Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on his or her experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

DEDICATION

Dr. Harold R. Roberts

The editors dedicate the second edition of *Consultative Hemostasis and Thrombosis* to Dr. Harold R. Roberts, Professor of Pathology and Medicine at the University of North Carolina (UNC) at Chapel Hill, in recognition of the enduring contributions he has made to the diagnosis and treatment of persons with inherited and acquired disorders of hemostasis and thrombosis. His accomplishments are the result of a long and distinguished career as a laboratory investigator, clinical researcher, and practicing physician.

A native of North Carolina, Dr. Roberts received both his undergraduate training and his medical degree from UNC. His postgraduate training included an internship, residency, and subspecialty training at the Vanderbilt School of Medicine in Nashville, Tennessee, and a year as a Fulbright Scholar in experimental pathology in Copenhagen, Denmark, where he worked in the area of fibrinolysis in the laboratory of Professor Tage Astrup. He then entered

a fellowship in the Department of Pathology at UNC under the direction of Dr. Kenneth Brinkhous. After completing his fellowship, Dr. Roberts became a research associate at UNC; seven years later he was named Chief of the Division of Hematology.

While exploring genetic alterations resulting in factor IX deficiency (hemophilia B), Dr. Roberts and his laboratory investigators were the first to recognize that persons with hemophilia B could have any one of numerous point mutations or deletions in the gene coding for factor IX. The gene alterations could result either in no expression of protein or in the expression of a protein that was recognized by immunologic methods but had little or no functional activity. Dr. Roberts' laboratory also was the first to discover that a patient who presented with deficiencies of factors II, VII, IX, and X had a congenital deficiency of the enzymes regulating the vitamin K- γ -carboxylase system.

As a clinical researcher, Dr Roberts focused on new and improved biologics for the treatment of bleeding disorders. His team was the first to test commercially prepared (large-scale) plasma fractions for the treatment of factor VIII deficiency (hemophilia A). These studies resulted in the development of purified concentrates of factor VIII, marking the beginning of a new era for the treatment of hemophilia. In a natural evolution of this work, Dr. Roberts and his team conducted some of the first clinical trials with recombinant factor VIII. His group also has been actively engaged in gene therapy as a next step in improving treatment for patients with hemophilia.

Dr. Roberts has played a seminal role in defining the mechanism of action of recombinant factor VIIa (rFVIIa), as well as in the commercial development of this agent for the treatment of hemophilia in patients who have inhibitors.

Throughout his career, Dr. Roberts has held leadership positions in professional societies nationally and internationally and has served on editorial boards or as editor of multiple journals. He has worked tirelessly with the International Society on Thrombosis and Haemostasis, the American Society of Hematology, the World Federation of Hemophilia, the College of American Pathologists, and the National Hemophilia Foundation. He has chaired study sections and served on councils for the National Institutes

of Health, and he has been an invited guest lecturer throughout North Carolina, the nation, and the world.

Numerous societies and governments have honored Dr. Roberts for his laboratory and clinical research, as well as for the establishment of centers for the treatment of disorders of thrombosis or hemostasis. Dr. Roberts was the 2001 recipient of the Henry M. Stratton Medal presented by the American Society of Hematology. As a tribute to the outstanding care and advances in treatment that Dr. Roberts has provided for patients at the former UNC Hemophilia Treatment Center, university officials have renamed the Center as the Harold R. Roberts Comprehensive Hemophilia Diagnostic and Treatment Center.

The outstanding academic work of Dr. Roberts is evident in the more than 300 articles that he has authored during his career. However, the publications do not begin to document completely all of the successes of the numerous students, fellows, and faculty whom he has trained and mentored. Those who have been privileged to work with him recount stories that reveal his warmth, humility, and wonderfully dry sense of humor. Dr. Roberts' ability to nurture and sustain long-lasting relationships with patients, health care providers, public advocacy groups, and government officials across multiple countries ensures that the advances in clinical care that he has developed are available to patients throughout the nation and the world.

Preface

We editors were pleased by the enthusiasm and success with which the first edition of *Consultative Hemostasis and Thrombosis* was met. Clearly, there is a niche for a mid-sized textbook on hemostasis and thrombosis that can authoritatively assist the busy consultant; thus, we are presenting an updated second edition.

Much has happened since the first edition appeared in early 2002. For example, the discovery of ADAMTS-13 and the elucidation of its role in thrombotic thrombocytopenic purpura were just being accomplished when the first edition was published.

The use of recombinant activated factor VII (rFVIIa) has expanded greatly beyond the original indication for which it was licensed. This is reviewed in detail in this new edition. We are now seeing the increased use of thrombin-specific inhibitors, and initial studies of the pentasaccharide fondaparinux in the treatment of heparin-induced thrombocytopenia are promising.

As editors of the book, we have focused on two primary goals. One was to provide updates on the “core material” for hemostasis and thrombosis, with internationally renowned experts writing chapters on deep vein thrombosis, pulmonary embolus, hypercoagulability, thrombocytopenia,

von Willebrand disease, and heparin-induced thrombocytopenia, as well as thrombotic thrombocytopenia purpura and other disorders. Our second goal was to ensure a very strong integration among the specialties that deal with clinical issues in thrombosis and hemostasis; these include cardiology, neurology, oncology, obstetrics, and vascular surgery. Accordingly, we tapped internationally renowned authors writing on hemostatic and thrombotic complications associated with such conditions as a patent foramen ovale, pulmonary hypertension, malignancy, indwelling catheters, trauma, and pregnancy.

We are deeply grateful to our contributing authors, and we appreciate the colleagues who have given us support and constructive criticism for this second edition. We hope that this book will serve as an improved and useful guide for all who are involved in providing consultation and care for patients with hemostatic or thrombotic disorders.

Part I

General Information

Chapter 1

The Consultative Process

Craig S. Kitchens, MD

Life is short, and the art long, the occasion fleeting, experience fallacious, and judgment difficult.

—Hippocrates^a

As long as medicine is an art, its chief and characteristic instrument must be the human faculty. We come therefore to the very practical question of what aspects of human faculty it is necessary for the good doctor to cultivate. The first to be named must always be the power of attention, of giving one's whole mind to the patient without the interposition of oneself. It sounds simple but only the very greatest doctors ever fully attain it. It is an active process and not either mere resigned listening or even politely waiting until you can interrupt. Disease often tells its secret in the casual parentheses.

—Wilfred Trotter^b

As a specialist, the hematologist is frequently asked to consult on a patient in order to clarify or solidify the diagnosis, prognosis, or treatment plan of another physician. Consultation is done in either the inpatient or the outpatient setting and can in turn be requested on a stat, urgent, subacute, or leisurely basis. By inference, the referring physician remains the physician in control of the patient's care, but the consultant's expertise, experience, judgment, wisdom, and even approval are sought in order to assist the referring physician's concept of the case in its entirety. In this era of cost containment and managed care, expert evaluation is cost-effective because it may curtail the diagnostic process, limit unnecessary or even ill-directed testing, and shorten overall hospital time as well as minimize patient suffering. A well-directed consultation is the best bargain for all stakeholders.

Several papers have discussed the mechanics and elements of a proper consultation and have suggested that just

so many items are necessary in the review of systems or family history in order to justify a certain billing code. This chapter does not attempt to address such impermanent or regional matters but focuses instead on foundations allied with the precepts of internal medicine

The diagnostic procedure is a fascinating exercise. It involves the most acute use of our senses and the accurate recording of our observations. It requires a logical synthesis of the central nervous system of the responsible doctor, of information from the patient and his family, from other doctors who have cared for the patient in the past, from colleagues in various specialties who are helping with the immediate problem, and from the laboratory. Prognosis and correct therapy depend upon the correct use of the diagnostic process.

—Eugene A. Stead, Jr.^c

[The] oldest and most effective act of doctors [is] touching. Some people don't like being handled by others, but not, or almost never, sick people. They need being touched, and part of the dismay in being very sick is the lack of close human contact. Ordinary people, even close friends, even family members, tend to stay away from the very sick, touching them as infrequently as possible for fear of interfering, or catching the illness, or just for fear of bad luck. The doctor's oldest skill in trade was to place his hands on the patient.

Over the centuries, the skill became more specialized and refined, the hands learned other things to do beyond mere contact. They probed to feel the pulse at the wrist, the tip of the spleen, or the edge of the liver, thumped to elicit resonant or dull sounds over the lungs, spread ointments over the skin, nicked veins for bleeding, but the same time touched, caressed, and at the end held on to the patient's fingers.

Touching with the naked ear was one of the great advances in the history of medicine. Once it was learned that the heart and lungs made sounds of their own, and that the sounds

^a Hippocrates (460–370 B.C.) is considered to be the founder of European medicine. He lived in Greece during the Classic Period and was a contemporary of Socrates, Plato, Herodotus, and others. He is credited with three advances in medicine: the separation of medicine as an art and science from magic, the development of the written detailed study of disease, and the promulgation of the highest of moral standards that characterize the profession. Descriptive bedside medicine was his forte. His writings showed him to be humble, containing frequent admissions of errors in his thinking in order that others might not stumble in the same manner. This timeless aphorism contains all the essential elements of clinical practice in a concise statement.

^b Wilfred Batten Trotter (1872–1939) was an English sociologist and neurosurgeon who was very interested in the sociologic aspects of medicine. He is credited with originating the term *herd instinct*. He was also a surgeon to King George V. This quote is taken from the chapter entitled “The Art of Being a Physician” by Lloyd H. Smith, Jr., in the 19th edition of the *Cecil Textbook of Medicine* (W. B. Saunders, Philadelphia, 1992).

^c Eugene A. Stead, Jr., (1908–2005) is a primary pillar of American internal medicine. He was born and educated in Atlanta and then went to Harvard University in Boston, where he was strongly influenced by Soma Weiss. He was a pioneer in clinical investigation of the human circulatory system. At 34 years of age, he returned to Emory University as the Chairman of Medicine in 1943 but was recruited to the new Duke Medical School in Durham, North Carolina, in 1947, where he was Chairman for 20 years, founding and elevating that department of medicine to one of the greatest in the nation. He trained innumerable professors and chairs of medicine. Dr. Stead was a master of clinical thought and piercing observations and had a keen wit bettered by none. The two quotes are from E. A. Stead, Jr., *What this Patient Needs is a Doctor*, edited by Wagner, Cebe, and Rozer (Carolina Academic Press, Durham, North Carolina, 1978).

were sometimes useful for diagnosis, physicians placed an ear over the heart, and over areas on the front and back of the chest, and listened. It is hard to imagine a friendlier human gesture, a more intimate signal of personal concern and affection, than these close bowed heads affixed to the skin. The stethoscope was invented in the nineteenth century, vastly enhancing the acoustics of the thorax, but removing the physician a certain distance from his patient. It was the earliest device of many still to come, one new technology after another, designed to increase that distance.

—Lewis Thomas^d

There are many facets of the consultative process, ranging from the extent and reason for the consultation to the nature of recommendations and outcomes expected. These are listed in Table 1-1.

EXTENT OF THE CONSULTATION

It is essential that both the referring physician and the consultant have in mind the extent of consultation requested, which will in turn govern the aim and comprehensiveness of the consultation.

Confirmatory Consultation

In this situation the referring physician is quite comfortable with the diagnosis, prognosis, and treatment. He or she generally wishes the consultant to focus on efforts already made and to corroborate those findings. This type is frequent in the second opinion consultation or one in which the referring physician needs encouragement as well as perhaps some advice garnered from the consultant’s experience. These consultations are therefore focused, often brief, yet may involve reviewing substantial previously collected data. In general, the consultant does not need to request extra tests.

A subtype of the confirmatory consultation exists when the referring physician does not think the services of the consultant are indicated but, because of uncertainty or pressure from family members, wishes the consultant to document such in the chart. The most common reason for not using specific services is severe illness in the patient, which would make the consultant’s services worthless, futile, or even contraindicated by unnecessarily extending the dying process. Examples in hematology might include evaluation for mild thrombocytopenia in an intensive care unit (ICU) patient with multiorgan dysfunction syndrome or whether a “hypercoagulable workup” is indicated in an elderly patient dying of carcinomatosis yet presenting with new

^d Lewis Thomas (1913–1993) was a native New Yorker and a graduate of Harvard Medical School. He was on the faculty of the University of Minnesota, and then became Dean of New York University Medical Center, followed by his appointment as Dean at Yale Medical School. He became president of Memorial Sloan-Kettering Cancer Center in New York City. He was a member of the National Academy of Sciences. His ability to translate with both clarity and intense interest things scientific, biologic, and medical into prose readable and enjoyable to the average reader was unparalleled. Three of his major works were *The Lives of A Cell*, *The Medusa and the Snail*, and *The Youngest Science: Notes of Medicine Watcher*, all of which received broad recognition and multiple prizes. The first citation comes from a short piece entitled “Leech Leech, et cetera,” and the second from “Housecalls.”

Table 1-1 The Consultative Process

Extent of the consultation

When a diagnosis is not forthcoming
When should a consultant request a consultation?

deep venous thrombosis. The referring physician should indicate to the consultant that services may not be indicated. The consultant should not be reluctant to see such patients.

Brief Consultation

In this consultation, the questions are more broad based and in an appropriately diagnosed and managed patient commonly involve long-term questions such as length of therapy with glucocorticosteroids in a patient with immune thrombocytopenia purpura before one proceeds to splenectomy or the duration of anticoagulant therapy in a patient with hypercoagulability who has developed a major thrombosis. The consultant’s long-term experience with many similar patients and knowledge of the literature are often more important than his or her diagnostic or therapeutic acumen.

Comprehensive Consultation

In a comprehensive consultation, the referring practitioner may not be a subspecialist but an internist or possibly another physician who needs comprehensive assistance regarding the diagnosis, prognosis, and therapy. This consultation often is generated by surgeons or obstetricians/gynecologists attending a patient with thrombosis who needs thorough evaluation for hypercoagulability. In these situations the

consultant more often than not is the manager of laboratory testing and can do so in a cost-effective manner based on his or her expertise. Key decisions are often made by the consultant with the approval of the referring physician. Occasionally, the referring physician will ask the consultant to manage entirely hematologic aspects of the patient's care, which can be easily done conjointly with the referring physician. A common example is consulting with an obstetrician attending a woman with antiphospholipid syndrome. Together they can discuss preconception issues, anticoagulant therapy throughout gestation, and anticoagulant management during and after delivery of the child with the patient and her family.

Urgent Consultation on a Catastrophically Ill Patient

Catastrophically ill patients are often hospitalized in an ICU and may be seen by multiple experts attempting to assist the attending physician in a diagnosis. These consultations require subspecialty expertise and a solid knowledge of general internal medicine. Anyone may make the single unifying diagnosis that underpins all manifestations in such extremely ill patients. The consultant hematologist may be the first to recognize that thrombocytopenia in a febrile, confused, azotemic patient supports an overall diagnosis of Rocky Mountain spotted fever, thus corroborating all findings made by all previous consultants.

"Undiagnosing" Consultation

Sometimes patients may be incorrectly diagnosed and thus inappropriately sent to the hematologist. In these situations one must be rather careful to exclude explicitly the diagnosis that the referring physician made. It is both professional and cost-effective to rule out the diagnosis that was being entertained. One must carefully garner laboratory data that justify the negation of the working diagnosis and compile corroborating evidence, such as historical and physical examination findings, that may be incompatible with that diagnosis. It is easier to diagnose a patient incorrectly than to undo a diagnosis. One could argue that higher standards are required for undiagnosing an illness than diagnosing that illness. An example is a physician who seeks your endorsement of his or her diagnosis of protein C deficiency only to learn the protein C level was low because of concurrent warfarin therapy. The incorrect diagnosis not only is wrong but has financial, familial, and insurability ramifications. A forthright consultation will steer the referring physician away from the incorrect diagnosis so that the diagnostic process may be redirected.

Telemedicine Consultations

In an increasingly electronic world, telemedicine (telephone, video, and electronic transmissions [e-mail]) of medical information is a reality. The accelerating use of telemedicine has left in its wake numerous unanswered legal, ethical, financial, and medical questions.

It is clear that such modern modalities are useful if for no other reasons than the rapidity of correspondence and the availability of consultative expertise in more remote and underserved areas. Because of uncertainty of its standing,

one must be cautious and expect rapid changes in resolutions of these questions from government, professional societies, and insurance carriers. Legal issues will arise, and precedents will be established.

In 2002 the American Medical Association (AMA) officially endorsed on-line consultation and billing of these services. A CPT code, 0074T, has been established. In a 2003 policy paper, the American College of Physicians (ACP), further urged the Center for Medicare and Medicaid Services (CMS) to reimburse for such services. Some third-party payors will reimburse fees whereas others have yet to decide. Several other related unresolved issues exist but are beyond the scope of this chapter. Most of these other issues have yet to be addressed, let alone solved.¹

1. Confidentiality, because telemedicine is not as secure as hoped. Encryption is recommended at a minimum.
2. Because confidentiality is not certain, issues will arise regarding the Health Insurance Portability and Accountability Act (HIPAA).
3. Because the consultant and consultee may reside in different localities, issues of licensure and jurisdiction are inevitable.
4. Differing from typical "curbside" consultation, a durable, retrievable, and probably discoverable written record exists, which could impact questions of establishment of a doctor-patient relationship.
5. Ethics and quality of care issues. One study reported 50% of physicians will respond to unsolicited e-mail consultations, and of these, 84% offer diagnostic and therapeutic advice.²

Traditional medicine requires face-to-face interactions and appropriate examination and testing prior to diagnostic and therapeutic considerations. If there exists a previous doctor-patient relationship then the traditional face-to-face evaluation has been established, so that this issue may be moot in most cases.

In this rapidly evolving and effervescent climate one should consult expert advice. The website eRisk Working Group for Healthcare (www.medem.com/phy/phy_erisk_guidelines.cfm) provides frequent updates.

The Curbside Consultation

Although many condemn "curbside consultations," they are a fact of professional life. These consults occur serendipitously in the doctors' lounge, in the hallway, or occasionally by telephone. They are unofficial, and both the "consultant" and the requesting physician must realize any suggestions arising from this act are not based on a real doctor-patient relationship because there is no traditional history, physical examination, or counseling of the patient; therefore a doctor (consultant)-patient relationship is not established. Accordingly, no fee is generated.

Liability for injury arising from one's unofficial advice can always be claimed. Considerable case law exists supporting that failure to have an established doctor-patient relationship is key to such a challenge. No duty is owed to a patient without creation of a doctor-patient relationship.³

A recent federal case (*Newborn v USA*) supported that even considerable and repetitious e-mail consultation between a Walter Reed Medical Center hematologist and

pediatricians at an Army medical facility in Germany did not establish “close management and control” in a disputed wrongful death case. The deciding judge noted that encroachment on such informal consultation would negatively impact accessibility of practitioners to consultation, resulting in grave public policy implications.⁴ That decision was upheld in the U.S. Court of Appeals.⁵

Rather, the requesting physician is inquiring in an unofficial broad manner about generalities that may well apply for a group of patients (e.g., those with mild thrombocytopenia undergoing colonoscopy) yet might not apply to a specific patient (e.g., as above but in a Jehovah’s Witness). Giving of one’s professional advice, even without compensation, is part of professionalism. Practitioners should not abuse this precept either by repeatedly taking advantage of this courtesy or by using the general unofficial advice in a specific official capacity.

A name provides an illusion of clarity where there was mystery and gives illness a tangibility which makes it seem more likely to be overcome. This applies not only to the patient but also to the doctor.

—Richard Asher^e

While a doctor’s knowledge may be extraordinarily precise for predicting what would happen to a thousand patients with a given condition, as the denominator becomes smaller, accuracy in prediction attenuates exponentially. It nearly disappears when the sample size recedes to unity, namely, when the doctor is called to prophesy outcome for a single individual. It is difficult to apply statistics to an individual patient. The unique challenge in doctoring is to determine where, if anywhere, a particular patient fits on the Gaussian distribution curve derived from a larger population. The decisive factor is the physician’s breadth of clinical experience.

—Bernard Lown^f

REASON FOR CONSULTATION

At first glance it seems intuitive that the reason to consult is to help another physician’s management of a patient.

^e Richard Asher (1911–1969) was a keen English clinician and consummate wordsmith. His writings and lecture style clearly showed that he liked what he did. He excelled especially at the interface of internal medicine and psychiatry. He coined the terms *Munchausen syndrome* and *myxedema madness*. His writings and lectures demonstrate that he made cogent observations from the simplest of medical situations and wrote about them in an economic style. This quote comes from a collection of his best essays on how doctors should use words, *Talking Sense* (University Park Press, Baltimore, 1972).

^f Bernard Lown (b. 1921) graduated from Johns Hopkins Medical School in 1942 and spent his clinical years in Boston. He was a cardiologist of the old school, giving most of his credit as a clinician to Dr. Samuel Levine. Dr. Lown taught a whole generation of clinical cardiologists not only cardiology but also the art of being a physician, with particular reference to listening to the patient and making a strong, empathetic connection. Dr. Lown’s contributions are numerous and include seminal observations on digitalis intoxication, use of lidocaine in arrhythmias, the establishment of DC cardioversion, and the establishment of what would become the modern coronary care unit. He won the Nobel Peace Prize in 1985 for his work in prevention of nuclear war. These quotations are taken from his 1996 book *The Lost Art of Healing* (Houghton, Mifflin, Boston, 1996), which is highly recommended to any physician cherishing aspects we may well be losing as the burden of the technological approach to medicine increases.

Although this view is fundamental, it is not all inclusive. Several reasons exist for the consultation and cover the entire spectrum of the consultant–patient interaction.

Helping Another Physician

This is still the most common reason for the consult to be requested. In these situations, the primary physician requests assistance in the patient’s diagnosis, prognosis, or treatment while he or she maintains overall care of the patient.

Second Opinion Requested by the Primary Physician

In this situation the primary physician has made a diagnosis and plan, but because of his or her unfamiliarity with the process or because of the seriousness of the illness, he or she requests a second corroborating opinion. In nearly all cases, the patient’s care remains with the referring physician.

Second Opinion Requested by the Patient

In this situation the patient either has pressed for a second opinion or may have secured the consultation without informing the primary physician. This circumstance should be elucidated early in the consultative process and is probably best done by asking to whom the report should be sent. The patient and family may vary in reasons for pursuing a second opinion, but more often than not it is the result of a benign motivation. They generally wish the report to go back to the referring physician. That should be done with an opening sentence in the consultation letter stating that the patient sought the second opinion and that your information is being transmitted to the primary physician.

Second Opinion Sought by a Third-Party Payor

Increasingly, third-party payors are requesting second opinions, especially if a new diagnosis or planned procedure has significant financial implications. These consultations are worthwhile financially to the payor but also especially to the patient because the correct diagnosis and treatment are always best for the patient. These second opinions should be honored and are part of good modern medicine.

Other Third Parties

Occasionally, because of disputes regarding quality of care, causation, injury, prognostication, and workers’ compensation, an independent medical evaluation (IME) is requested. This is one of the few situations in which a consulting physician should remain an uninvolved neutral party; the goal of this type of consultation is to remain objective and try to find facts to assist the mediation process while serving as an advocate for neither side. It is of great importance for the consultant to project this neutrality to the patient, his or her family, and both parties of a dispute and to document in the report that he or she is not and will not be a provider of care and thus no

traditional doctor–patient relationship has been established. Therefore, treatment will not be instituted (unless absolutely emergently so) but rather is described in the report, which should be an objective statement of findings. Some consultants do not do IME or workers' compensation consults, and this should be clearly stated to those who are requesting such consultation. Recently, Baum has described liability issues that can arise from IMEs.⁶

A physician shall, in the provision of appropriate patient care, except in emergencies, be free to choose whom to serve, with whom to associate, and the environment in which to provide medical service.

—AMA Code of Medical Ethics⁸

The Disgruntled Patient or Family

Occasionally a patient has lost confidence in a practitioner for either a real or perceived cause. These patients and especially their families may rail against a physician for missing or delaying a diagnosis, for treating too rapidly or too slowly, or for a less-than-perfect outcome. It is generally best to allow some degree of emotional venting by such parties during the consultation visit, but the consultant should make it clear soon thereafter that even if the patient is not to return to that initial practitioner, the patient's well-being remains dependent on records, reports, and tests from the other physician. At this time, the consultant should discuss with the patient the importance of the background work collected by the primary physician because it serves as the foundation for the consultation. All previous information is useful. Information from the first physician should be requested by the consulting physician (not by the patient) in a nonthreatening but honest manner, preferably face-to-face or by telephone rather than the mail; such direct discourse between the two physicians greatly facilitates the initial practitioner's efforts to elaborate his or her side of the story, to diminish concerns that the patient and consultant may be conspiring against the primary physician, and finally, in fact, to expedite patient care. The new consultant may assume primary care of the patient, find another qualified practitioner appropriate for the patient, or facilitate continued care of the patient by the original physician, especially if there have been only minor misunderstandings between these two parties.

In explaining to patients the failure of other physicians to have reached the correct diagnosis in the past, it should be pointed out that one cannot judge the past by the present. It often takes time for changes to occur to the point where a correct diagnosis is possible.

—Philip A. Tumulty^h

⁸ American Medical Association Code of Medical Ethics, 1997, a compilation of medical ethics with its supporting case law, opinions, and foundations is extremely concise and well written. Unfortunately, it is not regarded by enough physicians as a foundation for a most important part of modern medical practice.

^h Philip A. Tumulty (1912–1989) was the master consulting physician at Johns Hopkins Hospital and a professor of medicine for many decades. The three editors of this book were fortunate to have worked with Dr. Tumulty as house officers. Dr. Tumulty was the quintessential diagnostician and curator of the art of medicine exemplifying the highest attributes of an internist. His quotes in this chapter are taken from his book *The Effective Clinician* (W.B. Saunders, Philadelphia, 1973).

Acknowledged mistakes provide potent learning experiences. Admitting them helps ensure that they will not be repeated. The humbling avowal of error prevents doctors from confusing their mission with a divine one. We possess no omniscient powers, only intuition, experience, and a patina of knowledge. These are most effective when one is constantly probing to advance the interest of an ailing human being.

—Bernard Lown^f

Inappropriate Consultations

Occasionally consultations are requested that may be inappropriate. Although a consultant should always be at the service of a physician calling for a consultation, the consultant must be on guard against any consultation that reflects adversely on the patient, cost containment, or the profession. Physicians must minimize inappropriate consultations and identify abuses.

One such inappropriate consultation involves what the author refers to as “institutional elitism.” This may occur when a patient with an existing chronic condition is admitted to a hospital for an acute hematologic problem. Unless proved otherwise, assume that chronic problems that are managed by other physicians are adequately treated; new consultations for these problems need not be generated. For example, if a patient with bipolar disorder is admitted with acute idiopathic thrombocytopenia (ITP), assume that the patient's chronic bipolar disorder has been appropriately treated for many years by a physician who is regarded as an expert and with whom the patient and family are perfectly happy; it is inappropriate to ask one's own institutional psychiatrist to see the patient unless one can conceive of some situation in which the bipolarism or its treatment may have something to do with the acute ITP. If the bipolar disorder or its treatment has nothing to do with ITP, it is best to continue the patient's pharmacologic management and then send a copy of the discharge summary to the psychiatrist for his or her office file.

A second, more pervasive form of inappropriate consultation is often referred to as “churning.” In this situation, a patient is admitted, and each and every system or organ that is abnormal is immediately and with little forethought consulted on by experts. Basic internal medicine expertise should eliminate the notion that every murmur requires an immediate visit from a cardiologist, every wheeze requires a pulmonologist, and every arthritic joint requires a rheumatologist. This thesis is especially true with the very brief length of hospitalizations we currently endure. A consultation should be carefully chosen, and the question regarding the management should be focused toward any problem that is relevant to the current clinical setting.

A British study showed that 75 percent of the information leading to a correct diagnosis comes from a detailed history, 10 percent from the physical examination, 5 percent from simple routine tests, 5 percent from all the costly invasive tests; in 5 percent, no answer is forthcoming. Some of the most challenging medical problems I have encountered could be solved only through information provided by the patient. The time invested in obtaining a meticulous history is never ill spent. Careful history-taking actually saves time. The history provides the road map; without it the journey is merely

a shopping around at numerous garages for technological fixes.

—Bernard Lown^f

CONSULTANT'S POINT OF VIEW

As a general rule, the consultant should approach each case from the point of view of having a degree of training more specialized than the referring practitioner. If the referring physician is another hematologist/oncologist, one can more likely than not appropriately review the case as a subspecialist (e.g., coagulationist) for that hematology/oncology referring physician. The consultation will thus be quite focused. When another internist refers the patient to the subspecialist, the consultant should regard the patient from the position of a hematologist/oncologist and therefore approach the patient in a more general manner. Therefore, other hematologic matters such as anemia, elevated white count, or splenomegaly can and should be addressed if they are found by the consultant. When consultation is originated by a noninternist such as a surgeon, obstetrician/gynecologist, or psychiatrist, approach the patient from the point of view of a general internist. In these situations one might also want to address elevated blood glucose, hypertension, or a dermatologic process not previously appreciated by the referring doctor. Although it is not necessary to address each of these problems oneself, the fact that one has found them when they had not been previously appreciated warrants consideration. The consultant may evaluate these personally or may wish to refer these patients to a diabetologist, hypertension specialist, or dermatologist, respectively. However, the fact remains that the consultant as an internist has found these items that are of medical importance and clearly parts of the overall consultation process. Increasingly patients are being referred to subspecialists by nonphysicians such as dentists, physician assistants, advanced registered nurse practitioners, and even third-party payors. In these situations, the consultant must look at the patient from a physician's perspective as well as from a specialist's perspective unless this has clearly been done by someone else. The consultant serving as physician *and* specialist must often ascertain that a patient has had appropriate preventive care (e.g., Papanicolaou [Pap] smears and mammograms) or at least make sure that those very important points have been addressed in addition to addressing the question that is being directly asked by the referring health care provider.

I do not know a better training for a writer than to spend some years in the medical profession. I suppose that you can learn a good deal about human nature in a solicitor's office; but there on the whole you have to deal with men in full control of themselves. They lie perhaps as much as they lie to the doctor, but they lie more consistently, and it may be that for the solicitor it is not so necessary to know the truth. The interests he deals with, besides, are usually material. He sees human nature from a specialized standpoint. But the doctor, especially the hospital doctor, sees it bare. Reticences can generally be undermined; very often there are none. Fear for the most part will shatter every defense; even vanity is unnerved by it. Most people have a furious itch to talk about themselves and are restrained only by the disinclination of others to

listen. Reserve is an artificial quality that is developed in most of us but is the result of innumerable rebuffs. The doctor is discreet. It is his business to listen and no details are too intimate for his ears.

—W. Somerset Maughamⁱ

DUTIES OF THE REFERRING PHYSICIAN AND THE CONSULTANT

The consultant should focus as directly, efficiently, and cost effectively as possible on the precise question that the referring physician has formulated. This, of course, depends on the accuracy of the referring physician's question as well as the possibility that the referring physician may have missed some important points. In all cases, the consultant should provide that level of consultation that is best for the patient.

Consultants are increasingly working along with physician extenders such as physician assistants or advanced registered nurse practitioners. Such professionals are usually highly knowledgeable in their areas and clearly enhance the efficiency of the busy consultant. However, it must remain absolutely clear to the referring physician and the patient that the extender is working with the consultant and not independently. If the extender dictates the report, it is wise and reassuring to have joint signatures on the correspondence.

Too little has been made of the duties of the referring practitioner. In this era of brief visits in which time is at a premium, the referring physician cannot simply ask a consultant to go in depth into a patient's multiyear history of present illness with multiple hospitalizations, innumerable radiographs, biopsies, and sheaves of laboratory data just to "figure it all out" in a 45-minute consultation. Rather, the referring physician must prepare a brief (one-page) summary of what has happened and construct a chief question that is to be asked of the consultant. If radiographs, biopsies, or other special tests are of importance and pertinent, they must come with the patient, preferably hand-delivered by the patient directly to the consultant. Mailing important material that will be delivered a week after the consultation is perfunctory and disrespectful. On the other hand, if these previous records are not important, they are best left with the referring physician because they will only clutter the diagnostic process and further encroach on effective consultation time.

If I failed to send a letter along with a new referral, which I more often did than not, this man would call me before he saw the patient and bluntly ask, "Dr. Sams, what do you want me to do for this patient?" The first time this happened I was taken aback, for specialists are not usually that open or that direct, and I am afraid I stammered a little with confusion and surprise. Then I learned just as bluntly to reply, "Prove to me he does not have a brain tumor," or, "Tell me she is having migraines," or, "I am worried about multiple

ⁱ W. Somerset Maugham (1874–1965) was trained at St. Thomas' Hospital in London and used his medical background in his more famous career as a novelist, short-story writer, and playwright. He wrote more than 60 books. Of special interest to physicians is *Of Human Bondage*. This quote comes from his autobiography, *The Summing Up* (Bantam, Doubleday Dell Publishing Group, New York).

sclerosis and need you to confirm or deny it,” or even, “She is a crock and forgive me for dumping on you.”

—Ferrol Sams^j

We sometimes forget that the fifth Oslerian essential skill of an internist (and the most important) after observation, palpation, percussion and auscultation, was contemplation.

I had a patient once with multisystem complaints who carried with her folders full of lab results, reports of endoscopies and multiple imaging studies, and a variety of other test records. I set it aside. “Aren’t you going to look at this?” she asked. “If the answer to your problem was in there somewhere, you wouldn’t be here.” I said.

After a detailed history and physical examination I had some ideas but no answers. I wanted to read more about some possibilities that had come to mind. “I’ll call you in a couple of days,” I told her.

“No tests?”

“You’ve had plenty,” I said.

“Then what are you going to do?” she asked.

“I’m going to think,” I answered.

“Oh!” she said, “Nobody’s ever done that before.”

I believe that an internist’s expertise, annealed to experience and analytical thought process, and the time to fully engage these most powerful tools are not only the core of our craft, but assure the patient the most cost-effective and humane medicine possible.

—Faith Fitzgerald^k

TIMING

The timing of the consultation plays an important part in determining the tempo and depth of the consultant’s evaluation of a patient. For instance, for a coagulation evaluation, it is important to know whether the patient is being considered for impending surgery. In this situation the consultation would usually be more exhaustive because the hemostatic challenge of surgery is imminent. On the other hand, one may be asked to see a patient with postoperative hemorrhage in whom another operation is not currently planned. It is characteristically difficult to make sense out of postoperative intrahemorrhagic coagulation tests because most diagnostic hemostatic testing is designed to ferret out problems in stable situations. Hemostatic studies from a patient who has been stressed by operation and hemorrhage, and is in the midst of receiving a variety of therapeutic agents and blood products, are difficult to interpret. Another situation involves patients who seek

hemostatic evaluation as part of a kindred analysis when another family member, often a first-degree relative, has been found to have a genetic disease such as the factor V Leiden mutation.

Accurate diagnosis and knowledge of the prognosis, both with and without various modes of therapy, should guide the physician in answering three major questions of therapy: **Whether** to treat, **When** to treat, and with **Which** modality.

—Maxwell M. Wintrobe^l

HOW TO DO THE CONSULTATION

A consultation is fundamentally similar to an admission evaluation of a patient but can be and usually is more focused, because the consultant is answering specific questions posed by the referring physician. Nonetheless, a careful history and physical examination are still in order and should be in depth, particularly in the area of expertise of the consultant. If the question posed is clearly focused and the encounter is a simple confirmatory or second opinion consultation, the consultation can be brief and therefore very circumscribed with respect to laboratory tests. Stumbling blocks, particularly in the areas of coagulation and thrombosis, regard not only *what* laboratory studies are reviewed but also *when* the tests were drawn. Every hematologist has had the problem of finding low and then normal protein C and protein S activity levels randomly spread throughout a patient’s chart without clear indication whether the patient was receiving warfarin therapy at the time of testing. Similarly, a prolonged partial thromboplastin time may be the result of a traumatic venipuncture, contaminating heparin, or a true underlying process such as disseminated intravascular coagulation. One cannot simply look at raw laboratory data without knowing what the clinical circumstances were at that time in order to interpret those data. The obverse of this is that when the consultant performs laboratory tests, he or she is expected to state explicitly in the chart the ongoing events at the time those laboratory specimens were collected. It is important to know whether warfarin therapy or heparin therapy was concurrent, whether liver disease was manifest, or if there was a recent massive thrombosis. Otherwise one is unable to convert data into information useful to the patient and the physician.

ROLE OF THE CLINICAL LABORATORY

The traditional relationship between clinical hemostasis and the coagulation laboratory is longstanding, time-honored, and intertwined. At one time, diagnostic and investigational

^j Ferrol Sams (b. 1922) was educated at Emory University School of Medicine and still practices in southern Georgia. He is a master storyteller and has written several novels, including *Run with the Horsemen* and *Whisper of the River*. The quotation used comes from *The Widow’s Mite* (Peachtree Publishers, Atlanta, 1987).

^k Faith Fitzgerald (b. 1943) was born in Massachusetts and received her M.D. degree from the University of California, San Francisco, where she was also an intern and resident. She was then Chief Resident in Medicine at San Francisco General Hospital. She currently is Assistant Dean of Humanities and Bioethics at the University of California, Davis School of Medicine. Her bright intellect, quick wit, and sagacious personality make her a most popular medical speaker. This citation originated in an American College of Physicians chat room for Governors and Regents on February 24, 2003, and is too priceless to exist only in cyberspace, and so, with Dr. Fitzgerald’s permission, it is included.

^l Maxwell M. Wintrobe (1901–1986) is considered the father of American hematology. Born and trained in Canada, he joined the faculty at Johns Hopkins in 1929 and in 1943 became the founding icon at the new medical school in Salt Lake City, where he helped build that service into one of preeminence. A host of American hematologists can trace their academic lineage directly or indirectly to Dr. Wintrobe. His quotation is taken from the introduction to his textbook, *Clinical Hematology*, first published in 1942. It has been wisely retained by the current editors of the 10th edition (Williams & Wilkins, Baltimore, 1998).

laboratories were managed by clinicians, which significantly contributed to the clinicians' ability to unravel and understand the intricate complexities of physiologic and pathophysiologic events. Unfortunately, through modern regulations, laboratories are no longer supervised by clinicians. Residents in clinical training have considerably less exposure to even basic coagulation testing. It is strongly encouraged that residents in training seek out experience (hands-on if possible) in a diagnostic laboratory in order to understand the vagaries and underpinning of this craft. Effective consultative diagnostics requires that the laboratory not be viewed as an incomprehensible yet unquestioned "black-box" into which samples are placed and from which data emerge. What the chest x-ray is to the pulmonologist and the electrocardiogram is to the cardiologist, the coagulation laboratory is to the hematologist.

The weight of laboratory results in the diagnostic process varies considerably. On one extreme, no clinician, no matter how talented, can distinguish between congenital factor VIII deficiency and factor IX deficiency, given the identical manifestations and genetics, clinical expressions, and courses of these two disorders. The laboratory can promptly and easily distinguish these, a matter of considerable importance considering the key differences in treatment. On the other hand, the preponderance of diagnostic evidence is clinically derived with the laboratory serving primarily to confirm one's clinical diagnosis. Common clinical diagnoses include thrombotic thrombocytopenic purpura, immune thrombocytopenic purpura, disseminated intravascular coagulation, and heparin-induced thrombocytopenia. The more facile one becomes in laboratory methods, to consider its prelaboratory variables (e.g., wrong sample, wrong patient, heparin contamination) and false-positive and false-negative results, the more correctly the diagnostic laboratory will be viewed. The diagnostically naive clinician tends to rely inordinately and inflexibly on the laboratory.

RECOMMENDATIONS

A consultant's recommendations should be clearly stated and easily found. In urgent cases or especially if information is pivotal in patient management, the referring physician should be called as soon as feasible to discuss the events of the consultation. This rapid communication is then followed up with a more formal consultation note.

In preparing the final report, the consultant should state in the first sentence or two the reason for the consultation. An example may be "Thank you very much for sending this 37-year-old white man with clear-cut ITP in for consultation for my opinion regarding length of prednisone treatment prior to possible splenectomy." This first sentence thus makes clear at least what your expectations were of the consultation, and, if such expectations prove to be wrong, the consultation can be refocused. For inpatient consultation, particularly when the patient is not on an internal medicine service, one's diagnoses and recommendations are probably best tabulated in a numeric fashion, because the entire history, physical examination results, and recounting of laboratory data more likely than not will not be read by the busy referring doctor.

Genetic counseling also may be an aspect of the consultation. For example, when patients are found to have

heritable diseases, such as hemophilia or thrombophilia, it is wise to tell both the family and the referring physician that at least first-degree relatives might be screened for the presence or absence of the genetic disease. It is useful for first-degree relatives to know whether they do or do not have the defect, regardless of prior symptomatology, because future therapeutic plans are impacted by either positive or negative diagnoses of such illnesses.

One should be perfectly clear about to whom to send the consultation report. In inpatient work, the report is usually left on the chart for all appropriate persons to see.

In outpatient consultations, the initial copy is sent to that practitioner who referred the patient. Frequently patients wish to have copies of the consultation, and this should be honored in almost all respects. In rare situations in which the consultant feels uncomfortable, he or she should inform the patient that it is his or her obligation to send the consultation report back to the referring physician and let the referring physician and patient discuss those matters between themselves. Keep in mind, however, that any report is rightfully discoverable, so if a patient wishes to have a report, such inevitably will be accomplished.

More often than not patients will have seen other physicians who may have a stake in the patient's overall care, so it is pertinent to ask the patient whether he or she wishes to have a copy of the report sent to other health care practitioners who have cared for the patient or may in the near future.

In the special circumstances of IME and workers' compensation cases, the report is sent to the party who requested and paid for the consultation. Here it is not advisable to send copies to other practitioners without the explicit permission of the patient or the parties requesting the IME or workers' compensation evaluation.

Time after time I have gone out into my office in the evening feeling as if I couldn't keep my eyes open a moment longer. I would start out on my morning calls after only a few hours' sleep, sit in front of some house waiting to get the courage to climb the steps and push the front door bell. But once I saw the patient all that would disappear. In a flash the details of the case would begin to formulate themselves into a recognizable outline, the diagnosis would unravel itself, or would refuse to make itself plain, and the hunt was on.

—William Carlos Williams^m

CONCERNS

Sometimes circumstances develop during the consultation that place the consultant in an unenviable position. Maturity and professionalism will serve to direct the correct course of action even if initially it seems totally impossible. The fundamental commandment should be to do that which is best for the patient rather than one's own emotional comfort. These dilemmas usually involve the relationship between the referring physician and the patient.

^m The American physician William Carlos Williams (1883–1963) translated his hard work as a practitioner into everyday-life scenarios that characterized his enormous production of poetry and short stories. The quotation comes from a short story called "The Practice" from the *Autobiography of William Carlos Williams* (New Directions Publishing Company, New York, NY, 1951).

A patient or his or her family may be disgruntled with the original physician. Diagnoses are missed by all practitioners, and therapy provided can be incorrect. Bad outcomes should be clearly separated from deviation in standard of care. Tact with honesty and forthrightness should be employed. Often diagnoses that are perfectly clear in retrospect are in fact initiated and validated by prior efforts made on behalf of the patient. Treatments can be controversial, and even bizarre treatments have their vocal advocates. One should never openly fault another practitioner without knowing all the facts involved. It is best to limit oneself to what is known and carefully document such in the record because the stated facts may change if and when more data are collected. It is usually wise to refer such cases to a third practitioner or assume the care oneself rather than force the patient and physician back together if care does appear in fact to be suboptimal. One should find a way to discuss this matter with the other physician because it will eventually be revealed in some manner regardless. Early communication will allow the other practitioner to voice facts of which the consultant may not be aware. As mentioned previously, it is often possible to reconcile the patient's and the referring physician's problems. Early communication also allows the initial physician, if he or she indeed has practiced below the standard of care, to make amends with the patient or, if appropriate, for the physician to contact his or her risk management personnel sooner rather than later.

Some practitioners initially may be curt, hurried, or disrespectful or do not offer enough of their time to their patients, but nonetheless, are practicing within the medical-legal standard of care. If reparations cannot be made, the patient is best served by finding an equally intelligent but more humanistic physician.

Some patients are habitually malcontent; this can be determined by both discussion with the practitioner and discovery that the patient is persistently unable to establish and maintain profitable relationships with any health care provider. This category may include patients with personality disorders, drug-seekers, and persons with self-induced or factitious illnesses. These patients are most difficult because their problems are far deeper than just those that apply to one's subspecialty.

What the scalpel is to the surgeon, words are to the clinician. When he uses them effectively, his patients do well. If not, the results may be disastrous.

—Philip A. Tumulty^h

OUTCOMES

Total Agreement

In this situation the consultant totally agrees with the evaluation of the referring physician and consultation serves primarily to add a layer of understanding and confidence to the patient and his or her family. Almost always one can make some minor suggestions, the thrust of the consultation is clearly to agree with and support the diagnosis, prognosis, and treatment plan of the referring physician. In

almost all cases, the referring physician will continue with the assumption of care of the patient.

Supporting Consultation

Occasionally a physician will refer a noncompliant or doubtful patient to a consultant in order to have the latter reinforce a point with which the referring physician is having difficulty because of poor patient acceptance or compliance. Common examples of this type of consultation include the acceptance of certain diagnoses and especially cessation of smoking. Surprisingly, some patients refuse to accept the determination that they are normal despite all the supporting evidence. They continue to hang on to mildly abnormal laboratory data or minor findings such as normal bruising as evidence for some underlying pathologic process. Wisely, the referring physician usually communicates this informally with the consulting physician prior to the consultation. When it is clear that the referring physician will continue to assume care of the patient, the consultation is an opportune time for the consulting physician to strongly reinforce the stance of the referring physician (assuming that it is correct). Inappropriate behavior on the part of the patient can be addressed. This may occasionally generate some degree of resentment on the part of the patient, who may report such resentment to the referring physician or even distort details of the consultation. The strong advocacy role played by the consultant physician rightfully justifies the benevolent attempt of the consultant to positively modify the patient's understanding or behavior. One should promptly alert the referring physician of these events by telephone so that the referring physician will be forewarned regarding possible negative opinions of the consulting physician voiced by the patient.

Finding Another Physician for the Patient

It may become clear to the consultant that the referring physician has not made the correct diagnosis, prognostication, or treatment and that perhaps another primary physician should assume care of the patient. The consultant must be prepared to relate this opinion to the referring physician, especially if the patient or his or her family is obviously upset with the referring physician. The consultant, as a neutral third party, can sometimes improve patient care, but it is always still advisable as well as truthful to acknowledge to all parties the foundation work prepared and gathered by the original physician.

Consultant Assumes Primary Care of the Patient

Very rarely the consultant will assume primary care of the patient; this is not an advisable practice because if this does occur the relationship between the referring physician and consultant may be eroded. Transference of care is clearly understood whenever a patient moves from an area where he or she was previously attended by the referring physician to the consultant's geographic area. One may occasionally have a patient and his or her family so positively impressed by the attention and clinical sophistication of the consultant that they ask the consultant to assume their care. Flattering

though it may be, it is advisable not to do this unless there is absolute agreement from all parties, and to include third-party payors. It is not intrinsically unethical but generally should be held to an absolute minimum.

It is not unethical to enter into a patient–physician relationship with a patient who has been receiving care from another physician. By accepting second-opinion patients for treatment, physicians affirm the right of patients to have a free choice in the selection of their physicians.

—AMA Code of Ethics⁸

Serious Troubles

Rarely, a patient's case has been so mismanaged that there is clear and immediate danger to the patient. If this occurs, the consultant is helping the patient and also potentially the referring physician by extracting the patient from continued mismanagement. If the patient's care is severely compromised and immediate care is necessary, prompt hospitalization at the consultant's facility is a way to address the problem and defuse potential ill will with the referring physician. In this manner, diagnostic and therapeutic procedures can be initiated promptly and the consultant allowed time and data to justify this aggressive maneuver to the referring physician. Whether the patient should be returned to the referring physician may be a matter of the preference for the patient, the referring physician, or both, and the decision must take into consideration the referring physician's abilities to continue the correct treatment. Jones and colleagues outlined various communication options when discussing prior practitioners' mismanagement with patients and family.⁷

The best way to get a difficult job done is face-to-face or ear-to-ear. Sending notes is never satisfactory.

—Eugene A. Stead, Jr.^c

Redirecting the Thrust of a Workup

The consultant has the benefit of having more time, laboratory data, and response to therapy than the original physician. Occasionally the consultant may suddenly visualize the correct diagnosis, which, while explaining all the findings in the case, is far different from that of the referring physician. At this juncture the diagnostic and therapeutic thrusts must be changed from one direction to another. A example would be a patient who is being evaluated for anemia and is referred for a bone marrow examination because a myriad of tests have been negative. If the consultant recognizes that a history of fatigue, chills, fevers, weight loss, and night sweats has been overlooked and detects a new cardiac murmur, it is clear that the evaluation should be focused more toward infectious endocarditis than anemia of unknown etiology. Rarely do any parties become upset with this new direction, especially when the new diagnosis proves to be correct. Credit again must be given to the foundation of material gathered by the original physicians.

Major Disagreements between Physicians

This most unfortunate but rare situation usually occurs in the inpatient rather than the outpatient setting. Not all the

recommendations that a consultant makes need be carried out by any referring physician, and the decision to follow the recommendations is certainly the prerogative of the attending physician. No code holds that the attending physician must execute each and every recommendation made by the consulting physician. Lo and colleagues explored variables for and against adherence and lack of adherence to suggestions made by infectious disease consultants.⁸

On some occasions, however, the consultant's feelings are so strong and so clear that for the primary physician to continue to ignore the recommendations may well fall below the standard of care in the consultant's opinion. In this situation, frank face-to-face discussion with the attending physician is mandatory. This is particularly true in teaching institutions, where there are several buffers of communication between the consultant faculty member and the attending physician of record. If these matters cannot be resolved, it may be wisest to sign off a case in writing in the chart. Admittedly this should be a very rare event, but it does occur perhaps a few times in a decade among consultants in a very busy consultation service. The note need not be long or give reasons but simply state that one as the consultant is signing off this case but availability can be reestablished by reconsultation. The consultant might name other consultants who may be contacted on this case.

From the day you begin practice never under any circumstances listen to a tale told to the detriment of a brother practitioner. And when any dispute or trouble does arise, go frankly, ere sunset, and talk the matter over, in which way you may gain a brother and a friend.

—William Oslerⁿ

Duration of Consultation

There is often question about how long one should be involved as a consultant in the outpatient setting and in the inpatient setting. This question may be more pertinent on an inpatient basis. Some focused questions are effectively answered by an equally focused single note. In other situations, those questions are quickly and efficiently answered with one or two brief follow-up visits to ascertain results of certain requested laboratory data or the response to therapy after which the consultation can be terminated. It is advisable to sign off in writing in the medical record so that it is clear to all parties that one has ceased closely following the patient yet is still available if another question emerges or if things do not go as planned.

Some consultations involve "clearing a patient for surgery." All parties should understand that the term *cleared for surgery* implies clearance *at that time*. Therefore, any events that happen later cannot have been considered; a patient is not cleared for surgery in perpetuity. This often must be expressly written in the outpatient consultation as facts can change between the consultation and the actual surgery. For instance, a patient

ⁿ William Osler (1849–1919) received his M.D. degree from McGill University and was the founding physician of the new Johns Hopkins University. While helping to establish the preeminence of Johns Hopkins, he wrote his *Principles and Practice of Medicine* and subsequently became the Regis Professor of Medicine at Oxford University, the chair presently held by Dr. Weatherall, who was kind enough to write the preface to the first edition of this text. Dr. Osler wrote prolifically on medical and nonmedical subjects. The quotation used is one of his *Aphorisms*.

with chronic thrombocytopenia who has a platelet count of 60,000/ μ L may be currently cleared for nearly any surgery, but that clearance does not hold true forever. If the patient returns in a year for another operation, and the platelet count is 20,000/ μ L, the situation has clearly changed. It is wise to signify the limits of the clearance in the body of the consultation. Clearance is not to be confused with a guarantee of success but implies that the risk:benefit ratio is made as favorable as possible for the patient and that parties acknowledge the risk and agree that the perceived benefit is worth that risk.

In general the consultant should follow the case for as long as the expertise is needed. If one is consulted for preparing an individual with hemophilia for surgery, it would be wise for the consultant to see the patient several visits postoperatively because bleeding can be immediate, intermediate, or sometimes delayed.

Noncompliant Patients

We cannot assume that a course of treatment advised for a patient will be followed. Patients may have a variety of reasons to be noncompliant. This author found that approximately one half of prescriptions written for outpatient low-molecular-weight heparin are not filled when the patient leaves the hospital, primarily because of financial considerations. Some patients may have no faith in our suggestions, whereas others will deny they have any problem and therefore believe no nostrum is needed. Self-determination is held extremely highly in the United States. We do owe the patient a duty to fully explain our treatment and its best-estimated risk:benefit ratio. Often more disturbing is failure to address behavior that is unhealthy. It is important to continue to support the patient even (or specially) if one does not agree with the patient and their behavior.

Some physicians dismiss patients from their practice if they do not adhere to recommended treatment plans or correct harmful habits. Many more of us try to maintain a patient-doctor relationship even when our advice seems to be discounted. Perhaps we believe that we will eventually prevail in our advocacy for changed life-styles. More likely, we see within our patients certain characteristics that we also share and hence cannot honestly condemn. I never gave up the quest to convince [a particular patient] to care for his diabetes. Would it have made a difference in the coming collapse of his health? I do not know. Sometimes diabetes, and most other illnesses as well, behave in totally unpredictable fashions. Sometimes the most carefully followed treatment plan will not slow a disease at all. Sometimes a patient may ignore an illness and for many years seem none the worse. These instances force humility upon us. Our word is not law. It is to be considered advice in the light of an uncertain science that races ahead of us.

—Clif Cleaveland^o

^o Clif Cleaveland (b. 1936) grew up in Georgia and South Carolina and attended Duke University. He was a Rhodes Scholar and received his M.D. from Johns Hopkins Medical School. He completed his residency in internal medicine at Vanderbilt University Hospital. He has been practicing medicine in Chattanooga, Tennessee, for over 30 years. In 1995, he was President of the American College of Physicians. Dr. Cleaveland is a gifted writer who is able to translate day-to-day clinical experiences into prose that is humanistic, interesting, and poignant. He has penned two excellent books, *Sacred Space* in 1998 and *Healers and Heroes* in 2004.

End of Life Issues

It is all too common that major illnesses, including fatal illnesses, are encountered in consultative hematology. This is the nature of our work. At some point, the patient and the physician (i.e., those comprising the doctor-patient relationship) will elect to forgo further treatments, tests, and hospitalizations. This point in time will vary from patient to patient and may differ from a physician's own experience, beliefs and value systems, and views on quality of life. That these are variable and hard to define does not detract from their existence and importance. Palliative care is, appropriately, a rapidly developing area. Changing direction in a patient's care is not giving up.

Being an agent of healing for another human at the end of life confers a personal richness that is difficult to find elsewhere in medicine. It is not just the patient who is healed.

—Mary Bretscher^p

Family Members

No segment of society consumes fewer medical resources than physicians and their immediate families. This may be due in part to the familiarity with informed consent issues or that physicians may not wish to bother other physicians. To the extent that the latter is true, it is ill-advised for a practitioner to get more entwined in family care than anything more involved than the simplest issues. Conflict of interest and prescribing issues aside, it is the clearly recognizable inability of even the most veteran diagnostician to be objective that is the most obvious and concerning. One should get another physician to do this work.

At times of illnesses of our children, I experience almost unbearable conflict. Along with my wife, I need the informed comforting by an empathetic physician. I need the reassurance that all that is reasonable is being done. At the same time the scientist within me seeks insights into the disease process, and that invariably means becoming aware of the worst possible outcomes. Reassurance and fear compete. When one of my family members coughs or runs a fever, my senses sharpen. Am I over-responding, or am I at risk of ignoring something potentially dangerous? Our clinical work keeps us suspicious, observant, and uneasy, making it all but impossible to maintain balanced judgment when the patient is one of our flesh and blood.

—Clif Cleaveland^o

When a Diagnosis Is Not Forthcoming

Not all diagnoses can be established. The wise consultant should never feel pressed to force a diagnosis, because an

Dr. Cleaveland began the exceedingly popular Tennessee Literature and Medicine Reading Retreat in 1988 in which he leads discussions regarding medicine and its practitioners as portrayed in literature. His Reading Retreat has been emulated but never equaled. His first excerpt is from *Healers and Heroes*, and the second one from *Sacred Space*.

^p Mary E. Bretscher (b. 1959) is in the private practice of hematology and oncology in Springfield, Illinois. She received her medical degree from Southern Illinois University, where she also performed her residency and served as Chief Resident. She followed this with a fellowship at the Mayo Graduate School of Medicine in Minnesota. Her practice is hematology/oncology, but her passion is palliative care.

incorrect diagnosis is worse than no diagnosis. In making an incorrect diagnosis, one shuts the window of opportunity to pursue the correct diagnosis. It is wisest to realize and state that one affirmatively knows he or she does not know the answer rather than to force a diagnosis. It often is the responsibility of the consultant to energize the referring physician to continue observation in a conservative course. Failure to do so frequently results in erratic testing and troublesome indecisive therapeutics. If a therapeutic course is taken, it must be maintained sufficiently long enough to either succeed or fail on its own merits while one constantly reevaluates for signs of success or failure as well as entertains another diagnosis. Often the remaining and most important procedure in such cases is observation. Therapies that are not effective should be neither initiated nor maintained.⁹ With observation, some diagnoses become clear while other cases spontaneously improve.

The essential and wise thing to do is not to force a diagnosis when the answer is not evident, but rather to follow a conservative program of support and periodic reexamination, retaining an open mind as to the basis of the patient's complaints.

—Philip A. Tumulty^h

[My father] carried his prescription pad everywhere and wrote voluminous prescriptions for all his patients. These were fantastic formulations, containing five or six different vegetable ingredients, each one requiring careful measuring and weighing by the druggist, who pounded the powder, dissolved it in alcohol, and bottled it with a label giving only the patient's name, the date, and the instructions about dosage. The contents were a deep mystery, and intended to be a mystery. The prescriptions were always written in Latin, to heighten the mystery. The purpose of this kind of therapy was essentially reassurance. A skilled, experienced physician might have dozens of different formulations in his memory, ready for writing out in flawless detail at a moment's notice, but all he could have predicted about them with any certainty were the variations in the degree of bitterness of taste, the color, the smell, and the likely effects of the concentrations of alcohol used as solvent. They were placebos, and they had been the principal mainstay of medicine, the sole technology, for so long a time—millennia—that they had the incantatory power of religious ritual. My father had little faith in the effectiveness of any of them, but he used them daily in his practice. They were expected by his patients; a doctor who did not provide such prescriptions would soon have no practice at all; they did no harm, so far as he could see; if nothing else, they gave the patient something to do while the illness, whatever, was working its way through its appointed course.

—Lewis Thomas^d

Once a particular therapeutic program has been launched, give the patient's response to it time to mature and produce clear-cut answers before it is stopped or altered.

—Philip A. Tumulty^h

You can observe a lot just by watching.

—Yogi Berra^q

^q Yogi Berra (b. 1925) was born in St. Louis, Missouri, and became one of the greatest catchers in baseball history. He is well known for his malapropisms, usually now referred to as “Yogi-isms.” These have been richly collected in *The Wit and Wisdom of Yogi Berra* by Phil Pepe (Meckler Boos, Westport, Conn., 1988), from which this Yogi-ism was taken.

WHEN SHOULD A CONSULTANT REQUEST CONSULTATION?

Sometimes consultations can be extremely difficult, and a well-trained, experienced consultant may find that he or she needs a special laboratory test or special consultation with other experienced experts. These facts are clearly understandable, and often for geographic reasons such discussions are made telephonically. It is appropriate to enter such a secondary consultation in the body of the report, but one should recall that the secondary consultant has not had the benefit of seeing the patient first-hand and therefore is relying on the primary consultant's presentation, perception, and understanding of the case. Should blood or biopsy material be referred to yet another consultant, it is best to have the understanding and permission of the patient for reasons of confidentiality as well as the potential for fees generated for services.

There is always a strong impulse to do something to help a sick person, but no action is better than the wrong action.

—Philip A. Tumulty^h

Everyone is ignorant, only on different subjects.

—Will Rogers^r

In order to enhance this chapter, the editor has borrowed the thoughts and words of several highly regarded medical teachers and medical philosophers as well as five physician-writers of renown and two American icons of wit.

Students continue to enroll in medical school, coming to the profession for timeless reasons—because of a physician they admire, or because they want to serve, or because they have suffered or witnessed suffering. Perhaps some lucky ones even today have been called to medicine through the medium of a book. If they have a love for literature, reading might well help them to discover a way to understand and identify with the ambitions, sorrows, and joys of the people whose lives are put in their hands. In medicine, we often separate life events from their meaning for those who live them. In literature, the two are united. That is reason enough to keep reading. And writing.

—Abraham Verghese^s

^r Will Rogers (1879–1935) was one of our great American humorists. He was also a showman of great repute. His wit was usually sharp and at times critical. His favorite target was politics and any type of pretension. The quote is from *Will Rogers: Wise and Witty Sayings of a Great American Humorist* (Hallmark, Claremore, Oklahoma, 1969).

^s Abraham Verghese (b. 1955) was born in India and graduated with his medical degree from Madras University in 1979. He came to the United States as a resident in medicine to East Tennessee State University, and later served at that institution as Chief Resident. He was a Fellow in Infectious Diseases at Boston University. He has also received a Master of Fine Arts from the University of Iowa. Dr. Verghese's style is fluid, haunting, and piercing, as though he writes directly to one's subconscious. Two books, *My Own Country* (1994) and *The Tennis Partner* (1998), have been widely acclaimed and outstandingly reviewed, with both designated in the top ten books published during their respective years. Dr. Verghese is currently director for the Center of Medical Humanities and Ethics at the University of Texas, San Antonio, where he is the Forland Distinguished Professor of Medical Ethics and Professor of Medicine. The excerpt included is extracted from “The Calling,” which appeared in the *New England Journal of Medicine* (2005; 352:1844–1847).

Chapter 2

A Systematic Approach to the Bleeding Patient: Correlation of Clinical Symptoms and Signs With Laboratory Testing

Craig M. Kessler, MD • Nushmia Khokhar, MD •
Minetta Liu, MD

INTRODUCTION

In the current medical climate of laboratory automation, highly detailed radiographic techniques, and time/economic constraints on physicians in general and the hematologist specifically, the value of the comprehensive patient interview and medical history has been minimized. Furthermore, examination of the peripheral blood smear and bone marrow aspirate to establish a diagnosis based on visual and morphologic criteria has been supplanted by considerably more accurate and sensitive immunohistochemical, cytogenetic, and flow cytometric analyses with monoclonal antibodies. Perhaps more unique to the bleeding patient than to other categories of illness, the patient interview provides the foundation for making the diagnosis, determining which laboratory tests are most appropriate to order, and formulating treatment strategies. Careful attention to these elements of patient assessment substantially reduces morbidity, mortality, and the cost of care while minimizing the medical-legal exposure of the physician.

This chapter offers a systematic approach to the patient with a clinically significant risk of bleeding or an immediate history of spontaneous, excessive hemorrhage. Approaches to laboratory confirmation of the causes of bleeding are also presented because interpretation of data from the coagulation laboratory requires an understanding and appreciation of the vagaries of the techniques employed to generate them. In addition, this chapter discusses how the coagulation laboratory can provide insight into the pathophysiology of the patient's condition and presents a rationale for treatment.

The evaluation of patients with hemorrhagic complications is a multistep process that involves a complete history, a detailed physical examination, and a directed laboratory evaluation. The relative emphasis placed on each of these components varies according to each unique clinical situation, but all factors must be considered. Important points of differentiation include localized defects versus systemic defects, acquired defects versus inherited defects, and disorders of primary hemostasis (i.e., those related to platelet abnormalities) versus disorders of secondary hemostasis (i.e., those related to coagulation factor, fibrinogen, or connective tissue abnormalities).

It is important for the clinician to understand that some clinical situations do not allow for a comprehensive evaluation and may therefore require a more streamlined approach. Intubated patients who develop brisk bleeding during the immediate postoperative period, for example, will not be able to provide any information about their personal or family history; a determination of these patients' most likely cause for bleeding will therefore rest on the pertinent physical and laboratory findings. Of primary importance for all consulting hematologists is the realization that the management of coagulation abnormalities—which are often epiphenomena or complications of other medical illnesses—is often empirical and cannot always be approached through a standard algorithm.

THE CLINICAL EVALUATION

Each component of the clinical assessment provides critical information that supports or refutes the possibility that a true hemorrhagic disorder actually exists. The information garnered from the history and physical examination ultimately guides the direction and extent of the laboratory evaluation and helps the clinician to determine how future bleeding complications can be managed and/or prevented. This multifactorial approach is necessary because the likelihood of false-positive and false-negative diagnoses is high when the decision rests on one component alone. Consider, for example, the process required to obtain an accurate medical history. Patients' perception of their own bleeding tendency is often exaggerated or understated. In one study conducted in the Åland Islands, where von Willebrand disease (VWD) was originally detected in 1928, 65% of women and 35% of men from families with no history of bleeding and no personal laboratory evidence of a bleeding disorder answered a self-administered binary questionnaire with responses indicative of a symptomatic bleeding diathesis. In contrast, 38% of the women and 54% of the men with documented laboratory evidence of a coagulation defect and a positive family history of symptomatic VWD or qualitative platelet disorders answered the same questionnaire as if they were completely unaware of their bleeding diathesis.¹

Obtaining a Detailed History

Several authors have formulated basic comprehensive questionnaires in an effort to simplify and standardize the evaluation of individuals with easy bruising or bleeding.¹⁻³ Standardized questionnaire bleeding score systems have recently been devised to evaluate patient hemorrhagic symptoms and the potential to bleed for VWD (<http://www.euvwd.group.shef.ac.uk/files/scoremar04revision>),⁴ factor XI deficiency,⁵ Quebec thrombasthenia,⁶ and autoimmune thrombocytopenic purpura.⁷ The format of these questionnaires generally involves the use of binary (i.e., yes or no) questions that elicit immediate, unambiguous responses from patients; quantitative and qualitative qualifiers are used where appropriate. Examples of questions effectively applied to the present history are presented in the following sections.

Have you ever experienced a serious hemorrhagic complication during or after a surgical procedure?

The initial assessment of postoperative bleeding complications should differentiate between incomplete surgical ligation or cauterization of blood vessels and the presence of an underlying defect in hemostasis. Clinical suspicion of a bleeding diathesis should be substantiated with objective evidence from the case in question: a description of all wounds and venipuncture sites, an evaluation of all laboratory abnormalities (e.g., worsening anemia, thrombocytopenia, alterations in prothrombin time [PT] or partial thromboplastin time [PTT]), calculations of the estimated blood loss and subsequent transfusion requirements, knowledge of the means required to stop the bleeding, and documentation of a prolonged hospital stay. In addition, the timing of the hemorrhagic complication in relation to the procedure (i.e., immediate vs delayed) may provide important clues. Intraoperative and immediate postoperative bleeding at the surgical site is often due to defects in primary hemostasis, that is, abnormalities of platelet number, adhesion, and/or aggregation (Table 2-1). In contrast, delayed postoperative bleeding at the surgical site is typically due to coagulation factor deficiencies, qualitative or quantitative disorders of fibrinogen, or vascular abnormalities related to defects in collagen structure (Table 2-2); notably, factor XIII deficiency, fibrinogen deficiency, and several of the collagen disorders are often marked by poor wound healing and subsequent wound dehiscence as well. Furthermore, excessive bleeding from the umbilical cord stump at birth or bleeding from the circumcision site is strongly indicative of a severe inherited disorder, whereas bleeding related to abdominal or cardiothoracic surgery in a previously “normal” adult is not. Nevertheless, a number of cases of factor XI deficiency, mild VWD, and mild Ehlers-Danlos syndrome have escaped diagnosis until later in life when the defect in hemostasis is manifested as mucosal surface bleeding during or after routine surgery.

Have you ever experienced excessive vaginal bleeding during pregnancy or immediately after childbirth or perineal bleeding from an episiotomy?

Multiparous women should be questioned about each pregnancy in detail with regard to complications and outcomes.

Table 2-1 Disorders of Primary Hemostasis*

Hereditary Disease States
von Willebrand disease
Glanzmann thrombasthenia
Bernard-Soulier syndrome
Platelet storage pool disease
Gray platelet syndrome
Wiskott-Aldrich syndrome
May-Hegglin anomaly
Iatrogenic Disease States
Posttransfusion purpura
Drug-induced immunologic thrombocytopenia (e.g., quinine, heparin, sulfonamide antibiotics)
Drug-induced qualitative platelet disorders (e.g., aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs], ticlopidine, abciximab, mithramycin)
Acquired Disease States
Autoimmune thrombocytopenic purpura
Disseminated intravascular coagulation
Systemic amyloidosis
Hypersplenism
Aplastic anemia
Uremia
Mechanical platelet destruction from turbulent circulation (e.g., cardiac bypass, severe aortic stenosis)

*Primary hemostasis involves formation of the platelet plug. The above is a representative list of potential causes of abnormalities in platelet number, adhesion, or aggregation.

