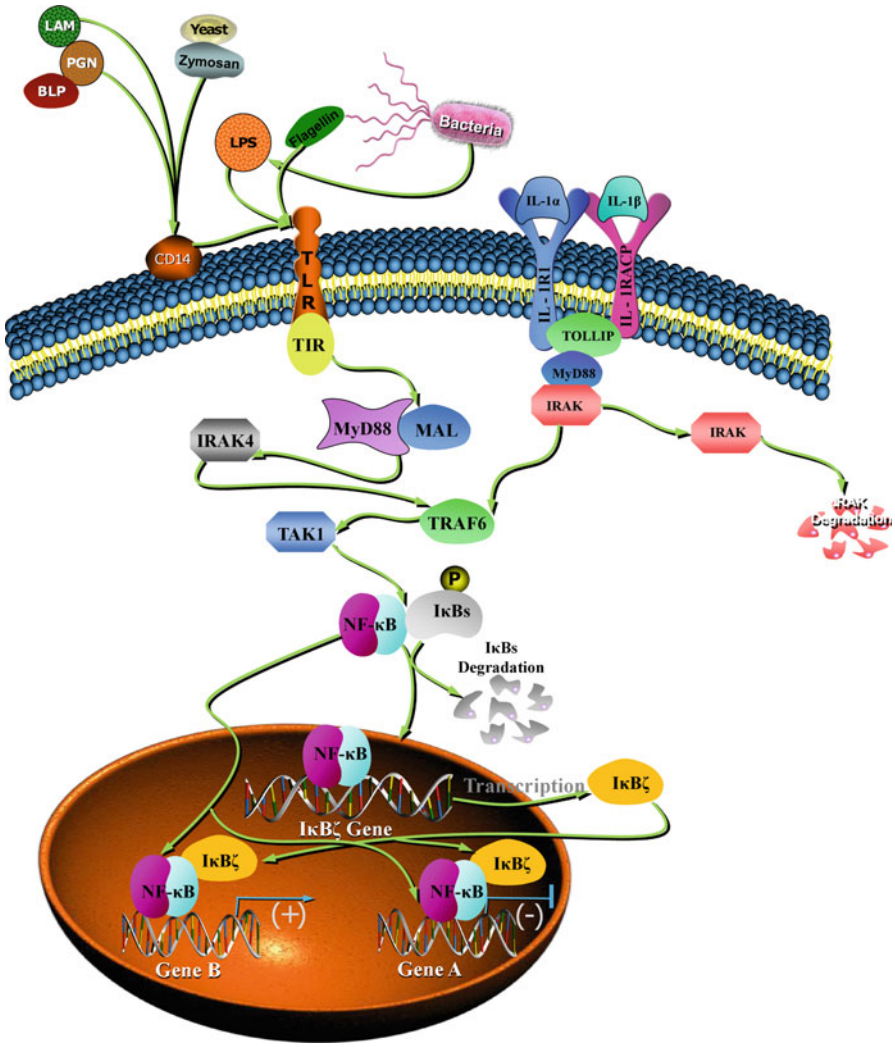
Historical Background

IκBζ, which is also known as molecule possessing ankyrin repeats induced by lipopolysaccharide (MAIL) or interleukin (IL)-1 inducible nuclear ankyrin-repeat protein (INAP), was discovered independently in three laboratories during 2000 and 2001 as a protein containing ankyrin repeats. The gene encodes a protein with an amino-terminal region nearly 450 amino acids in length of unknown structure that contains a nuclear localization signal (NLS) and a transactivation domain (TAD) followed by the seven recognizable ankyrin repeats at its carboxyl terminal. Treatment of cells with lipopolysaccharides (LPS) or the cytokine interleukin (IL)-1 (Haruta et al. 2001; Kitamura et al. 2000; Yamazaki et al. 2001) induced the expression of IκBζ, whereas tumor necrosis factor (TNF)-α (Totzke et al. 2006) treated cells did not show any IκBζ expression. The induced IκBζ is localized in the nucleus, where it interacts with the nuclear factor (NF)-κB subunit and other nuclear proteins via their ankyrin repeat domain (ARD), leading to a positive or negative regulation of its transcriptional activity depending on genes (Muta 2006). Thus, the innate immune system utilizes NF-κB as a major transcription factor and modulates its activity in a gene-specific manner via the regulatory factor IκBζ, which is specifically induced upon stimulation of the innate immune system. This multistep regulation of the transcriptions would be fundamental in the selective expression of genes upon cell activation. In this chapter, we summarize recent findings in nuclear IκBζ with an emphasis on its immunological aspects.

Induction of IκBζ and Its Functions

Many cellular responses are mediated by orchestrated gene expression. When cells are exposed to diverse inflammatory stimuli, such as microbial components, a large number of genes are induced to elicit inflammatory responses. These genes include cytokine/chemokine, antimicrobial peptides, and cell adhesion molecules, many of which are known to be induced through activation of transcription factor NF-κB (Akira and Takeda 2004; Hayden and Ghosh 2008; Hoffmann and Baltimore 2006). In resting cells, typical cytoplasmic IκB proteins (IκB-α, -β and -ε) mask the NLS of NF-κB, thereby preventing its translocation into the nucleus. The activation of cells with appropriate stimuli, particularly toll-like receptor (TLR) ligands or various host immune mediators such as proinflammatory cytokines and IL-1 superfamily proteins, induces activation of IκB kinase complex, which leads to the degradation of the cytoplasmic IκBs by the ubiquitin-proteosomal pathway. The NF-κB liberated from the IκBs is then translocated to the nucleus, where it binds to the promoter/enhancer region of the target genes, resulting in the regulation



IkBz, Fig. 1 Roles of IκBζ in inflammatory response. Activation of the TIR-containing receptors by TLR ligands elicits phosphorylation and ubiquitination-induced degradation of the cytosolic IκB proteins, which allows nuclear translocation of NF-κB. In the nucleus, NF-κB activates transcription of a subset of genes A, which includes IκBζ. The expression of IκBζ also requires a specific mRNA stabilization signal that comes from the TIR-containing receptor as well as activation of NF-κB. The expressed IκBζ associates with NF-κB, and the complex engages transcription of another subset of genes B. Simultaneously, IκBζ inhibits transcription of the subset of genes A

of transcription via recruitment of several co-activators and co-repressors. This transcriptional activation leads to the expression of primary/early response gene A, depicted in Fig. 1, which includes three atypical members, IκBζ, Bcl-3, and IκBNS. The induced IκBζ associates with NF-κB, and this complex then activates another subset of inflammatory gene B (Fig. 1). Simultaneously, IκBζ inhibits the transcriptional regulation of gene A.

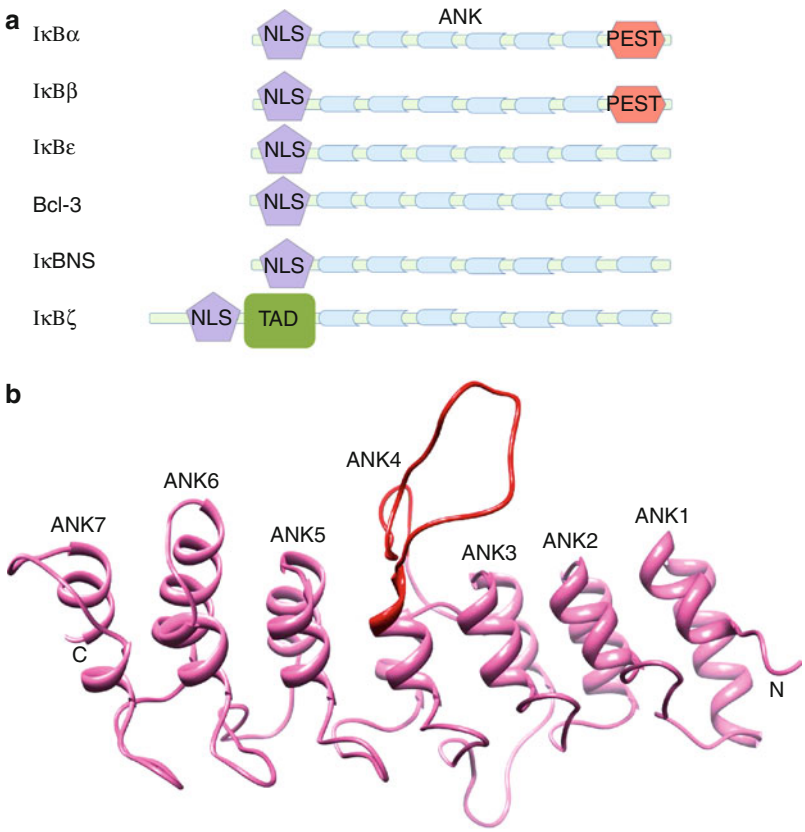
The predominantly expressed cytoplasmic IκB proteins, IκB-α, -β, and -ε, act exclusively as NF-κB inhibitors, whereas the nuclear IκB proteins, Bcl-3 and IκBζ, can both act as either a positive or negative regulator of NF-κB target genes. Bcl-3 can act as a positive regulator of NF-κB either by removing transcriptionally inactive p50 and p52 dimers from the IκB sites, thus allowing transcriptionally active heterodimers to take their places or by forming a ternary complex with DNA-binding p50 and p52 homodimers, thereby facilitating gene expression (Yamazaki et al. 2001; Totzke et al. 2006; Dechend et al. 1999; Fujita et al. 1993; Yamamoto et al. 2004). Unlike other classical IκB proteins, IκBζ is strongly expressed in response to treatment with different proinflammatory stimuli. IκBζ inhibits the transcriptional activity of NF-κB by associating with the p50/p65 heterodimer. More importantly and in contrast to other classical IκB proteins, IκBζ can also induce the expression of genes such as IL-6 and IL-12p40 by binding with the p50 homodimer.

IκBζ is encoded by a primary responsive gene, *Nfkbiz*, and its induction depends on NF-κB activation, suggesting that IκBζ regulated genes are induced via two-step machinery (Motoyama et al. 2005; Yamazaki and Takeshige 2008). Very little IκBζ is detected in unstimulated cells, and it is induced by various microbial substances that stimulate TLRs and IL-1β receptors, but not by TNF-α. Subsequent studies have shown that TNF-α induced transcription of *Nfkbiz* gene, but did not stabilize IκBζ mRNA, indicating that the stimulus-specific expression of IκBζ is determined post-transcriptionally. All TLRs possess ectodomains that recognize ligands from microbial substances and endodomains that facilitate the downstream signaling, which has been shown to be associated with the ectodomain through a transmembrane segment. With the exception of TLR3, which mediates downstream signaling through TRIF/TRAM (which is ▶ Myd88 independent), the other TLRs share common signaling pathways initiated by an adaptor protein, Myd88 (Myd88 dependent), which is necessary for the IκBζ induction. In macrophage cells, LPS stimulation leads to three variants (L, S, and D) that are generated by alternative splicing of IκBζ. The longer form, IκBζ (L, 1–728), is predominantly expressed upon LPS stimulation, while the shorter form IκBζ (S) has been observed at mRNA and protein levels in minor species. Although IκBζ (D) mRNA has been detected in macrophages, its corresponding protein level has not been found (Yamazaki et al. 2005). Overall, IκBζ (L and S) are functionally active when expressed in the cells.

IκBζ (1–728 amino acids) can be divided into N-terminal (1–450) and C-terminal (451–728) portions. The N-terminal region contains NLS and TAD, whereas the C-terminal region contains the ANK repeat domain, which plays an important role in interaction with NF-κB subunits, thereby regulating its functions (Fig. 2a). Truncated mutation studies of IκBζ (especially its N-terminal region) have shown $-K_{163}-R_{164}-X_{12}-K_{177}-R_{178}-$ to be indispensable for NLS, and the mutation of this portion has revealed that IκBζ localized in the cytosol and effectively inhibited NF-κB, which is similar to the cytosolic IκB proteins. IκBζ was initially characterized as a negative regulator of NF-κB, but subsequent studies demonstrated that it could also act as a positive regulator of NF-κB. Analysis using GAL4-fusion protein of IκBζ revealed that its N-terminal region (329–403) exhibits transcriptional activity after association with NF-κB (p50/p50) subunit (Yamazaki et al. 2005). To date, numerous functions of IκBζ have been reported, when bound to other nuclear proteins. (1) Overexpression of IκBζ augmented IL-6 production in response to LPS by interacting with p50 homodimer, whereas TNF-α production is inhibited through interaction with p50/p65 heterodimer, indicating specific target gene activity (Motoyama et al. 2005). (2) IκBζ physically and functionally interacts with STAT3, which is a member of the NF-κB signaling pathway, thereby inhibiting the transcriptional activation of STAT3 (Wu et al. 2009). (3) Human IκBζ expressed in response to TNF-α binds to the DNA-binding region of p50/p65 heterodimer, consequently leading to the inhibition of the TNF-α response (Totzke et al. 2006). (4) IκBζ mediates pre-initiation complex assembly and histone H3K4 methylation, leading to the activation of secondary response genes, thereby suggesting a role of IκBζ in the nucleosome remodeling (Kayama et al. 2008). (5) IκBζ is expressed in IL-17-producing helper T (T_H17) cells that play an important role in resistance to experimental autoimmune encephalomyelitis (EAE) (Okamoto et al. 2010).

Physiological Roles of IκBζ

Studies of IκBζ-deficient mice have demonstrated that IκBζ plays a role as a positive and negative regulator of NF-κB-mediated transcription (Yamamoto et al. 2004). Microarray studies have shown that IκBζ is an indispensable component of the LPS-induced transcription of genes represented by IL-6 and of the genes listed in Table 1. It should also be noted that IL-6 plays an important role in many inflammatory diseases including sepsis, heart attacks, and stroke, as well as in many human cancers including hepatocarcinoma, multiple carcinoma, and ovarian cancer. However, the transcription complex on IL-6 appears to differ depending on the stimuli. The role of IκBζ as a negative regulator was not evident in the isolated cells, probably because of redundant negative regulators of NF-κB. The inhibitory roles of IκBζ in NF-κB-mediated transcription are critical in fine-tuning to balance inflammatory reactions to maintain homeostasis in vivo. IκBζ knockout animals have atopic-like dermatitis and eye inflammation that supports a role of IκBζ in innate host defense. However, the inflammation caused by IκBζ deficiency is not so



IkBz, Fig. 2 IκB family members. (**a**) All IκB proteins harbor ankyrin repeats at their carboxy terminal region. The NH_2 terminal regulatory region of IκB-α, -β, and -ε contains specific sequences that are phosphorylated and ubiquitinated. The NH_2 terminal region of IκBζ contains the nuclear localization and transactivation domains that are necessary for the transcriptional process. (**b**) The homology models of the IκBζ ARD domain are shown in *bright pink*. The 28 amino acid residues occurring within the ANK4 are shown in *red*

IkBz, Table 1 Genes that require IκBζ for LPS-mediated induction

Category	Subset of genes
Cytokines	IL-6, IL-12 p40 subunit, IL-18, granulocyte macrophage stimulating factor (GM-CSF), granulocyte colony stimulating factor (G-CSF), growth-differentiation factor (GDF) 15, Epstein-Barr-virus-induced gene (EBI) 3
Chemokines	CXC chemokine ligand (CXCL)5, CXCL13, chemokine ligand (CCL)7, CCL17
Enzymes	Histidine decarboxylase, caspase11, inositol polyphosphate-5-phosphatase B, deltex 2B, glutathione reductase, guanylate nucleotide-binding protein (GDP) 1
Receptors	Formyl peptide receptor 1, macrophage receptor with collagenous structure (MARCO)
Biological active peptides	Endothelin 1, ghrelin
Transcription factors	Basic leucine zipper transcription factor (BATF), CCAAT/enhancer-binding protein (C/EBP)-δ
Antimicrobial substances	Lipocalin 2/neutrophil gelatinase-associated lipocalin (NGAL)
Others	Tax-1 binding protein, extracellular proteinase inhibitor, solute carrier family 11 member 2 (S1c11a2), Src-like adaptor protein (SLAP), immunoglobulin heavy chain, immunoglobulin light chain, membrane spanning 4-domains (MS4A1), thrombospondin 1, immediate early response 3 (IER3/IEX1), disabled-2

clear. Accordingly, it will be important to test whether the skin and eye inflammation in IκBζ knockout mice is due to the lack of host defense molecules such as lipocalin, or lack of essential cytokines such as IL-6. However, the other function of IκBζ, suppression of NF-κB activity, cannot be excluded. Atopic dermatitis and ocular inflammation may also occur due to the over expression of cytokines that IκBζ might inhibit via the C-terminal ankyrin repeat.

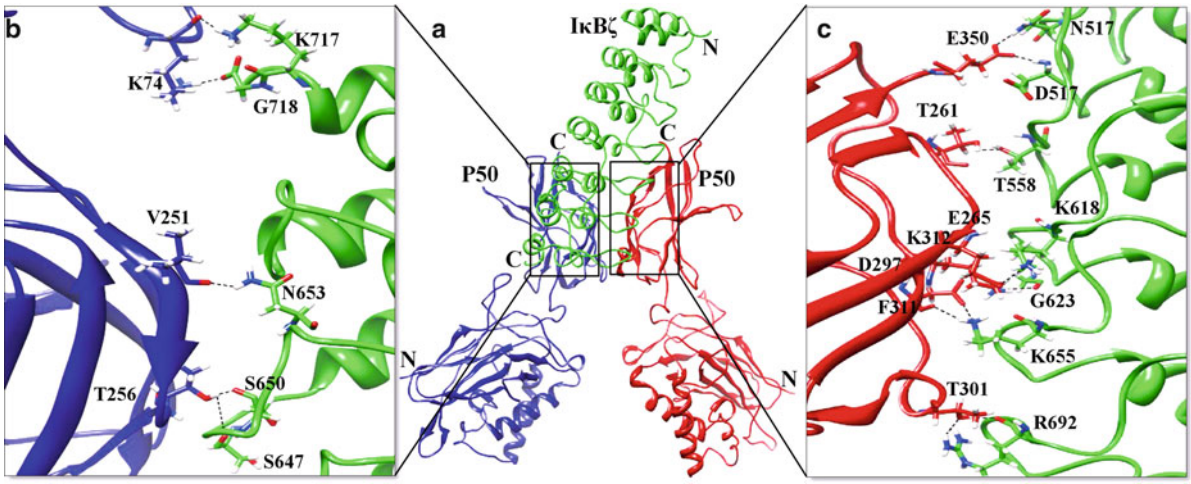
The factors that distinguish genes that are activated or inhibited by IκBζ appear to be present in the promoter of each gene. Biochemical studies have indicated that in addition to NF-κB binding sites, IκBζ is also required for transcriptional activation. Since the transcriptional activation activity of IκBζ on the GAL4-reporter system is much weaker than that of the NF-κB p65 subunit, other transcription factors are necessary for efficient IκBζ-mediated transcription (Yamazaki et al. 2008). IκBζ acts as a negative regulator of the promoter harboring canonical NF-κB-binding sequences alone. Moreover, all the nuclear IκB proteins are homologous to each other; therefore, these nuclear proteins may act as competitors for IκBζ or vice versa. In fact, IκBNS has been reported to inhibit LPS-mediated IL-6 production (Kuwata et al. 2006).

Structure-Based Activation and Inhibition Mechanism of Nuclear IκBζ

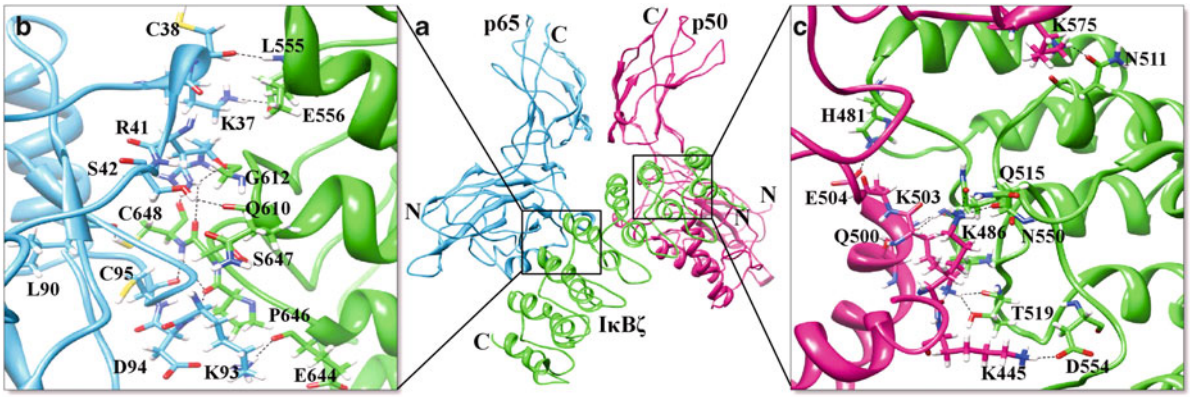
The primary sequence of human and mouse IκBζ share about 70% homology with the N-terminal region (1–450) and 97% sequence identity with the C-terminal ARD. Although there is sequence variation at the N-terminal region, the NLS and TAD are conserved. There has been speculation about the differences in the N-terminal region of human and mouse IκBζ, which differ in their ability to bind with NF-κB proteins. Mouse IκBζ binds only to p50/p50 homodimer, whereas human IκBζ binds to both the p65 and p50 subunits. Sequence analysis of the N-terminal region has not revealed any significant homology to proteins in the NCBI database. In addition, secondary structure prediction showed that the N-terminal has no ANK repeat followed by the C-terminal ARD. This type of architecture has also been reported in proteins such as the yeast ribosomal binding protein yar-1 (Lycan et al. 1996). No crystal structure is yet available for IκBζ ARD, but recent modeling studies have shown the IκBζ three-dimensional structure, which was built based upon the Bcl-3 crystal structure (Michel et al. 2001) (Fig. 2b). Each ANK repeat of the IκBζ models depicted two antiparallel α-helices, followed by a loop of variable length at a right angle. Each repeat began and ended with short β-hairpin turns that protruded away from the α-helix. This non-globular fold was stabilized through intra- and inter-repeat hydrophobic interactions. The represented structural motifs stack upon one another in a linear fashion to form a curved architecture. These motifs are known to facilitate protein–protein interaction, but have no known enzymatic activity (Mosavi et al. 2004). The presence of ankyrin repeats and their role in inflammatory signaling immediately suggested structural and functional homology with the ARD-containing classical IκB proteins. Despite the similarities, IκBζ differs structurally from the classical IκB inhibitors in its unique amino-terminal region, the number of ankyrin repeats, the presence of a unique 28 amino acids insertion within the helices of the α1 and α2 of ANK4 (similar to one that has been observed in IκBNS), and the complete absence of a PEST-like region within the IκBζ carboxy-terminus (Fig. 2b).

Recent studies have indicated that human TNF-α-induced IκBζ is associated with both the p50/p65 subunits of NF-κB in the nucleus, and inhibits the transcriptional activity of anti-apoptotic protein (Totzke et al. 2006). The structural basis of this inhibitory and activation mechanism was explained by docking studies (Manavalan et al. 2011), which have shown that IκBζ ARD associates with the DNA-binding domain of p50/p65 subunits of NF-κB and contains important residues that interact with the bases as well as sugar phosphate backbone present in the p50 and p65 subunit (Fig. 3). Hence, there will be no more p50/p65 subunits available to the promoter region, which ultimately results in inhibition of the transcription mediated by p50/p65 subunit. Generally, p65 subunits contain the TAD at the C-terminal end, which is important for its transcriptional activity (O'Shea and Perkins 2008). IκBζ inhibits p65 transactivation activity through its binding with the N-terminal DNA-binding domain.

Furthermore, IκBζ-p50/p50 complex revealed that ANK3-7 interact with the dimerization domain of the p50 subunit (Fig. 4). The binding orientation of IκBζ



IkBz, Fig. 3 Docking studies predict that the cofactor IκBζ ARD binds at the side of the p50/p65 heterodimer interface. (**a**) The p50/p65 heterodimers, represented as a ribbon diagram, are shown in magenta and cyan, respectively. Docked IκBζ is *green* in the ribbon diagram. (**b**) p65-IκBζ binding interface. Side chains of the amino acid contributing to the hydrogen bonding formation (marked as *black*) are represented by a stick model with the residue name and numbers shown next to them. (**c**) The p50-IκBζ binding interface is shown in a similar fashion as in (**b**)



IkBz, Fig. 4 IκBζ ARD-p50 homodimer interface. (**a**) The p50/p50 dimers are *blue* and *red* in the ribbon diagram. Docked IκBζ is *green* in the ribbon diagram. (**b**) The p50 (chain A)-IκBζ binding interface. Side chains of the amino acid contributing to the hydrogen bonding formation (marked as *black*) are represented by a stick model with the residue name and numbers shown next to them. (**c**) The p50 (chain B)-IκBζ binding interface is shown in a similar fashion as in (**b**)

with this homodimer is similar to that of the classical IκBα-p50/p65 heterodimer. Although the binding orientation is the same, there might be some differences in the regulation of NF-κB-dependent gene expression by IκBα and IκBζ. Activation of p65-containing NF-κB heterodimer by LPS or IL-1 leads to the expression of NF-κB-dependent genes, including IκB proteins IκBα and IκBζ. Following translocation, IκBα enters the nucleus, where it targets NF-κB p50/p65 dimers and removes them from DNA through the acidic PEST motif of IκBα and the basic DNA containing surfaces of the NF-κB p65 subunit that likely disrupt protein/DNA binding. In contrast, IκBζ enters into the nucleus and targets the p50/p50 homodimer, which is already bound to the promoter region, thereby blocking the transcription due to the unavailability of the TAD. Overexpression experiments have suggested that IκBζ exhibited transactivation potential (Motoyama et al. 2005); hence IκBζ mediates transcriptional activity by binding with DNA-bound p50/p50 homodimer,

thereby providing a transactivation domain to the NF-κB complex. Such IκBζ mediated transcription is important for the production of IL-6, antimicrobial peptides, lipocalin, hDB-2, and the genes listed in Table 1. Finally, it should be noted that, when compared with other IκB proteins, IκBζ possesses numerous functions that occur via binding with different nuclear proteins. Recent studies of MD (molecular dynamics) simulation of IκB have revealed that IκBζ possesses more thermodynamically flexible residues than other IκB members. These findings demonstrate that structural flexibility is the major factor that enables IκBζ to interact with different sets of nuclear proteins (Manavalan et al. 2010).

Summary

Studies of IκBζ have provided evidence for multistep regulation of inflammatory responses in TLR signaling. Upon cell activation by appropriate stimuli, primary responses are induced by rapid activation of the major transcription factor (NF-κB), which is activated through posttranslational modifications such as phosphorylation without *de novo* protein synthesis. During this period, transcriptional regulators such as IκBζ are induced via stimuli-specific mechanisms. Secondary response genes are activated and primary responses are gradually diminished via the combinations of major transcription factors and inducible regulators. Since the genes that are activated via secondary responses also include other transcription factors, stimulus-specific transcriptional activation would proceed in a multistep fashion with time after the stimulation. In vitro studies have shown that these nuclear IκB proteins interact with the p50 or p52 subunits of NF-κB. Only p50/p52 double knockout mice, but not single knockout mice, exhibit severely defective immune disorders such as osteopetrosis. However, some immunological phenotypes occur in mice lacking only one nuclear IκB protein. This condition may be compensated by utilizing other IκB proteins. Further studies are required to clarify and discover new and detailed physiological aspects of the nuclear IκB proteins in the future by using mice devoid of two or all three nuclear IκB proteins. In conclusion, it can be seen that nuclear IκBζ not only contributes to NF-κB mediated transcription, but also plays an important role in innate immune responses by modulating the expression of proinflammatory cytokines.

Synonyms

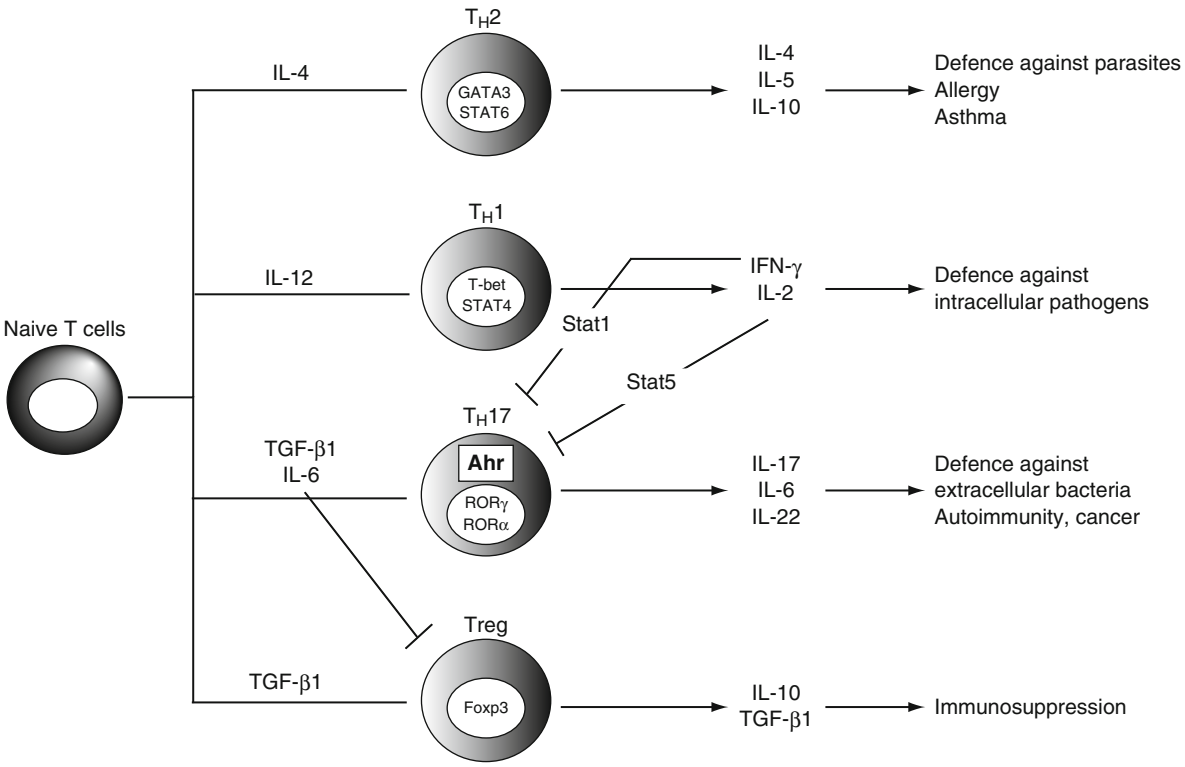
B cell stimulatory factor-2 (BSF-2); IFN-β2

Historical Background

IL-6 was cloned as B cell stimulatory factor-2 (BSF-2) in 1986 (Hirano et al. 1986). This molecule has various biological activities; a strong stimulatory effect on growth of murine plasmacytoma and human myeloma, its functions as a hepatocyte stimulating factor, and the induction of acute phase reaction. IL-6 knockout (KO) mice revealed the inhibition of the antiviral antibody response after immunization with a vesicular stomatitis virus, compared with wild-type (WT) mice. Thus, IL-6 is a pleiotropic cytokine that is involved in the physiology of virtually every organ system.

Introduction

$CD4^+$ T cells (Th) are essential regulators of immune responses and inflammatory diseases. They can be divided into different subsets such as Th1, Th2, and regulatory T (Treg) cells, whose development is specified by the transcription factors T-bet, GATA3, and fork head box p3 (Foxp3), respectively (Fig. 1). The development of Th1 cells, which activate macrophages and are highly effective in clearing intracellular pathogens, is coupled to the sequential actions of interferon-γ (IFN-γ) and interleukin-12 (IL-12). Th2 cells, which differentiation is driven by IL-4, are important for the production of immunoglobulin E and the clearance of extracellular organisms. In addition to these effector subsets, $CD4^+$ T cells can differentiate into distinct regulatory subsets (Treg), which express the fork head/winged helix transcription factor Foxp3. Transforming growth factor-β1 (TGF-β) promotes



IL6, Fig. 1 Th cell differentiation. Naïve T cells can differentiate into several subsets. Th17 cells were recently identified as a novel $CD4^+$ lineage. They are induced by TGF-β plus IL-6. RORγt and RORα act as the master transcriptional factors for Th17 cells. (See text for details about their differentiation)

the differentiation of Treg cells, which suppress adaptive T cell responses and prevent autoimmunity.

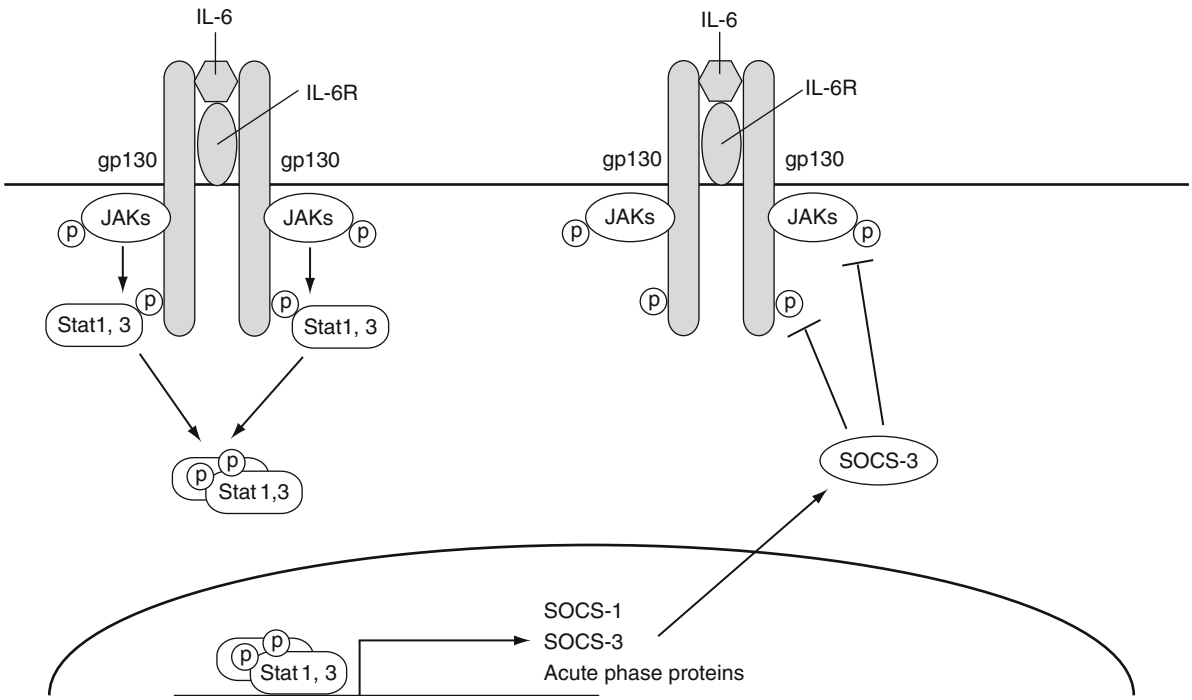
Until recent years, it has been believed that Th1 cells mainly dominate the induction and progression of many autoimmune diseases. However, IFN-γ deficient (KO) mice do not show resistance to autoimmunity. On the contrary, they are even more susceptible to autoimmunity, which led us to hypothesize that there may be an additional Th subset that is distinct from Th1 cells. Recently, a new subset of Th cells that produces IL-17 (Th17) has been identified and was shown to have a crucial role in the induction of autoimmune diseases, such as rheumatoid arthritis and experimental autoimmune encephalomyelitis (EAE), and allergen-specific responses. The differentiation of Th17 cells from naïve T cells requires stimulation by IL-6 and TGF-β, which induces the master transcriptional factors of the Th17 subset such as retinoid-related orphan receptor γt (RORγt) and RORα (Fig. 1) (Korn et al. 2009).

Interleukin-6 (IL-6)

IL-6 Receptors and Signaling

The IL-6 receptor (IL-6R) system consists of two polypeptide chains: an 80 kDa IL-6 receptor and a 130 kDa signal transducer (gp130) (Kishimoto 2005). IL-6R (80 kDa) exists in both a transmembrane form and a soluble form. IL-6 binds to both of these forms, which can then interact with gp130 and trigger signal transduction and gene expression. Gp130 is expressed ubiquitously in tissues. In addition to being a component of the IL-6R, gp130 is a component of receptors for other cytokines, such as leukemia inhibitory factor (LIF), IL-11, oncostatin M (OM), and cardiotropin-1 (CT-1), which explains the functional redundancy of IL-6 superfamily cytokines.

Although gp130 has no intrinsic kinase domain, members of the Janus kinase (JAK) family, such as JAK1, JAK2, and tyrosine kinase 2 (TYK2), are constitutively associated with gp130 (Kishimoto 2005). Complexes of IL-6, IL-6R, and gp130 phosphorylate



IL6, Fig. 2 IL-6 signaling and negative feedback regulation by SOCS. Upon IL-6 interaction, the IL-6R/gp130 complex phosphorylates JAKs and then activates STAT1 and STAT3. Activation of STAT1 and STAT3 induces *SOCS1* and *SOCS3* gene expression. SOCS1 binds primarily to phosphorylated JAK proteins through its SH2 domain, whereas the SH2 domain of SOCS3 binds to phosphorylated tyrosine residues in the cytoplasmic domain of receptors. These interactions terminate STAT activation and suppress downstream gene expression

these kinases and then activate the cytoplasmic transcriptional factors, signal transducers, and activators of transcription 1(STAT1) and STAT3 (Fig. 2) (Ihle and Kerr 1995). In addition, IL-6 activates mitogen-activated protein kinase (MAPK), which phosphorylates the nuclear factor for IL-6 (NF-IL6). Thus, IL-6 activates these kinases and transcriptional factors through IL-6R/gp130 complexes, which leads to gene expression.