Table 2-2 Disorders of Secondary Hemostasis*

Coagulation Factor Abnormalities
Hemophilia A (factor VIII deficiency)
Hemophilia B (factor IX deficiency)
Deficiencies in factor II, V, VII, or X
Acquired inhibitors to specific coagulation factors (e.g., factor VIII or factor V inhibitors)
Factor XIII deficiency
Contact Factor Abnormalities
Factor XI deficiency
Fibrinogen Abnormalities
Afibrinogenemia
Hypofibrinogenemia
Inherited dysfibrinogenemias
Hyperfibrinolysis
Connective Tissue Disorders
Ehlers-Danlos syndrome
Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia)
Scurvy (vitamin C deficiency)

*Secondary hemostasis involves humoral coagulation subsequent to formation of the platelet plug. The above is a representative list of potential causes of abnormalities in coagulation factors, contact factors, fibrinogen, or connective tissues.

Obstetric histories are particularly important because multiple spontaneous miscarriages and infertility may be associated with congenital maternal coagulopathies (e.g., factor XIII deficiency, the dysfibrinogenemias) and some acquired syndromes (e.g., anticardiolipin/antiphospholipid syndrome). Bleeding before 20 weeks gestation may be due to

miscarriage, ectopic pregnancy, or gestational trophoblastic disease. Bleeding after the 20th week of pregnancy usually results in placental abruption and placenta previa. Hemorrhage during delivery most commonly reflects evolving placental abruption, uterine rupture, or placenta accreta. The most common causes of postpartum hemorrhage are uterine atony, laceration, and retained placenta. Postpartum hemorrhage is defined as blood loss greater than 500 mL in a vaginal delivery or 1000 mL in a caesarean birth.⁸

In general, disseminated intravascular coagulation (DIC) is the most common cause of abnormal bleeding during the puerperium and is most frequently the result of abruptio placentae, eclampsia, retention of a dead fetus, amniotic fluid embolism, placental retention, or bacterial sepsis.⁹ It is interesting to note that women who have mild or moderate VWD or who are carriers of hemophilia A typically do not experience easy bruising or bleeding manifestations during pregnancy, during the delivery, or when they are taking such estrogen-containing compounds as oral contraceptives or hormone replacement therapy. This is most likely related to the increased synthesis of von Willebrand factor (VWF) and factor VIII as acute phase reactant proteins in response to high-estrogen states; the activity levels of these factors begin to fall immediately postpartum and do not reach baseline levels for weeks (or even longer in women who are nursing). In addition, acquired autoantibodies directed against factor VIII may occur within the first year postpartum after an otherwise normal delivery; this acquired postpartum hemophilia is marked by pronounced bleeding and bruising and by spontaneous remissions and rare recurrences with subsequent pregnancies.¹⁰

Have you experienced persistent menorrhagia in the absence of fibroids or other uterine abnormalities?

Menstrual histories often provide useful clues for an underlying hemostatic defect, particularly in those women with persistent menorrhagia and/or a microcytic anemia despite adequate iron supplementation. A history of severe iron deficiency in a young woman, the use of packed red blood cell transfusions for an anemia of unknown cause, the need for a dilation and curettage procedure for persistent uterine bleeding, or the need for a hysterectomy to treat menorrhagia should increase the suspicion for an underlying defect in hemostasis. Recent surveys suggest that a significant number of hysterectomies for menorrhagia are performed in women with VWD.¹¹ Unfortunately, each woman's definition of menorrhagia can be somewhat vague, rendering menorrhagia a relatively poor indicator of an underlying coagulation disorder. The poor specificity of menorrhagia as a bleeding symptom is further underscored by the fact that 23% to 44% of healthy, noncoagulopathic women claim to experience this symptom.¹² Numerous bleeding scales have been devised to circumvent this variability, but these may be very cumbersome to use. They all attempt to quantitate menstrual blood loss according to the duration of heavy flow (i.e., longer than 3 days), the duration of each menstrual cycle (i.e., longer than 7 days total), and the number of pads or tampons used. The accuracy of this latter factor, however, may vary as it depends on the individual patient's hygienic habits and fastidiousness. The

recent addition of menstrual symptometric devices, such as pictorial blood assessment charts,^{13,14} has improved the accuracy of quantifying excessive blood loss, which would be useful in diagnosing underlying coagulopathy. These tools appear to have a high level of patient acceptability and can provide instant feedback to the physician. Finally, the need for oral contraceptives to control excessive menstrual bleeding should be noted, because this may also serve as an indicator of the degree of menorrhagia that is present but may confound the clinician's ability to diagnose VWD, secondary to the acute phase reactivity of factor VIII and VWF.

Do you experience brisk or prolonged bleeding after epistaxis or minor cuts or exaggerated bruising after minor trauma?

Excessive and persistent bleeding or oozing from a relatively minor superficial injury and the appearance of ecchymoses or purpura (especially true hematomas) after minimal trauma may be indicative of an underlying congenital or acquired hemostatic defect. For example, profuse bleeding and the need for prolonged times of direct pressure for a small paper cut or razor nick are unusual; this crude bleeding time may be a manifestation of qualitative or quantitative platelet defects, or of VWD. The loss of deciduous teeth and extractions of molar teeth are also inadvertent but accurate tests of hemostasis; again, immediate bleeding after the initial event is consistent with a vascular or platelet abnormality, and delayed bleeding and/or rebleeding is more consistent with a coagulation factor deficiency. Finally, poor or delayed wound healing is uncharacteristic of platelet disorders but may be associated with factor XIII deficiency, hereditary dysfibrinogenemia, and Ehlers-Danlos syndrome.

Habitual non-trauma-induced epistaxis, particularly those episodes that occur in postpubertal individuals that last longer than 5 minutes and require medical attention, should raise suspicion for an underlying bleeding disorder. Symptom-specific assessment and severity grading tools for epistaxis are available to supplement clinical acumen.^{15,16}

Epistaxis is reported as a bleeding problem in 5% to 39% of healthy individuals,¹² but only approximately 27% of habitual nose-bleeders have hereditary coagulation defects, predominantly involving components of primary hemostasis (e.g., VWF protein).¹⁷

Inherited vascular abnormalities of the nasal mucosa, such as the observed angiodysplasia associated with hereditary hemorrhagic telangiectasia and VWD, should also be considered in the differential diagnosis of recurrent epistaxis. In fact, these two diseases have been reported to coexist within families.

Have you ever developed hemarthrosis, retroperitoneal hematoma, or soft tissue hematoma in the absence of major trauma?

These clinical events are typical manifestations of defects in secondary hemostasis, that is, problems of humoral coagulation subsequent to platelet adhesion and formation of the platelet plug. The hemophilias are good examples of this type of delayed but severe bleeding, which may persist until the involved compartment has achieved self-tamponade. Of note, individuals who develop acquired neutralizing autoantibodies against specific coagulation factors are clinically

similar but not identical to those with classic hemophilia; although both patient populations usually present with extensive spontaneous bleeds in critical areas, spontaneous hemarthrosis is remarkably rare in those with acquired coagulation factor autoantibodies but is very common among those with classic hemophilia.

Have you ever experienced spontaneous bleeding, poor wound healing, or dehiscence of a surgical wound?

A spontaneous hemorrhage is one that occurs in the absence of any identifiable trauma other than the stress of weight bearing. Bleeding that spontaneously originates from the mucous membranes (e.g., epistaxis, melena, menorrhagia) is more commonly associated with severe thrombocytopenia (defined as a platelet count $<10,000/\mu\text{L}$), qualitative platelet dysfunction, or VWD. Spontaneous cutaneous bruising in the form of purpura is often a feature of prolonged corticosteroid administration, Ehlers-Danlos syndrome, or the senile purpura syndrome. Dramatic ecchymoses frequently are observed in individuals who develop acquired autoantibodies that target factor VIII (acquired hemophilia A). Poor wound healing is a nonspecific indicator of an underlying coagulation defect; however, when it occurs around 7 to 10 days postoperatively at any age, and particularly after circumcision or loss of the umbilical cord in the infant, the clinician should consider the possibility of hypo(dys) fibrinogenemia, factor XIII deficiency, zinc deficiency, or hereditary connective tissue diseases such as Ehlers-Danlos syndrome and Marfan syndrome. Diabetes mellitus and Cushing syndrome may also be associated with delayed wound healing.

Spontaneous hemarthroses and intramuscular bleeds, on the other hand, are more characteristic of certain severe coagulation factor deficiencies. If bleeding is multifocal, an underlying acquired bleeding diathesis, such as DIC, should be suspected. As in all other bleeding situations, an objective clinical and laboratory assessment is critical to determine the need for and type of appropriate medical intervention. In addition, hematemesis, hematochezia, melena, hemoptysis, and hematuria may occur spontaneously in confirmed hemorrhagic disorders, but a thorough investigation should be pursued in an effort to identify a critical anatomic lesion as the source of bleeding.

Has any member of your family experienced severe bleeding complications, perhaps requiring transfusion of packed red blood cells?

The most common congenital hemorrhagic diatheses and qualitative thrombocytopathies follow distinct patterns of inheritance (Table 2-3). One must keep in mind, however, that a negative family history does not necessarily preclude the presence of a familial disorder; patients may not be aware of their family members' medical histories, the genetic defect may be characterized by variable penetrance, the coagulation disorder may lead to a mild bleeding diathesis that is not always manifested clinically, or the mutation may have occurred spontaneously. Nonetheless, a careful review of the patient's pedigree may reveal the underlying inheritance pattern to be one of the following: (1) sex-linked recessive, including hemophilia A, hemophilia B, and Wiskott-Aldrich syndrome; (2) autosomal dominant, including VWD, Osler-Weber-Rendu syndrome

Table 2-3 Congenital Coagulopathies and Qualitative Thrombocytopathies

Sex-Linked Recessive Disorders

Hemophilia A (factor VIII deficiency)
Hemophilia B (factor IX deficiency)
Wiskott-Aldrich syndrome

Autosomal Dominant Disorders

von Willebrand disease
Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia)
Dysfibrinogenemias

Autosomal Recessive Disorders

Deficiencies in factor II, V, VII, X, XI, or XIII
 α_2 -Plasmin inhibitor deficiency
Bernard-Soulier syndrome
Glanzmann thrombasthenia
Gray platelet syndrome
Afibrinogenemia
Hypofibrinogenemia
Type 3 von Willebrand disease

(hereditary hemorrhagic telangiectasia), and hereditary dysfibrinogenemia; or (3) autosomal recessive, including factor II deficiency, factor VII deficiency, and Bernard-Soulier syndrome.

Do you have any known medical problems?

A number of medical conditions are associated with the development of acquired defects in coagulation and/or hemostasis. One of the best documented associations is that between the lupus-type anticoagulants and systemic lupus erythematosus, other autoimmune disorders, medications (including phenothiazines and tricyclic antidepressants), acute infections, and some lymphoproliferative disorders. Although the lupus-type anticoagulants do prolong in vitro coagulation assays, the major risk is for thrombosis as opposed to bleeding. Hemorrhagic manifestations may occur, however, in those patients with the lupus anticoagulant who concurrently develop autoantibodies to prothrombin (resulting in a true decrease in the circulating half-life of factor II) or to platelet membrane glycoproteins (resulting in thrombocytopenia or platelet dysfunction).

Other medical conditions associated with a potential for bleeding complications warrant mention as well. For example, catastrophic and life-threatening hemorrhagic events may occur in cases of acute promyelocytic leukemia as a result of the secondary DIC that is induced by the release of tissue factor from the malignant promyelocytes. Uremia secondary to renal failure, on the other hand, is associated with qualitative as opposed to quantitative platelet defects. This is in contrast to severe end-stage hepatic dysfunction, which may lead to defects in primary and secondary hemostasis; thrombocytopenia caused by portal hypertension and hypersplenism; deficient synthesis and postribosomal modification of the vitamin K-dependent clotting factors; low-grade DIC resulting from decreased clearance of activated procoagulant proteins and decreased synthesis and clearance of such fibrinolytic modulatory proteins as α_2 -plasmin inhibitor, the primary inhibitor of plasmin; and acquired dysfibrinogenemia of liver disease, in which increased susceptibility

to fibrinolytic enzyme degradation may play a key role.¹⁸ In addition, systemic amyloidosis is associated with the development of factor X deficiency, which may result from the specific adsorption of the factor X protein by amyloid fibrils¹⁹; amyloid-induced gastrointestinal malabsorption syndromes may exacerbate this coagulation defect through vitamin K deficiency. Finally, associations between Gaucher disease and factor IX deficiency and between hypothyroidism, right-to-left cardiac shunts, and Wilms tumors and VWD have been reported, each with a different underlying cause.

Do you take any prescription medications, over-the-counter medications, or homeopathic remedies on a regular basis?

The use of warfarin or any of the heparin or heparinoid products poses obvious bleeding risks. Antiplatelet agents such as aspirin, cilostazol, clopidogrel, dipyridamole, ticlopidine, the traditional nonsteroidal anti-inflammatory drugs (NSAIDs), and the monoclonal antibody inhibitors directed against the platelet glycoprotein (GP)-IIb/IIIa complex, are of concern as well. Various “alternative medicines,” including the Chinese black tree fungus and large quantities of garlic, vitamin E, vitamin C, and ginger, have also been associated with abnormalities of platelet function as manifested by a prolonged bleeding time and an increased risk for clinically significant bleeding.²⁰ Physicians and patients alike should be aware that certain antibiotics are notorious for their ability to affect the synthesis of the vitamin K–dependent clotting factors; cephazolin, levofloxacin, and trimethoprim/sulfamethoxazole are just a few examples of these. In addition, the penicillins, sulfonamides, and tricyclic antidepressants are among the medications associated with the development of factor VIII autoantibody inhibitors and the lupus-type anticoagulants. Finally, the use of iron supplements should be noted, as this may be related to a previous diagnosis of iron deficiency anemia produced by severe or chronic blood loss.

Have you noticed any unusual rashes or easy bruisability?

Petechiae, purpura, ecchymoses, and telangiectasias are often indicative of an underlying coagulopathy or vasculitis. The definition of “easy bruisability” is entirely subjective; both terms should therefore be qualified with and substantiated by objective physical findings (see Chapter 11). Suspicious lesions include those that develop spontaneously or with minimal trauma and those that are located over the torso rather than on the extensor surfaces of the extremities. If a patient develops a painful eschar while on warfarin, the possibility of warfarin-induced skin necrosis, a prothrombotic disorder associated with warfarin-induced deficiencies of protein C or protein S, should be considered. Of note, heparin-induced thrombocytopenia with resultant thrombosis may also be associated with severe skin manifestations, although these are typically more variable in nature.

Objective Findings on the Physical Examination

The physical examination of individuals with suspected coagulation disorders should concentrate on detecting gross evidence of bleeding and bruising. This evidence may be seen as petechiae, purpura, ecchymoses, sites of previous or active hemorrhage, or signs of hemarthrosis or hematoma. Table 2-4 summarizes the major clinical manifestations and correlative laboratory data for some of the more common acquired causes of bleeding, particularly in patients without a previous history of hemorrhagic complications. In addition, characteristic cutaneous findings may provide clues to an underlying defect in hemostasis. Examples of these include the following: the joint laxity, skin hyperelasticity, and “tissue paper-thin” scars typical of patients with Ehlers-Danlos syndrome; the follicular keratoses, perifollicular purpura with associated

Table 2-4 Acquired Causes of Bleeding in Ambulatory Patients

Diagnosis	Manifestation	Confirmation
Thrombocytopenia Scurvy	Petechial bleeding Subcutaneous bleeding, especially in confluent sheets	Platelet count <20,000/ μ L Normal platelet count, dietary history
Acquired hemophilia	Soft tissue hemorrhage	Low factor VIII activity with factor VIII antibody; rarely, antibodies to factor V, XI, or XIII
Antibodies against factor II and/or V after use of “fibrin glue”	Soft tissue hemorrhage	History of recent use of “fibrin glue” prepared from bovine products; low levels of factors II and V with antibodies
Hyperfibrinolysis from acute promyelocytic leukemia (APL)	Multiple ecchymoses	Normal PT, PTT; often prolonged TT; low fibrinogen and plasminogen with elevated FSP; APL in marrow.
Amyloidosis	Soft tissue hemorrhage	Variable factor levels; fat pad biopsy for amyloid
Vitamin K deficiency	Soft tissue hemorrhage, hematuria	Dietary history; low factors II, VII, IX, and X levels; long PT, PTT; normal TT
Warfarin ingestion*†	Soft tissue hemorrhage, hematuria	Drug history; low factors II, VII, IX, and X levels; long PT, PTT; normal TT
Heparin administration*‡ Factitious purpura	Soft tissue hemorrhage Bizarre pattern of lesions	Long PTT; very long TT, heparin level Normal studies; psychological studies

*Inadvertent or surreptitious.

†Also caused by “superwarfarin” rodenticide exposure.

‡Rare cases of heparin production in systemic mastocytosis.

PT, prothrombin time; PTT, partial thromboplastin time; TT, thrombin time; FSP, fibrin split products.

“corkscrew hairs,” and diffuse petechiae characteristic of patients with vitamin C deficiency and scurvy; the subcutaneous extravasation of blood, “loose-fitting skin,” and loss of the subcutaneous fat pad seen in patients with senile purpura; the skin fragility and purplish striae (usually located on the flexor and extensor surfaces of the upper and lower extremities and on the torso) typical of patients with Cushing syndrome; and the macroglossia and non-thrombocytopenic purpura often seen in patients with systemic amyloidosis (see Chapter 11).

Petechiae measure less than 3 mm in diameter; purpura and ecchymoses are generally larger than 3 mm in diameter. These cutaneous lesions result from the rupture of venules, capillaries, or arterioles in the skin and may be related to a qualitative or quantitative platelet abnormality or vasculitis. Nonetheless, some bruising may occur in the absence of an increased risk of hemorrhage. Purpura simplex, a common and predominantly female phenomenon marked by excessive bruising in relation to menses; senile purpura, marked by the development of irregular, reddish-purple ecchymoses on the extensor surfaces of the upper extremities that result from decreased elasticity of blood vessels and subcutaneous fat with age; and psychogenic purpura, marked by bruises that repeatedly occur in areas accessible to the patient persist for months with denial of repeated trauma; they resolve only after the affected limb has been casted.

Telangiectasias, on the other hand, are blanching lesions that are frequently detected under the tongue and on the face, oral and nasal mucosa, vermilion borders of the lips, chest wall, shoulders, legs, and nail beds. These lesions may occur in association with (1) the normal aging process, (2) estrogen surges related to pregnancy or to the use of oral contraceptives or estrogen replacement therapy, (3) underlying liver disease, and (4) some of the collagen vascular diseases (e.g., the CREST syndrome, which is characterized by calcinosis, Raynaud phenomenon, esophageal disease, sclerodactyly, and telangiectasias). Mucosal and visceral telangiectasias, on the other hand, are the hallmarks of Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia) and serve as potential sources of bleeding, arteriovenous malformation, or aneurysm.

INTEGRATING PATIENT HISTORY AND PHYSICAL EXAMINATION FINDINGS WITH LABORATORY RESULTS

Basic Laboratory Evaluation of Coagulation and Hemostasis

No matter how comprehensive and careful the clinical assessment is in patients with bleeding manifestations, the findings are nonspecific. Furthermore, many disorders of coagulation are asymptomatic until the individual is surgically or traumatically challenged. Thus, information derived from the history and physical examination may increase clinical suspicion for a particular hemorrhagic disorder, but laboratory confirmation is required to define the specific defect and to develop a logical treatment or prophylactic strategy. Laboratory testing can also provide a risk assessment for potential bleeding tendencies and may offer insight into the pathophysiology of the clinical bleeding problem. Unfortunately, no validated assay is available to

Table 2-5 Basic Screening Tests for Patients with Hemorrhagic Complications

Automated complete blood cell count (with platelet count and mean platelet volume)

Plasma clot solubility assay
Fibrin clot retraction assay

assess global hemostasis, which necessitates the performance of nonspecific test panels to examine each generic phase of hemostasis and coagulation (Table 2-5). These screening laboratory tests are readily available and typically are automated, so that results are provided in real time, which is critical for decision making. These tests can usually distinguish between the broad categories of primary hemostatic defects (i.e., platelet disorders) and humoral coagulation disorders (see Table 2-5). Subsequently, more specialized and esoteric assays may be selected to establish the definitive diagnosis (Table 2-6). Initial testing requires some combination of the following: a complete blood cell count (CBC) with platelet count; examination of the peripheral blood smear for platelet and erythrocyte morphology and platelet number and clumping; a bleeding time; PT; PTT; thrombin time; and fibrinogen concentration. Examples of laboratory profiles for some of the more frequently encountered hemorrhagic disorders are provided in Table 2-7.

Clinicians should bear in mind that proper sample acquisition and technique are critical to attaining valid results. Erroneous findings may result from simple avoidable mistakes, such as inadequate filling or mixing of the collection tubes. Most assays require a precise final ratio of whole blood (from which plasma for testing will be separated) to anticoagulant, and this relationship is imperative for accurate results. The plasma:anticoagulant ratio is also disturbed in polycythemia vera, where a markedly elevated red cell volume in the citrated collection tube concentrates the anticoagulant in a decreased plasma volume. This results in spuriously prolonged clot-based assays because the amount of citrate present in the plasma cannot be overcome and/or neutralized by the usual amounts of calcium contained in the standardized commercial recalcification

reagents required to activate the coagulation process in vitro. This testing artefact may be circumvented by reducing the volume of citrate in the collecting tube by one half so that the whole blood/citrate ratio is approximately 19:1 (instead of 9:1). Another very common mistake in blood collection for coagulation testing occurs when whole blood is withdrawn from heparinized indwelling venous access devices and arterial catheters or from extremities in which intravenous fluids are actively running. Finally, for accurate results, the integrity of the blood specimen must be fastidiously maintained for coagulation testing. This includes constant low temperatures to prevent activation of the serine proteases, which can inactivate coagulation proteins, and reduced time of plasma contact with platelets in whole blood and with the wall of the siliconized collection tubes, because factor XII can be activated in vitro which subsequently may result in spuriously activated downstream clotting factors on screening and specific clotting factor assays. Similarly, the phospholipid proteins, which are made up of lupus anticoagulants, may become adsorbed to platelets over time and yield falsely normal PTTs. These artefacts are extremely problematic in today's climate of "send outs" for laboratory testing, instead of rapid processing of plasma and testing on fresh plasma in a specialized coagulation laboratory within a few hours. If the clinician is skeptical about the results from "send out" samples, particularly when they do not support clinical suspicions, these should be repeated in a specialized coagulation laboratory that can maintain the integrity of the specimen.

Basic Laboratory Tests to Distinguish Between Platelet and Coagulation Defects

Physiologic hemostasis is initiated when platelets encounter a breach in the microvasculature at the site of injury. Circulating platelets come into contact with VWF protein bound to collagen exposed in the subendothelial matrix, first through rheologically sensitive, high-affinity interactions of the platelet surface membrane GP-Ib-IX (integrin $\alpha_2\beta_1$) to VWF, and then by a low-affinity interaction with collagen itself that is mediated by GP-VI. These events trigger a series of cytoplasmic reactions that ultimately result in platelet activation with thromboxane A_2 generation and the transformation of platelet surface membrane GP-IIb/IIIa into an active receptor for VWF and fibrinogen (see Chapter 7). Subsequently, these activated platelets aggregate and recruit other circulating platelets in the environment to form a platelet plug that is mediated by fibrinogen and VWF crosslinking. Humoral coagulation can then proceed with the use of exposed phospholipids on the surfaces of activated platelets as a stable template. Thus, coagulation is localized at sites of vessel injury.

A platelet abnormality should be suspected in patients with a history of intraoperative or immediate postoperative hemorrhagic complications, frequent mucosal bleeds in the absence of known trauma, and/or frequent petechiae. Quantitative platelet abnormalities are immediately apparent once an automated blood cell count has been performed and the patient's peripheral blood smear has been reviewed. Platelet concentration is measured electronically with the use of instruments that detect cells through their effects on electrical impedance or light scatter. Thrombocytopenia, defined as a platelet count of less than 150,000/ μ L,

should be confirmed by direct observation to exclude the laboratory phenomenon of pseudothrombocytopenia, in which platelet clumping occurs in vitro in a temperature- and time-dependent manner in the presence of ethylenediaminetetraacetic acid (EDTA); the mean platelet volume (MPV) is therefore increased because the clumps of platelets are "sized" as single platelets as they pass through the apertures of automated cell counters. Repeat platelet counts in freshly collected, citrate-anticoagulated whole blood should provide substantially higher, more accurate values because platelet agglutination in pseudothrombocytopenia typically results from the chelation of calcium ions by the standard EDTA anticoagulant. Phase or manual platelet counts should also reveal more accurate platelet counts because the actual platelet count may be ascertained visually, whether or not clumping is present.

Finally, platelet size and morphology may help to differentiate between peripheral platelet destruction (which is marked by a higher MPV and an increase in platelet size) and decreased bone marrow production. Morphologic evaluation of the peripheral smear is critical when platelet counts are decreased or increased. For instance, thrombocytopenia in the presence of so-called helmet cells or schistocytes may alert the clinician to the possibility of a microangiopathic hemolytic process and thrombotic thrombocytopenic purpura (TTP) (see Chapter 24). Bleeding associated with marked thrombocytosis characterized by giant forms may suggest essential thrombocythemia with acquired VWD. Morphologic examination may also distinguish between various congenital causes of thrombocytopenia: the gray, vacuolated platelets seen in α -granule deficiency; the basophilic cytoplasmic inclusion bodies (Döhle bodies) found in the granulocytes of patients with the May-Hegglin anomaly; the microplatelets characteristic of Wiskott-Aldrich syndrome; and the massively giant circulating platelets associated with Mediterranean megathrombocytopenia are only a few examples (see Chapter 10).

Platelet counts may be obtained through manual methods, on the basis of direct visualization of platelets under phase contrast microscopy and a stained peripheral smear, or by automated multiparameter systems, which provide quantitative and qualitative information on all circulating cellular elements. Although direct visualization methods may also be helpful for the morphologic evaluation of platelets, they are most often reserved for assessment after abnormal platelet counts have been generated by automated, rapid, high-throughput screening methods. Automated platelet counting has traditionally been based on electrical impedance principles and is accurate for most clinical samples; however, impedance techniques may yield spurious results in severe thrombocytopenia or thrombocytosis. The former is illustrated by such pathologic states as TTP, idiopathic thrombocytopenic purpura (ITP), and hemolytic disease with considerable erythrocyte fragmentation. Essentially, cellular debris and fragments may be counted as platelets, resulting in overestimation of the platelet count. In contrast, impedance counting may exclude very large platelets (e.g., Bernard-Soulier syndrome, Mediterranean megathrombocytopenia syndrome, myeloproliferative diseases) and may yield spuriously low counts. The problems of counting imprecision in the low thrombocytopenic range appear to be minimized by the use of direct or indirect immunologic counting methods with monoclonal

antibodies such as CD61 (GP-IIIa) in an automated hematology blood-analyzer system (Cell-Dyn 4000; Abbott Diagnostics, Maidenhead, Berkshire, UK), or integrated into a flow cytometry–based counting method with or without a platelet-specific monoclonal antibody such as CD41a (GP-IIb).

If concomitant macrocytic anemia is noted, red blood cell folate levels and serum vitamin B₁₂ levels should be checked to exclude the possibility of megaloblastic anemia. If evidence of intravascular hemolysis (e.g., clinical icterus, low serum haptoglobin, reticulocytosis, hemoglobinuria, detection of urinary hemosiderin) accompanies thrombocytopenia, paroxysmal nocturnal hemoglobinuria (PNH) should be considered with or without evidence of systemic hypercoagulability. The sucrose hemolysis test and the Ham test have been supplanted by the more specific and sensitive flow cytometry of peripheral blood to assess for specific erythrocyte membrane protein deficiencies in CD59 (the membrane inhibitor of reactive lysis [MIRL]) and CD55 (the decay accelerating factor [DAF]).

If a patient's clinical picture is consistent with a defect in primary hemostasis, and platelet count is within normal limits, a qualitative platelet abnormality should be excluded. The severity of bleeding complications among patients with qualitative disorders typically is out of proportion to the platelet count. Congenital thrombasthenias are very rare in the absence of a family history. Acquired defects in platelet function are considerably more common and frequently are medication induced (e.g., aspirin, NSAIDs, selective serotonin reuptake inhibitors [SSRIs]).

Bleeding time (BT) is the traditional initial test for detecting and evaluating primary hemostasis. In general, it allows for a gross indication of overall platelet function and of the activity of those plasma proteins involved in the interaction between platelets and the subendothelial matrix (e.g., collagen and VWF). Since its initial development, the BT has been purported as a clinically useful tool for diagnosing qualitative platelet disorders, predicting significant bleeding propensity due to platelet dysfunction, and evaluating the adequacy of treatment modalities to reverse the bleeding potential. Unfortunately, the BT has exhibited shortcomings in all of these aspects of its use because it is affected by a large number of diseases, drugs, physiologic factors, test conditions, and therapeutic actions—not all of them platelet related.²¹ For example, BTs increased significantly after the removal of 2 U of red blood cells (RBCs) from normal individuals who had not taken medications that would affect platelet function; their prolonged BTs decreased significantly after RBCs were reinfused.²² In patients with VWD who underwent surgical procedures, the extent of decrease in prolonged BT after VWF replacement therapy frequently did not correlate with achieving or maintaining normal hemostasis or with the amount of bleeding observed during surgery.²³ Furthermore, serial measurement of BTs in patients with VWD may yield considerable intraindividual variability. In any case, the BT remains a widely used screening test for the diagnosis of VWD. BT measurements in individuals with VWD and thrombasthenia are not necessary or helpful after the diagnosis has been established.

BT is usually normal when platelet counts are higher than 100,000/ μ L, and it is usually prolonged proportionately as platelet counts decrease from 100,000/ μ L to 10,000/ μ L. In

autoimmune thrombocytopenic purpura, however, BT may remain normal despite a significant quantitative deficiency. This may reflect the fact that younger platelets are larger, contain a higher concentration of procoagulant proteins within their cytoplasmic granules, and are “more active” in their capacity to adhere to areas of damaged endothelium and to aggregate with other platelets to form a localized platelet plug.

BT is most frequently performed with the Ivy or Simplate II (BioControl, Bellevue, Wash, USA) method. With a blood pressure cuff inflated on the upper arm to maintain a consistent pressure of 40 mm Hg, the Ivy BT is determined after three puncture wounds are made with a sterile mechanical lancet (blade depth, 2.5 mm) on the ventral surface of the forearm, versus two incisions for the Simplate II technique with a standardized spring-loaded razor blade device (blade depth, 1 mm). Randomized, controlled studies show no significant differences between BT methods or results produced by incisions made horizontal to the antecubital crease and those made vertical/perpendicular to it, although better scar formation may be associated with the latter direction.²⁴ Filter paper is used to blot the blood at 15- to 30-second intervals, with care taken not to disturb the wounds. A stopwatch records the time taken to reach the end point, defined as the average time for bleeding to cease from all wounds, which presumably corresponds to the time required for formation of a hemostatic platelet plug. “Normal” bleeding time ranges between 2 and 9 minutes, depending on the technique used. The reproducibility and validity of BT results are determined most often by operator-dependent variables, such as depth of the puncture wounds made, the ability to maintain a constant venous blood pressure throughout the procedure, and the fastidiousness of filter paper blotting. The Duke bleeding time, first described in 1910, involves a prick or incision of the earlobe.²⁵ Because of its comparative imprecision and poor reproducibility, it is rarely used. Attempts to increase the sensitivity of BTs have proved impractical. An example of this was a technique called hemorrhagometry, which measured bleeding intensity and blood volume lost from a small standardized BT skin wound.²⁶

Because of the vagaries associated with BT techniques, standardized, automated techniques have been designed to examine and simulate the platelet contribution to primary hemostasis in a more specific manner. The Platelet Function Analyzer (PFA)-100 (Dade-Behring, Marburg, Germany) has been developed as an automated, rapid technique designed to assess platelet adhesion and aggregation. In many hospitals, it has replaced BT as the predominant assessment tool used to screen patients for their bleeding potential. The PFA-100 measures the ability of platelets activated in a high-shear environment to occlude an aperture in a membrane treated with collagen and epinephrine (CEPI) or collagen and adenosine diphosphate (CADP). The time taken for flow across the membrane to stop (closure time) is recorded.²⁷ Data from a small selected cohort revealed that BTs and PFA-100 were in agreement in 74.3% of patients, and that the PFA-100 was particularly more sensitive than the BT to aspirin-induced platelet dysfunction.²⁸ The sensitivity of the PFA-100 for identification of VWD appears significantly better ($P < .01$) than that of BT, with similar specificity. In contrast, the PFA-100 was

comparable but not superior to BT in detecting congenital or acquired platelet hypofunction.²⁹

In a prospective attempt to identify individuals with documented hereditary mucocutaneous hemorrhagic disorders, the BT and PFA-100 assays were equally insensitive (BT prolonged in 35.8% of all patients vs 29.7% for PFA-100 [$P = .23$]).³⁰ In patients with VWD, the PFA-100 performed slightly better (BT increased in 42% vs 61.5% for PFA-100 [$P = .18$]), whereas the opposite was observed for platelet secretion defects (BT increased in 42% vs 24% [$P = .11$]). In the group with undefined qualitative platelet defects, both tests lost sensitivity, but the BT detected 1.8 times more patients than were identified with the PFA-100 (BT increased in 27.5% vs 15% [$P = .06$]). On the basis of the published literature, the Platelet Physiology Subcommittee of the Scientific and Standardization Committee of the International Society on Thrombosis and Haemostasis determined that the PFA-100 does not have sufficient sensitivity or specificity to be used as a routine screening tool to detect platelet disorders or to monitor the efficacy of any therapeutic strategy.³¹

Platelet aggregation assays are the *in vitro* approaches most commonly used to assess platelet function. They focus on the later aspects of primary hemostasis, when platelets are stimulated to generate thromboxane A_2 , and they release their α granule and dense body constituents to recruit other platelets to “plug up” the bleeding site within a blood vessel (Fig. 2-1). This platelet plug serves as the template on which humoral coagulation can proceed. Although readily accessible in most comprehensive coagulation laboratories, aggregometry is very time consuming and labor intensive, and preanalytical preparation, choice of anticoagulant, and agonists have not been standardized. Agonists are added to

platelet-rich plasma isolated from the patient’s whole blood under controlled conditions of temperature and constant agitation. Platelets are stimulated to aggregate *in vitro*, and the extent of aggregation is quantitated as the increase in light transmission through a cuvette containing the originally turbid, untreated platelet-rich plasma. By convention, platelet-rich plasma has 0% light transmission and platelet-free plasma has 100% light transmission when compared with normal controls. The agonists typically used in platelet aggregation studies include ADP, epinephrine, and collagen (Fig. 2-2); arachidonic acid may be used to exclude the surreptitious ingestion of aspirin or NSAIDs as the underlying cause of abnormal, suboptimal platelet aggregation responses to standard agonists. High and low concentrations of ristocetin induce platelet agglutination (RIPA), as opposed to platelet aggregation, and help to differentiate among the classic type and variants of VWD (see Chapter 7). Bernard-Soulier syndrome, which is characterized by a suboptimal agglutination response to ristocetin, may also be diagnosed (see Chapter 10).

Normal responses in standard platelet aggregation assays will exclude most qualitative platelet defects as the primary cause of easy bruisability or abnormal bleeding, but mild VWD can remain a possibility. Platelet aggregation studies may be performed in the absence of an *in vitro* agonist to determine whether any evidence of spontaneous platelet hyperaggregability is present; this is apparent in some cases of essential thrombocythemia³² and in Kawasaki disease.³³

Other modifications of routine platelet aggregation techniques are intended to enhance the sensitivity of the assay. For instance, radiolabeled ^{14}C -serotonin–“loaded” donor platelets isolated from normal platelet-rich plasma may be activated by various agonists, and the release of the isotope

Figure 2-1 Platelet reaction in response to commonly used agonists. TXA₂, thromboxane A₂.

Figure 2-2 Platelet aggregation and adenosine triphosphate (ATP) release in response to adenosine diphosphate (ADP), epinephrine, and collagen. Primary and secondary waves of ADP-induced aggregation (*left panel*) are merged, but the secondary wave can be recognized by the ATP release. Two waves are distinguishable with epinephrine (*middle panel*); ATP release coincides with the second wave. With collagen (*right panel*), only one wave of aggregation occurs, and this appears simultaneously with ATP release. Shape change is induced by ADP and collagen but not by epinephrine.

from dense granules can be quantitated. Heparin-induced thrombocytopenia (HIT) may be diagnosed by the detection of >20% release of ^{14}C -serotonin from “loaded” platelets incubated with patient heat-treated serum in the presence of unfractionated heparin. Whole blood impedance lumi-aggregometry, which measures chemiluminescence-based platelet activation, aggregation, and adenosine triphosphate (ATP) release from dense granules, remains to be validated in its ability to predict clinical bleeding or thrombotic propensity (see Chapter 10).

Similarly, methods used to assess the vague clinical condition referred to as “aspirin resistance” remain to be correlated with the occurrence of myocardial infarction, stroke, or death from vascular events. Three assays have been approved by the U.S. Food and Drug Administration to specifically detect aspirin resistance; these are based on assessment of platelet cyclo-oxygenase enzyme pathway activity. Increased urinary excretion of 11-dehydro-thromboxane B_2 (indirect measurement of thromboxane A_2 activity *in vivo*) (AspirinWorks; Corgenix, Broomfield, Colo, USA) has been associated with increased cardiovascular event rates in a retrospective case-controlled study.³⁴ Aspirin resistance measured by the PFA-100 apparatus, with the use of CEPI cartridge closure time, has not gained favor because of its weak correlation with the occurrence of clinical cardiovascular and cerebrovascular events.³⁵ The VerifyNow Aspirin Assay (Accumetrics, San Diego, Calif, USA) detects aspirin resistance in terms of increased whole blood platelet agglutination on fibrinogen-coated beads after addition of an arachidonic acid agonist. Assay results correlated with significantly increased levels of serum cardiac enzymes as surrogate markers of cardiovascular events after percutaneous coronary interventions in the context of aspirin therapy.³⁶ Additional studies are needed to validate these assays in randomized, prospectively controlled studies of treatment strategies designed to reverse aspirin resistance.

Laboratory Assessment of the Procoagulant System

PT is an *ex vivo* coagulation assay performed by adding a commercial source of tissue factor (TF) and calcium to patient citrate-anticoagulated plasma. Time to clot formation reflects the activities of the coagulation factor proteins involved in the common and extrinsic pathways of coagulation factors II, V, VII, and X, as well as fibrinogen. Prolongation of PT correlates with the degree of deficiency of one or more of these procoagulant proteins, or with the extent of neutralization of their function, by circulating inhibitors in a specific (alloantibodies) or nonspecific (e.g., lupus anticoagulant, heparin, argatroban, hirudin) manner. Commercially available agents most often used to activate the clotting process in PT consist of standardized mixtures of tissue factor/thromboplastin (extracted from rabbit brain) and calcium chloride; however, preparations of recombinant human tissue factor mixed with synthetic phospholipids are becoming more popular because they are free of the contaminating coagulation factor proteins present in tissue factor extracts. This increases the sensitivity of the PT assay for factor deficiencies. Ox brain extracts of tissue factor/thromboplastin may be particularly useful in the detection of the rare congenital coagulopathy, variant factor VII Padua.³⁷

Because numerous tissue factor/thromboplastin reagents possess various procoagulant properties, PT results may vary widely from one laboratory to another—even for the same plasma specimen. Thus, PTs are reported as an international normalized ratio (INR), which was developed to minimize these differences when patients are anticoagulated with warfarin. This conversion allows for warfarin dosing to be reliably adjusted, regardless of where the PT assay is performed. Each thromboplastin reagent has an assigned international sensitivity index (ISI) that is derived by comparing its prothrombotic potential against an international reference

standard thromboplastin (with an ISI defined as 1.0) from the World Health Organization. The INR is calculated as the ratio of the patient's PT to the mean normal PT obtained from pooled normal plasma, which is then raised to the ISI as an exponential power: $INR = (\text{patient's PT} / \text{mean normal PT})^{\text{ISI}}$. The ISI of recombinant tissue factor-activating reagents is approximately 1.0. Low-ISI thromboplastins improve the sensitivity of the PT assay. Although the INR is employed in the safety monitoring and efficacy evaluations of anticoagulation with warfarin, it has *not* been a useful predictor of potential bleeding complications in patients with liver disease or congenital coagulopathy in the common or extrinsic pathways. In the presence of lupus anticoagulants, or when direct thrombin inhibitor (DTI) anticoagulants (such as argatroban and hirudin) are administered, PT may be increased but does not accurately reflect the actual degree of anticoagulation. In these situations, chromogenic measurements of factors X and II may be more predictive of hemorrhagic potential.

The PTT estimates the activities of the coagulation factor proteins involved in the common and intrinsic pathways of coagulation—factors V, X, II, VIII, IX, XI, and XII, along with fibrinogen, prekallikrein, and high molecular weight kininogen. The addition of phospholipids (variable ratios of phosphatidylserine and phosphatidylinositol), a phospholipid surface activator (kaolin, silica, or ellagic acid), and calcium to citrate-anticoagulated plasma triggers clot formation. Clotting factor activity levels must be decreased to at least 40% of normal if the PTT is to become prolonged. In addition, a deficiency of prekallikrein, which is one of the components of the contact phase of coagulation, results in a prolonged PTT that can be corrected with the extended incubation of the patient's plasma with an exogenous source of phospholipid and contact activator at 37°C prior to recalcification. Of note, deficiencies of factor XII, prekallikrein, and/or high molecular weight kininogen are not associated with a bleeding diathesis, despite the fact that they are associated with extreme prolongations of the PTT. Lupus anticoagulants, unfractionated (but not low molecular weight) heparin, long-term warfarin therapy, DTIs, and specific (alloantibodies or autoantibodies) neutralizing inhibitors of coagulation proteins prolong the PTT. The ability to correct prolonged PTT by mixing equal volumes of patient plasma with pooled normal plasma over 1 to 2 hours at 37°C indicates a clotting factor deficiency, which can then be identified with the use of assays and specific clotting factor-deficient substrates. If the prolonged PTT does not correct with mixing studies, then an acquired inhibitor—pharmacologic or immunologic in origin—must be considered. Alloantibodies or antibodies against factor VIII require 1 to 2 hours incubation at 37°C before they are maximally expressed in mixing studies; thus, the time 0 PTT mixing study may be normal. In contrast, the lupus anticoagulant mixing study will produce a prolonged PTT, which does not substantially increase with incubation. This distinction is critical to proper diagnosis and treatment of prolonged PTTs.

When 1:1 mixing studies of patient and normal plasma show normalization of prolonged PT and/or PTT in patient plasma specimens after 0, 60, and 120 minutes of incubation at 37°C, the presence of one or more coagulation factor deficiency(ies) is the most likely cause and should be confirmed by quantitation of specific clotting

factor protein activities. The choice as to which specific clotting factor assays should be performed is determined by whether one or both of these screening assays is prolonged, and whether the deficiency lies in the extrinsic (abnormal PT and normal PTT: measure factor VII), intrinsic (prolonged PTT and normal PT: measure factors XII, XI, IX, and VIII), or common pathways (prolonged PTT and PT: measure fibrinogen and factors II, V, X initially, and then, because of the possibility of multiple factor deficiencies, measure other vitamin K-dependent factors VII and IX, and subsequently factors XI and XII) (see Chapter 5).

Accordingly, many causes of prolongation of the PTT have been proposed. Some of these causes are of hemostatic importance, and others are not. No correlation has been made between the degree of prolongation of the PTT and hemorrhagic potential; rather, it is the cause of the prolongation that determines the risk. A prolongation of 20 seconds due to lupus anticoagulant (LA) is of no hemorrhagic risk, but an 8-second prolongation due to mild hemophilia A with 8% factor VIII activity represents extreme risk for bleeding with a surgical procedure. The PTT is frequently ordered so clinicians can prognosticate about whether a given patient will bleed or not—a question the PTT was never designed to do.³⁸

Specific clotting factor assays are performed by mixing patient plasma with “substrate” plasma that is deficient in the specific clotting factor to be measured. This substrate plasma may be obtained directly from individuals with a severe deficiency of that particular clotting factor, or it can be prepared commercially by rendering normal plasma deficient of a particular clotting factor through immunodepletion techniques. Specific assays performed to quantitate factors VIII, IX, XI, and XII are one-stage PTT-based assays; those for factors VII, X, and II are PT based. The activity of the specific clotting factor protein in patient plasma is determined on a standard curve in which the times (in seconds) required for various dilutions of normal plasma (presumed by convention to contain 100% activity of the specific clotting factor in question prior to dilution with physiologic buffer) to clot are plotted against the actual clotting factor activity levels of diluted normal plasma.

Specific clotting factor assays can also be measured with the use of chromogenic factor assays and immunoassays (antigen assays). Chromogenic assays are based on the principle that the thrombin or factor Xa generated after activation of the specific clotting factors in question can be measured directly by the ability of thrombin or Xa to proteolyze specific commercially available chromogenic substrates. The chromogenic substrates are complexed to a dye (p-nitroaniline) via an amide bond. When thrombin or factor Xa proteolyzes the substrate, the dye is released (amidolytic reaction) and is measured spectrophotometrically. These assays are more sensitive than clotting time-based assays and are not interfered with by LAs. Because of their increased cost per assay, they have not yet pervaded most of the coagulation laboratories in the United States.

Shortened PTTs and PTs have little clinical significance and probably reflect elevated FVIII activity levels or other clotting factors activated as a result of DIC or the presence of pregnancy (and its complications), use of estrogen hormones, active or occult thrombosis, carcinoma, or

infection. The risk of developing venous thromboembolic complications is increased by high levels of factors II, VIII, and XI, which are often determined by genetic polymorphisms (see Chapter 14). The use of prophylactic anticoagulants is not routinely recommended for those individuals with shortened PTs and PTTs in the absence of active or previous thrombosis.

Thrombin time (TT) (also known as thrombin clotting time [TCT]) is a very simple, underused, yet instructive assay that measures only the rate of conversion of fibrinogen to polymerized fibrin after the addition of a known amount of thrombin to platelet-poor plasma. A prolonged TT suggests the presence of heparin or pharmacologic DTIs (e.g., argatroban or lepirudin); greatly decreased fibrinogen levels, hypofibrinogenemia, or dysfibrinogenemias; high concentrations of immunoglobulins, particularly large monoclonal gammopathies, such as those seen in Waldenström macroglobulinemia; and the generation of fibrin degradation products. Because of its extreme sensitivity to even small amounts of unfractionated heparin, the TT is a useful screening test for excluding the presence of contaminating heparin in blood samples obtained from central venous access devices, which may spuriously alter PTT results. Rarely, but more and more often, acquired specific thrombin inhibitors (with or without concurrent factor V inhibitors) may develop in patients who have been exposed to topical bovine thrombin, particularly during cardiac or spinal surgery (see Chapter 6).

Fibrinogen concentrations are routinely measured in platelet-poor plasma to ascertain sufficient substrate for generated thrombin to form the fibrin clot end point necessary for chromometric clotting assays used for PT, PTT, TT, and specific clotting factor assays. Decreased fibrinogen concentrations should be complemented by the measurement of fibrinogen mass performed through an immunologic or chemical method. When a discrepancy of greater than 25% to 30% is detected between the lower fibrinogen concentration when measured as functional protein and the higher fibrinogen concentration when measured as immunologically detectable protein, a dysfibrinogenemia should be suspected. The definitive diagnosis is based on the identification of a specific structural or molecular defect: (1) confirmation of the abnormal fibrinogen structure using sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis; (2) evaluation of abnormal fibrinopeptide cleavage and release, as well as of abnormal fibrin polymerization; and (3) detailed analysis of the mutation site in the fibrinogen DNA and the fibrinogen gene product. It is important to note that structure/function relationships in the congenital dysfibrinogenemias remain unclear and have no established means by which to predict whether or not the abnormal fibrinogen protein will be associated with hypercoagulability or with a bleeding diathesis, poor wound healing, and/or recurrent spontaneous miscarriages (see Chapter 5).

Tests for Lupus Anticoagulants (LA)

When mixing studies indicate the persistence of a prolonged PTT, the presence of an LA should be confirmed with assays that show that the antibody is directed against the phospholipid component of coagulation. Because PTT is routinely performed on platelet-free plasma, phospholipids (in the

form of platelets) to accelerate the clotting system are extremely limiting, so that LA antibodies are rather easily detected. This is illustrated by the platelet neutralization assay, in which a lysate of normal platelets, serving as a copious source of phospholipids, is incubated with patient plasma to determine whether the initially prolonged PTT will be normalized. If this correction occurs, it is presumed that the LA antibody has been absorbed out of the test plasma. Other inhibitors of coagulation, such as heparin or acquired autoantibodies directed against specific clotting factors, would not be absorbed from plasma by phospholipids. A simplified commercial modification of the platelet neutralization assay involves incubating hexagonal phase phospholipids with patient plasma and showing decreased prolongation of the PTT toward normal—characteristic of the interaction between an LA and lipid.

In many coagulation laboratories, LA are diagnosed in patient plasma specimens with the use of clotting assays that detect interference with formation of the prothrombinase complex. The dilute Russell's viper venom test (DRVVT) is based on the activation of factor X to Xa to initiate coagulation without contributions from any of the other coagulation factor proteins proximal to the tenase complex. This is accomplished by the highly lipided proteolytic venom extracted from the *Vipera russelli pulchella* and *Vipera russelli siamensis* snakes found along the Indian-Pakistani border, peninsular India, Sri Lanka, Myanmar, and Taiwan. When lipided venom is diluted to yield a clotting time of 23 to 27 seconds, the assay becomes extremely sensitive to antibodies directed against the diluted phospholipid concentration. A prolonged DRVVT in patient plasma suggests the presence of LA, which should be confirmed through one of the other LA assays. The DRVVT test is considered more sensitive than the PTT for the detection of LA.

Kaolin is a negatively charged particulate activator of the intrinsic clotting pathway. The kaolin clotting time (KCT) is sensitive to LA because clotting is activated in the absence of exogenously added phospholipids to the patient plasma test system. A prolonged KCT is considered sensitive but nonspecifically indicative of an LA.

The diagnosis of LA requires at least two confirmatory tests. In addition, because of LA interaction with phospholipids, freshly obtained citrated whole blood specimens should be double-centrifuged and fastidiously handled before freezing; thawed plasma may contain enough platelets/platelet fragments with phospholipids to adsorb and sequester the lipophilic antibody, resulting in a false-negative test for LA and a normal PTT screening assay.

The possibility of factor XIII (FXIII) deficiency or α_2 -plasmin inhibitor (α_2 -PI) (also known as α_2 -antiplasmin [α_2 -AP]) deficiency should be excluded when all of the basic screening tests are unremarkable and clinical suspicion for a bleeding diathesis still remains. Factor XIII is a fibrin-stabilizing factor that functions through the covalent cross-linking of fibrin strands in the presence of calcium and thrombin. α_2 -PI, on the other hand, functions by controlling lysis of the fibrin plug through the regulation of plasmin activity. As such, neither qualitative nor quantitative defects in factor XIII or α_2 -PI may be detected by the standard assays used to evaluate clot formation, including PT and PTT (see Chapter 5).

The plasma clot solubility assay serves as a screening assay for factor XIII deficiency. Under normal conditions,

the addition of 1% monochloroacetic acid or 5M urea does not result in dissolution of a formed clot. If factor XIII activity level is less than 1%, the fibrin clot rapidly dissolves in the presence of monochloroacetic acid, or 5M urea. Because α_2 -PI deficiency may also be associated with increased urea clot solubility, α_2 -PI activity and antigen levels should be directly assessed to confirm the cause of the increased clot solubility, particularly given that both inherited deficiencies are exceedingly rare. In contrast, acquired decreases in α_2 -PI activity levels may develop as the result of consumptive hypercoagulable states, such as DIC. Activity levels below 30% of normal have been predictive of bleeding complications in patients with acute promyelocytic leukemia (APL). The propensity toward increased bleeding and the laboratory evidence of hyperfibrinolysis in APL may be reversed by administration of inhibitors of fibrinolysis, such as ϵ -aminocaproic acid.³⁹

Increased levels of plasmin:antiplasmin complexes (PAP), measured in patient plasma by commercially available enzyme-linked sandwich immunoassay kits, are surrogate indicators of hypercoagulability and reflect the effects of increased thrombin generation/fibrin formation and associated increased reactive plasminemia and endogenous fibrinolytic activity.

Euglobulin clot lysis time (ECLT) assay, a global measurement of fibrinolytic activity, is the net result of interaction between plasminogen and plasminogen activator inhibitor (PAI)-1 in whole blood or plasma. Clot lysis in this assay system is usually completed within 2 to 6 hours, and accelerated lysis (<2 hours; i.e., one of the few examples of a shortened time on a coagulation test that indicates hemorrhagic potential) is indicative of increased fibrinolysis, such as occurs in the rare condition of primary hyperfibrinolysis. ECLT is usually normal in early DIC; it becomes accelerated when endogenous plasminogen activator inhibitor type 1, α_2 -PI, or fibrinogen has been consumed. Other disease states associated with accelerated ECLT include cirrhosis, prostate cancer, and thrombotic states (e.g., acute myocardial infarction) that have been treated with thrombolytic agents, such as urokinase and recombinant tissue plasminogen activator. Vigorous exercise and increasing age are also associated with increased fibrinolysis and reduced ECLT. Reduced ECLT may precipitate or exacerbate clinical bleeding. Clinical states characterized by impaired fibrinolysis prolong the ECLT assay and include arterial (transient ischemic attack [TIA], cerebrovascular accident [CVA], and myocardial infarction [MI]) and venous thrombotic events (e.g., superficial and deep venous thrombosis, pulmonary embolism [PE]), advanced atherosclerosis, acute coronary syndrome, diabetes mellitus, and hypertriglyceridemia. Impaired fibrinolysis and prolonged ECLT assays reflect the presence of increased levels of plasminogen activator inhibitor type 1 and α_2 -PI or decreased levels of tissue plasminogen activator or plasminogen. Dysfibrinogens have been associated with both accelerated and prolonged ECLT assays, depending on their effects on plasminogen activation, their susceptibility to plasmin degradation, and their propensity to impair fibrin assembly and factor XIII-mediated crosslinking. Traditional ECLT is a time and labor intensive assay that is not performed widely. Newer automated assays may overcome the resistance of coagulation laboratories to make this test available.⁴⁰

Measurement of D-dimers detects the plasmin-degraded by-product of crosslinked fibrin that is indicative of thrombin generation, factor XIII activation and crosslinking of the fibrin clot, and reactive fibrinolysis. Because fibrinogen does not contain any crosslinked entities, this assay is useful in discriminating between fibrinolysis and fibrinogenolysis. Specific monoclonal antibodies are commercially available for use in measuring D-dimers in patient citrated plasma samples; these have been included in latex agglutination, immunoturbidimetric, and enzyme-linked immunosorbent assay (ELISA) assays. Latex agglutination assays are less sensitive than other assays techniques for detecting D-dimers in critical clinical situations, such as deep venous thrombosis and PE. These latter assays have a sensitivity greater than 90%, and a negative test for D-dimers carries a negative predictive value greater than 90% for the existence of venous thromboembolism (VTE). D-Dimers may be positive in a number of clinical conditions associated with inflammation and activation of the coagulation system; however, in this context, a positive value may be too nonspecific to establish clinical diagnoses. For example, D-dimers may be elevated in association with malignancies, obstetric catastrophes (e.g., HELLP [Hemolysis, Elevated Liver function tests, and Low Platelets syndrome], pre-eclampsia), DIC, sickle cell crisis, rheumatoid arthritis, subarachnoid hemorrhage, acute aortic dissection, and cirrhosis (www.pathology.vcu.edu/clinical/coag/D-Dimer.pdf).

The “holy grail” of the future for laboratory diagnoses of bleeding and thrombophilic disorders is the development of a single assay that could discern each of the elements of coagulation and could predict whether abnormalities detected by the assay would produce clinical bleeding or thrombotic complications. Furthermore, these assays should be useful for monitoring the effects of pharmacologic interventions and showing the reversal of thrombotic or hemorrhagic tendencies. To date, no automated system fulfills these desires or prerequisites. We have already described assays that have been developed to substitute for current techniques to assess platelet function. The thromboelastogram (TEG) and its modifications provide an automated measurement of interactive dynamic coagulation processes, starting with initial hemostasis and proceeding through humoral coagulation, clot crosslinking, and fibrinolysis.⁴¹ TEG has been particularly helpful in monitoring liver transplantation-related bleeding problems and has been used to minimize transfusion requirements in cardiovascular surgeries. Numerous investigations are under way to determine whether TEG would be useful in monitoring therapeutic interventions, such as ensuring the adequacy of dosing of recombinant factor VIIa concentrate for bleeding problems or determining the adequacy of low molecular weight heparin dosing for preventing hypercoagulable complications. Although study results show class effects and epidemiologic effects, TEG remains too insensitive for use in predicting the occurrence of bleeding or clotting events in an individual patient. The technique does, however, provide valuable insight into the pathophysiology of bleeding and clotting complications observed in a variety of clinical situations. Thus far, TEG has yet to be accepted as part of a routine hematologic evaluation of coagulation status in a variety of perioperative and critical care settings.⁴¹

Similarly, automated fluorogenic substrate-based techniques designed to measure endogenous thrombin potential

(ETP) are currently being developed. These assays quantify the enzymatic “work” that thrombin can accomplish over time⁴² and await clinical validation for the individual patient rather than for clinical disease scenarios in general. For example, all anticoagulants and antiplatelet aggregation medications reduce ETP; however, various individuals with reduced ETP continue to develop thromboses. Such assays have also been used to predict the likelihood of recurrence of VTE in high-risk populations. After 4 years, the probability of recurrent VTE was 6.5% among individuals with a thrombin generation of less than 400 nM compared with 20% recurrence among patients with higher values ($P < .001$). Conversely, those with thrombin generation of less than 400 nM had a 60% lower relative risk of recurrence than did those with higher levels ($P < .001$). Nevertheless, prediction of which individual was susceptible to recurrent VTE was not possible.⁴³

The coagulation laboratory can perform many esoteric assays to establish the causes of coagulation disorders. In today’s environment, many of these are so time and labor intensive that they are “send outs” that are usually not necessary or available for immediate diagnosis and initiation of treatment. These assays are discussed in greater detail in other specific disease-orientated chapters; they include techniques such as measurement of serum thrombopoietin to diagnose the causes of thrombocytopenia and thrombocytosis; flow cytometric evaluation of platelets to document storage pool deficiency and the presence of platelet membrane glycoproteins that may contribute to platelet dysfunction; and assays to measure functional ADAMTS13 (*a* disintegrin and metalloproteinase with thrombospondin motifs) activity for the appropriate diagnosis and treatment of TTP.

FORMULATION OF TREATMENT STRATEGIES FOR THE MANAGEMENT OF ACUTE HEMORRHAGIC EPISODES: HOW TO USE DATA FROM THE COAGULATION LABORATORY

It is not always possible to adhere to an algorithmic approach to the bleeding patient. This is especially true in cases of unexpected intraoperative or postoperative bleeding in which immediate intervention is required (see Chapter 37). Time may not allow for the completion of basic laboratory screening tests prior to initiation of therapy, so the clinician is often forced to treat the patient empirically. The first priority is to exclude the possibility of incomplete surgical ligation or incomplete cauterization of blood vessels. Surgeons usually consider this cause of bleeding to be a diagnosis of exclusion of acquired hematologic conditions; however, results of the coagulation assays are not likely to be available until after a therapeutic decision has been made or the acute situation has resolved. Nevertheless, blood should be collected prior to any intervention because that intervention may affect test results and may delay confirmation of the ultimate diagnosis.

One crude but helpful bedside screening test is the fibrin clot retraction assay. This assay is performed by collecting an aliquot of the patient’s blood into a plain glass tube that

does not contain any anticoagulant (e.g., a serum “red-top” tube). The blood is carefully observed over time for clot formation at room temperature. A normal response is characterized by clot retraction from one wall of the glass tube, whereas altered clot structure secondary to impeded fibrin formation or impaired platelet aggregation is marked by gelatinous clot formation without evidence of clot retraction. The fibrin clot retraction assay is therefore a “quick and dirty” test for hyperfibrinolysis, hypofibrinogenemia, dysfibrinogenemia, the presence of fibrin degradation products, thrombocytopenia, and qualitative platelet disorders. It can also be affected by an elevated hematocrit level, and results of this assay should be interpreted accordingly. It is interesting to note that normal clot retraction may occur despite the absence of factor XIII.

Empirical therapy in these acute bleeding situations typically begins with the administration of standard blood products—platelets, fresh frozen plasma, and, less often recently, cryoprecipitate. Single-donor or pooled random-donor platelets should be transfused, regardless of preoperative laboratory values, because infusion of normal unaffected platelets will transiently compensate for any undiagnosed platelet dysfunction that may be contributing to the bleeding diathesis. This type of scenario has been associated particularly with surgical procedures that involve cardiopulmonary bypass, in which both thrombocytopenia and platelet dysfunction can occur immediately after surgery and may last for several days into the postoperative period.

Fresh frozen plasma (FFP) contains physiologic levels of labile and stable components of the coagulation system and is indicated for the replacement of deficient coagulation factors. It may also be administered in cases of massive blood loss in which the transfusion of more than one blood volume is required over 24 hours; this occurs with a dilutional or “washout” phenomenon of coagulation factors and as the result of factor consumption through bleeding (see Chapters 12 and 46). In general, 3 to 5 U of FFP are needed for coagulation factors to be adequately replaced in an average-sized adult (10 to 20 mL per kilogram of body weight). Viral attenuated plasma-derived prothrombin complex concentrates (PCCs) may be considered in lieu of FFP when deficiencies of vitamin K-dependent clotting factors are contributing to active or potential bleeding complications (e.g., end-stage liver disease [see Chapter 39]). These products are useful because of their small volumes and rapid action in reversing coagulation defects, and because of their enhanced viral safety profile over FFP. PCCs are more expensive than single-donor units of FFP and may precipitate a thrombogenic state if used repeatedly and in large quantities. PCCs may also be used to reverse bleeding precipitated by the use of warfarin anticoagulation. No prospective, randomized, controlled studies have been conducted to determine whether PCCs are more efficient, safer, or more effective than FFP or rFVIIa concentrate in reversing warfarin-induced bleeding complications. Once PCCs have been administered, accurate coagulation testing cannot be performed because PCCs contain activated clotting factors that confound in vitro screening and specific clotting factor assays.

In the future, FFP, which has been used with solvent detergents, psoralen, or methylene blue, may become available commercially to improve the viral safety profile of FFP, because lipid-enveloped pathogenic blood-borne

viruses—including human immunodeficiency virus, hepatitis B virus, and hepatitis C virus—are virtually eliminated in the preparative process. Unfortunately, no FFP treatment method to date has been consistently successful in the removal of prions responsible for variant Creutzfeldt-Jakob disease (vCJD). In experimental animal models, prions appear to be transmissible in blood fractions; however, no cases of vCJD have been reported to occur in transfusion-dependent individuals given contaminated blood products, including packed RBCs, platelets, FFP, or pooled plasma-derived clotting factor concentrates in patients with hemophilia or VWD. Large government-funded surveillance projects in North America and the United Kingdom continue to monitor blood recipients for evidence of vCJD transmission. If specific deficiencies of factor VIII or IX are known to exist preoperatively, the corresponding recombinant factor concentrate should be administered (in the absence of high-titer inhibitors to the clotting factor protein) to eliminate the potential for transmitting infectious blood-borne pathogens associated with plasma.

Cryoprecipitate, on the other hand, is primarily used to correct quantitative or qualitative fibrinogen abnormalities. It is prepared by thawing FFP at 4°C and removing the supernatant. The remaining precipitate is rich in factor VIII, VWF multimers of various sizes, fibrinogen, fibronectin, and factor XIII. As a rough rule of thumb, 1 U of cryoprecipitate per 7 kg of body weight is necessary to increase the plasma fibrinogen level by 75 mg/dL. Formerly, cryoprecipitate was also administered as a source of VWF protein in individuals with VWD; because of its inferior viral safety profile, however, it should be used only in emergency life- and limb-threatening situations when viral attenuated factor VIII concentrates of intermediate purity are not available.

Recombinant factor VIIa concentrate (rFVIIa) (NovoSeven; NovoNordisk, Inc., Princeton, NJ, USA) has been used to reverse or prevent bleeding complications in individuals with severe FVII deficiency and in FVIII, FIX, or VWF protein-deficient states complicated by alloantibodies or autoantibodies that target the clotting factor and neutralize its coagulation function (see Chapter 6). Anecdotal data indicate that rFVIIa can also be used safely and effectively to reverse warfarin bleeding complications, although randomized, controlled trials with FFP or PCCs are lacking. rFVIIa has been used to limit acute intracranial hemorrhages not induced by anticoagulation (see Chapter 43). Despite the “pancoagulant” properties attributed to this new replacement therapy, its administration must be approached with extreme caution because thrombotic complications have occurred with its use. These have predominated in nonhemophilia bleeding states and in older populations. Patient selection and subsequent monitoring are critical to its careful use. It is evident that outside of the hemophilia bleeding scenario, smaller doses (e.g., 20 to 30 µg per kilogram) administered at one time may be safer than much larger doses yet equally effective.

Plasma-derived FXIII concentrate is undergoing clinical trials, and a recombinant FXIII concentrate is in development. FXI concentrate is available in Canada and the United Kingdom but not in the United States, because of vCJD issues related to plasma pools used to manufacture the concentrate. A fibrinogen concentrate is available in Europe but not in the United States.

If transfusion of platelets, FFP, and/or cryoprecipitate cannot reverse or prevent active bleeding not due to hemophilia A or B or VWD in cases where specific replacement therapy is indicated, the administration of DDAVP (1-deamino-8-D-arginine vasopressin), ε-aminocaproic acid, tranexamic acid, or topical fibrin sealants should be considered. DDAVP is a useful therapy for the qualitative platelet defects associated with uremia or with ingestion of aspirin, for mild or moderately severe hemophilia A, and for VWD (especially type 1). This agent is infused at a dose of 0.3 µg/kg of body weight intravenously over 15 to 30 minutes in 50 mL normal saline, to a maximum total dose of 20–25 µg. Although its exact mechanism of action remains unknown, DDAVP ultimately produces transient increases in levels of VWF antigen, factor VIII activity, ristocetin cofactor activity, tissue plasminogen activator, and PAI-1. It also increases the circulating concentrations of the highest molecular weight VWF protein multimers. Because of its antidiuretic effects, DDAVP is associated with a definite risk of water retention, which may lead to dilutional hyponatremia and seizures, particularly in infants and the elderly; free water intake should be minimized and sodium concentrations followed to monitor for this risk. Angina pectoris and thrombotic stroke have also been reported as potential complications in older, susceptible patients. The peak drug effect occurs within 30 minutes of administration and usually lasts for at least several hours. Of note, intranasal preparations of DDAVP do exist, but their use is usually reserved for situations of long-term administration and/or prophylaxis for simple surgical procedures in patients with mild hemophilia A or VWD.

ε-Aminocaproic acid (Amicar; Wyeth Pharmaceuticals, Madison, NJ, USA) and tranexamic acid (Cyclokapron; Pharmacia, Mississauga, Canada) are antifibrinolytic agents that are often used in the treatment of acute, severe mucosal hemorrhage associated with systemic hyperfibrinolysis. They are particularly useful adjunctive therapies in the management of mucosal bleeding, in that they modulate the effects of the tPA that is released when DDAVP is administered. These antifibrinolytic agents are generally well tolerated, although nausea, vomiting, diarrhea, dizziness, malaise, fever, rash, and transient hypotension or cardiac arrhythmias may occur. ε-Aminocaproic acid may also rarely cause rhabdomyolysis, particularly with prolonged use, in which cases appropriate laboratory monitoring is in order. It is important to note that neither drug should be administered to individuals who also have evidence of hypercoagulability. Finally, fibrin sealants are commercially available as topical procoagulants for active bleeding on surfaces; these are derived from plasma, are virally inactivated, and can be applied easily in the operative setting to sites of active bleeding and anastomosis (see Chapter 29).

In summary, effective diagnosis and treatment of bleeding disorders depend on the physician's expertise in eliciting specific answers to probing questions, in recognizing clinical signs and symptoms on physical examination, and in properly ordering and interpreting laboratory tests to confirm clinical suspicions. Each of these components by itself is too nonspecific and insensitive to be useful; however, when they are combined, high-quality, cost-effective medical care can be rendered and lives and limbs may be saved.