Negative Feedback Regulation of IL-6 Signaling

Although IL-6 is essential for the regulation of the immune process, overproduction of the cytokine causes inflammation and autoimmune diseases such as rheumatoid arthritis, systemic juvenile arthritis, and Crohn's disease. Therefore, negative feedback regulation of IL-6 signaling is required for immune homeostasis. Cytokine signaling, such as IL-6 signaling, is negatively regulated by the suppressor of cytokine signaling (SOCS) and the protein inhibitor of activated STATs (PIAS). The SOCS family is composed of eight members: cytokine inducible SRC homology 2 (SH2)-domain-containing protein (CIS) and SOCS1 to SOCS7. SOCS-1, also called STAT-induced STAT inhibitor-1 (SSI-1) and JAK-binding protein (JAB), was initially identified as an intracellular negative-feedback molecule that inhibits JAK-STAT signaling initiated by various stimuli, including IFN-g, IL-4, IL-6, and leukemia inhibitory factor (LIF) (Krebs and Hilton 2000). SOCS-1 mainly inhibits IFN-γ signaling in vivo by binding to JAKs to inhibit its following signal transduction. However, SOCS-1 also negatively regulates innate immune responses such as lipopolysaccharide (LPS) -Toll-like receptor 4 (TLR4) signaling. Thus, SOCS-1 acts as an essential negative regulator in not only cytokine signaling but also TLR signaling.

Although SOCS-3 is also induced by cytokines such as IFN-γ and IL-6, and it can inhibit JAK activation as well as SOCS-1, SOCS-3 binds the cytokine receptor through its SH2 domain (Fig. 2). The activation of Stat1 and Stat3 induced by IL-6 is prolonged in SOCS-3-deficient tissues and cells, but not in

SOCS-1-deficient tissues and cells, which indicates that SOCS-3 is a pivotal regulator of IL-6 signaling in vivo.

IL-6 and Immune Diseases

IL-6 is involved in many diseases such as rheumatoid arthritis, systemic-onset juvenile idiopathic arthritis, systemic lupus erythematosus, Crohn's disease, and inflammatory bowel disease (Kishimoto 2005). In addition, IL-6 is involved in multiple sclerosis (MS), which is a chronic inflammatory disease affecting the central nervous system (CNS) white matter. Patients with MS exhibit higher mean levels of IL-6 in their cerebrospinal fluid than normal controls, and the treatment with an anti-IL-6 receptor monoclonal antibody (anti-IL-6R mAb) inhibited the development of EAE, which is a murine model of human MS that shares many pathological and histological characteristics with human MS.

IL-6 blockade seems to be an innovative treatment strategy for the numerous immune diseases that are impacted by IL-6 overproduction. Actually, blocking IL-6 signaling with a humanized anti IL-6R monoclonal antibody (tocilizumab) is an effective treatment for patients with autoimmune diseases such as Castleman's disease and systemic onset juvenile arthritis (Venkiteshwaran 2009). Although many proinflammatory cytokines including IL-6, TNF-α, and IL-1β are increased in patients with autoimmune diseases such as rheumatoid arthritis and MS, the discovery of Th17 cells has defined IL-6 blockade as the potent and dominant treatment for these diseases. The details of the relationship between IL-6 and Th17 cells in autoimmune diseases will be discussed in section IL-6 and Th17 Cells in Autoimmune Diseases.

IL-17-Producing Helper T Cell (Th17)

Th17 cells produce IL-17A (IL-17), IL-17F, IL-22, IL-6, and TNF-α. The IL-17 family is composed of IL-17A, IL-17B, IL-17C, IL-17D, IL-17E (IL-25), and IL-17F. IL-17 is a potent inflammatory cytokine (Korn et al. 2009). As stated above, autoimmune diseases were previously assumed to be associated with dysregulated Th1 responses. However, IFN-γ deficiency did not attenuate some models of autoimmune diseases like EAE; on the contrary, IFN-γ deficiency worsened the disease. It was recently demonstrated that Th17 cells are dominantly associated with human and mouse autoimmune diseases such as rheumatoid arthritis, MS, and inflammatory bowel disease. In fact, IL-17 KO mice are resistant to the development of collagen-induced arthritis (CIA) and EAE, and IL-17 blockade by IL-17-blocking antibody prevents the development of EAE.

Th17 Cell Differentiation

Although initial reports claimed that IL-23 is required for the generation of Th17 cells from naïve T cells, it was subsequently demonstrated that IL-23R is not expressed on naïve T cells and that IL-23 acts as a survival signal for Th17 cells. At present, it is believed that Th17 cell differentiation is driven by the combination of IL-6 and TGF-β (Kimura and Kishimoto 2010). The orphan nuclear receptors, RORγt and RORα, are the key transcription factors that determine the differentiation of the Th17 lineage. IL-6 together with TGF-β induces these transcription factors, whereas IL-6 inhibits TGF-β-induced expression of Foxp3, a master transcriptional factor for Treg. The levels of RORγt and RORα are significantly reduced in Stat3-deficient T cells, but not in Stat1-deficient T cells under Th17-polarizing conditions, which indicates that Th17 cell differentiation is dependent on Stat3. In contrast to Stat3 activation, Stat1 activation inhibits the development of Th17 cells (discussed below). Although IL-6 activates both Stat3 and Stat1, Stat3 activation is maintained while Stat1 activation is suppressed in Th17 cells.

Conditioned medium from LPS-stimulated bone marrow-derived dendritic cells (DCCMs) can induce the production of IL-17 in naïve T cells. Interestingly, IL-17 was produced by DCCM even with the addition of anti-gp130 antibody or DCCM from IL-6 KO mice, which indicates that there is an IL-6-independent pathway in Th17 commitment. Although several cytokines including TNF-α and IL-23 participate in Th17 cell development, they are not required for the initiation of Th17 differentiation. What, then, is required for Th17 differentiation besides IL-6? It has been demonstrated that IL-21 acts as an initiator for Th17 commitment independently of IL-6. IL-21 is a novel cytokine produced by activated T cells and natural killer T (NKT) cells, and its receptor complex is composed of the common IL-2 receptor γ chain (γc) and IL-21 receptor (IL-21R). IL-21 and IL-6 inhibit TGF-β-induced Foxp3 expression and induce RORγt and RORα in a Stat3-dependent manner such that naïve T cells differentiate into Th17 cells.

Other Factors Involved in Th17 Cell Differentiation

The combination of IL-6 and TGF-β is unable to sustain the activation of Stat1 in Th17 cells, although it can sustain Stat3 activation. On the other hand, both Stat1 and Stat3 remained activated in Th17 cells induced by DCCM. These findings provide a novel and unknown basis for Th17 cell differentiation from naïve T cells. In fact, transcriptional factors such as Interferon-regulatory factor 4 (IRF4) and T-bet act as the positive and negative regulator for Th17 commitment, respectively. It has been also reported that retinoic acid inhibits Th17 cell development, and dioxin, a ligand of Aryl hydrocarbon receptor, promotes the generation of Th17 cells. Thus, IL-6 plays a central role in Th17 cell differentiation, whereas various factors regulate Th17 cell development.

Negative Regulation of Th17 Cell Differentiation

There is a negative regulatory system for Th17 cell differentiation. IL-27 and IFN-γ are responsible for the inhibition of its development in a Stat1-dependent manner. IL-27, another IL-12 family member, uses a receptor complex composed of IL-27R and gp130 to transduce its signal and activates both Stat1 and Stat3. Although both IL-6 and IL-27 transduce their signals via the gp130-JAK-STAT axis, IL-6 initiates Th17 commitment dependently on Stat3 activation, and IL-27 inhibits its development dependently on Stat1 activation. Additionally, IL-27 augments T-bet, the master transcriptional factor for Th1 cells, which indicates that IL-27 has both pro- and anti-inflammatory properties in Th cell differentiation.

It has been demonstrated that IL-2 also inhibits Th17 cell development. IL-2 cannot inhibit Th17 cell differentiation in Stat5-deficient T cells, and that there are Stat5 binding sites in the IL-17 promoter region; these findings suggest that Stat5 serves as a repressor. Thus, STAT family members activated by various cytokines provide positive and negative regulation of Th17 cell differentiation. However, the mechanisms of the regulation have not been elucidated.

Aryl Hydrocarbon Receptor: A New Player in Th17 Cells

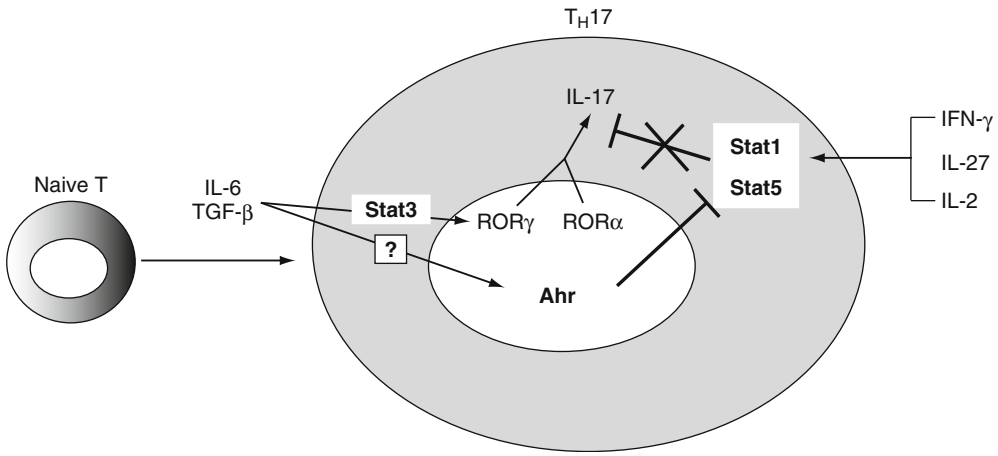
Aryl Hydrocarbon Receptor

Aryl hydrocarbon receptor (Ahr), also known as dioxin receptor, is a ligand-activated transcription factor that belongs to the basic-helix-loop-helix-PER-ARNT-SIM family. Ahr is present in the cytoplasm, where it forms a complex with heat shock protein (HSP) 90, Ahr-interacting protein (AIP), and p23. Upon binding with a ligand, Ahr undergoes a conformational change, translocates to the nucleus, and dimerizes with Ahr nuclear translocator (Arnt). Within the nucleus, the Ahr/Arnt heterodimer binds to a specific sequence, the xenobiotic responsive element (XRE), which causes a variety of toxicological effects. Interestingly, it has been recently reported that Ahr is a ligand-dependent E3 ubiquitin ligase, which implies that Ahr has dual functions in controlling intracellular protein levels, serving both as a transcriptional factor to promote the induction of target proteins and as a ligand-dependent E3 ubiquitin ligase to regulate selective protein degradation. Ahr activated by ligands, such as 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), regulates the generation of regulatory T cells (Tregs) and modulates the Th1/Th2 balance. In addition, it has been recently demonstrated that Ahr participates in Th17 cell differentiation. These data collectively demonstrate the importance of Ahr in the differentiation of T cell subsets.

Ahr Functions in Th17 Cells

Ahr is specifically induced in naïve T cells under Th17-polarizing conditions such as TGF-β plus IL-6 or TGF-β plus IL-21. Although the molecular mechanism of Ahr expression in Th17 development is not known, it is possible that its induction may be regulated downstream of Stat3 by IL-6 and TGF-β because Ahr expression was induced by TGF-β plus IL-6 in Stat1-deficient naïve T cells.

As stated above, Th17 differentiation is positively regulated by IL-6 or IL-21 in combination with TGF-β and negatively regulated by IFN-γ or IL-27. The positive regulation is controlled by Stat3, while the negative regulation is controlled by Stat1. It was found that Ahr binds to Stat1 and Stat5, but not to other members of the Stat family, in Th17 cells; this result suggests that Ahr may regulate the generation of Th17 cells by modifying the activation of Stat1 and Stat5, which negatively regulate Th17 generation. Indeed, Ahr deficiency prolonged Stat1 activation 24 h after stimulation with TGF-β plus IL-6, whereas its activation was relatively transient and returned to the basal level in WT naïve T cells during the same period. On the other hand, Stat3 activation was equally maintained in both Ahr WT and KO naïve T cells. The mechanism by which Ahr interacts with Stat1 and Stat5 and negatively regulates their activation in Th17 cell



IL6, Fig. 3 Ahr functions in Th17 cells. Ahr is induced under Th17-polarizing conditions. Ahr participates in Th17 cell differentiation by regulating Stat1 activation, which suppresses the development of Th17 cells. Ahr may regulate Stat1 activation by functioning as a ligand-dependent E3 ubiquitin ligase that degrades activated Stat1

differentiation is not yet understood. Given that Ahr serves both as a transcriptional factor and as a ligand-dependent E3 ubiquitin ligase, it is possible that Ahr marks activated Stat1 for degradation via its ubiquitin ligase function in Th17 cells (Fig. 3).

IL-6 and Th17 Cells in Autoimmune Diseases

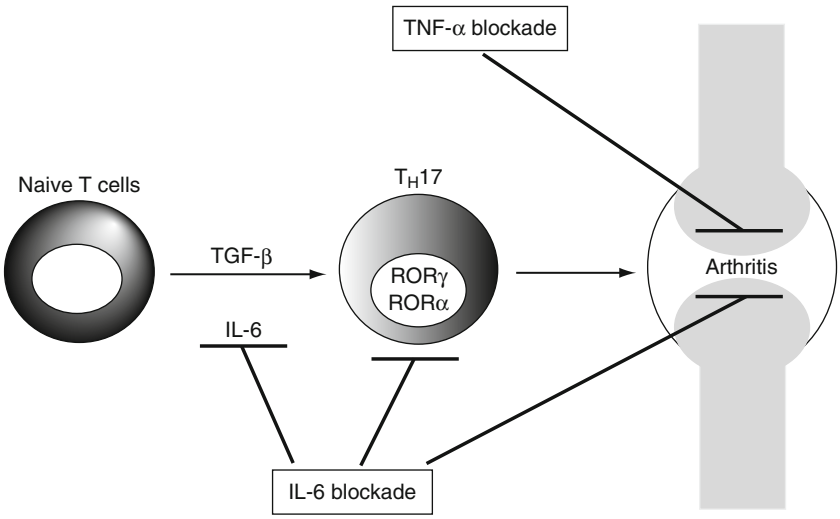
The overproduction of IL-6 or abnormalities in its signal transduction is causative factors in autoimmune disorders including rheumatoid arthritis. At present, there is increasing clarification of the role of IL-6 in diseases such as RA in which Th17 cells are considered to be the primary cause of pathology. Humanized anti-IL-6 receptor antibodies (Tocilizumab) are currently being used clinically as an IL-6-blocking therapy for several autoimmune diseases. This section focuses on the relationship between IL-6 and Th17 cells in the pathogenesis of inflammatory diseases and an effective approach by Tocilizumab for the treatment of several autoimmune diseases.

IL-6 and Th17 Cells in Mouse Autoimmune Disease Models (CIA, EAE)

Previously, Th1 cells were considered to play a major role in pathogenesis of CIA and EAE. However, in IFN-γ-deficient mice and IFN-γ receptor-deficient mice, CIA and EAE symptoms are not ameliorated but rather exacerbated. In contrast, these diseases are suppressed in IL-17-deficient mice, and are alleviated by treatment with IL-17-neutralizing antibodies. These results indicate that in diseases such as CIA and EAE, Th17 cells are actually the major population in their pathogenesis and the in vivo differentiation and propagation of Th17 cells can be used as an index of these disease models.

Previous analyses revealed that IL-6 deficient mice are resistant to CIA and EAE. However, the reason for this resistance has been poorly understood. In recent years, it has been clarified that Th17 cells are induced from naïve CD4 T cells by TGF-β and IL-6 in vitro; therefore, it is conceivable that the impaired Th17 cell differentiation in these mice is the major cause for the resistance to CIA and EAE. However, in genetically deficient mice, their susceptibility to diseases such as CIA and EAE may be influenced by possible intrinsic defects in immune cells or nonuniform genetic backgrounds. Therefore, the administration of anti-IL-6 receptor antibodies to congenic wild-type mice with CIA or EAE is required to investigate the in vivo action of IL-6 in Th17 differentiation.

CIA is induced by administering type II collagen together with an adjuvant on Day 0 and Day 21 in mice. Interestingly, although anti-IL-6 receptor antibodies administered on Day 0 suppressed the induction of Th17 cells in the regional lymph nodes and the development of arthritis, antibodies administered on Day 14 did not suppress Th17 cells or arthritic symptoms. These results indicate that the inhibition of Th17 differentiation caused by anti-IL-6 receptor antibodies is necessary for CIA suppression and that for CIA in the in vivo environment; IL-6 is required for the initial differentiation from naïve T cells to Th17 cells, but



IL6, Fig. 4 Different mechanisms between anti-IL-6 receptor antibodies and TNFR-Fc therapies in RA. Anti-IL-6 receptor antibodies inhibit IL-6 at inflammation sites, although they mainly act to suppress the onset of disease by suppressing the initial differentiation phase of Th17 cells. By contrast, TNF inhibition does not suppress the initial differentiation phase of Th17, but it is believed to inhibit TNF-α at inflammation sites

not for the maintenance of Th17 cells after differentiation. Additionally, it was investigated whether a suppressing effect of Th17 cell development is observed with TNF inhibitor therapy in CIA. Intriguingly, when a TNF-soluble receptor (TNFR-Fc) was administered during the initial CIA induction period (Days 0–14), arthritis and Th17 differentiation could not be suppressed. However, when TNFR-Fc was administered after Day 21, arthritis is substantially suppressed without any effects on Th17 cell development. These results suggest that IL-6 inhibitor treatment in CIA acts primarily on initial CD4 T cell response including Th17 cell differentiation, rather than on the effector phase including angiogenesis and osteoclast differentiation. By contrast, it is suggested that the main point of action in TNF inhibitor therapy is different from that in IL-6 inhibitor therapy; it does not play a role in initial Th17 differentiation but it does act in the effector phase.

EAE is induced by administering the myelin sheath framework protein myelin oligodendrocyte glycoprotein (MOG) peptide together with an adjuvant and pertussis toxin. When anti-IL-6 receptor antibodies were administered immediately after antigen stimulation, the occurrence of EAE could be suppressed in the same manner as for CIA. In EAE models treated with anti-IL-6 receptor antibodies, no Th17 cells were found in draining lymph nodes or the spinal cord. Moreover, immune cells such as T cells, B cells, and macrophages were hardly observed in the lesion of spinal cord. On the other hand, the effect of anti-IL-6 receptor antibodies on Th17 cells and the disease onset was abolished when their administration was delayed. Thus, IL-6 is required for the initial differentiation phase for Th17 in the EAE model, and it appears that IL-6 also acts on cells other than Th17 cells. These results show that IL-6 inhibitor therapy is highly effective in suppressing the occurrence of EAE. Analyses of CIA and EAE indicate that initial Th17 differentiation phase in these autoimmune diseases is fundamentally dependent on IL-6, which suggests that IL-6 is a promising therapeutic target for autoimmune diseases involving Th17 cell inflammatory functions.

IL-6-Blocking Therapy in Human Autoimmune Diseases

In humans, the therapy by Tocilizumab has become a novel therapeutic strategy for some inflammatory and autoimmune diseases, including RA, systemic-onset juvenile idiopathic arthritis (JIA), Crohn's disease (CD), Castleman's disease, multiple myeloma, and systemic lupus erythematosus (SLE) (Venkiteshwaran 2009). Tocilizumab can block the IL-6 signals induced by the interaction of IL-6 and IL-6R. In the RA patients, Tocilizumab significantly improved the symptoms and ACR (American College of Rheumatology) improvement scores 20, 50, and 70 were 89%, 70%, and 47%, respectively, and normalized CRP and SAA in the patients within 6 weeks. Although a role of Th17 in RA is less clear, it has been reported that IL-17 is detected in the synovial fluid from RA patients and acts as a potent stimulator of osteoclastogenesis. Given that IL-6 is important for Th17 cell differentiation not

only in mice but also in humans, Tocilizumab may improve the symptoms of RA through regulating the development of Th17 cells. As described above, it has been shown that IL-6 blockade by Tocilizumab is therapeutically effective for other inflammatory diseases such as Castleman's disease, JIA, and CD; however, it is also still controversial whether Tocilitumab can inhibit Th17 cell differentiation in the improvement of these autoimmune diseases. It is required to demonstrate how Tocilizumab contributes to the treatment for above autoimmune diseases and whether Tocilizumab can also bring the therapeutic benefits for other autoimmune disorders.

TNF-inhibitor therapies (infliximab, etanercept) as well as anti-IL-6 receptor antibodies are also clinically effective for the treatment of autoimmune diseases such as RA, JIA, and Crohn's disease. Although both TNF-α and IL-6 are conventional inflammatory cytokines, it was suggested that they clearly have different roles in Th17 differentiation and that their therapeutic effects are different in CIA (Fig. 4). Detailed elucidation of the relationship between Th17 and pro-inflammatory cytokines such as IL-6 and TNF-α in human autoimmune disorders will provide important information when considering the proper use and switchover of biological agents.

Summary

In the past two decades, the knowledge on IL-6 has advanced from basic science to medicine. IL-6 is a pleiotropic cytokine that plays a major role in immune response, inflammation and hematopoiesis and its levels are increased in various autoimmune diseases. Tocilizumab is a humanized antihuman IL-6R antibody that inhibits the biological activities of IL-6 by blocking the binding of IL-6 to IL-6R. IL-6 blockade holds therapeutic value in autoimmune diseases, including Castleman's disease, JIA, and RA. However, the precise reason why IL-6 blockade leads to the improvement of RA and other human autoimmune disorders is not well understood. The discovery of Th17 cells sheds light on the novel function of IL-6 and helps to address the above question. Th17 cells are IL-17-producing helper T cells and IL-17 is involved in the development of several autoimmune diseases. IL-6 is an essential factor for Th17 cell development, which is one of the reasons why targeting IL-6 activities is an effective approach. In the next phase, the potential of IL-6-targeting therapies in the treatment of various autoimmune diseases will be fully clarified.

Interleukin-7

Historical Background

Interleukin (IL)-7 is a secreted soluble globular protein 25 kDa in size encoded by the IL7 gene. It was first

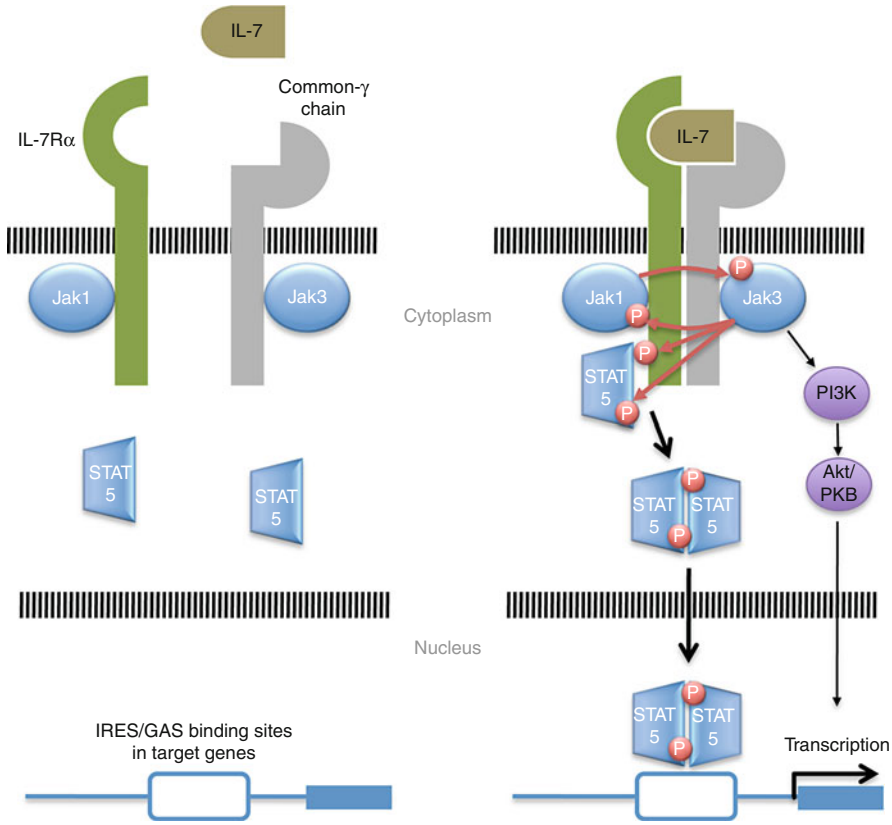
identified as a growth factor for murine B cell precursors found in the bone marrow. Other researchers found that mRNA encoding IL-7 was enriched in the thymus, the lymphoid organ in which T cells are made. Addition of recombinant IL-7 to in vitro cultures was found to promote survival and growth of thymocytes, the cells from the thymus that ultimately develop into mature T lymphocytes. These early experiments suggested that IL-7 was important for development of normal T lymphocytes in the thymus and B lymphocytes in bone marrow. The generation of genetically modified "knockout" mice, in which the IL-7 gene was specifically disrupted, ultimately confirmed these views (von Freeden-Jeffry et al. 1995). While these IL-7 deficient mice were grossly normal in appearance, the suggested importance of IL-7 for lymphocyte development was abundantly clear. These mice were virtually devoid of B lymphocytes and had greatly reduced numbers of T cells, but as will be discussed below, the highly distinctive phenotype of these mice revealed a number of other important functions of IL-7 in the immune system.

IL-7 Signaling

IL-7 belongs to a family of cytokines, termed the common gamma (γ)-chain family of cytokines (Rochman et al. 2009), that includes IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. These cytokines have been grouped in this way because their cell-surface receptors are either dimeric or trimeric complexes that all share a common component – the common γ chain (γc, CD132) of the high affinity IL-2 receptor. The IL-7 receptor is a heterodimeric complex consisting of the IL-7Rα chain (CD127), encoded by the gene IL7R, and the common γ chain, encoded by IL2RG. These two receptor components do not themselves have intrinsic enzymatic signaling properties. Signaling through the receptor complex is rather mediated by their association with members of the Janus kinase (JAK) family of non-receptor tyrosine kinases (Fig. 1). IL-7Rα is associated with JAK1, while the common γ chain is associated with JAK3. Binding of IL-7 to IL-7Rα promotes the heterodimerization of IL-7Rα and the common γ chain, thereby bringing the associated JAK1 and JAK3 kinases together (Fig. 1). JAK3 activates JAK1 and also phosphorlyates tyrosine docking sites on the cytoplasmic tail of IL-7Rα. This allows the recruitment of the transcription factor Signal transducers and activator of transcription (STAT)-5 to the IL-7Rα, where it is activated by tyrosine phosphorylation by the JAKs. Inactive STAT5 is monomeric. However, phosphorylation by JAKs promotes the homodimerization of STAT5 to become transcriptionally active. Active STAT5 dimers translocate to the nucleus and regulate expression of a wide range of genes, including those important in cell survival and cell division, such as Bcl2, Bcl-xL and members of the cyclin family. The serial activation of JAK kinases and STAT proteins is a signaling mechanism common not only to γ chain family members but also many other important cytokines and hormones, both in the immune system and other organ systems in the body (Shuai and Liu 2003). The well-characterized gene targets of activated STAT5 provide important insights into the cellular consequence of IL-7 signaling. Bcl-2 and Bcl-xL are anti-apoptotic factors that promote cell survival, while expression of cyclins is an essential step in cell cycle progression. Thus, in simple terms, IL-7 signaling is therefore expected to stimulate cell survival and cell division, as suggested by early studies describing IL-7 as a growth factor.

As well as activating the classical JAK-STAT signaling pathway, phosphorylation of the IL-7Rα cytoplasmic tail is also thought to allow recruitment and activation of Phosphoinositide 3-kinase (► PI3K). This kinase phosphorylates phosphoinositides (PIs), phospholipid components of the cell membrane, which in turn provide recruitment sites for proteins with pleckstrin homology (PH) domains. Phosphoinositide-dependent protein kinase 1 (PDK1) and Akt (also known as PKB) are kinases with PH domains that are recruited following PI3K activation. Importantly, PDK1 activates Akt. Akt is a serine/threonine protein kinase that has potential to regulate multiple cellular processes, including cell growth, glucose metabolism, apoptosis, cell division, and cell migration. Thus, activation of PI3K by IL-7 is known to be essential for cell growth and glucose metabolism, but not survival, of T lymphocytes.

An additional layer of complexity to IL-7R signaling that must also be considered is that the IL-7Rα chain is not exclusive to the IL-7R heterodimer complex. Interestingly, IL-7Rα can also couple with another membrane protein, TSLPR, to form a receptor for another cytokine, thymic stromal lymhopoietin (TSLP). While TSLP has distinct functions to IL-7,

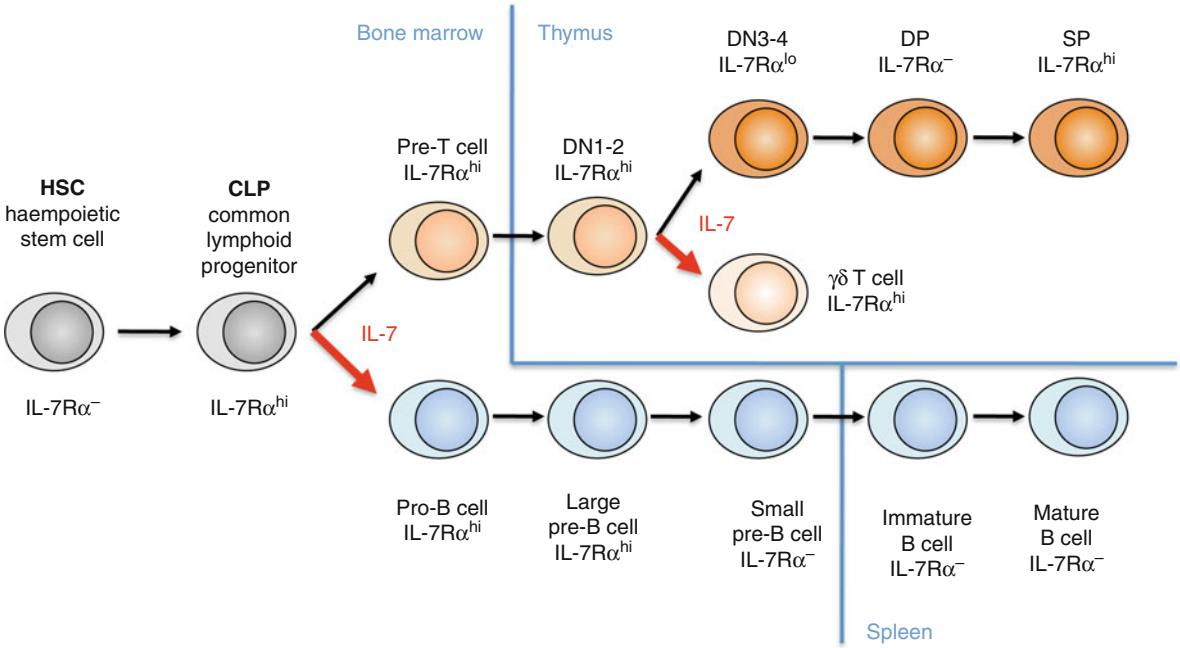


IL7, Fig. 1 Activation of the IL-7R complex by IL-7 binding

there are some instances, such as B-cell development in humans, in which TSLP shares a common function with IL-7, and is in fact even more important than IL-7 in supporting cell survival and development.

Developmental Functions of IL-7

Insights into the cellular roles of IL-7 can be made by examining where, and by which cells, the cytokine is made, and also by examining cells expressing the IL-7Rα chain that are in turn the targets of IL-7 activity. Studies of bone marrow chimeras, in which the complete bone marrow stem cell compartment of IL-7 knockout mice was replaced by normal bone marrow stem cells, revealed that such bone marrow transplantation could not cure the defects evident in IL-7 knockout mice. Conversely, similar chimeras in which normal mice had their bone marrow stem cells replaced with those from IL-7 knockout mice had none of the defects and problems inherent in the IL-7 knockout strains. These experiments clearly demonstrated that IL-7 is not produced by haematopoetic cells but must be produced by a stromal cell of mesenchymal origin. Recent studies have more clearly identified the cellular sources of IL-7 by generating mouse strains in which a specific reporter protein, in this case human CD25, is expressed from within the IL-7 gene locus (Repass et al. 2009). These studies show that IL-7 is indeed produced in the liver and small intestine, and is most highly expressed in the lymphoid organs of bone marrow, thymus, and lymph nodes (LNs). The cells that express IL-7 in these lymphoid organs are stromal cell components that also contribute to the formation of the three-dimensional framework of these organs. Thus, the significant sites of IL-7 production are also the organs in which lymphocytes are generated and where they reside as mature cells. The thymus is the organ in which T lymphocytes develop, while LNs are home to mature T and B lymphocytes and are the organs in which immune responses are initiated. The bone marrow is the main site of hematopoesis, in which pluripotent hematopoietic stem cells (HSCs) develop into all the different blood cell types.



IL7, Fig. 2 IL-7 signaling influences lineage decisions during lymphoid development. DN $CD4^{-}CD8^{-}$ double-negative thymocyte, DP $CD4^{+}CD8^{+}$ double-positive thymocyte, *SP* single-positive thymocyte

During the process of hematopoesis, HSCs develop into one of two main lineages – myeloid and lymphoid. Myeloid lineages include red blood cells, platelets, and cells of the innate immune system such as macrophages, monocytes, dendritic cells, eosinophils, and basophils. The lymphoid lineages include T lymphocytes, B lymphocytes, and NK cells. IL-7 plays an important role throughout the process of hematopoiesis, helping progenitors to make lineage fate decisions (summarized in Fig. 2). Researchers have made much progress in identifying bone marrow progenitor populations at different stages of hematopoiesis by their cell-surface phenotype. While there remains some controversy over the identity of the earliest lymphoid progenitor cell, the so-called common-lymphoid progenitor is in part characterized by its expression of IL-7Rα, and IL-7 signaling is thought to be important for lymphoid lineage specification, and in particular directing cells toward a B-lymphocyte fate in preference to a T-lymphocyte fate (Dias et al. 2005). While mature B cells do not express the IL-7R and therefore have no need for IL-7, developing B cells do express the receptor and require IL-7 for their growth, proliferation, and development.

Lymphoid progenitors destined to develop into T lineage cells leave the bone marrow and migrate to the thymus, another major site of IL-7 production. The thymus gives rise to numerous lymphoid lineages, including NK cells, γδ T cells, and the various αβ T lymphocyte lineages: CD4 T cells, CD8 T cells, regulatory T cells, and NK T cells, amongst others. IL-7 signaling in developing thymocytes influences lineage fates and cellular development. Pre-T thymocyte progenitors entering the thymus lack expression of CD4 and CD8 molecules and are termed double negative (DN). DN cells can be further subdivided into four populations (DN1-4) on the basis of expression of two markers, CD44 and CD25. Development of γδ T cells from DN2 thymocytes is absolutely dependent on IL-7, and strong IL-7 signaling is thought to specifically favor γδ T-cell development over αβ T cells (Riera-Sans and Behrens 2007). However, even in αβ T-cell development, IL-7 is essential as it provides both survival and proliferative signals to developing DN3 and DN4 thymocytes while they rearrange their T-cell antigen receptor (TCR) genes to generate mature TCRs. Crucially, thymocytes must test their newly generated TCR to ensure it is functional. This is achieved by up-regulating both CD4 and CD8 co-receptors to become double positive (DP), at which point DPs undergo the process of positive selection, in which only thymocytes with functional TCRs

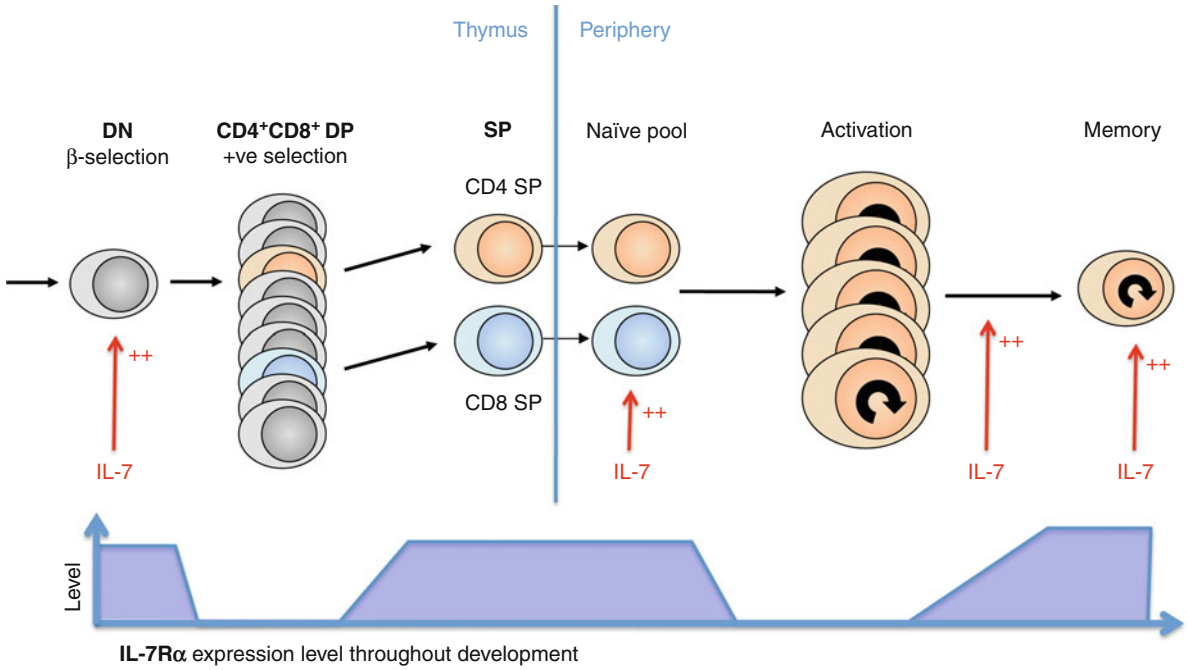
can survive and continue to develop into mature T lymphocytes. The criteria for a functional TCR are that it has the capacity to weakly recognize major histocompatibility complex (MHC) proteins on thymic epithelial cells. This proves to be the case for only a small minority of DP thymocytes, approximately 5%. It is therefore very significant that at the DP stage of thymocyte development, thymocytes completely lose IL-7R function. Doing so ensures that continued survival and development of thymocytes is entirely determined by their ability to successfully pass the stringent positive selection check point. This represents another important function of IL-7 during T lineage development, albeit a negative one. IL-7 signaling is essential throughout lymphoid development. However, loss of IL-7R function ensures that continued development depends solely on the generation of a functional and useful TCR and, therefore, ensures that the peripheral repertoire of T cells is mostly composed of cells with useful TCRs.