Chapter 3

Endothelium

William C. Aird, MD

The endothelium, which forms the inner cell lining of all blood vessels in the body, is a spatially distributed organ. The endothelium weighs approximately 1 kg in the average patient and covers a total surface area of 4000 to 7000 square meters. The endothelium is underappreciated as a clinically relevant organ. Indeed, the bench-to-bedside gap in endothelial biomedicine is wide.¹ The importance of closing this gap is highlighted by the fact that the endothelium is involved in most if not all disease states, either as a primary determinant of pathophysiology or as a victim of collateral damage. Moreover, the endothelium has a remarkable, yet largely untapped diagnostic and therapeutic potential. The overall goal of this chapter is to promote a better awareness of the endothelium as an organizing principle in health and disease. Given the current pace of basic and translational discoveries, it is likely that over the next two decades, the endothelium will gain recognition in the clinic as a bona fide organ system.

HISTORICAL OVERVIEW

Early descriptions of the cardiovascular system during the times of Hippocrates and Galen depicted the veins and arteries as separate, unconnected systems. Without the benefit of microscopy, these early investigators observed arteries as deeply situated, thick, pulsating vessels that contain red blood, and veins as superficial, distended, thin-walled, nonpulsating vessels that carry blue blood. The notion that veins and arteries constitute distinct systems would hold sway until William Harvey's discovery of the closed circulation in 1628. Harvey did not see the capillaries that connect arteries with veins but rather surmised their existence through a series of elegant physiologic studies. Marcello Malpighi was the first to actually observe the capillaries under light microscopy in 1659. The term *endothelium* was coined by Wilhelm His in 1865 to distinguish the inner lining of blood vessels from outer epithelial layers. In the early 20th century, most research in endothelial biology focused on physiologic assays of fluid transport across the endothelium. In the 1950s and 1960s, electron microscopy provided an exciting new window into the endothelium, revealing evidence for the existence of specialized organelles, such as Weibel-Palade bodies; unique junctional complexes; and remarkable structural heterogeneity between different segments of the vascular tree. The first successful, reproducible isolation and propagation of endothelial cells in the 1970s revolutionized the field of endothelial cell biology.^{2,3} Cell culture provided a means of carefully dissecting—under controlled conditions—fundamental aspects of endothelial

cell structure and function, leading to breathtaking advances in our understanding of this cell type, as well as an exponential increase in the number of publications related to endothelial cells and the endothelium.⁴ In vitro and in vivo studies in the 1980s led to the introduction of the descriptors, endothelial cell activation and endothelial cell dysfunction. The evolving definitions of these terms are discussed later in the chapter.

Over the past 40 years, there has been an increasing appreciation that endothelial cells behave very differently in vivo than they do in vitro, and that any interpretation of in vitro-based assays must be interpreted with caution and validated in the intact organism. Although this principle holds true for all cell types, it seems that endothelial cells, by virtue of their tight coupling to the tissue microenvironment, are particularly prone to phenotypic drift when isolated and cultured. Indeed, the application of novel genomic and proteomic approaches has led to the identification of previously hidden levels of complexity, and has provided important new insights into mechanisms of endothelial heterogeneity.^{5,6}

EVOLUTION AND DEVELOPMENT

Phylogeny

Most multicellular animals possess a circulation that provides bulk flow of oxygen to the various tissues of the body. Invertebrates typically possess an open circulation in which a heart pumps blood (called *hemolymph*) through one or more blood vessels into an open body cavity (called a *hematocoele*), where it bathes virtually every tissue in the body.⁷ In vertebrates, the cardiovascular system is “closed,” meaning that blood is always contained within the vasculature (one exception occurs within the spleen, where blood is permitted to exit from the circulation only to reenter after it has been scrutinized and filtered). The endothelium is present in all living vertebrates and absent in all extant invertebrates. Thus, it may be concluded that the common ancestor to vertebrates and invertebrates lacked an endothelium, and that this cell type evolved 450 million to 500 million years ago. In addition to the closed circulation and the endothelium, several other features of the vertebrate body plan seem to have evolved around the same time, including the formation of three distinct blood lineages (erythroid, myeloid, and megakaryocyte/platelet), the clotting cascade (consisting of serine proteases of the extrinsic and intrinsic pathways, and fibrinogen), and acquired immunity (antibody production). An interesting

question is: Which selective pressures were responsible for the evolution of the endothelium? Perhaps most important is that higher blood pressures associated with increasing body size would have required a mechanism for offsetting transmural leakage. If one considers the Starling-Landis equation (Equation 1), it is apparent that the permselective properties of a cellular lining would serve such a purpose; the endothelium is a major determinant of hydraulic conductivity and the reflection coefficient for plasma proteins.

$$J_c = L_p A [(P_c - P_t) - s_p (p_c - p_t)] \quad (\text{Equation 1})$$

where J_c = net transcapillary fluid shift, L_p = hydraulic conductivity of capillary wall, A = capillary membrane filtration area, P_c = capillary blood pressure, P_t = tissue fluid pressure, s_p = reflection coefficient for plasma proteins, p_c = capillary blood colloid osmotic pressure, and p_t = tissue fluid colloid osmotic pressure.

An important evolutionary consideration is that the modern human endothelium (similar to other organ systems) was “designed” to maximize fitness in a far earlier era, perhaps some 30,000 years ago. This is the time frame necessary to “filter” the gene pool through natural selection. The hunter-gatherers of the time lived a different lifestyle, that is, in terms of salt intake, fat intake, exercise, and life span. Although we will never know the precise details of the early ancestral environment, we can safely conclude that our endothelium is not optimized to withstand the rigors of high-density living (and resulting epidemics), a high-fat diet, a sedentary lifestyle, a prolonged life span, or artificial life support.

Ontogeny

During embryogenesis, the cardiovascular system is the first organ to develop. Blood vessels form via two mechanisms: vasculogenesis and angiogenesis.⁸ These processes are remarkably conserved between zebrafish, xenopus, avian species, and mammals. Vasculogenesis, the process that describes the in situ differentiation of endothelial precursor cells (angioblasts) from embryonic mesoderm (paraxial and lateral plate), results in the formation of the earliest vascular plexus (also called *primary capillary plexus*) in the embryo proper.⁹ Within a given embryo, some, but not all, angioblasts are derived from a common precursor of endothelial and hematopoietic cells (the hemangioblast). Later development of the mature vessel system involves angiogenesis, with proliferation and sprouting of new vessels from existing ones.¹⁰ Programmed branching (stereotypic patterning) of new blood vessels is governed by a delicate balance of attractive and repellent guidance cues.¹¹ It is interesting to note that the endothelium lining arteries and veins demonstrates site-specific properties (venous–arterial) even before blood flow is initiated, suggesting that artery–vein identity is epigenetically programmed.¹² This has important implications for an understanding of the focal nature of vasculopathic disease states in humans, in that the propensity for such diseases may be specified—at least in part—by a fixed program within the vessel. Finally, stabilization or maturation involves the recruitment of mural cells, including smooth muscle cells and pericytes.¹³

ENDOTHELIAL BIOLOGY

Levels of Organization

The cardiovascular system, consisting of the heart and blood vessels, is said to be closed because blood is always maintained within the vascular tree. Arteries have thick walls that consist of an endothelium-lined intima, smooth muscle cell-rich media, and an adventitia. The artery is a conduit vessel whose primary function is to provide bulk flow delivery of blood to the various tissues of the body. Arteries branch into arterioles, which are lined by a thinner layer of vascular smooth muscle cells. Arterioles are resistance vessels that mediate vascular tone and blood flow. The endothelium that lines arteries and arterioles is exposed to high flow rates and a relatively constant blood composition (an exception is the pulmonary artery, in which endothelial cells are bathed by mixed venous blood, and certain vascular beds that contain two arterial beds separated by capillaries [e.g., the glomerulus]). Blood flows from arterioles into capillaries. Capillaries are the “business end” of the circulation, in that they mediate the vast majority of exchanges of gases and nutrients between blood and underlying tissues. In keeping with Fick’s law of diffusion (Equation 2), capillaries account for the vast majority of the surface area of the vascular tree.

$$\frac{dQ_g}{dt} = D_g A \frac{dP_g}{dx} \quad (\text{Equation 2})$$

where $\frac{dQ_g}{dt}$ = rate of diffusion of gas (g)’, D_g = the Krogh diffusion coefficient; A = surface area; dP = partial pressure gradient; and dx = diffusion distance.

Also consistent with their primary role in diffusion, capillaries are extremely thin (thus minimizing dx). They are essentially three-dimensional tubes of endothelium that consist of little more than a single layer of flattened endothelial cells surrounded to a varying degree by extracellular matrix and occasional pericytes (see Chapter 11, Fig. 11-2). Deoxygenated blood is drained from capillaries into venules and subsequently into veins. The endothelium that lines the veins is exposed to blood with composition that varies according to the net exchange of substances that has taken place in the pre-venule capillaries.

Input–Output Device

Each of the human body’s 60 trillion endothelial cells is analogous to a miniature adaptive input–output device. Input arises from the extracellular environment and may include any number of biochemical and biomechanical forces. Examples of biochemical mediators include growth factors, cytokines, chemokines, temperature, pH, and oxygenation (Table 3-1). Output, or cellular phenotype, depends on the level of organization. Single endothelial cells may undergo a change in calcium flux or shape, or an alteration in protein or mRNA expression; they may migrate, proliferate, or undergo apoptosis. Monolayers of endothelial cells express barrier properties and may be assayed for leukocyte adhesion and transmigration. Finally, other phenotypes (called *emergent properties*), including endothelium-mediated changes in vasomotor tone, are apparent only at the level of the blood vessel, organ, or whole organism. Input is coupled to output through

Table 3-1 Examples of Endothelial Cell Input and Output

 Hemostatic balance

a complex array of nonlinear signaling pathways that typically begin at the level of cell surface receptors and end at the level of posttranscriptional modification or gene transcription.

Endothelial Cell Heterogeneity

At any given time, endothelial cells throughout the body are exposed to a myriad of microenvironments. For example, blood–brain barrier endothelium is exposed to a mixture of astroglial-derived paracrine factors that are critical for maintaining blood–brain barrier phenotype.¹⁴ In contrast, the endothelial lining of capillaries in the heart is exposed to regional forces generated by the pumping heart, as well as to paracrine factors derived from surrounding cardiomyocytes.^{15,16} As another example, endothelial cells in the vasa recta in the inner medulla of the kidney are exposed to a profoundly hypoxic and hyperosmolar environment. At any given site of the vasculature, the endothelium is exposed to temporal changes in input. For example, the endothelial cells in the portal vein and hepatic sinusoids are exposed to fluctuating concentrations of nutrients during preprandial and postprandial periods. In response to infection, trauma, or surgery, cytokines and other components may be released into the circulation during the innate immune response. Because input varies in time and space, and because endothelial cells are capable of sensing and responding to their extracellular environment, cellular output varies. Indeed, if one could “color code” the phenotype of an endothelial cell—for example, assign each phenotype with a shade of color—the endothelium would

display a richly colored palette that might fade in and out or blink on and off over time.

Nature versus Nurture

If the extracellular microenvironment were the sole mediator of endothelial cell heterogeneity, then the endothelium would be considered a “blank slate.” According to this model, all endothelial cells are “created equally” (through lineage determination/epigenetic modification), and any differences in phenotype merely reflect variation in the extracellular environment (i.e., spatial differences in net signal input). If one were to remove endothelial cells from various sites of the vasculature—say, from the pulmonary vein and from heart capillaries—and culture them in vitro under identical conditions, then differences in phenotype would “wash out” over time, and cellular phenotypes would ultimately reach identity. However, this is not the case. Evidence suggests that although many site-specific properties are indeed lost with culturing, others are retained during sequential passaging.^{17,18} These latter properties are epigenetically programmed and thus mitotically heritable. In the final analysis, both the microenvironment (nurture) and epigenetics (nature) contribute to endothelial cell heterogeneity.

Endothelial Functions

The endothelium plays an important role in physiology (Table 3-2), including barrier function, leukocyte trafficking, innate immunity, and vasomotor tone (discussed later), as well as hemostasis (discussed in a subsequent section).

Endothelial cells form a permselective (i.e., semipermeable) membrane that mediates transfer of ions, solutes, and fluids between the blood and interstitial compartments.¹⁹ As a general rule, gases pass through the endothelium via simple diffusion, whereas ions, solutes, and fluids require convective flow between endothelial cells (paracellular route) or through the endothelial cell (transcellular route). Transcellular flux is mediated by specialized transport processes, including transendothelial channels, caveolae, and vesicular-vacuolar organelles (VVOs). In keeping with the theme of heterogeneity, barrier properties differ significantly between different vascular beds. For example, the blood–brain barrier forms a highly efficient barrier by virtue of its tight junctional complexes (limiting paracellular transport) and paucity of caveolae (limiting transcellular transport). The blood–brain barrier relies on a unique repertoire of receptor-mediated transport systems and channels to deliver nutrients across the endothelium. In contrast, the liver sinusoidal endothelium is fenestrated

Table 3-2 Endothelial Functions

 Innate immunity

and possesses a discontinuous basement membrane; it is thus highly permeable.

The endothelium regulates the traffic of leukocytes between blood and underlying tissue. Under normal conditions, constitutive trafficking of lymphocytes from blood to lymph nodes occurs via specialized blood vessels, called *high endothelial venules* (HEVs).²⁰ In states of inflammation, endothelial cells in postcapillary venules (in nonlymphoid tissue) mediate the adhesion and transendothelial migration of leukocytes to the extravascular space.²¹ This process involves a highly orchestrated multistep adhesion cascade that begins with initial attachment, rolling, and arrest, and ends with diapedesis through the endothelium and migration through tissues. Over the past several years, significant advances have been made in our understanding of the molecular basis for leukocyte trafficking. For example, initial attachment is mediated primarily by E-selectin and P-selectin on endothelial cells, which bind to respective ligands on leukocytes, and L-selectin on neutrophils, which binds to endothelial ligands; arrest is mediated by endothelial intercellular adhesion molecule (ICAM)-1–leukocyte $\beta 2$ integrin interactions. In addition to regulating leukocyte transfer, the endothelium plays other roles in the innate immune response. For example, activated endothelial cells may express and/or release a multitude of inflammatory mediators.

The endothelium plays a key role in mediating vasomotor tone. Endothelial cells express several molecules that influence blood vessel diameter and flow dynamics, most notably nitric oxide (NO). The enzyme responsible for endothelial production of NO is endothelial nitric oxide synthase (eNOS).²² eNOS was once called a constitutive enzyme, but its expression or activity is now recognized to be modulated by many extracellular signals, including (but not limited to) shear stress and growth factors. Diagnostic flow studies of endothelial function provide indirect measures of NO release from the endothelium. Other vasomotor molecules released by the endothelium include prostaglandins and endothelin-1.

ENDOTHELIUM IN DISEASE

The two most common descriptors used to discuss the role of the endothelium in disease are endothelial cell activation and dysfunction. Both terms were coined in the early 1980s. *Endothelial cell activation* was introduced to describe agonist-induced hyperadhesiveness of cultured endothelial cells to leukocytes.^{23–25} Today, the term is used more broadly to characterize the response of endothelial cells to an inflammatory stimulus under in vitro and/or in vivo conditions. Activation is not an all-or-nothing response. Rather, activated endothelial cells display a spectrum of response. This caveat notwithstanding, the activation phenotype typically consists of some combination of increased leukocyte adhesion, a shift in the hemostatic balance toward the procoagulant side, and increased permeability. *Endothelial cell dysfunction* was originally introduced to describe increased platelet adhesion to endothelium.²⁶ Over the years, the term became synonymous with abnormal endothelium-mediated vasorelaxation in atherosclerotic arteries. However, the endothelium is (1) spatially distributed (endothelial coverage of the conduit vessels

represents a miniscule fraction of the total surface area of the endothelium), (2) involved in multiple functions (over and above regulation of vasomotor tone), and (3) involved in virtually every disease. Thus, the term *endothelial cell dysfunction* should not be restricted to a single function, organ/blood vessel type, or disease state. Indeed, endothelial cell dysfunction may be defined as an endothelial phenotype—whether or not it meets the definition of activation—that poses a net liability to the host, as occurs for example locally in coronary artery disease and systemically in severe sepsis.

ENDOTHELIUM AND HEMOSTASIS

Hemostasis represents a balance between procoagulant and anticoagulant forces. Procoagulant forces include tissue factor (TF), serine proteases of the intrinsic and extrinsic pathways, cofactors, fibrinogen, plasminogen activator inhibitor-1 (PAI-1), and an activated or negatively charged cell surface membrane. Anticoagulant forces include non-protein-specific mechanisms such as blood flow (which removes activated clotting factors and maintains protective flow at the level of the endothelium) and vascular integrity (causes separation of blood from underlying TF-rich adventitia and parenchyma), as well as protein-specific mechanisms such as antithrombin III (ATIII)–heparan (which inhibits the serine proteases of the clotting cascade), thrombomodulin (TM)–endothelial protein C receptor (EPCR)–activated protein C (aPC)–protein S (which inactivates factors Va and VIIIa and inhibits endothelial cell activation), tissue factor pathway inhibitor (TFPI) (which inhibits the extrinsic pathway by forming a ternary complex with TF and factors VIIa and Xa), and plasmin (which degrades fibrin).

A shift in hemostatic balance to one or the other side may result in bleeding or thrombosis. An interesting feature of congenital and acquired hypercoagulable states is that they are invariably associated with local thrombotic lesions. This may seem counterintuitive in conditions in which the abnormality lies in a systemically distributed factor, such as factor V Leiden or congenital deficiency of ATIII. A clue to the focal distribution of clots lies in the endothelium.¹⁶ The endothelium is a mini-factory for procoagulant and anticoagulant molecules. On the procoagulant side, endothelial cells synthesize PAI-1, von Willebrand factor (VWF), protease-activated receptors, and rarely, TF. On the anticoagulant side, endothelial cells express, synthesize, and/or release TFPI, TM, EPCR, tissue plasminogen activator (tPA), and heparan. However, these factors are not expressed uniformly throughout the vasculature. For example, VWF is expressed predominantly in venous endothelium,²⁷ TFPI in microvascular endothelium,²⁸ EPCR in large vessel endothelium,²⁹ TM in vessels of all sizes in all organs with the notable exception of the brain,³⁰ and tPA in arterioles (particularly in the brain and lungs).³¹ The picture that emerges is one of heterogeneity layered on heterogeneity. Indeed, if one were to survey endothelial cells from different sites of the vasculature, one would find that they mediate hemostasis via site-specific “formulas” of procoagulants and anticoagulants (Fig. 3-1).^{16,32}

These considerations give rise to a revised model of hemostasis (Fig. 3-2).³³ The liver synthesizes a relatively

Figure 3-1 Site-specific hemostatic formulas. Each endothelial cell contributes to the hemostatic balance by expressing and/or secreting surface receptors and soluble mediators. Receptors include the protease-activated receptors (or TR [thrombin receptor]), thrombomodulin (TM), tissue factor (TF), and ectoADPase (not shown). Soluble mediators include von Willebrand factor (VWF), plasminogen activator inhibitor-1 (PAI-1), tissue plasminogen activator (tPA), tissue factor pathway inhibitor (TFPI), and heparan. Each of these factors is differentially expressed from one site of the vascular tree to another. Thus, at any point in time, the hemostatic balance is regulated by vascular bed–specific “formulas.” Shown is a hypothetical example, in which an endothelial cell from a liver capillary relies more on VWF, PAI-1, and TFPI to balance hemostasis, whereas an endothelial cell from a lung capillary expresses more thrombin receptor, tPA, and heparan. (Adapted with permission from Aird WC: Crit Care Med 29[7 suppl]:S28–S34, 2001.)

Figure 3-2 Integrated model of hemostasis. The liver (*left*) produces the serine proteases, cofactors, and fibrinogen of the clotting cascade (shown as Y-shape) and many of the circulating natural anticoagulants (shown are protein C [C], protein S [S], and antithrombin III [ATIII]). The bone marrow (*right*) releases monocytes and platelets that are capable of expressing tissue factor and/or an activated cell surface. The liver- and bone marrow–derived proteins and cells are systemically distributed and integrated into the unique hemostatic balance of each vascular bed (shown are balances in two hypothetical vascular beds). Monos, monocytes; PLT, platelets. (Adapted with permission from Aird WC: Crit Care Med 29 (7 suppl):S28–S34, 2001.)

consistent quantity of serine proteases (factors XII, XI, X, IX, VII, and II), cofactors (factors V and VIII), fibrinogen, and anticoagulants (ATIII, protein C, protein S). Under normal conditions, the bone marrow releases a relatively constant quantity of monocytes and platelets, cells that are capable of expressing TF and activated cell surface membrane, respectively. Liver-derived soluble factors and

bone marrow–derived hematopoietic cells are systemically distributed where they are uniquely integrated into the hemostatic balance of each and every vascular bed. When a shift in systemic factors occurs—for example, increased release of hepatocyte proteins during an acute phase response, congenital deficiency of ATIII, or sepsis-mediated efflux and/or activation of monocytes and platelets—the

changes influence site-specific hemostatic formulas in ways that differ from one vascular bed to another, resulting in local thrombosis. This model provides several important perspectives, in that it (1) incorporates both the cellular phase (endothelium, platelets, and monocytes) and the soluble phase (circulating procoagulants and anticoagulants) of coagulation; (2) illustrates the various organs that contribute to hemostasis (endothelium, liver, and bone marrow); and (3) emphasizes the vascular bed–specific nature of hemostasis.

The endothelium also contributes in indirect ways to the hemostatic balance. For example, endothelium-mediated vasoregulation plays a key role in maintaining blood flow. Limited expression of cell adhesion molecules and induction of leukocyte adhesion minimizes blockage of vessel lumina and secondary disruption of flow. Endothelial dysfunction in any of these parameters may lead to an increased propensity to form clots.

DIAGNOSIS

Few symptoms are directly referable or specific to the endothelium. The endothelium is hidden from view and is not amenable to traditional physical diagnostic maneuvers such as inspection, percussion, palpation, or auscultation. In contrast to other organs that are difficult to examine at the bedside, such as the pancreas, the endothelium is not spatially confined and therefore is difficult to image with traditional imaging modalities.

The most commonly used diagnostic assays for endothelial function in the clinic are noninvasive flow studies that measure endothelium-mediated vasorelaxation in response to acetylcholine or release of external compression (Table 3-3).^{34–37} Abundant studies have shown abnormal endothelium-mediated changes in flow in patients with coronary artery disease or in those with risk factors for coronary artery disease.³⁸ An important limitation of these assays, as alluded to earlier, is that they provide limited information about other aspects of endothelial function or other sites of the vasculature (e.g., capillaries).

Circulating biomarkers for the endothelium include soluble and cell-based assays. Soluble mediators include endothelium-derived factors involved in hemostasis (e.g., VWF, PAI-1, tPA, sTM, sEPCR), cell adhesion (e.g., sE-selectin, sP-selectin, sICAM-1, soluble vascular cell adhesion molecule-1 [sVCAM-1]), and/or vasomotor tone (e.g., endothelin-1). Although many studies have reported the association of one or another of these mediators in different disease states, few if any markers consistently and reliably predict presence/stage of disease, prognosis, or response to therapy. It seems likely that advances will depend on the use of proteomic technology to simultaneously assay for multiple soluble mediators and the use of bioinformatics to identify the association between patterns of markers and disease. Given that the hemostatic balance is differentially regulated between different vascular beds, it may be possible to correlate changes in hemostatic parameters with the site of dysfunction. As an example, if the brain does in fact express little in the way of TM, then large increases in circulating sTM are unlikely to reflect primary or localized brain disease.

Cell-based assays offer considerable promise. For example, circulating endothelial cells (CECs) are increased in

Table 3-3 Diagnostic Markers for Endothelium

Marker	Comments
Pathology	Not readily available, except for skin biopsies. Results from skin biopsies may not be extrapolatable to other vascular beds
Soluble Mediators	
sICAM-1	Not specific to endothelial cells
sVCAM-1	Not specific to endothelial cells
sP-selectin	Not specific to endothelial cells
sE-selectin	Specific to endothelial cells
sTM	Specific to endothelial cells
tPA	Not specific to endothelial cells
PAI-1	Not specific to endothelial cells
VWF	Not specific to endothelial cells
sEPCR	Specific to endothelial cells
Others	
Cell-Based Mediators	
CECs	May be quantitated and phenotyped; limited by small numbers in the blood
MPs	May be quantitated and phenotyped
EPCs	May be quantitated and phenotyped
Molecular Imaging	Holds tremendous promise for vascular bed–specific diagnosis
Flow Studies	The only diagnostic assays that have reached the clinical mainstream

sICAM, soluble intercellular adhesion molecule; sVCAM, soluble vascular cell adhesion molecule; sTM, soluble thrombomodulin; tPA, tissue plasminogen activator; PAI-1, plasminogen activator inhibitor-1; VWF, von Willebrand factor; sEPCR, soluble endothelial protein C receptor; CEC, circulating endothelial cell; MP, microparticle; EPC, endothelial progenitor cell.

disease states such as sepsis, acute coronary syndromes, and connective tissue disease.^{39,40} These cells, which are derived from the blood vessel wall, may be quantified and phenotyped with the use of fluorescence-activated cell sorting (FACS) analysis. Quantitative and qualitative analyses of CECs may ultimately provide information about the health of the endothelium at the site of origin. Circulating microparticles are derived from multiple cell types, including leukocytes, platelets, red blood cells, and endothelial cells. Endothelial microparticles (EMPs) are increased in many disease states.⁴¹ As is the case with CECs, EMPs may be quantified and phenotyped by FACS. Increasing evidence suggests that different diseases are associated with distinct EMP phenotypes. Moreover, EMPs may carry TF and cell adhesion molecules on their surface, thus contributing to underlying pathophysiology. Endothelial progenitor cells (EPCs) are derived from the bone marrow and circulate in the blood. These cells are believed to be mobilized and taken up by newly formed blood vessels (although their role in replacing preexisting endothelium in established blood vessels is less clear). The latter process

has been called *adult vasculogenesis* because it mimics the process of vasculogenesis in the embryo, in which angioblasts from the mesoderm differentiate into endothelial cells and form the earliest blood vessels. Data suggest that the number of EPCs correlates inversely with the health of the endothelium and is associated with reparative potential.⁴² Because circulating blood cells are in intimate contact with the endothelium, they may carry special signatures related to these interactions. Indeed, studies of sepsis have revealed characteristic changes in monocyte transcriptome, some of which are presumably reflective of endothelial function or dysfunction. Another interesting concept is the use of vascular bed-specific catheters to sample local sites of endothelial dysfunction (hot spots), whose manifestations become “washed out” or diluted in blood from the peripheral vein or artery.

THERAPY

The endothelium is an attractive therapeutic target. Endothelial cells are preferentially and rapidly exposed to systemically delivered agents. Owing to its wide spatial distribution, the endothelium provides a window into each and every tissue of the body. Moreover, endothelial cells are highly malleable and thus modulatable from a therapeutic standpoint. The endothelium should be targeted for two main reasons: (1) to directly modulate endothelial function, and (2) to gain site-specific access to underlying tissue.

Treating the Endothelium

Therapy may be directed toward ameliorating endothelial function. To return to the analogy of the endothelial cell as an input–output device, therapy may be aimed toward cellular output (i.e., phenotype) and/or intracellular coupling mechanisms. Examples of targeting output include using neutralizing antibodies against adhesion molecules such as ICAM-1 or VCAM-1; inducing the expression/synthesis of TM, EPCR, TFPI, or heparan; and increasing barrier function. Examples of modulating intracellular coupling mechanisms include neutralization of cell surface receptors (e.g., antibodies against the vascular endothelial growth factor [VEGF] receptor) and administration of antioxidants or inhibitors of NF- κ B signaling. Increasing evidence suggests that certain U.S. Food and Drug Administration (FDA)-approved drugs exert their beneficial effect—at least in part—by attenuating endothelial dysfunction. For example, lipid-lowering statins have been shown to have pleiotropic effects at the level of the endothelium.⁴³ Recombinant human protein C, which is used to treat patients with severe sepsis,⁴⁴ has been shown to promote endothelial barrier function and inhibit endothelial apoptosis.^{45–47} It is tempting to speculate that the proved efficacy of tight glucose control⁴⁸ and low-dose steroids⁴⁹ in critically ill patients serves to attenuate the deleterious effects of high glucose and NF- κ B, respectively, on the endothelium. Indeed, given the remarkable capacity of the endothelium to sense and respond to its extracellular environment, it seems likely that most if not all drugs that are systemically administered to patients will alter endothelial phenotypes in one way or another—whether the effect is beneficial, toxic, or neutral.

Targeting the Endothelium as a Means of Gaining Access to Tissue

Most drugs are small lipophilic molecules that readily cross cell membranes and distribute throughout the body. An important goal in therapeutics is to develop strategies for selectively targeting organs of interest. In this regard, the permselective properties of the endothelium present both challenges and opportunities. For example, the blood–brain barrier poses a formidable obstacle to drug therapy in neurologic disease.⁵⁰ However, recent advances in the field of endothelial cell biology suggest that the transcytotic machinery (e.g., caveolae) may be exploited to deliver drugs to the extravascular compartment. Moreover, because the endothelium displays remarkable heterogeneity in cell surface receptor expression, it is hoped that these so-called vascular addresses may be selectively targeted to promote vascular bed-specific (hence, organ-specific) delivery of drugs.

CONCLUSIONS

Since 1950, more than 100,000 articles have been published on endothelial cells and the endothelium.¹ In contrast, the endothelium is underrecognized in the clinical setting. Many physicians are cognizant of its role in mediating vasomotor tone and its pathophysiologic involvement in atherosclerosis. However, appreciation for its myriad of functions in other vascular beds is typically divided along traditional “organ lines.” For example, neurologists consider the blood–brain barrier; ophthalmologists, the retinal circulation; nephrologists, kidney glomeruli; and urologists, the corpus spongiosum. Given that the endothelium is systemically distributed, is involved in many if not most disease states, and has remarkable diagnostic and therapeutic potential, an urgent need to adopt a more integrative approach to this cell layer has been acknowledged. Bridging the bench-to-bedside gap in endothelial biomedicine will require the dismantling of existing barriers between organ-specific disciplines. Indeed, acceptance of the endothelium as a clinically relevant system (i.e., organ) will provide a necessary foundation for future breakthroughs in the field.

Hemorrhagic Processes

Chapter 4

Hemophilia A and B

Lisa N. Boggio, MS, MD • Craig M. Kessler, MD

INTRODUCTION/EPIDEMIOLOGY/ GENETICS

The hemophilias are the best known of the hereditary bleeding disorders. Hemophilia A arises as the result of congenital deficiency of coagulation factor VIII, and those with hemophilia B lack coagulation factor IX. Both are transmitted genetically as X-linked recessive disorders, almost exclusively affecting males whose daughters and mothers are obligate carriers of the gene defect. Hemophilia A occurs in 1 of every 5000 live male births and accounts for approximately 80% to 85% of hemophilia cases. Hemophilia B is far less common, occurring in 1 of every 30,000 live male births. The incidence of these hemophilias is equal across all ethnic and racial groups.

The factor VIII gene comprises 186,000 base pairs and is considerably larger than the factor IX gene, which consists of 34,000 base pairs. These genes are located on particularly fragile portions of the X chromosome. By virtue of its size alone, the factor VIII gene is more susceptible to mutations; this may explain the greater prevalence of hemophilia A versus hemophilia B (4:1) in the population. The incidence of hemophilia has not changed over the years despite the availability of genetic counseling and prenatal testing of at-risk mothers. Approximately 30% of hemophilias present as spontaneous mutations, with no prior family history of coagulation disorders.

Symptomatic hemophilia A or B rarely affects females but can do so by virtue of any of the following genetic mechanisms: (1) high degree of lyonization of factor VIII or IX alleles in carriers; (2) hemizygosity of the X chromosome in females with Turner syndrome (XO karyotype); or (3) homozygosity in female progeny of hemophilia carriers and affected hemophilic males.¹ Females who are phenotypically hemophilic should undergo diagnostic evaluation for exclusion of von Willebrand disease variant type 2N or type 3, or testicular feminization syndrome.

The most common mutation of the factor VIII gene, responsible for at least 45% of cases of severe hemophilia A, involves the inversion of intron 22 on the X chromosome. This results from the translocation and exchange of DNA between either of 2 “nonfunctional” factor VIII–related genes within intron 22 and areas of homologous DNA within the functional factor VIII gene.² A second inversion, involving an inversion of intron 1, has been reported in up to 5% of cases.^{3,4} The recombination produces disjointed and inverted DNA sequences, preventing the transcription of a normal full-length factor VIII molecule. The coded protein typically possesses

no functional or immunologic factor VIII activity in severe hemophilia A.

Less commonly, severe hemophilia A may be due to large gene deletions involving multiple or single domains, small point mutations resulting in the formation of stop codon sequences, or insertions and/or deletions within the gene. Moderate and mild severity types of hemophilia A are mainly the result of missense mutations; many different point mutations and deletions have been identified in patients with mild or moderate hemophilia A.⁵ The incidence of alloantibody inhibitors in individuals with hemophilia A is highest in those with stop mutations in light-chain domains.⁶ This is significant in that alloantibodies (and autoantibody inhibitors) are directed against epitopes on the A₂>C₂>A₃ domains of the factor VIII coagulant protein. The A₂ and A₃ domains normally interact with factor IXa; C₂ interacts with phospholipid and von Willebrand factor protein. These inhibitors block these interactions and interfere with formation of the tenase complex of coagulation (Fig. 4-1). A resource for the known mutations of factor VIII, along with a method for inputting new mutations, is HAMSTeRS (Hemophilia A Mutation, Structure, Test, and Resource Site), which can be found on the Internet at the following address: <http://europium.csc.mrc.ac.uk/Web-Pages/Main/main.htm>.

Numerous point mutations and deletions have been identified in individuals with hemophilia B. These frequently result in the production of a defective, nonfunctioning, but immunologically detectable, factor IX protein (“cross-reacting material,” or CRM⁺) in the plasma. Individuals with large gene deletions and nonsense mutations are usually CRM[−] and are most susceptible to the development of factor IX alloantibodies.⁷ The Hemophilia B Mutation Database, which is an excellent resource for the factor IX gene, may be found on the Internet at the following address: <http://www.kcl.ac.uk/ip/petergreen/haemBdatabase.html>.

PRENATAL DIAGNOSIS/CARRIER TESTING

Evaluation of carrier status is a critical aspect in the routine medical care of carriers of the hemophilias and in the management of their future pregnancies. Genetic counseling and testing of obligate carriers and at-risk family members of the proband with hemophilia may be useful in family and peripartum planning. The most common methods for identification of carrier status include direct gene mutation analysis and linkage analysis with the use of DNA

Figure 4-1 Factor VIII gene structure reveals the structural domains and known “hot spots” for antibody formation.

polymorphisms. For patients with severe hemophilia A, first-line testing involves identification of the intron 22 inversion. In individuals in whom the inversion is not detected, or for whom no family members are available for testing, the more cumbersome and labor-intensive method of linkage analysis can be performed with restriction fragment length polymorphism (RFLP) in the search for DNA polymorphisms.⁸ Prior to any suggestion of testing, patients may be referred to a genetic counselor, who provides advice and recommends appropriate diagnostic testing. Gene mutations of the factor IX gene are more easily detected because it is one third the size of the factor VIII gene. More than 300 mutations of the factor IX gene have been identified, most common of which are single point mutations.⁹ Microarray analysis may provide rapid screening for factor IX gene mutations.¹⁰ The City of Hope National Medical Center has a central laboratory that provides much of this testing. (Contact Steve S. Sommer, MD, PhD, Clinical Molecular Diagnostic Laboratory, City of Hope National Medical Center Fox South, Second Floor, 1500 East Duarte Road, Duarte, CA 91010. Telephone: 888-8-COH-DNA; <http://www.cityofhope.org/cmdl>.) Other resources for gene testing may be found on the Internet at <http://www.genetests.org>.

Techniques for detecting hemophilia in the fetus include chorionic villous sampling at 12 weeks gestation or amniocentesis at 16 weeks. The risk of miscarriage from these procedures ranges between 0.5% and 1.0%. If DNA testing is unavailable, fetal blood sampling through fetoscopy can be performed at 20 weeks to measure factor VIII activity; however, this approach is associated with a significant (1% to 6%) risk of fetal demise.¹¹ This technique is not useful for measurement of factor IX levels because these are routinely reduced in newborns, along with the other vitamin K-dependent clotting factor proteins. The risks of prenatal testing must be balanced against the need for the clinician to know the diagnosis prior to delivery, or if termination is being considered. In a review by Ljung and Tedgård,¹² prenatal diagnosis was found to be more common among women who perceived hemophilia to be a very serious disease, had a positive attitude toward legal abortion, and belonged to a higher social class. Women with a brother or father with hemophilia considered the disease to be serious, but women with a hemophilic child did not.¹² This difference in perception may reflect the enhanced effectiveness of modern day treatment of patients with hemophilia, the reduced joint destruction and contracture formation, the ease of obtaining replacement products, and the use of central venous devices for delivery of treatment.

POSTNATAL DIAGNOSIS

Postnatal recognition and diagnosis of hemophilia A or B are facilitated when other family members are known to

have hemophilia. The degree of severity of hemophilia is usually similar in all affected family members. The exception is Heckathorn disease,¹³ in which considerable variability of factor VIII levels is noted among family members with hemophilia A.

Frequently, family members and the details of their medical histories are unavailable at the time of patient presentation. Moreover, approximately 30% of all hemophilia is due to spontaneous mutations in families without prior history of coagulation abnormalities. For instance, Queen Victoria of England appears to have spontaneously mutated her factor VIII gene and then spread it throughout European royalty. Measurement of factor VIII or IX activity in the affected individual is necessary to establish the diagnosis. For hemophilia A, factor VIII coagulant activity can be assessed through a direct functional plasma clot-based assay or with a chromogenic substrate-based assay. Factor IX activity levels also are measured with the use of a plasma clot-based assay. Hemophilia A must be differentiated from von Willebrand disease (VWD) by the measurement of von Willebrand factor (VWF) antigen and ristocetin cofactor activity, and by examination of the multimeric composition of the VWF protein with sodium dodecyl sulfate (SDS) gel chromatography, if clinically indicated. VWD variant types 2 Normandy (2N) and 3 may be phenotypically similar to severe hemophilia A, although the autosomally transmitted inheritance pattern of VWD should help to distinguish it from the sex-linked recessive genetic pattern of hemophilia A (see Chapter 7). In addition and in contrast to hemophilia A, replacement therapy with VWF-containing products produces an exaggerated recovery (higher than calculated incremental rise from baseline levels) and a sustained elevation and circulating half-life of factor VIII activity in individuals with VWD, particularly among those with severe type 3 VWD.

When hemophilia is suspected in a male fetus of a known carrier, factor VIII or IX activity (or both) should be measured from a cord blood sample. This avoids the need for venipuncture, which can produce clinically important bruising and/or hemorrhage in the severely affected neonate. The diagnosis of hemophilia B in the neonate may be confounded by the fact that factor IX levels (as well as those of other hepatically synthesized proteins) are significantly reduced at birth and may remain so for up to 6 months. Normal plasma activity levels of coagulation factors VIII and IX in individuals after infancy range between 0.5 and 1.5 IU/mL (50% and 150%). The severity of hemophilia is defined by the measured level of clotting factor activity: Severe hemophilia is defined as factor VIII or IX activity below 1% (<0.01 IU/mL); it occurs in approximately half of affected hemophiliacs. Moderate severity hemophilia occurs in about 10% of hemophiliacs, who have factor VIII or IX levels between 1% and 5% (0.01 and 0.05 IU/mL). Mild hemophilia occurs in 30% to 40% of hemophiliacs, who have factor VIII or IX activity levels above 5% (above 0.05 IU/mL).

Between 2% and 8% of hemophilic infants develop intracranial hemorrhage and scalp hematoma during the perinatal period. These complications are associated with prolonged and difficult labor, the use of vacuum extraction and forceps to facilitate delivery, the presence of cephalopelvic disproportion, and precipitous delivery.¹⁴ Caesarean section does not eliminate bleeding risks. The Medical and Scientific Advisory Council (MASAC) of the National Hemophilia Foundation (NHF) recommends that vacuum devices and instrumentation such as fetal scalp samples and internal fetal scalp monitors should not be used because of the risk of bleeding in the infant.¹⁵ Full recommendations may be found at the NHF website: <http://www.hemophilia.org/NHFWeb/MainPgs/MainNHF.aspx?menuid=157&contentid=347>.

Recently, intrauterine transfusion of clotting factor concentrate immediately before delivery of a male fetus known to have severe hemophilia A has been attempted in an effort to prevent such problems.¹⁶ Unfortunately, this resulted in the formation of a high-titer alloantibody inhibitor in the infant shortly after birth, which suggests that this approach should be avoided because of its potential adverse stimulation of the immature immune system. In general, the most common initial bleeding events in hemophilic children occur in association with circumcision and cord necrosis. Ecchymoses may develop during the first few months of life, but spontaneous hemarthroses, the hallmark of the hemophilias, usually do not occur until approximately 1 year of age with the onset of walking. The development of hematomas at the site of intramuscular injection of routine vaccinations or medications (including the postnatal administration of vitamin K) should increase the suspicion that an abnormality exists. This type of bleeding can be avoided by administering these injections subcutaneously or after pretreatment with clotting factor concentrates. Oral bleeding due to loss of deciduous teeth, tongue biting, and frenulum injury is common in the young child and may require clotting factor replacement and adjunctive use of antifibrinolytic agents, such as tranexamic acid or ϵ -aminocaproic acid.

Patients with moderately severe hemophilia usually do not experience spontaneous hemorrhagic episodes, but minor trauma or surgery can precipitate bleeding unless clotting factor replacement or 1-deamino-8-D-arginine vasopressin (DDAVP) is provided prophylactically. Mild hemophilia may be detected incidentally during routine preoperative screening of the coagulation mechanism, which reveals a prolonged partial thromboplastin time (PTT).¹⁷ Patients should be screened for VWD type 2N unless a definitive family history of hemophilia A has been established. Bleeding complications in hemophilia of moderate severity may occur after significant trauma or surgery, but spontaneous hemarthroses are rare, and some patients may never experience a bleeding event.

CLINICAL FEATURES OF THE HEMOPHILIAS

Intra-articular Bleeding: Hemarthroses and Hemophilic Arthropathy

The most common sites of spontaneous bleeding in individuals with severe hemophilia A or B involve the joints

and muscles. The knees (greater than 50% of all bleeding events), elbows, ankles, shoulders, and wrists are affected in decreasing incidence. It is the recurrent nature of the bleeds into these joints that results in degeneration of the cartilage and progressive destruction of the joint space. The pathophysiology of hemophilic arthropathy can be divided into three phases. After hemorrhage into the joint occurs, iron is deposited into the synovium and chondrocytes of the articular cartilage (the first phase). Subsequently, focal areas of villous hypertrophy develop on the synovial surface, which, because of their vascularity and friability, continue to rebleed with normal joint stresses even with routine weight bearing. This ultimately establishes the "target joint" situation, which is characterized by recurrent, painful, and destructive bleeds into the same joint.¹⁸

Associated with iron deposition is the release of inflammatory cytokines that recruit macrophages and fibroblasts into the joint space and establish a favorable environment for progression of joint disease. This second phase of hemophilic arthropathy involves the development of chronic synovitis, pain, fibrosis, and progressive joint stiffness with decreased range of motion. Within the joint space can be found hydrolytic and proteolytic enzymes, such as acid phosphatase and cathepsin D.¹⁹ In the final stage of hemophilic arthropathy (phase three), progressive and erosive destruction of the cartilage, narrowing of the joint space, subchondral cyst formation, and eventual collapse and sclerosis of the joint become apparent. Conventional roentgenographs traditionally have been used to monitor the progression of hemophilic arthropathy; however, until bone changes become apparent, the films appear normal and may cause the clinician to underestimate the extent of joint disease. Magnetic resonance imaging (MRI) is more sensitive than conventional radiographic studies for early identification of hemarthrosis, synovial hypertrophy, hemosiderin deposition, and osteochondral changes (cartilage thinning and erosion). Joint scoring systems have been developed for use in evaluating the degree of joint destruction over time.²⁰

The predominant clinical manifestations of recurrent joint hemorrhage are pain and swelling. Well before the onset of pain, patients describe prickly sensations and burning within the joint as the first signs of bleeding. If the bleeding is allowed to continue, pain and swelling lead to fixation of the joint in a flexed position until the swelling subsides. Early recognition and prompt treatment of acute bleeding episodes are essential for preventing excessive hemorrhage into the joint space and minimizing subsequent joint destruction. The goal of administration of replacement clotting factor concentrate to treat the acute bleed ("on demand" therapy) is to increase factor VIII or IX activity levels to 30% to 50% of normal. Occasionally, repeat infusions of factor concentrate are necessary to terminate bleeding and reduce pain, especially in target joints. If significant pain and swelling are protracted, a short course of corticosteroids (prednisone 1 mg/kg/day for 4–5 days) may be given. This has proved more beneficial in children than in adults and should probably be avoided in patients with human immunodeficiency virus (HIV) infection. Rarely, joint aspirations are performed for patients with intractable pain despite factor replacement therapy, or for those with fever and in whom septic arthritis

is suspected. Prior to joint aspiration, adequate factor replacement therapy should be administered. Aspiration should be avoided in patients with alloantibody inhibitors because of the increased risks of bleeding complications associated with the procedure.

Narcotic analgesics frequently are a necessary therapeutic adjunct for pain control, and application of ice packs and avoidance of weight bearing with the use of crutches reduce the inflammation and pain that accompany the hemarthrosis. Initiation of physical therapy as soon as pain control is achieved reduces the development of muscle atrophy around the affected joint and prevents permanent flexion contractures. Plaster casting of target joints should not be performed.

A secondary prophylaxis regimen of replacement therapy can be of immense benefit to patients with target joints. This consists of administering the appropriate clotting factor concentrate two or three times weekly, to maintain trough clotting factor activity levels of 1% to 3%. When sustained for at least 3 months, this approach can effectively interrupt the cycle of recurrent bleeding.^{21,22} In patients who have developed chronic synovitis that is refractory to medical management, surgical debridement and synovectomy should be considered to reduce the bleeding and pain; however, joint destruction may progress, albeit at a much slower pace. This procedure is of greatest benefit in patients with minimal hemarthropathy.

Radioactive and chemical nonsurgical synovectomies have been used to break the vicious cycle of hemarthrosis–chronic synovitis–hemarthrosis. These techniques currently are most commonly used in developing countries, where surgery and the required clotting factor replacement concentrates are not available. Nonsurgical synovectomies may also be beneficial for individuals with high-titer alloantibody inhibitors, in whom surgery is particularly risky and the ability to achieve adequate hemostasis is unpredictable, despite administration of inhibitor “bypassing” clotting factor replacement therapies. Most radionuclide synovectomies in hemophilia have been performed with the β emitter isotopes yttrium-90 (^{90}Y) and phosphorus-32 (^{32}P); these are less likely than γ emitters to be mutagenic and to produce localized inflammatory reactions within the synovium.²³ A greater than 50% reduction in frequency of bleeding events and pain occurs after radionuclide synovectomy, and the range of motion of the joints is stabilized or improved in more than 50% of patients.

Unfortunately, despite this treatment, long-term follow-up studies show that gradual deterioration in range of motion in the affected joint continues. Of concern is that acute lymphocytic leukemia recently was reported in two young hemophilic patients a few years after they underwent radioactive synovectomy.^{24,25} However, since 1988, more than 1000 joint injections of ^{32}P have occurred in more than 563 hemophilic patients, and because the incidence of acute leukemia in children in the United States is approximately 2.8 per 100,000 persons/year, it is difficult to determine whether these isolated cases of leukemia are due to radioactive synovectomy, or whether they represent coincidental events that occur in accordance with population statistical expectations. Chemical synovectomies with osmic acid or rifampicin reduce the frequency of hemarthroses but produce acute and painful inflammatory reactions, with overall results that are inferior to those of the

radionuclides. The best method of preventing progressive joint destruction is to prevent intra-articular bleeding in the first place. Thus, the use of primary prophylaxis regimens (twice or thrice weekly with clotting factor replacement therapy, beginning in infancy after the first bleed and continuing indefinitely thereafter) is being investigated as a means of achieving this goal.

Intramuscular Hemorrhage

Intramuscular hemorrhages, which represent the second most common site of bleeding in individuals with hemophilia, account for 30% of bleeding events. The location of the intramuscular hemorrhage determines the morbidity of the event. Hemorrhage into large muscles, although extensive, generally resolves without complications because it is not into a confined space. Bleeding into a closed fascial compartment may lead to significant compression of vital structures with resultant ischemia, gangrene, flexion contractures, and neuropathy (compartment syndrome). Intramuscular hematomas manifest with localized tenderness and pain and may be associated with low-grade fevers, large ecchymoses, and elevations of serum lactate dehydrogenase (LDH) and creatine kinase. Bleeding into the psoas muscles and retroperitoneal space can produce sudden onset of inguinal pain and decreased range of motion in the ipsilateral hip, which assumes a markedly flexed position, usually with lateral rotation. Hemorrhage may become life threatening if a large volume of blood is lost. In addition, femoral nerve compression can occur with permanent disability if a compartment syndrome develops. The diagnosis can be confirmed by pelvic ultrasonography or computed tomography (CT).²⁶ Bleeding into this area must be controlled rapidly by raising and maintaining clotting factor activity at 80% to 100% of normal for at least 48 to 72 hours. Surgery is to be strictly avoided in this situation.

Hematuria

Spontaneous gross hematuria occurs frequently in patients with hemophilia and is usually painless unless intraureteral clots develop. Hematuria may be precipitated by the use of nonsteroidal anti-inflammatory drugs, trauma, or exertion. Pelvic clots, obstructive hydronephrosis, compromised collecting systems, and retroperitoneal fibrosis can be demonstrated on intravenous pyelograms. The cause of spontaneous hematuria in individuals with hemophilia is unknown, but it may be due to direct tubular and glomerular damage caused by circulating immune complexes formed after clotting factor replacement therapy. Immune complexes may also mediate the development of anaphylaxis and nephrotic syndrome, which can occur after factor IX replacement therapy in patients with severe hemophilia B and alloantibodies directed against factor IX.²⁷ Individuals with large deletions in the factor IX gene appear to be at highest risk. This syndrome has been reported to occur with all commercially available factor IX products.²⁸ Avoidance of any or all sources of coagulation factor IX for replacement therapy is necessary, and recombinant factor VIIa (rFVIIa) concentrate has become the treatment of choice for acute bleeding events in these individuals.

Other causes of hematuria that should be considered include infection, neoplasm, and renal or ureteral stones.

Nephrolithiasis has been seen most commonly in HIV-infected hemophiliac patients who take the HIV protease inhibitor indinavir (Crixivan; Merck & Co., Inc., Whitehouse Station, NJ), which produces crystalluria and calculi consisting of the intact drug.

The generally recommended approach to the management of hematuria depends on the cause; however, the mainstay of treatment initially is hydration. If hematuria persists beyond several days, clotting factor replacement therapy to raise factor activity levels to 50% of normal should be administered. Antifibrinolytic agents generally should be avoided because they may precipitate intraureteral clot formation, which can lead to obstruction of the collecting system and eventual renal failure.

Intracranial Hemorrhage

The most common cause of death from bleeding in patients with the hemophilias is intracranial/intracerebral hemorrhage. Intracranial hemorrhage may occur with minimal trauma, particularly in children, or spontaneously in the absence of identifiable trauma; intracranial hemorrhage is spontaneous 50% of the time in affected adults. HIV-infected hemophilia patients who receive antiretroviral protease inhibitors may have an increased risk of developing spontaneous intracranial (and intramuscular) hemorrhage.²⁹ Fifty percent of patients with intracranial hemorrhage develop permanent neurologic sequelae, and 30% of events result in death. Presenting clinical symptoms usually include headaches, which can be associated with nausea and vomiting, and occasional seizures. Whenever an intracranial hemorrhage is documented, suspected, or even remotely possible after head trauma, it is imperative that factor VIII or IX concentrate (appropriate to the type of hemophilia) be administered immediately to achieve 100% of normal factor activity. This treatment must precede any diagnostic testing. CT scan of the head may show no evidence of bleeding immediately after the event. In patients who require a lumbar puncture, factor VIII or IX replacement therapy should be given 15 to 30 minutes prior to the procedure to increase the factor activity to 100% of normal. If the patient has not undergone a recent recovery study to assess response to factor infusion, a clotting factor level should be performed after the factor has been infused and prior to the procedure. Because of the serious implications of ignoring an intracranial bleed, even patients with mild hemophilia and factor VIII or IX activity levels below 50% of normal should receive clotting factor replacement therapy for severe head trauma.

Gastrointestinal and Oropharyngeal Bleeding

Gastrointestinal bleeding occurs in approximately 10% to 15% of adult hemophilia patients. Anatomic lesions are more common than is spontaneous hemorrhage. Neoplastic processes, peptic ulcer disease, gastritis, and varices should be excluded as sources of bleeding. In those individuals with chronic hepatitis C and cirrhosis, varices that result from portal hypertension are the leading cause of acute bleeds. Patients with gastrointestinal hemorrhage should be treated with clotting factor replacement to at least 50% of normal activity for several days.

The oropharynx is a highly vascular area, and excessive bleeding may occur from small lacerations, a bitten tongue, and even the appearance of a new tooth. Of particular concern are retropharyngeal bleeds that may lead to upper airway obstruction.³⁰ This type of hemorrhage is a hematologic emergency and requires clotting factor replacement to levels of 80% to 100% of normal. Bleeding associated with simple dental extractions after local injections of anesthesia can be managed with oral administration of antifibrinolytic agents and topical application of fibrin sealants. If nerve block injections are used for anesthesia in more complex oral surgery, clotting factor concentrate should be administered prior to the procedure to prevent untoward hemorrhage along fascial planes in the neck, which could result in airway compromise. Major oral surgery requires clotting factor replacement to levels of between 25% and 50% of normal, along with administration of antifibrinolytic agents following surgery for 3 to 10 days. Other comments regarding surgical procedures in hemophiliac patients are discussed in Chapter 37.

Pseudotumor Formation in Hemophilia

In 1% to 2% of those with severe hemophilia, hematomas produced by repetitive bleeding episodes continue to enlarge and may encapsulate. These have the appearance of expanding masses on roentgenography and may invade contiguous structures, including bone, muscle, or soft tissue organs. Pseudotumors themselves are composed of old clot and necrotic tissue and arise because of inadequate treatment during bleeding events. Symptoms associated with expanding pseudotumors are related to the size of the encapsulated mass and the degree of compromise of the integrity of the structures they are invading. Noninvasive techniques, such as MRI, ultrasonography, and CT, should be used to diagnose pseudotumor; needle biopsy may produce serious bleeding complications. Operative biopsies and subsequent surgical removal are associated with up to 20% mortality despite adequate coverage with clotting factor concentrates. Improved surgical results may be attained if the pseudotumor is evacuated and the cavity packed with copious amounts of fibrin sealant.³¹ Adequate and immediate clotting factor replacement therapy of acute bleeds should minimize the risk of pseudotumor formation.

LABORATORY CHARACTERISTICS

Hemophilia A or B should be suspected in male patients with unusually easy bruisability and abnormal bleeding, accompanied by an isolated prolongation of the PTT. Individuals with any of the hemophilias have normal prothrombin times, platelet counts, and platelet function studies. Usually, bleeding times are normal. Mixing studies performed with equal parts of patient plasma and normal pooled plasma incubated at 37°C should show complete and prompt correction of the prolonged PTT. Correction of the PTT in the mixture at 0 and 120 minutes of incubation essentially excludes the presence of an alloantibody inhibitor directed against a specific clotting factor or the presence of a lupus-like anticoagulant directed against phospholipid in the PTT assay system (see Chapter 6).

Correction of the PTT through the mixing studies conducted at 2 hours incubation eliminates the likelihood that any weak neutralizing inhibitors are present. Factor VIII alloantibody and autoantibody inhibitors interact with the factor VIII coagulant protein in a time- and temperature-dependent manner. If a lupus-like anticoagulant is suspected, a dilute phospholipid-based assay, such as dilute Russell's viper venom time, the tissue thromboplastin inhibition time, or the platelet neutralization procedure, which uses platelets as a source of phospholipid, should be performed to confirm its presence (see Chapter 19). If a clotting factor deficiency is suspected from the mixing study, assays should be performed to determine the activity levels of specific clotting factor proteins in the intrinsic pathway of coagulation, including factors XII, XI, IX, and VIII. Such assays also define the severity of the specific clotting factor deficiency.

In general, specific clotting factor assays are performed through a PTT-based one-stage clotting time. This type of assay assumes that the level of factor VIII is rate limiting, and that all other components of the assay are present at saturating levels. The one-stage PTT assay is the most physiologic of the factor VIII assays.³² Recently, chromogenic assays for factor VIII activity have been introduced that are based on the quantity of factor Xa generated in the presence of factor VIII:C, factor IX, thrombin, calcium, and phospholipid. Chromogenic assays generally yield about 30% higher levels of factor VIII activity, compared with the standard partial thromboplastin time (PTT)-based factor VIII:C assay, in individuals who have received the B-domain deleted form of recombinant factor VIII concentrate,³³ and to a lesser degree in individuals on recombinant full-length factor VIII concentrates. Discrepancies between the one-stage clotting assay and the chromogenic assay with recombinant B-domain deleted factor VIII concentrate probably reflect differences in phospholipid content between the two assay systems. The use of a B-domain deleted factor VIII specific reference standard has resolved this discrepancy among the clotting assays and has been used to confirm that B-domain deleted factor VIII and plasma-derived factor VIII are bioequivalent.³⁴ No standardization of inhibitor quantitation (Bethesda unit calculation) uses the chromogenic assay.

In individuals having low levels of factor VIII activity, especially females, VWD type 2N must be considered. These individuals are phenotypic hemophilic patients with normally functioning VWF protein in ristocetin-based assays and their VWF multimeric structure is normal on SDS polyacrylamide gel electrophoresis; however, assays that examine factor VIII binding to VWF protein are abnormal, reflecting the presence of an inherited point mutation in the VWF gene at the specific binding site for factor VIII. This results in a significantly decreased plasma circulation time and decreased plasma concentration for factor VIII. Additionally, the inheritance pattern is autosomal rather than X-linked.

Up to 35% of individuals with severe hemophilia A and 1% to 4% of those with hemophilia B will develop alloantibody inhibitors. These neutralizing alloantibodies should be suspected in hemophilic patients in whom recovery (the percent incremental response to clotting factor concentrate 15 to 30 minutes after administration) of clotting factor activity levels is less than 60% of the expected increase beyond baseline levels. The inhibitor can be quantitated

through the Bethesda assay,³⁵ in which residual clotting factor activity in a mixture of patient plasma and pooled normal plasma (PNP) is determined by means of a one-stage clotting time. One Bethesda unit (BU) is arbitrarily defined as the amount of antibody in a patient's plasma that causes a 50% decrease in factor VIII activity in PNP after incubation at 37°C for 2 hours. Although this assay originally was developed for use in patients with hemophilia A, the same procedure is useful for quantitating inhibitors in patients with hemophilia B and those with autoantibodies directed against clotting factors.

Autoantibody inhibitors directed specifically against factor VIII (acquired hemophilia) and less commonly against factor IX may occur in individuals with previously normal coagulation. In acquired hemophilia, quantitation through the Bethesda assay may not accurately reflect the bleeding tendency because these autoantibodies follow type II pharmacokinetics with a nonlinear neutralization pattern and incomplete inactivation of factor VIII activity, even at the highest concentrations (see Chapter 6).³⁶

Low-titer inhibitors (low responders) are defined as patients having less than 5 BU—a level that does not rise after reexposure to the clotting factor protein contained in replacement therapies (anamnestic response). High-titer inhibitors are defined as greater than 10 BU in association with significant anamnesis soon after reexposure to clotting factor concentrate (high responders). Individuals with antibody titers between 5 and 10 BU may be high or low responders, depending on the presence or absence of anamnesis. A modification of the Bethesda assay, the Nijmegen assay, was developed to improve the specificity and reliability of detecting low-titer inhibitors in the range of 0 to 0.8 BU. Both test and control mixtures are buffered with an imidazole buffer to stabilize the pH at 7.4, and the original buffer in the control mixture is replaced by immunodepleted factor VIII-deficient plasma to attain comparable protein concentrations in both mixtures.³⁷ This assay is generally reserved for clinical research studies in which detection of the presence of low-titer inhibitors is important.

THERAPEUTIC MODALITIES FOR THE HEMOPHILIAS

Hemophilia Treatment Centers

Hemophilia treatment centers (HTCs) provide comprehensive medical and psychosocial services to patients and their families with inherited bleeding disorders. Through a multidisciplinary team of nurses, physicians, psychosocial professionals, and laboratory technologists, state-of-the-art care is provided for patients with hemophilia and its complications. A survival advantage for patients with hemophilia has been shown for those patients followed and treated at an HTC.³⁸ Additionally, HTCs provide more cost-effective care, can distribute considerably less expensive clotting factor concentrates to patients (through the Public Health Service 340B Drug Pricing Program), and facilitate patient independence by training patients and family members to infuse clotting factor concentrate at the first sign of bleeding, or when prophylaxis against bleeding is desired. In the United States and Canada, HTCs are subsidized by funding from their respective federal governments.

Clotting Factor Replacement Therapy With Coagulation Factor Concentrates

Replacement of factor VIII or IX to hemostatically adequate plasma levels for prevention or treatment of acute bleeding forms the basis of management in hemophilia (Tables 4-1 and 4-2). Treatment should be administered at early onset of symptoms to limit the amount of bleeding and to prevent damage to the surrounding tissues. Replacement therapy should also be administered immediately before surgery to minimize intraoperative bleeding complications, or prophylactically to prevent hemophilic arthropathy.

Factor VIII and factor IX replacement products may be derived from plasma or may be genetically engineered through recombinant technology that uses mammalian cell lines transfected with normal human genes that code for clotting factor proteins (Tables 4-3 and 4-4). Factor replacement products are often classified on the basis of their final purity, defined as specific activity (international units [IU] of clotting factor activity per mg of protein). Intermediate purity products have relatively low specific activities (<50 IU/mg) because they are contaminated by additional plasma proteins, including von Willebrand factor, fibrinogen, fibronectin, and other noncoagulant proteins. High-purity (>50 IU/mg) and ultra-high-purity (>3000 IU/mg for factor VIII concentrates; >160 IU/mg for factor IX concentrates) products contain few or no contaminating plasma proteins other than albumin as a stabilizer. Recently, albumin-free final formulations of recombinant “full-length” and B-domain

Table 4-1 Product Dosing

Type of Bleed	Goal of Therapy (% Clotting Factor Activity Level)
Joint Dental	>30–50
Genitourinary Gastrointestinal	50
Muscle	>80
Intracranial	100
Factor IX dose to be administered = (weight in kg × desired change in clotting factor activity level)*; 1 IU factor IX concentrate per kilogram is estimated to raise the clotting factor IX activity level in plasma by 1%. Factor VIII dose to be administered = {1/2} factor IX dose; 1 IU factor VIII concentrate per kilogram is estimated to raise the clotting factor VIII activity level in plasma by 2%. Consider the use of recombinant factor VIII or IX concentrates in those individuals not previously exposed to blood products, or who are human immunodeficiency virus (HIV) and/or hepatitis C seronegative. For high titer or for refractory bleeding associated with factor VIII or IX alloantibody inhibitors: Recombinant factor VIIa concentrate, 90 µg per kilogram intravenous bolus every 2 to 3 hours until bleeding ceases (larger dosing regimens are experimental but may be useful in refractory bleeding). This product is the treatment of choice for individuals with factor IX alloantibody inhibitors and anaphylaxis and/or renal disease associated with the use of factor IX-containing concentrates. FEIBA VH: 50 to 100 IU per kilogram intravenous infusion, not to exceed 200 IU/kg/24 hr.	

*Need to multiply calculated factor IX dose by 1.2 when factor IX deficiency is replaced with recombinant factor IX concentrate.

Table 4-2 Options for Acute and Chronic Replacement Treatment of Individuals with Alloantibody Inhibitors to Factor VIII or IX

Desmopressin (0.3 µg per kilogram in 50 mL normal saline administered IV over 20 min); may be useful for raising factor VIII activity levels for a short time in individuals with low-titer FVIII alloantibodies and minor bleeds, or in anticipation of minor surgery. Not effective for factor IX.

High doses of FVIII or FIX concentrate (200 IU per kilogram); effective in preventing or treating acute bleeding episodes in low-titer inhibitors (≤5 Bethesda units and absent anamnestic responses); daily dosing may provide an effective approach to suppressing high-titer inhibitors (>5 Bethesda units with anamnestic responses) in immune tolerance induction regimens.

Daily administration of factor concentrates (50–200 IU per kilogram); may be an effective approach to suppressing low-titer inhibitors (≤5 Bethesda units), particularly when immune tolerance induction regimens are initiated within weeks after the alloantibody inhibitor is developed.

Cyclophosphamide, intravenous immune globulin, and daily factor concentrates (50–200 IU per kilogram); may be more effective in suppressing high-titer and high-responding anamnestic inhibitors or refractory low-titer alloantibody inhibitors as part of immune tolerance induction regimens; concern about increased susceptibility to opportunistic infections and potential leukemogenesis of alkylating agent.

Rituximab (375 mg/m²) to suppress the lymphocyte clone(s) responsible for synthesizing the alloantibody; to be used in conjunction with daily administration of clotting factor concentrates (experimental).

Treatment of bleeding episodes with “bypassing agents”; useful for reversing or preventing hemorrhagic complications in those with high- or low-titer alloantibody inhibitors; in those with factor IX alloantibody inhibitors and prior anaphylactic responses or nephrotic syndrome complications with plasma-derived bypassing agents, recombinant factor VIIa concentrate replacement therapy is considered the treatment of choice for acute bleeding episodes.

deleted factor VIII concentrates and a third-generation “full-length” factor VIII concentrate manufactured in the absence of any added mammalian protein have become available. Monoclonal antibody-purified, plasma-derived factor IX concentrate and recombinant factor IX concentrate are free of albumin.

All coagulation factor concentrates, plasma-derived and recombinant, have been subjected to some method of viral inactivation, attenuation, or elimination. These techniques include high dry heating, pasteurization, and solvent detergent extraction used singly or in combination. Viral safety may be further enhanced by the addition of immunoaffinity chromatography (monoclonal antibody purification) and gel filtration chromatography steps to segregate the desired therapeutic clotting factor protein from contaminating proteins and viruses. Viral attenuated plasma-derived factor concentrates have been eradicated of lipid-enveloped viruses such as HIV, West Nile virus, and hepatitis B and C, and no transmissions of these diseases have been documented since 1985 for factor VIII concentrates, and since 1990 for factor IX concentrates. Non-lipid-enveloped viruses such as hepatitis A and parvovirus B19 are not susceptible to these techniques, and sporadic outbreaks have been reported.^{39,40}

All patients who are to receive clotting factor concentrates should be vaccinated against hepatitis A and B during infancy. Recombinant factor concentrates by definition will not

Table 4-3 Clotting Factor Concentrates Available in the United States

Type/Product Name	Manufacturer	Method of Viral Inactivation	Specific Activity (IU/mg Protein, Discounting Albumin)
Ultrapure Recombinant			
Advate rAHF PFM (third-generation full-length rFVIII)	Baxter BioScience (Switzerland)	Solvent detergent (TNBP/polysorbate 80), Triton X 100; immunoaffinity chromatography; ion exchange	4000–10,000 (albumin free; no human or animal protein used in the culture medium or manufacturing process)
Helixate FS (second-generation full-length rFVIII)	CSL Behring (Germany)	Solvent detergent (TNBP/polysorbate 80); immunoaffinity chromatography; ion exchange; ultrafiltration	2600–6800 (human albumin-free final formulation; sucrose as stabilizer)
Kogenate FS (second-generation full-length rFVIII)	Bayer (USA)	Solvent detergent (TNBP/polysorbate 80); immunoaffinity chromatography; ion exchange; ultrafiltration	2600–6800 (human albumin-free final formulation; sucrose as stabilizer)
ReFacto (second-generation rFVIII, B-domain deleted)	Wyeth (Sweden)	Solvent detergent (TNBP/Triton X 100); immunoaffinity chromatography; ion exchange; nanofiltration	13,000 (human albumin-free final formulation)
Recombinate AHF (first-generation full-length rFVIII)	Baxter BioScience	Immunoaffinity, ion exchange chromatography (bovine serum albumin used in culture medium for Chinese hamster ovary cells)	>4000 (human albumin as a stabilizer)
Ultrapure Plasma-Derived (Immunopurified by Monoclonal Antibody Chromatography)			
Monoclante P	CSL Behring	Pasteurization (heated in solution, 60°C, 10 hr); immunoaffinity chromatography	No intact von Willebrand factor protein; >3000
Hemofil M AHF	Baxter BioScience	Solvent detergent (TNBP/octoxynol 9); immunoaffinity chromatography	>3000
Monarc-M	Baxter/American Red Cross (with recovered plasma from the American Red Cross)	Solvent detergent (TNBP/octoxynol 9); immunoaffinity chromatography	>3000
Intermediate-Purity and High-Purity Plasma-Derived			
Alphanate	Grifols (United Kingdom)	Solvent detergent (TNBP/polysorbate 80); affinity chromatography; dry heat (80°C, 72 hr)	140 (contains von Willebrand factor [VWF] protein; >400 IU per milligram after correction for VWF content)
Humate P	CSL Behring	Pasteurization (heating in solution, 60°C, 10 hr)	38 (contains large amount of VWF protein)
Koate DVI	Talecris (USA)	Solvent detergent (TNBP/polysorbate 80) and dry heat (80°C, 72 hr)	50–100 (contains VWF protein)

Table 4-4 Factor IX Concentrates Available in the United States

Type/Product Name	Manufacturer	Method of Viral Inactivation	Specific Activity (IU/mg Protein, Discounting Albumin)
Ultrapure Recombinant Factor IX			
Benefix	Wyeth (Sweden)	Nanofiltration; affinity chromatography	>200 (no albumin added to final product; no animal- or human-derived protein in cell culture)
Very Highly Purified Plasma-Derived Factor IX			
Alphanine	Grifols (United Kingdom)	Solvent/detergent (TNBP/polysorbate 80); dual-affinity chromatography; nanofiltration (viral filter)	>200
Mononine	CSL Behring (Germany)	Sodium thiocyanate and ultrafiltration; monoclonal antibody immunoaffinity chromatography	>190
Low-Purity Plasma-Derived Factor IX/Prothrombin Complex Concentrates (Nonactivated)			
Bebulin VH	Baxter BioScience (Austria)	Vapor heat (60°C, 10 hr, 1190 mbar; then 80°C, 1 hr, 375 mbar)	<50
Profilnine SD	Grifols	Solvent detergent (TNBP/polysorbate 80)	<50
Proplex-T	Baxter BioScience	20% ethanol, dry heat (60°C, 144 hr)	<50

transmit any of the hepatitis, HIV, or parvovirus B19; however, if they contain human albumin as a stabilizer, the theoretical concern has been raised that they could transmit the prion(s) associated with Creutzfeldt-Jakob disease (CJD) or variant CJD. Up until this time, longitudinal epidemiologic surveillance and autopsy studies analyzing postmortem brain tissue from individuals with hemophilia have yielded no evidence for transmission of CJD despite repeated exposure to blood products. However, recent reports from the United Kingdom confirm that variant CJD can be transmitted through blood transfusions, thus justifying longitudinal surveillance for this and other blood-borne pathogens within the hemophilia population.

All commercially available factor VIII replacement concentrates appear to be equally efficacious, with equivalent postadministration recovery levels observed for plasma-derived and recombinant full-length and B-domain deleted factor VIII preparations.^{34,41} The dosing of clotting factor replacement therapy in hemophilia is based on the patient's plasma volume, the distribution of the clotting protein between intravascular and extravascular compartments, the circulating half-life of the clotting factor within the plasma, and the level of clotting factor activity required to achieve adequate hemostasis or prophylaxis. Dosage is calculated by assuming that 1 IU per kilogram of body weight of factor VIII concentrate will raise the plasma activity of factor VIII by approximately 0.02 IU per milliliter (2%), and 1 IU per kilogram of factor IX concentrate, which has a larger volume of distribution, will increase plasma factor IX levels by 0.01 IU per milliliter (1%).

Administration of the recombinant factor IX concentrate may yield recoveries that are 80% of expected at 15 to 30 minutes, requiring a correction factor of 1.2 when the dose to be infused is calculated. Not all individuals with hemophilia B exhibit this variation in recovery, necessitating baseline recovery studies before treatment with the product is begun.

The circulating half-life for factor VIII is 8 to 12 hours; for factor IX, it is around 18 hours. Optimal hemostatic plasma levels of factors VIII and IX vary according to the clinical situation. "On-demand" regimens administer factor concentrate at the time of the hemorrhagic event; levels of 30% to 50% of normal clotting factor activity are required to control bleeding of minor to moderate severity, to prevent recurrent hemorrhage, and to support tissue healing. Levels of 50% to 100% clotting factor activity should be achieved and maintained for a minimum of 7 to 10 days to treat or prevent life- and limb-threatening hemorrhage or for major surgical procedures (see Chapter 37). Routinely, clotting factor replacement therapy is delivered by bolus infusion immediately after reconstitution.

The use of continuous infusion regimens for clotting factor replacement has become more common, especially in the postoperative setting. Continuous infusion maintains a stable and continuous therapeutic level of factor activity without a "peaks and troughs" effect. This translates into a decrease in the total amount of factor infused (and therefore decreased cost of care) and easy laboratory monitoring with random blood samples.⁴² None of the clotting factor concentrates have been licensed for use as

a continuous infusion. Many of the HTC's have developed their own protocols for preparation, infusion, and standards of safety with little risk of infection. These protocols are developed in cooperation with research pharmacists. How much added albumin is necessary to maintain the stability of a particular product is not defined. Currently, infusion pumps have not been licensed for use with clotting factor concentrates.

The choice of which clotting factor concentrate to administer to individuals with hemophilia A or B should be individualized; participation of the patient or family in this decision is essential. Consideration should be given to cost, age of the patient, presence of an alloantibody inhibitor, and HIV and hepatitis C virus (HCV) status. In addition, some practitioners who treat patients with hemophilia believe that the ultra-high-purity factor VIII concentrates (devoid of VWF protein), both plasma-derived and recombinant types, may have a greater tendency to induce alloantibody development.⁴³ Because of this belief, they will not use these products in previously untreated patients. The literature suggests, however, that the increased incidence of alloantibodies with these factor VIII concentrates actually may be related to increased surveillance testing for alloantibodies with the use of very sensitive assays.⁴⁴ Factor VIII concentrates of intermediate purity have been shown to inhibit normal lymphocyte immune responses *in vitro*, probably through extraneous proteins or the presence of transforming growth factor (TGF)- β within the preparations. Absolute CD4 lymphocyte counts have been shown to decrease more quickly in HIV-seropositive patients with factor VIII concentrates of intermediate purity than in those who use ultra-high-purity products⁴⁵; however, this has not been shown to affect survival in hemophiliacs with acquired immunodeficiency syndrome (AIDS) or with progression of asymptomatic to symptomatic HIV disease. Similar immune effects have been reported with factor IX concentrates.

The choice of which factor IX concentrate to administer should take into account the thrombogenic potential of the intermediate-purity products, which contain some activated factors II, VII, and X, in addition to IX. Prolonged and repeated use of these intermediate products has been associated with the development of disseminated intravascular coagulopathy, stroke, and myocardial infarction; this risk is increased further in patients with hepatic insufficiency. This fact may be related to the cumulative and sustained procoagulant effects of the activated clotting factors Xa and IIa, which have considerably longer circulating half-lives than factor IX. Little or no thrombogenicity has been observed with the ultra-high-purity factor IX plasma-derived or recombinant concentrates; therefore, these products are more appropriate for immune tolerance induction regimens, primary prophylaxis, and surgery. Despite the risk of thrombogenicity, when used appropriately, intermediate-purity factor IX concentrates are safe and effective.

New methods of delivering and producing factor concentrates are being investigated. Clinical trials have begun to study a factor VIII concentrate with a half-life of days rather than hours. A recent report described improved production of factor VIII via the mammary glands of transgenically altered pigs; this may provide a ready source of recombinant factor for developing countries.⁴⁶

DDAVP

1-Deamino-8-D-arginine vasopressin (DDAVP) plays an important role in the management of patients with mild hemophilia A. Intravenous infusion of DDAVP at a dose of 0.3 μ g per kilogram of body weight in 50 mL of normal saline over 30 minutes, or intranasal spray of 150 μ g per nostril produces a rise in circulating factor VIII and VWF protein levels by two- or threefold over the patient's baseline level through induction of exocytosis of factor VIII/VWF from Weibel-Palade bodies in endothelial cells, and perhaps from α granules in platelets. The peak effect of the intravenous form is seen in 30 to 60 minutes,⁴⁷ and the intranasal form peaks 60 to 90 minutes⁴⁸ after administration. Thus, DDAVP can be given in advance of dental work and minor surgical procedures or at the time of acute spontaneous or traumatic bleeding events to avoid the need for factor VIII replacement products. DDAVP can be administered every 12 to 24 hours; however, tachyphylaxis often develops because of the depletion of factor VIII/VWF from their storage sites. Common adverse effects associated with the use of DDAVP include flushing, hypertension, and retention of free water. This last effect can induce severe hyponatremia, especially in infants and the elderly, and can precipitate the onset of seizures. Therefore, free-water fluid intake should be restricted and serum sodium levels monitored in these individuals. Of concern in the elderly population is the occurrence of angina pectoris, stroke, and coronary artery thrombosis; DDAVP should be used cautiously in this population. DDAVP releases tissue plasminogen activator from endothelial cells and may stimulate local fibrinolysis, particularly on mucosal surfaces. Therefore, for bleeding in the gastrointestinal or genitourinary tract or in the oropharyngeal area, antifibrinolytic agents (see below) should be administered concurrently with DDAVP.

ANCILLARY TREATMENTS

Antifibrinolytic Agents

Antifibrinolytic agents are a useful but underused form of ancillary therapy in the management of patients with hemophilia A or B. By inhibiting fibrinolysis of the thrombus by plasmin, antifibrinolytics can maintain the integrity of the clot and prevent hemorrhage. They are particularly useful in the management of mucous membrane bleeding from the oropharynx, nose, and genitourinary tract because secretions from these sites naturally contain fibrinolytic enzymes. ϵ -Aminocaproic acid (EACA) (Amicar; Xanodyne Pharmaceuticals, Inc., Newport, Ky) and tranexamic acid (Cyklokapron) may be administered intravenously, orally, or topically in patients with hemophilia. These medications can be used alone or in conjunction with DDAVP for the prevention or control of bleeding. Optimum dose and duration have not been well defined, but Amicar is usually dosed at 50 mg per kilogram every 6 hours for 3 to 10 days, and Cyklokapron is given at a dose of 1.5 g every 6 hours for 3 to 6 days.

Fibrin Glues or Sealants

Fibrin glues, also known as fibrin sealants or fibrin tissue adhesives, are composed of thrombin, fibrinogen, and

sometimes factor XIII and antifibrinolytic agents (see Chapter 29). Major benefits have been attained when fibrin sealants are combined with continuous or bolus infusions of factor concentrate. A “swish and swallow” regimen with tranexamic acid solution daily for 2 weeks can be used after fibrin sealant has been applied topically to sites of oral surgery.⁴⁹ Fibrin tissue adhesives have been used very successfully and have reduced bleeding in patients with hemophilia who undergo orthopaedic surgery.⁵⁰ The fibrin sealants available in the United States have been virally inactivated.

PROPHYLAXIS/INDWELLING VENOUS ACCESS DEVICE

With the increased safety of coagulation factor replacement products, primary prophylaxis regimens with factor VIII or IX concentrates have become very acceptable. The goal of primary prophylaxis in severe hemophilia is to prevent hemarthroses and the subsequent development of hemophilic arthropathy. Primary prophylaxis is initiated prior to or after the first hemarthrosis, usually around the age of 14 to 18 months, at the time that the child begins to walk. Enough factor replacement therapy is administered to maintain coagulation factor trough levels of only 1% to 3% activity, which reduces the incidence of spontaneous hemarthrosis. In severe hemophilia A, this is usually achieved by infusing factor VIII concentrate on Monday and Wednesday at a dose of 25 to 40 IU per kilogram, and on Friday at a dose of 40 IU per kilogram. For severe hemophilia B, dosing with factor IX concentrate at 25 to 40 IU per kilogram occurs twice weekly, usually on Monday and Thursday. Primary prophylaxis has been shown (1) to decrease the total number and frequency of all bleeding episodes; (2) to decrease the frequency of repetitive joint bleeds; (3) to decrease the rate of deterioration of the joint as observed on x-ray; (4) to reduce the number of days lost from school; and (5) to decrease the number of days spent in the hospital undergoing treatment for severe bleeds.

To administer clotting factor two or three times per week, it may be necessary to implant an indwelling venous access device when peripheral access is unavailable. This is especially true for small children. Venous access devices consist of Port-a-Caths, which do not require daily care by the family, and Hickman or Broviac catheters. These indwelling venous access devices, however, are the cause of most of the complications associated with prophylaxis. Systemic infections complicate the long-term use of venous access devices in 10% to 50% of patients with hemophilia. Catheter-related thromboses in the upper extremities occur up to 50% of the time. To reduce the risk of thrombosis, it is standard procedure to flush the catheters after use with 20 mL of normal saline and 300 to 500 U of unfractionated heparin (3- to 5-mL volume).

The short-term costs of clotting factor replacement in primary prophylaxis are greater than those associated with on-demand therapy; however, the long-term cost savings may be greater with primary prophylaxis if patients' joints are preserved, if their lives are more productive financially and personally, and if expensive surgical interventions can be avoided.⁵¹ Longitudinal randomized controlled studies

currently are being conducted to confirm these premises. Secondary prophylaxis can be used in patients with target joints who are experiencing recurrent events. Coagulation factor concentrate is administered similarly to primary prophylaxis but over a limited period of 3 to 6 months.

Dental Care

Routine dental treatment can be a major source of morbidity in individuals with hemophilia. The best dental care is aimed at the prevention of dental caries, gingivitis, and periodontal disease. Caries are prevented by periodic fluoride applications. Sealants can be applied to the biting surfaces of molar teeth to reduce the incidence of caries. Gingival disease can be reduced by controlling the development of dental plaque through effective tooth brushing and the use of antibacterial mouth rinses such as chlorohexidine. Early dental care of children with hemophilia provided by a dental team whose members coordinate their efforts with the hemophilia treatment center is essential. If patients with severe hemophilia require extractions or oral or periodontal surgery, clotting factor replacement therapy may be necessary. For mild hemophilia, DDAVP administration immediately prior to the procedure is sufficient. Antifibrinolytic agents should be used as adjunctive therapy. The dose and duration of EACA therapy are variable but range from as low as 500 mg as a total dose for minor work to as high as 50 mg per kilogram of body weight every 6 hours for 3 to 10 days for extensive procedures.

TREATMENT COMPLICATIONS

Inhibitors

A major complication of treatment with coagulation factor concentrates in hemophilia is the development of alloantibodies directed against factor VIII or IX. The development of these alloantibodies in patients with severe hemophilia A occurs more frequently with the use of ultra-high-purity factor concentrates (plasma derived and recombinant) than with intermediate-purity factor concentrates (occurs in 15% to 35% of patients with hemophilia A and in 1% to 4% of those with severe hemophilia B).⁵² Approximately 50% of factor VIII or IX inhibitors are low titer and transient. High-titer, high-responding inhibitors present the major clinical concern. Alloantibody inhibitors occur after at least one infusion of factor concentrate and at a median of 9 to 12 exposure days. They do not occur naturally prior to any factor exposure. Most alloantibody inhibitors occur before the age of 20, are immunoglobulin G (IgG) subclass 4 or 1, and follow type 1 pharmacokinetics (characterized by specific and total neutralization of factor VIII or IX procoagulant activity). Risk factors for the development of these inhibitors include increased severity of hemophilia (patients with severe disease are affected to a much greater degree than are those with moderate or mild disease, probably because they are also more heavily treated), age (younger rather than older), race (blacks and Hispanics are more often affected than whites for factor VIII alloantibodies; Scandinavians are more commonly affected than other ethnicities for factor IX alloantibodies), family incidence of inhibitors (increased incidence among brother pairs and

maternal relatives), and extent and type of genetic mutation underlying the hemophilia (intron 22 inversion for factor VIII inhibitor; large gene deletions for factor IX inhibitor).

The development of an alloantibody inhibitor should be suspected when active bleeding does not subside despite the administration of clotting factor concentrate in doses deemed sufficient to raise factor VIII or IX activities to adequate hemostatic levels. Once suspected, the alloantibody inhibitor can be detected and measured in the laboratory with use of the Bethesda assay. By definition, the recovery study, performed by infusing clotting factor concentrate to achieve a level of 100% of normal activity, will yield less than 60% of expected values 15 to 30 minutes after factor infusion. Ideally, this maneuver should be performed after a “washout period” of 72 to 96 hours without factor administration. The immediate management of inhibitors consists of treating the acute bleeding event; long-range management involves the reduction/eradication of the inhibitor. Sources of the specific clotting factor should be withheld indefinitely unless immune tolerance induction is to be attempted. This withholding will allow the inhibitor titer to drop spontaneously over time. Acute bleeding events associated with low-titer factor inhibitors (<5 BU) can be managed by overwhelming the inhibitor with large doses of human clotting factor concentrate (200 IU/kg). For high-titer inhibitors, alternative clotting factor concentrates must be used because human factor concentrates cannot overwhelm the inhibitor (see Table 4-3). Porcine factor VIII concentrate (Hyate C; Ipsen, Maidenhead, UK) is particularly useful in allo- or auto-factor VIII antibody situations because low cross-reactivity is observed between anti-human factor VIII antibodies and the porcine-derived factor VIII coagulant protein. Porcine factor VIII concentrate is the only inhibitor treatment available that allows for the measurement of circulating factor VIII activity levels after infusion. Disadvantages of this product include anamnestic antibody generation against human or porcine factor VIII, episodic thrombocytopenia, and rare anaphylaxis. Although no transmission of blood-borne infectious agents, including parvovirus,⁵³ has been documented, Hyate C was removed from production in 2004 because of porcine parvovirus contamination. Clinical trials of a recombinant porcine factor VIII product are under way.

Infusions of so-called bypassing agents offer another useful treatment modality for bleeding associated with factor VIII allo- and auto-antibodies. These products include factor IX complex concentrates (also known as prothrombin complex concentrates, or PCCs) of the unactivated and activated varieties and recombinant factor VIIa

concentrate. PCCs have an increased risk of thromboembolic events, and repeat dosing is based on clinical response after infusion. Usual doses range from 50 to 100 IU per kilogram given as intravenous boluses every 8 to 12 hours, as needed. Recombinant factor VIIa (rFVIIa) concentrate (NovoSeven; Novo Nordisk, Princeton, NJ) has a low but finite risk of thromboembolic events, particularly in older individuals, and requires repetition of IV bolus infusions every 2 to 3 hours at a dose of 90 µg/kg until bleeding is controlled.⁵⁴ No useful laboratory measurement is available; factor VII levels are very high and prothrombin times are substantially reduced yet neither is predictive for adequate hemostasis. The management of acute bleeding events in hemophilia B complicated with high-titer inhibitors also involves the use of PCCs or recombinant rFVIIa (Table 4-5).

Immune tolerance induction (ITI) regimens have been devised to reduce the levels of alloantibodies against factors VIII and IX. ITI is a prolonged desensitization process in which immune system production of inhibitory antibody is suppressed permanently after prolonged daily infusions of clotting factor concentrate. During this induction period, anamnestic antibody responses may occur, necessitating the use of one of the bypassing agents to manage acute bleeding events. Successful ITI can be achieved in approximately 50% of high-titer inhibitors, but ITI has been most successful in low-titer inhibitors, which have been present for less than one year.⁵⁵ More than 60% of individuals achieve inhibitor levels lower than 1 BU within 6 months of initiating ITI; by 1 year, 80% have levels lower than 1 BU. By 30 months, 90% have been successfully tolerized according to clotting factor kinetics and recovery data. A variety of protocols for ITI have been developed, including high-dose regimens that infuse up to 200 IU of clotting factor concentrate per kilogram of body weight per day and low-dose regimens of 50 IU clotting factor per kilogram of body weight administered daily. Once the inhibitor resolves, patients are placed on prophylaxis regimens indefinitely, with bolus infusions of factor VIII concentrate thrice weekly or factor IX concentrate twice weekly. Initial immunosuppressive therapy with cyclophosphamide or glucocorticosteroids was included, as were infusions of intravenous immune globulin, in some ITI regimens; however, this approach has fallen out of favor because of its increased potential for resultant infection and malignancy. Because ITI success is better with low-titer inhibitors, occasionally, plasmapheresis is used to acutely decrease a high-titer inhibitor to low titers. This improves the success of clotting factor infusions given to reverse bleeding and facilitates the initiation of ITI.

Table 4-5 Inhibitor Therapy		
Type/Product Name	Manufacturer	Method of Viral Attenuation
FEIBA VH (pooled human plasma-derived prothrombin complex concentrates/factor IX complex concentrate-activated)	Baxter BioScience (Switzerland)	Vapor heat (60°C, 10 hr, 1190 mbar; then 80°C, 1 hr 375 mbar)
NovoSeven (recombinant factor VIIa [rFVIIa]) (no albumin added to final formulation; stabilized in mannitol; bovine calf serum used in culture medium)	Novo Nordisk (USA)	Affinity chromatography Solvent/detergent (TNPB/polysorbate 80)

INFECTIOUS COMPLICATIONS OF REPLACEMENT THERAPY IN HEMOPHILIA: HIV, HEPATITIS, AND PARVOVIRUS B19

AIDS was first identified in individuals with hemophilia in 1981, and by 1984, more than 90% of patients with severe hemophilia A and 50% with severe hemophilia B were HIV seropositive. The HIV virus was contracted from repeated infusions of plasma-derived coagulation factor replacement products in this population of obligate recipients. In 1984, high dry heating and pasteurization techniques for viral attenuation were introduced into the manufacturing process of factor VIII concentrates. Shortly thereafter, solvent detergent treatment regimens were developed. All of these processes were added to the manufacture of factor IX concentrates in the late 1980s. Combined with strict donor viral screening protocols and intensive donor self-exclusion programs in the United States, these viral attenuation processes have prevented since the late 1980s any documented HIV or HCV seroconversions produced by the use of plasma-derived clotting factor concentrates. Recombinant factor concentrates would not be expected to transmit these blood-borne pathogenic viruses. Unfortunately, viral attenuation processes are effective only against lipid-enveloped viruses such as HIV, HCV, and hepatitis B virus (HBV), but not against parvovirus B19, hepatitis A virus (HAV), or Creutzfeldt-Jakob prions.

Patients with HIV and hemophilia have benefited from the introduction of anti-HIV protease inhibitor medications. An increase in bleeding severity and frequency with unusual sites of bleeding has been a hallmark complication in some hemophilia patients treated with these medications. The cause remains unclear but may involve the development of qualitative platelet defects.²⁹

Prior to the availability of the specific hepatitis B vaccine, hepatitis B was found in as many as 70% to 90% of severe hemophilia patients. HCV seroprevalence is greater than 90% in hemophilia patients treated with plasma-derived factor concentrates prior to 1985. Coinfection of HCV and HIV has resulted in high morbidity, increasing the risk of cirrhosis, hepatocellular carcinoma, and liver failure. Currently, treatment with pegylated interferon-alpha and ribavirin provides the greatest response rate and longest duration of HCV suppression.⁵⁶ The best and most durable responses to this therapeutic regimen are observed in those with the lowest HCV RNA viral titers and with HCV genotypes other than type 1. Hemophilia patients most commonly have been infected with HCV genotypes 1 and 3. All those diagnosed with hemophilia should be vaccinated against HBV starting at birth or the time of diagnosis, and against HAV at 2 years of age, or older if found to be seronegative.

The seroprevalence of parvovirus B19 in hemophilia is 80%—significantly higher than the normal population matched for age and socioeconomic status. This non-lipid-enveloped virus, similar to hepatitis A, is not eradicated from plasma-derived clotting factor concentrates through currently used viral attenuation techniques. Acute parvovirus B19 infection usually is asymptomatic when acquired through blood products; however, rarely, it may induce aplastic anemia or pure red cell aplasia, particularly in the presence of HIV. The vertical transmission of parvovirus in pregnant women may cause hydrops fetalis.

Creutzfeldt-Jakob disease (CJD) is a rare, incurable, fatal degenerative disease of the central nervous system that has been described as a spongiform encephalopathy. The cause of CJD has been most recently linked to a disease-causing prion protein.⁵⁷ CJD is transmitted usually through direct inoculation (most commonly associated with implants of dura mater from infected individuals) or administration of growth hormone derived from the pituitary glands of infected cadavers, and after transplantation of organs from infected donors. A new variant form of CJD has been described in cattle (“mad cow disease” [bovine spongiform encephalopathy, or BSE]) and has been transmitted to humans via ingestion of contaminated beef. Sporadic cases of human transmission of variant CJD have been reported to result from blood transfusions (none in hemophilia patients). Furthermore, prions have been identified in the buffy coat leukocytes of variant CJD-affected humans and subsequently were transmitted experimentally to rodents after those cells were inoculated into the animals’ brains. Because of an incubation time as long as 35 years, the actual potential of human-to-human transmissibility through blood transfusions and components cannot be determined readily. To reduce the theoretical risk of CJD transmission to hemophilia patients through pooled plasma-derived clotting factor concentrates, donor pools have been reduced in number; the use of recombinant replacement products has been encouraged, and albumin-free formulations and mammalian protein-free manufacturing processes for these products have been developed; screening of blood donors for CJD risks has been implemented as well. No prospective studies have been performed to determine the incidence of parvovirus B19 transmission from plasma-derived products. This is an important issue for pregnant female carriers of hemophilia A or B, who may require replacement therapy for active bleeding, for delivery, or for other purposes. Parvovirus B19 transmission is not an issue for recombinant products. No HIV transmission from plasma-derived factor VIII concentrates has been documented since 1985, nor from factor IX concentrates since 1987, when viral attenuation processes were added to replacement product manufacturing. Although sporadic cases of HCV have been reported, this also occurs in the normal population. No epidemics of HCV infection have resulted from virally attenuated factor concentrates.

GENE THERAPY

Gene therapy in the treatment of patients with hemophilia A or B has received increased interest in recent years; results from clinical studies are somewhat disappointing but promising. Plasma factor levels increased to above 1% can make a dramatic difference in clinical outcomes and quality of life for individuals with severe hemophilia A or B. Coagulation factors VIII and IX can be synthesized efficiently in a variety of somatic cell types. Thus, the hemophilias are highly amenable to gene therapy. A number of viral vectors have been used to transfer human factor VIII or IX genes into target cells. These have included retroviral vectors, adenoviral vectors, adeno-associated viral vectors, and lentiviral vectors. Potential complications of gene therapy include the

development of inhibitory antibodies,⁵⁸ the risk of integration of the transgene into essential genes in the host, and the risk of inadvertent integration of the transgene into the germline with transmission to later generations. Furthermore, strategies for gene therapy in general have been modified since a death occurred in a gene therapy trial for ornithine transcarbamylase deficiency, and because cases of acute T-cell leukemia were reported in patients with X-linked recessive severe combined immunodeficiency (SCID) treated with retroviral vectors, attributable to insertional mutagenesis. To date, the promise of a gene therapy cure for hemophilia A or B has not been realized, primarily because no gene delivery system has been nonimmunogenic enough to permit long-term expression of clotting factor activity. Six gene therapy trials have been conducted in hemophilia patients with minimal and short-lived clinical and/or laboratory improvement. Currently, no gene therapy trials are open for hemophilia, although additional trials are under review.^{59–61} Even if future gene therapy clinical trials in both hemophilia A and B are successful, approaches based on current technology will only palliate disease severity (e.g., rendering severe hemophilia into a moderate or mild case), albeit disease morbidity and mortality should be substantially reduced. Safe, effective, and reasonably priced clotting factor concentrates will be needed, even after gene therapy, to provide prophylaxis during the perioperative period; patients with acute traumatic and surgical bleeds will be treated, and ITI will be initiated should these individuals develop alloantibody inhibitors.

Until gene therapy successes are realized, other novel therapeutic approaches may offer alternative benefits, including (1) gene delivery of engineered, secreted, activated FVII; (2) applications of new viral vector technology; (3) use of nanoparticle technology for the delivery of genes to hepatocytes; and (4) gene “pharming.” Any of these, if successful, could enhance the quality of life for the individual with hemophilia.⁶¹

Chapter 5

Less Common Congenital Disorders of Hemostasis

Harold R. Roberts, MD • Miguel A. Escobar, MD

In this chapter, the less common congenital disorders of hemostasis are discussed. These include disorders of fibrinogen, prothrombin, and factors V, VII, X, and XI. In addition, the nonbleeding disorders associated with deficiencies of factor XII (Hageman factor), prekallikrein (PK), and high molecular weight kininogen (HK) are discussed because these disorders are characterized by prolonged partial thromboplastin times (PTTs) and may be confused with the procoagulant defects associated with bleeding. Furthermore, the rare bleeding syndromes of factor XIII deficiency, α_2 -plasmin inhibitor (α_2 -PI) deficiency, and α_1 -antitrypsin Pittsburgh (α_1 -ATP) are described. For the sake of completeness, the potential role of protein Z and the protein Z-dependent protease inhibitor deficiencies is considered. Although protein Z deficiencies were initially believed to be a cause of hemorrhage in humans, recent animal data suggest that defects in protein Z and the protein Z inhibitor are more likely related to thrombotic phenomena.

Certain biologic and laboratory characteristics of these factors are important in determining their clinical consequences; these are depicted in [Table 5-1](#). Clotting factors discussed in this chapter can best be classified as proenzymes, cofactors, structural proteins, or physiologic inhibitors, as shown in [Table 5-2](#). The information in these tables will help the consultant to gain an understanding of the basis for the clinical condition, as well as the diagnosis and treatment options for each deficiency, as summarized in [Table 5-3](#).

As with all hereditary disorders, deficiencies of each of the clotting factors discussed in this chapter are genetically heterogeneous.¹ Selected genetic variants are described here for several clotting factors, but the reader is referred to up-to-date registries of websites because new variants are discovered almost daily. The two registries pertinent to the clotting factor deficiencies discussed herein are www.hgmd.org (Human Gene Mutation Database) and <http://193.60.222.13/>.

DISORDERS OF FIBRINOGEN

Congenital disorders of fibrinogen can be divided into afibrinogenemia and dysfibrinogenemia.

Afibrinogenemia

Congenital afibrinogenemia is a very rare disorder that occurs in patients who have no detectable circulating

fibrinogen in the plasma or blood platelets. It was first described in 1920, and since that time, more than 200 cases have been reported.² The heterozygous state of afibrinogenemia results in low circulating levels of normal fibrinogen. These hypofibrinogenemias are discussed in the section on dysfibrinogenemias.

Pathogenesis and Genetics

Three individual genes on the long arm of chromosome 4 encode for the α , β , and γ chains that constitute the fibrinogen molecule. Fibrinogen is a homodimer that consists of two identical pairs of three chains, intertwined to form a trinodular fibrinogen structure. Fibrinogen is converted to a visible fibrin clot by thrombin, which cleaves fibrinopeptides A and B from the α and β chains, respectively. Gene defects in any of the three chains can result in afibrinogenemia. A list of reported mutations resulting in this disorder (FGA, FGB, FGG) can be found on the Internet at www.hgmd.org. The most common mutations resulting in complete absence of fibrinogen occur in the gene that encodes for the α chain.^{3,4}

Afibrinogenemia is inherited in an autosomal recessive pattern, and symptomatic individuals are homozygotes. Heterozygous individuals usually have mild hypofibrinogenemia and are asymptomatic unless the fibrinogen level is less than 50 mg/dL. The estimated incidence of congenital afibrinogenemia is approximately 1 to 2 per million of the population, and usually, a history of consanguinity is reported within the family. This disorder occurs in either sex with no known racial predilection. The characteristics of two patients with afibrinogenemia are shown in [Table 5-4](#).

Clinical Manifestations

Individuals with congenital afibrinogenemia have a lifelong bleeding tendency of variable severity. Hemorrhagic manifestations are usually observed in the neonatal period with bleeding from the umbilical cord ($\approx 75\%$) and after circumcision.⁵ In infancy or childhood, intracerebral hemorrhage is a leading cause of death.⁶ Easy bruising and mucosal, gastrointestinal, and genitourinary hemorrhages are common. Hemopericardium, hemoperitoneum, and spontaneous splenic rupture have been reported rarely.⁷ Hemarthroses occur in up to 20% of patients, but musculoskeletal bleeding that leads to chronic hemophilic arthropathy, as seen in patients with classic hemophilia, is surprisingly uncommon.⁸ Spontaneous abortions, which usually occur early in pregnancy, are common in affected women, who are also prone to menometrorrhagia, abruptio

Table 5-1 Summary of Less Common Clotting Factor Deficiencies

Factor Deficiency	Biologic Half-life	Estimated Incidence	Type of Bleeding	Screening Abnormalities	
				Abnormal	Normal
I	2–4 days	1:1 million	None to severe	PT, PTT, TCT, BT	None
II	3 days	Very rare	Mild to moderate	PT, PTT	TCT, BT
V	36 hours	1:1 million	Moderate	PT, PTT, BT	TCT
VII	3–6 hours	1:500,000	Mild to severe	PT	PTT, TCT, BT
X	40 hours	1:500,000	Mild to severe	PT, PTT	TCT, BT
XI	80 hours	1:1 million*	Mild to moderate	PTT	PT, TCT, BT
XII	50–70 hours	Unknown	No bleeding	PTT	PT, TCT, BT
XIII	9 days	1:5 million	Moderate to severe	None	PT, PTT, TCT, BT
PK	35 hours	Unknown	None	PTT	PT, TCT, BT
HK	150 hours	Very rare	None	PTT	PT, TCT, BT
α_2 -PI	3 days	Unknown	Mild to moderate	None	PT, PTT, TCT, BT
α_1 -ATP	–	Very rare	Variable to severe	PT, PTT, TCT, BT	None
Protein Z	2–3 days	Unknown	None	None	PT, PTT, TCT, BT
ZPI	Unknown	Unknown	None	None	PT, PTT, TCT, BT

*More prevalent in countries with a large Jewish population.

α_1 -ATP, α_1 -antitrypsin Pittsburgh; α_2 -PI, α_2 -plasmin inhibitor; BT, bleeding time; HK, high molecular weight kininogen; PK, prekallikrein; PT, prothrombin time; PTT, partial thromboplastin time; TCT, thrombin clotting time; ZPI, protein Z-dependent protease inhibitor.

Table 5-2 Classification of Less Common Clotting Factors

	Clotting Factor	Gene	Activator	Product
Structural Protein	Fibrinogen	4q28	Thrombin	Fibrin
Zymogen	Prothrombin	11p11-q12	Xa/Va/Ca/PL	Thrombin
	Factor VII	13q34	? Xa	Factor VIIa
	Factor X	13q34	TF/VIIa or IXa/Ca/PL	Factor Xa
	Factor XI	4q32-q35	Thrombin	Factor XIa
	Factor XII	5q33	Factor XIa	Factor XIIa
	Factor XIII	A: 6p24-p25 B: 1q31-q32	Thrombin	Factor XIIIa
Cofactor	Prekallikrein	4q35	Factor XIIa	Kallikrein
	Factor V	1q21-q25	Xa or thrombin	Factor Va
	HK	3q26	Factor XIIa	Bradykinin
	Protein Z	13q34	?	?
Inhibitors	ZPI		?	Xa inhibitors
	α_2 -PI	17p13	–	Plasmin α_2 -PI complex
	α_1 -ATP		–	Thrombin α_1 -ATP complex

α_1 -ATP, α_1 -antitrypsin Pittsburgh; α_2 -PI, α_2 -plasmin inhibitor; Ca, calcium; HK, high molecular weight kininogen; PL, phospholipid (activated platelets); TF, tissue factor; Va, activated factor V; ZPI, protein Z-dependent protease inhibitor.

placentae, and postpartum hemorrhage.^{9–11} It is surprising that thrombosis has been reported in some patients with afibrinogenemia, even in the absence of replacement therapy, but whether such patients have true afibrinogenemia as opposed to dysfibrinogenemia is not completely clear. Thrombin generation is normal in these patients and platelet aggregation occurs, even though fibrinogen is absent, which may explain why patients with undetectable fibrinogen have fewer long-term effects from repeated hemorrhaging compared with patients with classic hemophilia and similar disorders.

Diagnosis

The diagnosis of afibrinogenemia can be made on the basis of careful history and coagulation screening tests. Patients

give a long history of intermittent hemorrhagic episodes, usually in the soft tissues, and all screening tests of coagulation, including prothrombin time (PT), partial thromboplastin time (PTT), and thrombin clotting time (TCT) (also known as thrombin time [TT]), exhibit infinite clotting times. These tests normalize in vitro through 1:1 mixing with normal plasma, thereby excluding an inhibitor.

To confirm the diagnosis of afibrinogenemia, specific fibrinogen assays should be used, including clotting and immunologic methods, both of which will show no detectable fibrinogen. Bleeding time in afibrinogenemic patients is prolonged because of the absence of platelet fibrinogen.^{12,13} Mild thrombocytopenia has also been reported in $\approx 25\%$ of patients with congenital afibrinogenemia, but platelet counts are usually not lower than 100,000/ μL .¹⁴

Table 5-3 Clotting Factor Deficiencies: Treatment

Deficiency	Bleeding Symptoms	Treatment*	Target Hemostatic Level
I	Umbilical stump, joints, mucous membranes, recurrent miscarriages	Cryoprecipitate, fibrinogen concentrate [†]	>50 mg/dL
II	Soft tissue, CNS, menorrhagia	FFP, PCCs	20%–40%
V	Soft tissue, umbilical stump, postpartum, postoperative	FFP	20%–50%
VII	Soft tissue, joints, mucosal membrane	rFVIIa	15%–20%
X	Soft tissue, joints, menorrhagia	FFP, PCCs	10%–15%
XI	Postoperative and after trauma	FFP, rFVIIa, FXI concentrate [†]	30%–40%
XIII	Umbilical stump, soft tissue, CNS	FFP, cryoprecipitate, FXIII concentrate [†]	2%–5%
FCFD-type I	Postoperative and after trauma	FFP and FVIII	30%
FCFD-type III	Umbilical stump, CNS, and after trauma	Vitamin K, PCCs	As needed
α_2 -PI	Joints, hematuria, menorrhagia	Antifibrinolytics	See package insert

α_2 -PI, α_2 -plasmin inhibitor; CNS, central nervous system; EACA, epsilon-aminocaproic acid; FCFD, familial combined factor deficiencies; FFP, fresh frozen plasma; PCCs, prothrombin complex concentrates; rFVIIa, recombinant factor VIIa; TA, tranexamic acid.

*Antifibrinolytic therapy is frequently used for most clotting factor deficiencies.

[†]Not available in the United States.

Table 5-4 Characteristics of Two Patients with Afibrinogenemia

Location Defect	Genetic Defect	Symptoms	Consanguinity
α Chain	Deletion Intron 1	Umbilical cord bleeding	No
β Chain	Missense mutations in exons 7 and 8	Umbilical cord bleeding Circumcisional bleeding Muscle hematoma Hemarthroses	Yes

Delayed-type hypersensitivity skin tests in individuals with afibrinogenemia typically show only erythema and no induration because of the lack of fibrin deposition in the subcutaneous tissue.¹⁵ The erythrocyte sedimentation rate is also very slow in these individuals because fibrinogen is one of the main determinants of this rate.¹⁶

Differential Diagnosis

Hereditary dysfibrinogenemia, especially in homozygotes or combined heterozygotes, may result in very low to virtually undetectable fibrinogen levels and must be distinguished from true afibrinogenemia. Sensitive tests for fibrinogen always detect some amount of protein in dysfibrinogenemia but not in true afibrinogenemia.

Acquired fibrinogen abnormalities must also be excluded. Severe disseminated intravascular coagulation can result in virtual absence of fibrinogen, but usually, other clotting factors and platelets are also markedly decreased. Acquired hypofibrinogenemia has been reported with liver disease and with the use of certain medications such as sodium valproate¹⁷ and L-asparaginase,¹⁸ both of which impair the hepatic synthesis of fibrinogen. These acquired defects can be excluded easily through a careful history.

Treatment

The treatment of choice for individuals with afibrinogenemia and hypofibrinogenemia is cryoprecipitate, a source rich in fibrinogen. Solvent detergent-treated products are preferred for inactivating the human immunodeficiency virus and hepatitis viruses. In European countries, purified and virally inactivated fibrinogen concentrates are available. Replacement treatment is obviously indicated for episodes of active bleeding, preoperatively and during pregnancy. For achieving hemostasis, maintaining the fibrinogen level at 50 to 100 mg/dL is usually adequate. Prophylactic therapy is always indicated before operations are performed and throughout pregnancy. To avoid miscarriage, a fibrinogen level above 60 mg/dL must be maintained during the entire course of pregnancy.¹⁹

Each bag of cryoprecipitate, which contains approximately 250 to 300 mg of fibrinogen, will raise the fibrinogen level by about 10 mg/dL with an in vivo half-life of about 2 to 4 days. Thus, 5 to 10 bags of cryoprecipitate are usually adequate for an individual who weighs 70 kg. However, daily monitoring of fibrinogen levels is necessary if the fibrinogen dose is to be determined because fibrinogen levels can vary over time. For major surgical procedures (e.g., knee replacement) or severe trauma, the duration of treatment with daily fibrinogen may be as long as 2 to 3 weeks. For minor trauma, a single dose of fibrinogen sufficient to raise the level to 50 to 100 mg/dL is adequate. Administration of 1-desamino-8-D-arginine-vasopressin (DDAVP) may reduce bleeding time in some patients, but given alone, it is not adequate for hemostasis.

Complications of replacement therapy include risk of allergic reaction, transmission of viral disease, and the development of antifibrinogen antibodies.²⁰ Thrombotic phenomena have been reported in patients after the fibrinogen level has been normalized. Some episodes have occurred in women who are taking oral contraceptives, suggesting that they may have had an underlying hypercoagulable state.^{21–23} Should thrombotic phenomena occur during the perioperative period, appropriate anticoagulation therapy should be used in combination with fibrinogen replacement.²⁴

Dysfibrinogenemia

The first case of dysfibrinogenemia was reported in 1964, but since that time, several hundred other cases have been described, and numerous genetic defects leading to abnormal function have been detected.²⁵ A list of dysfibrinogens (FGA, FGB, FGG) can be found on the Internet at www.hgmd.org.

Pathogenesis and Genetics

Congenital dysfibrinogenemia is characterized by the synthesis of an abnormal fibrinogen molecule that does not function properly in its conversion from fibrinogen to fibrin. Functional defects include (1) abnormal fibrinopeptide release, (2) defects in fibrin polymerization, (3) abnormal fibrin stabilization, and (4) resistance to fibrinolysis. The most common dysfibrinogenemias are those that cause polymerization defects.²⁶

In most cases, congenital dysfibrinogenemia is inherited as an autosomal dominant trait with high levels of penetrance, but some patients exhibit an autosomal recessive inheritance pattern. Patients may be homozygous or heterozygous for the defect. Most affected individuals are heterozygous with ≈50% of normal fibrinogen, which is adequate for normal hemostasis, unless the dysfunctional molecule disrupts the function of the normal fibrinogen component. Some individuals with dysfibrinogenemia have fibrinogen levels that are well below normal.

Clinical Manifestations

Clinically, patients with dysfibrinogenemia have one of the following phenotypes: no hemorrhagic manifestations; mild to moderate bleeding, usually after trauma; thromboses; or a combination of thrombotic and hemorrhagic manifestations. Approximately 43% of all individuals with congenital dysfibrinogenemia are asymptomatic, about 20% have bleeding symptoms, and 17% report thrombotic manifestations. About 20% of patients experience a combination of bleeding and thrombosis.^{26,27} The bleeding tendency is variable, and most individuals have mild to moderate hemorrhage. Easy bruising, soft tissue bleeding, menorrhagia, and intraoperative and postoperative bleeding are the most common events. Both venous and arterial thromboses, including deep vein thrombosis of the lower extremities, pulmonary embolism, recurrent spontaneous abortion, and thrombosis of the carotid arteries and

abdominal aorta, have been associated with congenital dysfibrinogenemia.²⁶ Dysfibrinogenemias most likely associated with bleeding occur with abnormalities in the amino terminus of the α chain, although exceptions to this generalization have been found. Thrombotic manifestations, on the other hand, are most often associated with fibrinogen variants that have a free cysteine residue that results in a disulfide linkage to albumin. These variants are resistant to lysis by plasmin, which probably accounts for their thrombotic tendency. In many cases, however, thrombotic manifestations may be related to concurrent disorders (e.g., factor V Leiden, protein C deficiency) rather than to the abnormal fibrinogen molecule itself, and clinicians should be aware of these possibilities. Because a normal fibrin clot provides the necessary framework for normal wound healing, it is not surprising that poor healing and dehiscence of wounds are seen in some patients with dysfibrinogenemia.²⁸ Examples of dysfibrinogenemia in the α, β, and γ chains are shown in Table 5-5.

Diagnosis

In most cases of dysfibrinogenemia, screening tests of coagulation such as PT, PTT, and TCT are prolonged and may or may not correct with 1:1 mixing with normal plasma. This occurs because some dysfibrinogenemias interfere with normal fibrin formation. In some dysfibrinogenemias associated with thrombotic episodes, the TCT may be shorter than normal. Fibrinogen levels are variable and can be relatively normal or low. Through immunologic methods, one may encounter normal levels of fibrinogen; at the same time, reduced levels of fibrinogen can be detected on functional analysis. Other important diagnostic tests include the reptilase time and fibrinogen immunoelectrophoresis. Reptilase, derived from snake venom, cleaves fibrinopeptide A from the α chain, resulting in the formation of visible clot, even in the presence of heparin. Reptilase time is often prolonged and may be more sensitive than the thrombin time. Fibrinogen immunoelectrophoresis sometimes shows an abnormal migration in agarose gel. However, definitive diagnosis depends on biochemical characterization of the fibrinogen defect, which may require amino acid sequencing. More sophisticated diagnosis requires genetic analyses that are not available in most clinical coagulation laboratories.

Table 5-5 Examples of Dysfibrinogenemia Variants*		
Variant	Clinical Effect	Functional Defect
Chapel Hill IV	Asymptomatic	Polymerization defect
Fukuoka II	Asymptomatic	Fibrinopeptide B release defect
Chapel Hill I	Bleeding	Polymerization defect
Christchurch II	Bleeding	Fibrinopeptide B release defect
Guarenas I	Bleeding	Fibrinopeptide A release and polymerization defect
Nijmegen	Thrombosis	Associated with disulfide-linked albumin and tPA-binding defect
Naples II	Thrombosis	Fibrinopeptide A and B release defects
Paris V	Thrombosis	Polymerization defect, decreased binding of plasminogen, and decreased tPA-induced fibrinolysis
Marburg	Bleeding/thrombosis	Deletion of 150 aa with linkage to albumin

aa, amino acid; tPA, tissue plasminogen activator.
*See references 26 and 27.

Differential Diagnosis

Dysfibrinogenemias can also be acquired, particularly in patients with liver disease of varying causes. Frequently, the abnormality is due to an increase in sialic acid residues.²⁹ In dysfibrinogenemia of liver disease, other clotting proteins synthesized by the liver are low. Autoantibodies against fibrinogen in nondeficient individuals should be distinguished from dysfibrinogenemia, in that they interfere with fibrinogen function and mimic the abnormalities seen with dysfibrinogenemia. Antifibrinogen antibodies have been associated with systemic lupus erythematosus, ulcerative colitis, liver cirrhosis, and other disorders. Fibrinogen degradation products seen in many diseases may also interfere with normal fibrinogen function and may produce a condition that resembles dysfibrinogenemia.

Treatment

Therapy is obviously not indicated in patients with congenital dysfibrinogenemia who are asymptomatic. To treat dysfibrinogenemic patients who are known to bleed, fresh frozen plasma, cryoprecipitate, or fibrinogen concentrates should be administered for bleeding episodes or for preoperative procedures. In the United States, cryoprecipitate is the most commonly used replacement therapy. Guidelines provided in the afibrinogenemia section can also be applied to the dysfibrinogenemias. Dysfibrinogenemic patients who have thrombotic episodes require anticoagulation with

heparin, followed by oral anticoagulants. Recurrent thrombotic episodes require prophylactic anticoagulation with the use of low molecular weight heparin or oral anticoagulants. Women with recurrent spontaneous abortion and dysfibrinogenemia should be treated with fibrinogen replacement therapy throughout the course of pregnancy, as is stated in the section on afibrinogenemia.

PROTHROMBIN DEFICIENCY (HYPOPROTHROMBINEMIA AND DYSPROTHROMBINEMIA)

Congenital prothrombin deficiency was first described by Quick and colleagues.^{30,31} Fewer than 100 cases have been reported; examples are listed in Table 5-6.

Pathogenesis and Genetics

Various mutations in the prothrombin gene have been discovered and are listed on the Internet at www.hgmd.org (F2). These usually are caused by a missense mutation (i.e., the substitution of a single amino acid in regions that affect the function and/or structure of the prothrombin molecule).³² These mutations result in dysprothrombinemia, in which prothrombin activity is reduced and the prothrombin antigen may be normal or decreased, as is shown in Table 5-6.

Table 5-6 Prothrombin Variants*

Variant	Activity, %	Antigen, %	Bleeding Tendency
Homozygous			
Barcelona/Madrid	5–15	100	Yes
Carora	4	0	Yes

*Modified from references 27 and 48.

Prothrombin is normally converted to thrombin, which is necessary for the formation of a normal fibrin clot. Molecular defects in dysprothrombinemia may affect the amino terminal pro-piece of prothrombin or the carboxyl terminal thrombin portion of the molecule. Defects in the pro-piece usually result in delayed thrombin generation, but the thrombin that is generated functions normally. An example of a defect in the pro-piece of the molecule is prothrombin San Juan. Defects in the thrombin end of the molecule result in the generation of an abnormal thrombin, such as that seen in prothrombin Quick II. In some patients, dysprothrombinemia may be homozygous; in others, it may be heterozygous or compound heterozygous.

Dysprothrombinemia is inherited in an autosomal recessive pattern. No predilection for race is known, although many patients are of Southern European ancestry.³³ Complete deficiency of prothrombin has not been reported and is probably incompatible with life. Mice in whom the gene has been knocked out do not survive in utero—a fact that supports the important role of prothrombin in embryogenesis.

Clinical Manifestations

A weak correlation has been found between functional prothrombin levels and the clinical picture of hemorrhage. All reported dysprothrombinemic patients have had measurable prothrombin activity. This is corroborated in knockout mice when complete deficiency of prothrombin results in fatal neonatal hemorrhage.^{34,35}

In general, heterozygous patients are asymptomatic or have minor bleeding symptoms, whereas homozygous or compound heterozygous individuals have more severe symptoms. Heterozygous individuals usually have prothrombin activity levels of 50%, along with normal antigen levels.³³ Such patients are usually asymptomatic but may develop bleeding after undergoing surgical procedures. Individuals who are homozygous or compound heterozygous have symptoms of mild to moderate bleeding. These include hemarthroses and intracranial bleeding, but hemorrhage is more likely to occur at these sites when prothrombin levels are in the 4% to 7% range, as was reported in a series of patients from Iran. Other types of hemorrhage include easy bruising, epistaxis, hematoma, and postoperative bleeding. In women, menorrhagia, postpartum hemorrhage, and miscarriage have been reported.^{36,37}

Diagnosis

The diagnosis of dysprothrombinemia is suggested by a lifelong history of bleeding in patients with prolonged PT and PTT values that are corrected when mixed 1:1 with normal plasma. Bleeding time and TCT are normal. Definitive diagnosis requires a specific assay for prothrombin functional activity. Immunologic assays of prothrombin may be helpful but are sometimes normal. Patients with type I deficiency have similar levels of prothrombin on functional and immunologic assays; in type II patients, prothrombin antigen levels are normal and functional prothrombin is low.

Differential Diagnosis

Hereditary prothrombin deficiency must be distinguished from other congenital deficiencies that are characterized by prolonged PT and PTT and normal TCT. The most common deficiencies seen with this pattern are factor V and factor X deficiencies; these can be diagnosed with the use of specific assays for factors V and X, respectively. Acquired prothrombin deficiency is commonly seen in patients with liver disease, vitamin K deficiency, or ingestion of vitamin K antagonists such as warfarin or super-warfarins, both of which are found in rodenticides. In all these conditions, all vitamin K–dependent factors, including protein C and protein S, are low. The surreptitious use of warfarin or super-warfarins such as brodifacoum should be suspected in individuals with a severe bleeding tendency who are otherwise apparently normal and without liver dysfunction. Such patients often ingest rodenticides and induce bleeding symptoms for secondary gain. Super-warfarins cannot be detected by simple warfarin assays, but specific testing is available at reference laboratories.

Dysprothrombinemias must also be distinguished from other causes of vitamin K deficiency, such as antibiotics that contain the N-methyl-thio-tetrazole side chain present in third-generation cephalosporins. This side chain inhibits the vitamin K–dependent γ -carboxylation of glutamic acid residues required for production of normal prothrombin and other vitamin K–dependent factors.³⁸

Antibodies against prothrombin can be seen in patients with the lupus anticoagulant, antiphospholipid syndrome (APLS), and systemic lupus erythematosus and, on rare occasions, in isolated cases.^{39,40} These antibodies usually cause a true prothrombin deficiency through accelerated clearance of the antibody–prothrombin complex.^{39,41} Patients with this type of acquired prothrombin deficiency report symptoms similar to those in patients with dysprothrombinemia, except that symptoms are not lifelong.

Treatment

Pure prothrombin concentrates are not available for clinical use. Patients with minor bleeding episodes may not need replacement therapy but may respond to infusion of fresh frozen plasma. Those with major hemorrhage can be treated with fresh frozen plasma at a loading dose of 15 to 20 mL per kilogram body weight, followed by 3 mL per kilogram body weight every 12 to 24 hours because the prothrombin half-life is approximately 3 days. Prothrombin levels of 20% to 40% are usually sufficient to maintain adequate hemostasis.⁴² In patients with recurrent bleeding episodes, prophylactic plasma infusions can be administered every 3 to 5 weeks.⁴³

An alternative treatment for dysprothrombinemia is the use of prothrombin complex concentrate (PCC). Some of these concentrates contain significant quantities of prothrombin and other vitamin K–dependent factors. Care should be taken when PCCs are used because they have been associated with thromboembolic complications, presumably caused by contamination with variable quantities of activated factors VIIa, Xa, and IXa.^{44,45} Two PCCs are commercially available on the U.S. market—Bebulin (Baxter Bioscience, Vienna, Austria) and Profilnine (Grifols, Inc.,

Table 5-7 Prothrombin Complex Concentrates

Product (Manufacturer)	Relative Amount of Factor			
	Prothrombin	VII	IX	X
Bebulin VH (Baxter Bioscience)	120	13	100	139
Profilnine SD (Grifols)	120	Trace	100	55–65

All factor levels are expressed relative to 100 U of factor IX.

Los Angeles, Calif, USA); these consist of varying levels of vitamin K–dependent factors. Therefore, before using PCCs for replacement therapy in patients with prothrombin deficiency, one should know the prothrombin level of a particular product, as is shown in Table 5-7. One regimen consists of an initial loading dose of 20 U of prothrombin per kilogram body weight, followed by 5 U of prothrombin per kilogram body weight every 24 hours.⁴⁶ Care should be taken to avoid exceeding the 20-U/kg dose because of the risk of dangerous thrombotic phenomena. Patients should be monitored for the development of disseminated intravascular coagulation during and after PCC use.⁴⁷ To avoid the use of PCCs in patients who need surgery, plasma exchange can be performed before the time of the operation so that near-normal levels of prothrombin can be achieved.⁴⁸

FACTOR V DEFICIENCY

In 1943, Quick⁴⁹ described a “labile factor” present in plasma that was required for normal PT. A few years later, Owren⁵⁰ reported a patient with a lifelong history of bleeding who was found to be deficient in a “labile factor.” Both were describing an activity that is now known as factor V. Factor V deficiency is an uncommon disorder with an estimated incidence of less than 1 in 1 million of the population.

Pathogenesis and Genetics

Factor V is a glycoprotein that is found in plasma and in the α granules of platelets. The origin of factor V found in platelets is not known for certain. Most secreted platelet-derived factor V is believed to be derived from plasma, although this concept has been challenged.^{51,52} Even though hepatocytes synthesize most of the plasma factor V, megakaryocytes have been shown to contain factor V mRNA.⁵³ Platelet factor V accounts for about 20% of the total body pool of factor V and is released on activation and degranulation of platelets.⁵⁴ The relative roles of plasma and platelet factor V in hemostasis are not precisely known, although platelet factor V is known to be fully functional.

Congenital factor V deficiency, which is inherited as an autosomal recessive trait, is characterized by decreased or absent factor V activity in plasma and platelets. Consanguinity is common. Molecular variants that account for factor V deficiency have been increasingly reported and can be found on the Internet at www.hgmd.org (F5).^{55,56} Although reports have described factor V deficiency in which neither plasma nor platelet factor V can be detected, there is reason to suspect that minute levels of factor V

sufficient to sustain life may be present in vivo. In at least one patient who had no detectable factor V, bleeding symptoms were minor; in other patients, bleeding symptoms have been more severe.

In any discussion of blood clotting factor V, one must remember that in addition to its role in preventing hemorrhage, factor V helps to regulate coagulation reactions, so that mutations that prevent its cleavage by activated protein C (factor V Leiden) predispose the patient to thrombotic rather than hemorrhagic complications.⁵⁷

Clinical Manifestations

Factor V deficiency occurs in mild, moderate, and severe forms. Patients with severe deficiency (<1%) usually develop symptoms within the first 6 years of life and present with umbilical stump bleeding, easy bruising, and epistaxis.⁵⁸ Menorrhagia and postpartum and postoperative hemorrhage have also been described. Hemarthroses may occur, but these are usually traumatic in origin. In contrast to patients with less than 1% factor VIII or IX who experience frequent spontaneous hemarthroses, those with less than 1% factor V activity have few joint hemorrhages. This suggests that even severely affected factor V–deficient patients are not completely deficient in the factor. For example, mice that are completely deficient in factor V—a condition derived through gene knockout techniques—suffer neonatal death but may be rescued by the insertion of a minigene that expresses less than 1% normal factor V activity.⁵⁹ Clinical evidence suggests that the bleeding tendency correlates to a greater extent with platelet factor V levels than with plasma levels.⁶⁰ Mildly affected patients are asymptomatic with factor V plasma levels above 20%, which makes diagnosis difficult; some cases may not be diagnosed until the patient reaches adulthood. Paradoxically, several reports have described patients with congenital factor V deficiency who presented with thrombosis.⁶¹ Inhibitors to factor V are very rare in patients with congenital factor V deficiency.⁶²

Diagnosis

Laboratory evaluation reveals prolonged PT and PTT and normal TCT. In severely affected patients who lack platelet factor V, bleeding time is also prolonged—sometimes longer than 20 minutes. Definitive diagnosis of factor V deficiency requires the use of a specific factor V assay.

Differential Diagnosis

Acquired factor V deficiency may be seen in patients with significant liver disease or in those with disseminated intravascular

coagulation. A syndrome of combined congenital deficiencies of factors V and VIII may be diagnosed and must be distinguished from simple factor V deficiency (see later).

Spontaneous inhibitors of factor V in patients without factor V deficiency have been frequently reported postoperatively and in association with the use of antibiotics such as aminoglycosides and penicillin. Some inhibitors have been reported with infection (tuberculosis) and certain malignancies. In more than half of patients with acquired inhibitors, antibodies disappear spontaneously within a period of several weeks to months. Some patients develop factor V antibodies after they have been exposed to topical bovine thrombin that contains bovine factor V. Human antibodies to these bovine products may cross-react with human thrombin and human factor V; in some cases, bleeding is severe. The treatment of choice for hemorrhaging patients consists of corticosteroids and exchange transfusion.⁶³ Frequently, no therapy is required and the event is transient. Platelet factor V deficiency initially reported as factor V Quebec has now been shown to be a platelet disorder caused by proteolysis of factor V, multimerin, and other proteins within platelet α granules.^{64,65}

Treatment

No commercial factor V concentrates are available for replacement therapy. Patients with minor bleeds such as those caused by epistaxis or dental extraction can be treated with local measures and antifibrinolytic therapy, including tranexamic acid and ϵ -aminocaproic acid. Fresh frozen plasma is the treatment of choice when more serious bleeding occurs. Patients with mild to moderate hemorrhagic episodes can be treated with plasma at a loading dose of 15 to 20 mL per kilogram body weight, followed by 3 to 6 mL per kilogram body weight every 24 hours, to achieve a level of approximately 25% of normal. More frequent infusions are not necessary, given the long half-life of factor V (≈ 36 hr).⁶⁶ Higher levels may be achieved through plasma exchange in patients with severe hemorrhage, in preparation for surgery, or when fluid overload is a concern.⁶⁷ Platelet transfusions have been reported to correct bleeding in some patients because they are a source of factor V; however, they are not always effective and have the potential for development of antiplatelet alloantibodies⁶⁸ (see Chapter 8). Factor VIIa has been used to staunch bleeding in a few patients; it is less likely to be effective in patients with undetectable levels of factor V.⁶⁹

FACTOR VII DEFICIENCY

Alexander and colleagues⁷⁰ described the first case of congenital factor VII deficiency in 1951. Over the years, many more cases have been described, and specific genetic defects have been characterized. Factor VII deficiency occurs at an estimated incidence of 1 in 500,000. No race or sex predilection has been observed for this defect.

Pathogenesis and Genetics

Because the factor VIIa/tissue factor complex is essential for the initiation of coagulation *in vivo*, a deficiency or a structural defect in the factor VII molecule can lead to

significant bleeding symptoms. The gene is located on the long arm of chromosome 13, close to the gene for factor X. About 1% of factor VII circulates in its active form; it has a biologic half-life of about 3.5 hours—very similar to the half-life of the zymogen. More than 50% of patients seem to have low functional activity and antigen levels; others have a dysfunctional molecule (normal antigen and reduced activity). Factor VII deficiency is inherited in an autosomal recessive fashion, with homozygotes and double heterozygotes exhibiting most of the bleeding symptoms. Numerous and various genetic mutations have been described, many with a phenotypic expression leading to mild, moderate, or severe bleeding manifestations.⁷¹ A detailed database of these mutations can be found on the Internet at <http://193.60.222.13/> or at www.hgmd.org (F7).

A remarkable difference has been observed between genotype and phenotype in factor VII variants. Some mutations show virtually undetectable factor VII levels through clotting or immunologic assays, and yet the patient suffers little or no bleeding. PT, which is prolonged in factor VII deficiency, is variable according to the source of the tissue factor. Ox brain and other tissue factor preparations of nonhuman origin may yield very different results from those obtained with the use of human tissue factor. Presumably, varying human polymorphisms may respond in variable manners to different tissue factor sources. It is generally agreed that human tissue factor should be used in all clotting assays for factor VII. Variability in the clinical expression of factor VII deficiency has led to confusion regarding treatment of patients with this disorder.

Clinical Manifestations

The clinical manifestation of factor VII deficiency varies widely from patient to patient, and a poor correlation has been found between plasma level of factor VII and bleeding symptoms. As was stated earlier, this may be explained by the fact that *in vitro* factor VII activity is dependent on the type of tissue factor used in the assay. Assay that uses human tissue factor seems to correlate best with the bleeding diathesis.⁷² In some patients, less than 1% factor VII activity is seen when rabbit tissue factor is used in the assay, although measurable factor VII activity is observed when human tissue factor is used.

In general, individuals with factor VII levels lower than 8% of normal are those more likely to exhibit hemorrhagic episodes than are those with higher levels of this factor.⁷³ Often, bleeding in factor VII-deficient patients involves easy bruising, epistaxis, and soft tissue hemorrhage. Women may present with menorrhagia, menometrorrhagia, and postpartum bleeding. Postoperative bleeding is not rare but almost always occurs in severely affected patients. Patients with factor VII levels lower than 1% may have severe bleeding, equivalent to that seen in hemophilia A or B with hemarthroses, retroperitoneal bleeding, muscle hematomas, and fatal intracranial hemorrhage. Rarely, however, patients with activity levels lower than 1% have no history of bleeding, yet are found by work-up of a prolonged PT. A high incidence of hemarthrosis, which occurs most often with grades 3 and 4 arthropathy, has been described in 40 patients from eight European hemophilia centers.⁷² Central nervous system bleeding has been reported most often in infants after vaginal delivery, with an incidence

of up to 16%.⁷⁴ A few cases of thrombosis have been described in factor VII-deficient patients, but in most cases, other risk factors have been identified.⁷⁵ Inhibitory antibodies against exogenously administered factor VII have been reported in very few patients with severe congenital deficiency of factor VII.^{75,76}

Diagnosis

Individuals with factor VII deficiency have an isolated, prolonged PT with normal PTT, TCT, and bleeding time. On rare occasions, the PTT may be prolonged—a condition that is usually due to unique genetic defects in the factor VII molecule. A specific factor VII assay that is usually based on the PT is required to confirm the diagnosis; in addition, activity may vary according to the species from which the tissue factor used in the assay was derived. Immunologic assays for factor VII may also be used, but these are not as readily available as clotting tests. Factor VIIa assays are also available and can be helpful when factor VIIa is used for treatment.⁷⁷

Differential Diagnosis

Acquired factor VII deficiency is the most common cause of prolonged PT. Warfarin use, vitamin K deficiency, and liver disease are the main causes of acquired factor VII deficiency. Individuals have low levels not only of factor VII, but of all other vitamin K-dependent factors as well. Other less common causes of factor VII deficiency include familial combined factor deficiencies (types III and IV), acquired factor VII inhibitors,⁷⁸ and homocystinuria⁷⁹ and aplastic anemia.⁸⁰ Seligsohn and colleagues⁸¹ described an association between hereditary factor VII deficiency and the Dubin-Johnson and Rotor syndromes.⁸¹ An association between Gilbert syndrome and factor VII deficiency has also been suggested.⁸²

Treatment

For mild hemorrhage, treatment to factor VII levels of 5% to 10% of normal are sufficient to stop bleeding. For individuals undergoing surgery, levels of 15% to 25% of normal are recommended. In the United States, products that are used for treatment include fresh frozen plasma, prothrombin complex concentrates, and recombinant factor VIIa. Given the short half-life of factor VII (3 to 4 hr), it is difficult to administer plasma every 4 to 6 hours to maintain normal levels without producing volume overload. Recombinant factor VIIa (NovoSeven; Novo Nordisk, Inc., Princeton, NJ, USA), which has been approved for use in the United States and other countries for individuals with hemophilia who have inhibitors and congenital factor VII deficiency, has been shown to be efficacious and is clearly the treatment of choice.⁸³ A dose of 15 to 30 µg per kilogram of body weight is sufficient for hemostasis. Frequency of dosing varies with severity of the bleeding episode. For mild to moderate bleeding, a single dose of factor VIIa may be sufficient. For more severe episodes, factor VIIa administered every 4 to 6 hours for several days may be required. Despite the reported short half-lives of factors VII and VIIa, cumulative experience suggests that the effects of factor VIIa last longer than one would expect,

given the reported short half-life of the product. Virally inactivated purified plasma-derived factor VII is available in some European countries.⁸⁴

FACTOR X DEFICIENCY

In the 1950s, two independent groups of investigators discovered factor X when they showed that two different patients lacked an identical factor that could be distinguished from all other known factor deficiencies.^{85,86}

Factor X plays a central role in coagulation and in the presence of its cofactor, factor Va, it converts prothrombin to thrombin. Factor X deficiency occurs worldwide, with an estimated incidence of 1 in 500,000. In countries in which consanguineous marriages are common, the relative frequency may be higher.

Pathogenesis and Genetics

Congenital factor X deficiency, which has been reported in more than 50 kindred, is inherited as an autosomal recessive trait. The gene for factor X is found on chromosome 13, close to the gene for factor VII. Genetic and molecular defects resulting in factor X deficiency include small deletions, missense mutations, and frameshifts.⁸⁷ Individuals with factor X deficiency may synthesize abnormal factor X molecules in normal or reduced amounts. One of the original patients had no detectable factor X antigen, and the genetic defect in this patient probably resulted in intracellular destruction of the molecule. An absolute deficiency of factor X may be incompatible with life; in mice in which the factor X gene has been knocked out, embryonic or neonatal death occurs regularly.⁸⁸ Genetic variants of factor X can be found on the Internet at www.hgmd.org (F10).

Clinical Manifestations

Hemorrhagic events in factor X-deficient patients may be mild, moderate, or severe, depending on the specific mutation. Bleeding symptoms seem to correlate roughly with level of factor X activity. Individuals with severe deficiency (<1% of normal) have bleeding episodes that are comparable with those experienced by patients with severe classic hemophilia, including hemarthrosis, soft tissue hemorrhage, retroperitoneal bleeding, central nervous system hemorrhage, hematuria, menorrhagia, and pseudotumor. In a study of 32 Iranian individuals with congenital factor X deficiency, 69% developed recurrent hemarthrosis and 16% experienced disabling joint disease.⁸⁹ In the same study, bleeding from the umbilical stump was described in 28% of infants. Patients with factor X activity of 15% or greater have fewer spontaneous bleeding episodes, although hemorrhage may occur in association with surgery or trauma. Neutralizing antibodies for factor X rarely occur in patients with hereditary deficiency of this factor.