Interestingly, mice and humans have evolved different mechanisms to inactivate IL-7R signaling. In mice, loss of IL-7R function is achieved by the near complete loss of IL-7Rα surface expression coupled with high expression levels of suppressor of cytokine signaling (► SOCS) proteins that inhibit cytokine signal transduction. In contrast, human thymocytes express entirely normal levels of IL-7Rα but rather lose expression of STAT5 protein, the transcription factor target of IL-7 signaling. The fact that mice and humans have evolved different mechanisms of abating IL-7 signaling during thymic development may be viewed as an example of convergent evolution and may, therefore, represent a relatively recently evolved optimization of thymic selection. Cells that successfully pass the test of positive selection continue development to either CD4 or CD8 lineage T cells. DP thymocytes that successfully undergo positive selection by Class I MHC molecules lose expression of CD4 and become CD8 single positive (SP) thymocytes, while positive selection by Class II MHC induces commitment to the CD4 lineage and loss of CD8 expression so that cells become CD4 SP. In both cases, IL-7 function is restored in SP thymocytes, and mature T cells all express functional IL-7R. Thus, not only does IL-7 play a crucial role for development of both T and B lymphocytes, it is also important in determining the direction that developing progenitor populations take during the development of these lymphocyte lineages.

The analysis of IL-7 deficient mice revealed another developmental role for IL-7, but one which has only recently begun to be understood. In addition to its characterized role in the lymphopoiesis, IL-7 is also essential for normal organogenesis of secondary lymphoid structures. IL-7-deficient mice have extremely small LNs, and other lymphoid structures, such as the Peyer's patches that are located in the gut, are absent. While it was initially thought that the reduced LN size was merely secondary to the reduced numbers of lymphocytes in these mice, closer investigation revealed that the non-lymphocyte cellular structures that form the LNs were in fact defective. During embryonic development, LN structures actually form prior to development and generation of mature lymphocytes that only later populate the mature LNs. Formation of these early LN anlagen is initiated by the aggregation of so-called LN inducer (LNi) cells at the site of future LNs. These cells are hemopoetic in origin and express IL-7Rα. They, in turn, recruit a second population of cells, LN organizer (LNo) cells that are of non-hemopoetic mesenchymal origin. A final stage of LN formation occurs after population with mature lymphocytes. In IL-7-deficient mice, these structures initially form normally but fail to develop into normal LNs after birth, and it appears that IL-7 signaling either in the LTi or newly generated T cells that colonize the LNs is required for the final stage of LN formation (Repass et al. 2009).

Control of Homeostasis and Function of Mature Naïve T Cells by IL-7

Although vital for their generation in the bone marrow, mature B lymphocytes do not express IL-7R. Their survival and maintenance is rather dependent on tonic signaling processes through the B-cell antigen receptor and cytokines such as BAFF. In contrast, all αβ T-lymphocyte populations express IL-7R, suggesting it plays a continuing role in their function (Fig. 3). Mature peripheral T lymphocytes largely reside in what are termed the secondary lymphoid organs, which are comprised of LNs and the spleen. To understand why lymphocytes reside in secondary lymphoid organs and why this is important for the function of IL-7, it is important to understand the role of LNs and



IL7, Fig. 3 Control of T-cell homeostasis by IL-7 and its regulation through expression of IL-7Rα

the lymphatic system in the function of the immune system. Lymphatic vessels, similar in structure and size to veins that carry blood back to the heart, provide fluid drainage from all peripheral tissues, such as the skin and intestine. The system of lymphatics resembles the tributaries of a river as many smaller vessels merge to form larger vessels, which ultimately combine to a single lymphatic vessel in the thorax which drains, via the thoracic duct, directly into the left brachiocephalic vein. The progress of these lymphatic vessels from tissues to thoracic duct is not uninterrupted however. At major junction points in the neck, under the arms and in the groin, the lymphatic vessels swell to form spherical nodular structures that are the LNs. Lymphatic vessels draining into the LNs are termed afferent, while those that connect the LNs ultimately to the thoracic duct are termed efferent. In the event of an infection in the tissues or at mucosal sites such as the gut or respiratory tract, the lymphatic system provides conduits to transport antigens and antigen-bearing immune cells from the site of infection to the nearest LN. The spleen serves a similar purpose but for blood-born antigens rather than those from tissues. Once in the LN, the high concentration of lymphocytes present greatly increases the chances that a T or B cell that can recognize the pathogen will do so and initiate an immune response. Mature T cells that have not previously encountered antigen and been activated are termed "naïve," while T cells that have previously taken part in an immune response are termed "memory." Naïve T cells are the raw material of the adaptive immune system, and it is essential to maintain a large and diverse repertoire of these cells in order to ensure an effective immune response against new pathogens. Researchers studying the mechanisms by which the naïve T-cell repertoire is maintained at an optimal condition soon noticed that the total number of T cells is maintained at a constant level, both in humans and in laboratory rodents. This is somewhat remarkable when one considers that the pool of naïve T cells is extremely dynamic in its behavior. New T cells are continually generated by the thymus but not in a consistent manner as thymus size is reduced with age. Furthermore, naïve T cells are also lost as a consequence of being activated to generate memory cells. So despite the unpredictable and changing dynamics, the size of the naïve T-cell pool is largely the same throughout life, revealing that there must be strict homeostatic mechanisms to regulate the overall size of the T-cell pool.

Like other cells in the body, lymphocytes require specific signals to actively keep them alive. In the

absence of such signals, cells undergo the process of controlled cell death, known as apoptosis. All naïve T cells express IL-7R, and IL-7 is one of several essential signals required for the long-term survival of these lymphocytes. Within the lymphoid system, naïve T cells are not static but rather actively migrate around LNs seeking antigen, and also recirculate via efferent lymphatic vessels to the blood and, thence, to other LNs or the spleen. IL-7 is produced by stromal cells in LNs but is also detectable in high concentrations in the fluid in efferent lymphatics and in serum of blood. Naïve T cells are therefore constantly exposed to IL-7 during their recirculation through the blood and lymphatic system, providing them with the constant signal that they require to prevent them from undergoing apoptosis.

In providing survival signals to naïve T cells, IL-7 plays a key role as a master regulator of the size of the naïve T cell pool. Although the thymus is constantly generating new cells, this does not appear to be the limiting factor in setting the size of the naïve T-cell pool. This is particularly evident in experiments analyzing mice that can only make one of either CD4 or CD8 lineage T cells. In normal conditions, there are approximately two CD4 T cells for every one CD8 T cell. However, in mice that cannot make CD4 T cells, the total number of naïve T cells, all of which are CD8, is much the same as the total number of naïve T cells in normal mice, which comprise both CD4 and CD8 lineages. This is the case, even though the rate of CD8 T-cell production by the thymus remains unchanged regardless of whether CD4 T cells are produced or not. Thus, the space created by the absence of CD4 T cells is filled by more CD8 lineage cells. For similar reasons, mice that cannot make CD8 T cells also have normal T-cell numbers, but are all CD4 lineage. This ceiling on total naïve T-cell numbers is set by the amount of IL-7 available. Experimental mice that have artificially elevated IL-7 levels also have larger T-cell pools. Therefore, IL-7 is controlling T-cell homeostasis by its requirement as a survival resource. If there are too many T cells in an individual, they will not all get sufficient access to IL-7 signals and some will die, until the numbers of T cells reach a level that can be sustained by the amount of IL-7 available. As well as promoting T-cell survival, IL-7 signaling can also promote cell division, another property that lends itself well to the homeostatic role of this cytokine. In conditions of T-cell deficiency, as occurs in HIV-infected individuals or following radio- or chemo-ablative therapies, naïve T cells can sense the "space" in the T-cell compartment and start to undergo cell divisions in an effort to restore normal T-cell numbers. This response is highly dependent on IL-7 signaling. Such cell division is particularly important in humans, where recently generated naïve T cells undergo several cell divisions even in a normal individual (Jameson 2005).

IL-7 is thought to be produced at a constant rate by stromal cells in lymphoid organs. Whether these cells can dynamically regulate production in specific situations to modify T-cell homeostasis, for instance, during an immune response, is not at present known. However, the dependence on IL-7 for naïve T-cell survival goes a long way toward explaining how the immune system solves a difficult homeostatic problem. The size of other organs in the body, such as the kidneys, the liver, and the brain are controlled through strict regulation of developmental processes. In contrast, T cells do not reside in any one place but are spread throughout the body and undergo dynamic changes in their rates of production and loss throughout life. The reliance on a fixed resource such as IL-7 explains how the T-cell pool can be so precisely regulated to prevent over- or underpopulation.

Memory Formation and Persistence

During an immune response, T cells that recognize specific antigen become activated, undergoing cell division and developing specific effector functions such as cytokine secretion for CD4 T cells and development of cytolytic activity in the case of CD8 T cells. Following T-cell activation, T cells rapidly lose expression of IL-7R. Maintenance of IL-7R expression in peripheral T cells is dependent on the activity of the ▶ Foxo1 transcription factor (Kerdiles et al. 2009). The activity of Foxo transcription factors is negatively regulated by their phosphorylation by Akt. TCR stimulation by antigen activates the PI3K pathway, resulting in activation of Akt and, therefore, causes loss of IL-7Rα expression by the repression of Foxo1 by Akt. An ongoing immune response represents a scenario that is analagous to thymic selection (Fig. 3). During such a response, the presence of antigen is a key determinant of T-cell behavior, inducing proliferation and differentiation. For an effective

immune response, it is important that a large number of effector T cells is quickly generated. Therefore, it makes sense to uncouple effector T cells from the shackles of normal T-cell homeostatic control by IL-7, and switch to autocrine-regulated T-cell proliferation by factors such as IL-2, synthesized by T cells following their activation by antigen. IL-2 is also a potent inhibitor of IL-7Rα expression, which may be mediated by similar mechanisms as TCR signaling since IL-2 strongly activates PI3K. However, similar to thymic positive selection, it is important that differentiation of T cells is strictly dependent on continued TCR signaling, and not IL-7, since persistence of the immune response should be closely allied to the ongoing presence of antigen to indicate the need for the response. This is very neatly achieved through the direct repression of IL-7Rα expression by antigen-dependent PI3K activation. Following the resolution of a successful immune response, most effector cells will undergo apoptosis. However, some survive to become long-term memory cells, a key feature of the adaptive immune system. IL-7 signaling plays a key role in the formation of this memory population. In the absence of antigen, TCR signaled repression of IL-7Rα expression is reversed, and effector T cells can start to reexpress IL-7Rα. In some experimental viral infections in mice, the effector cells that first reexpress IL-7Rα are the precursors of the long-term memory cells, suggesting that IL-7 could be instructing effectors to develop into memory cells. However, there is also evidence that effector T cells are far more predisposed to undergoing apoptosis than naïve or memory T cells. While reexpression of IL-7R can slow their death, the effector pool still undergoes a significant contraction because the effector cells are less able to compete and survive in response to IL-7 signaling than other T cells (Buentke et al. 2006). Nevertheless, IL-7 signaling represents a key gateway into the memory T-cell pool, ensuring only the most fit effectors persist. Like their naïve precursors, both CD4 (Seddon et al. 2003) and CD8 memory T cells (Schluns et al. 2000) are dependent on IL-7 for their long-term survival, although CD8 memory cells also have a strong reliance on the cytokine IL-15. Both CD4 and CD8 memory cells express higher levels of IL-7Rα than their naïve counterparts. However, in contrast to naive T cells, memory cells can also migrate to extra-lymphoid tissue sites in order to patrol them for the presence of their specific pathogen, returning to lymph nodes via the afferent lymphatic vessels. It is unclear whether these cells can obtain survival signals in such sites as IL-7 expression is largely limited to lymphoid organs. Therefore, higher cytokine receptor expression levels may be important for these cells to gain stronger survival signals sufficient to maintain their survival whilst patrolling peripheral T tissues and before their return to lymphoid tissue for "refueling."

IL-7 and Disease

IL-7 has been implicated in a variety of different disease processes. There are several recognized severe combined immunodeficiencies (SCID) that arise from mutations in either the human IL7 or IL7R genes that affect production of IL-7 or signaling through IL-7R. Such patients have a phenotype similar to that described for IL-7 deficient mice, although one notable difference is that human B cells are less reliant on IL-7 than mouse B cells, and there appears to be some redundancy with TSLP. Therefore, IL-7RA mutations are more severe than IL-7 mutations. Given the potent survival and proliferative properties of IL-7, it is unsurprising that mutations in the IL7 gene are also implicated as susceptibility factors in certain T cell acute lymphoblastic leukemias (T-ALL), and experimental work has shown that IL-7 can accelerate disease progression of T-ALL transplanted into mice. In addition, there is evidence to suggest IL-7 may be involved in development of some autoimmune diseases. A recent genetic linkage study identified a point mutation in a noncoding region of the IL7R gene as strongly associated with development of multiple sclerosis (Gregory et al. 2007). Furthermore, recent experiments suggest that IL-7 signaling may exacerbate the T-cell mediated autoimmune process that is thought to contribute to the nerve damage in the disease.

IL-7 is also under consideration as a potential therapeutic. In HIV patients with active disease, reduction in T-cell counts is often accompanied with raised serum levels of IL-7, probably secondary to the reduction in T-cell numbers. However, IL-7 treatment has been tested in patients to see whether it could aid immune reconstitution in HIV patients with dwindling T-cell numbers. In some cases, a relatively short treatment with IL-7 was able to produce lasting increases in T-cell numbers. The potential for immune reconstitution by IL-7 is also considered in the context of aging.

In humans, maximal thymic productivity is reached very early, at about 1 year of age, after which the thymus undergoes gradual atrophy, producing ever-decreasing numbers of T cells. Homeostatic mechanisms like those discussed earlier are successful in maintaining a diverse T-cell repertoire until old age, when there appears to be a sudden collapse in T-cell diversity. The lack of new thymically generated T cells is thought to be a contributing factor. One of the causes of thymic atrophy is a loss of IL-7 production by thymic stromal cells. Administering IL-7 to mice can successfully overcome some of the effects of reduced IL-7 production locally in the thymus. Therefore, immuno-reconstitution by IL-7 treatment is starting to be considered, at least for some specific conditions.

Summary

In conclusion, it is evident that IL-7 has a broad array of biological functions. It is vital for development of nearly all lymphoid lineages, but also has a role to play in controlling the lineage decisions at different stages of progenitor differentiation. The absolute number of mature T cells that an individual has is critically dependent on IL-7 availability, and all the mature subsets and lineages of T cells have at least some reliance on IL-7 for their survival. Even the absence of IL-7 signaling has a fundamental role to play in shaping the T-cell repertoire and memory populations. One of the greatest challenges for the future will be to understand how this one cytokine can influence such a diverse range of cellular properties. Our understanding of the molecular mechanisms of IL-7 signaling remains crude, and it is unclear whether all the potential signaling pathways are activated in different in vivo situations, and if not, which ones are important for different biological outcomes. Such understanding will be essential if the potent biological properties of IL-7 are to be fully exploited clinically.

Historical Background

The IRGs are a family of proteins that play critical roles in innate immune responses to intracellular pathogens (Martens and Howard 2006; Shenoy et al. 2007; Taylor 2007). IRG cDNAs were discovered independently by several scientists who were conducting screens to identify mouse genes transcriptionally upregulated by ▶ interferon-γ and/or lipopolysaccharide (LPS). These IRGs were thus named and described piecemeal, but were later recategorized in a comprehensive study of the gene family across vertebrates (Bekpen et al. 2005). The standardized nomenclature places the proteins into subfamilies based on amino acid homology within the GTP-binding regions. IRG proteins in most subfamilies contain the canonical GKS sequence within the G1 motif in the GTP-binding region including the IRGA, IRGB, IRGC, and IRGD subfamilies. Proteins in the IRGM subfamily contain the noncanonical GMS sequence with a lysine to methionine substitution positioned in the GTP-binding pocket. IRG proteins that have received the greatest amount of study include the GKS proteins Irga6 (IIGP1), Irgb6 (TGTP), Irgb10, and Irgd (IRG-47) in the mouse, and the GMS proteins Irgm1 (LRG-47), Irgm2 (GTPI), and Irgm3 (IGTP) in the mouse, and IRGM in humans. The IRG genes are not evenly distributed across vertebrates – mice for example contain about 23 members, and humans only two – which may reflect relatively recent evolutionary events in some species to combat unique pressures from endemic pathogens.

Gene Expression

Expression of most mouse IRG genes is highly induced by interferons (IFNs), most robustly by type II IFN (IFN-γ), and more weakly by type I IFN (IFNα/β). This is a consequence of multiple γ-activated sequences (GAS) and/or interferon-stimulated response elements (ISRE) that are found in the promoters of the genes (Bekpen et al. 2005). It is notable, however, that the positions of these elements vary from gene to gene in the mouse, implying that there has been evolutionary pressure to maintain IFN-regulated expression. The transcriptional response to IFN-γ is rapid; for Irgm3, mRNA accumulates within 1 h of stimulation, reaching maximal levels within 3 h, and having a half-life of about 4.5 h (Taylor et al. 1996). Irgm3 protein accumulates within 3 h of induction and reaches maximal levels within 8 h that does not decrease in the continued presence of IFN-γ. The induction by IFN has been noted in a wide variety of tissues and cell types. Although IRG genes are also induced by LPS, this is thought to be an indirect response resulting from LPS-induced production of type I IFN that then acts autocrinely. In contrast, a variety of other cytokines do not induce expression of IFN-regulated IRG genes, underscoring the specificity of IFN in controlling expression of these genes (Sorace et al. 1995).

Despite the dominant role of IFN, control of IRG gene expression by IFN is not absolute. There are some IRG genes that are not induced by IFNs: These include mouse Irgc and human IRGC that are constitutively expressed in testes, and human IRGM that is constitutively expressed in several cell types (Bekpen et al. 2005). In addition, among those IRG that are regulated by IFN, there is evidence for basal, constitutive expression, including that for Irga6 in liver (Zeng et al. 2009).

Biochemical Properties

IRG proteins can be placed functionally within the larger dynamin protein superfamily (Praefcke and McMahon 2004). Dynamins are large GTPases that have a high affinity for lipid membranes, on which they are able to self-assemble into structures that are thought to contract in a GTP-dependent manner and mechanically alter the membranes. Dynamins are therefore distinct from the smaller Ras-like GTPases, in which the guanine nucleotide moiety functions as a biochemical switch to place the protein in an active state when GTP bound, and then in an inactive state when hydrolyzed to GDP. In contrast, dynamins are "mechanochemical" enzymes, with the energy released by the hydrolysis of GTP to GDP inducing conformational changes in the protein oligomers that drive overall protein function. Through their ability to disrupt and distort membranes, dynamins have been implicated in many cellular processes, including vesicle formation and transport, organelle division, cytokinesis, and cell motility. Two other families of IFN-regulated GTPases – the guanylate-binding proteins (GBP) and the Mx proteins – are also functionally related to dynamins (Martens and Howard 2006).

The abilities to bind and hydrolyze GTP to GDP have been confirmed for IRG proteins (Taylor et al. 1997; Uthaiah et al. 2003). Overall affinities for GTP and GDP, however, vary among IRG proteins. For instance, Irgm3 is largely GTP bound, while Irga6 has a higher affinity for GDP. These differences may or may not stem from the unique GMS sequence found in the Irgm3 GTP-binding pocket as previously discussed. Currently, no GTPase-activating proteins (GAPs) or guanine nucleotide exchange factors (GEFs) have been identified for IRG proteins.

IRG proteins, like other dynamins, have been shown to localize strongly to various cellular membranes, including the Golgi and endoplasmic reticulum, through different localization moieties (Martens et al. 2004; Taylor et al. 1997). For example, Irga6 is largely ER-localized through an N-myristoylation motif; Irgm1 localizes to the Golgi and late lysosomes through an amphipathic helix near its C-terminus; Irgm2 and Irgm3 target the Golgi and ER, respectively, through helices analogously placed within the protein though not amphipathic; and human IRGM targets mitochondria, though targeting motifs have not been identified (Singh et al. 2010). Where tested, targeting to these membranes does not appear to be dependent on GTP hydrolysis. However, many IRG proteins also target the membranes of phagosomes containing certain pathogens, with the targeting of these membranes requiring GTP hydrolysis. Like other dynamins, IRG proteins have been shown to self-assemble, both into homotypic complexes as shown in in vitro assays using purified protein, as well as into heterotypic complexes with other IRG proteins as determined by pull-down, co-immunoprecipitation, and yeast two-hybrid studies (Hunn et al. 2008). The requirement for GTP hydrolysis in order to target phagosomal membranes suggests that the IRG proteins probably exist in oligomeric complexes on these membranes, and in fact, data suggest that there is a distinct temporal order to which various IRG proteins assemble on the phagosomal membrane (Khaminets et al. 2010).

Functions in Innate Immunity

The creation and analysis of mice lacking IRG proteins – Irgm1, Irgm3, Irgd, and Irga6 – have established the prominent role that the GTPases play in innate immunity to multiple intracellular pathogens (Al-Zeer et al. 2009; Collazo et al. 2001; Henry et al. 2007; MacMicking et al. 2003; Taylor et al. 2000). The clear but distinct phenotypes of the IRG-deficient mouse strains have also emphasized that the genes are nonredundant and of varying importance depending on the pathogen.

Many studies have focused on the role for IRG proteins in resistance to *Toxoplasma gondii*. Mice lacking Irgm1 or Irgm3 demonstrate acute susceptibility to this protozoan parasite, on par with the susceptibility in IFN-γ-deficient mice, thus suggesting an essential role for the Irgm proteins in IFN-γ-induced resistance. In contrast, Irgd- and Irga6-deficient mice demonstrate weak susceptibility that becomes manifest later during the infection, implying a generally weaker role for GKS IRG proteins. The role of the IRGs in resistance is tied to their ability to provide cell autonomous resistance to *T. gondii*: Macrophages or astrocytes that lack IRG proteins demonstrate varying degrees of impaired IFN-γ-induced *T. gondii* killing activity (Butcher et al. 2005). Data from several studies have suggested a model in which GKS IRG proteins load onto the *T. gondii* vacuole, where they drive vesiculation of that vacuole, releasing the parasite into the cytosol of the cell where it is destroyed (Ling et al. 2006; Zhao et al. 2009). GMS IRG proteins do not load to the same extent on the vacuole; rather, they regulate the GKS proteins. In the absence of the GMS IRG proteins, the GKS IRG proteins form aberrant aggregates and are consequently unable to load as efficiently onto *T. gondii* vacuoles (Hunn et al. 2008). Absence of even one of the three mouse GMS IRG proteins leads to altered positioning of most or all of the cellular complement of GKS IRG proteins on the *T. gondii* vacuole, thus explaining the more prominent role of GMS IRG proteins, relative to that of any one GKS IRG protein, in controlling resistance to *T. gondii*. The generally pivotal function of IRGs in this context is further implicated by the fact that virulent strains of *T. gondii* have acquired the ability to phosphorylate IRGs and prevent their loading onto the *T. gondii* vacuole (Fentress et al. 2010; Steinfeldt et al. 2010).

The roles of IRG proteins in resistance to bacterial infections vary somewhat with those in resistance to *T. gondii* or other protozoa. Irgm1-deficient mice display increased susceptibility to a wide range of intracellular bacteria including *Listeria monocytogenes, Salmonella typhimurium, Mycobacterium tuberculosis,*

Mycobacterium avium and *Chlamydia trachomatis* (Taylor 2007). In contrast, Irgm3-deficient mice have increased susceptibility to only *C. trachomatis*, and the Irgd- or Irga6-deficient mice have little or no increased susceptibility. Irgm1, therefore, plays a particularly important role in bacterial resistance, and may well possess function(s) not shared with the other mouse IRG proteins. Similarly, not only does the closest human homologue of Irgm1, IRGM, play a role in resistance to *M. tuberculosis*, but polymorphisms in the IRGM gene have been linked with susceptibility to *M. tuberculosis* infection (King et al. 2011) and to Crohn's disease (McCarroll et al. 2008). While the mechanism through which Irgm1 and IRGM regulate resistance to bacteria has yet to be clearly defined, there is no evidence to suggest that the GTPases regulate vesiculation of bacterial phagosomes, as is the case with *T. gondii*; rather, accumulating evidence supports a role in regulating autophagy and mitophagy, and removal of bacteria through these pathways (Singh et al. 2006, 2010). Along these lines, regulation of autophagy also leads to the ability of Irgm1 to modulate T cell homeostasis during infection (Feng et al. 2008). In addition, other cellular functions that have been suggested for Irgm1 – including regulating acidification and/or lysosome fusion of the bacterial phagosome (MacMicking et al. 2003) and controlling motility of macrophages (Henry et al. 2010) – may well be manifestations of its ability to control autophagy.

Summary

IRGs are critical mediators of interferon-γ-mediated resistance to a variety of important intracellular pathogens. The family is part of the larger dynamin protein superfamily, as a consequence of its member's GTPase function, affinity for lipid membrane compartments, and ability to modulate those membranes. Two major subcategories of IRGs exist: the GMS and GKS IRGs. The GMS IRG proteins appear to play a more important role in innate immunity, as evidenced by the more striking susceptibility of Irgm-deficient mice to a variety of intracellular pathogens. The exact mechanisms whereby IRG proteins mediate immunity are not fully defined, but include their ability to vesiculate the membranes of vacuoles that contain *T. gondii*, and to promote autophagy in several contexts. Given the large number of important pathogens to which the IRG family confers immunity, the study and understanding of these proteins has significant consequences for human health.

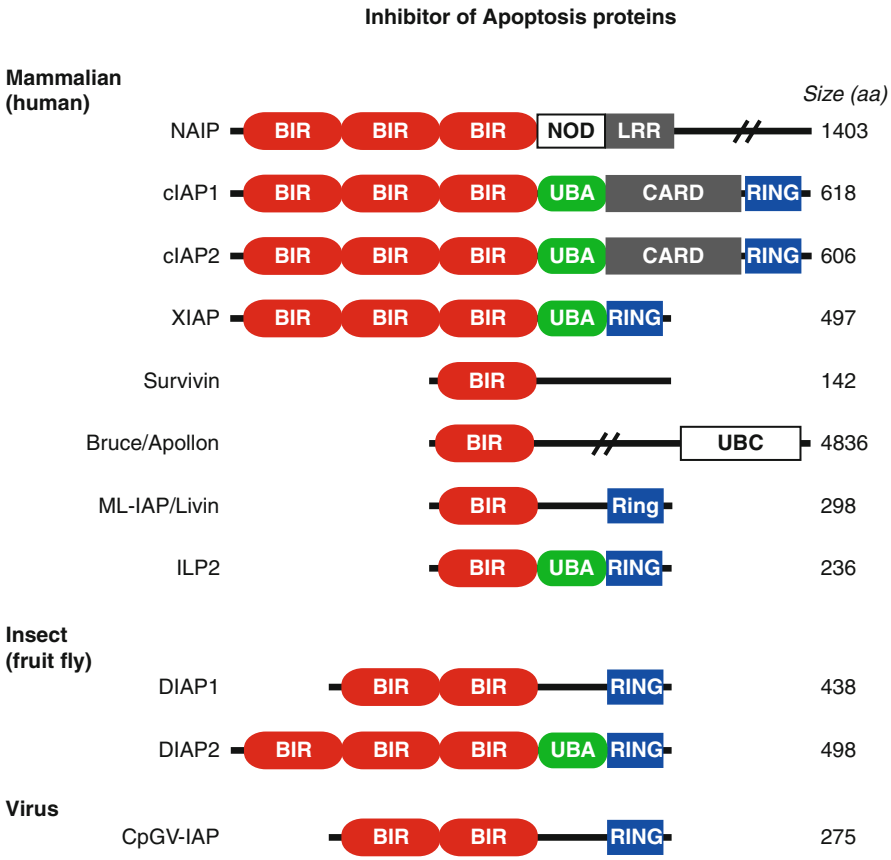
Inhibitor of Apoptosis (IAP) Proteins

Mads Gyrd-Hansen
Novo Nordisk Foundation Center for Protein Research, University of Copenhagen, Copenhagen, Denmark

Historical Background

Inhibitor of apoptosis (IAP) proteins were identified in 1993 in a cDNA-based screen for baculovirus genes that prevent the induction of apoptosis in *Spodoptera frugiperda* SF-21 insect cells after viral infection (Crook et al. 1993). *iap* genes were found in other baculoviruses, and further analysis of these IAP proteins led to the identification of their functional domains, namely, two baculovirus IAP repeat (BIR) domains and a C-terminal C3HC4-type Zn-finger, which is now known to be a *r*eally *i*nteresting *n*ew *g*ene (RING) domain (Vaux and Silke 2005) (Fig. 1).

In 1995 and 1996, the first IAPs were identified in insects and mammals, and based on the definition that BIR-containing proteins are designated as IAP proteins, eight IAPs are encoded in the human genome (Fig. 1). Most IAPs harbor several functional structural domains in addition to the BIR domains, and it is



Inhibitor of Apoptosis (IAP) Proteins, Fig. 1 *Schematic representation of IAP proteins*. The number of residues in each IAP as well as the functional motifs that they contain is shown. NAIP, survivin, BRUCE, ILP2, and ML-IAP are shown in this figure, but are not discussed in detail. In addition to DIAP1 and DIAP2, orthologues of survivin and BRUCE are also encoded in the genome of fruit flies (*Drosophila melanogaster*). Domain abbreviations used are as follows: *BIR* baculovirus IAP repeat, *UBA* ubiquitin-associated, *CARD* caspase-associated recruitment domain, *UBC* ubiquitin-conjugation, *NOD* nucleotide-binding oligomerization domain, *LRR* leucine-rich repeats

therefore not surprising that individual IAPs serve distinct biological functions. This entry will primarily go through what is currently known about three IAP proteins, cIAP1 (also termed BIRC2, MIHB, API1, and RNF48), cIAP2 (also termed BIRC3, MIHC, API2, and RNF49), and XIAP (also termed BIRC4, MIHA, API3, hILP, and XLP2), that are structurally related and share functions important for cellular signaling processes (Srinivasula and Ashwell 2008; Vaux and Silke 2005).

IAP Structural Domains

As mentioned above, the defining feature of an IAP protein is the presence of one or more BIR domains and mammalian IAPs contain either one or three copies. cIAP1, cIAP2, and XIAP all have three BIRs and a C-terminal RING domain (Fig. 1). In addition, they comprise an *ubi*quitin-*a*ssociated (UBA) domain, and cIAP1 and cIAP2 also contain a *c*aspase-*a*ssociated *r*ecruitment *d*omain (CARD). BIR domains are ca. 70 amino acids in size and mediate protein-protein interaction with partners that contain an IAP-binding motif (IBM) as well as other non-IBM-type protein interactions. IBMs are four amino acid motifs starting with an exposed N-terminal alanine. IBMs have been described in several proteins including the processed forms of the mitochondrial factors Smac/DIABLO and Omi/Htr2A and in cleavage-activated caspases. Through their RING domains, IAPs interact with ubiquitin-conjugating enzymes (E2s) and facilitate the transfer of activated ubiquitin from the bound E2 to lysine residues on target proteins (ubiquitylation). The UBA domain enables IAPs to directly interact with polyubiquitylated proteins (Gyrd-Hansen and Meier 2010). The CARD functions as a self-regulatory domain by keeping cIAP1 in a monomeric state, thus limiting its ubiquitin ligase activity (Lopez et al. 2011).

IAPs in Apoptosis

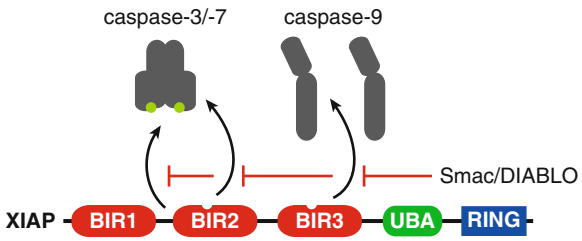
Apoptosis is executed by a family of proteases termed caspases and can be triggered by extrinsic signals such as ligands that activate death receptors on the cell surface (e.g., Fas Ligand (FasL; also known as CD95 ligand and APO-1 ligand) and tumor necrosis factor (TNF)) or by intrinsic insults including DNA damage, oncogene activation, oxidative stress, and growth factor deprivation (Meier and Vousden 2007). The extrinsic pathway leads to activation of caspase-8, which in turn activates downstream effector caspases (e.g., caspase-3 and caspase-7) either directly or via the mitochondrial apoptosis pathway. Activation of the mitochondrial pathway, which also is engaged by intrinsic insults, leads to the release of proapoptotic factors from the mitochondrial intermembrane space (e.g., cytochrome *c* and Smac/DIABLO). In the cytosol, cytochrome *c* associates with Apaf-1 and caspase-9 to form the caspase-9 activating platform, termed the apoptosome. In turn, the active caspase-9 activates effector caspases through proteolytic cleavage. The release of apoptogenic factors from the mitochondria is considered the "point of no return," and this process is tightly regulated by a network of pro- and antiapoptotic ▶ Bcl-2 family proteins including Bid, which links extrinsic signals and caspase-8 activation to the intrinsic mitochondrial pathway.

The strongest evidence that IAPs are important for regulation of apoptosis in vivo comes from studies of *Drosophila melanogaster* (fruit fly) IAP1 (DIAP1) (Ganesan et al. 2011; Orme and Meier 2009; Steller 2008). Genetic loss of DIAP1 results in spontaneous caspase activation causing widespread apoptosis and death of the embryo. Among the mammalian IAPs, XIAP is the only direct inhibitor of caspases, and overexpression of XIAP can inhibit caspase activation and apoptosis triggered by several stimuli (Eckelman et al. 2006; Srinivasula and Ashwell 2008). Conversely, cells that lack XIAP or are depleted for XIAP may become sensitized to apoptosis. Nonetheless, XIAP-deficient mice or mice expressing a truncated form of XIAP without the C-terminal RING domain are healthy and display no apparent defects, and cells isolated from these mice are not overtly sensitized to apoptosis except when treated with TNF in combination with cycloheximide (a protein synthesis inhibitor) (Gyrd-Hansen and Meier 2010). XIAP is therefore not essential for maintaining cell survival in mammals as DIAP1 is in flies, and the evidence rather suggests that XIAP modulates the apoptotic threshold under certain conditions and/or in certain cell types. This notion is supported by in vivo experiments showing that XIAP, in the absence of Bid, determines whether hepatocytes undergo apoptosis after exposure to FasL (Kaufmann et al. 2011). In wild-type mice, intraperitoneal injection of FasL results in massive apoptosis of hepatocytes in a manner that requires amplification of the caspase cascade through Bid-mediated release of apoptosis-promoting factors from the mitochondria. Bid-deficient mice are refractory to FasL treatment, but mice that are deficient for both Bid and XIAP are sensitive to FasL treatment and die from the injection of FasL akin to wild-type mice.

The inhibition of caspase activity/activation by XIAP involves different molecular mechanisms (Srinivasula and Ashwell 2008). By binding caspase-9 through its BIR3 domain, XIAP maintains caspase-9 in a monomeric inactive state. In contrast, caspase-3 and caspase-7 are inactivated primarily by the linker region immediately N-terminal to the XIAP BIR2, which fits the catalytic pocket of the active caspase in a backward orientation and blocks entry of substrates. The inhibition is, however, aided by an IBM-type interaction between BIR2 and the N-terminus of the processed caspase (Fig. 2). cIAP1 can also interact with active caspase-7 through an IBM-based interaction, but whether the BIR1-2 linker motif in cIAP1 contributes to caspase-regulation is not known.