Diagnosis

In general, the diagnosis of inherited factor X deficiency is suggested by a lifelong history of excessive bleeding and laboratory studies showing prolonged PT and PTT values that correct with 1:1 mixing with normal plasma. TCT and

bleeding time are normal. Russell's viper venom time, which measures the direct activation of factor X, is also prolonged. Definitive diagnosis of factor X deficiency requires a specific factor X assay because prolonged PT and PTT are also seen in other factor deficiencies (e.g., factor V, prothrombin).

Differential Diagnosis

Acquired factor X deficiency is most commonly seen in patients with liver disease and vitamin K deficiency. In these patients, levels of other vitamin K-dependent factors are also reduced. Isolated factor X deficiency has been reported in association with respiratory infection,^{90,91} acute myeloid leukemia,⁹² and other malignancies.⁹³ Acquired factor X inhibitors in patients without congenital factor X deficiency are rare, although cases have been described in patients with leprosy⁹⁴ and after antibiotic and agricultural chemical exposure, among others.^{95,96} Factor X deficiency in association with primary amyloidosis, which may be seen in up to ≈14% of patients with amyloidosis, is due to adsorption of factor X onto amyloid fibrils.^{97,98} Factor X levels in these patients range from 2% to 50% of normal, and usually, individuals have bleeding symptoms if factor levels drop to below 10% of normal.

Treatment

Replacement therapy should be guided by the severity of bleeding. Factor X levels of 10% to 15% should be sufficient for control of mild hemorrhagic episodes, including hemarthroses and uncomplicated soft tissue bleeds. Given the long half-life of factor X (≈40 hr), plasma replacement therapy can be used with an initial loading dose of 15 to 20 mL per kilogram of fresh frozen plasma, followed by 3 to 6 mL per kilogram every 24 hours. These amounts of plasma may cause congestive heart failure in patients with compromised cardiac and pulmonary function, so care must be taken to evaluate patients carefully before large amounts of plasma are infused.

For major bleeds, trauma, or surgical procedures, those prothrombin complex concentrates containing significant amounts of factor X can be used to maintain a factor X level of about 50% of normal. Factor X levels persistently above 50% of normal are not recommended when PCCs are used because of the risk of thromboembolic events. Administration of "factor X-rich" PCCs in doses of 20 to 30 U per kilogram body weight every 24 hours is sufficient to maintain hemostasis.⁸⁹ Patients undergoing surgical procedures may need treatment for several days (5 to 10 days) or until healing of surgical wounds is well under way. Only products that are virally inactivated should be used.

Factor X-deficient patients who develop inhibitors to this factor can be treated with larger than normal doses of factor X (with the use of PCCs) or by exchange transfusion. Long-term treatment of patients with factor X inhibitors consists of immunosuppression with alkylating agents and prednisone. Inhibitors that occur in patients without congenital factor X deficiency are usually transient, and patients should be treated with corticosteroids and intravenous gamma-globulin preparations. In some cases, exchange transfusion and activated PCCs may be useful.^{91,95}

Treatment of patients with factor X deficiency due to amyloidosis is difficult because the half-life of factor X is

shortened, most likely as a consequence of absorption of factor X by amyloid fibrils. Factor X replacement therapy may thus be virtually useless in some patients.⁹⁷ In those with amyloidosis and factor X deficiency, splenectomy, chemotherapy, and plasma exchange have all been tried with varying results.^{99–101} Recently, factor VIIa and PCCs have been used for the treatment of those with bleeding in factor X deficiency due to amyloidosis.^{102,103} It is important to know that for factor VIIa to be effective, measurable levels of factor X in vivo are needed.¹⁰⁴

FACTOR XI DEFICIENCY

The first report of congenital factor XI deficiency was published in 1953, when three related individuals were described who developed excessive bleeding after dental extractions.¹⁰⁵ Factor XI deficiency is more prevalent among Ashkenazi Jews, with a gene frequency of 4.3%, but the deficiency also occurs in non-Jewish populations.^{106,107}

Pathogenesis and Genetics

Factor XI is a homodimer that consists of two identical polypeptide chains and two active serine sites. The gene is located on the long arm of chromosome 4, a serine protease that is not dependent on vitamin K for synthesis. Factor XI deficiency is inherited in an autosomal recessive fashion, with no sex predilection. Three different common genotypes have been described; two of them (types II and III) occur with a higher frequency in the Ashkenazi Jewish population.^{107,108} Type I mutations occur at the intron–exon boundaries (splice junction mutations), type II mutations result from a premature stop codon (nonsense mutations), and type III mutations are caused by missense mutations. A database for factor XI mutations can be found on the Internet at www.hgmd.org (F11). It has been suggested that platelets have factor XI-like activity, but the clinical significance of this finding is unknown.¹⁰⁹

Clinical Manifestations

Factor XI-deficient individuals have a mild bleeding tendency or, in some cases, no bleeding tendency, even after surgery. However, in those patients who have a bleeding tendency, the most serious hemorrhage is likely to occur after surgical procedures or other trauma. The deficiency can occur in the heterozygous, homozygous, or combined heterozygous form. It is one of the procoagulant deficiencies for which bleeding has been reported in patients heterozygous for the condition. An explanation for why bleeding manifestations in factor XI-deficient patients are never as severe as those seen in severely affected patients with either hemophilia A or B is that the "tenase" and "prothrombinase" complexes that lead to ultimate thrombin generation are intact in patients with factor XI deficiency. Thus, factor XI serves to "boost" thrombin generation in subjects who need boosting, but thrombin generation is never as impeded in factor XI-deficient patients as it is in other factor deficiencies. This does not mean that severe bleeding is never seen in factor XI-deficient patients; bleeding can occur after surgery, such as prostatectomy or other procedures that involve tissues rich in fibrinolytic

activity. However, the general rule stands that under basal conditions, bleeding in pure factor XI deficiency is never as severe as that seen in severely affected patients with deficiency of factor VIII or factor IX.

Some patients with factor XI deficiency have close to normal thrombin generation, even when factor XI is virtually undetectable—an observation that explains why many severely affected factor XI-deficient patients exhibit normal hemostasis during surgery. The reason for this is not entirely clear but may be related to the amount of factor XI-like activity that occurs on platelets.

Even though factor XI levels do not always correlate with bleeding tendency, members of an affected family tend to have similar hemorrhagic symptoms. Individuals in whom factor XI activity occurs at less than 20% are most likely homozygotes or compound heterozygotes who can experience excessive bleeding. “Spontaneous” hemorrhagic episodes such as hemarthroses are not features of factor XI deficiency. Increased bleeding may be seen after aspirin ingestion, prostatectomy, and oral cavity surgery; it may also be noted in circumstances in which fibrinolytic activity is increased.^{110,111} Common bleeding manifestations include hematoma, epistaxis, menorrhagia, postpartum bleeding, hematuria, and postoperative hemorrhage. As a general rule, the best predictor of whether a factor XI-deficient patient will experience excessive hemorrhage is the presence or absence of a past history of significant bleeding.

Diagnosis

Individuals with factor XI deficiency have a prolonged PTT with normal PT and TT. As opposed to both hemophilia A and B, factor XI deficiency occurs in both males and females. Diagnosis requires a specific factor XI assay. In our experience, factor XI can best be assayed when plasma from patients is collected fresh in plastic containers and is processed rapidly; results may be affected if the plasma is processed in a glass tube or is frozen and thawed before it is assayed.

Differential Diagnosis

Congenital deficiency of factor XI may also be seen in individuals with familial combined factor deficiencies (types V and VI). It has been associated with Noonan syndrome,¹¹² factor VIII deficiency,¹¹³ factor IX deficiency,¹¹⁴ and von Willebrand disease,¹¹⁵ and it occurs in patients with platelet defects.¹¹⁶ Acquired factor XI inhibitors may be seen in patients with immunologic diseases such as systemic lupus erythematosus.

Treatment

Patients with mild bleeding episodes may not require treatment. A variety of successful surgical procedures have been performed in patients with factor XI deficiency who were receiving adequate replacement therapy,^{117,118} even though it is not established what level of factor XI would be ideal for maintaining hemostasis. It seems safe to maintain a minimum level of 45% of normal for major surgery and 30% for minor surgery. Some clinicians have found that lower levels are adequate for hemostasis, but others believe that higher levels may occasionally be necessary. When therapy is required, fresh frozen plasma can be used at a

loading dose of 15 to 20 mL per kilogram, followed by 3 to 6 mL per kilogram every 12 hours. The half-life of factor XI is approximately 50 ± 22 hours. On occasion, when bleeding cannot be controlled with plasma alone, plasma exchange may be helpful in maintaining higher levels of factor XI. Patients with factor XI deficiency, even when severe, who have no past history of bleeding after significant trauma or surgery usually do not require replacement therapy.

Antifibrinolytic agents, such as ϵ -aminocaproic acid or tranexamic acid, can be used alone or in combination with plasma to control bleeding. Berliner and coworkers¹¹⁹ successfully treated 19 patients with severe factor XI deficiency who underwent dental surgery with tranexamic acid alone without excessive bleeding. Caution should be used in patients with hematuria when antifibrinolytic therapy is administered because ureteral or urethral obstruction from clots that are refractory to lysis can occur. Fibrin glue alone has been used successfully for dental extractions.¹²⁰

Some clinicians now prefer to treat all factor XI-deficient patients with factor VIIa. This product has also been used successfully to control hemorrhage in factor XI-deficient patients, even in those patients who experience severe bleeding after surgery, and in those who have developed high titer inhibitors to factor XI.^{121,122} Factor VIIa has not been approved by the U.S. Food and Drug Administration for use in factor XI deficiency. However, we have found it to be an effective alternative to plasma therapy. A factor XI concentrate is available in Europe, but it has been associated with occasional thrombotic adverse effects.¹²³

Inhibitors to factor XI have been described in several affected factor XI-deficient patients; these usually consist of immunoglobulin (Ig)G alloantibodies. These inhibitors are rare, but they complicate replacement therapy and can prolong bleeding episodes in susceptible patients.^{124,125} The treatment of choice for inhibitors is recombinant factor VIIa. Commonly used doses of factor VIIa range from 90 to 120 μ g per kilogram of body weight adjusted every 2 to 4 hours until bleeding stops.¹²⁶ Eradication of factor XI inhibitor should be attempted through the administration of cyclophosphamide (100 to 200 mg/day) and prednisone (1 mg/kg/day) until the inhibitor disappears or adverse effects of therapy prohibit further treatment.

DEFICIENCY OF CONTACT FACTORS

The physiologic role of contact factors (factor XII [Hageman factor], PK, and HK) in coagulation is not yet well understood. Individuals with a deficiency of any of these contact factors do not have a bleeding tendency, even during major surgery. Reasonable evidence suggests that these factors may play a role in host defense mechanisms and may contribute to the interaction between coagulation, fibrinolysis, the complement system, and other pathways of the inflammatory response.¹²⁷

Factor XII Deficiency

Ratnoff and Colopy¹²⁸ were the first to describe a patient with congenital factor XII deficiency (Mr. Hageman) after he was found to have a prolonged clotting time in a glass tube in a routine preoperative evaluation. He had no personal or family history of excessive bleeding. Since then,

hundreds of cases have been described, but in only a few of these cases has the structural defect in factor XII been recognized.

Pathogenesis and Genetics

In general, congenital factor XII deficiency is inherited in an autosomal recessive pattern, although autosomal dominant inheritance has been described in one family.¹²⁹ Homozygous individuals usually have undetectable factor XII activity levels, and heterozygotes have factor XII levels between 20% and 60% of normal. Heterozygosity for factor XII deficiency was found in 2% of a series of 300 normal blood donors.^{129a} The Asian population seems to have lower factor XII levels when compared with whites.¹³⁰

Clinical Manifestations

Individuals with factor XII deficiency do not experience excessive bleeding, even after major surgical procedures or trauma. Various anecdotal case reports describing an association between factor XII deficiency and spontaneous abortion, premature delivery, arterial and venous thromboses, myocardial infarction, and pulmonary embolism have been published, but a definite cause and effect relationship has not been established. More likely, the decreased factor XII activity as well as these thrombotic symptoms are due to APLS.^{130a}

Diagnosis

Severe factor XII deficiency is characterized by a markedly prolonged PTT (>100 sec) with normal PT, TCT, and bleeding time in patients with no personal or family history of excessive bleeding. The PTT corrects with 1:1 mixing with normal plasma. Diagnosis requires a specific factor XII assay.

Differential Diagnosis

Spontaneous autoantibodies (inhibitor) against factor XII occur rarely.¹³¹ Sporadic case reports of inhibitors have been described in patients with autoimmune disorders and in individuals treated with procainamide or chlorpromazine.^{132,133} Congenital factor XII deficiency has also been described in association with other coagulation disorders, including von Willebrand disease and factor IX deficiency.^{134,135} Low factor XII levels may also be seen in patients with liver disease. Prekallikrein and HK deficiencies must be distinguished from factor XII deficiency by means of specific assays.

Treatment

No treatment is necessary for individuals with factor XII deficiency.

Prekallikrein Deficiency

In 1965, Hathaway and associates¹³⁶ described deficiency of prekallikrein (PK; Fletcher factor) in a family with prolonged PTT and no history of excessive bleeding. Prekallikrein deficiency is inherited in an autosomal recessive pattern. Homozygous individuals have less than 1% of activity, whereas heterozygotes have 20% to 60% of normal activity. Rare variants of abnormal prekallikrein molecules have been described. Paradoxically, some reports describe a possible association of prekallikrein deficiency with thromboembolic phenomena, but this seems more likely due

to APLS.^{130a,137} Individuals with this disorder have a markedly prolonged PTT that corrects to normal with the addition of normal plasma. PT, bleeding time, and TCT are normal. Prekallikrein deficiency is clinically identical to factor XII and HK deficiency, and diagnosis requires a specific assay. No specific therapy is required for patients with PK deficiency because they do not manifest excessive bleeding. The differential diagnosis includes other contact factor deficiencies. Because prekallikrein is synthesized in the liver, acquired deficiency can occur in liver disease.¹³⁸

High Molecular Weight Kininogen Deficiency

HK, also known as Fitzgerald factor, Williams factor, and Flaujeac factor, was first described in 1979.¹³⁹ Its deficiency is an autosomal recessive transmitted disorder. Individuals with HK deficiency have a prolonged PTT with no bleeding abnormalities. The PTT corrects through 1:1 mixing with normal plasma. Diagnosis requires a specific assay. No treatment is required.

Factor XIII Deficiency

In 1960, Duckert and colleagues¹⁴⁰ described the first case of congenital factor XIII deficiency in a patient with severe hemorrhage and poor wound healing. Since then, more than 200 cases of congenital deficiency of this protein have been reported in the literature.

Pathogenesis and Genetics

In vivo, factor XIII acts as a transglutaminase that stabilizes the fibrin clot by crosslinking fibrin fibers through formation of peptide bonds between specific amino acid residues on adjacent α and γ chains of fibrin polymers. In the absence of factor XIII, clots are unstable and are held together by weak hydrogen bonds and electrostatic forces. Such clots are permeable, form a poor framework for wound healing, and are extremely sensitive to fibrinolysis.

Human factor XIII is found in plasma and platelets. In plasma, it circulates as a tetramer consisting of two A chains and two B chains (A_2B_2). The B chains function as carriers for the A chains, which contain the enzymatic component of factor XIII. In platelets, factor XIII is a dimer composed of two A chains (A_2). Platelet factor XIII accounts for about 50% of total body factor XIII activity.¹⁴¹ Three forms of factor XIII deficiency have been described. In type I deficiency, there is absence of both A and B chains. Type II deficiency is characterized by lack of the A chain; in Type III, the B chain is absent.¹⁴² Most of the reported cases of factor XIII deficiency are due to the lack of A chains. Deficiency of factor XIII is an autosomal recessive disorder, with an estimated incidence of one in several million. Consanguinity is frequently found.

Clinical Manifestations

Symptomatic individuals with factor XIII deficiency have <1% of normal activity. Bleeding manifestations can present as early as the neonatal period with umbilical stump hemorrhage in up to 80% of cases. Hematoma, soft tissue hemorrhage, pseudotumor, and poor wound healing are other manifestations of severely affected individuals. Children can present with severe hemorrhage after circumcision

and recurrent gum bleeding while teething.¹⁴³ Women have recurrent spontaneous abortions,¹⁴⁴⁻¹⁴⁶ and males manifest oligospermia and infertility.¹⁴⁶ Trauma is usually the triggering factor for most of the bleeding episodes, except for intracranial hemorrhage, which can be spontaneous. Intracranial hemorrhage occurs at an incidence of up to 30% and is the leading cause of death in this disorder.¹⁴⁷ Some patients with congenital factor XIII deficiency develop alloantibodies against the factor after undergoing replacement therapy.

Diagnosis

The hallmark of diagnosis of factor XIII deficiency consists of normal routine coagulation studies (PTT, PT, TCT, bleeding time, and platelet count) in a patient who is clearly a bleeder. Diagnosis can be made through a simple clot solubility test, with the use of 5 M urea or 1% monochloroacetic acid. Plasma clots may be removed from thrombin-treated plasma samples and placed in one of the above solutions. Rapid dissolution of the clot within a few minutes will be noted in affected individuals, whereas normal clots remain insoluble for at least 24 hours. The patient's plasma mixed with normal plasma should also be tested to rule out an inhibitor to factor XIII. Factor XIII inhibitors neutralize factor XIII in normal plasma. Confirmation of the deficiency with the use of a quantitative test should be done if the clot solubility test result is abnormal. Quantitative tests are based on the amine-casein incorporation assay or on ammonia production through the transamidase activity of factor XIII.¹⁴⁸

Differential Diagnosis

Because inhibitory antibodies develop against factor XIII, acquired factor XIII deficiency may be seen in patients without a congenital deficiency. Such antibodies have been reported in association with isoniazid, penicillin, and phenytoin.¹⁴⁹⁻¹⁵¹ In some patients, antibodies against factor XIII are idiopathic.¹⁵²⁻¹⁵⁴ Decreased levels of factor XIII also have been described in patients with Henoch-Schönlein purpura, Crohn disease, and ulcerative colitis.^{155,156}

Treatment

Because only low levels of factor XIII activity ($\approx 5\%$) are needed to completely control bleeding and because its half-life is long (9 to 10 days), prophylactic therapy is indicated, especially if intracranial bleeds are to be prevented.¹⁵⁷ For prophylaxis, fresh frozen plasma can be administered in doses of approximately 2 to 3 mL of plasma per kilogram body weight.¹⁵⁸ Cryoprecipitate is another source of factor XIII and can be given in doses of 1 bag per 10 to 20 kg of body weight every 3 to 4 weeks. Plasma-derived pasteurized factor XIII concentrates are available in Europe (Fibrogammin-P; Aventis Behring Ltd., West Sussex, UK) and can be used prophylactically through intravenous administration every 5 to 6 weeks. Pregnancy in women with a history of spontaneous abortions can be carried to term with the use of fresh frozen plasma every 14 days or with factor XIII concentrates given every 21 days.¹⁴⁵ Complications from replacement therapy include blood-borne infection (hepatitis, HIV, other viruses), allergic reaction to plasma, and the development of antibodies to factor XIII in individuals with congenital deficiency.¹⁵⁹ Patients with factor XIII deficiency who develop antibodies

to exogenous factor XIII can be difficult to treat. Administration of normal platelets containing factor XIII can be tried. Exchange transfusion may be necessary. Combination therapy consisting of exchange transfusion and immunosuppression with intravenous gammaglobulin, cyclophosphamide, and steroids can also be tried.

FAMILIAL COMBINED FACTOR DEFICIENCIES

Multiple combined coagulation factor deficiencies have been described (Table 5-8). Type I (factor V–factor VIII deficiency) and type III deficiencies (combined factors II, VII, IX, and X deficiencies) are well characterized. Familial combined deficiencies may be due to a single genetic defect, resulting in multiple factor deficiencies, or to different genetic defects associated with each deficient factor. The latter situation is usually associated with consanguinity.

Combined Factor V–Factor VIII Deficiency (Type I)

More than 30 affected families have been described in the literature. Affected individuals have factor V and factor VIII levels between 5% and 15% of normal. These patients usually have bleeding symptoms after trauma and during or after surgery.

Pathogenesis and Genetics

Combined factor V–factor VIII deficiency is inherited in an autosomal recessive pattern. Defects in one of two genes appear to account for all cases of combined deficiencies of factors V and VIII. The lectin mannose binding gene (*LMAN-1*, initially referred to as *ERGIC53*) is located on the long arm of chromosome 18, and the multiple coagulation factor deficiency gene (*MCFD2*) is located on the short arm of chromosome 2. These two genes form a protein complex in the endoplasmic reticulum–Golgi apparatus that is necessary for the transport of factors V and VIII from the endoplasmic reticulum (ER) to the Golgi.¹⁶⁰

Diagnosis

Patients will have a mildly prolonged PT and PTT and a normal TCT. In patients who have lifelong bleeding episodes after undergoing surgery or trauma, and who have a prolonged PT and PTT, combined factors V and VIII deficiencies should be suspected.

Table 5-8 Familial Combined Factor Deficiencies

Type	Deficient Factors	Genetic Defect
I	V and VIII	<i>LMAN-1</i> and <i>MCFD2</i> genes
II	VIII and IX	Unknown
III	II, VII, IX, X	Vitamin K carboxylase or reductase deficiency
IV	VII and VIII	Unknown
V	VIII, IX, and XI	Unknown
VI	IX and XI	Unknown

Clinical Manifestations

Affected patients will have bleeding after trauma, surgical or otherwise. In patients with the combined disorder, mild factor V deficiency is sometimes misdiagnosed.

Treatment

Therapy consists of fresh frozen plasma (to replace factor V) and factor VIII concentrates. Whereas factor VIII levels can be made normal with the use of factor VIII concentrates, it is difficult to raise factor V levels to much above 30% of normal with plasma infusions, especially in patients with heart disease who may develop congestive heart failure from hypervolemia. For major surgery, it may be necessary to raise factor V to near-normal levels through plasma exchange. Platelet transfusions can be used to functionally elevate factor V levels. Factor levels can then be maintained with infusions of plasma and factor VIII concentrates.

Combined Factors II, VII, IX, and X, Proteins C and S Deficiencies (Type III)

Pathogenesis and Genetics

The combined deficiency of the vitamin K–dependent factors was first described by McMillan and Roberts in 1966.¹⁶¹ It is a very rare autosomal recessive disorder that has been described in fewer than 15 families.¹⁶² The combined deficiency of the vitamin K–dependent factors appears to be due to defects in the vitamin K carboxylase or reductase genes. These genes have already been characterized and identified in at least three individuals.^{163–166} Consanguinity has been described in some individuals.

Clinical Manifestations

Bleeding in individuals with combined deficiency of the vitamin K–dependent factors can on occasions be severe. Umbilical stump bleeding and intracerebral hemorrhage may occur when factor levels are severely low.¹⁶⁷

Diagnosis

Patients present with marked prolongation of the PTT and PT and a normal TCT. The PT and PTT correct with 1:1 mixing with normal plasma. Assays for proteins S and C are also low.

Treatment

In some patients with a congenital deficiency of vitamin K–dependent clotting factors, the use of high doses of oral vitamin K may be beneficial.^{161,168} In one patient, 50 mg of vitamin K daily partially corrected the markedly prolonged PT, although complete correction was never achieved. When excessive bleeding occurs, fresh frozen plasma or PCCs can be used to correct the clotting abnormality. PCCs should be used with caution in view of scattered reports of thrombotic complications with these products. Some investigators recommend that factor IX levels should not be raised more than 50% from baseline.

Differential Diagnosis

Hemorrhagic disease of the newborn may resemble the congenital deficiency syndrome and was once common. However, in recent times, most gravid women are given prophylactic vitamin K as well as their newborns, so this

condition is now rarely reported. When present, it can be easily treated with vitamin K, and symptoms do not return. Malabsorption can also cause vitamin K deficiency in children, but again, symptoms of malabsorption are evident, and the clotting defect is rapidly corrected by administration of vitamin K. Liver disease may cause a decrease in vitamin K–dependent factors, and this cause can be suspected on the basis of abnormal liver function test results.

Care must be taken to exclude the possibility of accidental or furtive administration of warfarin or “super-warfarin,” both of which may cause a deficiency of the same factors as those seen in a congenital deficiency syndrome. The difference is that congenital deficiency of vitamin K–dependent factors may cause bleeding at birth, but warfarin poisoning can produce an acquired deficiency of K-dependent clotting factors.

Special consideration must be given to a class of warfarins now referred to as “super-warfarins.” These were developed to overcome resistance of rats to warfarin-containing rodenticides. In contrast to warfarin, super-warfarins have an extremely long half-life and, when ingested, are stored in the liver and have a high affinity for lipids. Once ingested by humans, they may remain in the body for months and can closely resemble the congenital deficiency syndrome, unless one takes a careful history and determines that the bleeding symptoms were acquired. Poisoning with super-warfarin may result from accidental administration (most commonly seen in children), psychiatric conditions, industrial exposure, surreptitious ingestion, or deliberate self-poisoning with denial (Munchausen syndrome). Many cases of surreptitious ingestion of brodifacoum are seen in medical or paramedical personnel, who take the compound for secondary gain, for example, a spouse may ingest the substance to punish or get sympathy from the partner. The potency of super-warfarin is 100 times that of warfarin, and the half-life is between 16 and 69 days, compared with 37 hours for warfarin.¹⁶⁹ Three types of super-warfarins are available: (1) hydroxycoumarin derivatives with a 4-bromo (1-1 biphenyl) side chain, (2) coumatettrils, and (3) indanediones. Brodifacoum, a 4-hydroxycoumarin derivative, is the most commonly used super-warfarin and is primarily absorbed from the gastrointestinal tract, although skin absorbency is also possible. Super-warfarins block the carboxylation of vitamin K–dependent factors by inhibiting the vitamin K 2,3-epoxide reductase enzyme in the liver. Bleeding is the most common manifestation and may occur from any mucosal site, soft tissue, or organ. Coagulation studies show prolonged PT and PTT that are corrected with 1:1 mixing with normal plasma. TCT is normal. Decreased levels of vitamin K–dependent factors are the hallmark of this condition. Special assays are needed to detect the presence of warfarin or super-warfarin in blood. Assays for brodifacoum and other super-warfarins are not usually readily available in most clinical laboratories; thus, samples must be sent to special centers for measurement. Treatment of patients with super-warfarin poisoning requires the administration of fresh frozen plasma or PCCs if the patient is actively bleeding; in addition, large doses of vitamin K must be administered. The latter can be given orally or parenterally at a daily maintenance dose that can range from 20 mg to more than 100 mg, depending on the severity of the coagulopathy. Intravenous administration of vitamin K requires that the appropriate dose be given

in a dilute solution that is administered slowly with caution and constant observation. It is important to remember that because of the long half-life of the substance and its affinity for lipids, long-term treatment with vitamin K is necessary, requiring that the vitamin be given over a long period, sometimes for several months to a year.¹⁷⁰ In adult patients who surreptitiously take the drug or who have Munchausen syndrome, psychiatric counseling may help, but repeated ingestion of brodifacoum has been reported, even after counseling was provided. This clinical picture was recently discussed in a clinicopathology conference forum.^{170a}

Other Combined Familial Deficiencies

Other combined familial factor deficiencies (see Table 5-8) occur less often than those discussed previously. The genetic nature of these defects is largely unknown. When bleeding occurs, plasma or specific factor concentrates may be used for treatment.

α_2 -PLASMIN INHIBITOR DEFICIENCY

α_2 -Plasmin inhibitor deficiency was first described in 1976. Occasionally, it has been referred to as α_2 -antiplasmin deficiency. Since its discovery, more than 10 families have been identified who have this disorder.¹⁷¹ These patients may be “missed” unless a high index of suspicion is present, because routine test results of coagulation may be only slightly prolonged.

Pathogenesis and Genetics

Individuals with α_2 -plasmin inhibitor deficiency exhibit a hemorrhagic tendency caused by reduced inhibition of plasmin, accompanied by resultant increased fibrinolytic activity. Deficiency is inherited in an autosomal recessive pattern, with no predilection for sex or race. The gene is located on chromosome 17, and a variety of genetic defects, including additions, small deletions, and specific nucleotide substitutions, have been reported.

Clinical Manifestations

Bleeding manifestations are more pronounced in homozygous individuals and are characterized by easy bruising, epistaxis, hematuria, menorrhagia, and hemarthrosis. Bleeding after trauma or surgery may be severe and often is delayed. Heterozygous individuals usually have hemorrhagic symptoms only in association with trauma.

Differential Diagnosis

α_2 -Plasmin inhibitor deficiency may also be acquired and has been reported in individuals with liver failure, amyloidosis, solid tumor, acute promyelocytic leukemia, and disseminated intravascular coagulation.¹⁷² Decreased levels of α_2 -plasmin inhibitor have also been described in patients who received thrombolytic therapy and in those with other conditions associated with a hyperfibrinolytic state.¹⁷³

Diagnosis

Diagnosis of α_2 -plasmin inhibitor deficiency requires a high degree of suspicion because laboratory evaluation may reveal completely normal PT, PTT, TCT, and bleeding

time. Clots that are formed are not rapidly soluble in 5-molar urea as normal factor XIII activity is retained. However, whole blood and euglobulin lysis times are markedly accelerated. Definite diagnosis requires a specific α_2 -plasmin inhibitor assay.

Treatment

Antifibrinolytics are the mainstay of treatment. During bleeding situations, ϵ -aminocaproic acid may be used orally or intravenously at a dose of 2 to 3 g every 6 hours. Continuous intravenous infusion can also be provided at a dose of 1 g per hour. The maximum recommended dose is 30 g a day in patients with normal renal function. Some clinicians find that lower doses, for example, 4 to 6 g every 4 to 6 hours, are equally efficacious. Myolysis has been reported with long-term antifibrinolytic therapy.

α_1 -ANTITRYPSIN PITTSBURGH (ANTITHROMBIN III PITTSBURGH)

To date, only two individuals with this defect have been described.^{174,175} Both patients had the same genetic mutation, even though the hemorrhagic manifestations were different. Bleeding manifestations occurred after trauma, which induced an increase in the level of the mutant enzyme that is an acute phase reactant. The mutation observed in α_1 -antitrypsin Pittsburgh is characterized by the substitution of methionine for arginine at position 358 of the α_1 -antitrypsin AT (α_1 -AT) molecule. This substitution essentially converts α_1 -antitrypsin into an antithrombin with both antithrombin and antifactor Xa activity. One individual had severe bleeding episodes with soft tissue hematoma, hematuria, and melena. He died of massive hemorrhage. Another individual had only mild bleeding symptoms. PT, PTT, TCT, and bleeding time were prolonged in both individuals. Low protein C (13%) was also seen in the second individual, but its cause and role are not clear.

PROTEIN Z DEFICIENCY

Protein Z is a vitamin K–dependent protein that was first described in bovine plasma.¹⁷⁶ Human protein Z was discovered and purified by Broze and Miletich in 1984.¹⁷⁷ The plasma half-life is estimated to be 2 to 3 days. No correlation has been found between age and sex. Protein Z plasma concentration is variable. Because it is a vitamin K–dependent factor, its level is exquisitely sensitive to warfarin.¹⁷⁸ Protein Z is mentioned in this chapter because early studies suggested that patients with low protein Z levels have a mild bleeding tendency.¹⁷⁹ More recent reports, however, indicate that protein Z is a cofactor for a protein Z–dependent protease inhibitor (ZPI), a member of the serpin family of inhibitors.^{180,181} ZPI, with protein Z as a cofactor, inhibits factor Xa (a serine protease) on phospholipid surfaces. Thus, deficiency of protein Z has been shown to predispose protein Z–deficient mice to thrombosis rather than hemorrhage. This suggests that protein Z deficiency in humans may be prothrombotic.¹⁸² Reports suggesting that protein Z deficiency is associated with excessive bleeding may be inaccurate.

CONSULTATION CONSIDERATIONS

Although some factor deficiencies occur rarely, patients with these conditions are exactly the type of patient for whom the hematologist will be consulted. The consultant should be aware that mild prolongation on any of the screening tests of coagulation should be investigated. If such abnormalities appear to be lifelong, the patient most likely has a congenital bleeding disorder. However, it should be emphasized that the most important diagnostic information to be sought regarding a hereditary bleeding disease is a personal or family history of bleeding spontaneously or after trauma or surgery.¹⁸³ Mildly affected patients may have normal screening tests of coagulation; prolonged tests do not always denote a bleeding abnormality. Some mildly affected patients may have no bleeding until late in life, and the consultant will have to carefully assess the family history to rule out other acquired causes of a hemorrhagic disorder. Because many diseases are recessive in inheritance, a high degree of consideration must be given to consanguinity. Finally, the consultant should remember the importance of genetic counseling for affected patients and their families.

MEDICAL-LEGAL ISSUES

A firmly established diagnosis is important. It was not uncommon to see patients given a misdiagnosis of lupus anticoagulant or factor VIII or IX deficiency followed by treatment with concentrates that were dubious, expensive, and perhaps dangerous, when they had an acquired inhibitor to a specific coagulation protein (i.e., factor VIII). On the other hand, many patients receive fresh frozen plasma indiscriminately in the hope that "a missing factor" would be replaced and result in improvement in symptoms. Potential adverse effects of therapy, including possible allergic reactions and any specific adverse effects associated with therapeutic products, should always be explained to the patient.

When an unusual diagnosis is made in a family member, consideration should be given to notifying and possibly testing other members of the family. Genetic counseling should always be part of the consultation, when indicated.

COST CONTAINMENT ISSUES

Once the correct diagnosis has been established, patients should be treated with the most effective and safest material available. Cost consideration should not be the deciding factor in treatment but should always be considered. For example, recombinant products, although they often are more expensive than plasma-derived clotting factor concentrates, are preferred because they are less likely to be contaminated by potentially transmissible agents that are not susceptible to currently used eradication techniques. Specific therapy is preferred when available.

Chapter 6

Nonhemophilic Inhibitors of Coagulation

Bruce M. Ewenstein, MD, PhD

INTRODUCTION

Although not often encountered in clinical practice, patients with acquired inhibitors of coagulation provide unique challenges to medical personnel and institutional resources. Acquired inhibitors of coagulation include circulating immunoglobulins, usually of the immunoglobulin G (IgG) class, that neutralize the activity of a specific coagulation protein or accelerate its clearance from the plasma. These inhibitors are defined as *alloantibodies* when they arise after blood product exposure in individuals with congenital factor deficiencies (discussed further in Chapter 4), and as *autoantibodies* when they occur among patients without a preexistent coagulation defect. Autoantibodies against coagulation factors are associated with a variety of clinical conditions characterized by disturbed immune function but are also encountered among patients whose only identifiable risk factor is advanced age. Nonhemophilic inhibitors are rare but are associated with significant morbidity and mortality and should be suspected in any patient who presents with signs and symptoms of bleeding in the absence of a personal or family history of a coagulation disorder.

Loss of tolerance to endogenously expressed coagulation proteins in affected patients is not fully understood, but it is likely to involve dysregulation of both B- and T-cell responses. The most frequently affected coagulation protein is factor VIII, which results in a condition that has been called *acquired hemophilia*. Factor VIII-specific CD4+ T cells and low levels of anti-factor VIII antibodies, including some with inhibitory activity, can be detected through immunologic methods in a significant number of apparently healthy subjects.¹⁻³ These findings suggest that perturbations of normal immune responses to factor VIII may play an important role in the development of clinically significant anti-factor VIII antibodies.⁴ It remains possible that the pathogenic potential of autoantibodies that recognize factor VIII is also modulated through idiotypic determinants on these molecules.^{5,6} The presence of anti-idiotypic antibodies may be responsible, in part, for the ability of pooled IgG to suppress anti-factor VIII activity in some patients.^{7,8}

In general, the clinical and laboratory manifestations of nonhemophilic inhibitors resemble those of the corresponding inherited coagulation disorder, although often with important differences. This chapter focuses principally on the natural history, diagnosis, and clinical management of patients with acquired hemophilia; other inhibitors of coagulation are briefly reviewed. Lupus anticoagulants and

antiphospholipid and antiphospholipid/protein antibodies that interfere with coagulation-based laboratory assays but are principally associated with venous and arterial thrombosis, pregnancy loss, and other clinical manifestations are discussed further in Chapter 19.

LABORATORY DIAGNOSIS

Screening Tests

In routine laboratory testing, simple factor deficiencies and specific inhibitors result in prolongation of partial prothrombin time (PTT), prothrombin time (PT), or both. These conditions can be distinguished through mixing studies. In the presence of a simple factor deficiency, mixtures of equal volumes of patient and normal plasmas in vitro will correct the abnormality. In contrast, the presence of an inhibitor in patient plasma will inactivate the target protein in normal plasma, and the PTT or PT will remain prolonged.⁹ Inactivation is time and temperature dependent¹⁰ and may require several hours to prolong the PTT, especially in cases of weak inhibitors. Typically, the PTT or PT is measured immediately after normal and patient test plasmas are mixed and after 1 and 2 hours of incubation at 37°C. Because certain coagulation proteins, including factor VIII, are heat labile, the PTT derived from mixtures of normal and patient plasmas must be compared with those of control mixtures of normal plasma and buffer incubated under the same conditions. Prolongation greater than 10 seconds over the control value is typically taken as a positive inhibitor screen. The sensitivity of the screening assay may be improved by increasing the proportion of patient plasma to normal plasma to 4:1.⁹

Inhibitor Specificity

The next step in evaluation of a patient with a prolonged screening test and a positive mixing study is to determine the specificity of the inhibitor. One goal is to distinguish inhibitors of specific coagulation pathway components from “lupus anticoagulants”—antibodies with specificity for phospholipid or phospholipid-binding proteins that may prolong the PTT but are not usually associated with clinical bleeding. This distinction is especially important in the evaluation of patients for whom no antecedent diagnosis of a factor deficiency was confirmed. A second goal is to properly identify the specific coagulation protein targeted by the inhibitor.

Table 6-1 Laboratory Tests to Distinguish Antibodies to Specific Coagulation Factors from Lupus Anticoagulants

Method	Result	
	Specific Inhibitor	Lupus Anticoagulant
Normalization of all factor assays with increasing dilution of patient plasma	Negative	Positive
Kinetics of prolongation	Slow	Immediate
Prolonged RVVT	Negative ^a	Positive
Phospholipid neutralization procedure	Negative	Positive

^aExcept in the presence of inhibitors to factors in the "common pathway."

Several methods are commonly employed for distinguishing lupus anticoagulants from inhibitors of factor VIII or other specific coagulation factors (Table 6-1).^{11,12} The presence of a strong specific factor inhibitor may result in a modest reduction in the measurement of other factors when assays are performed at standard dilutions, leading to the false impression that the inhibitor is not specific. When assays are performed on a series of increasingly more dilute patient plasma samples, the apparent concentrations of all factors, except the one that is specifically inhibited, will rise into the normal range. In contrast, progressive normalization of all factor levels will be observed with increasing dilution of the test plasma that contains a lupus anticoagulant. Another commonly used technique, Russell's viper venom time (RVVT), makes use of an enzyme found in the venom of Russell's viper that promotes fibrin formation through the direct activation of factors V and X. The enzyme is dependent on the presence of phospholipid but independent of factor VIII or other intrinsic pathway factors. The RVVT is thus prolonged in the presence of antiphospholipid antibodies but not with inhibitors of

intrinsic pathway proteins.¹³ A third technique makes use of the observation that the addition of platelet membranes or hexagonal-phase phospholipid (phosphatidylethanolamine) will shorten the prolonged PTT caused by a lupus anticoagulant, but it will have little or no effect on prolongation of the PTT due to specific factor inhibitors.¹⁴ Diagnosis of a lupus anticoagulant is supported by the detection of antibodies to cardiolipin, β_2 -glycoprotein I (β_2 GPI), or prothrombin (see later) through the use of quantitative immunoassays. However, it should be recognized that not all lupus anticoagulant sera yield positive results in these immunoassays.¹⁵ Rarely, patients are encountered who have both lupus anticoagulant and specific factor VIII inhibitors, producing complex laboratory test results.^{16,17} Such patients present primarily with bleeding.

Quantitative Assays of Coagulation Factor Inhibitors

Once the presence of a specific factor inhibitor has been established, it should be quantified because this result will influence treatment strategy. Methods are best characterized for anti-factor VIII inhibitors. The most widely used assay today is the Bethesda method, which measures residual factor VIII activity after dilutions of inhibitor patient plasma have been incubated with pooled normal plasma for 2 hours at 37°C.¹⁸ Because factor VIII is labile, the residual factor must be compared (through mixture of control and patient plasmas) with factor VIII activity that remains after control plasma has been mixed with buffer under identical conditions.¹⁹ The quantity (in Bethesda units [BU]) of inhibitor is defined as the reciprocal of the titer that produces 50% inhibition. The Bethesda assay may yield false-positive results because of nonspecific loss of factor VIII activity. The Nijmegen modification, which includes the addition of buffers in the assay to minimize shifts in pH, permits more accurate measurement of low-titer inhibitors.²⁰

Inhibitor titers may be determined reliably only for antibodies that display second-order concentration dependence (type 1); the titer of antibodies with more complex kinetics (type 2) can only be approximated (Fig. 6-1). Particularly in

Figure 6-1 Inactivation of factor VIII by type 1 and type 2 inhibitors. Type 1 inhibitors, when present in excess, produce complete inactivation; a linear relationship exists between inhibitor concentration and the logarithm of residual factor VIII activity. Type 2 inhibitors, which are typical of non-hemophilic autoantibodies, do not produce complete inactivation of factor VIII. (Based on the work of Gawryl MS, Hoyer LW: Inactivation of factor VIII coagulant activity by two different types of human antibodies. Blood 60:1103–1109, 1982. Permission granted for the previous edition.)

the case of type 2 inhibitors, it is essential that dilutions of patient plasma that produce residual factor VIII activity as close to 50% as possible should be used when the inhibitor titer is calculated. This method has been extrapolated to the detection and quantification of other factor inhibitors as well.

Other assays of factor inhibitors that rely on immunologic rather than functional methods are extremely sensitive but are generally confined to research settings. These include immunodiffusion and enzyme-linked immunosorbent assay (ELISA).^{21–23} Each of these methods is able to detect antibodies that accelerate clearance of the coagulation protein from the circulation without inhibiting its activity *in vitro*.²⁴ With the immunodiffusion assay, patient plasma is allowed to diffuse in an agarose gel that contains citrated plasma that is then incubated with a calcium-containing solution to initiate the coagulation cascade *in situ*. Inhibition of fibrin formation, evident as a clear ring in the gel, provides a sensitive measure of factor inhibitors. The distinct advantage of this system is that inhibitory activity is measurable even after factor replacement therapy has been provided. With the ELISA system, samples that contain the inhibitor are applied to wells in which factor VIII has been previously immobilized. Monospecific antisera are then added so that the immunoglobulin class and subclass and light-chain type of the inhibitor can be determined.

ACQUIRED INHIBITORS OF FACTOR VIII

Presentation and Natural History

The estimated incidence of acquired hemophilia is approximately 1.0 per million, although it is likely that not all affected patients are reported.^{25,26} Bleeding manifestations are often severe and may occur spontaneously or after minor trauma. In contrast to patients with congenital factor VIII deficiency, in whom intra-articular bleeding is the archetypal manifestation, those with acquired hemophilia principally experience soft tissue bleeding. Clinical features include intramuscular hemorrhage (spontaneous or following minor stress such as an intramuscular injection) and bleeding in the gastrointestinal or urinary tract.^{25–30} Retroperitoneal bleeding appears to be especially common and is sometimes fatal.^{27,31} Hemorrhage limited to subcutaneous ecchymosis, although frequently dramatic (see Fig. 11-9), can be tolerated without specific therapy in the absence of more serious hemorrhage.

Overall mortality associated with acquired hemophilia has been reported at between 8% and 42%^{25,28,32}; most hemorrhagic deaths occur within the first few weeks after presentation. Median age of patients at the time of diagnosis is 60 to 70 years (Fig. 6-2A)—a fact that may underscore, in part, the relatively high rates of morbidity and mortality that are associated with the disorder.^{25–31} Acquired inhibitors occur with similar frequency in males and females (see Fig. 6-2B), although the age distribution for females is younger than that for males, likely because of the additional risk of postpartum inhibitors.

Concomitant Conditions

In approximately half of patients with inhibitors, no concomitant disease can be found. In the remainder of

patients, the conditions most commonly associated with factor VIII inhibitors include connective tissue disease, inflammatory bowel disease, the puerperium, malignancy, and some dermatologic disorders (see Fig. 6-2C).^{25,31}

The development of a postpartum inhibitor to factor VIII is a serious and potentially life-threatening complication of an otherwise normal pregnancy. Symptoms generally appear at term or within 3 months of delivery, and less commonly prior to parturition. If postpartum hemorrhage is the presentation and an acquired factor VIII inhibitor is possible, it is strongly advised that this matter be resolved prior to the performance of surgical or obstetric procedures. Severe vaginal bleeding is extremely common, as are soft tissue and intra-articular hemorrhages.³³ The vast majority of, if not all, postpartum inhibitors ultimately disappear, but this may take up to 2 years, with or without the use of immunosuppressive drugs.³⁴ Among patients whose inhibitors have abated, reemergence of the inhibitor in subsequent pregnancies appears to be rare. Indeed, some reports have described instances in which the inhibitor disappeared during a subsequent pregnancy.^{35,36} Transplacental transfer of the inhibitor can be detected in the newborn and may lead to a severe, albeit transient, bleeding diathesis.^{37,38}

Systemic lupus erythematosus (SLE) and rheumatoid arthritis are the most frequently encountered autoimmune disorders associated with factor VIII inhibitor development.^{25,39–41} Moreover, several dermatologic conditions with a known autoimmune basis, such as psoriasis and pemphigus vulgaris, are also associated with acquired hemophilia.^{25,39} Because these disorders are also associated with the development of antibodies to other coagulation factors and phospholipid-binding proteins (see later), special care must be taken to identify the specificity of the inhibitor in this group of patients.

Factor VIII inhibitors also arise among patients with a variety of solid tumors and hematologic malignancies. Perhaps the first reported case of acquired hemophilia, in 1940, was that of a 61-year-old man who died of hemorrhage after undergoing lymph node excision.⁴² In view of the relationship between factor VIII inhibitor formation and altered immune status, it is not surprising that the most common association is with lymphoproliferative disorders.^{25,43–47} Factor VIII inhibitors have been detected in association with numerous solid tumors, including neoplasms of the colon, pancreas, kidney, prostate, testes, brain, and lung.^{25,29,31,44} As is often true in rare disease associations, it is uncertain whether these reports represent chance occurrences or potentially causative events.⁴⁴ For example, the use of radiation therapy or systemic chemotherapy may induce generalized immunologic alterations that predispose to autoantibody formation.

Severe drug reactions, most commonly to penicillin, sulfa antibiotics, chloramphenicol, and phenytoin, have been associated with factor VIII inhibitor formation.⁴⁸ It appears likely that alterations in the immunologic state induced by the hypersensitivity reaction, rather than the drug-specific antibody itself, are responsible for development of the inhibitor. Recent viral infections appear to be common among the rare nonhemophilic children who develop acquired inhibitors of coagulation.⁴⁹

Figure 6-2 Demographics of patients with nonhemophilic inhibitors to factor VIII. **A.** Age distribution. **B.** Sex. **C.** Underlying disorder. In most patients, advanced age is the only identifiable risk factor. See text for references to primary data.

Immunochemistry of Factor VIII Inhibitors

Factor VIII circulates as cation-linked heterodimers in which heterogeneous 92- to 200-kD heavy chains (domains A1, A2, and B) are associated with 80-kD light chains (domains A3, C1, and C2).⁵⁰ In plasma, factor VIII is non-covalently bound to von Willebrand factor (VWF), which serves to localize factor VIII to sites of vascular injury and to protect it from inactivation by activated protein C (APC).⁵¹ Activation of factor VIII by thrombin results in its release from VWF and promotion of binding to phospholipid surfaces on the platelet.⁵² The VWF and phospholipid binding regions of factor VIII are found on the light chain. Detailed studies in which competitive binding and neutralization assays were used have shown that most factor VIII autoantibodies are directed against the C2 domain and other light-chain sequences.^{53–55} Antibodies that recognize the A2 domain of the heavy chain have also been described. Unexpectedly, alloantibodies and autoantibodies bind to similar epitopes on factor VIII, although the pattern of reactivity tends to be simpler in nonhemophilic patients with factor VIII inhibitors.^{53,54} Further elucidation of the immunochemical complexity of acquired factor VIII inhibitors ultimately may explain observed differences between laboratory assays and clinical manifestations.^{56,57}

Anti-factor VIII antibodies exhibit a number of biochemical characteristics that are relevant to their detection and clinical manifestations. Almost all are high-affinity IgG immunoglobulins of restricted polyclonal origin.⁵⁸ A predominance of the IgG₄ subclass and of κ and λ light chains can be found with approximately equal frequency. IgG₄ antibodies do not fix complement; consequently, patients do not develop renal or vascular complications, even in the presence of endogenous factor VIII. Although the vast majority of inhibitors found in patients with acquired hemophilia are of the IgG class, isolated instances of IgM^{47,59} and IgA⁴⁶ also have been reported. Progression from a predominantly IgM to an IgG profile was observed on at least one occasion.⁶⁰

Factor VIII inhibitors promote the increased catabolism of factor VIII or interfere with coagulation function through a variety of mechanisms. These include inhibition of the interaction of factor VIII with phospholipid⁶¹ or VWF^{58,62} or factor IX,⁶³ and interference with thrombin-mediated factor VIII activation.^{64,65} It is possible that some anti-factor VIII autoantibodies also interfere with VWF or platelet function, thus explaining their propensity to produce mucocutaneous bleeding.

Inactivation of factor VIII by acquired inhibitors is time and temperature dependent.⁴⁰ Two types of inactivation patterns are described (see Fig. 6-1).^{66,67} Type 1 antibodies, when present in excess, produce complete inactivation of factor VIII, and a linear relationship exists between the concentration of inhibitor and the (logarithm of) residual factor VIII activity. This pattern of inactivation permits accurate measurement of inhibitor potency with the Bethesda assay. In contrast, type 2 antibodies do not produce complete inactivation unless the factor VIII is first dissociated from the VWF with which it is normally complexed.⁶⁸

Patients with acquired hemophilia almost always develop inhibitors that exhibit type 2 inactivation kinetics, and often, residual factor VIII levels may be measured, even

while patients are experiencing severe bleeding complications. Factor VIII inhibitors in individuals with congenital hemophilia characteristically exhibit type 1 kinetics. The reason for partial inhibition of factor VIII by type 2 antibodies is unclear but may be related to the target epitope (s) or to the formation of immune complexes.^{68,69}

Treatment

When treatment strategies are considered, two objectives must be met: (1) immediate control of bleeding manifestations, if present, and (2) long-term suppression of the inhibitor, if possible. In both instances, one must take into consideration a variety of details, including the severity of the clinical symptoms, the patient's previous history of blood product exposure, the availability of therapeutic products, and the costs associated with treatment.

Management of Acute Bleeding

When possible, optimal management of bleeding is achieved through normalization of the plasma factor VIII level.⁷⁰ For patients with low-titer inhibitors (<5 BU), this goal can best be attained through the infusion of exogenous factor VIII in concentrations great enough to overwhelm the inhibitor, so that hemostatic levels of factor VIII are achieved and therapeutic efficacy assured. In the face of high-titer inhibitors (≥ 5 BU), this approach is not practical, and strategies to bypass the inhibitor are required (Fig. 6-3).

Figure 6-3 Suggested algorithm for the management of patients with nonhemophilic inhibitors to factor VIII who experience a serious bleeding event. Antifibrinolytics (e.g., ϵ -aminocaproic acid) should not be given concomitantly with FEIBA and should be used with caution in all patients with risk factors for thromboembolic disease. BU, Bethesda units; FEIBA, factor VIII inhibitor bypassing activity; inh, inhibitor; rFVIIa, recombinant activated factor VII.

Hemostatic Agents that “Bypass” the Inhibitor

When the inhibitor titer is high, as is generally the case, strategies to bypass the inhibitor must be used. These strategies consist of infusing activators of the extrinsic or common coagulation pathways, with the effect of generating thrombin in the absence of factor VIII.⁷¹

Historically, both prothrombin complex concentrates (PCC) and activated prothrombin complex concentrates (APCC) have been used extensively to treat patients with factor VIII inhibitors, including those with acquired hemophilia.⁷² In the only large, blinded study of the efficacy of PCC and APCC, patients with severe hemophilia, inhibitors, and acute hemarthroses received single doses of each of the two products infused at 50 to 75 U per kilogram; clinical improvement was noted in 52% and 64% of patients, respectively.⁷³ No comparable study has focused on patients with acquired hemophilia, although the use of APCC in the management of hemophilia A with inhibitors and acquired hemophilia is generally recommended.⁷⁴

At this time, Factor Eight Inhibitor Bypassing Activity (FEIBA VH; Baxter Healthcare, Deerfield, Ill) remains the sole APCC available for general clinical use. The recommended dose of activated concentrate is 50 to 100 U per kilogram; maximum daily dose is 200 U per kilogram.⁷⁵ Sallah⁷⁶ reported an overall response rate of 86% for this APCC in the management of bleeding episodes in 34 patients with acquired hemophilia. Most received dosing regimens of 75 U per kilogram every 8 to 12 hours. A similar dosing regimen of 70 U per kilogram every 8 hours was successfully used⁷⁷ in the treatment of bleeding episodes and minor invasive procedures. FEIBA was similarly administered to 60 patients with factor VIII inhibitors, 6 of whom were given a diagnosis of acquired hemophilia, at an average dose of 70 U per kilogram every 8 to 12 hours.⁷⁸ In this series, the effective response rate was reported to be 81%.

The mechanisms by which APCC promotes hemostasis have recently become more fully elucidated. Reconstitution experiments with recombinant proteins showed that a complex of activated FX and prothrombin substantially reproduced the thrombin generating properties of FEIBA.⁷⁹ In the current model, other zymogens and activated factors in APCC may further enhance the hemostatic properties of the product.

Despite the proven usefulness of APCC in the treatment of patients with acute bleeding episodes who had inhibitors to factor VIII, these products have some limitations. APCC are derived from plasma, and the infectious risks associated with all plasma-derived products have been dramatically attenuated but cannot be fully eliminated.⁸⁰ Further, the absence of laboratory measurements that accurately reflect the pharmacodynamics of the product means that only clinical end points have been generally used to monitor treatment. Even with repeated infusions, a substantial proportion of patients appear to gain little clinical benefit. However, recent reports have suggested that the thrombin generation assay (TGA) may prove useful in assessment of the bioavailability of APCC, resulting in precise dosing adjustments.⁸¹

APCC has been associated with rare thrombotic events, including disseminated intravascular coagulation (DIC)⁸² and myocardial infarction.⁸³ An incidence of 4 to 8 events per 10⁵ infusions has been estimated from pharmacovigi-

lance data.^{84,85} Thromboembolic risk appears to be greatest among patients who exceed the recommended daily dose of 200 U per kilogram, and in those with significant other morbidities such as advanced liver or ischemic heart disease.⁸⁴ Finally, although the concentrates are often used to avoid exposure to factor VIII and anamnestic immune response, increases in factor VIII inhibitor titers have been reported in a small percentage of patients,⁸⁶ most likely resulting from the presence of small quantities of factor VIII in some products.⁸⁷ However, in patients with acquired hemophilia, in whom exposure to endogenous factor VIII is ongoing, this risk would appear to be negligible.

Recombinant Activated Factor VII

Recombinant activated human factor VII (rFVIIa; NovoSeven; Novo Nordisk, Denmark) is a procoagulant protein concentrate developed to “bypass” factor VIII or IX inhibitors.⁸⁸ Several plausible mechanisms of action have been defined. At physiologic concentrations, the activity of rFVIIa is absolutely dependent on tissue factor (TF), a membrane protein expressed on cellular components of the vascular wall that is exposed only at times of injury. The rFVIIa:TF complex activates factor X to Xa and thus promotes thrombin generation and fibrin formation. In the absence of the intrinsic pathway, tissue factor pathway inhibitor (TFPI) inhibits this activity, and only small amounts of thrombin are generated. Pharmacologic concentrations of rFVIIa may escape this inhibition by competing with zymogen factor VII for binding to TF,⁸⁹ or by directly generating Xa, and subsequently thrombin, on the surfaces of activated platelets.⁹⁰ The ability to activate factor X in the absence of a functional tenase complex provides a rationale for its use in the management of patients with factor VIII or factor IX inhibitors; its usefulness in treating patients with inhibitors to common pathway factors (V, X, and prothrombin) would appear to be less well founded.⁹¹

Hay and colleagues³² reported the use of rFVIIa to treat 74 bleeding episodes in 38 patients who participated in a compassionate use program. A median of 28 doses were infused over a median of 3.9 days. The response rate at 24 hours was good in 75% of the 60 bleeds in which rFVIIa was used as salvage therapy; a good response rate was seen in all 14 bleeds in which the drug was employed as first-line therapy. Smaller series have also shown rFVIIa to be effective in most patients with acquired hemophilia when used as salvage therapy.^{92,93}

The recommended dose for rFVIIa is 90 µg per kilogram every 2 hours until hemostasis is achieved, or the drug is deemed ineffective. Typically, initial doses of 90 to 120 µg per kilogram every 2 hours have been used with a wide range of subsequent dosages, dosing intervals, and durations. Higher doses have been considered, especially in children with congenital hemophilia and inhibitors, with variable results.^{94,95} rFVIIa appears to be more effective when treatment is initiated early, at least in the treatment of acute hemarthrosis.^{96,97} Whether this is also true in acquired hemophilia has not been established. The feasibility of using rFVIIa by continuous infusion has also been considered.^{98,99}

Many of the limitations previously described for the use of APCC also apply to rFVIIa. Laboratory markers that accurately predict clinical efficacy have yet to be developed. The PT shortens to approximately 7 seconds at FVII:C concentrations of approximately 5 U per milliliter, but this level of drug is not hemostatically effective in patients with inhibitors. FVII:C levels can be measured, but these values have been inconsistent with respect to clinical efficacy.

Variability among patients in ability to generate thrombin on activated platelet surfaces may influence the efficacy of rFVIIa, leading to the need for higher dosing and higher plasma levels in some patients.¹⁰⁰ More global tests of hemostasis, such as TGA and thromboelastography (TEG),^{81,91} may eventually prove useful. Thromboembolic complications have been reported after the use of rFVIIa, some in patients with acquired hemophilia.^{85,101,102} However, concomitant risk factors or the use of PCCs co-existed in most of these situations. It is important to note that antibodies to factor VII or rFVIIa have yet to be observed in infused patients, other than those with congenital factor VII deficiency, after repeated administration of these products.¹⁰³

Factor VIII Replacement Therapy

When the inhibitor titer is low, human factor VIII concentrates may be used. The factor VIII present in intermediate-purity concentrates is complexed with VWF, and it has been proposed that these may be less susceptible to inactivation, especially by antibodies directed against the C2 domain.¹⁰⁴ Most autoantibodies, and some alloantibodies, neutralize porcine-derived factor VIII to a much lesser extent than factor VIII derived from human plasma¹⁰⁵; however, porcine factor VIII concentrate (Hyate C; Ipsen, Maidenhead, UK) is no longer produced. A recombinant porcine factor VIII is currently undergoing clinical trials but is not yet commercially available.

In treating patients with hemophilia A, the initial dose of factor may be calculated roughly with the following formula: 40 IU factor VIII per kilogram + 20 IU factor VIII per kilogram per BU of inhibitor.⁷⁰ However, as was mentioned previously, inhibitor titers among patients with acquired hemophilia are notoriously inaccurate, and post-infusion factor VIII levels should be monitored closely as measured Bethesda titers may not be predictive of response. If the inhibitor titer has not yet been determined, one may consider the use of an empirically determined initial dose of 75 to 100 IU per kilogram.¹⁰⁶ A particularly useful strategy involves the administration of a bolus dose to neutralize the inhibitor, followed by a continuous infusion of factor to achieve hemostatic levels (30 to 50 IU/dL).^{106–108} This approach takes advantage of the fact that the kinetics of factor VIII inhibition is time dependent, so that a steady state of uninhibited factor VIII can be achieved. The continuous, albeit low, availability of uncomplexed factor VIII may help to explain observed clinical improvement in response to factor VIII infusion, even among patients in whom increases in plasma factor VIII activity cannot be proved.

DDAVP

Intravenous administration of 1-deamino-8-D-arginine vasopressin (DDAVP [desmopressin]) at a dose of 0.3 µg

per kilogram results in rapid increases in VWF and factor VIII levels in normal individuals.¹⁰⁹ DDAVP may also increase circulating factor VIII sufficiently to treat minor non-life-threatening bleeding in patients with acquired hemophilia.^{110–112} Treatment is generally effective in cases in which the inhibitor titer is low and the residual factor VIII level measurable. As might be predicted, DDAVP is associated with tachyphylaxis but does not produce anamnesis to factor VIII.

Transient Reduction in Inhibitor Titers

The treatment of a life-threatening hemorrhage in a patient with a high-titer inhibitor who has not responded to bypass strategies is particularly difficult. In such circumstances, a temporary reduction of the inhibitor titer may be attempted to improve the efficacy of exogenous factor VIII infusions. This can be accomplished through exchange plasmapheresis,¹¹³ with or without extracorporeal immunoadsorption.¹¹⁴ Because most factor VIII inhibitors are of the IgG class, the extent of reduction in titer is limited by the inability of plasmapheresis to directly access the extravascular space in which IgG is partly distributed. Nevertheless, it may be possible to achieve as much as a 90% reduction in inhibitor titer.¹¹⁵ Volume replacement usually consists of normal plasma followed by factor VIII infusion, although factor concentrate has also been used in the initial replacement fluid in a preoperative setting. Plasmapheresis cannot be used in patients who are hemodynamically unstable, or in whom vascular access cannot be easily achieved (see Chapter 30).

Extracorporeal reduction in inhibitor titer can be improved dramatically by the addition of an immunoadsorption step.¹¹⁶ Staphylococcal protein A, which binds with high affinity to the Fc portion of all IgG subclasses except IgG₃, provides an effective means of selectively depleting plasma of a variety of autoantibodies and alloantibodies. Because the predominant IgG subclass of factor VIII inhibitors is IgG₄, protein A appears to be ideally suited to the treatment of this disorder. For each plasma volume that is immunoadsorbed, plasma level is reduced by approximately 50%; thus, an 80% to 90% reduction in inhibitor titer is possible after three plasma volumes have been processed.¹¹⁷ After adsorption exchange plasmapheresis has been completed, patients are infused with immune globulin and human or porcine factor VIII. An even more specific immunoadsorption method has been developed in which inhibitor plasma is passed through a column of agarose coupled to monoclonal antihuman IgG₄ antibodies.¹¹⁸ Despite the inherent logic of these approaches and the favorable outcomes reported in small groups of patients, technical difficulties associated with the adsorption columns have prevented their widespread application.

Intravenous Immune Globulin

Intravenous administration of immune globulin (IVIg) (2 g/kg total dose administered in two or five daily fractions) results in at least partial suppression of factor VIII inhibitors in a subset of patients with acquired hemophilia.^{6,119,120} In general, the best results are achieved in patients who have low initial antibody titers. The rapid decline in measurable titer that is observed in some

patients^{119,120} suggests that the success of intravenous IgG may be related to the presence of anti-idiotypic antibodies in plasma pools derived from normal donors.^{7,121}

Immunosuppression of Factor VIII Inhibitors

The long-term goal in the treatment of patients with acquired inhibitors of factor VIII is eradication of the auto-antibody. Although a small proportion of patients may never require hemostatic treatment, and spontaneous remissions are not uncommon,²⁷ most patients are likely to develop life- or limb-threatening hemorrhage, and the immediate initiation of immunosuppressive therapy as soon as the diagnosis of acquired hemophilia has been established is recommended.⁷⁴

Once the decision for pharmacologic intervention has been made, the initial choice is most often between glucocorticoid alone¹²² and glucocorticoids in combination with azathioprine or cyclophosphamide.¹²³ In a large, multicenter, retrospective study, clinical response was documented in 78 of 145 patients (54%) who received immunosuppression with one or more of these drugs, whereas only 11 of 39 (28%) patients improved without specific treatment.²⁵ In the only prospective, randomized study on the subject, patients were treated initially with prednisone alone at a dose of 1 mg per kilogram daily for 3 weeks.¹²⁴ If antibody continued to be detectable, patients were randomly assigned to receive additional prednisone, prednisone with oral cyclophosphamide (2 mg/kg/day), or cyclophosphamide alone. Approximately one third of patients responded to the initial prednisone course; approximately 50% of steroid-resistant patients responded to the cyclophosphamide-containing regimens. The combination of prednisone (50 to 80 mg/day) and oral cyclophosphamide (100 to 200 mg/day) was similarly effective in other small series of patients.^{125,126} A prospective study reported a 91% response rate in 12 patients treated with repeated cycles of factor VIII concentrate, cyclophosphamide, vincristine, and prednisone, although none of the 11 good responders had initial antibody titers greater than 50 BU.¹²⁷ More favorable responses were also noted among patients with low-titer inhibitors in other studies.^{122,124} It has been proposed that the addition of factor VIII to the regimen enhances responsiveness to immunosuppressive agents,¹²⁷ although this assertion has been disputed.¹²⁵ Cyclosporine may be useful for patients who are unresponsive to these agents.⁹⁸

Recently, rituximab, a monoclonal antibody directed against CD20 antigen on B lymphocytes,¹²⁸ has been successfully used in the treatment of patients with acquired hemophilia. This drug is currently approved for use in non-Hodgkin's lymphoma (NHL), but it has proved effective in many autoimmune disorders.¹²⁹ Wiestner and colleagues¹³⁰⁻¹³² described eight patients with acquired hemophilia, including two with titers over 200 BU, who responded to rituximab with or without other immunosuppressive agents. Rapid and complete remission was achieved in 8 of 10 patients with rituximab alone. Patients who relapsed after cessation of the drug, could be successfully retreated with the previous regimen of rituximab. It is important to note that responses to rituximab have been observed after failure was observed with prednisone and/or other immunosuppressive regimens.¹³³ Typically, the dosing regimen was adopted from that used to treat

patients with NHL—375 mg per meter squared intravenously given once weekly in 4-week cycles. Fever and rigors were observed in most patients. Serious infections and adverse immunologic reactions due to the development of anti-rituximab antibodies have each been reported in a small percentage of treated patients.

Immune tolerance induction (ITI) is a possibility for the eradication of alloantibodies that one may encounter as a complication in the management of patients with hemophilia A. This approach is discussed in Chapter 4.

INHIBITORS OF VITAMIN K-DEPENDENT PROTEINS

Inhibitors of Prothrombin and Thrombin

Antiprothrombin and antiphosphatidylserine/prothrombin antibodies are commonly detected as “lupus anticoagulants” in patients with SLE and have been described in a large proportion of patients in whom antiphospholipid syndrome has been diagnosed.¹³⁴⁻¹³⁶ In this setting, their presence has been associated with increased thromboembolic risk.^{136,137} Antiprothrombin antibodies may also produce a reduction in the level of prothrombin sufficient to produce clinical bleeding.^{138,139} Antithrombin antibodies are also commonly seen after exposure to bovine thrombin preparations in association with anti-factor V antibodies, in which they may be detected only as a laboratory abnormality or may contribute to the bleeding diathesis (see later).^{140,141} Case reports, at least one with a fatal outcome, have described patients in whom antibodies against thrombin arose in the setting of autoimmune disease or liver cirrhosis.^{142,143} In the laboratory, one observes prolonged PT, PTT, and thrombin time, which are not corrected in mixing studies.