IAPs may also regulate the activity of caspases through RING-dependent ubiquitylation (Broemer and Meier 2009; Vucic et al. 2011). The RING activity of DIAP1 is important for inhibition of caspase activity and proper regulation of cell death in the fruit fly. DIAP1 ubiquitylation of active effector caspases does not cause proteasomal degradation of the caspases but inhibits their activity. Similarly, XIAP can facilitate caspase-3 ubiquitylation in a RING-dependent manner to regulate its activity, although here the ubiquitylation is also reported to target caspase-3 for proteasomal degradation.

cIAP1 and cIAP2 are poor direct inhibitors of the catalytic activity of caspases but serve an important function in determining cell survival in response TNF receptor 1 (TNFR1) activation (Eckelman et al. 2006; Wu et al. 2007). This realization was sparked by the use of IAP-antagonistic compounds, so-called Smac



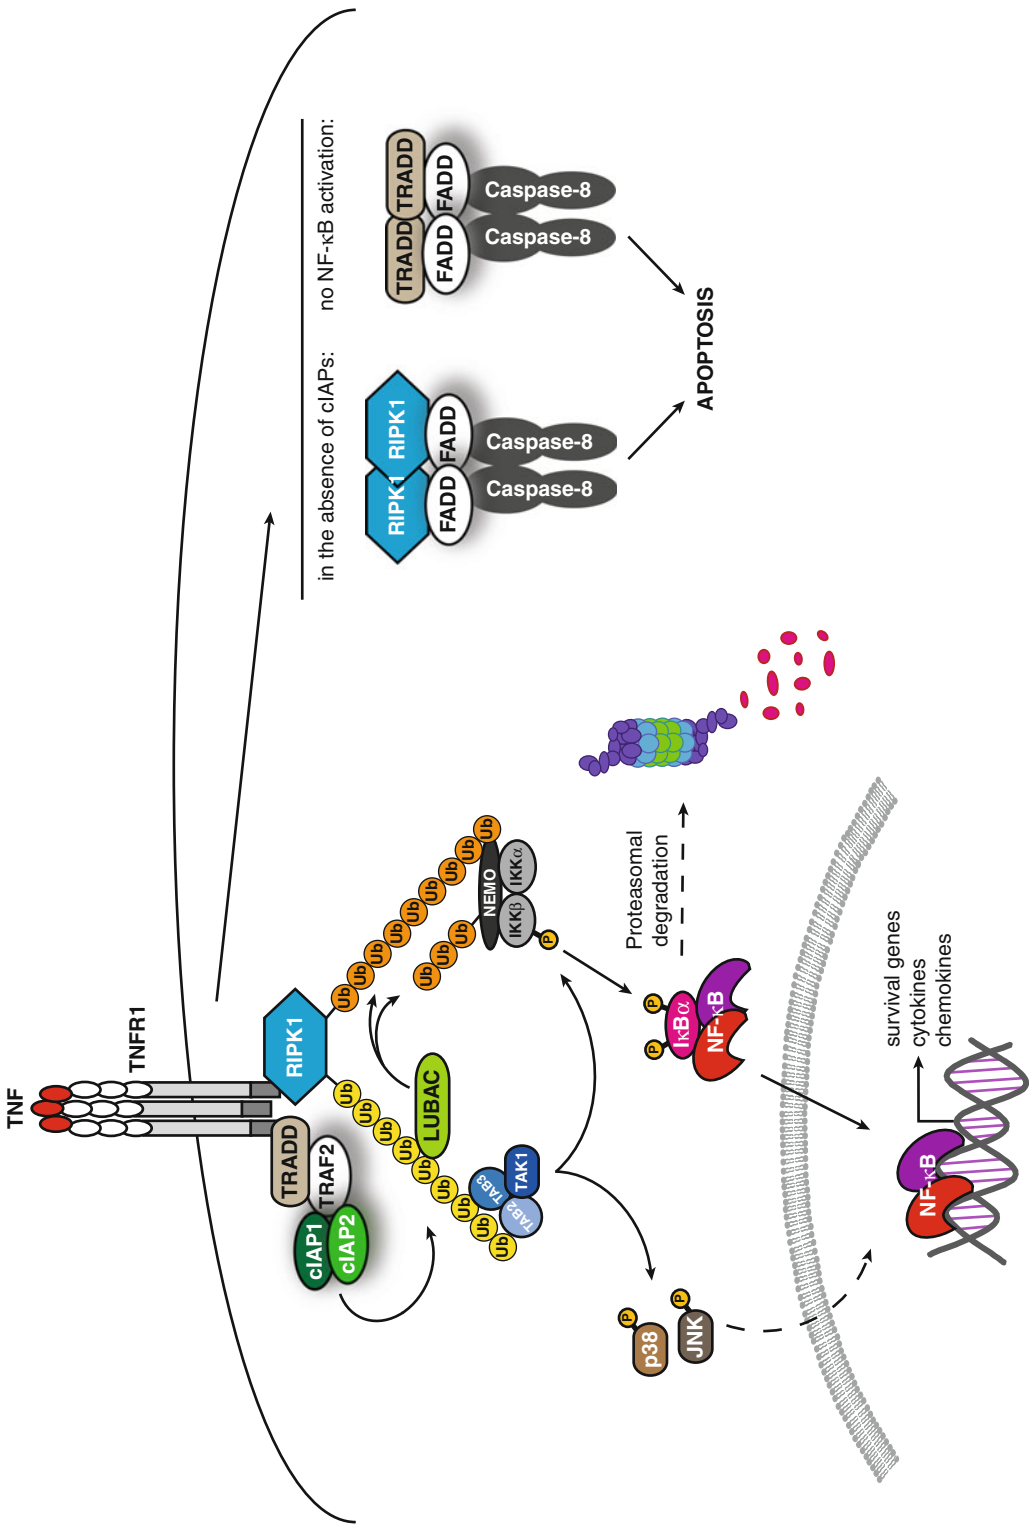
Inhibitor of Apoptosis (IAP) Proteins, Fig. 2 *XIAP-mediated inhibition of caspases*. The linker sequence between the BIR1 and BIR2 domains of XIAP occupies the catalytic pocket of caspase-3 and caspase-7 and thereby blocks substrate entry. In addition, the BIR2 domain interacts with the IBM of caspase-3 and caspase-7, which is exposed after their cleavage-mediated activation. XIAP inhibits caspase-9 activation by preventing dimerization, which is a prerequisite for initiator caspase activity. The N-terminal tetrapeptide IBM of processed Smac-DIABLO relieves caspase inhibition by competing for binding to BIR2 and BIR3. *Green circles* indicate the catalytic pocket in active caspase-3 and caspase-7

mimetics (SM), originally developed with the objective to interfere with the interaction between XIAP and active caspases and thereby render cells (in particular cancer cells) more susceptible to apoptosis. SMs mimic the structure of the Smac/DIABLO IBM (Ala–Val–Pro–Ile) and compete for binding with proteins that, like active caspases, contain IBMs (Fig. 2). SM compounds have proven effective in sensitizing cells to apoptosis (or induce cell death as a single treatment), but surprisingly, the mechanism behind this sensitization is primarily indirect and results from rapid proteasomal degradation of cIAP1 and cIAP2 rather than derepression of caspases (Vucic et al. 2011; Wu et al. 2007). From the use of SM compounds, cIAPs were found to prevent spontaneous activation of the so-called non-canonical ▶ NF-κB signaling pathway, which in some cells leads to secretion of TNF and thereby autocrine TNFR1 signaling. In turn, because cIAPs are absent, RIPK1 is not ubiquitylated by TNFR1 stimulation, and this interferes with NF-κB activation and favors the formation of a death-inducing signaling complex consisting of RIPK1, FADD, and caspase-8. This complex resembles the death-inducing complex formed when ▶ NF-κB activation is inhibited but contains RIPK1 instead of TRADD (Gyrd-Hansen and Meier 2010) (Fig. 3). In cells with high levels of the RIP family member RIPK3, TNF may also induce another type of programmed cell death termed necroptosis, which executes without caspase activity but rather is negatively regulated by caspase-8 (Declercq et al. 2009). Although mammalian IAPs under experimental settings either in cells or in vivo have been clearly demonstrated to have the capacity to determine cell survival, the physiological conditions where this occurs are less well established. Contrary to this, accumulating evidence now points to IAPs having a key function in innate immunity through regulation of inflammatory signaling pathways.

IAPs in Immune Signaling

The first evidence that IAP proteins regulate inflammatory signaling and activation NF-κB transcription factors came from genetic studies in fruit flies. Here, DIAP2 was found to be indispensable for NF-κB activation and innate immunity in response to Gram-negative bacteria (Ganesan et al. 2011; Lopez and Meier 2010). Infection with Gram-negative bacteria elicits an innate immune response by activating the *immune deficiency* (Imd) pathway, which is critically dependent on the ubiquitin ligase activity of DIAP2. DIAP2 conjugates lysine (K) 63-linked ubiquitin chains onto Imd, which facilitates activation of downstream of kinases that, in turn, activate the transcription factor Relish (a NF-κB-like transcription factor) (Ganesan et al. 2011; Lopez and Meier 2010). Accordingly, DIAP2-deficient flies fail to induce Relish-mediated expression of antimicrobial peptides and rapidly succumb to bacterial infections. Intriguingly, XIAP-deficient mice were recently found to be unable to efficiently clear bacterial infections and to ultimately die from the infection (Damgaard and Gyrd-Hansen 2011).

The domain organization of DIAP2 is very similar to that of the mammalian IAPs and akin to the role of DIAP2; cIAP1, cIAP2, and XIAP have emerged as regulators of the inflammatory response downstream of pattern recognition receptors (PRRs) and members of the TNF receptor superfamily (Lopez and Meier 2010). cIAPs regulate activation of NF-κB transcription factors downstream of TNFR1, Toll-like receptor 4 (▶ TLR4), and the cytosolic bacterial sensors NOD1 and NOD2. A unifying point in these pathways is the activation of TAK1 (TGFβ-activated kinase 1; also known as mitogen-activated protein kinase kinase kinase 7 (MAP3K7)) which in turn facilitates activation of ▶ MAP kinases and the IκB kinase (IKK)



Inhibitor of Apoptosis (IAP) Proteins, Fig. 3 (continued)

complex consisting of the catalytic subunits IKKα and IKKβ and the obligate regulatory subunit *N*F-κB *e*ssential *mo*difier (NEMO; also known as IKKγ). Once activated, IKK phosphorylates IκBα, an inhibitory subunit of NF-κB, which leads to its ubiquitylation and degradation by the proteasome. This enables nuclear translocation of ▶ NF-κB where it drives transcription of target genes required for the inflammatory response (Fig. 3). Activation of TAK1 and IKK is dependent on recruitment of the kinases to ubiquitin-modified proteins via the associated regulatory proteins TAB2/3 and NEMO, respectively. TAB2/3 and NEMO harbor ubiquitin-binding domains that mediate the recruitment to ubiquitylated proteins within the receptor complexes. In response to TNFR1 activation, ubiquitylation of RIPK1 and other components by cIAPs promotes the association of a trimeric ubiquitin ligase complex, termed LUBAC (linear ubiquitin chain assembly complex) (Walczak 2011). LUBAC expands ubiquitylation at the TNFR1 complex to enable efficient signaling and activation of the downstream kinases (Fig. 3). In addition, cIAPs are essential for signaling downstream of NOD1/2 where they are reported to ubiquitylate RIPK2 – a required adaptor similar to RIPK1. XIAP is also implicated in NOD2 signaling and was found to associate with RIPK2, but how XIAP contributes to signaling is currently unknown (Damgaard and Gyrd-Hansen 2011).

As mentioned above, cIAP1 and cIAP2 are required to prevent spontaneous activation the non-canonical NF-κB signaling pathway. This pathway is activated by receptors such as the B cell activating factor receptor (BAFF-R) and ▶ CD40 that are important for B cell function and lymphoid organ development. BAFF-R and ▶ CD40 stimulation leads to accumulation and self-activation of the NF-κB-inducing kinase (NIK). Upon activation, NIK activates an IKK complex consisting of IKKα dimers, and in turn, IKK facilitates activation of the NF-κB transcription factors (Bonizzi and Karin 2004).

The pathway is kept in check by a complex consisting of cIAP1, cIAP2, TRAF2, and TRAF3. TRAF3 links the complex to NIK, and the cIAP proteins ubiquitylate NIK (Lopez and Meier 2010). In response to CD40 or BAFF-R stimulation, cIAPs, through an unknown mechanism, shift target and instead ubiquitylate TRAF3, which leads to its degradation. This stabilizes NIK and allows activation of IKK and NF-κB. Treatment of cells with SM compounds results in a similar activation of NF-κB since cIAPs are degraded by the compound and no longer can mark NIK for degradation. This pathway is also activated by stimulation of the cytokine receptor Fn14 by its cognate ligand TWEAK. However, in this setting, Fn14 activation causes lysosomal degradation of the TRAF-cIAP complex, which thereby causes stabilization of NIK and subsequently activation of NF-κB.

cIAP-mediated ubiquitylation and degradation of TRAF3 also seems to contribute to TLR4 and RIG-I signaling (Lopez and Meier 2010). In response to TLR4 activation by LPS (a component of the bacterial cell wall), cIAPs are reported to ubiquitylate TRAF3 and cause its degradation which contributes to activation of MAP kinases, but not activation of NF-κB. RIG-I is an intracellular sensor of double-stranded viral RNA, and RIG-I activation leads to production of type I interferons such as IFNβ. cIAP-mediated degradation of TRAF3 after RIG-I activation is reported to be essential for IFNβ production after Sendai virus infection.

Inhibitor of Apoptosis (IAP) Proteins, Fig. 3 *cIAPs in TNFR1 signaling*. Activation of tumor necrosis factor receptor 1 (*TNFR1*) stimulates the formation of a signaling complex that consists of TNFR1, TNFR-associated via death domain (*TRADD*), RIPK1, TNFR-associated factor 2 (*TRAF2*), cellular inhibitor of apoptosis 1 (*cIAP1*), and cIAP2. cIAPs ubiquitylate (through K63-linked chains, shown in *yellow*) RIPK1, and probably other components of the receptor complex (not shown). This facilitates ubiquitin (*Ub*)-dependent recruitment of the linear ubiquitin chain assembly complex (*LUBAC*), transforming growth factor-β (*TGFβ*)-activated kinase (*TAK1*)/TAB2/TAB3 through their respective Ub-binding domains (*UBDs*). LUBAC conjugates linear ubiquitin chains (shown in *orange*) on to NEMO and RIPK1, which stabilizes the receptor complex, and allows efficient activation IKK and MAP kinases. This leads to activation of NF-κB transcription factors and induction of target genes important for inflammation and cell survival. In addition to stimulating TNF-mediated activation of nuclear factor-κB (*NF-κB*), cIAPs also suppress the formation of a death-inducing complex, which is the activation platform for caspase-8 that induces death by the extrinsic pathway. In the absence of cIAPs, this complex is formed by RIPK1 and Fas-associated via death domain (*FADD*), but in the absence of NF-κB activation, it is formed by TRADD and FADD

Other IAP Functions

IAPs are reported to negatively regulate the Ras-Raf-ERK signaling pathway. The pathway is activated by multiple growth factors and is frequently hyperactivated in cancer. XIAP, cIAP1, and cIAP2 were shown to interact with ▶ C-Raf and reduce the cellular levels of ▶ C-Raf in a ubiquitin-dependent manner, which involves the Hsp90 cochaperone and ubiquitin ligase CHIP (Gyrd-Hansen and Meier 2010). Accordingly, knockdown of XIAP or cIAPs led to an increase in cell motility and the invasive potential of HeLa cells in response to growth factor stimulation. Contrary to this, however, XIAP has been suggested to promote cell migration and metastasis in vivo in cooperation with survivin. The mechanism for this is not fully uncovered but appears to involve NF-κB activity.

XIAP is involved in the regulation of intracellular copper levels through its ubiquitylation of COMMD1 (copper metabolism gene MURR1 domain 1; also known as MURR1) (Srinivasula and Ashwell 2008). Defects in regulation of copper levels may cause severe pathologies such as Wilson's disease, an autosomal recessive condition that presents with neurological damage to the basal ganglia and cirrhosis due to accumulation of copper, particularly in brain and liver. XIAP binds COMMD1 via its BIR3 domain and ubiquitylates it in a RING-dependent manner, which targets COMMD1 for proteasomal degradation. The physiological relevance of this function of XIAP is supported by the finding that liver tissue and fibroblasts from XIAP-deficient mice have increased COMMD1 levels and decreased copper levels compared to wild-type controls (Srinivasula and Ashwell 2008).

IAPs in Human Diseases

Deregulation of several IAP family members has been observed in cancer. Although most links are correlative, there is evidence that cIAP1 and cIAP2, in particular, may contribute directly to cancer development. For example, the locus harboring *BIRC2*/*cIAP1* and *BIRC3*/*cIAP2* as well as *Yap1* and several *MMP* genes (11q21–q22) is found to be amplified in multiple human cancers including hepatocellular carcinoma (HCC), lung cancers, oral squamous cell carcinomas, medulloblastomas, glioblastomas, and pancreatic cancers (Gyrd-Hansen and Meier 2010; Srinivasula and Ashwell 2008). This is further supported by tumor models in mice where recurrent amplification of the 9qA1 locus, which is syntenic to the human 11q22 locus, was found in ▶ c-Myc-driven HCC in $p53^{-/-}$ mice and in spontaneously occurring osteosarcomas in $p53^{+/-}$ mice (Gyrd-Hansen and Meier 2010). In a separate report, cIAP1 was shown to positively regulate ▶ c-Myc activity by ubiquitylating the Myc-antagonistic protein, Max-dimerization protein-1 (Mad1), and facilitate its degradation (Vucic et al. 2011). The cIAP1-dependent decrease in Mad1 level correlated with increased proliferation and cell transformation in cell culture studies. However, whether this fully explains the role of cIAP1 in tumorigenesis in vivo needs further investigation.

Intriguingly, biallelic deletion of the locus encoding cIAP1 and cIAP2 is frequently observed in multiple myeloma (MM) together with other genes involved in regulation of ▶ NF-κB activity. MM is a B cell malignancy characterized by accumulation of antibody producing B cells (clonal) in the bone marrow. Combined, genetic lesions that cause deregulation of ▶ NF-κB activity were identified in ca. 20% of cases. Among the most frequent genetic alterations found were deletion of the *BIRC2*/*cIAP1* and *BIRC3*/*cIAP2* locus, deletion of *TRAF3*, *TRAF2*, and *CYLD*, and enhanced expression of lymphotoxin beta receptor (LTβR), ▶ CD40, TNFRSF13B/TACI, NFKB1, NFKB2, and NIK (Gyrd-Hansen and Meier 2010).

The mechanistic understanding of how amplification or deletion of the cIAP genes contributes to cancer development is currently not fully understood. In the case of MM, however, the identification of multiple genetic and expression abnormalities in MM that all affect genes involved in NF-κB signaling strongly suggests that unrestrained ▶ NF-κB activity contributes to driving these tumors. Analogous to this, chromosomal translocations that favor unrestrained NF-κB activity are frequent in MALT lymphoma (Ye et al. 2005). MALT lymphoma is an extranodal B cell lymphoma that arises in mucosa, primarily in the gastric tract and lungs, and is closely linked to *Helicobacter pylori* infections. The most common genetic lesion in MALT lymphomas is the reciprocal chromosomal translocation t(11;18)(q21;q21) that generates a fusion gene whose product consists of the N-terminal part of cIAP2 and the C-terminal portion of ▶ MALT1. The resulting chimeric protein cIAP2-MALT1 (also known as API2-MALT1) drives constitutive canonical

NF-κB signaling without requirement for activation of cell surface receptors (Ye et al. 2005). The cIAP2-MALT1 fusion bypasses the normal regulation of B cell receptor signaling by facilitating constitutive K63-linked ubiquitylation of NEMO by the ubiquitin ligase ▶ TRAF6. In turn, ubiquitylated NEMO is retained by the cIAP2 UBA domain present in cIAP2-MALT1 to enable activation of IKK and ▶ NF-κB (Gyrd-Hansen and Meier 2010).

Although XIAP is described to be overexpressed in many types of cancer, no genetic lesions affecting *XIAP* in human malignancies have been identified. In contrast, *XIAP* mutations have recently been reported in patients suffering from X-linked lymphoproliferative syndrome type 2 (XLP-2), a condition characterized by deregulation of the immune system and defined by hemophagocytic lymphohistiocytosis (Pachlopnik Schmid et al. 2011). Following viral infection, XLP-2 patients frequently develop cytopenia, fever, splenomegaly and hemorrhagic colitis, suggesting that mutations in *XIAP* predispose patients to the development of immunodeficiency (Pachlopnik Schmid et al. 2011). This is consistent with the experimental evidence which indicates that XIAP contributes to innate immunity to bacteria by facilitating NOD2 signaling, but whether XIAP also functions in other immune-related signaling paradigms is yet to be investigated (Damgaard and Gyrd-Hansen 2011).

Summary

The understanding of the cellular functions of individual IAP proteins has come a long way since the initial observation that expression of a viral IAP can maintain viability of cells after viral infection. In addition to their well-described role as gatekeepers of caspase activity and apoptosis, IAPs have now emerged as key regulators of signaling pathways important for inflammation and innate immunity. The molecular details of how IAPs impinge on these processes are still scarce, and in-depth understanding of these processes will undoubtedly be pursued in the years to come. Intriguingly, the realization that IAPs regulate immune-related processes may have unanticipated implications for the clinical applications of IAP-antagonistic compounds to also include treatment of immune-related syndromes as well as cancers driven by uncontrolled inflammatory signaling.

Inhibitor of DNA Binding 4 (ID4)

Giovanni Blandino and Giulia Fontemaggi
Translational Oncogenomics Unit, Regina Elena Cancer Institute, Rome, Italy

Synonyms

bHLHb27; ID4; IDB4

Historical Background

Transcription factors containing a basic helix-loop-helix (bHLH) motif regulate expression of tissue-specific genes in a number of mammalian and insect systems, playing a key role in the differentiation processes. These proteins contain an HLH domain, which mediates homo- and heterodimerization, plus an adjacent DNA-binding region rich in basic amino acids. The bHLH proteins bind to a DNA sequence known as E-box (CANNTG).

Dominant-negative HLH proteins encoded by Id-related genes, such as Id4, also contain the HLH-dimerization domain but lack the DNA-binding basic domain. Consequently, Id proteins inhibit binding to DNA and transcriptional transactivation by heterodimerization with bHLH proteins (Pagliuca et al. 1995). In mammals, there are four known Id gene family members, known as Id1, Id2, Id3, and Id4. The identity between the HLH regions of Id proteins is very high, while the remaining regions of the proteins are not conserved. The N- and C-terminal fragments of Id proteins do not adopt a helical conformation, with the exception of Id4 fragment 27–64. This helix propensity is dictated by the presence of an Ala-rich motif between residues 39 and 57. It can be hypothesized that Id4 might exert unique functions through this structural feature (reviewed in Dell'Orso et al. 2010). Despite the high similarity in the HLH domain, the Id proteins bind different targets with different affinities; for example, Id2 is the only Id family member that recognizes the retinoblastoma protein.

Typically, Id proteins are highly expressed during embryogenesis and expressed at lower levels in mature tissues, with the exception of some stem cells and many cancers (reviewed in Perk et al. 2005). Id proteins were described initially as inhibitors of differentiation and more recently as regulators of cell cycle progression, senescence, apoptosis, and tumorigenesis. Concerning the ability of Id proteins to control the developmental processes, Id4 in particular was shown to be involved in the differentiation of neurons, adipocytes, and osteoblasts, and in the nervous system and mammary gland development. Deregulated Id4 expression is also frequent in tumors. Specifically, Id4 was found upregulated in glioblastoma multiforme (GBM) and breast cancer (BC) and amplified in ovarian carcinomas (Cancer Genome Atlas Research Network 2011). Conversely to what observed in GBM and BC, an Id4 underexpression due to promoter hypermethylation was observed in carcinomas of the gastrointestinal tract, indicating a possible role for Id4 in tumor suppression.

Id4 Regulates Neural Progenitor Proliferation and Differentiation

It is well documented that the expression of each Id gene occurs in many regions of the developing nervous system in a complex and dynamic manner. Id4 expression is essentially restricted to the developing nervous system, whereas expression of Id1-3 is much more widespread during mouse embryogenesis (Jen et al. 1997). Early in neurogenesis, Id4 expression is prominent in the ventricular zone (VZ) of specific regions of the central nervous system (CNS), including the developing forebrain. Later, Id4 expression is apparent in the cortical plate of the telencephalon and the subventricular zone (SVZ) of the basal ganglia (Jen et al. 1997). Id4 expression is also observed in the postnatal and adult brains (Andres-Barquin et al. 1999).

Studies on knockout mice revealed that Id4 is required for normal brain size and regulates neural stem cells' proliferation and differentiation. In particular, Id4 regulates lateral expansion of the proliferative zone in the developing cortex and hippocampus. Since Id4 is required for the normal G1/S transition in early cortical progenitors, the absence of its expression

compromises the proliferation of stem cells in the ventricular zone (Yun et al. 2004).

Id4 is expressed in oligodendrocyte precursor cells and may control the timing of oligodendrocyte differentiation. Enforced expression of Id4 in vitro stimulates proliferation and blocks differentiation of oligodendrocyte precursor cells (Bedford et al. 2005). Id4 was recently found in neural progenitor cells to directly interact with bHLH OLIG1 and OLIG2, two crucial transcription factors responsible for oligodendroglial differentiation. Id4 also mediates the inhibitory effects of bone morphogenetic protein-4 (BMP-4) on oligodendroglial differentiation that leads to astrocytic differentiation (Yun et al. 2004).

The molecular mechanism by which Id4 expression is downregulated during oligodendrocyte differentiation has remained unknown. Accumulating evidence however suggests that Id4 expression is repressed by DNA methylation at neighboring CpG islands. Interestingly, it was found that PRMT5, a type-II protein arginine methyltransferase, is required for maintaining the methylation status of CpG islands of Id2 and Id4, leading to gene silencing during glial cell differentiation (Huang et al. 2011). In addition, a transcriptional factor, Rp58, was very recently reported to negatively regulate all four Id genes (Id1–Id4) in developing cerebral cortex. Consistently, Rp58 knockout (KO) mice demonstrated enhanced astrogenesis accompanied with an excess of neural stem cells (NSCs). Rp58 KO phenotypes were rescued by the knockdown of all Id genes in mutant cortical progenitors but not by the knockdown of each single Id gene. These findings establish RP58 as a novel key regulator that controls the self-renewal and differentiation of NSCs and restriction of astrogenesis by repressing all Id genes during corticogenesis (Hirai et al. 2012).

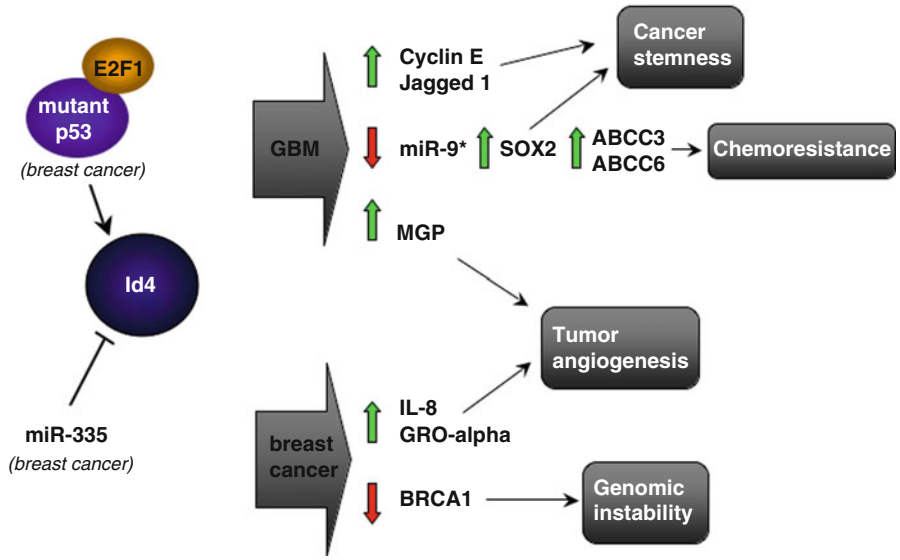
Id4 Maintains the Stem Cells Compartment in Glioblastoma Multiforme

The expression of Id proteins, which is very low in adult tissues, can be reactivated in human cancers. It has been proposed that deregulated Id signaling may promote multiple attributes of malignancy, like unrestricted proliferation, loss of differentiation (anaplasia), invasiveness, and neoangiogenesis (Perk et al. 2005). Elevated levels of Id proteins have been reported in several malignancies (carcinoma, squamous cell carcinoma, adenocarcinoma, neural tumors, melanoma, sarcoma, seminoma, and leukemia). In some cases, high levels are associated with tumor stage/grade and with prognosis. Analysis of genetic alterations of Id genes in human tumors has found no mutations. This may indicate that Id genes are not common oncogenes. Nevertheless, the overexpression of Id genes in cancer is frequently governed by bona fide oncogenes, such as ▶ MYC-driven Id2 expression in neuroblastoma cells, ▶ beta-catenin-driven Id2 expression in colon cancer cells, and mutant ▶ p53-driven Id4 expression in breast cancer cells.

Id4 was found overexpressed in glioblastoma multiforme (GBM) when compared to normal brain tissue. The effects of Id4 overexpression in GBM are summarized in Fig. 1. In GBM, it shows a robust expression with heterogenous staining pattern within the same tumor tissue. In particular, Id4 is preferentially expressed in cells of astrocytic lineage in oligodendroglioma and oligoastrocytoma tumors (Liang et al. 2005). Interestingly, the analysis of Id4 protein expression in human GBM specimens evidenced that the majority of Id4-positive cells resides near the vasculature, a location postulated to be the niche for brain tumor stem cells (Jeon et al. 2008).

Enforced Id4 expression can drive malignant transformation of primary murine Ink4a/ARF−/− astrocytes via deregulation of cell cycle and differentiation control. Id4 indeed increases the levels of both cyclin E (that leads to a hyperproliferative state) and Jagged1 to drive astrocytes into a neural stem-like cell state. These findings highlight the role of Id4 in controlling the "stemness" of neural cells during development of the central nervous system (Jeon et al. 2008). Further studies showed also that Id4 expression contributes to the chemoresistance of glioma stem cells. In particular, Id4 suppresses the expression of microRNA-9*, leading to the de-repression of SOX2, a crucial player in cancer stem cells. SOX2 upregulation contributes, on one hand, to the maintenance of cancer stem cells compartment, and on the other hand, to glioma chemoresistance, through the transcriptional induction of drug resistance genes, such as those encoding the ATP-binding cassette transporters ABCC3/ABCC6 (Jeon et al. 2011).

Moreover, human glioblastoma xenografts overexpressing Id4 are characterized by higher tumor sizes compared to controls. This is not due to a higher proliferation rate of Id4-overexpressing cell clones but instead due to the better vascularization of the derived xenograft tumors compared to control xenografts.



Inhibitor of DNA Binding 4 (ID4), Fig. 1 *Id4 network in cancer*. Deregulated Id signaling has been reported in glioblastoma multiforme (GBM) and breast cancer and may promote multiple attributes of malignancy. In glioblastoma multiforme, Id4 was shown to contribute to the maintenance of stem cells compartment (through the induction of cyclin E, jagged1, and SOX2), to chemoresistance (through the induction of ABC transporters), and to angiogenesis (through the release of MGP in the extracellular matrix). In proliferating breast cancer cells carrying mutant p53, the protein complex mutp53/E2F1/p300 assembles on specific regions of Id4 promoter and positively controls Id4 expression. The newly synthesized Id4 protein binds to mRNAs encoding proangiogenic factors, like IL8 and GRO-alpha, causing their stabilization and enhancement of translation. This results in an increase of the angiogenic potential of cancer cells expressing mutant p53. In breast cancer cells, Id4 mRNA is targeted by miR-335. Low miR-335 levels correlate with high Id4 expression which in turn results in downregulation of BRCA1 and genomic instability

Superficial blood vessels in xenografts expressing high Id4 levels are larger and more numerous than vessels in control tumors. The Id4-dependent mediator responsible for the enhanced angiogenesis is matrix GLA protein (MGP), a member of vitamin-K-dependent family of proteins, which includes prothrombin (Kuzontkoski et al. 2010).

Id4 Controls Mammary Gland Development and Cancer

During the normal mammary gland development, Id4 expression is required for ductal expansion and branching morphogenesis as well as cell proliferation induced by estrogen and/or progesterone. p38 MAPK is activated in Id4-null mammary cells and this activation is required for the reduced proliferation and increased apoptosis observed in Id4-ablated mammary glands. Therefore, ID4 promotes mammary gland development by suppressing p38 MAPK activity (Dong et al. 2011).

A positive role for Id4 in mammary and ovarian tumorigenesis was also proposed (reviewed in Dell'Orso et al. 2010). The modulation of Id4 expression in these systems indeed resulted in inversely regulated expression of BRCA1 (Fig. 1). An increase of Id4 expression was associated with the ability of ovarian and breast cancer cells to exhibit anchorage-independent growth, while its depletion determined morphological change to a large and flat epithelial phenotype. The expression of Id4 and BRCA1/ER (► estrogen receptor) inversely correlated in sporadic breast cancers. Id4 3'-UTR was also recently found to be targeted by microRNA-335 in breast cancer cells, resulting in BRCA1 induction and decrease in genomic instability. Accordingly, Id4 and miR-335 expression are inversely correlated in breast cancer specimens (Heyn et al. 2011).

The expression of Id4, as well as that of Id2, can be induced by mutant ► p53 proteins (Fontemaggi et al. 2009, 2010; Dell'Orso et al. 2010). In breast cancer cell lines, the transcriptional transactivation of Id4 promoter is exerted by the complex mutant p53/E2F1/p300. Accordingly, Id4 protein expression is enriched in breast cancer tissues, showing p53

overexpression (predicting the presence of p53 mutations). This association is particularly evident in the HER2 subtype, where Id4 is expressed in nearly 80% of p53-positive cases, compared to 40% of the p53-negative cases. HER2-overexpressing breast cancer subtype presents very high frequency of ▶ TP53 mutations, like all ER-negative breast cancers. The net biological output of the transcriptional activation of Id4 gene by mutant ▶ p53 is the increase of the angiogenic potential of mutant ▶ p53-carrying tumor cells. The mutant ▶ p53/Id4 axis promotes endothelial cells' proliferation and migration in vitro. In addition, the analysis of human breast cancer cases revealed that a higher microvessel density is present in the Id4-positive population than in Id4-negative one.

At the molecular level, Id4 protein binds to the mRNAs of proangiogenic factors like CXCL8 (IL8) and CXCL1 (GRO-alpha) (Fig. 1), containing AU-rich (ARE) elements in their 3'UTR, resulting in an increased stability and a higher rate of translation of these transcripts (Fontemaggi et al. 2009). Significantly, the most expressed cytokines in HER2 tumors, displaying the highest correlation between p53 and Id4 expressions among all breast cancer subtypes, are just CXCL8 and CXCL1.

Studies performed in 4 T1 invasive mouse mammary cancer cells also evidenced the ability of Id4 to promote features typical of the cancer stem cells, such as the tumor sphere-forming ability (Park et al. 2011). In addition, Id4 is involved in the induction of the expression of ABCC3, belonging to the family of ABC transporters.

Summary

Id4 is a member of the inhibitor-of-DNA-binding family of HLH proteins that comprises four members (Id1-4). The Id group of proteins was reported to promote proliferation and inhibit differentiation in several cell types. Because they lack a DNA-binding domain at the N-terminus, Id proteins are generally thought to exert their function by forming heterodimers with bHLH proteins, preventing these other proteins from forming transcriptionally active homodimers or heterodimers with the ubiquitous E proteins on consensus E-boxes present on target promoters. The gene encoding Id4 is required for neuroprogenitor cell proliferation and proper differentiation. The expression of Id proteins, which is very low in adult tissues, can be reactivated in human cancers and deregulated Id signaling may promote multiple attributes of malignancy. Id4 is overexpressed in glioblastoma multiforme, where it promotes the maintenance of cancer cell stemness and neovascularization. A proangiogenic role of Id4 was also reported in breast cancer, where mutant p53 proteins induce Id4 promoter transactivation.

Inositol 1,4,5-trisphosphate-associated cGMP kinase substrate

Michael A. Grillo and Peter Koulen
Department of Ophthalmology and Department of Basic Medical Science, University of Missouri - Kansas City School of Medicine, Vision Research Center, Kansas City, MO, USA

Synonyms

IP3 receptor–associated cGMP kinase substrate a; IRAG; Iraga; JAW1-related protein isoform a; MRV integration site 1; Mrv1; Mrv1a; Mrvi1; Murine retrovirus integration site 1 homolog

Historical Background

Inositol 1, 4, 5-trisphosphate (IP_3) receptor–associated cyclic GMP (cGMP) kinase substrate (IRAG) is a 125-kD type 2 integral endoplasmic reticulum (ER) membrane protein. IRAG is 900 amino acids long and encoded by the Mrvi1 gene. Two splice variants exist in both mouse and humans with the IRAGa isoform containing an extra 84 amino acids in the N-terminus. Both variants contain a C-terminal hydrophobic domain, α-helix coiled-coil domain, basic N-terminal region, and multiple glycosylation and phosphorylation sites (Ammendola et al. 2001; Schlossmann et al. 2000; Shaughnessy et al. 1999). IRAG forms a complex with the Inositol 1, 4, 5-trisphosphate receptor (IP_3R) and cGMP kinase I-β (cGKIβ), and is involved in nitric oxide (NO),cGMP, and cGKIβ signaling pathways. IRAG plays a role in transcription modulation, smooth muscle contraction, platelet aggregation, cell growth, differentiation, and possibly tumorigenesis.

Expression Pattern

Expression of IRAG is found in the heart, lungs, liver, pancreas, smooth muscle, colon, small intestines, pancreas, trachea, hippocampus, nucleus motorius, and nucleus trigemini (Graham et al. 2008). Perinuclear immunostaining and immunoprecipitation with resident ER proteins suggests IRAG localization to the ER membrane (Ammendola et al. 2001; Fritsch et al. 2004; Geiselhöringer et al. 2004a; Schlossmann et al. 2000; Shaughnessy et al. 1999). Downregulation of IRAG coincides with siRNA knockdown of the transcription factor BTF3 in pancreatic cancer cell lines (Kusumawidjaja et al. 2007), and knockout of Ca^{2+}-dependent K^+(BK) channel in trachea causes an upregulation in IRAG protein concentration (Sausbier et al. 2007). Deletion of exon 12 coding for the N-terminus coiled-coil domain of IRAG resulted in a 25% decrease in protein concentration in mouse intestine (Geiselhöringer et al. 2004).

Interactions with Ligands and Other Proteins

IRAG co-immunoprecipitates with both IP_3R1 and cGKIβ/cGKI in smooth muscle from bovine trachea (Schlossmann et al. 2000). Interaction with IP3R1

possibly occurs at the IRAG N-terminus coiled-coil domain. Deletion of this region of the protein in mice shows disruption in IRAG/IP_3R coupling in aortic and intestinal smooth muscle (Geiselhöringer et al. 2004). Interactions between IRAG and cGKIβ occur between amino acids 152 and 184 of IRAG, through possible electrostatic interactions, and the N-terminal leucine zipper motif, amino acids 1–53, of cGKIβ but not cGKIα or cGKII (Ammendola et al. 2001; Casteel et al. 2005). Upon cGMP stimulation, cGKIβ phosphorylates IRAG at ser 644 and ser 677 in human platelets and ser 696 in bovine trachea cells (Schlossmann et al. 2000; Antl et al. 2007). Phosphorylation of IRAG causes a decrease in IP_3R1 function (Schlossmann et al. 2000), with ser 696 phosphorylation being essential for this response (Schlossmann et al. 2000). In COS-7 cells, expression of phospholambin, IP_3R1, cGKIβ, and IRAG resulted in co-immunoprecipitation of these proteins in complex (Koller et al. 2003).

Protein Function

As previously stated, upon phosphorylation, IRAG decreases calcium release from IP3R-mediated stores (Schlossmann et al. 2000). The interaction of IRAG and cGKIβ has been shown to mediate translocation of cGKIβ to the nucleus, thus attenuating cAMP-response element–dependent genes in hamster kidney cells (Casteel et al. 2008). Deletion of the IRAG/IP3R association in platelets caused NO/cGMP inhibition of platelet aggregation and control of thrombosis to be lost (Antl et al. 2007), and this loss of association in smooth muscle caused a loss in cGMP-dependent relaxation of hormone receptor smooth muscle contraction (Hoffman et al. 2004). In colonic smooth muscle, siRNA interference of IRAG caused a loss of NO-induced relaxation (Fritsch et al. 2004), and deletion ablated cGMP relaxation (Frei et al. 2009). Deletion of IRAG causes a loss in atrial natriuretic peptide (ANP) and NO relaxation of smooth muscle tone (Desch et al. 2010). Osteoclast attachment is impaired in siRNA knockouts of the IRAG protein (Yaroslavskiy et al. 2010).

Summary

IRAG is involved directly or indirectly in many signaling pathways. IRAG regulates the intracellular calcium concentration through an interaction with IP_3R (Schlossmann et al. 2000), affects transcription through its anchoring of cGKIβ (Casteel et al. 2008), and controls NO, ANP, and cGMP relaxation of smooth muscle in multiple tissues throughout the body (Hoffman et al. 2004; Fritsch et al. 2004; Desch et al. 2010). Due to its essential role in NO/cGMP signaling, IRAG provides an interesting target for diseases involving cardiovascular dysfunction.

Acknowledgments This study was supported in part by grants EY014227 from NIH/NEI, RR022570 from NIH/NCRR and AG010485, AG022550 and AG027956 from NIH/NIA, by the Felix and Carmen Sabates Missouri Endowed Chair in Vision Research (PK). We thank Margaret, Richard, and Sara Koulen for their generous support and encouragement.

Insulin-like growth factor receptor type I (IGF1R)

Historical Background

The IGF1R, a Protein Tyrosine Kinase Receptor, is expressed in many tissues and can be activated by its physiological ligands IGF-I and IGF-II, which are available systemically and from local sources. Activation of the IGF1R promotes cell growth and survival in a cell-autonomous manner. Because of a wide distribution of IGF1R and good bioavailability of its ligands, under pathological conditions this cytoprotective intracellular signaling pathway may be activated in cells that also receive stimulation by pathology-specific factors. Cross-regulation between IGF1R signaling and pathways activated by

inflammation has recently been in the focus of attention in several laboratories because pro-inflammatory factors are a common cause of cellular pathology in many different conditions (O'Connor et al. 2008).

Resident parenchymal cells activated by pro-inflammatory cytokines in tissues affected by inflammation are characterized by several features, including increased activity of the stress-related Mitogen-Activated Kinases (MAPK) and transcription factors of nuclear factor-κB (▶ NF-κB) family, stress of the endoplasmic reticulum (ER), and generation of reactive oxygen species (ROS). Several components in inflammation-activated pathway may be cross-regulated by IGF1R-activated signaling, and there are signaling molecules in the IGF1R pathway that are subject to cross-regulation by pro-inflammatory factors. Here IGF1R signaling has been reviewed and biochemical events that may facilitate cross-regulation of this pathway and those activated by inflammation have been elucidated. The generic signaling networks presented here are based on molecular interaction shown in non-transformed nonimmune cells. There is a considerable variation between cells of different lineages and differentiation states in usage of these networks.

IGF1R Signaling Cascade

IGF1R Activation

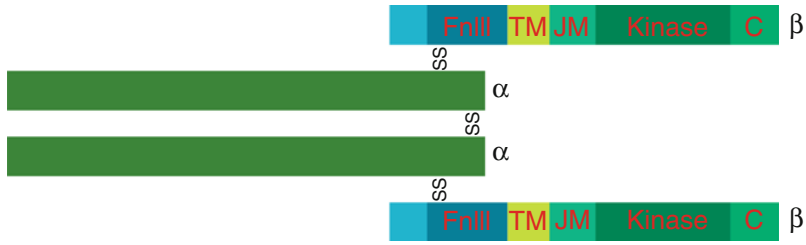
The IGF1R (Adams et al. 2000) consists of two α- and two β-chains (Fig. 1). The α-chains are extracellular and associated by disulfide bonds. They form a ligand-binding pocket, which can accommodate one ligand molecule. A ligand that has the highest affinity to the IGF1R is IGF-I. Two other ligands, IGF-II and insulin, can also bind to the receptor with, respectively, 6–8 and 100 times lower affinity than IGF-I. A single disulfide bond binds the α-chain to the extracellular fibronectin type III homology domain of the β-chain. Therefore, the receptor consists of two αβ heterodimers covalently linked by the disulfide bonds between the α-chains (Fig. 1).

The β-chain is transmembrane, with its cytosolic portion containing the catalytic kinase domain flanked with the juxtamembrane region and the C-terminal tail. In the absence of ligand, the autocatalytic activity of the IGF1R is inhibited by conformational constraints imposed by the extracellular and juxtamembrane portions of the β-chain. The autoinhibition is relieved when ligand binds to the α-chains, facilitating phosphorylation of three tyrosines in the activation loops of the first kinase domain by the second kinase domain and vice versa (transphosphorylation, Fig. 2). This is followed by phosphorylation of several additional tyrosines in the IGF1R and other signaling proteins. Three serine residues in the C-terminal tail of the receptor are also phosphorylated upon ligand binding via an incompletely understood mechanism. Different segments of the IGF1R signaling portion appear to be linked to different arms of the IGF1R signaling pathway and different cellular responses.

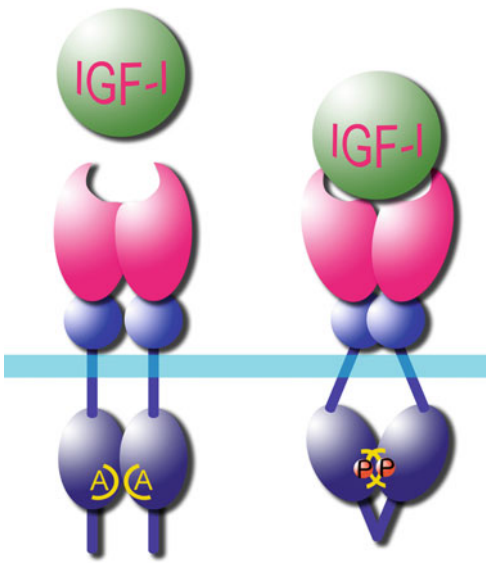
IGF1R Signaling Complex

Ligand binding initiates formation of a protein complex consisting of kinases and adaptor proteins around the IGF1R. An important component of this complex is Insulin Receptor Substrate (IRS), a scaffolding protein containing N-terminal Pleckstrin Homology (PH) domain, the Src Homology 2 (SH2) domain, and several tyrosine and serine residues that can be substrates of protein kinases. Isoforms 1–4 of IRS have been implicated in IGF1R signaling, with IRS-1 and -2 being the most widely distributed. The SH2 domain of IRS-1 binds to tyrosine phosphorylated Asn-Pro-X-Tyr motifs in the juxtamembrane region of the IGF1R. Another signal positioning IRS near the activated IGF1R is the interaction between PH domain of IRS and 3'-phosphorylated phosphoinositides formed in the vicinity of the activated IGF1R as described below.

Phosphotyrosines of IRS provide docking sites for several SH2 domain-containing proteins, associating IGF1R activation with downstream signaling pathways. One of these pathways is initiated by binding of the regulatory p85 subunit of ▶ Phosphatidylinositol 3 Kinase (▶ PI3K) to IRS (Fig. 3). This releases the catalytic subunit of PI3K p110 from p85-mediated inhibition. PI3K converts phosphatidylinositol lipids to 3-phosphorylated forms, most importantly phosphatidylinositol 3,4,5 triphosphate (PIP3). PIP3 provides docking sites for IRS and promotes activation of other PH domain-containing molecules, including serine/threonine kinases v-akt murine thymoma viral oncogene homolog (Akt), 3-Phosphoinositide-Dependent Protein Kinase (Pdk) 1 and 2, and Protein Kinase C ζ (PKCζ). Pdk is an upstream kinase of several signaling molecules, including Akt and PKCζ. Pdk phosphorylates Akt on Thr^{308}, and full activation of Akt requires phosphorylation on Ser^{473},



Insulin-like Growth Factor Receptor Type I (IGF1R) Signaling and Inflammation, Fig. 1 *Subunit structure of the IGF1R*. α α-chain, β β-chain, ss disulfide bonds, FnIII fibronectin type III homology domain, TM transmembrane domain, JM juxtamembrane domain, Kinase kinase domain, C C-terminal tail



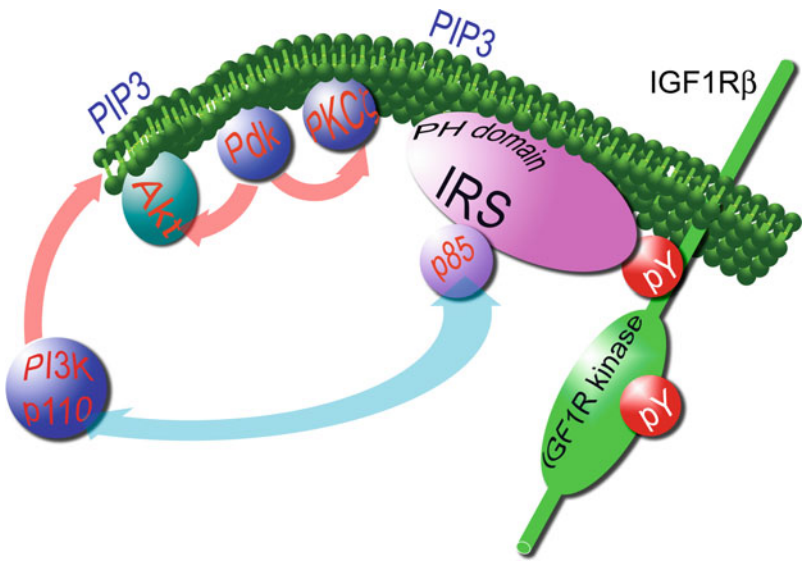
Insulin-like Growth Factor Receptor Type I (IGF1R) Signaling and Inflammation, Fig. 2 *IGF1R activation*. Without ligand, the activation (A) loop in the kinase domain of the receptor has conformation that is unfavorable for transphosphorylation. This may be a result of constraints imposed by the extracellular portion of the β-chain. Binding of IGF-I to the α-chains causes conformational changes relieving these constraints and facilitating kinase domain transphosphorylation (P)

which is achieved by autophosphorylation or mediated by other kinases.

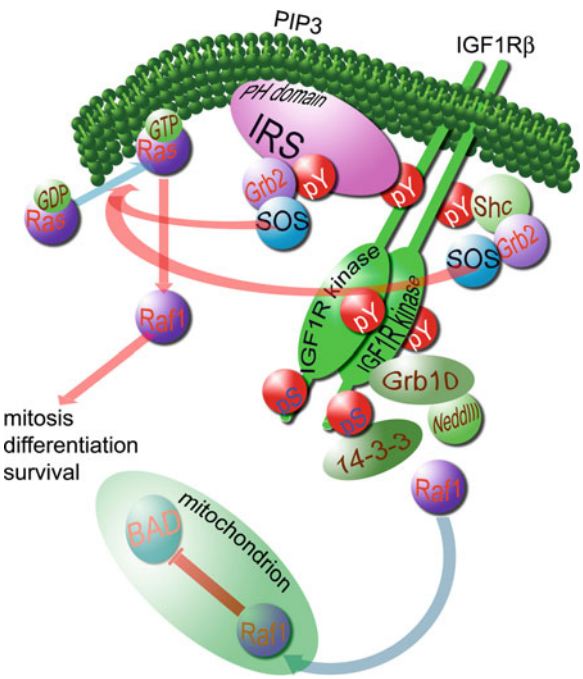
Another adaptor protein, Shc, is recruited to the tyrosine-phosphorylated signaling domain of the IGF1R with a slower binding kinetics than IRS-1. Tyrosine phosphorylation of Shc induced by binding to the receptor facilitates its interaction with the adaptor protein growth factor receptor-binding protein 2 (Grb2). Grb2 may also bind to phosphorylated IRS-1 in some cell types (Fig. 4). The SH2 domain-containing protein tyrosine phosphatase Shp2, another binding partner of IRS, is required for optimal association of the IGF1R with downstream targets and its deficiency is associated with reduced activation of MAPK, although Shp2 inactivates IRS-1 by dephosphorylation. Stoichiometry of the protein complex formed around the activated IGF1R may vary depending on the cell type.

To various degrees, all four groups of conventional MAPK are involved in signal transmission from the activated IGF1R. These include Erk1/2, c-jun NH_2-terminal protein kinase (JNK) 1/2/3, p38α/β/γ/δ, and Erk5. MAPK are activated by dual specificity MAPK kinases (MKK or MAP2K) phosphorylating Thr and Tyr residues within a conserved Thr-X-Tyr motif in the MAPK activation loop. Upstream of MAP2K are their activators MAP2K kinases (MKKK or MAP3K) (Cargnello et al. 2012). Signal wiring within the MAPK cascade is dependent on substrate specificity of second and third tire MAPK and participation of scaffolding proteins. Increased signaling activity of MAPK is associated with their nuclear translocation.

Erk1 and Erk2, the first MAPK to be cloned and characterized in early 1990, are most frequently associated with mitogenic effects of the activated IGF1R and other receptor tyrosine kinases in different cell lineages (Cargnello et al. 2012). The Erk1/2 module of the MAPK cascade includes the MAP2K MEK1 and MEK2, as well as the MAP3K ▶ Raf1. The serine/threonine kinase Raf1 is activated by the small guanosine triphosphate (GTP)-binding protein Ras. Ras is inactive when bound to guanosine diphosphate (GDP) and becomes activated when associated GDP is replaced by GTP. This exchange is promoted by the guanine nucleotide exchange factor (GEF) son of sevenless, which is activated by recruitment to the IGF1R signaling complex via interaction with Grb2



Insulin-like Growth Factor Receptor Type I (IGF1R) Signaling and Inflammation, Fig. 3 *PI3K activation*. IRS binds to the juxtamembrane portion of the activated IGF1R and activates PI3K, which generates PIP3. Akt and PKCζ, as well as their kinase Pdk, bind to PIP3 and become activated. Only β-chain of the IGF1R is shown (IGF1Rβ). Here and in other figures bars show inhibitory interactions and arrows show activating interactions or transition between different states



Insulin-like Growth Factor Receptor Type I (IGF1R) Signaling and Inflammation, Fig. 4 *MAPK and ubiquitous adaptor proteins in IGF1R signaling*. Shc and IRS bind to specific phosphotyrosine-containing motifs (pY) in the activated IGF1R. Grb2 is recruited to the IGF1R signaling complex by binding to Shc or IRS. The GEF son of sevenless (SOS) is activated by binding to Grb2 and induces exchange of Ras-bound GDP to GTP, thereby activating Ras, which activates Raf1. In addition, phosphorylated serines (pS) at the C-terminus of the receptor may bind 14-3-3. This and Grb10-mediated recruitment of NeddIII is required for mitochondrial translocation of Raf1

(Fig. 4) and a mechanism that requires Shp2. In addition, IGF1R-agonist-induced Raf1 activation may occur independently of IGF1R autocatalytic activity, and Raf1-independent Erk1/2 activation in response to IGF1R ligation has been shown.

The stress MAPK p38 and JNK, which are usually associated with apoptosis and cell differentiation, as well as Erk5, are also involved in IGF1R signaling, but less frequently than Erk1/2. IGF1R-induced JNK activation may be dependent on receptor-interacting protein, a death domain-containing serine/threonine kinase with a well-documented function of linking JNK activation to the Tumor Necrosis Factor Receptor (TNFR) type 1.

Ubiquitously Expressed Adaptors

The activation status of the IGF1R signaling cascade is a subject to modulation by several ubiquitously expressed scaffolding or adaptor proteins. IRS family proteins belong to the group classified by some authors as docking proteins (Brummer et al. 2010) on the basis of having a N-terminal PH domain and SH2 domain, as well as multiple tyrosine residues. In addition to IRS, docking proteins participating in IGF1R signaling include members of two families, Grb-associated binder (Gab) and downstream of tyrosine kinases (Dok). ▶ Gab1, one of the best studied docking proteins of Gab family, binds to several components of the IGF1R signaling complex, including Shp2, p85, and Grb2, and its deficiency is associated with reduced proliferation in response to IGF-I.

Another adaptor, Grb10, binds to a diverse range of partners through SH2 and PH domains, including the IGF1R, Raf1, MEK, Akt, the regulatory subunit of PI3K and Gab1, and has the capacity to positively and negatively regulate IGF1R signaling. Grb10 may promote Ras-independent activation of Raf1 in response to IGF1R activation. Grb10 also provides a link between the IGF1R and Nedd4, an E3 ubiquitin ligase, which is required for optimal IGF1R signaling (Fig. 4).

Among molecules interacting with Grb10 is the ubiquitously expressed adaptor 14-3-3 which has affinity to phosphorylated serine and threonine residues. Binding partners of 14-3-3 isoforms are found in different intracellular signaling pathways. Regulatory effects of 14-3-3 isoforms are mediated by restricting subcellular localization of client proteins and shielding them from interaction with other molecules (Darling et al. 2005). Several signaling molecules in IGF1R- and inflammation-activated pathways, including IGF1R, IRS-1, PI3K, ASK1-interacting protein 1 (AIP1), as well as the third tire MAPK Raf, apoptosis signal-regulating kinase 1 (ASK1), and MEKK3, may generate binding sites for this adaptor by phosphorylation of serine and threonine residues. Therefore, serine/threonine phosphorylation of a signaling molecule in a given pathway by a kinase activated in another signaling pathway may be a 14-3-3-dependent mechanism of cross-talk between these pathways.

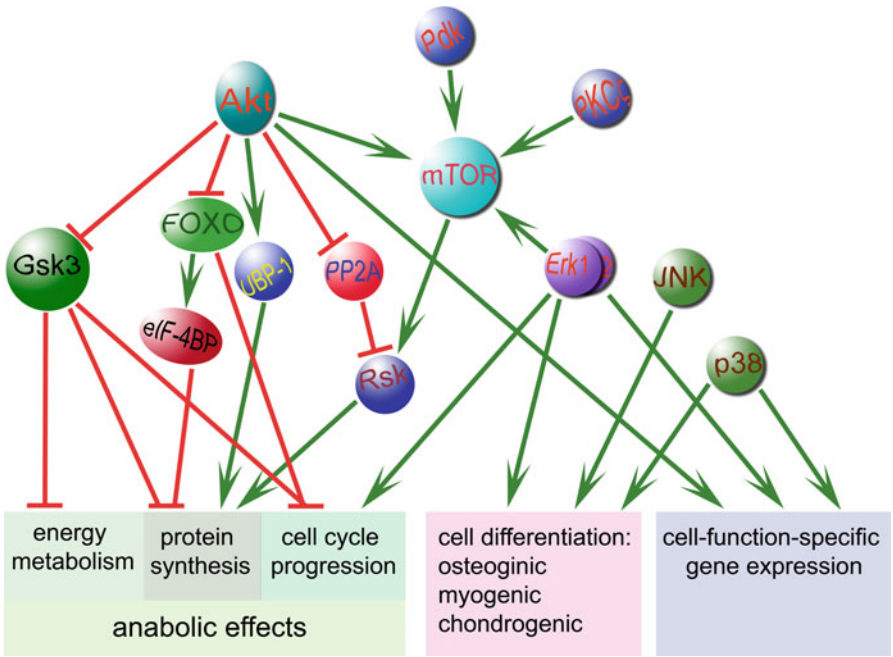
Grb10 and 14-3-3 may be involved in one of the IGF1R-dependent anti-apoptotic pathways. Association of 14-3-3 with IGF1R C-terminal serines, phosphorylated during receptor activation by a mechanism that might involve autophosphorylation, may induce translocation of the MAP3K Raf1 to the mitochondrion where it inhibits the pro-apoptotic ▶ Bcl-2 Family protein BAD. The effect of Raf1 is independent of Erk1/2 activation and may require interaction of Raf1 with Grb10 and Nedd4 (Fig. 4). This may provide cytoprotection against mitochondrial cell death, which is often induced by pro-inflammatory conditions in resident cells.

Cellular Responses to IGF1R Activation and Intracellular Signaling Pathways Involved

IGF1R activation has anabolic effect in many different cell lineages. In the absence of other growth factors, IGF1R-dependent signaling alone is sufficient for maintenance of cellular energy metabolism and protein synthesis. Akt is an important mediator of anabolic response to IGF1R activation because this serine/threonine kinase modulates activation status of several effector kinases and transcription factors that suppress or promote cell growth (Manning and Cantley 2007) (Fig. 5). One of the Akt targets is the serine/threonine kinase Glycogen Synthase Kinase (Gsk)-3, an inhibitor of cell metabolism, growth, and differentiation. Another target is forkhead transcription factors (FOXO), a subclass of transcription factors inhibiting cell growth and survival. Their effects include activation of Eukaryotic Initiation Factor 4E binding protein 1, a global translational repressor, as well as activation of pro-apoptotic pathways and inhibition of cell cycle progression (Hedrick 2009). FOXO protein nuclear translocation is regulated by multiple types of post-translational modifications, with Akt-dependent phosphorylation resulting in their nuclear exclusion and transcriptional inactivation.

Another IGF1R-dependent effector is mammalian target of rapamycin (▶ mTOR), which positively regulates protein translation by activating p70 Ribosomal S6 Kinase (Rsk), a kinase activating the 40S ribosomal protein. Akt and other kinases in the IGF1R signaling cascade, including Pdk-1, PKCζ, and Erk1/2, can activate mTOR and Rsk, thereby promoting protein synthesis (Kuemmerle 2003). Finally, IGF1R signaling activates upstream binding factor 1, which regulates cell size by transcriptionally activating RNA polymerase I, a limiting factor in ribosome biosynthesis (Fig. 5).

By promoting cell growth IGF1R signaling indirectly promotes cell proliferation. This pathway also has a direct mitogenic effect on selected lineages, for example, myoblasts, by modulating activity of proteins regulating cell cycle progression, such as Cyclins, their kinases and c-▶ Myc, effects that are often dependent on Erk1/2. Furthermore, Akt and the aforementioned 14-3-3/Raf1-dependent mechanism mediate anti-apoptotic effects of activated IGF1R by targeting BAD. In addition, IGF-I and -II are differentiation factors for several cell lineages, including osteoblasts, chondroblasts, and myoblasts, because in these cells they induce expression of lineage-specific genes. Finally, IGF1R signaling may lead to cell activation and increased functional competence in several cell types, for example, steroidogenesis in ovarian cells or expression of cytokines in various immune and non-immune cells (Fig. 5).



Insulin-like Growth Factor Receptor Type I (IGF1R) Signaling and Inflammation, Fig. 5 *Downstream effectors of cellular responses to IGF1R activation*. GSK3 and FOXO transcription factors, negative regulators of cell growth, are inhibited by Akt-mediated phosphorylation. mTOR and its effector Rsk, are maintained in the activated state by phosphorylation on multiple serine and threonine residues mediated by Akt, Pdk, PKCζ and Erk1/2. Akt prevents inhibitory dephosphorylation of Rsk mediated by protein phosphatase 2A (PP2A). eIF4E-BP – eukaryotic initiation factor 4E binding protein

Cross-Regulation Between IGF1R and Inflammation-Activated Intracellular Signaling Pathways

ASK1

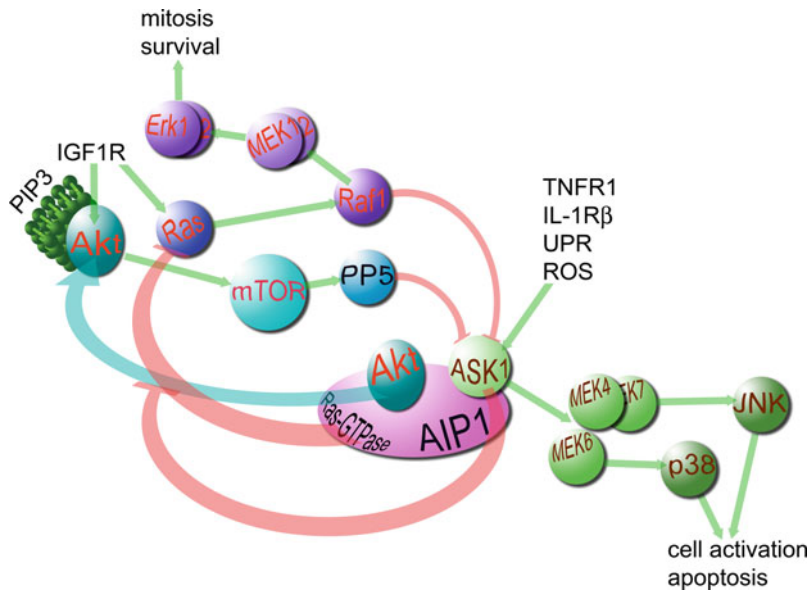
While Erk1/2 associates IGF1R activation with cell growth and differentiation, cytotoxic effects of inflammation are often mediated by the stress kinases JNK and p38 (Fig. 6). Preferential use of different MAPK modules by IGF1R and inflammation-associated pathways, however, is not absolute. Inflammation-activated MAP3K of the JNK and p38 MAPK modules include ASK1, MEKK2, MEKK3, and Mixed Lineage Kinase (MLK). Activation of ASK1 and its downstream effector MAPK is an evolutionarily conserved pathway mediating cellular pathology in inflammatory and other diseases (Takeda et al. 2008). Inflammation-related pathways of ASK1 activation include the pro-inflammatory cytokines TNFα and IL-1β, ROS, and cellular response to ER stress.

Perhaps unsurprisingly, cytoprotective effects of the IGF1R pathway are in part mediated by inhibition of ASK1 (Fig. 6). ASK1 may be inhibited by recruitment to the IGF1R signaling complex via a mechanism that requires Raf1. In addition, two modifications of ASK1 molecule that lead to its inactivation can be induced by the IGF1R signaling pathway. They are dephosphorylation of Thr^{838} by protein phosphatase 5 (Fig. 6), which is activated by mTOR, and Akt-induced phosphorylation on Ser^{83}.

On the other hand, ASK1 may inhibit IGF1R signaling. This may involve AIP1. Under inflammatory conditions, AIP1 is activated in response to cytokines and ER stress. AIP1 has the ability to inhibit Ras because it has Ras-GTPase activity. It also contains domains that bind ASK1 and Akt, bringing them together. This sequesters Akt in cytosol, preventing its translocation to the plasma membrane and interaction with PIP3. The Akt-inhibiting function of AIP1 is increased by phosphorylation at Ser^{604} induced by ASK1 (Xie et al. 2009). Therefore, AIP1 inhibits both Erk1/2 activation and the PI3K/Akt pathway. These properties implicate AIP1 in the inhibition of IGF1R signaling during inflammation (Fig. 6).

Stress of the ER

Proteins are synthesized and folded in ER. Overloading of ER with nascent protein molecules or decrease in its functional capacity may lead to an adaptive cellular response, known as unfolded protein response (UPR), which attempts to restore ER functions. The major adaptive effect of UPR is inhibition of translation, resulting from inactivation of eukaryotic initiation factor 2 by double-stranded RNA-activated protein kinase (► PKR) and PKR-like ER kinase.



Insulin-like Growth Factor Receptor Type I (IGF1R) Signaling and Inflammation, Fig. 6 *ASK1 in cross-regulation of IGF1R and inflammation-activated signaling pathways*. ASK1 may be inhibited by IGF1R signaling via Akt- and MAPK-dependent pathways. ASK1 interaction with AIP1 negatively regulates IGF1R signaling because docking to AIP1 and phosphorylation by ASK1 sequesters Akt in the cytosol preventing its translocation to PIP3 in the plasma membrane. Furthermore, because of its Ras-GTPase activity AIP1 inhibits Ras

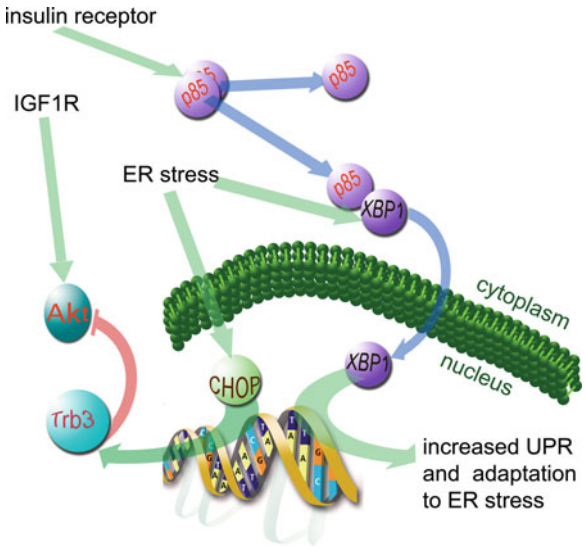
These kinases are activated together with the other sensors of ER stress, which include activating transcription factor 6 and inositol-requiring enzyme-1 (Ire1). Activated Ire1α subunit removes an internal fragment from X box-binding protein 1 (XBP1) transcript, generating thereby a stable transcriptionally active splice variant of XBP1 (Zhang and Kaufman 2008). UPR leads to the induction of gene expression programs that restore protein folding capacity of ER. Therefore, adaptive role of UPR is mediated by relieving ER overload, increasing its protein folding capacity and sparing cellular resources.

UPR is a common feature of cellular pathology in inflammation. Moreover, since IGF1R activation has a potent anabolic effect, it leads to increased loading of ER with nascent proteins, also predisposing cells to ER stress. This, however, does not compromise IGF1R-dependent cytoprotection because IGF1R signaling can promote cell adaptation to ER stress, regardless of its causes, by inducing expression of chaperones, such as Grp78 (Pfaffenbach and Lee 2012), and via several other mechanisms.

Failure to resolve ER stress by UPR results in the activation of cell death pathways. UPR-specific transcription factor, core/emopamil binding protein homologous protein, activates several genes in pro-apoptotic pathways. One of its targets is the intracellular pseudokinase ▶ Tribbles-related protein 3 (Trb3), which is expressed in response to ER stress in different cell types, including neuronal cells, chondrocytes, skeletal muscles, and cardiac myocytes. Trb3 inhibits the PI3K/Akt pathway by dephosphorylation of Akt, but its effect may be counteracted by IGF1R activation (Fig. 7). IGF1R role in UPR enhancement may also be mediated by increased nuclear translocation of XBP-1 induced by monomeric p85 subunits of PI3K, which are released from dimers when PI3K becomes activated (Fig. 7). Furthermore, UPR enhancement by IGF1R activation has been shown that is independent of any known arm of the IGF1R signaling cascade (Novosyadlyy et al. 2008). Therefore, increased adaptation to ER stress may play a role in cytoprotective action of IGF1R in inflammation.

NF-κB Signaling Pathway

NF-κB family of transcription factors transduce signals from several receptors activated by pro-inflammatory factors, including the receptors of TNFα and IL-1β, as well as TLR, receptors recognizing pathogen molecular patterns (Wajant and Scheurich 2012). The five members of this family of transcription factors form homo- and heterodimers maintained in transcriptionally inactive state by interaction with an inhibitor of κB (IκB). NF-κB dimers are activated when IκB is inhibited by phosphorylation mediated by IκB kinase complex (IKK). The sequence of events leading to nuclear translocation of NF-κB dimers after they have been released from IκB-mediated inhibition is known as the classical pathway of NF-κB activation. This pathway is characterized by



Insulin-like Growth Factor Receptor Type I (IGF1R) Signaling and Inflammation, Fig. 7 *IGF1R signaling and UPR*. PI3K activation results in dissociation of p85 dimers, and monomeric p85 enhances nuclear translocation of XBP1, promoting adaptation to ER stress. At the same time, ER stress may inhibit Akt by induction of Trb3 expression. This may be counteracted by IGF1R activation. CHOP core/emopamil binding protein homologous protein

predominant formation of heterodimers consisting of p50 and p65 proteins of NF-κB family (Wajant and Scheurich 2012). Activation of the classical NF-κB pathway in resident nonimmune cells at sites of inflammation may induce production of pro-inflammatory cytokines and improve cell survival, which in many instances results from inhibition of JNK-induced apoptosis.

NF-κB does not appear to be a major signaling pathway mediating cellular responses to IGF1R activation, but nuclear translocation of p65 and NF-κB-mediated transcriptional control have been implicated in a diverse range of biological effects elicited by IGF1R signaling, including stimulation of endothelial cell migration, chondroblast proliferation, lung fibroblast differentiation, cytoprotection of keratinocytes from UV, neuroprotection, and MHC I promoter activation. IGF1R-induced NF-κB activation is dependent on MAPK and Akt, but, unlike NF-κB activation in response to pro-inflammatory factors, may not require IκB phosphorylation.

NF-κB signaling activated by pro-inflammatory factors may be inhibited or modified by co-activation of the IGF1R, as shown in untransformed cells of different lineages, including keratinocytes, astrocytes, and vascular smooth muscle cells. Co-activation of the IGF1R may change the composition of NF-κB dimers formed in response to pro-inflammatory factors. This may inhibit nuclear translocation of NF-κB or change the array of genes activated by this pro-inflammatory pathway. These effects of IGF1R signaling might be in part mediated by phosphorylation of NF-κB subunits.

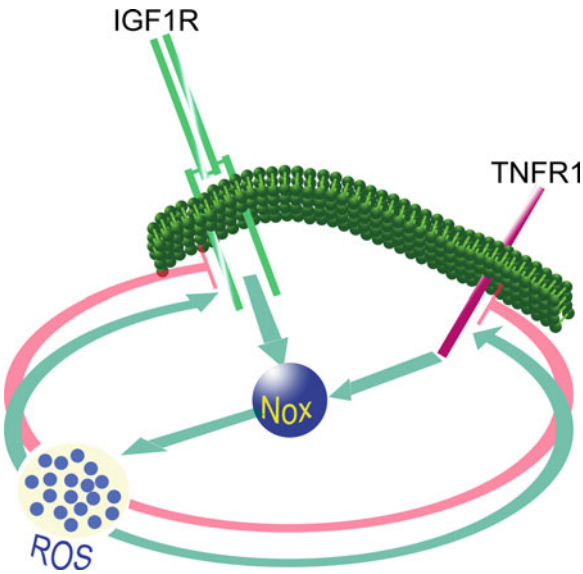
Oxidative Stress

ROS are generated during oxygen metabolism, predominantly in mitochondria by electron transfer from nicotine amid dinucleotide phosphate (NADPH) to O_2 by NADPH oxidases (Nox). Pro-inflammatory cytokines, as well as insulin and IGF-I, have the capacity to increase cellular oxidative potential by inducing increased Nox activity (Meng et al. 2008). Nox are regulated by changes in the phosphorylation status of their regulatory subunits. The association of IGF1R activation with increased ROS production may also be mediated by Rac1, a member of Rho Family GTPases (Meng et al. 2008).

ROS may modify intracellular signal transduction pathways of several receptors. Enhanced signaling of the IGF1R, as well as receptors of several pro-inflammatory cytokines and insulin, may result from inhibition of protein phosphatases by reversible oxidation of cysteine residues in the signature motif (Vardatsikos et al. 2009). Whether oxidants inhibit or activate the IGF1R signaling cascade may be dose- and cell-type-dependent, because ROS transactivated IGF1R in vascular smooth muscle cells, increasing IGF1R-depednent activation of Erk1/2 and Akt, but in microglia and neurons IGF1R-dependent Akt phosphorylation was inhibited by ROS. Therefore, ROS may be involved in cross-regulation of IGF1R and inflammation-activated signaling pathways (Fig. 8).