The mechanisms by which antiprothrombin antibodies exert their influence are heterogeneous. Some hamper prothrombin activation by coagulation factors Xa and Va and thus behave *in vitro* as acquired phospholipid-dependent inhibitors.¹³⁴ In many instances, antibodies are directed against nonfunctional epitopes on prothrombin (e.g., fragment 1); they thus promote accelerated clearance of the coagulation factor from the circulation but are not detectable in mixing studies.¹⁴⁴ Nonneutralizing antiprothrombin antibodies have also been described in a patient without evidence of a lupus anticoagulant.¹⁴⁵ In one instance, an autoantibody was described that aberrantly activated prothrombin, thereby permitting subsequent neutralization by antithrombin III. The prothrombin molecule was not cleaved to thrombin and remained unable to convert fibrinogen to fibrin, resulting in a significant bleeding diathesis.¹⁴⁶

Therapeutic benefit in patients with acquired antiprothrombin and antithrombin antibodies has been shown after therapy with prednisone,¹⁴⁵ danazol,¹⁴⁷ and high-dose immunoglobulin.^{148,149} rFVIIa was successfully used to provide immediate hemostatic coverage in a patient with acquired hypoprothrombinemia who required a minor surgical procedure.¹³⁹

Inhibitors of Factor IX

Inhibitors of factor IX arise in approximately 3% of patients with congenital factor IX deficiency after exposure

to exogenous sources of the coagulation protein.¹⁵⁰ Factor IX inhibitors have also been reported in nonhemophilic patients in association with systemic autoimmune disorders.^{151,152} In general, factor IX inhibitors are polyclonal immunoglobulins of the IgG class,¹⁵³ although at least one case of a factor IX inhibitor produced by monoclonal gammopathy has been reported.¹⁵⁴ In the laboratory, factor IX inhibitors are first detected by the failure of normal plasma to correct the PTT in mixing studies; these times may be quantified through modification of the Bethesda assay.¹⁸ However, different from the behavior of most factor VIII antibodies in vitro, anti-factor IX antibodies induce an immediate loss of factor IX activity that does not require prolonged incubation.¹⁵¹

Inhibitors of Factor X

Acquired factor X deficiency occurs in approximately 5% of patients with systemic amyloid disease.¹⁵⁵ In contrast to other acquired factor deficiencies, the bleeding diathesis in this instance arises not from a circulating inhibitor, but from adsorption of factor X on the amyloid fibrils, particularly in the spleen.¹⁵⁶ Bleeding into soft tissues is often severe.¹⁵⁵ Replacement therapy with factor X, with the use of fresh frozen plasma or factor IX complex concentrates, is often only partially effective because of the shortened half-life of the infused factor. Splenectomy may produce a rapid improvement in factor X levels caused by the physical removal of amyloid binding sites.¹⁵⁷ Chemotherapy drugs, such as melphalan and prednisone, may further limit amyloid deposition.¹⁵⁸ rFVIIa was reported to be effective in achieving immediate hemostasis in a bleeding patient.¹⁵⁹

INHIBITORS OF FACTOR XI

Factor XI is one of the contact phase coagulation factors; it displays both procoagulant (through direct action on factor IX) and antifibrinolytic (through activation of thrombin-activated fibrinolysis inhibitor [TAFI]) activities.¹⁶⁰ Factor XI inhibitors have been observed rarely among patients with congenital factor XI deficiency who have been exposed to exogenous factor XI.¹⁶¹ Factor XI antibodies are also seen in association with a variety of autoimmune disorders, principally SLE.¹⁶² Acquired factor XI deficiency has been observed rarely in association with a number of malignancies, particularly those of hematologic origin.^{163,164} Many older reports of factor XI antibodies among patients with SLE and thrombosis are likely to be misdiagnosed lupus anticoagulants.¹⁶⁵ Bleeding manifestations in this setting appear to be decidedly uncommon.

The laboratory diagnosis of factor XI inhibitors is usually made on discovery of a prolonged PTT, normal PT, normal thrombin time, and lack of correction in mixing studies. Specific factor assays performed at progressive plasma dilutions yield a persistently low factor XI level, with normalization of remaining factors, although factor XII levels may remain falsely low unless sufficient dilutions of patient plasma are prepared.

Although patients with congenital factor XI deficiency who develop inhibitors usually do not develop spontaneous hemorrhage, perioperative bleeding has been reported to be severe.^{161,166} Because titers of factor XI inhibitors

are generally low, adequate replacement therapy with fresh frozen plasma can sometimes be provided. Alternatively, factor IX complex concentrates, their active forms, or rFVIIa may be effective in achieving hemostasis.^{88,167} High-dose prednisone, 60 to 80 mg per day, is often effective in suppressing the inhibitor.¹⁶²

INHIBITORS OF FACTOR V

Numerous reports have described factor V inhibitors arising in individuals without a prior history of abnormal hemostasis. Approximately 20% of cases are idiopathic, but the most common associations involve recent surgery, drug exposure (aminoglycosides, β -lactam antibiotics), autoimmune disorders, and pregnancy.¹⁶⁸ Of these, the occurrence of factor V inhibitors after topical bovine thrombin preparations that contain bovine factor V have been administered is the best described and most important.^{169,170} An immune response to bovine protein generates antibodies that cross-react with endogenous human factor V. Most of the inhibitors are composed of polyclonal IgG, although instances have been reported of IgG in association with IgM¹⁷¹ or IgA.¹⁷² Interference with the interaction between the C2 domains of factor Va and phospholipid was demonstrated in the analysis of one such inhibitor, and hemorrhagic manifestations appear to correlate well with the degree of inhibition of the prothrombinase complex.¹⁷³

Factor V inhibitors initially are detected during routine laboratory evaluation by the prolongation of PT and PTT, both of which fail to correct on mixing with normal plasma. As in the case of lupus anticoagulants, the RVVT is prolonged, but factor V inhibitors can be distinguished from the latter by their failure to correct in the presence of excess phospholipid and by specific factor assays performed on progressive dilutions of patient plasma.

Clinical manifestations in the setting of factor V inhibitors are highly variable. Bleeding, which is seen in the great majority of cases, is typically severe and frequently fatal.^{168,170,174,175} Mucocutaneous bleeding and bleeding at the surgical site are the most commonly observed events. In the postoperative setting, factor V inhibitors are first observed approximately 7 to 10 days after surgery and may intensify with repeated exposure to bovine preparations. In general, the titer of the inhibitor correlates with clinical severity. However, in some instances, little if any clinical bleeding is observed, even in postsurgical settings, despite overtly abnormal in vitro laboratory findings.¹⁷⁶

Most factor V inhibitors that arise in association with bovine protein exposure appear to be of short duration, usually disappearing within 8 to 10 weeks; they can be managed expectantly in the absence of bleeding manifestations. Factor V inhibitors associated with other risk factors typically persist for significantly longer periods, and immunosuppressive therapy is usually warranted. Glucocorticoids, cyclophosphamide, and other regimens that contain these agents have been successful in the treatment of 65% to 74% of patients.^{170,177} Immunomodulation with IVIg has also proved generally successful in some settings.¹⁴¹ In many instances, exposure to bovine protein can be avoided by the use of a commercial fibrin sealant that contains virus-inactivated human fibrinogen, factor XIII, and thrombin.¹⁷⁸

The management of acute bleeding with acquired factor V inhibitors can be especially challenging. Because these inhibitors interfere with prothrombinase complex formation, replacement therapy with fresh frozen plasma or the use of “bypassing agents” such as APCC or rFVIIa is likely to be of limited value.¹⁶⁸ Platelet transfusion, with response rates of 30% to 40%, appears to be an especially useful means of “bypassing” the inhibitor in that transfused factor V is stored in the intracellular α granules and becomes accessible to the inhibitor only after platelet activation has occurred.¹⁷⁷ Replacement therapy may become transiently feasible after rapid reduction in antibody titer achieved through the use of plasmapheresis or immunoadsorption.¹⁷⁹

INHIBITORS OF FIBRINOGEN AND FACTOR XIII

Thrombin-mediated conversion of fibrinogen to fibrin, formation of a fibrin mesh, and crosslinking of the α and γ chains of fibrin by factor XIIIa make up the final steps in blood coagulation.¹⁸⁰ Rare inhibitors of factor XIII, some specifically characterized as immunoglobulins, have been reported in congenitally deficient patients who have received exogenous factor XIII, as well as in previously normal individuals. In the case of spontaneously acquired inhibitors, prior exposure to isoniazid¹⁸¹ or procainamide¹⁸² has also been implicated in the pathogenesis. It is known that isoniazid can be incorporated into protein by factor XIIIa, although the relationship of this action to inhibitor formation remains unclear.¹⁸³

Inhibitors of factor XIII, principally immunoglobulins, act through a variety of molecular mechanisms to produce functional derangement. These include inhibition of thrombin activation, transamidase activity and fibrin crosslinking, and inhibition of factor XIIIa binding to fibrin.^{182,184} In some cases, the antibody may exert the same effects by reacting with the crosslinking site on the fibrin substrate.¹⁸⁵ Other antibodies, both polyclonal and monoclonal, have been described that inhibit the conversion of fibrinogen to fibrin.^{186,187} Generally, these antibodies can be detected in the laboratory by their effects on fibrin clot stability in dissolving agents such as 5M urea (urea clot solubility test).¹⁸²

Clinically, patients with acquired defects in fibrin crosslinking often present with massive, and sometimes fatal, spontaneous hemorrhaging. These patients exhibit high-titer inhibitors and are not easily treated by factor XIII replacement therapy. In one reported case, resolution of an acute bleeding episode was achieved after plasma immunoadsorption was accomplished with staphylococcal protein A.¹⁸⁸ Fortunately, in many cases, the inhibitors regress spontaneously over time or in response to immunosuppressive agents such as cyclophosphamide.¹⁸⁹ Administration of a factor XIII concentrate can sometimes be sufficient to overwhelm the inhibitor and achieve transient hemostasis.¹⁹⁰

INHIBITORS OF VON WILLEBRAND FACTOR

von Willebrand factor (VWF) is large, multimeric glycoprotein with two principal functions. It forms an essential bridge between platelets (via platelet glycoprotein-Ib-IX)

and subendothelial components (e.g., collagen) at sites of vascular injury, and it serves as a carrier protein for circulating factor VIII.¹⁹¹ Acquired von Willebrand syndrome (AVWS), a collection of acquired disorders that resemble congenital forms of von Willebrand disease (VWD), is described in association with numerous other diseases.^{192,193} Most common among these are lymphoproliferative disorders, monoclonal gammopathies, autoimmune diseases, and myeloproliferative disorders.^{194–197} AVWS is also seen in association with acquired or congenital heart disease¹⁹⁸ and with Wilms tumor in the pediatric setting.¹⁹⁹ Several pathogenic mechanisms are described: adsorption of VWF, particularly high molecular weight forms, by tumor cells; loss of larger VWF multimers in the high-shear stress environment of an abnormal vasculature and specific or nonspecific binding of VWF to circulating immunoglobulins.^{200,201} Most often, the latter represent true autoantibodies; less frequently, the paraprotein itself may be the offending agent. AVWS is also seen in some patients with hypothyroidism as a result of decreased synthesis and/or release of the VWF protein.²⁰²

In the laboratory, factor VIII, VWF antigen, and VWF ristocetin cofactor activity are reduced, although not always to the same extent (see Chapter 7). The absence of the largest multimeric forms of VWF and the decreased ratio of VWF activity to antigen, a pattern resembling congenital type 2A VWD, is frequently seen in cases caused by protein adsorption. Among autoantibodies to VWF, approximately 15% inhibit function (e.g., VWF binding to platelet glycoprotein Ib) and therefore can be shown in mixing studies based on the VWF:RCO assay. Noninhibitory antibodies, which promote the accelerated clearance of factor VIII/VWF complexes, can be detected only with immunoassays that are available in research laboratories.¹⁹²

The clinical manifestations of AVWS resemble those of congenital VWD (spontaneous mucocutaneous bleeding and postsurgical hemorrhage) and should be considered in all patients with recent onset of such symptoms in the absence of a personal or family history of VWD.²⁰³ Bleeding from angiodysplastic lesions in the gastrointestinal tract is particularly common and often serious.²⁰⁴ Overall, patients with autoantibodies to VWF are more severely affected than are those individuals with other forms of the disease.²⁰⁵ Treatment of the underlying disease through surgical or medical means often leads to improvement in the bleeding diathesis associated with AVWS.^{199,206} AVWS associated with SLE is typically responsive to glucocorticoids, and reduction in autoantibody titer and correction of laboratory parameters can often be accomplished with IVIg therapy in patients with monoclonal gammopathy.^{192,193,204,207,208} Particularly in instances of non-immune-mediated AVWS, transient correction of factor VIII and VWF activity levels and favorable hemostatic responses may be achieved with DDAVP or VWF/factor VIII concentrates.^{209–211} Patients with refractory AVWS have been successfully treated with rFVIIa.²¹²

FINAL CONSIDERATIONS

The acquired disorders of coagulation described in this chapter are only infrequently encountered in general medical practice but are characteristically challenging to

diagnose and costly to manage. Once considered, specialized laboratory evaluation is invariably required and consultation with a specialist with expertise in hemostasis is strongly advised. Often these conditions present as but one manifestation of other serious medical disorders and close and ongoing collaboration between the hematology consultant and referring physician is essential. A systematic approach to treatment, in the context of the frequently observed co-morbidities, is likely to lead to improvements in both the medical outcome and resource utilization.

Chapter 7

von Willebrand Disease

Margaret E. Rick, MD

INTRODUCTION

von Willebrand disease (VWD), which is transmitted in an autosomal dominant fashion, is the most common of the inherited bleeding disorders. It is caused by a decrease in the quantity of circulating von Willebrand factor (VWF) or by a qualitatively abnormal VWF in the circulation. VWD also may rarely present as an acquired disorder. Patients come to medical attention because of skin and mucosal bleeding symptoms such as epistaxis, gum bleeding, or hemorrhage from other mucosal surfaces; symptoms may be so mild that they are not recognized by the patient and are discovered only during testing that occurs because another family member has VWD. Diagnosis depends on laboratory tests that measure the VWF antigen, VWF activity (ristocetin cofactor and/or collagen-binding activity), and factor VIII activity; classification of the type of VWD (types 1–3) depends on additional assays, including the VWF multimer assay and ristocetin-induced platelet aggregation (RIPA) studies. It is important to classify the type of VWD because VWD type influences choice of therapy. The treatment of choice in most cases is desmopressin, which releases synthesized VWF and factor VIII from body storage sites, transiently increasing their levels. Treatment of more severe VWD includes replacement therapy with plasma-derived concentrates of VWF. Other topical and antifibrinolytic therapy modalities are also used as adjuncts.

VWD is an inherited autosomal dominant bleeding disorder that is found in approximately 1% of the population when random laboratory screening is carried out.¹ Only a fraction of these individuals is symptomatic, however, and most have mild or moderate manifestations that do not significantly affect daily living activities. Estimates derived from patients attending hemostasis treatment centers indicate that the number of patients with symptomatic VWD is 23 to 110 per million; this estimate predicts that approximately 580,000 patients worldwide are at risk for bleeding from VWD.² Easy bruising, epistaxis, and oral bleeding with dental procedures are often the primary symptoms. In most cases, the bleeding results from decreased VWF-mediated binding of platelets to the vascular subendothelium and decreased VWF-mediated platelet–platelet interactions that occur in areas of high shear (arterial circulation).³

Biochemical and physiologic information about VWF has enhanced our understanding of the functions of this molecule and has allowed clarification of the terminology for its activities. VWF was originally believed to be a part of the same protein as coagulation factor VIII because these

molecules circulate in plasma as a complex, the VWF acting as a carrier for factor VIII; VWF was called “factor VIII–related antigen” until the 1980s. (The current terminology and definitions are presented in [Table 7-1](#).) Genetic information promoted the development of a new classification of VWD,^{4,4a} and this is important not only for an understanding of the structure–function relationships of the protein, but also for the selection of optimal therapy for patients.

HISTORICAL OVERVIEW

Erik von Willebrand described the first patient with VWD in 1926, when he cared for a young patient and her extended family who lived on the Åland Islands in the Gulf of Bothnia. The proband was severely affected and died at the age of 13 years, when she had uncontrollable menstrual bleeding; 4 of her 11 siblings were also severely affected. After evaluating 66 other family members and identifying the disease in 24, von Willebrand recognized that the inheritance pattern of this disease was autosomal dominant, different from that seen in hemophilia A (which is sex-linked recessive), and he named the disorder “hereditary pseudohemophilia.” He also recognized that patients’ platelet counts were normal, and that this disease was different from the other inherited bleeding disorders known at that time.⁵

When the laboratory test for factor VIII was developed in the 1950s, it was shown that patients with VWD had decreased levels of factor VIII activity,⁶ and that the bleeding could be corrected with transfusion of plasma or partially purified preparations of factor VIII.⁷ Considerable debate focused on the nature of the von Willebrand protein until factor VIII and VWF were cloned in the 1980s^{8–11}; before this, there was uncertainty about whether one bifunctional protein or two different proteins carried out the platelet-related functions (VWF) and the task of promoting fibrin formation (factor VIII). We now know that these are two entirely different molecules encoded by different genes, and that factor VIII is bound to VWF, forming a noncovalent complex in the circulation that prolongs factor VIII survival.^{12,13}

PHYSIOLOGY AND STRUCTURE–FUNCTION RELATIONSHIPS

VWF has two primary functions ([Table 7-2](#)): It binds to both platelets and subendothelial structures, acting as a

Table 7-1 Nomenclature		
Designation	Function	Assay
von Willebrand factor (VWF)	Multimeric glycoprotein that promotes platelet adhesion and aggregation and is a carrier for factor VIII in plasma	See below
von Willebrand factor activity (VWF:RCO)	Binding activity of VWF that causes binding of VWF to platelets in the presence of ristocetin with consequent agglutination Ability of VWF to bind to collagen	Ristocetin cofactor activity: Quantitate platelet agglutination after addition of ristocetin and VWF Collagen-binding activity: Quantitate binding of VWF to collagen-coated plates (ELISA format)
von Willebrand factor antigen (VWF:Ag)	VWF protein as measured by protein assays; does not imply functional ability	Immunologic assays such as ELISA, RIA, Laurell electroimmunoassay
von Willebrand factor multimers	Size distribution and analysis of VWF multimers as assessed by agarose gel electrophoresis	VWF multimer assay: Electrophoresis in low-concentration agarose gel and visualization by monospecific antibody to VWF
Factor VIII (FVIII)	Circulating coagulation protein that is protected from clearance by VWF and is important in thrombin generation	Factor VIII activity: Plasma clotting test based on PTT assay using FVIII-deficient substrate; quantitates activity
Ristocetin-induced platelet aggregation (RIPA)	Test that measures the ability of patient VWF to bind to platelets in the presence of various concentrations of ristocetin	RIPA: Aggregation of patient PRP using various (low) concentrations of ristocetin

ELISA, enzyme-linked immunosorbent assay; RIA, radioimmunoassay; PTT, partial thromboplastin time; PRP, platelet-rich plasma.

Table 7-2 Functions of von Willebrand Factor
Platelet–Subendothelium Binding von Willebrand factor (VWF) binds to platelet receptor glycoprotein Ib (GP-Ib) and to subendothelial collagen and other matrix molecules, binding platelets to damaged vessel.
Platelet–Platelet Binding VWF binds to platelet receptor GP-Ib in areas with high shear (arterial circulation) and binds platelets together, causing platelet aggregation.
Carrier for Factor VIII in Plasma VWF binds to factor VIII by a site in the aminoterminal of VWF, protecting factor VIII from proteolysis and prolonging its half-life.

bridging molecule for initial reactions during primary hemostasis,³ and it binds factor VIII, averting proteolysis of factor VIII in the circulation.^{14,15} VWF is a huge multimeric glycoprotein that is synthesized in endothelial cells and megakaryocytes.^{16,17} The largest multimers are created by the polymerization of subunits that all contain the same binding sites (Fig. 7-1); these repeated binding sites make VWF particularly well suited to act as a bridge between cells and other structures of the vasculature. Synthesis of VWF includes the initial formation of a dimer between the basic subunits and subsequent multimerization of the dimers to form multimers of a magnitude greater than 20 million daltons. The newly synthesized VWF is secreted constitutively or is targeted to storage granules such as the Weibel-Palade bodies in endothelial cells or α granules in megakaryocytes.¹⁸ These storage granules contain the larger, more hemostatic forms of VWF that are released upon stimulation with agonists such as thrombin, epinephrine, and fibrin.^{19–21} The VWF within storage granules

contains newly synthesized, even larger multimers than are usually found in the circulation. Limited proteolysis occurs in plasma and targets especially these very large prothrombotic multimers¹⁸; the protease, ADAMTS13 (*a* disintegrin and metalloproteinase with thrombospondin subunits), has been shown to be responsible for this cleavage.^{22–24} Other evidence suggests that another protein, thrombospondin-1, may also reduce the size of these unusually large multimers by acting as a protein disulfide reductase.²⁵

Also contained within the storage granules and released upon stimulation is a propolypeptide, von Willebrand antigen II, which contains a large sequence of the originally synthesized VWF that is cleaved near the time that multimerization takes place (see Fig. 7-1).¹⁸

The gene for VWF is located on chromosome 12, and a number of polymorphisms and mutations have been identified in the gene sequence, the latter most often in patients with qualitative defects of VWF (type 2 VWD) (reviewed in detail by Nichols and Ginsburg²⁶). Many of the mutations responsible for type 2 VWD are located in areas of the gene that are responsible for the structure of important binding sites or cleavage sites in VWF (see Fig. 7-1). The genetic abnormalities responsible for many patients with VWD have not been identified. In type 1, approximately 50% to 65% of kindreds have recognized mutations accounting for their disease.^{27,28,28a,28b}

A website that contains information on reported mutations and polymorphisms is administered by the University of Sheffield in the United Kingdom (<http://www.shf.ac.uk/vwf/>).

Platelet-Related Functions of von Willebrand Factor

VWF circulates in a tangled coil configuration,²⁹ enclosing some of the subunits and binding sites; the molecule likely

Figure 7-1 A, Von Willebrand factor (VWF) mRNA is shown, with domain designations noted inside the figure. Various types of VWD are shown in the areas where mutations that result in a particular type of VWD are most commonly found. **B**, The mature VWF subunit, aligned with the mRNA above, is depicted with amino acid numbering and binding sites shown below. (From Rose BD [ed]: UpToDate. Wellesley, MA, 2001. Copyright 2001 UpToDate, Inc.)

assumes a more linear configuration upon binding to a surface or when flowing through high-shear vessels in the arterial circulation.³⁰ The linear form allows the binding sites on many more of the subunits to become accessible for binding to receptors such as platelet glycoprotein Ib (GP-Ib)³¹ and to subendothelial collagen, one of the important vascular cell molecules that binds VWF.³² The binding of VWF to these ligands results in the tethering (adhesion) of platelets to the subendothelium in damaged blood vessels and in platelet–platelet interaction (aggregation) in high-shear vessels via a VWF bridge. The binding of VWF to platelet GP-Ib does not require prior activation of platelets and, in fact, such binding initiates intrinsic platelet activation.³³ VWF contains a second binding site for another platelet receptor, platelet glycoprotein IIb/IIIa (GP-IIb/IIIa), and this binding requires prior activation of platelets for exposure of the receptor. It is important in the later, irreversible binding of platelets to the subendothelium.³⁴ Other binding sites for heparin and sulfatides are also present in the VWF monomer.^{35,36}

Factor VIII–Related Functions of von Willebrand Factor

VWF contains a binding site for factor VIII that protects factor VIII from proteolysis in the circulation.¹⁴ This non-covalent interaction of VWF with factor VIII prolongs the half-life of factor VIII in the circulation by fivefold.¹⁵ In addition to the platelet interactions described earlier, the binding and protection of factor VIII are other important functions of VWF. As one might anticipate, a defect in this part of the VWF molecule leads to a bleeding disorder in

which one finds a decreased level of circulating factor VIII owing to its rapid clearance; the VWF-mediated platelet functions of VWD, however, are normal (see later, type 2 Normandy).

von Willebrand Factor Levels in Health and Disease

In addition to a broad normal range of VWF in plasma (≈ 30 IU/dL to 200 IU/dL), physiologic and pathologic conditions may alter the level of VWF in the circulation. Estrogen and thyroid hormone are important in regulating the synthesis of VWF,^{37,38} and a low level of thyroid hormone can lead to clinically important decreases in VWF.³⁹ Levels of VWF are at their baseline in women during the follicular phase of their menstrual cycle, and despite considerable day-to-day variation, they are generally higher during the late luteal phase.⁴⁰ During the second and third trimesters of pregnancy, VWF increases by two- to threefold, often leading to “normal” levels of VWF in patients with mild VWD; VWF levels may fall within hours after delivery.⁴¹ As an acute phase reactant, VWF (and factor VIII) levels are increased during the physiologic changes that occur with inflammation.⁴² An important variation occurs in the level of VWF in subjects with different blood groups: Individuals with type O blood have circulating levels of VWF that are approximately 30 IU/dL lower than in those with type A, B, or AB.⁴³ The latter must be taken into account when one attempts to make a definitive diagnosis of VWD in a patient who presents with “slightly low” laboratory values for VWF (see Pitfalls in Making the Diagnosis of VWD, later).

The role of VWF in atherogenesis and coronary artery syndromes is still being defined. Although markedly decreased levels of VWF play a protective role in preventing the development of coronary atherosclerosis in an animal model with type 3 VWD, it has not yet been proved that extremely low VWF levels reduce atherosclerosis in humans.^{44,45} However, studies of animals with more moderate (heterozygous) VWD and a few autopsy studies in humans with type 2 or type 3 VWD have shown that reduced VWF levels can prevent occlusive thrombi in atherosclerotic vessels.^{46,47}

CLINICAL PRESENTATION

Patients with moderate and severe VWD present with bleeding symptoms in childhood or young adulthood; however, patients may present at any age because of the wide spectrum in the severity of bleeding symptoms. Males and females are equally affected, and most patients (with type 1 and some with type 2) have minimal, mild, or moderate disease. Because one of the primary functions of VWF is to support normal platelet function, the bleeding manifestations in patients with VWD are similar to those observed in platelet disorders—bruising and mucous membrane bleeding such as epistaxis, oral bleeding, menorrhagia, and gastrointestinal bleeding.⁴⁸ Patients may come to attention as a result of postsurgical bleeding, particularly that involving mucous membrane surfaces (e.g., tooth extractions, tonsillectomy) or the onset of menses. The most serious bleeding is generally gastrointestinal hemorrhage, and it can be life-threatening, particularly when it is associated with angiodysplasia.⁴⁹ The rare homozygous or doubly heterozygous (type 3) patients are severely affected and have low factor VIII levels (2 IU/dL to 10 IU/dL) associated with extremely low VWF levels; they have severe bleeding, which includes hemarthroses and soft tissue bleeding similar to the symptoms seen in hemophiliacs, in addition to platelet-related bleeding symptoms. Homozygotes most likely represent the cases originally described by von Willebrand.

The severity of bleeding can vary modestly among affected family members and, to a much lesser degree, within an individual patient. Recent evidence suggests that normal variation (polymorphisms) in the level of other “unrelated” components of hemostasis (e.g., the platelet collagen receptor) may affect the degree of bleeding in patients with mild VWD.⁵⁰ As mentioned earlier, levels of VWF (and hence bleeding tendency) also vary with inflammatory processes, adrenergic stimulation, and pregnancy, and during estrogen replacement therapy.

DIAGNOSIS

Laboratory Assays for von Willebrand Factor

Laboratory testing essential for the diagnosis of VWD includes the following (Table 7-3):

1. VWF antigen
2. VWF activity (measured as ristocetin cofactor activity and/or collagen-binding activity)

Table 7-3 Assays for Diagnosis of von Willebrand Disease

Diagnostic Assays

von Willebrand factor antigen
von Willebrand factor activity (measured as ristocetin cofactor and/or collagen-binding activity)
Factor VIII activity (abnormal only in moderate to severe von Willebrand disease [VWD])

Other Assays

Bleeding time (prolonged only in moderate to severe VWD)
Partial thromboplastin time (PTT) is not recommended as a “rule-out” test because it is too insensitive and results may be normal in VWD.

Assays for Classification

RIPA (ristocetin-induced platelet aggregation) or quantitative platelet-binding assay
von Willebrand factor multimers

3. Factor VIII activity (abnormal only in moderate or severe disease)
4. Tests that measure the ability of VWF to support platelet plug formation (platelet function analyzer [PFA-100] or bleeding time). These tests are also abnormal in intrinsic platelet disorders and are prolonged only in moderate and severe VWD (limited specificity and sensitivity), so although the PFA-100 may be helpful, its diagnostic value is debated.^{51,52}

After the initial diagnosis of VWD, the following assays are used to classify the type of VWD:

1. Ristocetin-induced platelet aggregation (RIPA) or platelet-binding studies
2. VWF multimer studies

VWF antigen, activity, and multimer studies can also be performed on platelet VWF.⁵³ In rare cases of VWD, only the platelet VWF is decreased, and plasma levels are normal (designated “platelet-low” VWD).⁵⁴

The VWF antigen (VWF:Ag) is generally assayed using an enzyme-linked immunosorbent assay (ELISA) method, although electroimmunoassays and radioimmunoassays may be used.⁵⁵ Automated turbidometric tests that use latex particles coated with antibodies to VWF have also been used; the addition of plasma dilutions containing VWF causes clumping of the particles, and the VWF can be thus quantified. False positives may be seen in patients with rheumatoid factors.⁵⁶

VWF activity can be measured by a number of different functional tests, including the ristocetin cofactor (VWF:RCO) assay, which is the most commonly used assay and the “gold standard,” despite the fact that standardization of it from laboratory to laboratory is difficult.⁵⁷ The test is performed by making dilutions of patient plasma (the source of VWF) and mixing the dilutions with normal platelets or platelet membrane fragments that have been washed to remove any adherent VWF; ristocetin, an antibiotic that promotes binding of VWF to platelets, is added at 1.0 to 1.2 mg/mL, and the time to platelet aggregation/agglutination is assessed visually or with a platelet aggregometer. The use of ristocetin for evaluation of VWF activity was first suggested by Howard and Firkin,⁵⁸ who discovered that this antibiotic caused thrombocytopenia

in individuals who had normal VWF but not in VWF-deficient subjects. A number of automated ristocetin cofactor methods have been introduced, some using the same reagents noted above and others measuring direct VWF binding to a purified GP-Ib; these have varying diagnostic sensitivity.^{59–61} A sensitive ELISA that measures binding of plasma VWF to GP-Ib looks promising as a more quantitative assay for VWF platelet binding; further experience with this assay will allow assessment of its usefulness in terms of the ristocetin cofactor assay.⁶² It is important to inquire about the method used and its sensitivity if results are to be accurately interpreted for diagnostic purposes.

A second *VWF activity* can be measured by testing the collagen-binding activity (VWF:CB) of VWF. In this test, ELISA plates are coated with collagen, dilutions of normal or patient plasma are added, and bound VWF is measured with the use of an antibody. This assay is usually performed in conjunction with other tests such as the ristocetin cofactor and VWF:Ag.^{63,64} In rare cases of VWD in which the mutation affects only the collagen-binding site, the diagnosis could be missed if VWF:CB is not performed.

Factor VIII activity is measured in a functional assay, generally with the use of a modified partial thromboplastin time (PTT) and clot end point. The PTT itself is also used as a screening test, although it is less sensitive than the factor VIII assay. Both of these tests are abnormal only when the patient has a sufficiently low level of VWF to cause a low factor VIII, or when the VWF has defective binding for factor VIII that leads to a low level of factor VIII. Normal values for these tests cannot be used as exclusionary criteria for VWD.

The *PFA-100* measures the ability of platelets in whole blood to form a plug that occludes an aperture in a membrane. It requires VWF and normal platelet function. Fresh citrated whole blood is aspirated at arterial shear rates through tubing to a collagen-coated membrane with a central aperture; epinephrine or ADP is added to the blood, in addition to the collagen, to activate the platelets. The end point is measured as the time necessary for the platelet plug to form, closing the aperture and reducing pressure in the system.⁶⁵ The sensitivity of the PFA-100 for the diagnosis of VWD is debated.⁵²

Bleeding time is a global assessment of vascular integrity, platelet function, and plasma factors, including VWF. If it is prolonged, the bleeding time is helpful in the diagnosis of VWD, but a normal bleeding time may be found in mild and even moderate VWD.^{66,67} Quick⁶⁸ reported a marked prolongation of bleeding time after aspirin ingestion in patients with mild type 1 VWD as compared with normal subjects. Although bleeding time often is more prolonged after aspirin ingestion in patients with VWD than in patients without VWD (a fact that emphasizes that patients should avoid aspirin), many patients do not want to undergo multiple bleeding times; this test is not widely used at the present time.

Ristocetin-induced platelet aggregation (RIPA) is different from the ristocetin cofactor test and is used to aid clinicians in classifying the type of VWD that a patient has. RIPA is used to detect a qualitative abnormality in VWF, a “gain of function” that occurs in type 2B VWD (see Classification below). In RIPA, the patient provides both platelets and VWF as platelet-rich plasma (PRP). Different

concentrations of ristocetin are added separately to the PRP (usually varying progressively in final concentration from 0.4 to 1.2 mg/mL), and the presence or absence of platelet aggregation is assessed on an aggregometer. If platelets aggregate with low concentrations of ristocetin (less than 0.7 mg/mL), the VWF may have a “gain of function” abnormality (see later, type 2B). The same information can be obtained by directly measuring the amount of VWF bound to normal platelets at different concentrations of ristocetin.⁶⁹

VWF multimers are evaluated by electrophoresis of plasma in low-concentration (1% or lower) agarose gels, followed by detection with a specific antibody to VWF for visualization of multimers.⁷⁰ These gels are used to detect decreased or absent high molecular weight multimers of VWF, which occur in the more common subtypes within type 2 VWD (types 2A and 2B) (Fig. 7-2). The gels can also detect the unusually high molecular weight multimers of VWF that may be present in patients with thrombotic thrombocytopenic purpura and in the rare cases of an inherited defect in which larger than normal multimers are present in the circulation (see type 2M, later). Electrophoresis in agarose gels of slightly higher concentration (1.2% to 1.5%) is used to study the components making up each multimer.

The factor VIII-binding assay measures the ability of a patient's VWF to bind normal factor VIII. This assay is used to test for a qualitative abnormality in VWF that impairs binding of FVIII and results in loss of protection and low circulating FVIII levels (VWD type 2N, see Classification later). The test is performed by coating ELISA plates with the patient's VWF (usually by means of a capture antibody), removing any endogenous bound FVIII, and then adding a known quantity of purified FVIII. After washing, the bound purified FVIII is measured by a chromogenic assay for FVIII.

The ristocetin cofactor:VWF antigen ratio is used to detect VWF that has relatively less activity compared with antigen, including VWF with qualitative defects such as those seen in types 2A, 2B, and 2M VWD. Unfortunately, at this time, criteria for the “normal” ratio are not uniform among laboratories (normal ratio is usually set at >0.5 to 0.7), and very few laboratories have used their local reagents and methods to establish a “normal” reference range for normal individuals or those with type 1 VWD. This calculated value, however, when it is abnormally low, can be helpful in suggesting the need for a VWF multimer study.

Pitfalls in Making the Diagnosis of VWD

The diagnosis of mild type 1 von Willebrand disease (see Classification below) is difficult. There is neither a simple genetic screening test nor a qualitative defect that defines type 1 VWD, and because the lower range of normal VWF activity and antigen overlaps with the levels of patients with mild VWD, one cannot simply use a laboratory “cutoff” level with confidence. Levels below 20 IU/dL are more likely to be associated with a significant personal and family bleeding history and mutations in the VWF gene, but levels between 30 and 50 IU/dL may not be definitive for VWD.^{28,71,72} The lower levels of VWF in normal individuals with blood type O add another level of complexity for the diagnosis. A further confounding fact is that

Figure 7-2 Left, Normal and variant von Willebrand factor (VWF) multimeric patterns. Lane 1, Normal VWF. Lane 2, Type 2B von Willebrand disease (VWD), showing decreased high molecular weight multimers. Lane 3, Type 2A VWD, showing a decrease in high and intermediate molecular weight multimers. Right, Densitometric tracing of lanes 1 to 3. (From Krizek DM, Rick ME: A rapid method to visualize von Willebrand factor multimers using agarose gel electrophoresis, immunolocalization and luminographic detection. *Thromb Res* 97:457–462, 2000, with permission from Elsevier Science.)

normal individuals report mild bleeding symptoms when asked in questionnaires, so a bleeding history cannot always be relied upon. For instance, up to 41% of normal subjects report bleeding after dental extractions, 28% report postoperative bleeding, 22% report epistaxis, and 68% report menorrhagia.^{73–75} It may be helpful to repeat VWF testing 2 to 3 times at intervals in individuals and to test family members in some cases. However, continued testing may not clarify the dilemma and may lead to patient confusion. Additionally, it is important to avoid testing during the second and third trimesters of pregnancy when low VWF levels in patients may be elevated into the normal range; diagnosis should be delayed until several weeks after parturition.

It has been suggested that a category of “possible” VWD or “low” von Willebrand factor should be used, without the clinician actually making a diagnosis of von Willebrand disease in these individuals.^{75a} Levels of VWF between 50 and 150 IU/dL might be viewed as optimal in terms of hemostasis and thrombosis, and slightly low levels, in the absence of a convincing bleeding history in the patient and family, may be better referred to as “low VWF” than VWD. No consensus has yet been reached among hemostasis experts about this, and vigorous discussion is ongoing. Regardless of the criteria used for the diagnosis of VWD, bleeding symptoms occur more frequently in subjects who have lower levels of VWF, and these individuals may benefit from prophylactic measures such as administration of desamino-D-arginine vasopressin (DDAVP) or antifibrinolytic medications in appropriate circumstances. These treatments do not require that a firm diagnosis for or against VWD be established, and they should be employed as appropriate in individuals with levels of VWF in the 30 to 50 IU/dL range, even in the absence of a definitive diagnosis.

Several papers concerning the diagnostic process for VWD have been published,^{76,77} and a group has been assembled by the National Heart, Lung, and Blood Institute

to evaluate the diagnosis and management of VWD; recommendations will be available in 2007.

CLASSIFICATION

VWD is classified into three types according to the results of laboratory and molecular genetic testing (Table 7-4):^{4,4a} type 1, a partial quantitative deficiency of VWF, affecting approximately 70% to 75% of patients with VWD; type 2, a group of qualitative variants identified in approximately 20% to 25% of patients with VWD; and type 3, a rare homozygous or doubly heterozygous complete deficiency of VWF, which occurs in about 1 in every million persons.

Type 1

This dominantly inherited common type of VWD is usually associated with mild or moderate bleeding symptoms, although occasionally, bleeding can be severe, especially after administration of antiplatelet medications such as aspirin or other nonsteroidal anti-inflammatory medications. Bleeding may also be nonexistent, with “patients” discovered only through family studies. Childhood epistaxis is characteristic and may be outgrown after puberty. A number of mutations causing type 1 have been described, but many have not yet been identified. These mutations affect different areas of the gene and may reduce intracellular transport of the VWF dimer within the cell, or they may cause increased clearance of VWF from the circulation.^{72,78}

VWF antigen and activity (ristocetin cofactor and collagen binding) are usually decreased concordantly, and factor VIII activity is decreased if the VWF deficiency is sufficiently severe (see Table 7-4). RIPA is decreased, and all VWF multimers are present (normal distribution). The bleeding time or PFA-100 will be prolonged if the deficiency is severe enough.

Table 7-4 Classification of von Willebrand Disease

Type	Inheritance	VWF Activity	RIPA	Multimer Pattern
Type 1 (Classic)	Autosomal dominant	↓	↓	Uniform ↓ but all multimers present
Type 2 (Variant)				
2A	Autosomal dominant (and recessive)	↓	↓	↓ Large and intermediate multimers
2B	Autosomal dominant	↓	↑	↓ Large multimers
2M	Autosomal dominant (and recessive)	↓	↓	Normal multimers
2N	Autosomal recessive	Normal	Normal	Normal multimers
Type 3 (Severe)	Autosomal recessive	↓↓	↓↓	Undetectable (usually cannot be visualized)

Type 2

Type 2 VWD is divided into four subtypes.

Type 2A

This subtype is usually inherited as an autosomal dominant trait and accounts for 10% to 15% of VWD cases. It usually is associated with moderate to severe bleeding symptoms. Mutations in type 2A cause a defect in the intracellular assembly and transport of VWF monomers (2A, type 1) or an increased susceptibility to proteolysis by ADAMTS13 (2A, type 2).^{79,80} A number of mutations have been identified in the region that encodes the A2 domain of the VWF monomer, where a normal cleavage site is situated. Mutations are also described in the D2, D3, and A1 domains that result in a type 2A phenotype (see Fig. 7-1; see also Internet VWF database).

The VWF antigen is normal or decreased, and ristocetin cofactor activity is usually decreased out of proportion to the antigen, resulting in a decreased ratio of VWF activity to antigen. Factor VIII activity may be normal or decreased (see Table 7-4). RIPA is reduced, and the VWF multimers show an abnormal distribution, with an absence of high and intermediate molecular weight multimers (see Fig. 7-2). The bleeding time or PFA-100 is usually prolonged.

Type 2B

This subtype is transmitted as an autosomal dominant trait and usually manifests as moderate to severe disease; it accounts for approximately 5% of VWD cases. Mutations have been identified in an area of the gene that encodes the binding region for GP-Ib (see Fig. 7-1), and these give rise to a VWF molecule with a gain of function defect. These mutations cause the larger multimers of VWF to bind spontaneously to platelets in the circulation, resulting in removal of the multimers and, in some instances, thrombocytopenia^{81,82}; the latter is likely due to the formation of small platelet aggregates and sequestration. The VWF antigen is normal or decreased, and the ristocetin cofactor is low because of the decrease or absence of the more functional high molecular weight multimers (leading to a reduced ratio of VWF activity to antigen, as in type 2A). On the other hand, the RIPA is increased, that is, there is aggregation of the patient's

PRP with concentrations of ristocetin lower than 0.6 mg/mL.⁸³ Factor VIII activity is normal or decreased, and VWF multimers usually show decreased or absent high molecular weight forms, usually less severe than those seen in type 2A.

A platelet defect that causes the same phenotype (fewer high molecular weight multimers of VWF and reduced ristocetin cofactor) is called platelet-type or pseudo-von Willebrand disease.^{84,85} It is caused by an abnormal platelet GP-Ib receptor that binds normal VWF more avidly than usual, decreasing the number of high molecular weight multimers of VWF and often resulting in thrombocytopenia. Type 2B VWD and pseudo-VWD can be distinguished by a modification of the RIPA, with patient platelets mixed with normal plasma and, separately, patient plasma mixed with normal platelets. Type 2B VWD can also be distinguished from pseudo-VWD by genetic studies that indicate whether the mutation resides in the VWF gene or the platelet GP-Ib gene and by specific binding studies of VWF to platelets.

Type 2M

This subtype of VWD is an uncommon disorder that is usually inherited in an autosomal dominant manner. It presents as moderate or moderately severe disease and is characterized by reduced binding of the abnormal VWF to GP-Ib; however, all multimers are present, thus differentiating it from type 2A VWD.^{4,4a} On gel electrophoresis, individual multimer bands may show abnormal patterns (formerly called types 1C and 1D)^{86,87}; in other instances, larger than normal multimers are present in plasma (Vicenza variant),^{88,89} or the variant VWF retains the propeptide within the multimers.⁹⁰ VWF antigen is variably decreased and ristocetin cofactor is more markedly decreased; factor VIII activity is reduced if the VWF is sufficiently low. Mutations that cause type 2M are clustered in the A1 domain in a separate area from the mutations that cause type 2B VWD.

Type 2N

One of the first two patients with type 2N VWD was described in France (in Normandy) and presented with a low factor VIII level that had been inherited in an autosomal pattern.^{91,92} Patients with this subtype usually present

with the constellation of autosomal inheritance and low factor VIII levels. Bleeding symptoms are moderate to moderately severe and include episodes of soft tissue bleeding and bleeding with invasive procedures that are more characteristic of factor VIII deficiency than the mucocutaneous bleeding usually seen in VWD. This variant is characterized by mutations in the aminoterminal of the VWF monomer within the binding site for factor VIII, which lead to decreased binding and diminished protection of factor VIII in the circulation.^{93–96} The half-life of factor VIII is decreased from 8 to 12 hours to approximately 2 hours because of the lack of protection by VWF.¹⁵ Platelet-related functions of VWF are usually intact, unless (uncommonly) a second mutation has been inherited in the other VWF allele that causes another VWF defect, such as those present in type 1 or a different type 2 VWD. Because the concentration of VWF in plasma is so much higher than the concentration of factor VIII, the binding defect must be inherited in a homozygous fashion, or a second defect must be present that limits synthesis of VWF by the other allele. Factor VIII levels are low (usually, 5 to 15 IU/dL), and the VWF antigen, ristocetin cofactor, RIPA, and VWF multimers are usually normal.

Because patients with type 2N VWD present with factor VIII deficiency, it is possible that they will be misdiagnosed with hemophilia A. The presence of an autosomal inheritance pattern and the presence or history of bleeding in women suggests that the patient and kindred should be tested for type 2N VWD. This is accomplished by testing the ability of the patient's VWF to bind factor VIII^{91,92}; genetic studies are under way to establish this diagnosis.^{93–96}

Type 3

Type 3 VWD is characterized by a severe deficiency of VWF and by a moderately severe deficiency of factor VIII. It is rare and is inherited in a homozygous or doubly heterozygous manner.⁴⁵ Patients present with mucocutaneous bleeding (from decreased VWF) and with soft tissue and joint bleeding (from decreased factor VIII). Deletions, compound heterozygous mutations, and nondeletion defects leading to decreased mRNA expression have been identified in these patients.^{4,4a} Laboratory testing shows that VWF antigen is extremely low or unmeasurable, ristocetin cofactor is below the limits of detection, RIPA is absent, and VWF multimers usually cannot be visualized. Factor VIII activity is in the range of 2 to 10 IU/dL.

ACQUIRED VON WILLEBRAND DISEASE

Acquired VWD may appear spontaneously, or it may be associated with diseases that lead to decreased levels of VWF by one of several mechanisms: antibodies to VWF, increased proteolysis of VWF, abnormal binding to cells (usually tumor cells), or decreased synthesis. A number of recent reviews and an international survey have addressed this topic.^{97–100}

The diagnosis of acquired VWD is made when decreased levels of VWF activity and antigen (and some-

times factor VIII activity) are detected in a patient who does not have a past history of bleeding and lacks a family history of bleeding. Antibodies to VWF most often occur in autoimmune or lymphoproliferative disease, and they may be difficult to identify in most patients with the use of functional studies^{101–103}; other methods for antibody detection may be more sensitive.¹⁰⁴ Increased proteolysis occurs in patients with accelerated fibrinolysis, in those with noncyanotic congenital heart disease or high-grade aortic stenosis,^{105,106} and possibly, in patients with myeloproliferative disease.^{107,108} Tumor adsorption has been described in Wilms tumor,¹⁰⁹ and decreased synthesis has been described in hypothyroidism.^{39,110} Some medications, such as valproic acid, dextrans, and hydroxyethyl starch, have also been associated with acquired VWD.^{111–113}

TREATMENT

Inherited VWD

Selection of proper treatment depends on the type of VWD that a patient has, so a thorough laboratory evaluation should be completed before therapy is chosen, if time permits. In addition, the patient's general medical condition, associated illnesses, and medications (particularly aspirin-containing medications, nonsteroidal anti-inflammatory agents, or other antiplatelet agents) should be taken into account. These factors may influence decisions about the duration of treatment and whether to give additional medication or replacement therapy, including platelet concentrates, in cases of serious bleeding. The need for treatment in women with mild VWD may be minimized by scheduling elective minor surgical procedures during the latter half of the menstrual cycle, when slightly higher levels of VWF can be anticipated. In patients with type 1 VWD with atherosclerotic heart disease who need heart catheterization for evaluation or treatment, the choice of a short-acting nonsteroidal anti-inflammatory agent over aspirin is prudent for the procedure. No studies are available to assess the relative risk of long-term use of low-dose aspirin or other antiplatelet agents in patients with VWD who have atherosclerotic heart disease. If a patient with mild to moderate type 1 VWD is reliable and has a good understanding of VWD and how antiplatelet agents may aggravate bleeding, it is reasonable to give a trial of an antiplatelet agent to assess whether the patient has increased bruising or other bleeding. Depending on the response and the perceived relative risks presented by the heart disease compared with possible bleeding with VWD, a longer course of treatment may be given. Patients should be aware that they should discontinue the medication before undergoing invasive procedures (including dental work) and if any bleeding occurs.

Because no laboratory tests predict or correlate well with the severity of bleeding, it is necessary to monitor the patient clinically.¹¹⁴ However, as a general and empirical goal, therapy is usually given in the amount predicted to increase the level of VWF activity and factor VIII to 50 to 100 IU/dL (Table 7-5).¹¹⁵ In practice, it is often only the factor VIII level that may be available in a timely fashion for decision making, and this can be followed safely in many patients to evaluate therapy for adequate hemostasis,

Table 7-5 Treatment of Patients with von Willebrand Disease

Medication	Dose	Comments
DDAVP (desmopressin)	Intravenous (IV): 0.3 µg/kg in 50 mL saline over 20 min. Nasal spray: Weight >50 kg, 300 µg (1 spray in each nostril); <50 kg, 150 µg (1 spray in only one nostril)	Useful in most patients with type 1; variable in type 2.* Not useful in type 3. Patient should be given therapeutic trial before invasive procedure. May repeat dose after 12 hr and every 24 hr.† Tachyphylaxis and hyponatremia may occur; patients must be monitored.
VWF concentrates that contain all VWF multimers	Initial dose, 40–60 U/kg. Then, 20–30 U/kg q12h to keep VWF levels at 50%–100%, or to control clinical bleeding. Levels should be maintained for 3–10 days for major surgery.	Dose and duration based on clinical experience.
Antifibrinolytic agents: ε-Aminocaproic acid tranexamic acid	50 mg/kg (maximum, 5 g dose) 4× daily 25 mg/kg 3× daily	Use alone or in conjunction with other therapy. Especially useful for mucosal bleeding (often for dental procedures).
IVIg (immune acquired inhibitors of VWF)	1 g/kg daily for 2 days; infusion over 8–12 hr	Use after trial of DDAVP or other measures in patients with acquired VWD, particularly when associated with autoimmune disease.

VWF, von Willebrand factor; IVIg, intravenous immune globulin; VWD, von Willebrand disease.

*Thrombocytopenia may worsen in some patients with type 2B disease.

†Total dose usually should not exceed 3 to 4 doses because of tachyphylaxis and possible hyponatremia.

as indicated by the clinical experience of experts who treat VWD.^{116,117} Treatment modalities include DDAVP (desmopressin), replacement therapy with VWF-containing plasma products, antifibrinolytic and topical therapies, and estrogen (in women) (see Table 7-5).

DDAVP

DDAVP (desmopressin) is a synthetic analogue of antidiuretic hormone that causes release of VWF and factor VIII from body stores by an indirect mechanism that is not yet understood.¹¹⁸ DDAVP is the treatment of choice in most patients with type 1 and in many with type 2 VWD.¹¹⁹ It is administered in a much larger dose than the dose used for antidiuretic hormone replacement therapy.

Although most patients with type 1 VWD respond to DDAVP, it is recommended that patients undergo a trial before the first therapeutic use of the agent. DDAVP is given as an intravenous infusion at a dose of 0.3 µg/kg (not to exceed 20–25 µg) or as an intranasal spray at a dose of 300 µg (2 sprays) for patients who weigh more than 50 kg, or 150 µg (1 spray) for patients who weigh 50 kg or less. (It should be noted that this dose is 10-fold higher than the DDAVP dose used for replacement therapy in posterior pituitary gland disease.) For intravenous infusion, DDAVP is diluted in 50 mL saline and administered over 20 to 30 minutes. Levels of ristocetin cofactor, VWF antigen, and factor VIII should be determined before infusion and at 2 to 4 hours; the use of bleeding times to assess whether prolonged values decrease significantly 2 or 4 hours after infusion has declined because of patient concerns about multiple bleeding times, and because it is not necessary to normalize the bleeding time before a procedure is performed. An increase of two- to fivefold in VWF and factor VIII levels is expected 30 to 60 minutes after infusion; these values return to baseline in approximately 4 to 6 hours.¹²⁰

Adverse effects include flushing, hypertension or hypotension, headache, and, rarely, tingling; these can usually be controlled by slowing the infusion of DDAVP. Although thrombosis has occurred after administration of DDAVP, it is uncertain whether this is causal.¹²¹ Tachyphylaxis occurs after repeated administration, and serious hyponatremia has been observed, especially with concomitant intake of free water.¹²² For these reasons, DDAVP administration is usually limited for any single procedure; it is usually given 0.5 to 2 hours before a procedure and may be repeated 8 to 12 hours later and daily on the following 2 to 3 days if necessary, while free water intake is limited and serum sodium concentrations are monitored.

DDAVP is useful in most patients with mild and moderate type 1 VWD, except those rare patients with type 1 who do not have normal levels of platelet VWF (platelet-low patients).¹²³ Patients with type 2A VWD respond variably to DDAVP,¹²⁴ and those with type 2B may experience a decrease in platelet counts following the increase in plasma levels of abnormal 2B VWF.¹²⁵ Despite this possible drawback, a number of patients with type 2B VWD have undergone procedures after administration of DDAVP, and any reduction in platelet count has usually normalized after 2 hours.¹²⁶ It is especially important to use a trial infusion to evaluate the effects of DDAVP in patients with type 2A and type 2B disease before they undergo surgery. DDAVP is not helpful in patients with type 3 VWD, who rarely have sufficient stores of VWF.

Intranasal DDAVP has proved extremely useful and convenient for patients because they are able to administer the medication “on the spot” when bleeding occurs without delaying treatment. A good example is its use in helping to control menstrual bleeding in women with VWD.¹²⁷ Oral bleeding and epistaxis have also been controlled by this method.

Replacement Therapy With VWF

Several preparations that contain VWF are available for use in patients with VWD. These include intermediate-purity factor VIII concentrates that contain VWF (not monoclonally purified or recombinant factor VIII concentrates, which lack VWF), more highly purified VWF concentrates, and cryoprecipitate. Most experts do not recommend cryoprecipitate unless no other VWF concentrate is available because of the potential for transmission of viruses.¹²⁸ The other concentrates mentioned here undergo a step such as pasteurization to decrease the risk of viral transmission.

The VWF concentrate available in the United States that is labeled with the concentration of ristocetin cofactor units per vial is Humate P (ZLB Behring). Others are available in Europe.^{129,130} These concentrates are usually administered as a short (approximately 15 minute) intravenous infusion, although studies have shown that when therapy is needed for several days, the total dose used is reduced by 20 to 50 IU/dL when the concentrate is given by constant infusion.^{131,132} The dose for major bleeding challenges is estimated at the amount that will raise the ristocetin cofactor to 50 to 100 IU/dL (loading dose, 40 to 60 U/kg; maintenance dose, 20 to 40 U/kg) (see Table 7-5). Repeat infusions may be necessary at 12-hour intervals for 3 to 10 days for major surgery or serious bleeding. If bleeding is not controlled by replacement therapy, patients may benefit from platelet transfusions, in addition to VWF.¹³³

Replacement therapy is used for patients with type 3 VWD, for those with type 2 disease who do not respond to DDAVP, and for patients with the more severe type 1 disease who have not responded to DDAVP or have responded but need further long-range hemostatic support that cannot be provided with just 2 to 3 days of DDAVP therapy.

Antifibrinolytic Therapy

Both ϵ -aminocaproic acid (EACA) and tranexamic acid have been used alone and as adjuncts to other therapies for patients with VWD, particularly those with oral and other moderate mucous membrane bleeding. When given orally for this use, they are administered 3 or 4 times daily (see Table 7-5) for 3 to 7 days.¹¹⁵ Doses must be adjusted in patients with renal failure. These medications may also be given by the intravenous route. Prolonged use of either medication may lead to thrombosis in susceptible patients.

Topical Agents

These agents are usually used for oral or nasal bleeding; they provide local therapy to the bleeding surface. Gelfoam or Surgicel (Johnson and Johnson and others) may be soaked in topical thrombin before application to the site. Micro-nized collagen (Avitene, C.R. Bard) and fibrin sealant have also been used topically.¹³⁴ (see Chapter 29).

Estrogen

Estrogen can enhance the synthesis of VWF, and women with mild to moderate VWD may benefit from therapy with estrogen. Its use, however, has been tempered recently because of the potential adverse effects of estrogen. It is usually administered in doses equivalent to those used for hormone replacement therapy.¹³⁵

von Willebrand Disease During Pregnancy

Because levels of VWF increase two- to threefold over baseline during the second and third trimesters of pregnancy, treatment typically is not needed during delivery in many patients with type 1 VWD. Qualitative defects present in type 2 VWF do not correct, however, and increases in VWF levels may be variable.¹³⁶ Additionally, VWF levels fall rapidly and excessive bleeding may occur in the weeks following delivery. DDAVP therapy is used after labor has been initiated in those patients who are responsive and have moderately severe disease with persistently lower levels of VWF during the third trimester; VWF replacement therapy is usually not required but should be used when patients are not responsive to DDAVP and bleeding occurs.^{41,137} No standard recommendation can be made for the level of VWF that is safe for regional anesthesia; it is usually considered safe when VWF:RCo is 50 IU/dL or greater.¹³⁸

Acquired von Willebrand Disease

Different mechanisms may lead to acquired VWD, and treatment may vary with the underlying pathophysiology. Treatment of an associated primary disease is usually undertaken in those cases where it can be identified; this is particularly important in unusual cases in which hypothyroidism is the underlying cause, because treatment with thyroid hormone normalizes VWF levels.^{39,110} Many times, selection of a treatment regimen involves a process of empirical trials undertaken to determine which treatment is most useful; often, a trial of DDAVP is given initially, followed by replacement therapy (if DDAVP is unsuccessful in stopping bleeding). If neither is successful, a trial of high-dose intravenous immune globulin (IVIg) is recommended (1 g/kg daily for 2 days), particularly if the cause is believed to be an acquired inhibitor associated with autoimmune disease or a monoclonal gammopathy.¹³⁹ In all situations, response should be monitored by measurement of VWF and factor VIII levels over the first hours after treatment and by following clinical responses. Less commonly, plasmapheresis or extracorporeal immunoadsorption may be used to remove an antibody, at least temporarily, if clinical bleeding is occurring.¹⁴⁰ Immunosuppressive medications used for the treatment of underlying disease, such as rituximab, may decrease the antibody in some patients.

Practical Considerations for Therapy

Because of enhanced awareness and increased diagnosis of VWD, a number of patients who have an undocumented diagnosis of VWD may present emergently with bleeding that requires urgent treatment. A careful past bleeding history and family history can be particularly helpful to the clinician who is deciding whether the patient should receive treatment for VWD. If the patient does require treatment, it is likely that DDAVP may be used successfully and the patient can be spared exposure to blood products. For serious bleeding (brisk gastrointestinal or central nervous system bleeding), replacement therapy should be given, along with other therapy as indicated, to maintain VWF between 50 and 100 IU/dL, until a more definitive diagnosis can be established. Structural lesions

may co-exist. After bleeding is controlled and baseline health returns for 3 to 4 weeks, the patient should be asked to return for a full evaluation and should be given information to carry that provides test results and recommendations for treatment in an emergency situation.

Chapter 8

General Aspects of Thrombocytopenia, Platelet Transfusions, and Thrombopoietic Growth Factors

David J. Kuter, MD, DPhil

INTRODUCTION

Of the circulating blood cells, the platelet was the last to be fully described and its attributes determined. Although early studies by Osler, Hayam, and Bizzozero identified small particles in the blood, these were believed to be bacteria, fragments of red blood cells, or other hematopoietic elements.^{1,2} It was not until the development of a novel blood staining method by James Homer Wright that the true identity of these circulating blood cells and their relationship to hemostasis became apparent.^{3–5} After observing their common tinctorial properties, Wright showed that blood platelets (initially called “plates”) arose from bone marrow megakaryocytes. He found that these megakaryocytes extended a portion of their cytoplasm into the bone marrow sinusoids and shed platelets into the circulation (Fig. 8-1).

These observations were carried one step further in 1910 by William Duke,⁶ who described three patients at Massachusetts General Hospital who were bleeding and had low platelet counts, as determined by early cell counting procedures. He was able to show that “certain types of hemorrhagic disease may be attributed to an extreme reduction in the number of platelets.” Indeed, Duke showed that on creating a venous shunt between a normal donor and a thrombocytopenic recipient, the platelet count would increase in the thrombocytopenic recipient, and bleeding would cease. Although platelet transfusions had unknowingly been given in the form of whole blood transfusions over many centuries, this was the first time it was shown that transfused platelets could ameliorate bleeding.

Since the time of these seminal observations, evaluation of disorders of blood platelets and of treatment of thrombocytopenia has become a common hematology consultation. Indeed, on a general inpatient hematology consultation service, approximately one third of all consultations are requested for assessment of thrombocytopenia (D. Kuter, personal observation, 2005). Some 5% to 10% of all hospitalized patients are thrombocytopenic, and for patients in medical and surgical intensive care units, this figure rises to as high as 30% to 35%. Indeed, some data suggest that thrombocytopenic patients suffer a twofold greater mortality rate than those who are not thrombocytopenic.^{7–10}

The primary reason for evaluating any thrombocytopenic patient is to assess the risk of bleeding. In general, patients with platelet counts less than 20,000/ μ L are at increased risk of spontaneous bleeding and bleeding with procedures. These individuals are commonly the subjects of consultative hematology evaluations because they may need treatment with transfusions or more specific therapies to ameliorate the bleeding risk.

A more common source of hematology consultations are those patients with milder degrees of thrombocytopenia and platelet counts ranging from 20,000/ μ L to 50,000/ μ L. These individuals rarely have any risk of spontaneous bleeding but may have increased bleeding risk with procedures.

A final group of patients who are commonly the subject of hematology consultations are those with platelet counts ranging from 50,000/ μ L to 100,000/ μ L. Such patients do not have an increased risk of spontaneous bleeding and can probably undergo most procedures without an increased risk of major bleeding complications. Nonetheless, this patient population is oftentimes strikingly limited in its access to medical care. Surgeons are often reluctant to operate on patients whose platelet counts are in this range, albeit for poorly documented reasons. Epidural anesthesia for pregnant patients with platelet counts below 100,000/ μ L is often withheld; finally, procedures as routine as colonoscopy, dental extraction, dental prophylaxis, prostate biopsy, and breast biopsy are often not undertaken in patients whose platelet counts fall within this range. Effective antiviral treatment frequently is not administered to individuals with hepatitis C who have such mild thrombocytopenia.

Aside from the risk of bleeding, another reason for consultation on the thrombocytopenic patient is to determine whether some other underlying medical condition is involved. Thrombocytopenia is often associated with other diseases such as thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), systemic lupus erythematosus (SLE), heparin-induced thrombocytopenia (HIT), and primary bone marrow disorders.

The goals of the hematology consultant in evaluating the thrombocytopenic patient consist of the following:

1. To assess the risk of bleeding
2. To diagnose the underlying cause of the thrombocytopenia
3. To treat the thrombocytopenia as indicated

Figure 8-1 Megakaryocyte protruding into the bone marrow sinusoid and producing platelets. Camera lucida drawing by James Homer Wright.⁵

RELATION OF BLEEDING RISKS TO PLATELET COUNT

Except for situations in which the platelet count drop is indicative of other disorders, such as heparin-induced thrombocytopenia, antiphospholipid antibody syndrome, or collagen-vascular disorders, a platelet count above 100,000/ μ L is rarely associated with any significant bleeding risk or thrombotic difficulty. For the purposes of this discussion, clinically significant thrombocytopenia occurs when platelet counts are lower than 100,000/ μ L. As suggested earlier, such subjects can be roughly grouped into three categories. The first are those whose platelet counts are between 50,000/ μ L and 100,000/ μ L for whom spontaneous bleeding does not occur and for whom surgical bleeding risk is low. The second group includes those whose platelet counts are between 20,000/ μ L and 50,000/ μ L; for this group, spontaneous bleeding rarely occurs, but the risk of bleeding with surgical procedures may be increased. Finally, the group that is of greatest concern consists of those whose platelet counts are lower than 20,000/ μ L for whom the risk of spontaneous bleeding is increased and for whom surgical bleeding risks usually are increased.

Although seemingly intuitive, the relation of platelet count to bleeding risk is poorly defined. This is not only due to inadequate clinical studies but also to the inability of clinicians to measure accurately the second important platelet variable, platelet function. Indeed, in some situations of increased platelet destruction such as immune thrombocytopenic purpura (ITP), as the platelet count declines, mean platelet volume (MPV) rises, which tends to offset the decline in total platelet function. This increase in MPV has been attributed to “phylogenetic canalization,” suggesting some feedback system wherein increased platelet volume (and hence increased function) tends to mitigate against decreased platelet numbers.¹¹ Alternatively, drugs or intrinsic platelet defects may reduce the function of platelets, thereby increasing the bleeding risk at any degree of thrombocytopenia. This is commonly seen in situations in which patients have taken antiplatelet agents such as aspirin, or when they are uremic. Fever and other medical conditions also affect hemostatic risk at any degree of thrombocytopenia.

Even though it is convenient to think of hemostatic risk solely as a function of platelet count, this is an oversimplification because of the many other variables that affect hemostatic risk. Rigid adherence to customary threshold values of 50,000/ μ L for surgical hemostasis and 5000/ μ L to 10,000/ μ L for prophylaxis is inappropriate. Nonetheless, these platelet numbers are generally helpful and are based on the following evidence.

One example of the increased risk of bleeding with thrombocytopenia is seen in studies that showed the relation of bleeding time to platelet count.¹² Below a platelet count of 100,000/ μ L, a linear relation is observed between the decline in platelet count and the increase in bleeding time. Although bleeding time is an unreliable predictor of bleeding risk,¹³ this is perhaps the clearest visual demonstration of the relation between the decline in platelet count and the increase in bleeding risk.

Early studies in leukemic children showed a direct relation between platelet count and risk of spontaneous bleeding. As the logarithm of the platelet count fell below 100,000/ μ L, a linear increase was reported in the amount of hemorrhage that occurred. Most of this was accounted for by milder forms of hemorrhage such as petechiae, ecchymoses, and epistaxis, which tended to occur particularly when the count was below 50,000/ μ L. If only more major forms of hemorrhage were analyzed, an increase was evident as counts fell below 100,000/ μ L, but most bleeding events occurred at platelet counts lower than 10,000/ μ L; of this latter group, most bleeding events occurred at below 5000/ μ L. For both minor and major bleeding episodes, the authors emphasized that no threshold platelet count was used, but rather, a continuous increase in hemorrhagic risk was noted as platelet count fell. These often-quoted studies are confounded by the fact that many subjects were also treated with antipyretics that adversely affected platelet function, the use of capillary platelet counts, and the lack of adequate antibiotic treatment of these often febrile patients. Nonetheless, these studies confirm the relation between bleeding risk and platelet count and have been used (despite the authors' exhortations) to support the concept of the 50,000/ μ L threshold for surgical hemostasis and the 5000/ μ L to 10,000/ μ L threshold for prophylaxis.

More recent bleeding studies by Rebull^{14,15} and Wandt¹⁶ have shown that in leukemic patients given chemotherapy, hemorrhage occurs to the same extent at 10,000/ μ L and at 20,000/ μ L.

A biologic estimate of the lowest effective platelet count comes from the work of Slichter,¹⁷⁻¹⁹ who used 51Cr-labeled red blood cells (RBCs) to quantify fecal blood loss in stable aplastic thrombocytopenic patients who were treated only with anabolic steroids. At platelet counts above 10,000/ μ L, patients had a normal blood loss of less than 5 mL per day. At platelet counts of 5000/ μ L to 10,000/ μ L, this loss rose slightly to 9 ± 7 mL per day; however, at platelet counts below 5000/ μ L, this was markedly elevated to 50 ± 20 mL per day.

To assess further this apparent critical platelet threshold of 5000/ μ L to 10,000/ μ L, Hanson and Slichter²⁰ performed platelet kinetic studies in thrombocytopenic patients with platelet counts ranging from 12,000/ μ L to 70,000/ μ L. They found a fixed minimum requirement for 7100 platelets/ μ L per day to maintain vascular integrity; this was 18% of the

normal daily turnover of 41,200 platelets/ μL per day. These studies have provided the experimental explanation for current recommendations that prophylactic platelet transfusions should be given only to those patients whose platelet counts are lower than 5000/ μL to 10,000/ μL .^{21,22}

One final pathophysiologic basis for the bleeding risk recommendations just described is supported by recent data on the precise role that platelet surface activation plays in the coagulation cascade. With the use of real-time measurements during clotting, thrombin generation appears to be maximal as long as the platelet count is above 10,000/ μL ; below this value, thrombin generation declines in direct proportion to the platelet count.^{23,24}

THE BIOLOGY OF PLATELET PRODUCTION

As a pathophysiologic basis for clinical evaluation of the thrombocytopenic patient, a brief review of the biology of platelet production is helpful. This approach allows the hematology consultant to relate the various causes of thrombocytopenia to relevant aspects of platelet production.

The pluripotential stem cell gives rise through a stochastic differentiation process to precursor cells committed to megakaryocyte differentiation, called megakaryocyte colony-forming cells (Meg-CFCs).^{25,26} The viability of the Meg-CFC depends on the presence of numerous hematopoietic cytokines, including thrombopoietin (TPO). Meg-CFCs are mitotically active until some triggering event, as yet unidentified, causes them to stop their mitotic divisions and enter a process called endomitosis, in which DNA replication ensues but neither the nucleus nor the cytoplasm undergoes division. This gives rise to polyploid megakaryocyte precursor cells that contain anywhere from 4 to 16 times the normal diploid complement of DNA—all contained within a single nuclear envelope. Initially, these cells are morphologically indistinct, but once they complete their endomitotic divisions, they grow into large, morphologically identifiable megakaryocytes.