IRS as a Target of Inflammation-Activated Pathways

IRS-1 is a substrate of several serine/threonine kinases found in the signaling pathways activated by the IGF1R, as well as those activated during inflammation, such as Erk1/2, JNK, IKK, mTOR, Rsk, PKR, Protein Kinase C δ, and PKCζ. Serine phosphorylation of IRS inhibits its function as a signaling molecule in the IGF1R complex by inducing dephosphorylation of IRS tyrosines, which results in IRS dissociation from the IGF1R and plasma membrane. Targeting IRS by serine kinases activated in response to IGF-I may



Insulin-like Growth Factor Receptor Type I (IGF1R) Signaling and Inflammation, Fig. 8 *ROS in cross-talk between IGF1R and inflammation*. Agonist-dependent activation of the IGF1R and TNFR1 leads to increased activity of Nox and ROS production. ROS may positively or negatively regulate activation status of the receptors

mediate negative feedback, whereas IRS inhibition by inflammation-activated kinases may reduce cellular sensitivity to cytoprotective effects of IGF-I under inflammatory conditions. IRS inhibition, together with some other mechanisms, implicates low-level chronic inflammation in the development of systemic insulin resistance (Hotamisligil 2010). Dephosphorylation of tyrosines by protein phosphatases is also inhibitory for IRS-1.

Few serine phosphorylation sites are found in IRS-2, making this isoform less amenable to regulation by differential phosphorylation. IRS-2, however, may be transcriptionally inhibited during ER stress.

The IGF1R Signaling Pathway and Inflammatory Diseases

Inflammatory mechanisms are involved in tissue degeneration in many diseases. These include a group of chronic tissue-specific autoimmune conditions, which are characterized by inflammation-dependent tissue loss followed by functional deficit, with examples including demyelination in multiple sclerosis, cartilage destruction in rheumatoid arthritis, and inflammation-mediated degeneration of pancreatic β-cells in type I diabetes. Both IGF1R-mediated cytoprotection and inhibition of IGF1R signaling by pro-inflammatory factors have been shown in these conditions (Glass 2005; Ye et al. 2007). It remains to be elucidated to what extent cytoprotective mechanisms mediated by endogenous IGF-I and -II modify the course of these inflammatory diseases.

Pro-inflammatory factors, including cytokines, ER stress, and ROS, contribute to the pathogenesis of type 2 diabetes and the metabolic syndrome by suppression of intracellular signal transmission from insulin receptor and IGF1R. Interplay between IGF1R signaling and inflammation may also play an important and complex part in pathogenesis of atherosclerosis. IGF1R signaling is required for maintenance of vascular smooth muscle cells in differentiated status, which is an atherosclerosis-inhibiting effect, but dedifferentiated vascular smooth muscle cells proliferate and migrate in response to IGF1R activation, thereby promoting atherosclerotic lesion formation. Furthermore, tissue hyperplasia in several inflammatory conditions, such as Crohn's disease and allergic airway inflammation, may be dependent on IGF1R-mediated signaling.

Testing experimentally all possible interactions mediating cross-regulation of the IGF1R signaling cascade by inflammation-activated signaling and vice versa may be inefficient because of the complexity of these intracellular signaling networks. Computational modeling is, therefore, an important approach for understanding network dynamics and underlying mechanisms. In one of the pioneering studies in this area, a discrete modeling approach in combination with experimental data analysis has been applied in order to analyze the involvement of PKR in cross-regulation of the insulin receptor signaling network (Wu et al. 2009).

Summary

Cells of different lineages express the IGF1R beginning from early developmental stages into adulthood. This receptor mediates effects of the growth factors IGF-I and -II. Cellular responses to IGF1R activation include increased cell growth, inhibition of apoptosis, cell division, differentiation and acquisition of new phenotypic features required for functional competence. Depending on the cell type these responses are activated in various combinations. Effects of IGF1R ligation are mostly mediated by activation of MAPK family proteins and PI3 kinase. Phosphatidylinositol 3,4,5 triphosphate generated by PI3K from plasma membrane lipids activates Akt and several other

pleckstrin homology domain containing proteins, which regulate cell growth and survival by targeting several effectors, including GSK3, FOXO transcription factors, and mTOR. As IGF1R is so widely distributed, it is important to understand how this cytoprotective signaling cascade interacts with signaling pathways activated by pathological processes leading to tissue degeneration, in particular, inflammation-activated pathways. IGF1R activation may counteract cytotoxic effects of pro-inflammatory factors by inhibiting some of the components in their signaling pathways, including the stress MAPK JNK and p38, NF-κB transcription factors, pro-apoptotic Bcl-2 family members, and mediators of endoplasmic reticulum stress. On the other hand, inflammation-activated signaling pathways may inhibit IGF1R signaling, for example, by targeting IRS and Akt. Reactive oxygen species, which are generated during cell activation by IGF1R ligands and pro-inflammatory factors, may also mediate cross-regulation between the IGF1R and inflammation-activated signaling pathways. This cross-talk, rather than an isolated response to pro-inflammatory factors, may drive a number of pathological processes, including tissue-specific autoimmune diseases, atherosclerosis, and the metabolic syndrome.

Integrin Alpha 11

Cédric Zeltz and Donald Gullberg
Department of Biomedicine, University of Bergen, Bergen, Norway

Historical Background

Integrin α11 is the last member of the integrin family to be discovered. This integrin subunit was initially named α_{mt}, since it was first identified on cultured

human fetal myotubes (Gullberg et al. 1995). In 1995, Velling et al. identified the β1-associated α11 as a collagen-binding integrin. Two years later, Tiger et al. (2001) described the α11β1 integrin as a collagen receptor involved in cell migration and collagen reorganization. The generation of α11 integrin $^{-/-}$ mice was a major advance in determination of α11 integrin functions (Popova et al. 2007).

Gene and Protein Structure of the α11 Integrin

The human α11 integrin gene (*ITGA11*) is localized on chromosome 15q23 and consists of 130 kb, whereas the mouse α11 integrin gene (*Itga11*; length of 106 kb), has been mapped to chromosome 9. Both the human and mouse genes contain 30 exons and 29 introns.

ITGA11 encodes a mature protein of 1,166 amino acids. The extracellular domain contains seven FG-GAP (Phe-Gly – Gly-Ala-Pro) repeats and a 195-amino acid-long I domain inserted between the repeats 2 and 3. The I domain presents a metal ion-dependent adhesion site (MIDAS) motif and three potential divalent cation-binding motifs. The short cytoplasmic tail of 24 amino acids contains the motif Gly-Phe-Phe-Arg-Ser (GFFRS) instead of the conserved Gly-Phe-Phe-Lys-Arg (GFFKR) sequence described in most of α subunits. A 23-amino acid-long transmembrane domain links the extracellular and cytoplasmic domains (Velling et al. 1999).

The mouse α11 integrin shows an 89% identity with human α11 at the protein level, 97% in the I domain (Popova et al. 2004).

Expression and Regulation of the α11 Integrin

Distribution

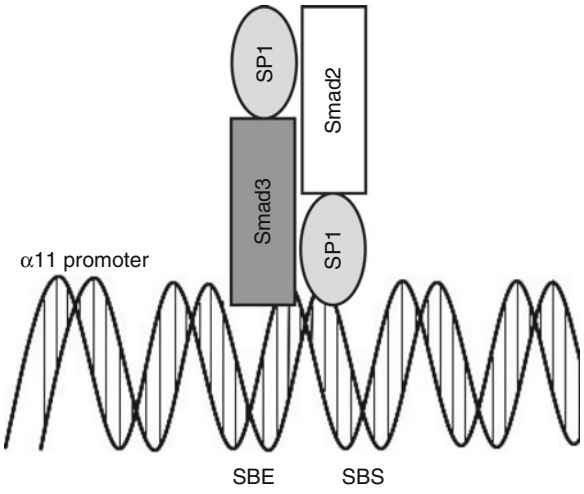
The expression of integrin α11 was first described in cultured human fetal muscle cells in vitro (Gullberg et al. 1995). In human adult tissue, α11 mRNA was expressed in high levels in uterus and heart and in intermediate levels in skeletal muscle (Velling et al. 1999). However, in human and mouse embryos, no expression of α11 was detected in muscle cells (Tiger et al. 2001; Popova et al. 2004). Later it was shown that in muscle tissue α11 is expressed in fibroblasts. α11 is present in fibroblasts around ribs, vertebrae, in intervertebral disks, and in keratocytes of the cornea of 8-week human embryos. In the mouse embryo, α11 is prominent in the ectomesenchyme in the head including the periodontal ligament, in tendons and intestinal villi fibroblasts. The α11 chain expression appears to be specific to mesenchymal non-muscle cells in vitro and in vivo. α11 expression has also been reported in tumor tissue from melanoma and lung carcinoma (Vuoristo et al. 2007; Zhu et al. 2007). The high levels of α11 integrin expression in lung carcinoma in situ are derived from the cancer-associated fibroblasts and is thus in the lung not contributed by the cancer cells. Recent RNA data indicate that α11 might be involved in epithelial mesenchymal transition (Ke et al. 2008).

Regulation

The α11 integrin proximal promoter, which is important for basal transcription, contains some regulatory elements. The presence of two Sp1 sites and an Ets-1 site is necessary to the control of the α11 integrin gene expression (Lu et al. 2006). Cytokines are able to regulate the α11 integrin expression by inducing signaling molecules, which regulate transcription factor binding to these responsive elements.

Thus, TGF-β1 was shown to up-regulate the α11 expression in HT1080 fibrosarcoma cell line as well as in primary fibroblasts and MRC-5 human myofibroblasts (Honda et al. 2010; Lu et al. 2010). The responsiveness to TGF-β1 is dependent on Smad2/3 and Sp1-regulated transcription. The Smad-binding element SBE2 and the Sp1-binding site SBS1 are located in close region on the proximal promoter (nt –182/–176 and –140/–134, respectively). This proximity could promote a possible interaction between the Smad and Sp1 proteins (Fig. 1). Activin A, which belongs to the TGF-β family, is involved in the up-regulation of α11 in mouse embryonic fibroblasts (MEFs), in a mechanosensitive manner (Carracedo et al. 2010). This induction of α11 expression requires the Smad3 protein. It is also not excluded that collagen could activate α11 expression via the induction of the Smad signaling pathway, independently of the TGF-β ligand (Garamszegi et al. 2010). Since this crosstalk signaling requires β1-integrins, α11β1, like α2β1, might also exert a positive feedback on its expression using this pathway.

Type I interferons, including IFN-α and IFN-β, have also been described to regulate the α11



Integrin Alpha 11, Fig. 1 The schematic representation shows the Smad-binding element (*SBE*) and the Sp1-binding site (*SBS*) of the *ITGA11* promoter. Sp1 is predicted to form a dimer with Smad2. Direct binding of Smad3 to SBE is predicted to occur. This interaction might also cooperate with Sp1 binding to SBS

expression. IFNs are able to stimulate α11 mRNA and protein expression in glioblastoma-derived cell line T98G (Leomil Coelho et al. 2006).

Up to now, down-regulation of α11 was only reported in mesenchymal stem cells treated with ▶ FGF-2 (Varas et al. 2007). However, the responsive elements involved in the down-regulation have not yet been determined in the α11 promoter.

Integrin α11 Functions

In Vitro Functions

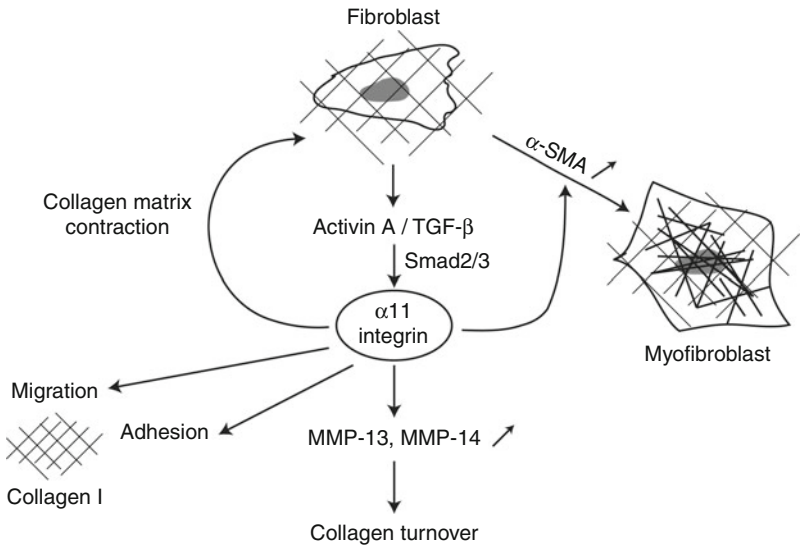
The α11 integrin chain is exclusively associated with the β1 subunit at the cell surface, to form the α11β1 integrin. Tiger et al. (2001) have demonstrated that α11β1 promoted cell attachment to collagen I. Integrin α11β1 displays certain collagen specificity, since it binds preferentially type I collagen, whereas it interacts with collagen IV with a low affinity. The α11 I domain recognizes the triple-helical GFOGER (where single letter amino acid is used, O = hydroxyproline) sequence present in collagen I as well as the GLOGER motif (Zhang et al. 2003; Siljander et al. 2004). Thus, α11β1-mediated cell responses could differ depending on the GxxGER collagen motif that interacts with this integrin. Another study has identified the GLPGER motif of the recombinant Scl1 protein, a prokaryotic collagen, as an α11β1 binding sequence (Caswell et al. 2008). The interaction between the cell surface streptococcal Scl1 and the human α11β1 integrin might increase host colonization by pathogenic bacteria, but the details of this process remains to be determined.

The role of α11β1 in platelet-derived growth factor (PDGF)-stimulated cell migration on collagen I coating seems to be cell type dependent. The C2C12 mouse satellite cells, stably transfected with human α11 integrin cDNA, showed a stronger chemotactic response to PDGF-BB, compared to C2C12 wild-type cells, which lack endogenous collagen receptors (Tiger et al. 2001). In contrast, MEFs depleted in α11β1 migrated more on collagen I in comparison to wild-type embryonic fibroblasts (Popova et al. 2004). However, in this last case, a compensatory mechanism, involving other collagen receptors, cannot be excluded.

α11β1 also showed an ability to contract collagen lattices, an important function which contributes to the reorganization of collagen matrices (Tiger et al. 2001).

Under certain conditions, fibroblasts can be activated and differentiated into so-called myofibroblasts. Myofibroblasts are characterized by α-smooth muscle actin (α-SMA) incorporated into stress fibers. Corneal fibroblasts, under action of TGF-β, overexpress α-SMA. Since siRNA directed against the α11 integrin completely abrogated α-SMA up-regulation, it was shown that α11β1 also plays a role in myofibroblast differentiation (Carracedo et al. 2010). The regulation of myofibroblast differentiation by α11β1 could be relevant in pathological processes such as tumor–stroma interactions and fibrosis, where myofibroblasts are involved.

Integrin turnover is an essential process involved in cell adhesion and migration. Generally, integrins present on the cell surface are either released and used in new adhesion sites or internalized by endocytosis. Rab proteins, including Rab21, regulate the traffic of endocytotic vesicles via interaction with the cytoplasmic tail of α integrin subunit, as shown for ▶ integrin α2β1 (Pellinen et al. 2006). The C-terminal part of Rab21 was also able to bind to the cytoplasmic domain of α11 integrin, thus suggesting that α11β1 could be regulated by endocytosis. Since Rab21 activity has been shown to regulate the motility of breast and prostate cancer cells, it could be interesting to examine if an association between this small GTPase and α11β1 occurs in cancer-associated fibroblasts and if it might have an impact on the tumor progression.



Integrin Alpha 11, Fig. 2 α11 is induced in a mechanosensitive manner via activin A. It promotes cell adhesion and migration on type I collagen and participates in the contraction of collagen lattices. α11 is also involved in the regulation of collagen turnover and in myofibroblast differentiation. The different functions of α11 occur in various contexts

In Vivo Functions

The in vivo function of the α11 integrin was partially elucidated using the knockout mouse model. The α11-deficient mice were smaller and displayed increased mortality compared to the heterozygous and wild-type mice (Popova et al. 2007). Dwarfism observed in these α11-deficient mice was not due to structural defects in forming cartilage or bone. Instead, the smaller size and malnutrition of α11-deficient mice appear to correlate with delayed incisor eruption and altered tooth shape. The incisor periodontal ligament (PDL), which plays a central role during rodent incisor eruption, showed increased thickness due to increased amount of collagen. In this mutant tissue, a decrease of MT1-MMP and MMP-13 mRNA level was also noted. A reproducible result was obtained in vitro, where MEFs isolated from α11-deficient embryos showed reduced MT1-MMP and MMP-13 mRNA expression, whereas MMP-2 and MMP-9 activities were not affected. These observations suggest that α11 could be involved in the regulation of metalloproteinases as MMP-13 and -14, thus controlling the collagen turnover in PDL (Fig. 2).

As described above, α11β1 has been reported to be up-regulated in some tumor forms. It might be used as marker for diagnosis, as suggesting in human non-small cell lung cancer (Chong et al. 2006). α11 was also shown to enhance tumorigenicity of this type of tumor by regulation of the IGF2 expression, a potent growth stimulator of epithelial tumor cells (Zhu et al. 2007). However, the exact role of α11 in the tumor stroma during TGF-β1-dependent myofibroblast differentiation, tumor growth, and tumor metastasis remains to be determined.

Summary

Integrin α11β1 is expressed in mesenchymal non-muscle cells in vitro and in vivo at sites where collagens are organized in a highly ordered manner. It appears as a multifunctional integrin in different contexts (Fig. 2). However, little is known about the detailed molecular mechanisms involved in α11β1 functions, and thus, the major signaling pathways utilized by α11β1 remain to be determined.

Historical Background

Integrins are heterodimeric glycoproteins composed of non-covalently associated α and β subunits, and constitute one of the *largest* families of adhesion molecules. Integrins mediate cell-to-cell and cell-to-extracellular matrix interactions and are involved in a wide range of physiological processes such as development, immune regulation, and hemostasis.

Mammalian genomes contain 18 α subunit and 8 β subunit genes which generate 24 different αβ heterodimer combinations.

The α_4 integrin subunit is expressed on the cell surface associated with β_1 or β_7 integrin chains (Hemler et al. 1987; Sanchez-Madrid et al. 1986). These α_4 integrins ($\alpha_4\beta_1$, also known as VLA-4, and $\alpha_4\beta_7$) are involved in important cell differentiation processes such as neural and muscle cell differentiation and hematopoiesis. The importance of α_4 integrins in development is demonstrated by the embryonic lethality of disruption of the α_4 integrin gene in mice; a fraction of these embryos die due to a defect in the development of the placenta, while the rest die after hemorrhage in the heart region. The generation of chimeric mice revealed that α_4 is essential for hematopoiesis and also for epicardial development (Arroyo et al. 1996). α_4 integrins also play a key role in the adhesion interaction between stem/progenitor cells and bone marrow stromal cells and their matrix (Miyake et al. 1991). The most well-documented role of α_4 integrins is in leukocyte adhesion, motility, and extravasation during the inflammatory response. All of these functions are mediated through the binding of α4 integrins to their ligands, which include fibronectin, and the Ig Superfamily members VCAM-1, JAM-B, and MadCAM.

α4 Integrin Expression

The α_4 integrin subunit is expressed as an integral membrane protein on the surface of several cell types, mostly restricted to the hematopoietic lineage in adults (Hemler et al. 1987; Sanchez-Madrid et al. 1986). Bone marrow progenitor cells and several mature cells, including mononuclear leukocytes and eosinophils, express α_4, mainly as $\alpha_4\beta_1$. Myocytes, thymocytes, osteoclasts, cardiac cells, placental cells, erythrocytes, neutrophils, and fibroblasts also express α_4, but expression on these cells depends on developmental stage and stimulation. Melanoma and neural-crest-derived tumor cell lines express $\alpha_4\beta_1$. $\alpha_4\beta_7$ is expressed at high levels by a small subset of circulating memory T cells that preferentially localize to gut-associated lymphoid tissue. This homing is mediated by the interaction of this integrin with MAdCAM-1, an addressin molecule selectively expressed on intestinal endothelial cells (Holzmann and Weissman 1989).

α4 Integrin Ligands

The most important $\alpha_4\beta_1$ integrin ligands include the extracellular matrix molecules fibronectin (FN; (Wayner et al. 1989)), osteopontin and thrombospondin, the immunoglobulin superfamily member VCAM-1 (Elices et al. 1990), which is expressed by activated endothelium, and the junctional adhesion molecule JAM-B (also known as JAM-2) (Cunningham et al. 2002), which localizes at endothelial cell–cell junctions. $\alpha_4\beta_1$, like other β_1 integrins, also interacts with the bacterial coat protein invasin (Isberg and Leong 1990), mediating bacterial entry into mammalian cells. $\alpha_4\beta_7$ integrin binds to fibronectin, VCAM-1, and the gut addressin MAdCAM-1 (Berlin et al. 1995).

α4 Integrin Function

α_4 integrins are important for the motility of many types of leukocytes, including hematopoietic stem cells, eosinophils, mast cells, and T and B lymphocytes. During inflammatory responses leukocytes interact with the activated endothelium in order to migrate from the bloodstream to peripheral tissue. This extravasation process consists of the steps of tethering and rolling, firm adhesion, and diapedesis. α4 integrins, by interacting first with VCAM-1 (vascular cell adhesion molecule-1) and then with JAM-B (junctional adhesion molecule-B), participate in all of these steps (Berlin et al. 1995; Elices et al. 1990). α_4 integrins are involved in the recruitment of bone marrow-derived endothelial progenitors to the neovasculature and mediate their adhesion to VCAM-1 on endothelial and mural cells in neovessels (Garmy-Susini et al. 2005). Integrin $\alpha_4\beta_1$ is enriched at the immune synapse during activation of T lymphocytes and acts as a co-stimulatory molecule driving T helper (T_H)1/T_H2 cell differentiation (Mittelbrunn et al. 2004). Integrin $\alpha_4\beta_7$, through its interaction with MAdCAM-1 expressed on intestinal endothelial cells (Holzmann and Weissman 1989), acts as a homing receptor for a subset of memory T cells that preferentially migrate to gut-associated lymphoid tissue.

Regulation of α_4 Integrin Function

The capacity of α_4 integrins to bind their ligands is regulated both by intracellular signaling mechanisms and by extracellular stimuli. Intracellular signals induce conformational changes (integrin activation) that result in increased ligand-binding affinity, while

extracellular stimuli modify the expression and activation status as well as the level of receptor aggregation/clustering on the plasma membrane. The conformational change of integrin activation involves the cytoplasmic domains of the α and β subunits. Under resting conditions, these domains associate with each other. This association is thought to function as a "clasp" that keeps integrins in a low ligand-affinity bent conformation. When the cells are activated, the cytoplasmic domains dissociate and the extracellular domains form an open conformation that allows interaction with ligands. The association of the α and β cytoplasmic domains is regulated by the GFFKR sequence, a well-preserved motif in the α4 cytoplasmic domain.

The signaling pathway that underlies the inside-out activation mechanism of $\alpha_4\beta_1$ upon stimulation of the B-cell receptor has been described, and involves the consecutive activation of Lyn, Syk, phosphatidylinositol-3′ hydroxy kinase, Bruton's tyrosine kinase (Btk), phospholipase C (PLC)γ_2, Ins(1,4,5)P_3-receptor-mediated Ca^{2+} release, and protein kinase C (Spaargaren et al. 2003). The affinity of α_4 integrins is also regulated by divalent cations; Mn^{2+} and Mg^{2+} modulate the strength of binding to VCAM-1 and MAdCAM-1, while Ca^{2+} facilitates the binding of $\alpha_4\beta_1$ to VCAM-1. The small GTPase Rap 1 and its effector RAPL play a role in the activation of β_1 and β_2 integrins induced by the T-cell antigen receptor (TCR), CD31, and cytokines (Katagiri et al. 2004). Clustering of integrins on the cell membrane also increases their adhesiveness as a result of cooperative binding (Hogg et al. 2003). An additional factor that might contribute to α_4 integrin function is their lateral association with CD44 and the tetraspanins CD53, CD63, CD81, and CD82, which might facilitate integrin receptor clustering.

Signaling

The cytoplasmic domain of the α_4 subunit can bind directly to paxillin, a signaling adaptor molecule that has been reported to regulate the function of α_4 integrins in immune cells (Liu et al. 1999). Paxillin binds to the α_4 cytoplasmic domain upon dephosphorylation of Ser988. The paxillin–α_4 interaction inhibits the formation of focal adhesions, stress fibers, and lamellipodia by triggering the activation of various tyrosine kinases, such as focal adhesion kinase (FAK), Pyk2, Src, and Abl. The paxillin–α_4 complex inhibits the formation of stable lamellipodia by sequestering ADP-ribosylation factor (Arf)-GTPase-activating protein, thereby decreasing Arf activity and inhibiting Rac. It has recently been reported that dissociation of ▶ Vav1 from talin generates alpha4beta1-talin complexes, resulting in high-affinity alpha4beta1 conformations and efficient integrin activation (Garcia-Bernal et al. 2009). Moreover, recent evidence suggests that Kindlins, a group of 3 structurally related adaptors, cooperate with talin in activating integrins through binding to the integrin β subunits (Montanez et al. 2008).

Therapeutic Applications

It is well recognized that inflammatory responses form part of the pathogenesis of many disorders, including autoimmune diseases. The integrins $\alpha_4\beta_1$ and $\alpha_4\beta_7$ are fundamental for the adhesion and migration of leukocytes to different inflammatory scenarios and have therefore been investigated as potential therapeutic targets. Administration of anti-α_4 mAb or various synthetic blockers has shown beneficial effects in several animal models, including experimental allergic encephalomyelitis, adjuvant-induced arthritis, diabetes mellitus of NOD mice, experimental graft-versus-host disease, allograft rejection, and immediate hypersensitivity reactions (Yusuf-Makagiansar et al. 2002).

In a clinical setting, the humanized anti-α_4 mAb natalizumab (Tysabri) has been approved for treatment of the relapsing forms of multiple sclerosis and Crohn's disease (Gonzalez-Amaro et al. 2005). Multiple sclerosis is an inflammatory demyelinating disease of the central nervous system that is presumably caused by activated T cells specific for myelin antigens. Crohn's disease is an inflammatory bowel disease (IBD), a group of chronic systemic diseases involving inflammation of the gastrointestinal tract. Patients with multiple sclerosis or Crohn's disease show significant improvements with natalizumab (Gonzalez-Amaro et al. 2005).

Another recently suggested application for α_4 blocking agents is the treatment and prevention of epilepsy. Recent findings indicate that seizure activity is associated with leukocytic inflammatory changes in the central nervous system vasculature. α_4-specific antibodies decrease leukocyte adhesion to the brain vessel wall and have anti-epileptogenic properties, reducing and preventing subsequent seizures (Fabene et al. 2008).

It has been assumed that the therapeutic effect of this type of mAb is a consequence of the inhibition of the interaction of α_4 integrins with VCAM-1 and MAdCAM-1, thus inhibiting leukocyte extravasation to inflammatory foci. However, the complex role of α_4 in immune cells, including its involvement in leukocyte activation and T_H1/T_H2 polarization (Mittelbrunn et al. 2004), might lead to undesired side effects with anti-α_4 mAbs. This possibility should be considered, especially in relation to the treatment of autoimmune and inflammatory diseases associated with T_H1/T_H2 imbalance. Further studies are needed to minimize risks and optimize benefits of long-term maintenance therapy with these antibodies.

Summary

Integrins are one of the largest families of adhesion molecules that mediate cell–cell and cell–matrix interactions. α_4 integrins are expressed on many types of hematopoietic cells, including stem/progenitor cells, and are critical regulators of hematopoiesis and leukocyte trafficking.

Inhibition of leukocyte trafficking by antibody blockade of α4-integrins is a validated therapeutic approach for the treatment of multiple sclerosis and Crohn's disease. It remains unclear, however, why anti-α_4-based therapies are effective in some chronic autoimmune and inflammatory conditions but not in others, and this is an area that deserves further research. The onset of demyelinating diseases such as progressive multifocal leukoencephalopathy (PML) in some antibody-treated patients suggests that the mechanism of action of these drugs is not fully understood and forces us to carefully consider the potential risks associated with long-term administration of anti- α_4-integrin antibodies. These risks might include alterations to T helper cell differentiation, thereby distorting the population profile of T helper cells and subverting the type of immune response. Further studies are therefore needed to define the regulatory mechanisms that mediate α_4 function. The development of a new generation of modulators of α_4 integrin function, small molecules that block interaction with ligands or intracellular-associated proteins, is likely to lead to novel therapies not only for multiple sclerosis and Crohn's disease but also for others inflammatory/autoimmune diseases.

Integrin Alpha V (*ITGAV*)

Bethany A. Kerr and Tatiana V. Byzova
Department of Molecular Cardiology, Joseph J. Jacobs Center for Thrombosis and Vascular Biology, Lerner Research Institute, The Cleveland Clinic, Cleveland, OH, USA

Synonyms

Alpha v integrin; CD51; Vitronectin receptor alpha (VNRA); Vitronectin receptor, alpha polypeptide

Historical Background

The term "integrin" was coined by R.O. Hynes in 1986 to describe a family of adhesion proteins which integrate the cytoskeleton with the extracellular matrix and external stimuli. These integrins are composed of alpha and beta subunits to form a complete signaling molecule. The α_v subunit forms a complete integrin complex through heterodimerization with one of five β subunit binding partners: beta 1 (β_1), beta 3 (β_3), beta 5 (β_5), beta 6 (β_6), or beta 8 (β_8). The first α_v integrin characterized was $\alpha_v\beta_3$, which was originally termed the "vitronectin receptor," as it bound to plasma-derived vitronectin. The $\alpha_v\beta_3$ integrin was purified from plasma in 1985 by R. Pytela and then cloned and sequenced in 1986 by S. Suzuki. The name "vitronectin receptor" was quickly proven to be a misnomer as $\alpha_v\beta_3$ displays highly promiscuous binding (Table 1). The other α_v integrins were then identified over the next decade, and their binding to various extracellular ligands (Table 1), expression sites, and physiologic and pathologic functions are still being characterized.

Expression Sites

Integrin α_v is essential for embryonic and perinatal development, with a complete knockout being lethal. Approximately 80% of integrin α_v-null mice die between embryonic day (E) 10 and E12 due to placental defects, while the remaining 20% die perinatally from massive hemorrhages or cleft palates. Using conditional knockouts, the α_v integrin was proven to be important for the development of cardiomyocytes, eye basal epithelium, glial cells, sebaceous glands, pancreatic cells, the palate, and limbs (Fig. 1a). In adult tissues, the integrin α_v regulates angiogenesis, wound healing, tumorigenesis, bone remodeling, vasculogenesis, inflammation, atherosclerosis, and neurogenesis (Fig. 1b) (Bouvard et al. 2001). The role of α_v integrin in these tissues is based on its ability to switch between active and inactive conformations, resulting in the activation of signaling cascades.

Alpha V Structure

The α_v subunit N-terminus contains a β-propeller domain consisting of seven 60-amino-acid repeats which fold to create a seven-bladed β-propeller structure (Fig. 2a). Blades 4–7 of this β-propeller each contain a Ca^{2+}, Mg^{2+}, or Mn^{2+} cation in the β-hairpin loop, which may interact with the upper leg to maintain rigidity of the integrin. This ligand-binding, seven-bladed head connects to the cell membrane by a ~170-Å "leg." The leg contains an Ig-like "thigh" domain and two large β-sandwich domains in the "calf" region. The second β-sandwich domain includes a proteolytic cleavage site. In the "knee" region of the α_v subunit leg, a metal ion is bound when the integrin is ligated (Mg^{2+}) or unligated (Ca^{2+}). Mn^{2+} binds to the

Integrin Alpha V (*ITGAV*), Fig. 2 (continued)

α_v integrin knee region and stimulates activation by imitating ligand binding. This knee region is also the site of a 135° hinge which is in a sharp bend when the integrin is inactive, but is linear in the activated integrin (Fig. 2a) (Arnaout et al. 2005; Byzova et al. 1998; Plow et al. 2000; Qin et al. 2004; Takada et al. 2007). Under non-reducing conditions, the α_v subunit has an apparent molecular weight of approximately 150 kDa. However, once reduced, the α_v subunit splits into a heavy chain of 120 kDa and a light chain of 25 kDa (Byzova et al. 1998). The α_v integrin subunit's tail associates with the β integrin subunit cytoplasmic tail through a conserved GFFKR motif proximal to the transmembrane region (Fig. 2b) (Takada et al. 2007). The α_v integrin complexes bind to a variety of extracellular ligands and cluster with growth factor receptors, tyrosine kinase receptors, and other membrane glycoproteins to mediate intracellular signaling.

Integrin Alpha V Activation and Signaling

Integrin Activation

Integrins on the plasma membrane exist in a low-affinity or high-affinity state (Fig. 2c). The low-affinity, resting state is maintained by interactions between the transmembrane domains and cytoplasmic tails of the α_v and β subunits. The state of the α_v integrin is partially controlled by divalent cations. Ca^{2+} association inhibits ligand binding of the α_v integrins, while the presence of Mg^{2+} is required for ligand binding. Association of Mn^{2+} with the α_v integrin imitates ligand binding leading to signaling. Once Mg^{2+} is associated, an extracellular ligand has bound, and intracellular signaling proteins are present, the integrin rapidly switches to a reversible high-affinity state with signaling between the cytoplasmic tail, the transmembrane domain, and the extracellular ligand binding pocket (Fig. 2c) (Plow et al. 2000; Qin et al. 2004). Conformational changes in the extracellular domains control integrin activation and are necessary for ligand binding. The transmembrane domains contribute to integrin activation through alterations in the interaction of their GxxG dimerization motifs. Separation of the transmembrane domains is proposed to be necessary for integrin activation and signaling (Fig. 2c). The cytoplasmic tails of the integrins have essential roles in regulating the signaling responsible for and in response to integrin activation.

Inside-Out Signaling

Activation signals can be transduced from the cytoplasmic tail to the extracellular domain in response to intracellular activation or in response to mechanical stress, known as inside-out signaling. Conversely, the binding of integrins to soluble or fixed ligands stimulates intracellular cascades, known as outside-in signaling (Arnaout et al. 2005; Qin et al. 2004). In inside-out signaling, integrins are activated by signals from G protein–coupled receptors, by growth factor receptors, or due to mechanical stresses which activate the α_v subunit. Integrin activation and intracellular signaling molecules lead to phosphorylation of the β subunit cytoplasmic tail and its interaction with cytoskeletal adaptor proteins. The cytoskeletal adaptor proteins talin and kindlin regulate integrin activation and affinity. The talin head region binds the β subunit cytoplasmic tail and results in increased ligand affinity of the α_v integrin (Qin et al. 2004; Takada et al. 2007). In addition, kindlin proteins facilitate talin binding and coordinate control of integrin affinity, cell spreading, and cell adhesion (Plow et al. 2009). The adaptor proteins involved inside-out signaling are described in greater detail below.

Outside-In Signaling

Outside-in integrin signaling results in clustering of integrins and their binding partners on the plasma membrane and the transmission of signals to the cytoplasmic tail leading to cytoskeletal reorganization

Integrin Alpha V (*ITGAV*), Fig. 2 The structure and activation of integrin alpha v. (Arnaout et al. 2005; Qin et al. 2004). The various proteins involved in membrane clustering and signal transduction are described in detail below. Once in the high-affinity state, integrins cluster together with other cellular receptors to transmit signals. The final activation step is increased avidity of integrins for their ligands. The inactivation of integrins has not been elucidated. Integrins must separate from their ligands and intracellular partners to terminate signaling or for cell migration. Adhesion complexes can disassemble, remodel, or slide by changes in integrin affinity and association. Competitor binding and proteolysis of binding partners and β cytoplasmic tails can also return integrins to their inactive state (Qin et al. 2004).

Clustering

Integrin activation results in the clustering of integrins with growth factor receptors on the plasma membrane. This interaction facilitates signaling and leads to specificity and synergistic effects on several signaling pathways. The α_v integrins modulate transforming growth factor β (TGFβ) by binding to the TGFβ latency–associated peptide (LAP-TGFβ) and by directly binding to the TGFβ receptor (TGFβR). This clustering activates TGFβRII resulting in the recruitment of TGFβRI and stimulation of the TGFβ pathway. Integrin $\alpha_v\beta_3$ is also involved in another cell-surface complex with urokinase-type plasminogen activator (uPA), ▶ uPA receptor (uPAR), and the low-density lipoprotein receptor. The activation of ▶ uPAR and $\alpha_v\beta_3$ results in activation of TGFβ, initiating an autocrine activation loop. Thus, these receptors are internalized and recycled after activation to stop the autocrine loop and ▶ uPAR is inactived by the plasminogen activator inhibitor protein. Integrin $\alpha_v\beta_3$ also interacts with the vascular endothelial growth factor (VEGF) receptors (VEGFR2) on blood vessels to coordinate and amplify angiogenesis (Somanath et al. 2009). VEGF stimulates the formation of a complex between VEGFR2 and $\alpha_v\beta_3$ on endothelial cells. Further, VEGFR2 phosphorylation is diminished in the absence of $\alpha_v\beta_3$. In addition, $\alpha_v\beta_3$ directly interacts with the receptors: platelet-derived growth factor (PDGF) receptor, fibroblast growth factor receptor (FGFR3), insulin receptor substrate (IRS)-1, and Met. The IRS-1 complexes with $\alpha_v\beta_3$ integrin with Grb2 and phosphoinositide-3 kinase (PI3k). Interactions between vitronectin and hepatocyte growth factor stimulates the clustering of $\alpha_v\beta_3$ integrin with Met. Integrin $\alpha_v\beta_3$ also binds insulin-like growth factor-1 (IGF-1) directly and can also cluster and bind to the IGF-1 receptor (IGF1R) (Somanath et al. 2009). This binding triggers IGF1R phosphorylation and stimulation of the Akt and ERK1/2 pathways and enhances cell proliferation. The IGF-1, IGFR1, and $\alpha_v\beta_3$ integrin were shown to cluster in a ternary complex on the cell surface (Somanath et al. 2009). In addition to integrin $\alpha_v\beta_3$, integrin $\alpha_v\beta_5$ has been shown to cross-talk with the epidermal growth factor (EGF) receptor (EGFR). The EGFR and α_v integrins cooperate to control cell-cycle progression. EGFR stimulates Raf, while integrins stimulate Ras. These two proteins can then interact to induce ERK signaling (Rüegg and Mariotti 2003).

In addition, activated integrins can associate with lipid membrane rafts and membrane glycoproteins. Membrane rafts are composed of sphingolipids tightly packed with cholesterol and are ringed by flexible phospholipid-rich regions. Integrin $\alpha_v\beta_3$ localizes to membrane rafts, where it interacts with CD47 (integrin associated protein, IAP), a membrane glycoprotein. CD47 also binds thrombospondin to control the function of $\alpha_v\beta_3$ in cell migration and spreading. The binding of these two proteins recruits the Gαi subunit and diminishes intracellular cAMP leading to stimulation of G protein signaling (Rüegg and Mariotti 2003). CD47 also activates $\alpha_v\beta_3$ directly through the Gαi. These two membrane proteins may also act synergistically to effect osteoclast function, endothelial cell attachment, and cancer metastasis. The clustering of α_v integrins with membrane proteins results in synergistic effects on signaling and increased binding avidity of intracellular proteins.

Intracellular Binding Partners

Integrins bind several classes of intracellular proteins: structural, adaptor, and signaling proteins, which form focal adhesions. A majority of integrin binding to intracellular partners is through the β-subunit; however, the α_v subunit directly binds caveolin, calreticulin, and Rack-1. The binding of caveolin to the α_v subunit occurs within the transmembrane region. Caveolin physically links the α_v integrins to signaling proteins, such as Fyn, leading to the recruitment of Shc. Shc then induces signal transduction through pathway such as MAPk to promote DNA synthesis and cell-cycle progression. In addition, α_v binds directly with calreticulin through the GFFKR

motif to induce signaling pathways (Fig. 2b). Calreticulin is a luminal endoplasmic reticulum calcium-binding protein, which may modulate cell adhesion and signal transduction. Receptor for activated protein kinase C (Rack-1) interacts with the α_v subunit. Rack-1 also binds to several of the β subunits.

In α_v integrin activation, actin-binding proteins are recruited to focal adhesions and bind the cytoplasmic tail of the β subunits. These actin-binding proteins include talin, filamin, and kindlin. Talin binding to the proximal NxxY motif of the β tail induces conformational changes of the integrin subunits resulting in activation of the α_v integrin (Rüegg and Mariotti 2003). Talin also binds several of the signaling kinases that function downstream of integrins. Recruitment of talin to integrins is stimulated by the unmasking of the integrin binding site, FERM (4.1, ezrin, radixin, and moeisin) domain, in the talin head by the PKC-Rap1-RIAM pathway, ▶ calpain, or PIP2. The PKC pathway and calpain activity may control the activation state of $\alpha_v\beta_3$ on endothelial and smooth muscle cells through their effects on talin binding. The FERM domain of talin binds tyrosine 747 in the β_3 subunit tail to induce signaling (Arnaout et al. 2005). In addition, talin functions as an initial contact between integrins and the actin cytoskeleton. Talin is responsible for the association of vinculin and Arp2/3 complex to actin, resulting in the stabilization and attachment of actin filaments to the focal adhesion complexes. In addition, the interaction between talin and the $\alpha_v\beta_3$ integrins is required for mechanotransduction.

Filamins also associate with the β subunit of the α_v integrins. Filamins can be found in the focal adhesions with integrins, but are mainly found along the cortical actin cytoskeleton and along stress fibers. The recruitment of filamin to focal adhesions can be stimulated by mechanical stress. Filamin also binds signaling proteins that control the actin cytoskeleton, including Rho, Rac, Cdc42, and MAPK signaling proteins (Plow et al. 2009).

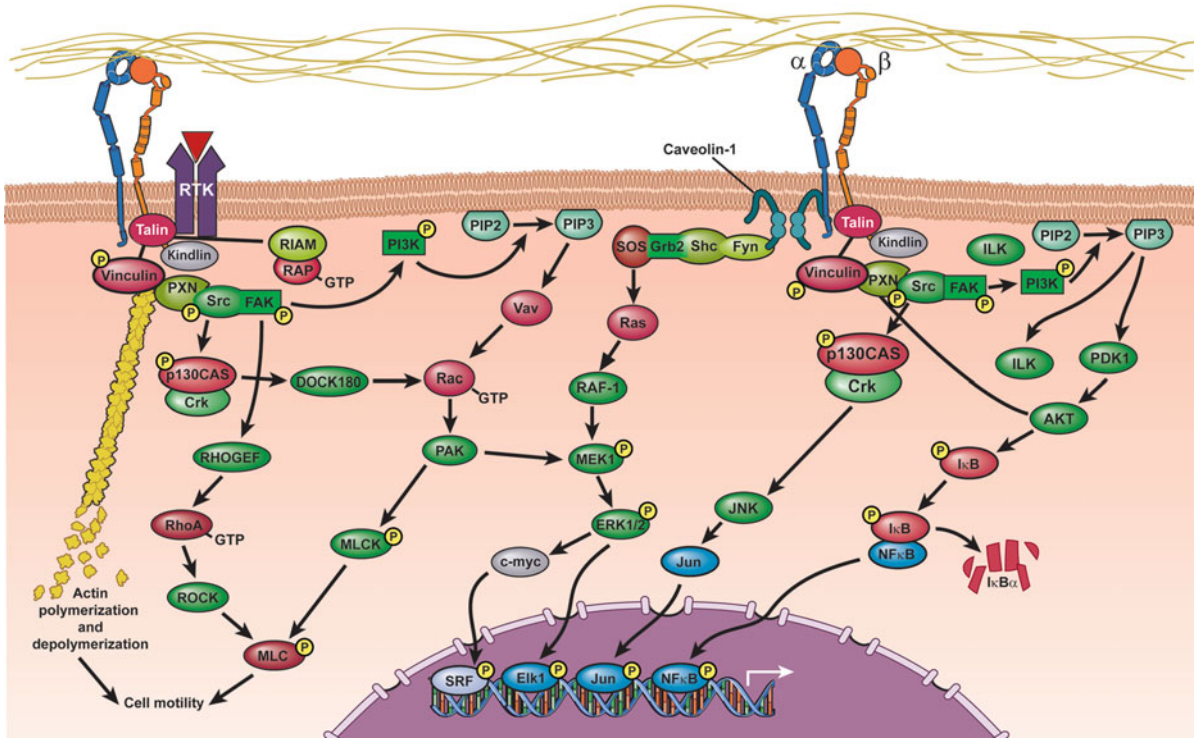
Recently, additional integrin-binding proteins, the kindlin protein family, have been identified, although their complete functions remain to be elucidated. The kindlins interact with the cytoplasmic tails of β_1 and β_3, which localize with α_v integrin. The kindlin-binding domain is located at the C-terminus of the β subunit and is separate from the domain used by talin. Kindlin binds the distal NxxY motif (tyrosine 795) of the β subunit. Kindlin and talin cooperate to control integrin affinity, with kindlins aiding talin function (Plow et al. 2009). Interestingly, the absence of kindlin-3 results in the dysfunction of integrin signaling resulting in severe defects in platelet and leukocyte function, as well as osteopenia (Malinin et al. 2010). Kindlins do not have known catalytic domains, but interact with other adaptor and signaling proteins, such as integrin-linked kinase.

The α_v integrins cross-talk with proteins involved in cell–cell junctions, such as adherens junctions. One molecule in adherens junctions is nectin, which associates with the actin cytoskeleton through afadin. Nectin creates cell–cell adhesions and stimulates c-Src-mediated activation of Rap1, Cdc42, and Rac. Nectins 1 and 2 associate with $\alpha_v\beta_3$ through their extracellular domains at cell–cell adhesion sites.

Intracellular Signaling

Integrin signal transduction requires the binding of signaling proteins including protein kinases, lipid kinases, small GTPases, and phosphatases (Fig. 3). Many of these pathways are also activated by growth factors, and through their clustering with integrin, α_v may have synergistic effects. The main protein kinase that is activated by the α_v integrins is focal adhesion kinase (FAK). FAK localizes to focal adhesions, where it interacts with the β subunit of the α_v integrins. The phosphorylation and tyrosine kinase activity of FAK is stimulated by integrin activation and binding to the extracellular matrix. FAK can also be phosphorylated by the clustering of isolated β subunit tails. FAK binds directly to talin and can also interact with vinculin and paxillin to control cell signaling and actin cytoskeletal formation. FAK activation recruits ▶ Src or Fyn, ▶ PI3k subunit p85, or PLCγ. These interactions stimulate the signaling cascades of Ras/Erk, ▶ PI3k/Akt, and Crk/Dock180/Rac (Rüegg and Mariotti 2003).

Further, the α_v integrins bind integrin-linked kinase (ILK), a serine/threonine kinase that binds directly to β_1 and β_3 cytoplasmic tails of the α_v integrins in focal adhesions (Fig. 3). The C-terminal of ILK binds the integrin β subunit, while the N-terminal domain binds PINCH, a LIM domain protein. PINCH binding to other adaptor proteins and ILK stimulation leads to the activation of several signaling pathways and actin polymerization. Further, ILK activation recruits several binding partners which result in the interaction of ILK with growth factor receptors (Siebers et al. 2005).

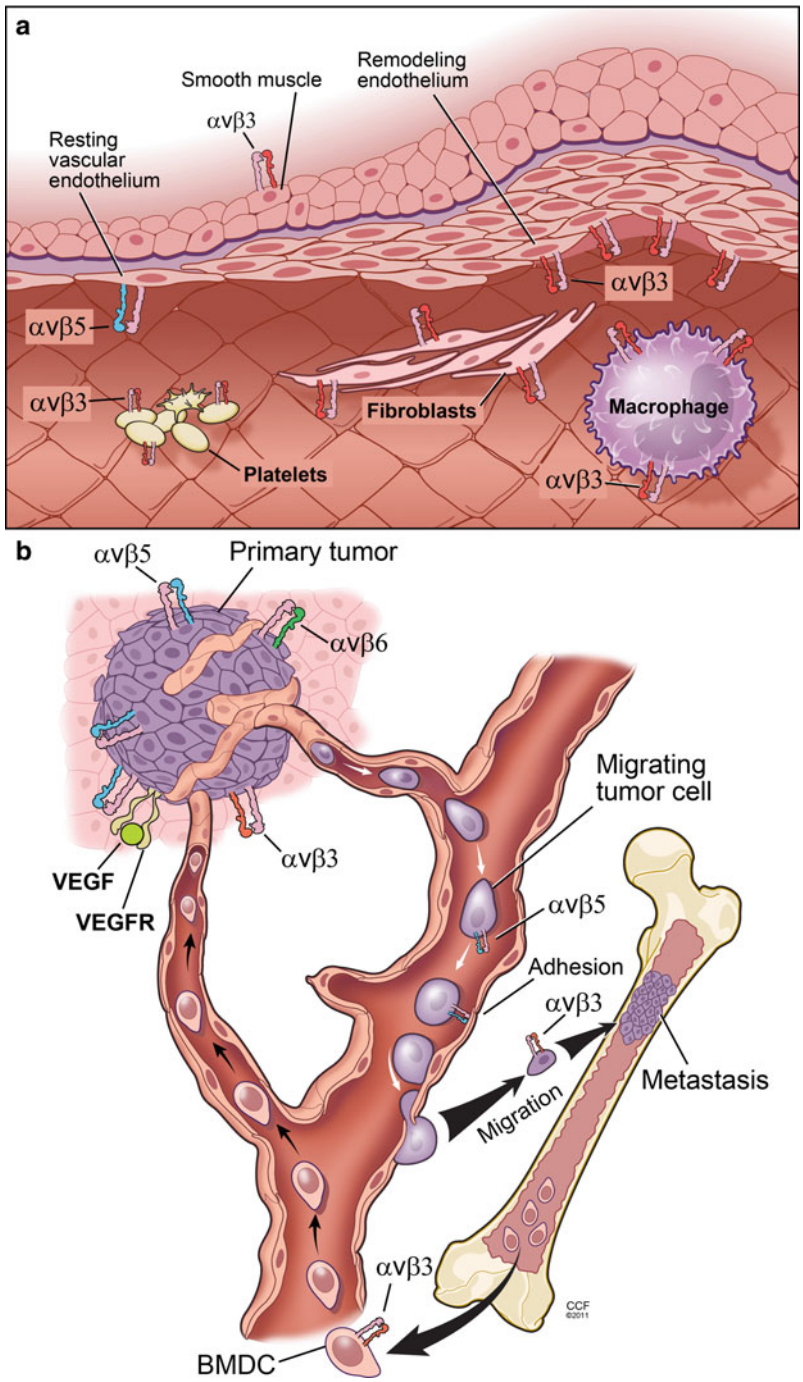


Integrin Alpha V (*ITGAV*), Fig. 3 Integrin alpha v activation stimulates signaling pathways controlling cytoskeletal organization, cell proliferation, and integrin modulation. The alpha v integrin is either bound to the actin cytoskeletal proteins or clusters with other integrins, growth factors, and membrane proteins to promote signaling through talin, vinculin, and caveolin resulting in the activation of the Src kinases (Shc, Fyn, Grb2), MAP kinases, FAK, PI3 kinase, Rho family, or Ras family signaling pathways (Illustration by David Schumick, BS, CMI. Reprinted with the permission of the Cleveland Clinic Center for Medical Art & Photography © 2011. All Rights Reserved)

The stimulation of ILK, FAK, and the α_v integrin β subunits results in the activation of a variety of intracellular signaling pathway including ▶ PI3k/Akt, Ras/▶ MAP kinase, ▶ Src family kinases, and the Rho GTPases: Rac, Rho, and Cdc42 (Fig. 3) (Rüegg and Mariotti 2003; Somanath et al. 2009). The ▶ PI3k/Akt pathway regulates gene transcription, cell proliferation, migration, and survival. The Ras-MAPK signaling pathway may mediate the effects of integrins on cell proliferation, survival, and migration. Integrin stimulation of the MAPK pathways can regulate ▶ p53, $p21^{WAF1/CIP}$, ▶ Bcl-2, and Bax, thus controlling cell-cycle progression and cell survival in response to α_v activation (Rüegg and Mariotti 2003). The ▶ Src family kinases play important roles in integrin and growth factor interaction and signaling. The signaling pathways of the ▶ Src kinases further cross-talk with the other integrin responsive pathways (Somanath et al. 2009). The Rho GTPase family, Rho, Rac, and Cdc42, is responsible for actin polymerization, the formation of focal adhesions, cell proliferation, and regulation of gene expression. Thus, through the regulation of various signaling pathways, the α_v integrins control cell survival, migration, and function within tissues (Rüegg and Mariotti 2003).

Integrin Alpha V in Angiogenesis and Wound Healing

Conditional knockout mice have demonstrated that integrin α_v is not necessary for vascular development; however, it is important in adult vascular remodeling (Fig. 4a). On the resting endothelium, $\alpha_v\beta_3$ is minimally expressed, while it is upregulated during development and on vascular cells in tumors and ischemic tissues. Expression of $\alpha_v\beta_3$ on endothelial cells can also be induced by cytokines and growth factor exposure or by shear stress. Prothrombin is responsible for $\alpha_v\beta_3$ adhesion of endothelial and smooth muscle cells,



Integrin Alpha V (*ITGAV*), Fig. 4 Integrin alpha v supports angiogenesis and tumorigenesis. (**a**) The $\alpha_v\beta_5$ integrin is expressed on resting endothelium, while the $\alpha_v\beta_3$ integrin is only expressed on remodeling endothelium and smooth muscle cells. Integrin $\alpha_v\beta_3$ is also expressed on platelets, macrophages, and fibroblasts involved in angiogenesis. (**b**) Integrins $\alpha_v\beta_3$, $\alpha_v\beta_5$, and $\alpha_v\beta_6$ are involved in tumorigenesis. Integrins $\alpha_v\beta_3$, $\alpha_v\beta_5$, and $\alpha_v\beta_6$ are expressed on primary tumor cells. In addition, integrins $\alpha_v\beta_3$ and $\alpha_v\beta_5$ are expressed on migrating tumor cells during metastasis. Integrin $\alpha_v\beta_3$ is also integral to adhesion at metastatic sites. Further, $\alpha_v\beta_3$ is located on bone marrow–derived cells (BMDC) which are recruited to tumors to support tumor growth (Illustration by David Schumick, BS, CMI. Reprinted with the permission of the Cleveland Clinic Center for Medical Art & Photography © 2011. All Rights Reserved)

thus controlling hemostasis (Byzova et al. 1998). Knockin mice (DiYF) with $\alpha_v\beta_3$ phosphorylation ablated demonstrate impaired angiogenesis. Endothelial cells from these DiYF mice display defective cell adhesion, spreading, migration, and capillary tube formation (Mahabeleshwar et al. 2006). In addition, $\alpha_v\beta_5$ integrins are located on quiescent endothelial cells. Integrin $\alpha_v\beta_5$ binds Del-1, a pro-angiogenic factor, leading to the activation of a pro-angiogenic expression program. This angiogenic program

includes inducing $\alpha_v\beta_3$ and ▶ uPAR expression. Partially, through its effects on angiogenesis, the α_v integrin regulates wound healing.

Integrin $\alpha_v\beta_3$ expression is increased during wound healing, including on platelets, endothelial cells, macrophages, and fibroblasts responsible for repairing the dermis. Interestingly, mice deficient in $\alpha_v\beta_3$ demonstrate enhanced wound healing, which appears to be due to increased fibroblast recruitment and elevated TGFβ signaling. In addition, $\alpha_v\beta_5$ and $\alpha_v\beta_6$ have increased expression during wound closure of the epidermis. Integrin $\alpha_v\beta_6$ is not expressed in healthy epithelia, but is upregulated during wound healing. In epithelial cells, integrin $\alpha_v\beta_6$ bind the LAP-TGFβ promoting the interaction of TGFβ with its receptors by inducing a conformational change. Thus, expression of $\alpha_v\beta_6$, through its effects on TGFβ, controls inflammation and the response to local injury (Nemeth et al. 2007). The control that the α_v integrins exert over angiogenesis and wound healing is recapitulated in tumorigenesis.

Integrin Alpha V in Cancer and Metastasis

Integrins $\alpha_v\beta_3$, $\alpha_v\beta_5$, and $\alpha_v\beta_6$ regulate tumor formation and progression in a variety of cancers (Fig. 4b) (Nemeth et al. 2007). Integrin $\alpha_v\beta_3$ mediates the tumor growth, migration, and metastasis of several cancers including breast and prostate. The adhesion of these cancers to bone is $\alpha_v\beta_3$ dependent and is integral to the development of bone metastases. Further, a variety of cancer-derived cell lines, including those from bone marrow aspirates, express $\alpha_v\beta_3$ (De et al. 2005). In addition, $\alpha_v\beta_3$ integrin expression increases the recruitment of bone marrow–derived cells (BMDCs) to angiogenic sites within tumors and wounds. Integrin $\alpha_v\beta_3$ activation on the BMDC mediates their adhesion and migration through the endothelial layer (Fig. 4b) (Feng et al. 2008). This BMDC recruitment is mediated by platelets and is required for continued tumor growth. Further, $\alpha_v\beta_3$ integrin expression is integral to prostate cancer metastasis, where it is required for tumor growth and for tumor-induced bone formation. The activation state of the $\alpha_v\beta_3$ integrin controls the recognition of bone matrix proteins by prostate cancer cells, thus controlling metastasis (Mahabeleshwar et al. 2006; McCabe et al. 2007). In prostate cancer cells, $\alpha_v\beta_3$ also mediates cell adhesion and migration on vitronectin and osteopontin. Further, in response to EGF activation, $\alpha_v\beta_3$ stimulates the ▶ PI3k/Akt pathway in prostate cancer cells. EGF activation signaling also cross-talks with the $\alpha_v\beta_5$ integrin–induced pathways. Stimulation of carcinoma cells by EGF induces cell migration mediated by the $\alpha_v\beta_5$ integrin. EGFR induces ▶ Src activity and can mediate the $\alpha_v\beta_5$ integrin control of metastasis. ▶ Src activity also mediates the $\alpha_v\beta_3$-controlled metastatic progression of pancreatic cells. Integrin $\alpha_v\beta_5$ has also been implicated in prostate cancer metastasis to bone. Expression of VEGF and its receptor VEGFR2 on prostate cancer cells results in activation of $\alpha_v\beta_3$ and $\alpha_v\beta_5$. These integrins then stimulate the migration of prostate cancer cells toward SPARC protein in bone. The activation of $\alpha_v\beta_5$ induces augmented VEGF expression creating a positive-feedback loop stimulating further prostate cancer migration (Fig. 4b) (De et al. 2003). Further, integrin $\alpha_v\beta_5$ is involved in carcinoma cell invasion and metastasis. IGF-1 can cooperate with the $\alpha_v\beta_5$ integrin to induce pulmonary metastases. Additionally, expression of $\alpha_v\beta_6$ is increased in carcinomas of the colon, ovary, lung, breast, pancreas, stomach, salivary gland, and also skin and oral squamous cell carcinomas. The $\alpha_v\beta_6$ integrin promotes carcinoma progression by stimulating invasion, inhibiting apoptosis, regulating matrix metalloproteinase (MMP)-2 and −9 expressions, and activating TGF-β. Lastly, α_v is highly expressed in ovarian carcinomas, while β_1 is detected in both the tumor and stroma (Nemeth et al. 2007). Thus, the α_v integrin expression and function are important targets in cancer research. Correspondingly, several therapeutic agents targeting the alpha v integrin are in clinical development (Table 2).

Integrin Alpha V in the Bone

The α_v integrins are expressed on several skeletal cells: osteoblasts, osteoclasts, and odontoblasts, during various stages of development. Expression of $\alpha_v\beta_1$ has been described at a low level on osteoclasts (Nakamura et al. 2007), while integrin $\alpha_v\beta_3$ is expressed on both osteoclasts and osteoblasts (Siebers et al. 2005; Takada et al. 2007). In the skeleton, the $\alpha_v\beta_3$ controls osteoclast migration and resorption ring formation through its effects on actin cytoskeletal organization (Bouvard et al. 2001; Nakamura et al. 2007). Osteoclasts with

Integrin Alpha V (*ITGAV*), Table 2 Integrin alpha v therapeutic agents in clinical development

Therapeutic	Agent	Developer	α_v Target	Pathological target
LM609 (Vitaxin, MEDI 522, Abegrin)	Antibody	MedImmune	$\alpha_v\beta_3$	Melanoma, prostate carcinoma
CNTO 95	Antibody	Centocor	α_v	Solid tumors
Cilengitide (EMD 121974)	Small cyclic RGD peptide	Merck	$\alpha_v\beta_3$	Pancreatic adenocarcinoma, melanoma, lymphoma
ATN-161	Peptide	Attenuon	$\alpha_v\beta_3$ (also $\alpha_5\beta_1$)	Solid tumors
SM256	Small molecule agonist	Bristol-Myers Squibb[a]	$\alpha_v\beta_3$	Tumor neovascularization
SD983	Small molecule agonist	Bristol-Myers Squibb[a]	$\alpha_v\beta_5$	Tumor neovascularization
Abciximab (ReoPro)	Chimeric antibody	Centocor	$\alpha_v\beta_3$ (also $\alpha_{II}\beta_3$)	Coronary intervention, psoriasis, stroke

[a]These agents were developed by DuPont Pharmaceuticals, which has since been acquired by Bristol-Myers Squibb

mutated $\alpha_v\beta_3$ integrins do not from a ruffled membrane and are unable to resorb bone, resulting in hypocalcemia (Bouvard et al. 2001). Conversely, osteoblasts overexpressing $\alpha_v\beta_3$ integrin proliferate more quickly, uptake less calcium, and have impaired mineral deposition. In addition, increased $\alpha_v\beta_3$ expression in osteoblasts correlated with increased ERK and AP-1 activity and decreased JNK activity. Interestingly, blocking $\alpha_v\beta_3$ interaction with the extracellular matrix also results in decreased mineralization. This expression of the α_v integrins on bone cells regulates their attachment to the extracellular matrix and orthopedic implants.

The α_v integrins are expressed on osteoblasts and osteoclasts, which are often in contact with synthetic substrates covering orthopedic implants. The success or failure of these implants is contingent upon osseointegration. The composition and topography of the implant surface can influence integrin expression and cell behavior and thus dictate the failure rate. Osteoblasts express α_v integrins when exposed to titanium alloy, polystyrene (PS), or cobalt-chrome-molybdenum. In addition, implants are often coated with a variety of substrates derived from extracellular matrix proteins. Integrin α_v is upregulated on osteoblasts attaching to implants coated with laminin, but not fibronectin or collagen type I (Siebers et al. 2005), while integrin α_v is expressed by osteoclasts attaching to PS, collagen-coated PS, laminin-coated PS, titanium, and cobalt-chrome. In addition, the α_v and β_1 subunits are expressed by osteosacromas when attaching to Thermanox, uncoated titanium, hydroxyapatite, and hydroxyapatite-coated titanium. Further, Arg-Gly-Asp (RGD) peptides derived from extracellular matrix proteins have been used to coat implants improving osseointegration. Osteoblast binding to RGD peptides is dependent on the α_v integrin, and synthetic RGD motifs can induce cell attachment mimicking that found on parental molecules (Lebaron and Athanasiou 2000). Different RGD peptides stimulate attachment of different integrins and can thus be used to control the attachment of specific cell types. Cyclic RGD-coated ceramic implants or hydrogel disks promote bone regeneration via osteoblast attachment to the RGD peptide through the $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins (Hersel et al. 2003). The coating of titanium with RGD peptides induces osteoblast attachment, stimulates differentiation, and inhibits apoptosis. In addition, RGD motifs have been used to promote nerve regeneration, spinal cord repair, and corneal tissue repair in vivo (Hersel et al. 2003). Thus, RGD-based and other biomimetic coatings stimulate the adhesion of α_v-expressing cells, enhancing tissue responses to implants and stimulating tissue regeneration.

Summary

The widely expressed α_v integrin subunit heterodimerizes with several β-subunits to create an integrin complex capable of recognizing a plethora of extracellular ligands. These activated integrin complexes can then cluster with different growth factor receptors, including IGF, PDGF, IRS, EGF, VEGF, TGFβ, uPA, and ▶ FGF, to stimulate several families of signaling cascades: ▶ PI3k/Akt, MAPK, Rho GTPase family, and ▶ Src family kinases. Thus, α_v integrin activation is integral to cell survival, proliferation, and function under physiological and pathological conditions. Integrin α_v activation contributes to angiogenesis, wound healing, tumorigenesis, and

bone remodeling. Targeting the α_v integrin provides an important therapeutic approach for cancer research, regenerative medicine, and tissue engineering.

Integrin α1 (ITGA1)

Jyrki Heino
Department of Biochemistry and Food Chemistry, University of Turku, Turku, Finland

Synonyms

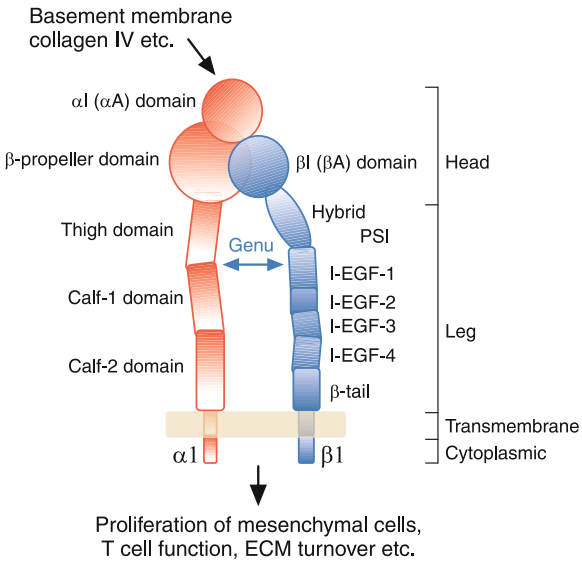
CD49a; Very late activation antigen 1 (VLA-1)

Historical Background

Integrin α1 subunit forms a heterodimer with integrin β1 subunit and acts as a cellular collagen receptor. α1β1 was one of the first integrins found and it was originally described as T lymphocyte very late activation antigen 1 (VLA-1). Today the human integrin family is known to contain 24 α/β heterodimers that mediate adhesion to extracellular matrix (ECM), plasma proteins, or counter receptors on other cells. The cytoplasmic domains of integrin α and β subunits are connected to cytoskeletal filaments and also to multiple cellular signaling pathways (Hynes 2004).

Structure

Integrins are single-pass type I membrane glycoproteins. Integrin α1 subunit contains short intracellular domain, transmembrane anchor, and an extracellular part, composed of α1I, β-propeller, thigh, calf-1, and calf-2 domains (Fig. 1). Thus, α1 belongs to a subgroup of integrins that contain an αI domain (inserted domain that is often called as A domain, based on its structural similarity with von Willebrand factor A domain). Integrin αI domain adopts a dinucleotide-binding or Rossmann fold and binds to ligands using a magnesium-containing metal ion dependent coordination site (MIDAS). The formation of α1–β1 complex is based on the non-covalent binding of β-propeller



Integrin α1 (ITGA1), Fig. 1 Domain structure of integrin α1β1, a collagen receptor. αI (αA) domain is a high affinity binding site for basement membrane collagen IV, but the receptor has been reported to bind numerous other ligands, as well. Ligand binding leads to signaling that regulates for example cell proliferation, differentiation, and survival

domain (α subunit) to β1I domain (β-subunit). Together with the α1I these two domains form the "head" part. The "leg" part of α1 subunit is composed of thigh, calf-1, and calf-2 domains, while hybrid, PSI, four I-EGF (1–4), and β-tail domains form the β1 leg part. In many integrins the leg parts can be bended in "knees" between thigh and calf-1 domain (α subunit) or between hybrid and I-EGF-1 domain (β subunit). This may also be the case with α1β1 integrin, but direct evidence is still lacking (Luo et al. 2007; Arnaout et al. 2007).

Evolution and Tissue Distribution

Based on their structure and phylogeny human integrin α subunits can be divided into four different subfamilies. Nine out of 18 human integrin α subunits belong to the group of the αI domain integrins. Integrin αI domains are only found in Chordates. The αI domain integrins can be further divided into leukocyte integrins and collagen receptor integrins. Integrin α1β1 forms together with three other heterodimers, namely, α2β1, α10β1, and α11β1, the collagen receptor subfamily. The biological functions of the integrin-type collagen receptors are often related to immunity and tissue regeneration. (Popova et al. 2007; Johnson et al. 2009)

Integrin α1 is expressed on mesenchymal cells, including fibroblasts, chondrocytes, osteoblasts, endothelial cells, and smooth muscle cells. It cannot exist on cell surface alone, but it is always in complex with integrin β1 subunit. Many inflammatory cells, including activated T lymphocytes, natural killer cells, and monocytes/macrophages are α1 positive (Ben-Horin and Bank 2004).

Ligands

Integrin α1β1 is a high avidity receptor for several collagen subtypes. The collagen family contains 28 members, and for most of the subtypes detailed information about receptor interactions is not available. Many published reports have emphasized the role of α1β1 as a receptor for basement membrane type IV collagen, whereas the receptor seems to have a relative low avidity to fibril-forming collagen subtypes (I, II, III, V). Thus, its preference to collagen subtypes seems to be different when compared to the other major collagen receptor, α2β1 integrin. Like all collagen receptor integrins α1β1 can recognize the triple helical motif formed by peptides containing a GFOGER (O = hydroxyproline) sequence or similar GLOGER and GASGER motifs. In addition to the GFOGER site α1β1 binds with high affinity to a separate triple helical motif found in collagen IV. In this site α1I domain recognizes two aspartic acid and one arginine residue, all located in different α chain. Thus, α1β1 may bind to fibril-forming and basement membrane collagens with a different mechanism. α1β1 has also been reported to recognize network-forming collagens (VIII), fibril-associated collagens with interruptions in triple helix (FACITs; IX, XVI), and transmembrane collagens (XIII). Presently, it is not possible to estimate what collagen subtypes are acting as the main α1β1 ligands during different physiological processes linked to this receptor.

Proteolytic fragments of ECM proteins have been reported to regulate biological processes. The cellular responses are often mediated by integrin-type receptors. The NC1 domain of α1(IV) collagen α-chain, also called as arresten, can be proteolytically released from collagen IV and has anti-angiogenic properties.

Arresten has been reported to bind to α1β1 and this may explain the mechanism of its function (Heino 2007; Leitinger 2011; Herr and Farndale 2009).

Other ligands of α1β1 integrin include various laminin subtypes. Laminin are the main structural proteins in basement membranes. Matrilin-1, a cartilage ECM protein, and Galectin-8, a β-galactoside binding lectin, can also bind to α1β1. Semaphorin 7A (Sema7A) is a glycosylphosphatidylinositol-linked membrane associated protein, known to have two receptors, plexin C1 and α1β1 integrin. Sema7A is expressed on neural cells, activated T cells, platelets, skin keratinocytes, and fibroblasts. In axon guidance, T cells activate cytokine production in monocytes and macrophages, as wells as in the attachment of skin melanocytes the effects of SemaA7 are dependent on β1-integrins. In addition to physiological ligands, snake venom KTS/RTS disintegrins can block α1β1 function (Eble 2010; Ivaska and Heino 2011).

Signaling Function

Like all integrins, also α1β1 may have several different conformation based functional states (Luo et al. 2007; Arnaout et al. 2007). Proteins, such as talin or kindlins can bind to the cytoplasmic domain of β1 subunit and activate the integrin. In some integrins the activation is associated to a conformational change from a bent to an extended state, in which the integrin is standing tall on cell surface. Ligand binding to αI domain is considered to lead to the opening of the domain, further changes in the conformation of the β1 subunit and finally to the separation of α and β legs. After binding to ECM α1β1 is concentrated to focal adhesion sites. The cytoplasmic domain of β1 subunit binds to cytoskeleton associated proteins, including talin, filamin, ▶ myosin, and tensin (Legate and Fässler 2009). Signaling and adapter proteins, such as focal adhesion kinase (FAK), integrin linked kinase (ILK), Yes, and Lyn can bind to β1 cytoplasmic domain and trigger further signaling events (Legate and Fässler 2009).

Detailed mutation-based analysis has revealed the important role of α1 cytoplasmic tail for α1β1 mediated cellular functions and for the activation of p38 and ERK MAP-kinase pathways. T-cell protein tyrosine phosphatase (TCPTP) is reported to bind to α1 cytoplasmic domain and negatively regulate epidermal growth factor (EGF) receptor function (Ivaska and Heino 2011).

Integrin α1β1 has been reported to regulate several signaling proteins and pathways. It can activate tyrosine kinases Fyn and Lck, which lead to phosphorylation of Shc. In arteries α1β1 plays an important role in the shear stress induced activation of Akt and ▶ PI 3-kinase. Furthermore, the production of reactive oxygen species (ROS) is controlled by α1β1 (Ivaska and Heino 2011).

In addition to their own signaling function the integrins have the ability to modify the signaling by many growth factor receptors. Often integrins are essential for the formation of molecular platforms that are needed for growth factor-dependent activation of growth factor receptors. In some cases integrins can directly activate the growth factor receptors in a growth factor independent manner. Furthermore, integrins may also regulate the recycling of growth factor receptors and regulate their number on cell surface (Ivaska and Heino 2011).

Function In Vivo

The in vivo function of α1β1 integrin has been analyzed by using knockout mice or by studying the effect of function blocking antibodies in various mouse models. In general α1 null mice are viable and fertile and harbor no remarkable developmental defects. Still, these animals are not fully normal since their skin is hypocellular, proposing that stem cell proliferation may be affected. The turnover rate of the skin collagenous matrix is also altered, confirming the in vitro observations that α1β1 is a negative feedback regulator of collagen synthesis. Despite the increased collagen synthesis, α1 knockout animals develop no obvious fibrotic disease, because the lack of α1 also seems to lead to increased production of matrix metalloproteinase. Conforming the affected regulation of collagen synthesis, α1 deficient mice are more sensitive to adriamycin-induced kidney fibrosis than their normal littermates.

The healing of bone fractures is compromised in α1 null mice due to the defected proliferation of bone marrow mesenchymal stem cells. Accordingly, α1 deficient animals seem to develop aging dependent osteoarthritis. These observations support the idea that one of the main functions of α1β1 integrin is to support the proliferation of specific mesenchymal stem cells populations. In α1 null animals also cancer

related angiogenesis, normal kidney function and retina development are affected (Heino 2007; Pozzi et al. 2009; Johnson et al. 2009; Ivaska and Heino, 2011).

Antibodies against α1 integrin can inhibit angiogenesis, lymphangiogenesis, and inflammation. α1β1 seems to augment T cell activation and proliferation and the important role of α1β1 integrin for cell mediated immunity has been shown in numerous animal experiments, including models for graft-versus-host disease, arthritis, colitis, allergen-induced bronchoconstriction, and glomerulonephritis. Integrin α1β1 may also play an important role in the pathogenesis of Alport syndrome, since in Alport mice collagen XIII in kidney endothelial cells mediates the selective recruitment of α1β1 integrin-positive monocytes (Ben-Horin and Bank 2004).

The important role of α1β1 integrin in the maintenance of bone metabolism is also proposed based on the observation that polymorphism in integrin α1 gene is associated with osteoporosis and related fracture risk in Korean females.

Summary

Integrin α1 subunit forms a heterodimer with integrin β1 subunit. Integrin α1β1 is an abundantly expressed mesenchymal collagen receptor that predominantly mediates cellular interactions with basement membrane collagen IV. Based on in vivo experiments with specific inhibitors and knockout animals α1β1 has multiple physiological roles. First, α1β1 supports the proliferation of cells, e.g., mesenchymal stem cells. Second, α1β1 regulates extracellular matrix turnover, including the synthesis of collagen and matrix metalloproteinases. Third, inflammatory cells, especially T cells and monocytes, use this collagen receptor. Integrin α1β1 is a potential target molecule for drug development in inflammation and fibrosis.