Megakaryocytes occupy unique positions within the bone marrow. Early megakaryocyte precursor cells and stem cells occupy a niche close to the bone.^{27–30} As megakaryocytes differentiate, they appear to follow a stromal cell–derived factor-1 (SDF-1) gradient and migrate close to the endothelial cells that line the bone marrow sinusoids. Cytoplasmic projections from the megakaryocytes then pass through the endothelial cell—not between its gap junctions—and appear in the bone marrow sinusoid, where they appear to undergo cleavage into platelets and long strands of megakaryocyte cytoplasm destined to become platelets (called “proplatelets”).²⁷ Whether platelet production occurs entirely in the bone marrow sinusoids or in other tissues such as the lungs has been the subject of much speculation for decades.^{31–34} What is clear is that platelets or proplatelets bud into the bone marrow sinusoid from megakaryocytes within the marrow. What is unclear is whether these proplatelets then undergo subsequent processing into platelets within the lung parenchyma. Mathematical models suggested that this occurs, although biochemical data have not supported this.^{33–35}

Once in the circulation, the human platelet survives for 10 days; it then probably undergoes programmed cell death and is removed from the circulation. Data to support

programmed cell death have come from several recent experiments but have not been conclusive.^{36–38} An alternative hypothesis suggests that surface glycoprotein changes result in clearance of the older platelets by the reticuloendothelial cell system, such as that which occurs with senescent red cells. No evidence suggests that platelet activation plays a major role in platelet clearance; indeed, most platelets that enter the circulation do not undergo platelet activation before they undergo senescence and clearance. The tissue responsible for the clearance of senescent platelets has not been well defined. In animal models, splenectomy does not seem to alter the platelet life span; therefore, one can assume that clearance in humans also occurs through a nonsplenic mechanism.³⁹

The key hematopoietic regulators of platelet production appear to be TPO and SDF-1. TPO is necessary for platelet production, and in its absence, platelet counts in animals and humans drop to about 10% of normal.⁴⁰ Nonetheless, platelets continue to be made, albeit from a reduced number of polyploid megakaryocytes. TPO appears to be made in a constitutive fashion by the liver, and its rate of synthesis is not affected by any known cytokine or disease.²⁶ The only exception appears to be the reduction in TPO production that occurs in patients with liver dysfunction such as chronic hepatitis and after partial hepatectomy^{41,42}; in this setting, platelet count declines in direct proportion to the reduction that occurs in liver function. TPO is therefore made constitutively by the liver; it enters the circulation and is cleared by avid receptors on platelets and probably bone marrow megakaryocytes.^{43–45} This results in a basal level of TPO that is necessary for normal megakaryocyte growth, polyploidization, and development.

The relationship of circulating TPO levels to platelet count depends on the nature of the thrombocytopenia.^{46,47} In situations in which the marrow has been damaged and platelet production is decreased, TPO clearance is decreased and TPO levels rise. For example, in patients with aplastic anemia with platelet counts of 10,000/ μL , TPO levels rise from normal values of about 100 pg per milliliter to 2000 to 3000 pg per milliliter. However, when thrombocytopenia is due to peripheral destruction of platelets, and when the megakaryocyte mass is normal or increased, net clearance of TPO may be nearly normal and TPO levels may not be elevated. An example is ITP in which the increased bone marrow megakaryocyte mass and the increased release of platelets into the blood result in almost normal TPO clearance and virtually normal TPO levels. Although TPO levels might be helpful in distinguishing between patients with decreased platelet production and those with increased platelet production, plasma TPO levels are not currently clinically available.

Less well appreciated is the role that SDF-1 plays in platelet production.²⁸ When SDF-1 was administered to thrombocytopenic animals that lacked TPO, platelet count rose to nearly normal levels. In normal healthy animals in which SDF-1 was transiently removed, platelet count fell. SDF-1 appears to guide megakaryocyte progenitors toward bone marrow sinusoids and to trigger their shedding of platelets. The main problem in platelet biology at the present time involves an understanding of the mechanism of platelet shedding from bone marrow megakaryocytes. This appears to be a very finely tuned mechanism that involves TPO, SDF-1, and endothelial cells.

As is discussed later, with this understanding of platelet biology, several general mechanisms for thrombocytopenia become apparent. Thrombocytopenia will occur if platelet destruction due to immune or nonimmune mechanisms overwhelms the compensatory ability of the bone marrow to increase platelet production. Thrombocytopenia will also arise from disorders that decrease platelet production. With reduced numbers of progenitor cells such as those seen after chemotherapy, the platelet count will certainly fall. If TPO production is reduced, such as after liver resection or in severe liver disease, a concomitant drop in platelet count occurs. Less well understood are the mechanisms by which other medications cause decreased platelet production. Recent data suggest that drugs such as gemcitabine and bortezomib may actually reduce platelet shedding from megakaryocytes with little effect on the number of megakaryocytes or their progenitors.⁴⁸ It has been suggested that this is due to alteration in the SDF-1 gradient.

CAUSES OF THROMBOCYTOPENIA

Table 8-1 lists a general classification of the causes of thrombocytopenia.

Laboratory artefact (“pseudothrombocytopenia”) occurs in up to 0.2% of patients who have blood counts performed.^{49–51} Although this may be due to the use of therapeutic antiplatelet antibodies such as abciximab,^{52,53} most cases of pseudothrombocytopenia result from the clumping of platelets that occurs *ex vivo* in anticoagulated blood samples. Several mechanisms have been proposed for this.^{54–57} Most involve conformational changes in the IIb-IIIa receptor that are due to the low divalent cation concentration and/or the lower temperature of anticoagulated blood; novel GPIIb/IIIa epitopes appear to be exposed that react with preexisting antibodies in the patient’s blood, causing aggregation. In both of these situations, collecting the blood in an acid-citrate-dextrose (ACD; yellow-top) or heparinized (green-top) tube, as well as keeping samples at 37°C, usually prevents clumping and permits an accurate blood count. Although most modern cell counting devices “flag” samples that contain platelet clumps, review of the peripheral blood smear may be the only way to detect this phenomenon (Fig. 8-2). Certainly, patients reported to have a very low platelet count but who lack signs and symptoms of thrombocytopenia should be evaluated for pseudothrombocytopenia through review of the peripheral blood smear.

A second important but easily diagnosed cause of thrombocytopenia occurs primarily in intensive care unit and postsurgical patients who have received multiple RBC transfusions and developed dilutional thrombocytopenia. Given that fresh whole blood is rarely used anymore, transfusion with large amounts of packed RBCs, fresh frozen plasma (FFP), and fluids may result in dilution of platelets. In massive trauma, it is important that adequate platelet transfusions be provided, along with RBC and plasma transfusions.

A third cause of mild thrombocytopenia (with platelets usually in the 40,000/ μ L to 60,000/ μ L range) is the splenic sequestration commonly seen in patients with severe liver disease or other causes of splenomegaly. Because the body

conserves the circulating platelet mass and not the platelet count, approximately one third of the total platelet mass is normally sequestered in the spleen.^{58–62} With splenic enlargement, additional platelets become sequestered within the spleen.^{60–62} In patients with liver disease and splenomegaly, the situation may be more complicated. Because the liver is the main source of TPO production, thrombocytopenia can be attributed to sequestration and diminished TPO levels.⁶³

As with many other hematologic conditions, the two remaining major categories of thrombocytopenia can be attributed to decreased production of platelets or increased destruction of platelets, or some combination of the two.

Decreased platelet production occurs in many situations, ranging from bone marrow replaced by metastatic cancer to lack of bone marrow due to bone marrow failure syndromes. Toxins, ethanol ingestion, vitamin B₁₂ deficiency, and some medications can decrease megakaryocyte endomitosis and inhibit megakaryocyte maturation.^{64,65} Furthermore, some drugs such as gemcitabine and bortezomib may actually decrease the shedding of platelets from existing megakaryocytes. With these chemotherapies, the number of megakaryocytes may be normal or elevated, although effective platelet production (thrombopoiesis) may be reduced. Finally, it should not be forgotten that ITP is also a disease of decreased platelet production in that megakaryocytes may be undergoing programmed cell death from the antiplatelet antibody.^{66,67} In human immunodeficiency virus (HIV) thrombocytopenia, megakaryocyte mass and megakaryocyte ploidy are markedly increased but effective thrombopoiesis from these megakaryocytes is markedly diminished, presumably because of early programmed cell death of these megakaryocytes.^{68,69}

Disorders of increased platelet destruction are relatively common and include both nonimmune and immune disorders. Nonimmune thrombocytopenic disorders consist of disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), and HUS, as well as pulmonary hypertension, veno-occlusive disease, and full-thickness burns. Immune causes of thrombocytopenia can be divided into those that are related to antigen/antibody complex deposition onto platelet Fc receptors and those in which the antibody Fab region directly binds to the platelet. An example of the former is heparin-induced thrombocytopenia (HIT), in which immune complexes cause platelet activation. An example of the latter is ITP, in which antibodies are directed against IIb/IIIa and Ib-IX glycoproteins on the platelet surface; this results in opsonization of platelets and their removal by FcγRIII receptors on macrophages in organs such as the spleen.

EVALUATION OF THE THROMBOCYTOPENIC PATIENT

For the hematology consultant, the urgency and pace of evaluation are determined by platelet count, extent of bleeding or thrombosis, the need for procedures, the presence of antiplatelet agents, the extent of nonhematologic symptoms, and concurrent anemia and/or leukopenia. The following general approach to evaluating the patient is useful

Figure 8-3 Bone marrow megakaryocytes in idiopathic thrombocytopenic purpura (ITP). Bone marrow biopsy of patient with chronic ITP shows increased megakaryocyte number and size, as well as increased megakaryocyte nucleus size (ploidy).

but should be individualized. Pseudothrombocytopenia should always first be excluded by a careful review of the blood smear. This examination also helps to assess for TTP and HUS because these usually preclude treatment with platelet transfusions. For patients on unfractionated or low molecular weight heparin, the drug should be stopped until HIT is excluded; the presence of HIT is another contraindication to platelet transfusion. Dilutional thrombocytopenia may be uncovered by a review of the transfusion record. The presence of splenic sequestration may be determined by physical examination or radiographic procedures such as ultrasound or computed tomography (CT). Finally, to determine whether platelet production is adequate, a bone marrow examination may be performed (Fig. 8-3).

As in the assessment of any other medical disorder, careful attention to the history and symptoms, physical examination findings, and appropriate laboratory investigations is essential. Although these suggestions are not meant to be exhaustive, the following approaches are often helpful in evaluating the thrombocytopenic patient.

Medical History

Given the potential myriad causes of thrombocytopenia, a careful history is in order. Prior platelet counts are important for documenting the chronicity of the thrombocytopenia and for excluding rare cases of familial thrombocytopenia and macrothrombocytopenia. Recent viral infections and vaccinations may cause transient thrombocytopenia. It is mandatory for the clinician to inquire about exposure to new medications such as antibiotics and antiplatelet drugs. The former (e.g., linezolid, vancomycin, nafcillin) commonly cause thrombocytopenia,^{70,71} and the presence of the latter (e.g., aspirin, nonsteroidal anti-inflammatory drugs, ketorolac) may explain ongoing bleeding. Current or recent exposure to unfractionated or low molecular weight heparin must be documented. Excessive ethanol ingestion may directly cause thrombocytopenia, or it may occur indirectly through hepatic cirrhosis. In pregnant patients, platelet counts from prior pregnancies may suggest gestational thrombocytopenia or recurrence of ITP; a history of hypertension and proteinuria may indicate

HELLP (Hemolysis, Elevated Liver function tests, and Low Platelets) syndrome. Recent headache, visual changes, confusion, or personality changes in patients with thrombocytopenia may suggest intracranial hemorrhage. A history of lymphoma or autoimmune disease (SLE, Hashimoto thyroiditis, anticardiolipin antibody syndrome) may suggest a diagnosis of ITP.

In hospitalized patients, a history of recent RBC or platelet transfusion may be associated with posttransfusion purpura (PTP). The response to prior platelet transfusions may also be helpful in assessing whether platelet destruction is ongoing; if such destruction is present, the corrected platelet count increment will be low and the rise in platelet count transient. The use of devices such as continuous venovenous hemofiltration⁷² and intra-aortic balloon pump counterpulsation⁷³ is commonly associated with thrombocytopenia. The presence of renal failure may also predict an increased risk of hemorrhage due to uremic platelet dysfunction.

Symptoms and Signs of Thrombocytopenia

Patients will have symptoms or signs of thrombocytopenia in accordance with platelet count and platelet function.¹⁰ Most thrombocytopenic patients have no symptoms and no signs. Such patients, as indicated earlier, usually have platelet counts above 50,000/ μ L and lack any significant platelet dysfunction. Such individuals are usually evaluated for assessment of the risk for future bleeding during procedures or for determination of the underlying cause of thrombocytopenia.

Patients who warrant the greatest amount of attention are those who have signs and symptoms of thrombocytopenia, usually with platelet counts less than 20,000/ μ L. Such individuals may have a wide range of bleeding complications, ranging from modest bruising to intracranial hemorrhage. Assessment of the patient for ongoing bleeding is of paramount importance for the consultant who is evaluating the patient at the bedside. Close examination of the patient for bruises and petechiae should be undertaken. In hospitalized bedridden patients, petechiae often occur on the back and dependent surfaces of the body rather than on the lower extremities, as is more common in ambulatory patients. Signs of “wet purpura” such as conjunctival hemorrhage, gum bleeding, and oral blood blisters are of great consequence and have been shown in some studies to herald more severe bleeding.^{74,75} Patients should be assessed for evidence of gastrointestinal bleeding such as melena and a positive test for fecal occult blood. Thrombocytopenic women often have menorrhagia. Careful abdominal examination usually provides an adequate assessment of splenic size. Cutaneous signs of giant cavernous hemangioma may be found. Although they are uncommon, signs and symptoms of central nervous system (CNS) bleeding range from subtle events (e.g., headache, mild gait abnormalities, confusion) to catastrophic occurrences (e.g., paralysis, coma). CNS bleeding has been reported to occur in 0.2% to 1% of children with ITP.^{74,75}

Signs of thrombosis should not be overlooked in thrombocytopenic patients. This is an important finding because it may indicate underlying disorders of platelet activation such as TTP, HUS, anticardiolipin antibody syndrome, DIC, and HIT.

*In evaluation of the thrombocytopenic patient, some of these tests may be helpful; see text discussion.

Laboratory Investigations

A number of laboratory tests may be used to assess the thrombocytopenic patient (Table 8-2). The importance of reviewing the blood smear to exclude pseudothrombocytopenia has already been mentioned. The blood smear also reveals the relative size and granularity of platelets; large granular platelets (megathrombocytes) are characteristic of disorders of platelet destruction and may suggest a low bleeding risk^{76,77}; hypogranular platelets may indicate myelodysplastic syndrome (MDS) and an increased bleeding risk. The mean platelet volume (MPV) and the platelet histogram help to confirm these visual findings. In addition, review of the smear reveals the presence of schistocytes that may be indicative of TTP, HUS, or DIC, or the presence of spherocytes, which might indicate Evans syndrome.

Measurement of the rate of platelet production may be assessed by flow cytometric measurement of reticulated platelets. However, this procedure has not been validated in most clinical settings and is not widely available.^{63,78,79}

Repeating the complete blood count (CBC) without delay with a heparinized (green top) or citrate (yellow top) tube kept at 37°C will assist the clinician in evaluating for pseudothrombocytopenia. The presence of coagulopathies such as DIC may be detected with the use of prothrombin time (PT), partial thromboplastin time (PTT), D-dimer, and fibrin split product (FSP) assays. The PF4-heparin antibody test can be used to assess for HIT. Antibodies to human platelet antigen (HPA)-1a (PLA1) may be identified serologically to assess for PTP. ITP may be investigated with the use of antiplatelet antibodies, but this test has a poor predictive value⁸⁰; rather, the direct antiglobulin test (DAT; Coombs test), antiphospholipid antibodies, antinuclear antibody (ANA), and hepatitis C serologies may be more helpful in revealing an autoimmune cause of thrombocytopenia.

Abdominal ultrasound or CT scan may be useful in assessing for splenomegaly or abdominal aortic dissection. A bone marrow examination may be useful but is often not required; thrombocytopenia rarely causes major hemorrhage with this procedure, and prophylactic platelet transfusions usually are not indicated.

Although platelet function tests cannot be reliably performed at platelet counts lower than 100,000/ μ L, most thrombocytopenic patients should have blood urea nitrogen (BUN) and creatinine checked for assessment of uremic platelet dysfunction.

TREATMENT OF PATIENTS WITH THROMBOCYTOPENIA

Although most patients with thrombocytopenia do not require immediate treatment, treatment of thrombocytopenia is often indicated when the patient has bleeding, reduced platelet function, platelets below 10,000/ μ L, or the need for procedures. As is discussed in the following sections, general treatment approaches include (1) specific treatment of the underlying cause; (2) platelet transfusions; (3) methods designed to enhance hemostatic function; and (4) the use of thrombopoietic growth factors.

Treatments for Specific Causes of Thrombocytopenia

If the condition is identified, treatment of the underlying cause of thrombocytopenia is indicated; treatment methods are discussed elsewhere. For TTP, treatment may include plasma exchange, as well as corticosteroids (see Chapter 24). For ITP, corticosteroids, intravenous immunoglobulin (IVIg) and splenectomy are commonly effective (see Chapter 9). For HIT, stopping the heparin and starting an alternative anticoagulant would be advised (see Chapter 25). Other drugs that are believed to cause thrombocytopenia should be discontinued.

Platelet Transfusions

Platelet transfusion is the mainstay for the treatment of thrombocytopenia. Each year, more than 2 million platelet transfusions are given at a cost of over \$1 billion.^{81–83} About 75% are apheresis platelets, and the rest are whole blood–derived platelet concentrates. About one third of all platelet transfusions are used to treat active bleeding; the rest are administered prophylactically.⁸⁴

Although considerable consensus has been reached about the use of therapeutic platelet transfusions to treat bleeding in thrombocytopenic patients, much debate continues about the use of prophylactic platelet transfusions in the nonbleeding patient. Table 8-3 provides suggested guidelines for administration of platelet transfusions. In the following discussion, data are presented to support these recommendations.

What is the transfusion target for bleeding patients?

In bleeding patients, transfusion is indicated to increase platelet count to at least 40,000/ μ L until the bleeding stops, although some prefer a target of 100,000/ μ L.⁸² These recommendations are not based on any clinical trial data.

Table 8-3 Platelet Transfusion Guidelines*

Platelet transfusions are contraindicated in the following situations:

- Thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome
- Heparin-induced thrombocytopenia

Platelet transfusions may be of minimal effect in the following situations, and use should be limited to situations of life-threatening bleeding:

- Idiopathic thrombocytopenic purpura (ITP)
- Disseminated intravascular coagulation (DIC)
- Platelet alloimmunization (with high panel-reactive antibody [PRA] titer and/or no demonstrable corrected count increment [CCI])
- Patients with chronic thrombocytopenia due to aplastic anemia, myelodysplastic syndrome (MDS) in the absence of bleeding

Platelet transfusions can be administered in the following situations without restriction:

- Active bleeding and platelet count <50,000/ μ L or demonstrable platelet function defect (uremia, known storage pool defect, after cardiac bypass)
- Nonbleeding patients who have the following:
 - Temporary myelosuppression and platelets <10,000/ μ L (<20,000/ μ L if febrile or with minor bleeding)
 - Need for major surgery or central nervous system (CNS) procedures and platelet count <100,000/ μ L
 - Other surgery or procedures in which potential bleeding can be visualized or external pressure applied and platelet count <50,000/ μ L
 - Need for surgery or procedure in a patient with known platelet dysfunction (von Willebrand disease [VWD], uremia) for whom other measures (1-deamino-8-D-arginine vasopressin [DDAVP], dialysis) may be ineffective
- Cardiac bypass patients who have the following:
 - Increased chest tube bleeding and no abnormal coagulation abnormalities with platelets <100,000/ μ L
 - Increased chest tube bleeding and known platelet function defect

*From Massachusetts General Hospital Transfusion Committee Guidelines based on AABB and other guidelines.⁹⁹

What is an adequate platelet count for procedures?

In thrombocytopenic patients who are about to undergo procedures, the platelet target has not been established by clinical studies. The British Committee for Standards in Haematology has recommended the following:⁸⁵

1. Routine dentistry—10,000/ μ L
2. Dental extractions—30,000/ μ L
3. Regional dental block—30,000/ μ L
4. Minor surgery—50,000/ μ L
5. Major surgery—80,000/ μ L

A recent study has suggested that a platelet count of 50,000/ μ L is safe in patients with ITP who are undergoing epidural anesthesia.⁸⁶

When should prophylactic platelet transfusions be given?

Whether prophylactic platelet transfusions enhance survival and decrease bleeding has never been the subject of a placebo-controlled clinical trial. Certainly, clinical experience from William Duke to the present has convinced clinicians of their important effects in both areas.^{87,88} A matter of concern involves the question of what platelet count

“trigger” patients should be given. Although current data suggest that this trigger is probably 10,000/ μ L in most subjects (possibly 5000/ μ L in some), treatment of each patient should be individualized. Factors other than platelet count help the clinician to determine the overall bleeding risk of a thrombocytopenic patient. These include underlying disease, fever, infection, coagulopathy, and concurrent medications. For these reasons, the decision about prophylactic platelet transfusions must take into account the patient’s condition and the clinical setting in which thrombocytopenia occurs.^{14,15}

Several studies in leukemic patients have convincingly showed that a prophylactic platelet transfusion trigger of 10,000/ μ L (10,000/ μ L to 20,000/ μ L if febrile, bleeding, or undergoing procedures) results in the same rate of major bleeding as a transfusion trigger of 20,000/ μ L. In one study,¹⁴ major bleeding (defined as any bleeding greater than petechial, mucosal, or retinal bleeding) occurred in 21.5% and 20% of patients, and on 3.1% and 2.0% of hospital days in the two groups, respectively. Red cell transfusions were the same in the two groups, but platelet transfusions were 21.5% fewer in the group transfused at 10,000/ μ L. In another study of leukemic patients,¹⁶ bleeding complications (World Health Organization [WHO] grades 2 to 4) occurred in 18% of those transfused at 10,000/ μ L versus 17% of those transfused at 20,000/ μ L. Serious bleeding events (WHO grades 3 to 4) were unrelated to platelet count but were associated with local lesions, sepsis, or coagulation abnormalities. Those transfused at 10,000/ μ L required one third fewer platelet transfusions. Several other studies in patients with leukemia and stem cell transplants have also confirmed these findings.^{89–91} It is possible that in patients without leukemia who are given chemotherapy, a trigger of 5000/ μ L may be adequate.⁹²

What platelet product should be used?

At equivalent doses, pooled single-donor platelets have the same hemostatic benefit as apheresis platelets. Apheresis platelets are often preferred for presumed reasons of efficiency, testing, bacterial contamination, white blood cell (WBC) removal, reduced donor exposure, and possible future bacterial and viral inactivation. Platelets that have been leukoreduced by bedside filtration or apheresis are preferred in most situations to reduce alloimmunization, febrile nonhemolytic transfusion reactions, and cytomegalovirus (CMV) infection (something accomplished equally well by selection of CMV-negative donors). This is particularly important in patients who will be receiving repeated transfusions, in those who are immunocompromised, and in those receiving chemotherapy; it is probably not important in surgical patients or those who have experienced trauma. To eliminate the small risk of acquired graft-versus-host disease, platelets should be irradiated if obtained from a related donor, or if the recipient is highly immunocompromised.

What dose of platelets should be given?

The average whole blood–derived platelet concentrate is required to contain 5.5×10^{10} platelets, but it usually contains 8.0 to 9.0×10^{10} platelets.⁹³ Apheresis platelets are required to have on average 3.0×10^{11} platelets, but centers may collect 3 to 4 times that amount from any single donor. Administration of 1×10^{11} platelets for each meter

of body surface area should increase the platelet count by 8000/ μ L to 10,000/ μ L 1 hour after transfusion; this provides the basis for the corrected count increment (CCI). These anticipated increments are affected by multiple other variables ranging from fever to splenomegaly to alloimmunization.

In bleeding patients, the dose should be that which increases the platelet count to the target ranges described previously.

Unfortunately, the dose in prophylactic settings has not been well established. It has become customary to transfuse 4 to 6 U of whole blood–derived platelet concentrates or a single apheresis platelet unit. However, lower doses may be effective. In a recent trial, thrombocytopenic leukemic or transplant patients received a low dose (three random donor concentrates = 2×10^{11} platelets) or a standard dose (five random donor concentrates = 4×10^{11} platelets) of platelets. Minor bleeding events occurred in 20% of low-dose and 40% of standard-dose patients, and major bleeds occurred in 10.7% of low-dose and 7.3% of standard-dose patients; 25% fewer platelet units were used in the low-dose group.^{94,95} A larger multicenter trial is currently under way to test the hemostatic benefits of various dose levels. Mathematical models suggest that small daily platelet doses are more economical and produce fewer donor exposures than do larger, less frequent transfusions.^{96,97} In contrast, one study showed that larger doses of platelets markedly reduced the frequency of prophylactic platelet transfusions⁹⁸ and may have reduced bleeding.

What are the complications of platelet transfusions?

These are well described in other reviews and monographs.⁹⁹ In brief, these include bacterial infection, hepatitis, alloimmunization, febrile nonhemolytic transfusion reactions, urticarial reactions, and CMV infection.

Enhanced Hemostatic Function

In some thrombocytopenic patients, platelet transfusions may not be effective because of alloimmunization; in others, the platelet count may be moderately depressed (30,000/ μ L to 60,000/ μ L), but platelets are dysfunctional because of uremia. Others may refuse blood products. In such settings, efforts to enhance overall hemostatic function may be helpful.

In both situations, the use of antifibrinolytics such as ϵ -aminocaproic acid (EACA) (Amicar; Wyeth, Madison, NJ, USA) or tranexamic acid (Cyclokapron; Pharmacia, Mississauga, Canada) may be effective. (The latter agent is currently available only as an intravenous formulation.) Daily doses of 2 to 24 g of EACA have been found to decrease bleeding in immune and nonimmune thrombocytopenias.^{100–102}

A more recent therapeutic option has been the use of recombinant factor VIIa (rFVIIa) (NovoSeven; Novo Nordisk, Princeton, NJ, USA). A recent report analyzed 24 cases of hemorrhage in patients with thrombocytopenia and hematologic malignancy.¹⁰³ All but one patient improved, and 46% experienced abrupt cessation of bleeding. This modality warrants further clinical study.

In addition to dialysis, a number of modalities improve platelet function in uremia. Whether these improve platelet function in nonuremic, thrombocytopenic patients has

been the subject of anecdote only. By raising the hematocrit to greater than 30% through transfusion or erythroid growth factors, bleeding is reduced in uremic patients.^{104–107} A proposed mechanism for this effect is that because red cells flow in the center of the blood vessel lumen, a higher hematocrit “pushes” the platelets to the periphery and increases interactions with the endothelium.¹⁰⁸ Other modalities that have proved effective involve the administration of DDAVP (1-deamino-8-D-arginine vasopressin), cryoprecipitate, and estrogens. Although DDAVP and cryoprecipitate work within 15 minutes and last for 4 to 6 hours, it may take weeks for the effects of estrogens to become apparent.

Thrombopoietic Growth Factors

Over the past decade, a number of hematopoietic growth factors have been shown to increase platelet production. These include interleukin (IL)-3, IL-6, and IL-11, as well as TPO and various TPO mimetics.²⁶ Of these, only IL-11 and the TPOs have been developed for clinical use. Although these therapies may ameliorate chronic thrombocytopenia, they will never replace platelet transfusions for the acute treatment of thrombocytopenia; with all of these treatment approaches, at least 5 days must pass before platelet count is increased, and usually 10 to 14 days are needed for maximal effect. Only one platelet growth factor, IL-11, has been approved by the U.S. Food and Drug Administration (FDA); TPOs and TPO mimetics are still in clinical development, but several should become available soon.¹⁰⁹

IL-11

IL-11 is not required for platelet formation in normal physiology; animals that are deficient in it have normal platelet counts but are sterile.¹¹⁰ Nonetheless, IL-11 increases megakaryocyte number and platelet count. In studies in patients undergoing standard chemotherapy, administration of a daily 50-μg per kilogram dose of recombinant IL-11 (oprelvekin) (Neumega; Wyeth Pharmaceuticals, Philadelphia, Pa, USA) reduced the need for platelet transfusions from 96% in the placebo group to 70% in the treated group.¹¹¹ Oprelvekin is currently FDA approved at that dose for the prevention of thrombocytopenia in patients undergoing nonmyeloablative chemotherapy who have experienced thrombocytopenia during a prior cycle, and for whom dose reduction is not appropriate. Oprelvekin is not widely used because of its significant adverse effects, which include dilutional anemia, fluid retention, congestive heart failure, arrhythmias, and anaphylaxis. At a daily dose of 10 μg per kilogram, some patients with bone marrow failure have had an increase in platelet count.¹¹²

Thrombopoietin and Thrombopoietin Mimetics

TPO, the primary regulator of platelet production in normal physiology, accounts for more than 90% of all platelet production.¹¹³ The first generation of clinical thrombopoietins included recombinant human TPO (rHTPO, a glycosylated, full-length version of the native molecule) and pegylated recombinant human megakaryocyte growth and development factor (PEG-rHuMGDF, a nonglycosylated, truncated TPO coupled to polyethylene glycol). Both of these recombinant TPOs bound to the TPO receptor and were very potent stimulators of platelet production

in healthy individuals. These platelet growth factors increased the nadir platelet count in patients undergoing nonmyeloablative chemotherapy and reduced the need for platelet transfusions.^{114,115} In patients with ITP and MDS, they increased platelet counts,¹¹⁶ and when given to platelet apheresis donors, they increased platelet yield.^{98,117,118} However, in stem cell transplantation and acute leukemia treatments, they had no effect on time to platelet recovery or number of platelet transfusions.¹¹⁹ These recombinant TPOs did increase the yield of CD34 cells when added to standard stem cell mobilization schemes, but the mobilized product was only marginally more effective during engraftment.¹²⁰ After antibodies developed against PEG-rHuMGDF and caused thrombocytopenia, development of both of these growth factors ceased.¹²¹

Recently, a second generation of platelet growth factors has been developed to avoid the problem of antibody formation. One of these, AMG-531, is a TPO mimetic that contains four peptides that bind and activate the TPO receptor and that are incorporated into the immunoglobulin Fc domain.^{122,123} This molecule is not antigenic, has a half-life of longer than 120 hours, and is a potent stimulator of platelet production in healthy humans. It has been shown to normalize platelet count in more than 85% of patients with ITP, when given weekly by a subcutaneous route.¹²⁴

A second family of platelet growth factors consists of the small nonpeptide molecules that bind the TPO receptor at a site distant from the binding site for TPO.^{125–132} These dimerize and activate the TPO receptor and promote platelet production in healthy humans. One of these, eltrombopag, has been extensively developed and has been shown to normalize the platelet count in 85% of patients with ITP, when given orally on a daily basis. It also normalizes the platelet count in patients with thrombocytopenia due to liver disease.

Both AMG-531 and eltrombopag are in the late stages of clinical development and will probably initially receive FDA approval for the treatment of ITP. They should also be effective in treating thrombocytopenia related to liver disease, nonmyeloablative chemotherapy, and possibly MDS. Both should be effective in increasing platelet apheresis yields. So far, use of neither has shown any major toxicity.

Chapter 9

Immune Thrombocytopenic Purpura

James N. George, MD • Kiarash Kojouri, MD, MPH

Immune thrombocytopenic purpura (ITP) is defined as isolated thrombocytopenia with no clinically apparent associated conditions or other causes of thrombocytopenia.¹⁻⁴ No specific criteria establish the diagnosis of ITP; the diagnosis requires the exclusion of other causes of thrombocytopenia.¹⁻⁴ ITP can be an acute disorder, with abrupt onset of bleeding symptoms and spontaneous resolution in several weeks or months. These clinical features may occur in adults,⁵ but they are more common in children younger than 10 years old, in whom acute and spontaneously resolving ITP is the rule.⁶⁻⁸ ITP can be a chronic disorder, with an insidious onset of minor bleeding symptoms and persistent, perhaps even permanent, thrombocytopenia. This thrombocytopenia may be unexpectedly discovered on routine blood studies in asymptomatic patients. This is the common clinical course in adults⁹ and adolescents.¹⁰ In some patients, long-term durable remission may be punctuated by an acute episode of symptomatic thrombocytopenia that may be caused by a viral illness and may not indicate recurrence of chronic, persistent thrombocytopenia. This chapter focuses on the issues of diagnosis and management of ITP in adults.

Because ITP is a persistent disorder, and because the mortality is negligible, the prevalence is great. The incidence of ITP in adults has been estimated in two recent prospective studies to be 16 to 27 patients newly given the diagnosis per million population per year.^{11,12} Both of these studies^{11,12} documented the following consistent and important observations: (1) The incidence of ITP has increased, principally because of heightened detection of asymptomatic patients with mild thrombocytopenia—an inevitable result of the wider use of routine platelet counts. Currently, as many as one third of patients with ITP may be discovered incidentally.¹¹⁻¹⁴ (2) A surprising observation was that incidence increases with age.^{11,12} (3) The female predominance that was so characteristically present in previous case series and that was present in the study from Denmark¹¹ of patients younger than 60 years old was not evident in patients older than 60 years of age. Therefore, the common assumption that ITP in adults is primarily a disease of young women may be incorrect; ITP is now recognized with increasing frequency among older patients of either sex.

PATHOGENESIS

The principal cause of ITP is increased platelet destruction caused by antiplatelet autoantibodies. However, some studies have shown a concomitant lack of compensatory increase in marrow production of platelets, or even a

decrease in platelet production, in patients with clinically typical ITP.¹⁵ Diminished platelet production may be the result of suppression of marrow megakaryocytes by antiplatelet autoantibodies.¹⁶⁻¹⁸ Interpretation of these observations is difficult because the methods required to document these abnormalities—increased destruction and relative marrow failure—are complex and are not easily reproducible. Measurement of antiplatelet antibodies is not a routine clinical laboratory test, and even in research laboratories, sensitivity and specificity are low and of limited clinical value.¹⁹ Estimates of platelet kinetics to document platelet production rates are dependent on radioisotope labeling of autologous platelets, and these studies are technically difficult. For example, even though they may be preferred for avoidance of alloantibody sensitization,¹⁵ the use of autologous platelets is associated with the risk that a patient's platelets that remain in the circulation may be younger and relatively less susceptible to destruction, and may therefore survive longer. This would be interpreted as indicating less platelet turnover and therefore less platelet production when compared with kinetic studies, in which isotope-labeled donor platelets from a normal subject who may have a shorter survival time are used.

In spite of these technical issues, the principal cause of increased platelet destruction is supported by *in vivo* studies in human volunteers that demonstrate the presence of antiplatelet antibodies in the plasma of patients with ITP. The initial classic report of Harrington, Hollingsworth, and others, in which they described infusing themselves with plasma from a woman with acute, severe ITP and the resulting prompt, profound thrombocytopenia,²⁰ has been retold in graphic detail.²¹ Shulman and others subsequently extended these studies with quantitative assessment of infusions of ITP plasma into normal and asplenic subjects (Fig. 9-1).²² Increasingly larger volumes of plasma from a patient with ITP that were transfused into a recipient who did not have ITP caused increasingly severe thrombocytopenia. Higher doses of ITP plasma were required to cause the same degree of thrombocytopenia in an asplenic subject, thus documenting the role of the spleen in removing antibody-sensitized platelets. Glucocorticoids administered to the recipient also blunted the ability of ITP plasma to cause thrombocytopenia when infused into a normal subject (see Fig. 9-1). In this series of investigations, an estimate of the titer of antiplatelet antibody could be deduced by infusion studies in normal subjects: Table 9-1 shows that patients with higher titers of antiplatelet antibodies were those with more severe ITP who were less responsive to treatment. The epitope specificity of antiplatelet antibodies may also contribute to the

Figure 9-1 Responses to infusions of plasma from patients with ITP into normal subjects. The left two panels illustrate the occurrence of thrombocytopenia in a normal subject following different doses of plasma from a patient with ITP, as well as the results of infusion of the same ITP plasma into a splenectomized subject. Note that the ITP plasma dose that did not produce thrombocytopenia in the splenectomized subject was greater than the dose that produced marked thrombocytopenia in the normal subject. The right panel illustrates the effects of prednisone on response to ITP plasma. Plasma from a patient with ITP was infused into three normal subjects without and with treatment with prednisone, 60 to 80 mg/day. Prednisone was begun 3 hours, 1 day, or 3 days before the plasma was infused and was continued for a minimum of 7 days. Control infusions were given 1 and 2 months before, and 3 weeks after, treatment with prednisone was administered. (Adapted from Shulman NR, Weinrach RS, Libre EP, Andrews HL: The role of the reticuloendothelial system in the pathogenesis of idiopathic thrombocytopenic purpura. *Trans Assoc Am Physicians* 1965;78:374-390, with permission.)

Table 9-1 Correlation Between In Vivo Assessment of the Titer of Antiplatelet Antibody and Response to Treatment

Patient With ITP	Titer of Antiplatelet Antibody	Platelet Count (per μ L)		
		Before Prednisone	After Prednisone	After Splenectomy
1	<1:3	12,000	70,000	200,000
2	<1:3	5000	200,000	400,000
3	<1:3	<1000	200,000	-
4	<1:3	2000	200,000	-
5	1:3	5000	100,000	-
6	1:20	5000	25,000	30,000
7	1:20	3000	10,000	10,000
8	1:20	9000	12,000	15,000
9	1:40	<1000	2000	2000
10	1:50	1500	2000	2000

Antiplatelet antibody titer was determined as the dilution of the plasma of each patient with immune thrombocytopenic purpura (ITP) that caused an approximately 50% decrease in platelet count in a normal recipient, similar to the dose of 1.25 mL/kg in Figure 9-1 (*left*). If a plasma volume of 40 mL/kg is assumed, this plasma would have an estimated titer of 1:32. Plasma from patients with estimated titers of less than 1:3 did not cause a 50% decrease in a normal recipient's platelet count, even when 15 mL/kg (approximately 1 L) was infused. Patients 3, 4, and 5 did not undergo splenectomy. Adapted from Shulman NR, Weinrach RS, Libre EP, Andrews HL: The role of the reticuloendothelial system in the pathogenesis of idiopathic thrombocytopenic purpura. *Trans Assoc Am Physicians* 1965;78:374-390, with permission.

severity of bleeding symptoms. Antiplatelet antibodies that react with the fibrinogen-binding site of glycoprotein (GP)-IIb/IIIa may interfere with platelet function.²³

EVALUATION OF A PATIENT WHO PRESENTS WITH ISOLATED THROMBOCYTOPENIA

An algorithm for a diagnostic approach to isolated thrombocytopenia is presented in Figure 9-2. Medical history, physical examination, and examination of peripheral blood

smear are sufficient to exclude other possible causes of thrombocytopenia and to establish the diagnosis of ITP in most patients. Certainly, these time-honored activities are sufficient in patients with incidentally discovered asymptomatic thrombocytopenia; they may also be the only items that are essential for the evaluation of patients who present with severe, symptomatic thrombocytopenia. The response to treatment and the clinical course of symptomatic patients provide additional diagnostic confirmation.

Several features of peripheral blood morphology are critical in the diagnosis of ITP (Table 9-2). First, actual thrombocytopenia should be confirmed. No abnormalities of red

Figure 9-2 Algorithm for the evaluation of isolated thrombocytopenia in an otherwise healthy person. (From George NJ: Platelets. Lancet 2000;355:1531–1539, with permission from Elsevier Science.)

Table 9-2 The Peripheral Blood Smear in Immune Thrombocytopenic Purpura (ITP)

Features Consistent With the Diagnosis of ITP

Thrombocytopenia, with normal platelet size and morphology, or slightly larger than normal platelets
 Normal red cell number and morphology. Exceptions may be abnormalities from expected associated conditions, such as iron deficiency from chronic bleeding, or incidental conditions, such as thalassemia minor
 Normal white cell number and morphology

Features Not Consistent With the Diagnosis of ITP

Predominance of giant platelets with diameters similar to those of red cells
 Red cell abnormalities, such as schistocytes, oval macrocytes, teardrop cells, and nucleated red cells
 Leukocytosis or leukopenia with immature or abnormal cells

cell or white cell number or morphology should be present, other than expected associated conditions such as iron deficiency from chronic bleeding or incidental conditions such as thalassemia minor. Platelet morphology should be normal, although some reports describe a larger size of platelets in ITP, postulated to represent younger “stress” platelets produced in response to accelerated peripheral platelet destruction. However, the presence of truly giant platelets, approaching or exceeding the size of red blood cells, is

not consistent with the diagnosis of ITP but suggests the presence of congenital thrombocytopenia.²⁴

Tests for antiplatelet antibodies are *not* recommended for the diagnostic evaluation of patients with suspected ITP.^{1,3,4} Measurements of platelet-associated immunoglobulin (Ig)G merely reflect the plasma IgG concentration and platelet α granule content of plasma proteins.²⁵ In multiple studies, the sensitivity and specificity of commercial tests for antiplatelet antibody detection are poor,^{19,26} and results with multiple assays for antiplatelet antibodies in which identical split samples were used in multiple research laboratories were inconsistent in one study.²⁷ Therefore, the possibility of misinformation is high.

Contrary to the opinion of some physicians, splenomegaly is rarely present in ITP. One large study reported palpable spleens in only 7 of 271 (2.6%) patients²⁸—a frequency similar to the 2.9% incidence of palpable spleens noted in healthy college students.²⁹ Enlargement of the spleen should broaden the differential diagnosis to include thrombocytopenia that may be part of immune disorders characterized by an enlarged spleen, notably chronic lymphocytic leukemia. Additionally, the spleen may be enlarged when patients have concomitant Coombs-positive hemolytic anemia (so-called Evan syndrome) or when patients actually have hypersplenism rather than ITP.

The role of bone marrow aspirate examination is controversial. Some hematologists believe that it is necessary

in all patients who present with a new observation of thrombocytopenia; other hematologists believe that a bone marrow aspirate examination in all patients with suspected ITP is inappropriate.¹ Guidelines for the evaluation of patients with suspected ITP have suggested that bone marrow aspirate examination conducted to exclude the possibility of myelodysplasia may be appropriate in patients older than 60 years of age.^{1,3} Bone marrow aspirate examination may also be appropriate when a patient is unresponsive to initial treatment, or when splenectomy is considered.^{1,3,4} However, in most patients, bone marrow aspirate examination is not helpful in the differential diagnosis. For example, other than in myelodysplasia and acquired pure megakaryocytic aplasia, bone marrow aspirate examination would not be helpful

for the differential diagnostic possibilities listed in Table 9-3. Systematic studies in adults³⁰ and children³¹ with suspected ITP have documented that bone marrow aspirate examination provided an alternative diagnosis only when abnormalities were identified during the initial evaluation by history, physical examination, and examination of the peripheral blood smear.

DIFFERENTIAL DIAGNOSIS OF ITP

The differential diagnosis of ITP includes all disorders that can manifest with unexpected observation of a low platelet count or purpura. Because the diagnosis of ITP requires

Table 9-3 Differential Diagnosis of Immune Thrombocytopenic Purpura (ITP)

Disorders	Clinical Features
Pseudothrombocytopenia	
EDTA-dependent clumping	Actual platelet count normal but falsely low on laboratory report because platelets are clumped in vitro and on blood smear
Platelet satellitism	Actual platelet count normal; in vitro platelets adhere to granulocytes or monocytes
Common Causes of Thrombocytopenia	
Drug-induced thrombocytopenia	Initially indistinguishable from ITP. Diagnosis established by prompt recovery on withdrawal of the drug and, in some circumstances, rechallenge. May also be caused by nutritional supplements, herbal remedies, foods
Pregnancy	Asymptomatic, mild thrombocytopenia common near term and may actually be an exacerbation of subclinical ITP. More severe thrombocytopenia may accompany preeclampsia/HELLP syndrome
Hypersplenism	Asymptomatic mild thrombocytopenia may be the initial clue to occult liver disease
Infection	Asymptomatic mild thrombocytopenia may occur with HIV infection, viral immunization, or EBV infection. More severe thrombocytopenia may be prominent with rickettsial infection, <i>Ehrlichia</i> , or leptospirosis
Less Common Causes of Thrombocytopenia	
Congenital thrombocytopenias	
Bernard-Soulier syndrome	Typically mistaken for ITP and inappropriately treated
<i>MYH9</i> -related thrombocytopenia	Giant platelets. Autosomal recessive, therefore consanguinity common. Bleeding symptoms greater than expected because of GP-Ib-IX abnormality and defective VWF binding
Fanconi syndrome	Giant platelets, granulocyte inclusions. Autosomal dominant. Typically mild bleeding symptoms. Also, sensorineural deafness and nephritis may occur
Wiskott-Aldrich syndrome	Autosomal recessive, short stature. May manifest in adults with isolated thrombocytopenia but typically progresses to aplasia or myelodysplasia
Thrombocytopenia with absent radius	X-linked. Small platelets. Typically associated with eczema and immunodeficiency but may manifest as isolated thrombocytopenia
Other uncharacterized congenital thrombocytopenias	Autosomal recessive, associated with multiple skeletal anomalies. Typically manifests as severe thrombocytopenia in infancy but may cause mild thrombocytopenia in adults
von Willebrand disease, type 2B	May be autosomal dominant, recessive, or X-linked. Family history is the key to diagnosis
Myelodysplasia	Autosomal dominant thrombocytopenia due to in vivo platelet clumping and clearance caused by abnormal VWF. Bleeding symptoms more serious than expected because of associated VWF deficiency
Chronic disseminated intravascular coagulation	May manifest as isolated thrombocytopenia in older patients
Thrombotic thrombocytopenic purpura-hemolytic-uremic syndrome	May be detected initially because of thrombocytopenia
Acquired pure megakaryocytic aplasia	Typically acute onset with multiple organ dysfunction, but may have a prodrome of isolated thrombocytopenia
	Indistinguishable from ITP until marrow aspirate is done because of poor response to treatment

EDTA, ethylenediaminetetraacetic acid; HELLP, syndrome of hemolytic anemia, elevated liver enzymes, and low platelet count; HIV, human immunodeficiency syndrome; EBV, Epstein-Barr virus; GP, glycoprotein; VWF, von Willebrand factor.

the exclusion of other causes of thrombocytopenia, the conditions listed in Table 9-3 must be considered.

Pseudothrombocytopenia

Pseudothrombocytopenia is consistently observed in 1 in 1000 subjects and is not related to the presence or absence of any disease (Figs. 9-3 and 9-4) (Table 9-4).³²⁻³⁷ The most common cause of pseudothrombocytopenia is a “naturally occurring” autoantibody against a neo-epitope on GP-IIb/IIIa, exposed by the ethylenediaminetetraacetic acid (EDTA) anticoagulant used for routine blood counts.³⁸ In EDTA, these autoantibodies cause platelet clumping and falsely low platelet counts in vitro. Platelet counts in citrate-anticoagulated blood are usually, but not always, normal, as calcium chelation by citrate is not strong enough to alter the configuration of the GP-IIb/IIIa molecule. EDTA-dependent platelet agglutinins are of no clinical importance,³⁹ except that they may contribute to the acute thrombocytopenia that can occur with initial administration of GP-IIb/IIIa–blocking antithrombotic agents, which may cause structural alteration of GP-IIb/IIIa, similar to EDTA.⁴⁰ Pseudothrombocytopenia may result from in vitro platelet adherence (“satellitism”) to leukocytes, typically granulocytes.⁴¹ This phenomenon may occur only in EDTA-anticoagulated blood.⁴¹ Either cause of pseudothrombocytopenia will be clearly seen during examination of the peripheral blood smear.

Figure 9-3 Platelet clumping. Note that several platelets clump to one another on the peripheral blood smear. This clumping is independent of the nearby neutrophils.

Drug-Induced Thrombocytopenia

Drug-induced thrombocytopenia cannot initially be distinguished from ITP. A careful history not only of drugs⁴² but also of foods,⁴³ herbal remedies,^{44,45} and nutritional products⁴⁶ must be obtained. Especially in patients with intermittent acute thrombocytopenia,⁴⁶ these agents must be excluded as the cause before a diagnosis of ITP can be confidently established. A critical purpose for the investigation of drug-induced thrombocytopenia is to emphasize to the patient that it is not only prescription drugs that may be involved. For example, quinine is probably the most common currently reported cause of drug-induced thrombocytopenia,^{12,42} but patients may not recognize quinine as a “drug”; therefore, they may continue to use it, even after they have been advised to discontinue all medications.⁴⁶ Furthermore, quinine is present in tonic water,⁴⁷ as well as in over-the-counter nutritional supplements,⁴⁶ in sufficient concentrations to cause profound thrombocytopenia. Drug-dependent antibodies are not demonstrable in all patients with drug-induced thrombocytopenia.⁴⁸ Effective diagnostic strategies include observation of recovery from thrombocytopenia within 7 days after discontinuation of all drugs and other potentially causative compounds, and fortuitous observations after the offending agent is reintroduced.⁴² Patients with symptomatic thrombocytopenia are typically treated with prednisone; therefore, even platelet

Figure 9-4 Platelet satellitism. Platelets adhere in a necklace-like pattern around two neutrophils yet do not clump together.

Table 9-4 Frequency of Pseudothrombocytopenia Caused by EDTA-Dependent Platelet Agglutinins

Study	Frequency
Payne and Pierre: ³² All platelet counts for 1 yr at Mayo Clinic	124/143,000; 0.09%
Savage: ³³ All platelet counts for 9 mo at Cleveland Clinic	154/135,806; 0.11%
Vicari et al: ³⁴ All platelet counts for 1 yr at Istituto S. Raffaele, Milan	43/33,623; 0.13%
Garcia Suarez et al: ³⁵ Ambulatory patients, Asturias Hospital, Madrid	23/20,760; 0.11%
Sweeney et al: ³⁶ Healthy blood donors, Norfolk, Virginia	2/945; 0.21%
Bartels et al: ³⁷ Hospital and clinic patients in The Netherlands	46/45,000; 0.10%

EDTA, ethylenediaminetetraacetic acid.

count recovery may not allow a distinction from ITP. Some “complete remissions” of ITP after prednisone is taken may actually be due to occult drug-induced thrombocytopenia. Continuing systematic reviews, updated through October 2006, have evaluated all published case reports with the use of standardized criteria for assessing the causal relationship of drugs to thrombocytopenia (<http://moon.ouhsc.edu/jgeorge>).

Pregnancy

Mild thrombocytopenia, typically with platelet counts above 70,000/ μ L, occurs in 5% of women as pregnancy approaches term, and it resolves spontaneously after delivery.⁴⁹ This abnormality has been called “gestational thrombocytopenia” or “incidental thrombocytopenia of pregnancy,” and it has been deemed to be a pregnancy-related syndrome, distinct from ITP.¹ Diagnostic features include (1) asymptomatic, mild thrombocytopenia, (2) with no past history of thrombocytopenia (except possibly during a previous pregnancy), (3) occurring during late gestation, (4) that is not associated with fetal thrombocytopenia, and (5) that resolves spontaneously after delivery.¹ However, several observations suggest that gestational thrombocytopenia may be only a common, mild, and transient presentation of ITP, perhaps an exacerbation of platelet destruction for which compensation is normally provided by increased platelet production. First, multiple different methods for detecting antiplatelet antibodies could not distinguish patients with a clinical diagnosis of ITP from those with gestational thrombocytopenia who were diagnosed by the previous criteria.⁵⁰ Second, patients with ITP and mild or moderate thrombocytopenia may have lower platelet counts toward the end of pregnancy that return to previous levels after delivery.⁵¹ This is consistent with clinical observations in other autoimmune disorders that can become exacerbated during pregnancy. For example, hemolysis increased in 18 of 19 patients with autoimmune hemolytic anemia during the third trimester of pregnancy and resolved during the first 3 months postpartum.⁵² Third, the risk of neonatal thrombocytopenia may be related to the severity of maternal thrombocytopenia,⁵³ consistent with early observations on higher titers of antiplatelet antibodies in patients with severe ITP (see Table 9-1).²² Therefore, it may be anticipated that women whose ITP becomes clinically apparent only during pregnancy, but who otherwise have normal platelet counts, would not be expected to have thrombocytopenic infants at birth.

Hypersplenism

Perhaps the most common cause of thrombocytopenia among hospitalized patients is the mild thrombocytopenia caused by splenic pooling due to portal hypertension and congestive splenomegaly. The most common cause of portal hypertension is intrinsic liver disease, but other causes include extrahepatic portal hypertension due to splanchnic venous thrombosis or systemic venous hypertension, such as from cardiopulmonary disease (see Chapter 39). In these patients, thrombocytopenia is typically mild, with platelet counts rarely below 40,000/ μ L and with most in the range of 50,000 to 90,000/ μ L. Total body platelet counts are actually normal, as is platelet survival; the only abnormality is

passive pooling of most platelets in the congested, enlarged spleen.⁵⁴ Patients with severe thrombocytopenia associated with liver disease may also have decreased platelet production caused by decreased thrombopoietin synthesis in the liver.⁵⁵

Infection

Human immunodeficiency virus (HIV) may cause thrombocytopenia that is indistinguishable from ITP due to infection of marrow stromal cells⁵⁶ (see Chapter 13). Other viral infections and even immunizations⁵⁷ commonly cause a decreased platelet count, although rarely to levels that are symptomatic. Thrombocytopenia mimicking ITP may be the initial manifestation of disseminated tuberculosis.⁵⁸ In some infections, such as Rocky Mountain spotted fever and ehrlichiosis,⁵⁹ severe and symptomatic thrombocytopenia may occur, but other systemic signs and symptoms distinguish these disorders from ITP (see Chapter 11).

Congenital Thrombocytopenias

(see Chapter 10)

Adults with newly recognized congenital thrombocytopenia are almost always mistakenly given the initial diagnosis of and treatment for ITP.²⁴ Many well-described syndromes of congenital thrombocytopenia have been described (see Table 9-3), but perhaps most common are disorders that fit no described syndrome.²⁴ Syndromes previously described as May-Hegglin anomaly, Epstein, Fechtner, and Sebastian syndromes, or Alport syndrome variants are now known to have the same genotypic origin: mutation of *MYH9*, the gene that encodes the nonmuscle myosin, heavy-chain IIA.^{24,60} The key diagnostic feature is a family history of a low platelet count, which is often not initially recognized. Problematic with the misdiagnosis of ITP are unfortunate therapeutic interventions with glucocorticoids, rituximab, or even splenectomy that are not efficacious. Congenital thrombocytopenia should be considered in patients whose platelet counts are unresponsive to initial prednisone treatment, who have unusually large platelets or neutrophil inclusions (e.g., Döhle bodies) on their peripheral blood smear, who have other inherited anomalies such as skeletal deformities, or who have a family history of consanguinity, which increases the opportunity for expression of autosomal recessive traits.

The presence of truly giant platelets that are similar in diameter to red cells should suggest congenital thrombocytopenia (see Table 9-2). Inherited giant platelet disorders are heterogeneous, typically are associated with minimal bleeding symptoms, and often are initially misdiagnosed as ITP.^{61–64} In some inherited syndromes, abnormalities such as skeletal deformities, nephritis, and sensorineural deafness may be associated (see Table 9-3). In some syndromes, a greater amount of bleeding may occur than would be expected for the degree of thrombocytopenia because of an associated platelet function defect, as in Bernard-Soulier syndrome, or an associated hemostatic disorder, as in von Willebrand disease, type 2B (see Table 9-3). However, most patients with congenital thrombocytopenia have no distinguishing clinical features other than moderate thrombocytopenia.^{24,65,66}

Myelodysplasia

Myelodysplasia may manifest as isolated thrombocytopenia,^{67,68} but this is uncommon. Patients with chronic ITP may have monoclonal hematopoiesis,⁶⁹ suggesting the possibility that in some patients, ITP and myelodysplasia may be overlapping syndromes.⁷⁰ Because myelodysplastic syndromes are much more frequent among older patients, bone marrow aspiration and biopsy are appropriate when patients present with apparent ITP at the age of 60 years or older.^{1,3} This was, of course, a consideration in a recent epidemiologic study on the incidence of ITP¹¹ that documented a higher than expected occurrence among older men. However, in this study, most older patients had bone marrow examinations that were normal, and no patient with ITP from the study period subsequently developed a myelodysplastic syndrome.¹¹

Disseminated Intravascular Coagulation

Although it is very rare for disseminated intravascular coagulation (DIC) to occur in the absence of an overt clinical cause, and even more rare for chronic, indolent DIC to present as isolated thrombocytopenia, this has been observed.⁷¹ Patients with large hemangiomas may have localized intravascular coagulation, which may first be recognized in adulthood as asymptomatic thrombocytopenia. A comparable but more severe disorder that presents in infancy is the Kasabach-Merritt syndrome.⁷² Recognition of this possibility is important for an awareness of the broad spectrum of abnormalities that can mimic ITP and lead to inappropriate treatment (see Chapter 12).

Thrombotic Thrombocytopenic Purpura–Hemolytic-Uremic Syndromes

The thrombotic thrombocytopenic purpura–hemolytic-uremic syndromes (TTP-HUS) typically present as acute severe illness with symptoms and signs of multiple organ dysfunction. However, patients may have a syndrome of isolated, asymptomatic thrombocytopenia that is indistinguishable from ITP. This is increasingly apparent with close follow-up of patients who have recovered from TTP-HUS. In these patients, incidentally discovered thrombocytopenia may or may not predict a relapse of acute TTP-HUS (see Chapter 24).

Acquired Pure Megakaryocytic Aplasia

Autoantibodies to thrombopoietin or megakaryocytes may cause severe thrombocytopenia associated with absent marrow megakaryocytes, which may be indistinguishable from ITP until a bone marrow aspiration is done. Patients may not respond to prednisone and intravenous immune globulin (IVIg) but can achieve durable remission with cyclosporine and antithymocyte globulin—the more intensive immunosuppressive regimen used for aplastic anemia.⁷³

Thrombocytopenia Associated With Other Autoimmune Disorders

Patients in whom thrombocytopenia is part of a clinically overt autoimmune or lymphoproliferative⁷⁴ disorder are

considered to be distinct from those with ITP because the clinical course is determined by the primary disease. For example, in patients with Graves disease and thrombocytopenia, thrombocytopenia often resolves with effective treatment of hyperthyroidism.⁷⁵ However, isolated abnormalities of serologic tests for antinuclear antibodies or antiphospholipid antibodies are frequently encountered in patients with typical ITP and do not influence its management or clinical course.^{76–78}

MANAGEMENT OF ITP

The single goal in the management of ITP is to prevent major bleeding. Therefore, the practical goal is to maintain a safe platelet count. Cure is not a goal. Although simple in concept, this principle of management is essential for preventing the common occurrence of making adverse effects of treatment worse than symptoms of the disease.

What is a Safe Platelet Count?

The consistent clinical observation is that most patients with ITP never have clinically important bleeding, even when their platelet counts are very low. Easy bruising may be common and petechiae may be numerous, but truly extensive purpura with innumerable petechiae and extensive ecchymoses is very rare. These cutaneous bleeding symptoms are often referred to as “dry purpura,”⁷⁹ to distinguish them from overt mucous membrane bleeding, such as persistent epistaxis or gingival bleeding, referred to as “wet purpura.” Wet purpura is less common but more alarming and may be associated with greater risk for major bleeding. The feared complication of ITP is intracranial hemorrhage, which is too rare to have a documented incidence among patients with ITP. Suggestions have been made that the incidence may be 0.1% to 1.0%,¹ but this high frequency, if true, would be relevant only to patients with severe and symptomatic thrombocytopenia.

Few platelets are required to provide adequate hemostasis. Clinical studies in other disorders, such as aplastic anemia⁸⁰ and thrombocytopenia after chemotherapy for acute leukemia,^{81,82} suggest that spontaneous, clinically important bleeding does not occur with platelet counts above 5000 to 10,000/ μ L. Because younger platelets are assumed to have greater hemostatic capability than older platelets,⁸³ patients with ITP may have even less risk for bleeding at comparable platelet counts compared with patients with thrombocytopenia caused by marrow failure. Therefore, an analogy may be made to patients with hemophilia, in whom the presence of any measurable factor VIII or factor IX transforms a disease with severe bleeding risk to a clinically occult disorder.⁸⁴

Initial Management of ITP in Children

Conservative management of ITP in children yields important lessons for its management in adults. Because spontaneous remission occurs in most children within several weeks to months, some pediatric hematologists believe that careful observation without specific treatment is sufficient, even when thrombocytopenia is severe.^{6,85} Although platelet counts in children recover more quickly with

glucocorticoid or IVIg treatment,⁸⁶ no studies have shown that more rapid recovery results in less bleeding. Although many pediatric hematologists treat children initially with IVIg or anti-D,⁸⁷ these agents are expensive, are not always promptly available, may require hospitalization, and produce frequent adverse side effects of headache with nausea and vomiting⁸⁸ that can mimic intracranial hemorrhage, causing severe alarm and thus requiring further diagnostic study.^{88,89} Anti-D can cause severe intravascular hemolysis with frequently fatal DIC.⁹⁰

For children whose ITP does not spontaneously resolve, conservative management without specific treatment remains a common practice. In a recent audit of 427 children with ITP in the United Kingdom, only 3 had undergone splenectomy.⁹¹ Avoidance of splenectomy is in part related to the continuous occurrence of spontaneous remission in children, even after many years,^{92,93} but this decision is made also because of concern for subsequent severe sepsis, particularly when splenectomy is performed before age 5.⁹⁴

Although bleeding risks may be greater in older adults than in children because of comorbidities such as hypertension,^{95,96} adults have the advantage of moderating their activity and avoiding trauma; these are difficult assignments for young children.

Initial Treatment of Adult Patients who have Incidentally Discovered Asymptomatic Thrombocytopenia

If the patient is asymptomatic, probably no specific therapy is indicated. However, in standard practice, the method of treatment of patients with ITP is linked to the level of thrombocytopenia. If it is assumed that a platelet count above 10,000/ μ L is safe,^{80–82} then a reasonable belief would be that treatment is unnecessary for patients with platelet counts above 20,000/ μ L.⁴ Although observation without specific treatment is a common standard of care for children who present with a new diagnosis of acute ITP, even when platelet counts are less than 10,000/ μ L,^{6,85} in adults, because of uncertainty regarding the stability of persistent thrombocytopenia and because of the simplicity of initial oral prednisone therapy, initial treatment with prednisone is inevitably prescribed unless the platelet count is significantly higher than 10,000 to 20,000/ μ L.

Multiple case series have followed adult patients with newly diagnosed ITP and platelet counts above 20,000 to 50,000/ μ L^{12–14,96,97} who were given no specific treatment. In these case series with median follow-up durations of 3 to 10 years, no adverse outcomes of major bleeding were reported. A few of these patients may develop more severe thrombocytopenia and may require treatment; also, in a few patients, the platelet count may spontaneously return to normal.^{12,97} However, it appears that in most patients, incidentally detected mild thrombocytopenia is persistent for the duration of follow-up.¹⁴ If no specific treatment is prescribed, then the interval for measuring the platelet count becomes an issue. If the interval between platelet counts seems too long, the patient becomes apprehensive and the physician may appear unconcerned. On the other hand, platelet counts measured too frequently may cause patient apprehension that results from an obsessive focus

on clinically unimportant variations. Resolution of this issue requires thorough patient education about the nature of ITP, its clinical course, its risks, and the goals of treatment. Resources for reliable patient education include the websites of the National Heart, Lung, and Blood Institute (http://dci.nhlbi.nih.gov/Disease/Itp/ITP_What_Is.html), the ITP Support Association (<http://itpsupport.uk>), and the University of Oklahoma (<http://ouhsc.edu/jgeorge>). After several platelet counts have been taken to establish the consistency of thrombocytopenia, patients must be gradually weaned from dependence on knowing their current platelet count.

Initial Treatment of Adult Patients who Present with Severe Thrombocytopenia and Symptomatic Purpura

Adults with symptomatic purpura are treated initially with glucocorticoids.⁴ Prednisone is a commonly used agent; the dosage is empirical, but 1 mg/kg/day given as a single dose is a common standard regimen, but lower doses may be as effective.⁹⁸ Most, but not all, patients respond with a decrease in formation of new petechiae and an increase in platelet count; then the dose is gradually tapered. A case can be made for more rapid tapering of prednisone to determine whether severe, symptomatic thrombocytopenia at presentation was perhaps a transient, reversible occurrence in the course of more mild ITP, or perhaps occult drug-induced thrombocytopenia.¹² If severe thrombocytopenia recurs on tapering of prednisone, this becomes an indication for splenectomy. Patients may urge withdrawal of prednisone because of the misery caused by symptoms of emotional lability, inability to concentrate, tremulousness, difficulty sleeping, and the inevitably depressing “moon facies.” Of greater concern is that prednisone doses equivalent to or even less than physiologic cortisol secretion (2.5 to 5.0 mg prednisone/day) may cause bone loss within several months through impairment of normal diurnal cortisol secretion.^{99,100} In spite of the rationale for quick tapering of the prednisone dose, some hematologists believe that a greater opportunity to achieve durable remission and to avoid splenectomy arises when a more prolonged course of prednisone therapy with gradual tapering is carried out.

An alternative initial glucocorticoid regimen is dexamethasone 40 mg/day given for 4 days.¹⁰¹ In this report, 106 (85%) of 125 patients whose initial platelet counts were lower than 20,000/ μ L responded; 53 (50%) of those who responded maintained this safe platelet count without further treatment for the duration of follow-up (median, 2.5 yr).¹⁰¹ If the success reported by this experience¹⁰¹ is confirmed by outcomes described in subsequent reports, this regimen has the advantage of a brief course, although with a very high dose, of glucocorticoids. Short-term complications of mood disturbance and hyperglycemia may be important, but the destructive long-term complications of prolonged glucocorticoid treatment can be avoided.

IVIg and anti-D are treatments given to temporarily increase platelet count; they have occasionally been used in the initial treatment of patients with ITP. IVIg may cause systemic symptoms of myalgia, fever, nausea, and headache

in one third of patients.⁸⁸ Actual aseptic meningitis may occur,⁸⁹ with signs mimicking intracranial hemorrhage. Acute renal failure has also been reported and appears related to osmotic injury to proximal renal tubules associated with the sucrose content of the IVIg product.^{102,103} Therefore, older patients, those with preexisting renal insufficiency, and those who are receiving concomitant nephrotoxic drugs should be given IVIg only with caution.

An anti-Rh(D) product developed for the treatment of patients with ITP was based on the hypothesis that hemolysis caused by alloantibodies in IVIg may be the mechanism for blocking sequestration of autoantibody-coated platelets. This product is a preparation of anti-Rh(D) alloantibodies, often referred to simply as anti-D. Anti-D is easier to administer than IVIg (a 3- to 5-minute infusion compared with administration over several hours), but it is effective only in patients whose red cells are D positive and appears to be effective only in nonsplenectomized patients.¹⁰⁴ It causes fewer systemic symptoms, and the major and dose-limiting adverse effect is alloimmune hemolytic anemia; severe, life-threatening intravascular hemolysis with DIC has been reported.^{90,105} Although the typical regimen of anti-D (50 to 75 µg/kg given once) costs less than a regimen of IVIg (the approximate cost for a course of IVIg in an adult is \$10,000 to \$15,000; for anti-D, \$5000 to \$8000), these are both expensive treatments. Much less expensive (approximately \$100) is the use of intravenous methylprednisolone, which may have efficacy comparable with that of IVIg and anti-D.

A randomized clinical trial conducted to determine whether intermittent initial treatment of adults with anti-D may allow spontaneous remission to occur and splenectomy to be avoided, while avoiding complications of glucocorticoids has been performed.¹⁰⁶ Although splenectomy was deferred, it was not avoided,¹⁰⁶ consistent with other experiences in which spontaneous remissions of ITP were uncommon in adults.