Integrin α2 (ITGA2)

Jyrki Heino
Department of Biochemistry and Food Chemistry, University of Turku, Turku, Finland

Synonyms

CD49b; Extracellular matrix receptor II (ECMR II); Platelet glycoprotein Ia; Very late activation antigen 2 (VLA-2)

Historical Background

The integrin family of cellular receptors contains 24 α/β heterodimers that mediate adhesion to extracellular matrix (ECM), plasma proteins, or counter receptors on other cells. The cytoplasmic domains of integrin α and β subunits are linked to cytoskeleton and cellular signaling pathways. Integrin α2 subunit forms a heterodimer with integrin β1 subunit and acts as a cellular collagen receptor. Before this receptor was

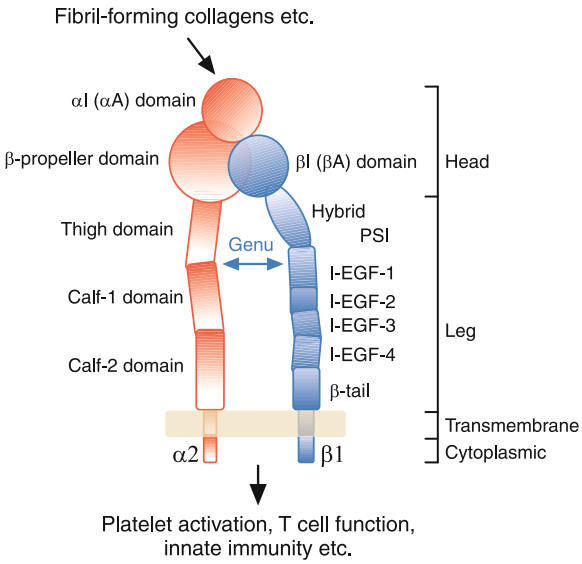
realized to be a member of the integrin family, the α2 subunit had already been named as the α subunit of T lymphocyte very late activation antigen 2 (VLA-2), platelet collagen receptor (glycoprotein Ia), and the larger subunit of collagen-binding extracellular matrix receptor II. Integrin α2β1 forms together with three other heterodimers, namely, α1β1, α10β1, and α11β1, the collagen receptor subfamily of the integrins (Hynes 2004).

Structure

Integrins are single-pass type I membrane glycoproteins. α2 belongs to a subgroup of integrins that contain an inserted domain (I domain that is often called as A domain, based on its structural similarity with von Willebrand factor A domain) (Fig. 1). Integrin αI domains recognize and bind ligands using a magnesium-containing metal ion dependent coordination site (MIDAS). Integrin α2 subunit contains short intracellular domain, transmembrane anchor, and an extracellular part, composed of α2I, β-propeller, thigh, calf-1, and calf-2 domains. In α2–β1 complex the β-propeller domain (α subunit) binds to β1I domain (β-subunit) in a non-covalent manner. These two domains, together with the α2I domain, form the "head" part of the heterodimer. Thigh, calf-1, and calf-2 domains form the "leg" part of α2 subunit, while β1 leg is composed of hybrid, PSI, four I-EGF (1–4), and β-tail domains. The leg parts of many integrins can be bended in "knees" between thigh and calf-1 domain (α subunit) or between hybrid and I-EGF-1 domain (β subunit) (Arnaout et al. 2007; Luo et al. 2007).

Evolution and Tissue Distribution in Human

Based on their structure and phylogeny human integrin α subunits can be divided into four different subfamilies, namely, RGD-motif binding integrins, α4/α9 integrins, laminin binding integrins, and αI domain integrin. While all metazoans have integrins, integrin αI domains exist in Chordates only. Accordingly, the collagen receptor integrins, including α2β1, are not found in non-vertebrates. The evolutionary history of the collagen receptors is in accordance with the fact that their biological functions are often related to immunity and tissue regeneration (Johnson et al. 2009)



Integrin α2 (ITGA2), Fig. 1 Domain structure of integrin α2β1, a collagen receptor. αI (αA) domain is a high affinity binding site for fibril-forming collagen, but the receptor has been reported to bind numerous other ligands, as well. Ligand binding leads to signaling that regulates, for example, cell proliferation, differentiation, and survival

Integrin α2β1 is abundantly expressed in human tissues. This integrin is considered to predominantly be epithelial, but also fibroblasts, chondrocytes, osteoblasts, and endothelial cell are α2 positive. Integrin α2β1 is one of the collagen receptors on platelets. Activated T lymphocytes (e.g., Th17 cells), mast cells, and neutrophils express this receptor, as well (Eckes et al. 2006; Heino 2007; Johnson et al. 2009; McCall-Culbreath and Zutter 2008; Popova et al. 2007).

Ligands

Distinct members of the collagen family are the major ligands for α2β1 integrin. In collagenous ligands α2I domain interacts with special triple-helical motifs, containing amino acid sequences such as GFOGER (O = hydroxyproline), GLOGER, GASGER, GROGER, and GLOGEN. The collagen family contains 28 different members and many of them are only known at nucleic acid level and, therefore, it has not been possible to test them in binging assays with integrins. At least fibril-forming collagens (I, II, III, V, XI), basement-membrane collagen (IV), fibril-associated collagens with interruptions in triple-helix (FACITs, IX, XIV), network-forming collagens

(VIII, X), beaded-filament forming collagens (VI), and anchoring filaments forming collagens (VII) are ligands for α2β1. Collagen XIII (a transmembrane collagen) seems to be a low affinity ligand, and negative binding results have been published with collagens XIV (FACIT) and XVII (a transmembrane collagen; COL15 domain). In general α2β1 integrin is considered to favor fibril-forming collagens over other collagen subtypes. Integrin α2β1 can also bind to collagen I fibrils. However, in tissues collagen fibrils are often covered with other proteins and proteoglycans and it is not clear, whether in vivo α2β1 or other collagen receptors mediate cell adhesion directly to the collagen fibrils. Instead, some in vitro observations suggest that α2β1 could regulate the formation of new collagen fibrils. The binding preference of α2β1 to collagen subtypes seems to be different when compared to the other major collagen receptor, α1β1 integrin. However, α11β1 may be more similar to α2β1 as a receptor for fibril-forming collagens (Heino 2007; Herr and Farndale 2009; Leitinger 2011)

In addition to collagens α2β1 can recognize a large number of other proteins, including different members of the laminin family and proteoglycans, such as decorin, endorepellin (a fragment of perlecan), and lumican. Tenascin C, chondroadherin, matrix metalloproteinase 1, E-cadherin, and collectin-family members (C1q complement protein, mannose-binding lectin, surfactant protein A) have been reported to be ligands for α2β1 integrin (Heino 2007; Herr and Farndale 2009; McCall-Culbreath and Zutter 2008).

Pathogens binding to α2β1 include echovirus-1 and rotavirus. These viruses use α2β1 as their cellular receptor and may take advantage of the integrin-mediated endocytosis mechanisms. Group A Streptococcus express a collagenous protein, named as Scl1, that is a ligand for α2β1. Snake venoms are known to contain toxins, such as EMS16, rhodocetin, and VP12, which block α2β1 function (Eble 2010).

Signaling Function

Like all integrins, also α2β1 can have several different conformation based functional states (Arnaout et al. 2007; Luo et al. 2007). Inactivated α2β1 is a low avidity collagen receptor, but can still attach to large ligands, for example human echovirus 1. Intracellular proteins, such as talin or kindlins can bind to the cytoplasmic domain of β1 subunit and activate the integrin (Legate and Fässler 2009). Ligand binding leads to the opening of the α2I domain, further changes in the conformation of the β1 subunit and finally to the separation of α and β legs (Arnaout et al. 2007; Luo et al. 2007).

After binding to extracellular matrix (ECM) α2β1 is concentrated to focal adhesion sites. The cytoplasmic domain of β1 subunit binds to cytoskeleton associated proteins, including talin, filamin, ▶ myosin, and tensin (Legate and Fässler 2009). Signaling and adapter proteins, such as focal adhesion kinase (FAK), integrin linked kinase (ILK), Yes, and Lyn can bind to β1 cytoplasmic domain and trigger further signaling events (Legate and Fässler 2009). Much less is known about the putative α2 cytoplasmic domain binding proteins. At least F-actin, calreticulin, Rap21, and vimentin have been reported to interact with α2 subunit. Deletion of α2 tail does not inhibit collagen binding, but leads to ligand-independent accumulation of the receptor to focal adhesion sites, suggesting that α2 tail may control the function and interactions of β1 cytoplasmic domain.

In various cell culture models α2β1 signaling has been connected to the activation of p38 and ERK MAP kinases, p27kip, Osf2, protein phosphatase 2A (PP2A), Akt, PI-3-kinase, Rac-1, and ▶ vav-2. In cell culture experiments α2β1 regulates cell proliferation, differentiation, migration, survival, ECM synthesis, and matrix degradation (Heino 2007; Ivaska and Heino 2011; McCall-Culbreath and Zutter 2008).

The role of α2β1 signaling in platelets has been studied in detail. The major platelet collagen receptors, glycoprotein VI and α2β1, seem to regulate each others activity and at least partially the same signaling proteins, including ▶ Src, Syk, ▶ SLP-76, and phospholipase Cγ2. Integrin α2β1 can also regulate Ca^{2+} concentration inside platelets. It is has been reported to induce specific rapid α-like peaks, but not longer-lasting γ-like peaks.

In general, the integrins have the ability to modify the signaling function of many growth factor receptors. They may create a proper environment for growth factor induced signaling or in some cases directly activate the growth factor receptors in a growth factor independent manner. Integrins may also orchestrate endocytosis and trafficking of growth factors receptors and regulate their number on cell surface (Ivaska and Heino 2011).

Function In Vivo

The in vivo function of α2β1 integrin has been analyzed by using knockout mice or by studying the effect of function blocking antibodies in various mouse models. The results from experiments utilizing null animals or specific inhibitors have in some cases produced conflicting results, which makes its sometimes difficult to estimate the actual biological function of α2β1 integrin. In human the role of α2β1 has been estimated in epidemiological studies that have been able to connect this receptor to specific human diseases.

In general α2 null mice are viable and fertile and harbor no obvious developmental defects. The architecture of mammary glands may be slightly altered. Their platelets show reduced response to collagen and slightly prolonged bleeding time. In addition, in an endothelial injury model, the lack of α2β1 integrin inhibits thrombosis. The small defects detected in the platelet function are in full agreement with the epidemiological data concerning human thrombotic diseases. Due to genetic polymorphism some individuals have elevated levels of α2β1 integrin on platelets. These persons may have elevated risk for myocardial infarction or cerebrovascular stroke. Furthermore, the medical literature knows one individual lacking α2β1 integrin on platelets and suffering from a mild bleeding disorder. Thus, α2β1 seems to be a functional collagen receptor on platelets. However, its relative importance, when compared to other collagen-binding mechanisms, namely, GPVI receptor or von Willebrand factor/GPIα system, has sometimes been challenged (Varga-Szabo et al. 2008).

In α2 deficient mice increased angiogenesis has been reported during wound healing. Similarly, cancer-related angiogenesis is enhanced. Paradoxically, antibodies against α2 can inhibit cancer-related angiogenesis. Furthermore, endorepellin, an inhibitor of angiogenesis seems to work in an α2β1 dependent manner. Similar controversy has been reported in the studies focused on the role of αV integrins in angiogenesis. The reason for this discrepancy is not clear, but integrin may orchestrate the endocytosis and trafficking of growth factor receptors and have indirect effects on many biological processes (Eckes et al. 2006; Ivaska and Heino 2011; Johnson et al. 2009; McCall-Culbreath and Zutter 2008).

Antibodies against α2β1 integrin can block the function of immunological cells and the null animals have defects in both native and acquired immunity (Eckes et al. 2006; Johnson et al. 2009; McCall-Culbreath and Zutter 2008).

In human cancer α2β1 integrin expression has been associated to the progression of melanoma, gastric, and ovarian cancer. Integrin α2β1 is a marker of prostate stem cells and it has been linked to prostate cancer invasion. However, in breast cancer α2β1 expression often decreases and α2β1 may even suppress metastasis.

Integrin α2β1 is considered to be a putative target for drug development in thrombosis related diseases, cancer, and inflammation.

Summary

Integrin α2 forms a heterodimer with integrin β1. α2β1 is an abundantly expressed receptor for various collagen subtypes as well as for many other ECM molecules. Based on the data from α2 null mice, as well from a human lacking α2 on platelets, the receptor participates in platelet binding to collagen. In thrombosis α2β1 acts together with another collagen receptor, namely, GPVI. Furthermore, α2β1 seems to participate in acquired as well as native immunity. The data related to the putative role of α2β1 during wound healing and angiogenesis is still incomplete. Polymorphism in ITG2A gene has been correlated to higher expression levels of α2β1 on platelets and increased risk to myocardial infarction and stroke. Integrin α2β1 is considered to be a potential drug target in thrombosis, cancer, and inflammation.

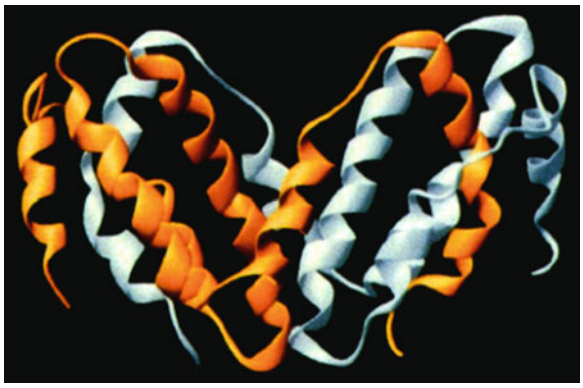
IFNG; IFN-gamma; IFN-γ; Immune IFN; Type II interferon

Historical Background

Interferons (IFNs) were first described in 1957 by Issacs and Lindenmann as substances that restrict viral replication (Issacs and Lindenmann 1957). In mid-1960, Wheelock reported that human leukocytes stimulated with phytohemagglutinin expressed IFN-like inhibitors (Wheelock 1965). However, these IFN-like substances had less resistance to heat and acid than the interferons described previously. In the 1970s, these substances were further characterized based on the inducing properties and cell-type expression patterns, and first named Immune IFN, then later Type II IFN. This nomenclature was originally a subject of some debate as the Type II IFN was thought to be physicochemically and also biologically different from Type I IFNs (IFN-α, IFN-β, IFN-ω, and IFN-τ) (Billiau 2009). In 1980, a panel of experts acknowledged the differences between Type I and Type II IFNs, and gave the Type II IFN the name IFN-γ.

IFN-γ and IFN-γ Receptor Complex

The major sources of IFN-γ are natural killer (NK) cells, T cells, and NKT cells. NK and NKT cells constitutively express IFN-γ mRNA retained in the nucleus, which allows rapid induction of IFN-γ upon stimulation. In T cells, the efficiency of IFN-γ induction is enhanced following activation (Hodge et al. 2002; Schoenborn and Wilson 2007). IFN-γ expression is induced by cytokines, e.g., Interleukin-12 (IL-12) and IL-18 secreted by antigen presenting cells (APC), and suppressed by IL-4, IL-10, transforming growth factor-β (TGF-β), and glucocorticoids. The IFN-γ mRNA contains a highly conserved AU-rich region in the 3′ untranslated region (UTR) that mediates the stability of the mRNA. Furthermore, Savan and colleagues have observed stabilization of the IFN-γ mRNA facilitated by microRNA 29 (Savan et al. unpublished data) resulting in increased protein expression. The active IFN-γ molecule, encoded by a single copy gene, consists of two antiparallel and intercalating polypeptides that then fold into a symmetrical twofold axis (Fig. 1). The dimer formation and the folding are important to the biological function and have been shown to be conserved among vertebrates (Savan et al. 2009).



Interferon-Gamma, Fig. 1 *IFN-γ structure*. The active IFN-γ molecule consists of two antiparallel and intercalating identical polypeptides that then fold into a symmetrical twofold axis. The structure was solved and published by Ealick et al. Science. 1991 May; 252(5006):698–702 (Printed with permission from Steven E. Ealick)

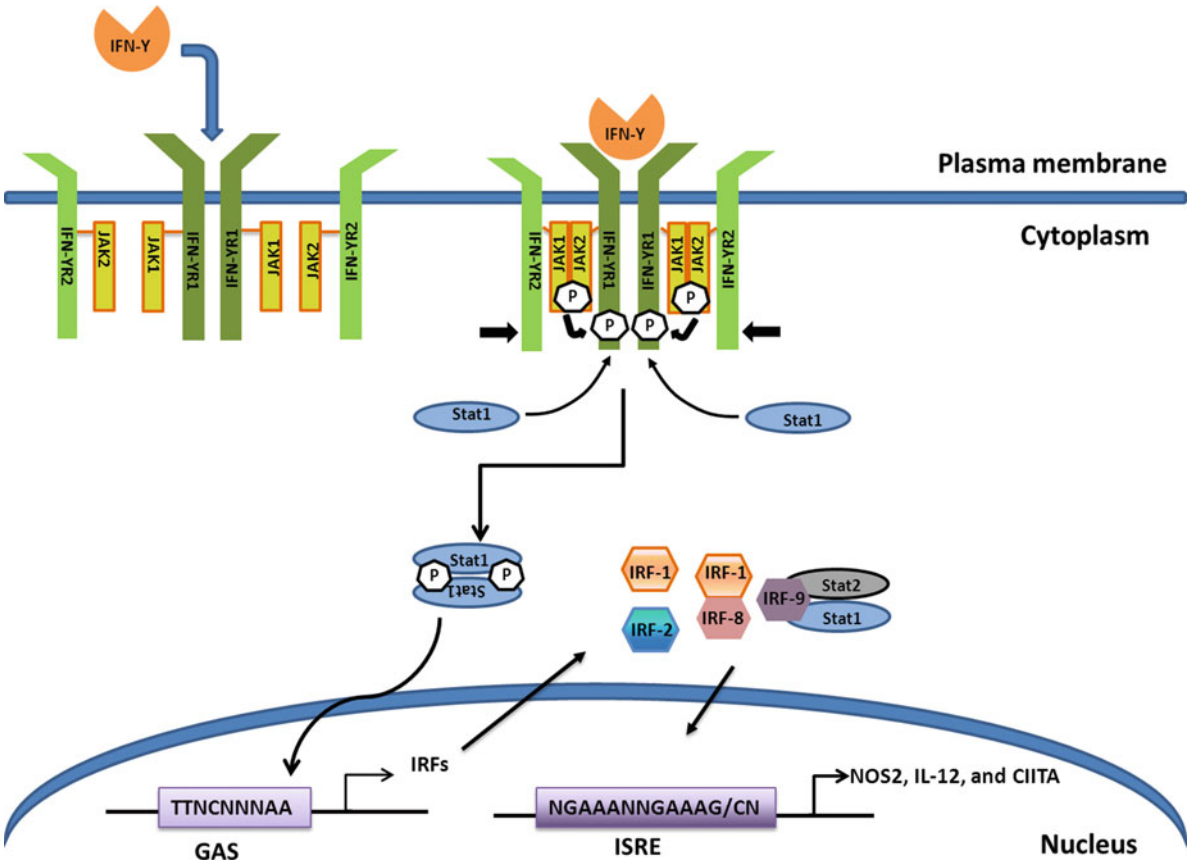
The biological activity of IFN-γ is initiated upon binding of the dimer to its receptor. The IFN-γ receptor consists of two ligand-binding IFN-γR1 chains and two signal-transducing IFN-γR2 chains. These proteins are encoded by separate genes (*IFNGR1* and *IFNGR2*, respectively) that are located on different chromosomes (Bach et al. 1997). Both chains are constitutively expressed on most cells. While the expression level of IFN-γR1 is usually strong, the expression level of IFN-γR2 is determined by the cell types, differentiation stages, and activation status of the cells. T cells have a lower IFN-γR2 expression level than B cells and monocytes. Compared to $CD4^+$ Th2 cells, Th1 cells have significantly lower expression of IFN-γR2. IFN-γ first binds to IFN-γR1, and the IFN-γ: IFN-γR1 oligomerization prompts its association with IFN-γ R2 that then initiates the downstream signaling events (Schroder et al. 2004). The interaction between IFN-γ: IFN-γR1 and IFN-γR1: IFN-γR2 has been shown to be species specific, e.g., mouse IFN-γ does not interact with the human IFN-γ receptors.

IFN-γ Signaling

The formation of the IFN-γ: IFN-γ receptor complex triggers the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) pathway. Inactive JAK1 and JAK2 constitutively bind IFN-γR1 and IFN-γR2, respectively, through their N-terminal domains. After the formation of ligand receptor complex, the close proximity of JAK1 and JAK2 allows them to transactivate each other. The activated JAKs then phosphorylate the Tyr440 residue on each IFN-γ R1 chain to form the docking site for latent STAT1 monomers via src-homology 2 (SH2)-domains (Fig. 2). The recruited STAT1s are then phosphorylated at Tyr701 residue by the JAKs. The phosphorylation allows the two STAT1s to form a homodimer and dissociate from IFN-γR1. The homodimer STAT1 then translocates into the nucleus, binds to the gamma-activated sequence (GAS, TTCNNNGAA) in the promoter region of IFN responsive genes (ISGs; ISG database http://www.lerner.ccf.org/labs/williams/xchip-html.cgi), and initiates the transcription of the target genes (Saha et al. 2010). The activity of the STAT1 homodimer is significantly enhanced when the ser727 residue is phosphorylated by serine kinases such as p38 mitogen-activated protein kinase (MAPK) and phosphatidylinositol 3-kinase (▶ PI3K) (Gough et al. 2008).

The primary gene products of IFN-γ stimulation are transcription factors, e.g., interferon-regulated factors (IRFs), which will then initiate the secondary transcription of ISGs. Both IRF-1 and IRF-2 interact with the interferon-stimulated response element (ISRE, NGAAANNGAAAG/CN) of ISGs. While IRF-1 initiates the transcription of genes, such as *NOS2*, *IL-12*, and *CIITA*, IRF-2 suppresses gene expression. Interestingly, IRF-8 and IRF-9 cannot bind to an ISRE and they regulate ISG transcription by binding to other transcriptional factors, e.g., IRF-8 forms a dimer with IRF-1 and IRF-9 forms a trimer with STAT1 and STAT2 (Fig. 2) (Savitsky et al. 2010).

IFN-γ also can activate STAT1-independent pathways, although it still requires the activation of JAKs. The profile of proteins recruited to IFN-γR1 shows that IFN-γ stimulation triggers the MAP kinase pathway. JAKs activate IFN-γR1 associated Raf1 and Rap1 serine kinases, which then phosphorylate ERK kinase. p38 MAP kinase is the other target of the MAP kinase pathway that has been shown to be activated after IFN-γ treatment. PI3K pathway is another pathway stimulated by IFN-γ that activates protein kinase C (PKC) α, δ, and ε isotypes. PKCα directly magnifies the transcription of ISGs. In contrast, PKCε amplifies transcription by phosphorylating MAP kinase, while PKCδ does so by phosphorylating ser727 on STAT1. It also has been shown that IFN-γ stimulation activates



Interferon-Gamma, Fig. 2 *IFN-γ signaling*. The IFN-γ: IFN-γR1 prompts its association to IFN-γR2 that results in the phosphorylation of JAKs. Activated JAKs then phosphorylate IFN-γR1 chains to form the docking sites for latent STAT1s. The recruited STAT1s are phosphorylated by the JAKs, form a homodimer and dissociate from IFN-γR1. The homodimer STAT1 translocates into the nucleus, and binds to GAS. The primary gene products, IRFs, then initiate the secondary transcription of ISGs by interacting with ISRE

► NF-κB pathway by degrading the inhibitor of κB (IκB) and triggering the phosphorylation of the IKKα and β subunits (Gough et al. 2008).

As stated above, the JAK-STAT pathway is the primary signaling pathway initiated by IFN-γ stimulation. With the activation of JAKs, the signal is further amplified by initiating other signal transduction pathways and maximizing STAT1 activity. To prevent undesirable outcomes, such as uncontrolled expression of specific genes resulting in tissue damage and autoimmunity, IFN-γ signaling needs to be tightly regulated. This is accomplished by the existence of a negative feedback mechanism that results in the IFN-γ induced expression of the suppressor of cytokine signaling genes (► SOCS). SOCS proteins negatively regulate IFN-γ signaling by inhibiting JAK catalytic activity. The IFN-γ signaling pathway is then suppressed within hours of IFN-γ treatment (Croker et al. 2008).

Biological Functions of IFN-γ

An antiviral effect was the first observed biological function of IFN-γ and thus accounts for its original designation as an interferon. IFN-γ exercises its antiviral activity by modulating both innate and adaptive immune responses. During virus infection, IFN-γ triggers the expression of protein kinase dsRNA-regulated and dsRNA-specific adenosine deaminase, proteins that inhibit viral protein synthesis. In addition, IFN-γ augments the antiviral state of the cells by enhancing Type I IFN expression and the formation of ISGF3, the main protein complex

involved in stimulating Type I IFN-induced gene expression. IFN-γ also plays a role in conveying antiviral signals from the innate to the adaptive immune response. Increased chemokine/chemokine receptors, induced by IFN-γ, recruit T cells to the infection site. Upon receiving the IFN-γ signal, APCs increase MHC class II: peptide complex and costimulatory molecule expression levels, hence facilitating peptide-specific $CD4^+$ T cell activation and initiation of the adaptive immune response against viral infection. IFN-γ can also limit viral infection by upregulating MHC class I pathway allowing cells to present a higher quantity and more diverse peptide repertoire to $CD8^+$ T cells (Schroder et al. 2004). In modulating adaptive immune responses, IFN-γ facilitates and maintains the commitment of $CD4^+$ T cells to the Th1 lineage that is crucial in controlling viral infection. IFN-γ also induces the expression of IL-12 by APCs. IL-12 not only activates NK cells, a major antiviral component of innate immunity, but also drives Th1 development. Additionally, IFN-γ signaling facilitates Th1 development and its own expression by inducing T-bet expression and suppressing the expression of GATA3, a protein that drives T cell Th2 differentiation. To further solidify the commitment to the Th1 lineage, IFN-γ signaling also inhibits the Th2 essential IL-4-STAT6 signaling pathway (Hu et al. 2008).

Another important biological function of IFN-γ is macrophage activation, a critical component in controlling microbial infection by the host. In fact, the original "Macrophage Activating Factor" was later determined to be IFN-γ. Once stimulated with IFN-γ, macrophages are primed and more responsive to pro-inflammatory mediators such as a tumor necrosis factor (TNF) and toll-like receptor (TLR) ligands. IFN-γ priming amplifies TLR signaling in macrophages by both increasing the expression of TLRs and activating the transcription factor NF-kB. As a result, macrophages increase the expression of inflammatory mediators and immune effectors including multiple cytokines and chemokines (Hu et al. 2008). IFN-γ suppresses the anti-inflammatory signaling triggered by IL-10 and TGF-β, thus IFN-γ primed macrophages are able to kill ingested pathogens through the generation of NADPH oxidase and nitric oxide synthase associated with the production of reactive oxygen species and reactive nitrogen intermediates, respectively (Saha et al. 2010). Furthermore, in response to IFN-γ, macrophages upregulate the expression of complement components which opsonize extracellular pathogens.

In contrast to the pro-inflammatory effects described above, modulation of an anti-inflammatory response is another major aspect of IFN-γ biological function. IL-17 is a pro-inflammatory cytokine produced by Th17 cells. IL-17 generates an inflammatory environment by enhancing the production of pro-inflammatory cytokines and chemokines. Thus, Th17 response is vital for protection against extracellular pathogens. However, if the response is not regulated, tissue damage may occur. IFN-γ inhibits the development of Th17 cells by inhibiting the effects of IL-6, IL-1, TGF-β, IL-21, and IL-23, all of which promote Th17 cell development. STAT1 inhibits STAT3, a critical component used by the IL-6, IL-23, and IL-21 signaling pathways. In addition, IFN-γ signaling downregulates the expression of both IL-23 and IL-1 receptors on Th17 cells (Bettelli et al. 2007). IFN-γ also plays a critical role in maintaining the homeostasis of the immune response. When stimulated with IFN-γ, $Foxp3^+$T cells upregulate the expression of T-bet. These Foxp3 + T-bet + regulatory T cells (Tregs) specialize in confining the Th1 immune response (Koch et al. 2009). IFN-γ also induces STAT1-dependent apoptosis in macrophages by upregulating caspases-1 to reduce the inflammation resulting from macrophage infiltration. For T cells, the apoptosis effect is associated with the strength of IFN-γ signaling. When treated with a high level of IFN-γ, T cells stop the internalization of IFN-γR2. The overexpression of IFN-γR2 then induces the expression of Fas ligand (FasL), promoting Fas-dependent apoptosis (Regis et al. 2006).

In summary, the data generated thus far clearly demonstrates that there are two arms of IFN-γ biological functions, i.e., pro- and anti-inflammatory pathways, and both arms are critical for a balanced immune response. The complex yet delicate signaling network allows IFN-γ to tailor the immune response either for defense against infection or toward maintaining the homeostasis of the host.

IFN-γ: Friend or Foe to Autoimmune Diseases

Due to its pro-inflammatory properties, IFN-γ has been associated with promoting different autoimmune

diseases. Systemic lupus erythematous (SLE) is a complex autoimmune disease and its main characteristic is the generation of autoantibodies by active B cells. The antibody-complement complex causes local and systemic inflammation and may result in kidney failure. In SLE patients, elevated pSTAT1 was observed in peripheral blood lymphocytes and similar results have also been seen in an SLE mouse model (Mozes and Sharabi 2010). Hodge and colleague has developed a mouse where the RNA stability element (ARE) in the 3′UTR of the IFN-γ mRNA has been removed. Without ARE-mediated decay of IFN-γ mRNA, the animals constitutively express low levels of IFN-γ. A significant finding resulting from the constitutive expression of low levels of IFN-γ is the rapid appearance of SLE-like symptoms (Hodge et al. unpublished data). While IFN-γ has not been shown to cause SLE (the pathogenesis of SLE remains unclear), the presence of IFN-γ exacerbates the disease. IFN-γ upregulates the expression of IFN-α whose signaling induces the transcription of the B-cell activation factor (BAFF). BAFF gives rise to the expansion of B cells and autoantibody production. Additionally, macrophages and fibroblasts increase the secretion of complement proteins in response to IFN-γ, resulting in complement deposition in the kidney. Furthermore, IFN-γ promotes widespread inflammation by inducing chemokines to recruit monocytes to different target organs. As a whole, various novel mouse models of lupus-like disease demonstrate that low levels of IFN-γ, if persistent, are capable of promoting autoimmunity.

In contrast to SLE, IFN-γ has been shown to mitigate the severity of disease in multiple sclerosis (MS). MS is an autoimmune disease caused by infiltration of lymphocytes into the central nervous system. As there is increased IFN-γ in the brain of MS patients, it was proposed that self-reactive Th1 cells maybe the culprit in promoting the destruction of the myelin sheath. However, the results of experiments using neutralizing anti-IFN-γ antibodies in an experimental autoimmune encephalomyelitis animal model showed otherwise. Injection with anti-IFN-γ antibodies did not ameliorate the symptoms, but actually aggravated the disease. Furthermore, recent reports have found multiple polymorphisms in the genes encoding IFN-γ/IFN-γR in MS patients. The defect in IFN-γ signaling may result in heightened Th1 immune responses due to the failure to generate Th1-specific Treg cells and induce apoptosis in active immune cells. Also, without the inhibition of IFN-γ, Th1 cells will commit to the Th17 lineage. Due to the defect in IFN-γ signaling found in MS patient, the involvement of Th17 cells in the pathogenesis of MS has been suggested (Billiau and Matthys 2009). However, IFN-γ treatment in MS patients often resulted in disease relapse. A recent report suggested the effect of IFN-γ on patients may differ based on the pathogenesis of demyelination. IFN-γ can be detrimental for patients with remyelination of oligodendrocytes (ODCs) but beneficial for those with ODC death (Lees and Cross 2007).

With respect to another autoimmune disease, rheumatoid arthritis (RA), the effect of IFN-γ depends on the stage of disease. RA is characterized by the accumulation of effector T cells that target the synovial membrane, cartilage, and bone. In the collagen-induced arthritis animal model, there was an acceleration of disease progression when treated with IFN-γ in the early phase of disease induction. As expected, the symptoms improved when animals were treated with anti-IFN-γ antibodies; however, symptoms became worse when the antibodies were given during the later stage of the disease (Saha et al. 2010). It is possible that IFN-γ promotes the activity of effector T cells during initiation of disease, and dampens the immune responses during disease progression by inducting apoptosis of effector T cells and generation of Tregs.

Autoimmune diseases are complex and the systems biology that affects disease development and progression is yet fully comprehended. Experimental studies thus far demonstrate that the effects of IFN-γ vary depending upon the types and progression status of disease. To utilize IFN-γ or antibodies to neutralize IFN-γ as a treatment for autoimmune disease, more work is needed to better understand disease pathogenesis.

IFN-γ and Cancer

The effect of IFN-γ on containing tumor progression and growth is well documented. IFN-γ augments the immunogenicity of tumor cells by increasing tumor antigen presentation to tumor-specific T cells and NK cells. IFN-γ also enhances the antitumor activity of T and NK cells. For example, it has been shown that IFN-γ can induce FasL on tumor cells which would promote Fas-dependent apoptosis. Furthermore, IFN-γ

inhibits the growth and proliferation of tumor cells by arresting the cell cycle (Saha et al. 2010). Also, depletion of IFN-γ promotes the growth of chemically induced tumors. However, a recent report suggested that the inflammatory environment driven by IFN-γ signaling may play a role in promoting cancer cell survival, immunoinvasion of the tumor cells, and immunosuppression of the host response in UVB-induced melanoma (Zaidi et al. 2011). The result implies that the effect of IFN-γ on cancer may be dependent on the local tumor environment.

Summary

IFN-γ is an extraordinarily pleiotropic cytokine. It can not only heighten both the innate and adaptive immune response against pathogens and tumors, but also has the ability to maintain immune homeostasis. IFN-γ has such diverse functions because its effect differs based on the cell type and the activation level of the response to receptor triggering. Utilizing IFN-γ for clinical trials in autoimmune disease and cancer therapy has been attempted, albeit with only modest success. The experimental data obtained thus far indicates that one needs to consider the fine balance between pro- and anti-inflammatory effects of IFN-γ when considering an effective clinical use for this important immunoregulatory protein. More than five decades after the discovery of IFN-γ, the complexity of the effects of IFN-γ has yet to be fully appreciated. Further investigation into the interactions among the different signal transduction pathways affected by IFN-γ will help to map out the network from a systems biology perspective. This knowledge will be beneficial in understanding the pathogenesis of multiple disease states, and will result in the identification of the appropriate clinical intervention strategy for either administering or neutralizing the effects of this key immunoregulatory protein.

Historical Background

All eukaryotic cells extrude Ca^{2+} from their cytosol. They have probably done so since the evolution of a phosphate-based energy economy, which preceded the appearance of eukaryotes, demanded a low cytosolic free Ca^{2+} concentration ($[Ca^{2+}]_c$) to avoid precipitation of calcium phosphate within the cell. The result of these selective pressures is that today, the free cytosolic Ca^{2+} concentration in most eukaryotic cells is about 100 nM. It is important to note the reference to *free* cytosolic $[Ca^{2+}]$ because up to 99% of the Ca^{2+} present in the cytosol is not free but bound to Ca^{2+} buffers. Aside from massively reducing the $[Ca^{2+}]_c$, these ubiquitous Ca^{2+} buffers also slow the rate at which Ca^{2+} diffuses in the cytosol. This occurs because for ~99% of the time each Ca^{2+} ion is bound to a large molecule (typically proteins like calmodulin), and big molecules diffuse more slowly than small ones. Slow diffusion of cytosolic Ca^{2+} is, as we shall see, a key feature without which spatially organized Ca^{2+} signaling would be impossible. Buffering alone is not enough to maintain the low $[Ca^{2+}]_c$; active extrusion of Ca^{2+} from the cytosol across the plasma membrane, the membranes of the endoplasmic reticulum (ER), and, to a lesser extent across the membranes of other intracellular organelles (secretory vesicles, Golgi, lysosomes and mitochondria, for example) is also required (Berridge et al. 2003). These active transport processes, mediated by both Ca^{2+} pumps and ion exchangers, ensure that every eukaryotic cell maintains steep $[Ca^{2+}]$ gradients across at least the plasma membrane and the membranes of the ER. Most

extracellular stimuli that evoke Ca^{2+} signals do so by opening Ca^{2+}-permeable channels in one or other of these membranes, allowing Ca^{2+} to flow rapidly down its concentration gradient into the cytosol. Slow diffusion of Ca^{2+} away from the mouths of these open Ca^{2+} channels ensures that local elevations of $[Ca^{2+}]_c$ can persist around them for long enough to be decoded by intracellular proteins. An important consequence is that Ca^{2+}-binding proteins in close proximity to one Ca^{2+} channel may be activated when it opens, while different proteins may be activated by other Ca^{2+} channels. Ca^{2+} entering the cell through different Ca^{2+} channels can thereby selectively regulate different processes (Berridge et al. 2003; Rizzuto and Pozzan 2006) (Fig. 1). This spatial organization of Ca^{2+} signals adds enormously to their versatility. Before turning to the details of these Ca^{2+} channels, it is worth considering why cells should have evolved signaling pathways that regulate Ca^{2+} fluxes across both the plasma membrane and membranes of the ER.