Treatment of Patients with Acute Bleeding Due to Severe Thrombocytopenia

Patients must be alert for the symptoms and signs of acute bleeding, and physicians must be prepared for emergency care. For a bleeding emergency, in addition to conventional critical care measures, appropriate treatments include platelet transfusions, high-dose parenteral glucocorticoids, and IVIg.¹ Emergency splenectomy may also be important in providing more immediate and durable recovery from severe thrombocytopenia.¹⁰⁷ Despite a presumably short platelet survival time, platelet transfusions may provide substantial platelet count increments in some patients.^{108,109} Continuous infusion of platelets to provide continual hemostatic support has been suggested.¹¹⁰ High-dose glucocorticoids, such as 1 g/day of methylprednisolone given by intravenous infusion and repeated daily for 2 additional days, can rapidly increase the platelet count. IVIg, given as 1 g/kg/day for 2 days, increases the platelet count in most patients within 3 days. Furthermore, IVIg given before a platelet transfusion may increase the platelet count increment and prolong the duration of response.¹¹¹ In patients with critical bleeding who do not respond to these treatments, recombinant factor VIIa may be effective.^{112,113}

Splenectomy

In adult patients who continue to have severe and symptomatic thrombocytopenia after initial glucocorticoid treatment, splenectomy is traditionally the next treatment consideration. Although splenectomy is not universally effective (or else it would be recommended sooner and more often), the relative efficacy of splenectomy is better than that of any other treatment given to patients with ITP.¹¹⁴ The response to splenectomy may be prompt, supporting experimental observations (see Fig. 9-1) that the spleen is the principal source of removal of autoantibody-coated platelets. The response to splenectomy may also be durable, consistent with the spleen as the major source of autoantibody production. Most case series suggest that approximately two thirds of patients achieve and sustain a normal platelet count after splenectomy, thereby requiring no additional therapy.¹¹⁴

Historically, splenectomy was the first effective treatment for ITP; it was established long before glucocorticoid therapy was initiated in the 1950s. Numerous case series describe the results of splenectomy, but many of these reports describe patients who lived decades ago, when splenectomy was often performed as initial therapy at diagnosis and was routinely performed in children and adults. These earlier studies included patients who would now retrospectively be expected to have undergone spontaneous recovery; therefore, they consistently reported better than average outcomes. Even among adults, younger patients respond better to splenectomy than do older patients.¹¹⁴ Although many other preoperative variables, such as previous response to prednisone or IVIg, or degree of splenic sequestration of radioisotope-labeled platelets, have been reported to correlate with patient response to splenectomy, none is sufficiently consistent to influence the decision to perform a splenectomy.¹¹⁴

Consistent with an apparent trend toward conservative management of adults with ITP attained by not treating patients with asymptomatic thrombocytopenia, the frequency of splenectomy appears to be decreasing. For example, in a case series of patients accrued from 1974 to 1994, 78 (51%) of 152 patients underwent splenectomy.¹³ In a more recent case series, with patients accrued from 1993 to 1999, the rate of splenectomy was lower: 30 (12%) of 245 patients.¹² Also, a randomized controlled trial of anti-D given to prevent splenectomy noted a significantly decreased rate of splenectomy during the course of the study.¹⁰⁶

The morbidity and mortality that result from splenectomy are often reported to be minimal, but mortality may be as high as 1%, and the rate of major complications may be as high as 10%.¹¹⁴ These high rates are an important consideration when the decision regarding splenectomy is discussed; however, these rates of mortality and complications may not be greater than those associated with alternative treatment approaches for patients with severe and symptomatic thrombocytopenia. In preparation for splenectomy, the platelet count should be elevated by treatment with steroids and/or IVIg. If the patient is unresponsive to treatment and has severe, symptomatic thrombocytopenia, a platelet transfusion given when surgery begins may help hemostasis. The frequency of death and complications may be lessened by laparoscopic procedures.¹¹⁴

Because splenectomy will often be considered in adult patients who present with severe and symptomatic thrombocytopenia, it is appropriate for the clinician to immunize these patients on diagnosis, in anticipation of possible splenectomy. Earlier immunization provided before immunosuppression with prednisone becomes established may be more effective. Although the occurrence of overwhelming sepsis in adults after splenectomy is too rare for its incidence to be known, most reports of this lethal complication date from the era before pneumococcal immunization and modern antibiotic treatment were available; anecdotes of overwhelming sepsis continue to be reported.^{115,116} Therefore, immunization at least 2 weeks before elective splenectomy is appropriate because the potential benefits of immunization outweigh its risks in all subjects. Current recommendations are that patients should be immunized with pneumococcal polysaccharide vaccine, *Haemophilus influenzae* b vaccine, and quadrivalent meningococcal polysaccharide vaccine.^{1,3} Most cases of overwhelming sepsis in asplenic subjects are due to pneumococci.^{115,116} Five years after undergoing splenectomy, patients should be revaccinated with pneumococcal vaccine. Children are routinely placed on daily oral prophylactic penicillin after splenectomy is performed, at least up until age 5 years but often into adolescence; this is not routine care for adults in the United States. In the United Kingdom, prophylaxis with daily oral penicillin is recommended for all subjects, both children and adults, after splenectomy,¹¹⁷ although this practice is often not followed.¹¹⁶ Splenectomized patients must be instructed to seek medical attention immediately when they have symptoms of fever and chills; this may be the single most important aspect of education for patients before splenectomy and in the management of patients after splenectomy. Possible long-term complications of splenectomy include myocardial infarction^{118,119} and pulmonary hypertension¹²⁰ that may be related to protective immunity against atherosclerosis provided by splenic B cells.^{121,122}

Treatment of Patients who have Failed to Respond to Prednisone and Splenectomy

The treatment of patients with chronic, refractory thrombocytopenia, defined as those who do not respond to initial treatment with prednisone followed by splenectomy,¹²³ is a dilemma. No clear priority of treatment strategies after splenectomy has been delineated. No evidence suggests that any treatment is more effective than another, or indicates which treatments result in more good than harm.^{1,4,123,124} Although some patients with chronic, refractory ITP have significant morbidity, most patients do well, with or without additional treatment.^{124–126}

But perhaps this dilemma is overstated in that many patients are safe and relatively asymptomatic with no specific treatment. Initial treatment of adults with newly diagnosed ITP is guided by platelet count; however, with initial prednisone prescribed for essentially all patients with platelet counts below 20,000 to 30,000/ μ L, the indications for treatment intervention in patients after failure of prednisone and splenectomy must be more stringent.¹²⁷ For these patients, the chance for success is less and the risk is great that the adverse effects of treatment will be worse than the symptoms of bleeding. For example, in one case series

of 134 patients, 4 deaths were caused by infection related to treatment compared with only 1 death that was caused by bleeding.¹³ It may be appropriate to only carefully observe patients who have negligible bleeding symptoms, even if their platelet counts are very low, even less than 10,000/ μ L. However, in practice, patients with such low platelet counts are inevitably believed to be at risk for major bleeding and therefore are given some form of immunosuppressive treatment, often a sequence of several different treatments. Too often, sufficient motivation to merely observe the patient without treatment occurs only when the doctor and the patient become frustrated because the platelet count fails to increase despite intolerable adverse effects. For some patients, quality of life with no treatment is far better than that with any of the commonly prescribed treatments for chronic refractory ITP.

Treatment decisions are traditionally based solely on the severity of thrombocytopenia, but consideration of other factors is critical. The absence of overt bleeding should make physicians cautious about recommending aggressive immunosuppressive therapy. Treatment decisions must also consider assessment of lifestyle and other medical conditions that could influence the risks of bleeding and immunosuppressive treatment. Older patients, who have a greater frequency of hypertension and a greater risk of intracerebral hemorrhage,^{95,96} may require higher platelet counts, but these patients are also more vulnerable to the adverse effects of treatment.⁹⁵ Younger patients with a more vigorous lifestyle may also require higher platelet counts. However, most patients, after experiencing limited efficacy and the major problems caused by immunosuppressive regimens, comfortably adapt to low platelet counts and minor bleeding symptoms. These issues illustrate the need for the physician and the patient to discuss and decide together future management approaches that are based on best estimates of the benefits and risks of treatment compared with the risks of no specific treatment.

A sequence of management options for patients with chronic refractory ITP is presented in Table 9-5. Even this sequence may overemphasize the need for treatment interventions. The most important consideration is to avoid basing treatment decisions solely on platelet count; instead, treatment intensity should be measured against actual bleeding symptoms. This rule was stated succinctly in Gilbert and Sullivan's *Mikado*: "Let the punishment fit the crime."¹²⁸

Once a decision for intervention has been made, a choice is often made among the following regimens.

Glucocorticoids

In some patients, a safe platelet count can be maintained on very low doses, or even intermittent doses, of prednisone that do not cause disturbing adverse effects. However, even very low doses of prednisone may cause or contribute to osteoporosis.^{99,100} One report describes success in 10 selected patients with a regimen adapted from the management of multiple myeloma: dexamethasone 40 mg/day for 4 days, repeated every 4 weeks.¹²⁹ Six of these patients had failed to respond to splenectomy, and all apparently responded with normal platelet counts sustained after treatment had been discontinued.¹²⁹ However, no subsequent reports have confirmed these results, and some reports have described serious adverse events with this regimen.¹²³

Table 9-5 Sequence of Management Options for Patients with Chronic, Refractory Immune Thrombocytopenic Purpura (ITP)

Intervention	Indication	Outcome
Observation with supportive care	No bleeding symptoms; platelet count $>20,000/\mu\text{L}$	Stable asymptomatic thrombocytopenia may persist. Morbidity of any treatment may exceed risk of bleeding. Some patients with greater risk for bleeding may require treatment
Glucocorticoids	Bleeding symptoms; platelet count $<20,000/\mu\text{L}$	Goal is a safe platelet count with a minimal dose, such as (1) prednisone, 10 mg every other day, or (2) dexamethasone, 10-40 mg/day for 4 days, repeated every 4 weeks or as needed
Immunosuppressive agents/combinations	Bleeding symptoms unresponsive to glucocorticoids	Goal is a safe platelet count with control of bleeding symptoms
Investigational protocols	Severe bleeding symptoms unresponsive to conventional immunosuppressive combination regimens	Goal is a safe platelet count with control of bleeding symptoms
Observation with supportive care	Unresponsive to treatment	Some patients may have minimal or no bleeding in spite of persistent severe thrombocytopenia

This sequence is empirical and has not been validated by controlled clinical observations. The goal of management is to prevent major bleeding, which rarely occurs unless the platelet count is below 10,000/L, and to minimize risks associated with treatment. Aggressive immunosuppressive treatment is appropriate only for patients with severe symptomatic thrombocytopenia. For patients with major bleeding unresponsive to conventional regimens, investigational treatment is appropriate. Finally, some patients refractory to all treatments may actually have minimal or no bleeding symptoms in spite of prolonged, severe thrombocytopenia. Adapted from George JN, Kojouri K, Perdue JJ, Vesely SK: Management of patients with chronic refractory idiopathic thrombocytopenic purpura. *Semin Hematol* 2000;37:214-218, with permission.

Removal of Accessory Spleens

Accessory spleens are found and removed at the time of splenectomy in 15% to 20% of patients. Additional accessory spleens may be found at a later time in as many as 10% of patients who are refractory to splenectomy, or who relapse after splenectomy. In spite of suggestions of the efficacy of surgical removal of accessory spleens in patients with refractory or recurrent ITP, durable remissions have been very rarely reported in patients with severe thrombocytopenia.¹²³

Helicobacter pylori eradication

Eradication of *H. pylori* from the gastric mucosa has been associated with improvement in patients with autoimmune disorders, including ITP.¹³⁰ However, data on the prevalence of *H. pylori* infection among patients with ITP and the effects of *H. pylori* eradication on platelet counts are not consistent; reports of success from Italy¹³¹ and Japan^{132,133} are more numerous than from the United States.^{4,130,134} The appeal of this therapeutic approach, in spite of limited success rates, is the safety of antimicrobial therapy.¹³⁰

Rituximab

Because of its selective immunosuppressive effects, the chimeric anti-CD20 monoclonal antibody, rituximab, has become a common therapy for patients who require treatment after failure of splenectomy.⁴ Although it has been approved by the U.S. Food and Drug Administration (FDA) only for patients with refractory low-grade B-cell lymphoma, rituximab is now commonly used for many autoimmune disorders.¹³⁵ For ITP and most other

autoimmune disorders, the regimen developed for lymphoma is used, that is, 375 mg/m² given intravenously weekly for 4 weeks. In contrast to other immunosuppressive regimens, infectious complications rarely occur with rituximab. The efficacy of rituximab is similar to that of other immunosuppressive agents; complete remission occurs in about 30% of patients.^{123,127} A recent meta-analysis found a 63% response rate but a 3% fatality rate with rituximab use in chronic ITP.^{127a}

Cyclophosphamide

Uncontrolled and selected case series have reported complete responses to cyclophosphamide in 20% to 40% of patients in whom previous treatment with prednisone and splenectomy was unsuccessful.^{123,136-138} Complete responses have occurred after 1 to 6 months of treatment with daily oral cyclophosphamide, typically given in a dosage of 1 to 2 mg/kg/day, adjusted for leukopenia. Intermittent intravenous doses of 1000 mg/m², repeated at 4-week intervals for one to five doses, have also been recommended.¹³⁸ Risks associated with cyclophosphamide therapy include dose-related marrow suppression, which may exacerbate thrombocytopenia and may actually increase the risk for bleeding. Other potential risks include teratogenicity in pregnant women, infertility, alopecia, hemorrhagic cystitis, and potential leukemogenesis.

Vinca Alkaloids

Vinblastine and vincristine have been administered by intravenous bolus injection or by intravenous infusion; results are comparable with both agents regardless of method of administration.¹²³ A common approach is to give vincristine by intravenous bolus, 2 mg once weekly for up to 3 to 6 weeks, until the dose-related adverse effect of peripheral

neuropathy inevitably occurs. A platelet count response may occur within several days, although in most responding patients, the platelet count returns to pretreatment levels within several weeks.¹²³

Azathioprine

Uncontrolled and selected case series have reported approximately 20% complete responses with azathioprine given at a daily oral dose of 1 to 2 mg/kg.^{123,137,139} The average time required for response is 4 months, and most patients require continued treatment to sustain a remission.¹³⁹ As with cyclophosphamide, marrow suppression may occur with worsening of thrombocytopenia, thereby increasing the risk for hemorrhage.

Danazol

Although danazol may cause sustained platelet count responses for as long as treatment is continued, durable responses after treatment is stopped probably do not occur.¹²³ Danazol may be more effective when given together with immunosuppressive agents.⁴ The recommended dosages of danazol for ITP vary greatly, ranging from 50 mg/day¹⁴⁰ to 600 to 800 mg/day.^{4,141} Adverse side effects include headache, nausea, breast tenderness, skin rash, and liver function abnormalities. Hirsutism and a deeper voice may occur in women. Particularly disturbing are reports of drug-induced thrombocytopenia in five patients given danazol for endometriosis or to stimulate erythropoiesis; in two of these patients, acute thrombocytopenia recurred with readministration of danazol.^{142,143}

Combination Therapy

One report described the use of several different regimens, adapted from the treatment of patients with malignant lymphoma, in 10 patients with severe chronic refractory ITP; 5 had a complete response.¹⁴⁴ More recent reports have described patients treated with even more intensive chemotherapy, with¹⁴⁵ or without¹⁴⁶ peripheral blood stem cell support.

Other Treatments

Multiple other treatments have been used in patients with chronic refractory ITP. All are supported by anecdotal reports of success in a few patients, often in patients with only moderate thrombocytopenia who may have needed no treatment¹²³; none can be recommended for routine use.

Investigational Treatment

A new approach to treatment, the use of thrombopoietic agents, is based on increasing platelet production rather than, as with all other therapies, decreasing platelet destruction. This concept is based on observations of inappropriately low platelet production rates¹⁵ and relative endogenous thrombopoietin deficiency¹⁴⁷ in many patients with ITP. An initial trial reported increased platelet counts in three of four patients.¹⁴⁸ Current clinical trials with a thrombopoietin mimetic molecule have documented sustained platelet count responses in most patients with weekly subcutaneous injections.^{149–151} Thrombopoietic agents may become effective maintenance therapy for patients with severe, symptomatic thrombocytopenia who do not achieve remission with standard treatment.

MANAGEMENT OF ITP IN PREGNANT WOMEN AND THEIR NEWBORN INFANTS

The diagnostic distinction between ITP and gestational thrombocytopenia, which was described earlier, is not relevant to management decisions. Mild thrombocytopenia, whatever the cause, requires no treatment; it can be expected to resolve after delivery, especially if thrombocytopenia first occurs late during the third trimester. Indications for treatment during pregnancy are not different from those for treatment of any other patient with ITP, except for the recommendation of greater caution with any intervention. Treatment with prednisone and intermittent IVIg is considered safe and appropriate when severe, symptomatic thrombocytopenia is present.¹ Splenectomy may also be appropriate for severe, symptomatic thrombocytopenia that is unresponsive to prednisone and IVIg, although the risk exists that miscarriage may be induced early during pregnancy and that premature labor may occur later during pregnancy; greater technical difficulty has also been noted because of the gravid uterus, with splenectomy that is performed late during pregnancy. Other than possibly exacerbating the severity of thrombocytopenia, pregnancy itself does not present risks for the patient with ITP. To decrease the risk of postpartum hemorrhage, some patients may require treatment with glucocorticoids or IVIg in anticipation of a scheduled delivery. Epidural anesthesia appears to be safe if the platelet count is greater than 50,000/ μ L.¹⁵²

The major concern for a woman with ITP who is considering pregnancy is the risk to the newborn infant, who may be thrombocytopenic at birth from passive transfer of maternal antiplatelet antibodies and therefore may be at risk for bleeding. This risk occurs at delivery and during the first week of life; with the exception of a single report,¹⁵² no thrombocytopenic bleeding in utero has been described, distinct from alloimmune thrombocytopenia, which can cause severe intrauterine fetal hemorrhage. Although two reports have documented a correlation between the severity of maternal ITP and an infant's platelet count at birth,^{53,153} other data suggest no correlation.¹⁵² Among all women with ITP, approximately 10% of their infants have platelet counts below 50,000/ μ L at birth, and 4% have platelet counts below 20,000/ μ L.^{152,154}

In spite of the risk for neonatal thrombocytopenia, reports of intracranial hemorrhage among newborn infants are extremely rare. Most intracranial hemorrhages occur during the first several days after birth—not at birth.¹⁵⁴ This is so because platelet counts in infants born to mothers with ITP characteristically fall during the first few days after birth¹⁵⁵ because of the rapid development of splenic function after birth. Hyposplenism at birth is documented by the appearance of pitted red cells and Howell-Jolly bodies within the circulation¹⁵⁶; these signs correlate with the degree of prematurity of the infant and disappear within the first 2 months of life. Decreasing platelet counts after birth in infants born to mothers with ITP are similar to observations in infants born with hereditary spherocytosis, in whom hemoglobin values are usually normal at birth but may decrease sharply during the first several weeks.¹⁵⁷ The important lesson to be learned from these observations is that most neonatal hemorrhage is

preventable through careful observation of the infant's platelet count during the first weeks of life and effective treatment of patients with thrombocytopenia with glucocorticoids and IVIg as needed. These observations also support the current recommendation that caesarean section offers no advantage to the infant over routine vaginal delivery.¹⁵²

Chapter 10

Congenital and Acquired Disorders of Platelet Function and Number

Shawn Jobe, MD, PhD • Jorge Di Paola, MD

INTRODUCTION

Platelet dysfunction and thrombocytopenia result from a variety of inherited and acquired disorders. When a patient with mucocutaneous bleeding is first evaluated, the list of differential diagnoses is usually extensive. Elements of the medical history, physical examination findings, and laboratory workup results are critically helpful to the clinician in determining whether the bleeding is due to a platelet disorder. The intent of this chapter is to provide the hematologist with a rational approach to common questions that arise during the evaluation of a patient with a suspected platelet defect. It is also intended to offer a brief discussion of the genetics, pathophysiology, and management of platelet-related bleeding disorders (Fig. 10-1).

HISTORICAL PERSPECTIVE

In 1918, Eduard Glanzmann, a Swiss pediatrician, described a group of individuals with a mucocutaneous bleeding disorder he then called *thrombasthenie* (weak platelets).¹ These patients exhibited grossly abnormal clot retraction yet normal platelet counts. Platelets appeared normal under the light microscope. About 50 years later, the identification of several nuclear families with thrombasthenia confirmed the inherited nature of the disorder, and in the late 1960s, platelet aggregation techniques showed the inability of thrombasthenic platelets to bind fibrinogen and aggregate after stimulation with physiologic agonists.^{2,3}

In 1974, while using sodium dodecyl sulfate (SDS)–polyacrylamide gel electrophoresis, Nurden and Caen noted the absence of one of three major platelet membrane glycoproteins in platelets obtained from thrombasthenic patients.^{4,5} Over the next few years, it was gradually recognized through the work of several laboratories that two glycoproteins, identified as IIb and IIIa, were absent in platelets from patients with Glanzmann thrombasthenia.^{6,7}

In the early 1980s, platelets obtained from thrombasthenic patients were once again critical in the identification and characterization of the fibrinogen receptor glycoprotein (GP)-IIb/IIIa (also known as integrin α IIb β 3) and in the subsequent development of monoclonal antibodies that recognize this molecule.^{8–10} One of these monoclonal antibodies, 7E3, was evaluated further as an antiplatelet agent in different animal models.^{11,12} These promising preclinical

study results led to the development of the chimeric monoclonal antibody abciximab (Reopro), which, in subsequent clinical trials, showed its efficacy in the prevention of thrombosis and restenosis after percutaneous coronary interventions.^{13,14}

Therefore, the study of individuals with Glanzmann thrombasthenia was essential in the development of the anti-IIb/IIIa antiplatelet agents abciximab, eptifibatide, and tirofiban. Translational research, in this case from bedside to bench and back to bedside, has represented a fundamental principle in platelet research over previous decades. Additional studies of rare, inherited platelet disorders will likely result in a better understanding of the platelet “machinery” and ultimately will lead to the development of new treatments that are beneficial to affected individuals and to patients with other bleeding and thrombotic illnesses.

CLINICAL MANIFESTATIONS OF PLATELET-RELATED BLEEDING AND TESTS OF PLATELET FUNCTION

Does the Patient Have a Platelet-Related Bleeding Disorder?

Although our understanding of the mechanisms of platelet dysfunction and thrombocytopenia has significantly improved since Glanzmann’s initial case report was presented, tests and skills required for the identification of individuals with platelet-specific bleeding disorders have essentially remained unchanged. Typically, most individuals with a platelet-related bleeding disorder have their first encounter with a hematologist because of patient or physician concerns about excessive mucocutaneous bleeding, thrombocytopenia, or a family history of bleeding. Frequently, to exclude other causes of bleeding, a referring physician will have already performed several screening laboratory tests, including prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen level. Sometimes, other screening tests, such as bleeding time or the more recently developed Platelet Function Analyzer (PFA-100), may have been used. Therefore, on initial evaluation by the hematologist, including a history, physical examination, and careful evaluation of blood smear, most of the information that is critical for a correct diagnosis will have been obtained.

Figure 10-1 Schematic algorithm of differential diagnosis of mucocutaneous bleeding with and without thrombocytopenia.*

*For didactic reasons, not all described platelet disorders have been included.

CAMT, congenital amegakaryocytic thrombocytopenia; FPD/AML, familial platelet disorder/acute myeloid leukemia; MPV, mean platelet volume; TAR, thrombocytopenia with absent radii; TXA2, thromboxane A2; VWD, von Willebrand disease.

Bleeding associated with platelet disorders primarily involves the skin and mucous membranes. Spontaneous joint or deep muscle bleeds are relatively uncommon in patients with platelet disorders. Bleeding manifestations within the skin can be characterized by their size, elevation, and distribution. Petechiae, purpura, ecchymoses, and hematomas may be found (see Chapter 11). Close attention should also be given to the distribution and elevation of lesions because this information can be helpful to the clinician in distinguishing bleeding related to platelet disorders from that associated with other causes, such as vasculitic disease or nonaccidental injury. For example, the lesions associated with Henoch-Schönlein purpura, a leukocytoclastic vasculitic disease, are raised (“palpable purpura”) and often appear in a classic distribution that involves dependent surfaces and the lower extremities. Unusual or regular patterns of skin lesions (e.g., handprint, linear pattern) may suggest the possibility of nonaccidental injury.

Platelet-related bleeding, including epistaxis, bleeding within the oral cavity, upper and lower gastrointestinal hemorrhage, hematuria, and menorrhagia, is also associated with mucosal surfaces. Menorrhagia is a common presenting symptom in young women, and it is estimated that up to 15% of women with menorrhagia will have platelet dysfunction or von Willebrand disease (VWD).^{15,16} Platelet dysfunction should also be suspected

in the presence of increased bleeding after dental extraction, tonsillectomy, and other surgical procedures.

Screening methods have been used in an attempt to identify individuals with a high likelihood of developing a platelet-related bleeding disorder or VWD. A rapid assay with high sensitivity would be expected to lower the need for further, more costly, invasive testing. Bleeding time was the first of these methods to be widely used, but its clinical usefulness is questionable because of difficulties with standardization, reproducibility, and lack of sensitivity and specificity.¹⁷ The recently introduced PFA-100 has also been proposed to have a role in the screening of individuals with suspected platelet dysfunction. The PFA-100 is a high-shear-stress-inducing device that simulates primary hemostasis by facilitating the flow of whole blood through an aperture cut into a membrane coated with collagen and adenosine diphosphate (ADP) (50 µg) or epinephrine (10 µg). Platelets adhere to the collagen-coated surface and aggregate at the rim of the aperture. The platelet plug enlarges until it occludes the aperture, causing cessation of blood flow. The time to cessation of flow is recorded as closure time (CT).

Initial studies focused on the efficacy of the PFA-100 in the evaluation of individuals with known VWD and severe platelet disorders, such as Glanzmann thrombasthenia and Bernard-Soulier syndrome (BSS). In these patient popula-

tions with VWD (von Willebrand factor [VWF] <25%) or severe platelet disorders, the sensitivity and specificity of the PFA-100 approach 90%. These results suggest that the PFA-100 could have usefulness as a diagnostic tool in the initial evaluation of individuals with a suspected platelet-related bleeding disorder.^{18–20} Recently, however, the initial enthusiasm for the usefulness of the PFA-100 as a screening tool has diminished because of the low sensitivity (24% to 41%) of the device reported in individuals with mild platelet secretion defects or storage pool disorders.^{21–23}

DIFFERENTIAL DIAGNOSIS OF PLATELET-RELATED BLEEDING

Is the Defect Acquired or Congenital?

After the decision has been made to pursue the investigation of platelet-related bleeding, a careful medical history, physical examination, and evaluation of platelet count and smear can rapidly narrow the diagnostic possibilities. Several elements of the history provide critical information and should be explored in detail. History should be obtained about medication usage, particularly the use of aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs). Although aspirin and NSAIDs are the most highly recognized drugs or groups of drugs associated with platelet dysfunction, all medications should be evaluated because the list of possible interactions is long and will continue to grow.

Close evaluation of the family and past medical history may provide clues about whether the bleeding disorder is acquired or congenital. Platelet dysfunction may be related to other systemic disorders. Uremia from renal impairment may also cause platelet dysfunction. Cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO) may result in decreased effectiveness of circulating platelets. Careful evaluation of the peripheral blood smear and blood count, as well as assessment of hepatosplenomegaly and lymphadenopathy, may reveal the need for further workup for myeloproliferative disease, malignancy, or aplastic anemia.

Additional elements of the history, physical examination, and peripheral smear are especially useful in the differentiation of immune thrombocytopenic purpura (ITP) from a congenital platelet disorder. The persistence of neonatal thrombocytopenia or a low platelet count despite the use of several standard therapies (e.g., intravenous immune globulin [IVIg], steroids) for ITP also points toward a congenital cause of the thrombocytopenia. Bleeding symptoms out of proportion to the platelet count should prompt consideration of a congenital platelet disorder. Patients with ITP typically have minimal bleeding until their platelet count decreases to below 10,000/ μ L. Even at those low values, the presence of “fresh reticulated platelets” usually is enough to secure hemostasis. Bleeding observed at platelet counts greater than 30,000/ μ L suggests the presence of a coexisting underlying platelet dysfunction.

Many congenital platelet disorders are associated with other diseases, unique physical characteristics, or findings on the peripheral blood smear. For example, thrombocytopenia in the presence of auditory or renal dysfunction suggests an *MYH9*-related thrombocytopenia, and the presence of skeletal abnormalities may lead to the diagnosis of thrombocytopenia with absent radii (TAR) or amegakary-

cytic thrombocytopenia with radioulnar synostosis (see later in the chapter).

ACQUIRED PLATELET DISORDERS (TABLE 10-1)

Medication-Related Disorders

Numerous medications have been associated with platelet dysfunction or thrombocytopenia. Inhibitors of platelet cyclooxygenase-1 (COX-1)—aspirin and NSAIDs—are the most commonly used drugs known to affect platelet function by decreasing the platelet production of the prostaglandin, thromboxane A₂ (TXA₂), which is a potent secondary mediator of platelet activation; its production within the platelet is mediated by the enzyme cyclooxygenase. Aspirin inhibits cyclooxygenase function through an irreversible covalent modification of the enzyme’s active site; as little as 80 mg is required to completely inhibit TXA₂.²⁴ Because of this irreversibility, the effectiveness of aspirin in inhibiting platelet function persists until platelets circulating at the time of administration are replaced (days).²⁵ NSAIDs, however, act as reversible competitive inhibitors of platelet cyclooxygenase, and the duration of platelet inhibition correlates with the half-life of the NSAID used (hours).

Both thienopyridines—ticlopidine and clopidogrel—inhibit platelet activation through covalent modification of the P₂Y₁₂ receptor, a platelet receptor for the secondary mediator ADP.^{26,27} Both of these agents are prodrugs that require cytochrome P450–dependent pathways for their activation. Similar to aspirin, the effects of ticlopidine and clopidogrel persist during the entire life span of the platelet.

Inhibitors of the fibrinogen receptor, GP-IIb/IIIa, also block platelet function. The reversible competitive inhibitors tirofiban, eptifibatide, and abciximab are frequently administered in conjunction with vascular procedures, and all are rapidly cleared from the circulation after administration.

Several other drugs whose primary target is not the platelet may also cause platelet dysfunction. The β -lactam antibiotic penicillins and cephalosporins have been reported to affect platelet function. The mechanism of this inhibition is unclear, although it appears to be related to the effects of the drugs on agonist–platelet receptor interaction.²⁸ This effect typically occurs 2 to 3 days after initiation of treatment.²⁹ Drugs with primarily cardiovascular effects that may inhibit platelet function

Table 10-1 Acquired Disorders Associated With Platelet-Related Bleeding

Medication related
Renal failure/uremia
Cardiopulmonary bypass/extracorporeal membrane oxygenation (ECMO)
Hypersplenism (e.g., lysosomal storage diseases, portal hypertension)
Myeloproliferative disorders
Immune thrombocytopenia (neonatal, acute, chronic) (see Chapter 9)
Myeloproliferative disorders (leukemia, metastasis, fibrosis)
Aplastic disorders (immune, congenital, infectious)

include nitrates, the calcium channel blockers,³⁰ and propranolol.³¹ The nitrates act as nitric oxide (NO) donors. NO inhibits platelet function by decreasing platelet adhesion and recruitment to the forming thrombus.³² Among the psychotropic agents, the selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs) may inhibit platelet function by decreasing the serotonin content of platelet-dense granules. Retrospective clinical studies suggest an increased risk of bleeding in patients who receive SSRIs or TCAs.^{33–35} Consumption of alcohol has long been associated with platelet function changes.³⁶ The impact of this effect appears to be sex dependent, and the effect is greater on men.³⁷ Both protective and detrimental effects on the cardiovascular system have been described, although moderate alcohol consumption seems to confer protection against cardiovascular disease.³⁸ Therefore, although it is clear that alcohol has definitive effects on platelet activation and other components of the hemostatic and vascular system, the extent of these effects and their clinical correlation with outcomes are unclear and require further investigation. Often, these agents with their mild antiplatelet effects combine with other mild hemostatic defects (such as VWD) to serve as a “second hit,” resulting in a more apparent hemorrhagic condition.

Cardiopulmonary Bypass/Extracorporeal Membrane Oxygenation

Both cardiopulmonary bypass (CPB) and ECMO require circulation of blood over an artificial surface. Because the membrane lacks the antihemostatic properties of endothelium, platelets can become activated.^{39,40} Platelet activation may result in platelet dysfunction and increased platelet clearance. With the use of flow cytometry for evaluation of platelet P-selectin expression and the formation of platelet–monocyte aggregates, increased platelet activation has been detected in patients after cardiopulmonary bypass.⁴¹ Remaining circulating platelets also exhibit decreased expression of the VWF receptor GP-Ib and the fibrinogen receptor GP-IIb/IIIa, suggesting a possible explanation for platelet dysfunction. After CPB has ceased, normalization of the level of platelet receptors occurs gradually over 3 to 4 hours.^{42,43} It is not clear which laboratory tests of platelet function are useful for identifying patients at excessive risk of post-bypass bleeding or thrombosis.^{44,45} Because of this underlying platelet dysfunction, platelet transfusion is frequently employed in post-CPB hemorrhage despite the presence of an adequate platelet count (see Chapter 37).

Uremia

Patients with chronic renal failure and uremia have long been recognized to be at increased risk of bleeding. The cause of this tendency toward increased bleeding is multifactorial and has been related to vascular abnormalities, anemia, and defects of platelet function and adhesion.^{46,47} Correction of the anemia of chronic renal failure with erythropoietin or red blood cell transfusion often results in normalization of abnormal bleeding times and improved platelet adhesion and aggregation.^{48–50}

Additionally, multiple abnormalities of platelet function have been described. Among these are defects in platelet

adhesion noted in various in vitro flow models in which blood from uremic patients was used,^{51,52} as well as decreased synthesis of the secondary mediator of platelet activation, TXA₂.⁵³ Many different circulating metabolites are increased in the uremic patient, and controversy continues regarding the identity of substances within uremic plasma that are responsible for observed hemostatic abnormalities. One of the metabolites that increases in uremic patients, guanidinosuccinic acid, can function as an NO donor and in some studies can recapitulate several observed defects. Phenolic acid has also been proposed as a candidate agent because it is present at concentrations within the plasma shown to affect platelet function in vitro.^{54,55}

Management of bleeding in uremic patients can be challenging. 1-Deamino-8-D-arginine vasopressin (DDAVP) remains the agent of choice and has been shown to effectively shorten bleeding time in uremic patients.^{56,57} However, 4 to 8 hours after its administration, bleeding time returns to baseline. Also, tachyphylaxis to repeated doses of DDAVP may occur.⁵⁸ Improvement of anemia through packed red cell transfusion may aid in hemostasis.⁵⁰ Because the bleeding is presumed to be due to the presence of circulating metabolites, dialysis has been recommended in some circumstances. The benefits of dialysis must, however, be weighed against the potential hazards of anticoagulation and exposure of platelets to an artificial membrane with the potential for undesired platelet activation. Platelet transfusion will be only transiently effective, in that the transfused platelets will be inhibited quickly within the uremic host. Recombinant factor VIIa (rFVIIa) has also been reported to effectively stop bleeding in uremic patients.^{59,60} The use of rFVIIa should be carefully considered, however, because of the potential for thrombotic complications (e.g., catheter thrombosis).

Myeloproliferative Disorders

Both hemorrhagic and thrombotic complications have been reported in individuals with myeloproliferative disorders; however, reportedly, the most common manifestation is thrombosis (reviewed in Elliott and Tefferi⁶¹). Hemorrhage can be problematic, and several possible reasons have been cited for the observed platelet defect. Megakaryocytic clonal abnormalities have been proposed to result in the production of defective platelets.^{62,63} Recently, the effect of JAK2 on the stability and localization of the thrombopoietin receptor c-MPL has been shown, indicating a possible mechanism for the platelet abnormalities seen in these syndromes.⁶⁴ Abnormal in vivo platelet activation may result in the premature release of platelet granules, causing an acquired platelet defect.^{61,62} Loss of the highly hemostatic, large VWF multimers has been associated with essential thrombocythemia, resulting in an acquired form of VWD.⁶⁵ Concomitant use of antithrombotic agents increases the risk of bleeding in this patient population.

The use of platelet aggregation tests to define a set of patients with myeloproliferative disorders who are at risk for bleeding has limited clinical efficacy.⁶¹

Hypersplenism

Hypersplenism refers to the thrombocytopenia that (1) often occurs in individuals with splenic enlargement and (2) cannot be accounted for by other causes. Hypersplenism has been

associated with a variety of diseases, including portal hypertension, lysosomal storage disorders, and myeloproliferative diseases.⁶⁶ Both increased pooling of the circulating platelet population within the enlarged spleen and immunologic mechanisms have been suggested as causes.^{67,68} In general, platelet survival is normal but up to 50% to 90% of circulating platelets are sequestered in the large spleen. Thrombocytopenia associated with hypersplenism is usually mild (50,000 to 100,000/ μ L) and requires no specific treatment. Severe thrombocytopenia or thrombocytopenia that interferes with required therapy may require intervention, although this is rare. Different surgical approaches, including splenectomy, partial splenic embolization, and use of a distal splenorenal shunt, have been used and may result in long-term normalization of the platelet count.^{69–71}

CONGENITAL PLATELET DISORDERS (TABLE 10-2)

Congenital platelet disorders can be categorized according to several distinguishing characteristics. In many individuals, a family history of bleeding or thrombocytopenia allows identification of the inheritance pattern. Autosomal recessive, X-linked, and autosomal dominant inheritance patterns can be found in individuals with platelet-related bleeding. For example, in the evaluation of a patient with a suspected platelet defect, a history of a brother, maternal uncle, or grandfather with thrombocytopenia would suggest an X-linked disorder such as Wiskott-Aldrich syndrome (WAS) or *GATA1*-related thrombocytopenia as the cause. Also, a particular platelet aggregation pattern can often be diagnostic of a specific disorder, such as Bernard-Soulier syndrome or Glanzmann thrombasthenia. Finally, the presence of associated congenital malformations or abnormalities on the blood smear, within both platelets and leukocytes, may simplify the diagnostic workup.

As a first step in the evaluation, two values of the complete blood count—platelet count and mean platelet volume (MPV)—should be carefully reviewed because these can provide critical information in the differential diagnosis. Several platelet-related bleeding disorders are associated with thrombocytopenia; others have normal platelet count and morphology but clinical and laboratory evidence of platelet dysfunction.

Many of the congenital thrombocytopenias can also be characterized by their platelet size. The normal MPV is 7 to 11 fL, and platelets smaller or larger than this, as well as giant platelets, are unique to particular congenital thrombocytopenias.

Table 10-2 Reasons to Suspect a Congenital Platelet Disorder

Persistence of neonatal thrombocytopenia (onset at birth) or onset of bleeding symptoms in childhood
Family history of thrombocytopenia or mucocutaneous bleeding/bruising
Mucocutaneous bleeding/bruising out of proportion to the platelet count
Presence of associated clinical or laboratory features
Platelet count unresponsive to typical treatments for ITP
Typical causes of acquired platelet-related bleeding do not account for symptoms

These two features—platelet count and platelet size—then become excellent tools for classification of congenital platelet disorders. Although no clear definition can be provided for large versus giant platelets, on the basis of laboratory and clinical experience, we classify large platelets as those whose diameter is similar or larger to that of a lymphocyte; we reserve the definition of giant for those platelets that reach the diameter of a neutrophil.

Several other features of the blood smear should be also closely evaluated. Automated blood cell counters often base their assessment on cell size. Therefore, platelet counts are frequently underestimated in the large and giant platelet syndromes; thus, a manual count of the blood smear should also be performed. Additionally, several inherited disorders are associated with unique features observable in the neutrophil population; these cells should be scanned closely for the presence of unique features such as Döhle-like bodies (*MYH9*-related disorders) or giant cytoplasmic granules (Chédiak-Higashi syndrome).

CONGENITAL PLATELET DISORDERS WITH A NORMAL PLATELET COUNT

If a congenital platelet disorder is strongly suspected in an individual with a normal or near-normal platelet count, one of the first tests that should be considered is platelet aggregation. Platelet aggregation tests the ability of platelets to aggregate in stirred platelet-rich plasma (PRP) in response to a panel of platelet agonists. Typical agonists evaluated include collagen, ADP, arachidonic acid, ristocetin, and epinephrine. Upon stimulation, platelets within the suspension become activated, change shape, release their granular contents, and aggregate. All these events can be recorded by modern luminoaggregometry. When the turbid PRP is illuminated before addition of the agonist, transmitted light is scattered. Addition of the platelet agonist then results in an initial peak of increased transmission, corresponding to a rapid change in platelet shape. After this shape change, the amount of light transmitted increases because of platelet clumping or aggregation. Two phases of aggregation can then be evaluated—a primary reversible aggregation phase due to an immediate response of the platelets to exogenous agonists, and a secondary irreversible phase corresponding to the response of the platelets to secondary mediators endogenously released by the platelets (Fig. 10-2). Absence of, or a large decrease in, any of these components may be indicative of a particular congenital platelet disorder. Luminometry, used in combination with platelet aggregation, provides a sensitive evaluation of dense granular release of adenosine triphosphate (ATP). ATP released by platelets provides energy for the added light-producing enzyme luciferase, and a burst of light is recorded. In patients with a dense granular deficiency or platelet release defect, this burst will be impaired. Without the platelet's own “agonists” (e.g., ADP), often the secondary wave of platelet aggregation will be absent as well (Fig. 10-3). Electron microscopy can then be used to distinguish a dense granular deficiency from a platelet release defect. Closer evaluation of other platelet features by electron microscopy is often critically helpful as well.

Figure 10-2 Normal aggregation pattern. Adenosine diphosphate (ADP) and collagen were used as agonists. The curve reflects percentage of aggregation as a function of time. The arrows indicate the different steps observed during platelet aggregation. The first wave of aggregation is caused by exogenous agonists, in this case, collagen and ADP; the second wave is due to endogenous release of dense granular content. Curves in green and black indicate adenosine triphosphate (ATP) release.

Figure 10-3 Abnormal aggregation pattern. Adenosine diphosphate (ADP) was used as an agonist. The first wave of aggregation (due to the exogenous agonist) is conserved in the patient and the normal control subject. However, the second wave of aggregation and adenosine triphosphate (ATP) release are absent in this patient, indicating an intrinsic defect in platelet activation. A similar pattern of aggregation and desaggregation is observed when platelets are inhibited by aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs).

Although luminoaggregometry and electron microscopy provide useful information about many structural and functional components of platelets, it should be emphasized that not all aspects of platelet activation are evaluated by these tests. Platelet function defects have been described in patients with a normal platelet count and a normal pattern of platelet aggregation, such as occurs in Scott syndrome. Also, platelet aggregation presents some of the same issues that are encountered with other platelet tests. It is fairly accurate for diagnosing severe platelet disorders such as Glanzmann thrombasthenia and BSS, but it seems to lack sensitivity and specificity for milder platelet defects.

CONGENITAL PLATELET DISORDERS WITH NORMAL PLATELET COUNT AND ABNORMAL AGGREGATION (TABLE 10-3)

Glanzmann thrombasthenia

Glanzmann thrombasthenia (GT) represents the prototypical inherited platelet defect; it occurs as the result of mutations in the genes that encode for the two polypeptide

chains that constitute the platelet fibrinogen receptor, integrin GP-IIb/IIIa. Its inheritance is autosomal recessive, and in most patients with GT, mutations within the gene *ITGA2B* (that encodes for IIb) or *ITGB3* (that encodes for IIIa) result in significantly low or absent surface levels of GP-IIb/IIIa, as measured by flow cytometry. The severe quantitative deficiency (<5%) is also known as type 1 GT, and the moderate decrease in surface expression (10% to 20%) is known as type 2 GT.^{72,73}

Several different functional mutations have been identified in individuals with GT. Similar to other integrins, GP-IIb/IIIa requires an activation step before it can recognize its ligand. The series of intracellular events that facilitate exposure of the GP-IIb/IIIa fibrinogen binding site and allow fibrinogen to bind are known collectively as inside-out signaling. Mutations that affect the intracellular domain of GP-IIb/IIIa can consequently result in the impairment of inside-out signaling and GP-IIb/IIIa activation.^{74,75} Mutations that prevent appropriate exposure of the fibrinogen binding site after activation but do not affect surface expression of GP-IIb/IIIa have also been reported to result in a very rare qualitative GT defect.^{76,77} It is interesting to note that constitutive activation of GP-IIb/IIIa may also be

Table 10-3 Pattern of Inheritance of Hereditary Platelet Disorders and Gene Defects Responsible for Them

Pattern of Inheritance	Disease	Gene (Entrez Gene ID*)
X- linked	Wiskott-Aldrich syndrome	WAS (7454)
	X-linked thrombocytopenia	GATA1 (2623)
	X-linked dyserythropoiesis with or without anemia	
	X-linked thrombocytopenia/thalassemia	
	May-Hegglin anomaly	
	Fechtner syndrome	
	Sebastian syndrome	MYH9 (4627)
	Epstein syndrome	AML1 (861)
Autosomal dominant	Familial platelet disorder/acute myeloid leukemia (FPD/AML)	Unknown
	Thrombocytopenia with absent radii (TAR)	HOXA11 (3207)
	Amegakaryocytic thrombocytopenia with radioulnar synostosis	GP1BA (2811)
	Mediterranean macrothrombocytopenia	FLI1 (2313)
	Velocardiofacial syndrome/DiGeorge	Unknown
	Platelet VWD/type 2B VWD	
	Paris-Trousseau syndrome/Jacobsen syndrome	
	White platelet syndrome	
	Glanzmann thrombasthenia	ITGA2B (3674) and ITGB3 (3690)
	Bernard-Soulier syndrome	
Autosomal recessive	Gray platelet syndrome	GP1BA (2811)
	Hermansky-Pudlak syndrome	Unknown HPS1 (3257)

*Entrez Gene: <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=gene>

associated with GT. The *Cys560Arg* mutation results in the presence of GP-IIb/IIIa at decreased levels (20%) on the platelet surface. However, the remaining GP-IIb/IIIa has a constitutively high affinity for fibrinogen and exists in an activated conformation.⁷⁸

Patients with GT typically present with moderate to severe mucocutaneous bleeding and often require multiple platelet transfusions from early infancy. However, the variability of bleeding phenotypes can be striking, even in patients with the same genetic mutation.⁷⁹ In all described subtypes of GT, platelet aggregation will be absent or greatly diminished in response to all agonists tested except for the agglutinating agent, ristocetin, which does not require interaction with the fibrinogen receptor. Flow cytometry in the experimental setting can then be used to distinguish the various subtypes; however, its clinical usefulness is uncertain.

Platelet transfusion is the treatment of choice for significant bleeding episodes in GT. However, in some cases, alloimmunization with platelet refractoriness has been described; this leaves the practicing hematologist with limited alternatives to treatment. Recently, the successful use of rFVIIa, alone or as a supplement to platelet transfusion, during bleeding episodes has been reported.⁸⁰ This concept is partially supported by experimental data that demonstrate enhanced GT platelet adhesion to collagen in the presence of rFVIIa through a tissue factor-independent pathway.⁸¹ Before invasive procedures or surgeries are performed in severe cases of alloimmunization, the immunoadsorption protein A column has been successfully used to transiently remove platelet antibodies.⁸² Finally, a few patients with extremely severe bleeding due to alloimmunization have undergone bone marrow transplantation with full engraftment and resolution of the platelet defect.^{83,84}

Other receptor defects

Several other receptor defects on the platelet surface have been implicated as causes of platelet dysfunction and bleeding. TXA₂, collagen, and ADP receptor abnormalities have been described in several patients and families. Patients with these disorders are typically identified by the absence of an aggregation response to a particular agonist. A few examples are presented here. (For a more extensive review, see Rao.⁸⁵)

Individuals with a dominantly inherited mild bleeding diathesis and an impaired aggregation response to TXA₂ have been found to have a mutation of the gene *TBAX2R* that encodes for the TXA₂ receptor, resulting in defective signal transduction despite normal TXA₂ binding activity.^{86,87} Two platelet surface receptors—integrin $\alpha_2\beta_1$ and GP-VI—are critical for adhesion of platelets to collagen and collagen-induced signaling. Mutations in each of these receptors have been reported in patients with impaired aggregation to collagen and a bleeding diathesis.^{88,89}

Mutations in the gene *P2RY12* that encodes for the P2Y₁₂ receptor, the target of the antithrombotic compounds clopidogrel and ticlopidine, have been described; they result in a mild bleeding diathesis and a decreased aggregation response to ADP.^{27,90} Also, a dominant negative mutation has been identified in the ADP/ATP receptor, *P2RX1*, which results in a moderate bleeding disorder with impaired ADP-induced aggregation.⁹¹ In some families with a mild bleeding disorder, decreased density of α_2 -adrenergic receptors and an abnormal aggregation response to epinephrine have been described.⁹² However, it is noteworthy that up to 10% of “healthy controls” may exhibit an abnormal aggregation response to epinephrine.⁹³

In summary, mutations in genes that encode for platelet receptors other than GPIIb/IIIa α IIb β 3 (fibrinogen receptor) and GP-Ib α (VWF receptor) have been described in isolated case reports or affected families. Bleeding manifestations appear to be mild, and the clinical impact is uncertain. Common polymorphisms in these genes may, however, act as modifiers of clinical bleeding when associated with an established underlying bleeding disorder such as VWD.^{94,95}

Hermansky-Pudlak syndrome

Patients with the autosomal recessive disease, Hermansky-Pudlak syndrome (HPS), have dysfunctional platelets with absence of dense granules in association with oculocutaneous albinism. Mutations of the genes responsible for the packaging and formation of specialized lysosomes, such as melanosomes and platelet-dense granules, are responsible for the observed phenotypes. This disease exhibits considerable locus heterogeneity, and mutations in seven different genes can result in the HPS phenotype.⁹⁶ It is interesting to note that each of the seven genes affected in human disease has been identified in mouse models of HPS as well.^{97,98} The most common of the seven HPS subtypes (HPS1-7), HPS-1, is caused by mutations in the *HPS1* gene and is responsible for approximately 90% of cases. Most cases of HPS-1 occur in members of an extensive pedigree from the Caribbean island of Puerto Rico as the result of a founder effect.⁹⁶

Although albinism and platelet dysfunction are predominant features in the early stages of this disease, several other organ systems appear to require appropriate trafficking of these specialized lysosomes.⁹⁶ Pulmonary fibrosis occurs in 60% of patients with HPS-1, and initiation of pulmonary symptoms typically occurs in the fourth decade of life.⁹⁹ Granulomatous colitis affects approximately 15% of HPS-1 patients, and ophthalmologic complications, including nystagmus and cataracts, occur frequently as well.

Patients with HPS typically have a mild bleeding diathesis. The platelet aggregation pattern demonstrates an absent second wave of aggregation, and luminometry shows no release. Electron micrographs show absence or extreme paucity of dense granules (Figs. 10-4 and 10-5). The treatment of choice for severe life-threatening hemorrhage in patients with HPS is platelet transfusion given to replace defective platelets. The antifibrinolytic agents, DDAVP, and rFVIIa have also been used with limited success.^{100,101} Recently, it has been reported that administration of DDAVP to many Puerto Rican descendants did not significantly shorten bleeding time.¹⁰²

Chédiak-Higashi syndrome

Although the characteristic deficiency of platelet-dense granules in Chédiak-Higashi syndrome (CHS) is similar to that seen in HPS, CHS is also characterized by neutropenia and pronounced immunodeficiency. CHS is frequently associated with the development of life-threatening lymphohistiocytic infiltration in the first decades of life, referred to as the accelerated phase.¹⁰³ Additionally, varying degrees of oculocutaneous albinism are noted. The blood

Figure 10-4 Platelets prepared by the whole mount technique from a normal individual. Electron opaque dense bodies (DB) are clearly present without fixation.

Figure 10-5 Whole mount preparation of platelets from a patient with the Hermansky-Pudlak syndrome (HPS). Dense bodies are completely absent from the platelets. Together with albinism, this finding is diagnostic of HPS.

smear is remarkable for the presence of granulocytes with very large cytoplasmic granules.¹⁰³ Similar to HPS, the gene responsible for CHS, *LYST*, has a corresponding mutation in a mouse model and is presumed to play a role in vesicular trafficking.¹⁰³ Bone marrow transplant cures the hematologic manifestations of the illness, but neurologic aspects such as ataxia and decreased cognitive abilities continue to progress, manifesting later in life.¹⁰⁴ Management of bleeding complications is based on transfusion of platelets and antifibrinolytic agents.

Other Dense Granule Defects: Storage Pool Defect

In clinical practice, many patients identified as having dense granular deficiency or impaired dense granular release do not have the genetic syndromes described earlier. These patients are classified as having a storage pool defect, and diagnosis is usually based on the presence of a mild mucocutaneous bleeding disorder, along with lack or a diminished secondary wave of aggregation and absence or paucity of platelet-dense granules.

Defects of Intracellular Signaling Pathways

After agonist binding to a surface receptor (e.g., ADP to the receptor P2Y₁₂), numerous downstream events occur through G-protein-coupled, tyrosine kinase, and prostaglandin-mediated signaling. Defects in these intracellular signaling pathways have been identified in several patients with a mild bleeding diathesis (for review, see Rao⁸⁵) and varying patterns of platelet aggregation. Often, the aggregation response to multiple agonists will be affected.

GTP-binding proteins often function as a link between surface receptors and intracellular enzymes, and significantly decreased levels of the G-protein, G α_q have been found in a patient with a mild bleeding diathesis and decreased aggregation to multiple agonists.¹⁰⁵ In several patients, the production of TXA₂ from arachidonic acid is impaired. Most of these individuals have been characterized as having a cyclooxygenase deficiency, but deficiencies in other enzymes within this pathway have been reported as well.^{106–108} Various individuals with bleeding symptoms or decreased platelet activation have been shown to have other defective intracellular responses as well, such as altered calcium mobilization, decreased tyrosine kinase activity, and decreased phospholipase activity.⁸⁵

Quebec Platelet Syndrome

The Quebec platelet syndrome is an autosomal dominant disorder described in two French-Canadian pedigrees. It is characterized by normal-appearing α granules seen under the electron microscope, with increased degradation of their content due to the accumulation of abnormally high amounts of urokinase-type plasminogen activator (u-PA).¹⁰⁹ This leads to increased spontaneous intracellular fibrinolytic activity with intraplatelet plasmin generation and normal to elevated u-PA plasma levels.¹¹⁰ Affected individuals may exhibit low platelet counts and abnormal aggregation responses to collagen and ADP. The use of antifibrinolytic agents has been advocated; they have been shown to decrease bleeding risk during hemostatic challenge.¹¹¹

Congenital Disorders With Normal Platelet Count and Normal Pattern of Aggregation

Scott Syndrome

The coagulation response requires the coordinated activities of both plasma-borne enzymes and platelets for optimal thrombus formation at the site of injury. Rapid exposure of negatively charged phospholipids, primarily phosphatidylserine, on the platelet surface follows platelet activation. Exposed phospholipids can then facilitate the activities of

the plasma enzymes prothrombinase and tenase by providing a discrete surface for their localization at the injured site and by directly stimulating enzyme activity.¹¹²

In individuals with Scott syndrome, external exposure of negatively charged phospholipids is impaired in response to physiologic agonists or a calcium ionophore.^{113–115} Patients heterozygous for the defect may exhibit intermediate responses. Recently, an individual with Scott syndrome has been identified who has a mutation in the membrane protein ABCA1.¹¹⁶ However, the significance of this finding is uncertain in that patients with Tangier disease who have complete absence of ABCA1 have no impairment in platelet phosphatidylserine exposure after platelet activation in response to varying concentrations of collagen and ionomycin.¹¹⁷

The few described patients with this rare syndrome have a mild bleeding diathesis. Platelet aggregation patterns are normal. Impairment of phosphatidylserine exposure seen in these patients can be evaluated by flow cytometry with the use of labeled annexin V (a naturally occurring plasma protein with a high affinity for phosphatidylserine). In individuals with Scott syndrome, annexin V binding is absent.¹¹⁴ Bleeding episodes can be efficiently treated with platelet transfusion.

DISORDERS WITH THROMBOCYTOPENIA AND SMALL PLATELETS

Wiskott-Aldrich Syndrome/X-linked Thrombocytopenia

Wiskott-Aldrich syndrome/X-linked thrombocytopenia (WAS/XLT) is a moderate to severe X-linked thrombocytopenia that is often associated with eczema and immunodeficiency (reviewed in Ochs and colleagues^{118,119}). The MPV in affected individuals ranges from 3.5 to 5.0 fL (Fig. 10-6). The phenotype of this disease is variable; some individuals exhibit only moderate thrombocytopenia (XLT), and others have severe disease that encompasses all components of WAS, including (1) eczema, ranging from mild to severe, (2) immunodeficiency with both cellular and humoral components, (3) autoimmune diseases, such as autoimmune

Figure 10-6 Wiskott-Aldrich syndrome. There are three platelets on this blood smear. Notice their small size. Department of Haematological Pathology, Tygerberg Hospital and University of Stellenbosch, South Africa, with permission.

hemolytic anemia,¹²⁰ and (4) increased risk of lymphoma, particularly in adulthood.

Patients with WAS/XLT have decreased or absent production of the Wiskott-Aldrich syndrome protein (WASp),¹²¹ an intracellular protein critical for the regulation of actin polymerization and cellular signaling. The phenotype of patients with WAS mutations is most closely correlated with the degree of residual WASp expression in patients' lymphocytes.¹²² Patients with a milder phenotype have been described to have intact WASp, although often in reduced amounts; in more severely affected individuals, WASp is absent or is present in a truncated form. Genotype–phenotype correlations have also been described; missense mutations are associated with milder disease, and nonsense mutations and larger gene deletions are associated with severe WAS.¹²²

Although splenectomy has been reported to improve the platelet count in individuals with XLT, the consequences of asplenia could be catastrophic for individuals with severe underlying immunodeficiency.¹¹⁸ Treatment of patients with WAS/XLT focuses on care for acute hemorrhage and prevention or treatment of infection and autoimmunity. Allogeneic bone marrow transplantation (BMT) may be curative and should be considered in severe cases, particularly when matched sibling donors are available.¹¹⁸

CONGENITAL DISORDERS WITH THROMBOCYTOPENIA AND NORMAL PLATELET SIZE

Familial Platelet Disorder/Acute Myeloid Leukemia

Familial platelet disorder/acute myeloid leukemia (FPD/AML) is an autosomal dominant disorder characterized by thrombocytopenia and platelet dysfunction associated with a strong predisposition to the development of hematologic malignancies. Up to 30% of affected individuals develop myelodysplasia or acute myeloid leukemia by the sixth decade of life.^{123,124} Loss of function mutation within a single copy of the *AML1* gene (also known as *CBFA2* or *RUNX1*) has been shown to be responsible for FPD/AML.¹²⁴ *AML1* is a transcription factor important in thrombopoiesis, and decreased expression of the *AML1* protein resulting from the loss of a single *AML1* allele has been proposed to be sufficient cause for the decrease in thrombopoiesis that is observed (gene dosage effect).^{125,126}

Affected individuals are thrombocytopenic in the first decade of life and have an increased bleeding tendency. Abnormalities in platelet aggregation, particularly with arachidonic acid, have been noted. Myelodysplasia, acute myeloid leukemia, particularly of the M0 subtype, and lymphosarcoma have all been reported in affected individuals.^{123,124}

Thrombocytopenia with Absent Radii

As the name of this autosomal recessive syndrome implies, TAR is characterized by neonatal thrombocytopenia and absent radii; various upper limb abnormalities, including phocomelia and abnormalities of the shoulder girdle, have also been reported. Other prominent features of this syndrome include renal and cardiac defects, skeletal abnormalities of the lower limbs, and a high incidence of

milk–protein allergy.^{127,128} The gene responsible for TAR is unknown. Several candidate genes such as *HOX* (involved in skeletal development) and *MPL* (thrombopoietin receptor) have been excluded.^{129,130} TAR combined with a chromosomal translocation involving 7p suggests that this region may be involved in the pathogenesis of TAR.¹²⁸ Other studies suggest that a blockade of megakaryocytic maturation and decreased responsiveness of megakaryocytic precursors to various cytokines underlie the observed thrombocytopenia.¹³¹

Although the thrombocytopenia observed in neonates with TAR may be severe and often requires multiple platelet transfusions for bleeding, it is notable for its gradual remission.¹²⁸ In older individuals, platelet counts within the lower limits of normal have been reported. Because of the reportedly high incidence of milk–protein allergy in individuals with TAR, removal of milk-containing products has been attempted and has been reported to improve thrombocytopenia.¹²⁸ It is significant that in the differential diagnosis of TAR, two other specific disorders also associated with limb abnormalities must be reported. These include Fanconi anemia (distinguished by the absence of thumbs and chromosomal breakage testing) and 22q11 microdeletion; this latter syndrome can also involve thrombocytopenia (see GP-Ib/IX/V receptor defects), which has been reported to cause limb abnormalities, including absent radii.¹²⁸

Amegakaryocytic Thrombocytopenia with Radioulnar Synostosis

Although similar to TAR in its involvement of the hematopoietic and skeletal systems, amegakaryocytic thrombocytopenia with radioulnar synostosis represents a distinct syndrome caused by a mutation of the *HOXA11*,^{132,133} a gene in the homeobox family that is involved in skeletal development. Individuals with this syndrome present with neonatal thrombocytopenia and proximal radioulnar synostosis combined with digital abnormalities such as syndactyly and clinodactyly.¹³² Another common feature is hip dysplasia. Radioulnar synostosis may be identified on physical examination by limited pronation. Also in contrast to TAR, the natural history of this disorder often involves worsening thrombocytopenia and involvement of other blood cell lines, often requiring BMT.¹³²

Congenital Amegakaryocytic Thrombocytopenia

Patients with congenital amegakaryocytic thrombocytopenia (CAMT) present with neonatal thrombocytopenia. Examination of the bone marrow reveals almost complete absence of megakaryocytes. Serum thrombopoietin (TPO) levels are markedly elevated, and when the few remaining megakaryocytes are evaluated following stimulation by TPO, no response is observed.^{134,135} CAMT follows an autosomal recessive pattern. Mutations within both alleles of the *MPL* gene that encodes for the TPO receptor c-MPL have been identified in patients with CAMT, and the phenotype can be recapitulated in the mouse on disruption of the *MPL* gene.^{134–136}

A gradual decline in other hematologic cell lines is frequently observed in patients with CAMT, and cases of aplasia have been reported. Allogeneic BMT, the only

curative therapy, has been successfully used in the treatment of patients with CAMT.^{134,135}

11q Terminal Deletion Disorder (Paris-Trousseau/Jacobsen Syndrome)

Patients with thrombocytopenia due to an 11q terminal deletion disorder (11q⁻) have platelets with abnormally large α granules and a distinct clinical syndrome. Abnormally large α granules, seen in a fraction of the platelet population, exhibit abnormal responses to thrombin. Numerous micromegakaryocytes may be identified on evaluation of the bone marrow.^{137,138} Other clinical abnormalities associated with this syndrome include characteristic dysmorphic facies, abnormalities of the upper extremities, cardiovascular defects (>50% of cases), and mild to moderate mental retardation.¹³⁹

The pathogenesis of thrombocytopenia associated with 11q⁻ provides an example of a unique mechanism responsible for an autosomal dominant inherited disorder. The *FLI1* gene that encodes for a critically important transcription factor in platelet development known as FLI1 is located in the deleted region of chromosome 11.¹³⁸ Although this deficiency of FLI1 may account for the platelet disorder, one of the crucial remaining questions regarding the pathogenesis of 11q⁻ thrombocytopenia is why the remaining copy of FLI1 is not sufficient for adequate platelet development. The answer may lie in the fact that only one of the two *FLI1* alleles is expressed (monoallelic expression) at a critical stage in megakaryocyte development. Heterozygous deficiency of *FLI1*, as occurs in patients with 11q⁻, would therefore result in the absence of FLI1 expression in a subset of megakaryocytes. Megakaryocytes expressing FLI1 from the unaffected allele develop normally, and those that attempt to express the deleted allele fail to do so and exhibit the affected phenotype (micromegakaryocyte). Therefore, monoallelic expression of FLI1 at a critical point in megakaryocyte development may account for the two distinct subpopulations of megakaryocytes/platelets observed in 11q⁻ patients.¹⁴⁰

Thrombocytopenia of 11q⁻, which can be severe at a young age, frequently resolves by adolescence.¹³⁹ However, despite resolution of thrombocytopenia, platelet structural abnormalities characteristic of 11q⁻ can still be observed on evaluation of the peripheral blood smear. Bleeding manifestations of 11q⁻ thrombocytopenia are variable, and some platelet abnormalities and clinical symptoms of bleeding may persist after the platelet count has been normalized.¹³⁹

Other Familial Thrombocytopenias

Many hematologists are aware of individuals or families with congenital thrombocytopenia who do not fit any of the described categories. Investigation into the cause of the thrombocytopenia in these individuals may provide greater insight into platelet formation and function. For example, using linkage analysis, Drachman and colleagues¹⁴¹ identified a gene located on the short arm of chromosome 10 as the cause of moderate thrombocytopenia in a pedigree with a mild bleeding diathesis. It is expected that the use of similar genetic techniques, along with a better understanding of platelet physiology, will allow the characterization of other families as well.

DISORDERS WITH THROMBOCYTOPENIA AND LARGE OR GIANT PLATELETS

GP-Ib/IX/V Receptor Defects (Bernard-Soulier Syndrome, Mediterranean Macrothrombocytopenia, and Velocardiofacial [DiGeorge] Syndrome)

The GP-Ib/IX/V complex, the primary platelet receptor for VWF, is composed of the products of four separate genes (*GP1BA*, *GP1BB*, *GP5*, and *GP9*). Mutations in the genes that encode for components of this receptor have been implicated in several thrombocytopenic syndromes, including Bernard-Soulier syndrome (BSS), Mediterranean macrothrombocytopenia, and thrombocytopenia observed in velocardiofacial (22q11 microdeletion) syndrome.

BSS is an autosomal recessive disorder characterized by the presence of giant platelets, with some platelets measuring up to 20 μ m in diameter and thrombocytopenia ranging from 20,000/ μ L to nearly normal (Fig. 10-7).⁷² The association of GP-Ib α , GP-Ib β , and GP-IX is required for efficient transport of the complex to the platelet surface,¹⁴² and homozygous or compound heterozygous mutations of each of these components have been identified in BSS.⁷² Platelet aggregation studies exhibit a typical pattern of lack of response to ristocetin, even in the presence of added normal plasma.

Evaluation of BSS platelets reveals absence of the receptor on the platelet surface; however, variant forms of BSS, in which a nonfunctional GP-Ib/IX/V complex is expressed at low levels, have been identified.⁷² Patients with BSS typically exhibit mucocutaneous bleeding manifestations, although the clinical presentation is variable. Platelet concentrates are the choice for life-threatening bleeds, but as in patients with Glanzmann thrombasthenia, alloimmunization may occur.¹⁴³ DDAVP and factor rVIIa have also been used with success.¹⁴⁴

Autosomal dominant Mediterranean macrothrombocytopenia and velocardiofacial syndromes are disorders in which only a single allele of a component of the GP-Ib/IX/V complex is mutated. Different from BSS, these syndromes are characterized by large but not giant platelets and a mild bleeding diathesis. Linkage analysis of several families with the autosomal dominant Mediterranean

Figure 10-7 Bernard-Soulier syndrome. There are six platelets on this blood smear. Notice that two platelets are very large.

macrothrombocytopenia syndrome led to the identification of a heterozygous missense mutation (Ala156Val) of GP-Ib α as the cause of thrombocytopenia in 10 of 12 pedigrees analyzed.¹⁴⁵ Heterozygous absence of a component of the GP-Ib/IX/V complex also accounts for the thrombocytopenia observed in approximately 40% of patients with velocardiofacial syndrome (22q11), often referred to as DiGeorge syndrome.^{146,147} The GP-Ib gene that encodes for GP-Ib β is located within the commonly deleted region. It is interesting to note that only 60% of patients heterozygous for the absence of the GP-Ib/IX/V complex exhibit macrothrombocytopenia. Accordingly, manifestations of heterozygote carriers of mutations known to cause BSS are variable.

Platelet-type von Willebrand Disease (Gain of Function Mutation of GP-Ib/IX/V)

Platelet-type VWD, also known as pseudo-VWD, is an autosomal dominant disorder characterized by mild to moderate mucocutaneous bleeding, mild thrombocytopenia, and decreased plasma levels of the VWF high-molecular-weight multimers.¹⁴⁸ Mutations within the VWF binding domain of GP-Ib α and deletion of a portion of the macroglycopeptide region of GP-Ib α have been identified in patients with platelet-type VWD.^{149,150} These gain of function mutations prompt GP-Ib α to exhibit an increased affinity for VWF, and spontaneous binding of VWF to platelets occurs. As a result, circulating plasma levels of VWF multimers are low, and thrombocytopenia is noted, presumably caused by the increased clearance of VWF/platelet complexes. Impaired platelet production may also contribute to thrombocytopenia, as evidenced by the presence of giant platelets on evaluation of several patients with platelet-type VWD. Mean platelet volume was elevated in three unrelated families who were tested, suggesting that macrothrombocytopenia may be a feature of this disorder as well.¹⁵¹

It is critical to differentiate this syndrome from type 2B VWD, a more common disorder that is caused by gain of function mutations within the VWF binding site for the platelet GP-Ib α . This increased binding affinity also leads to rapid clearance of the platelet/VWF complex, mimicking the platelet-type phenotype. Increased platelet aggregation in response to low doses of ristocetin is noted in both syndromes; however, aggregation will occur in the platelet-type patient sample only if the patient's platelets instead of fixed control platelets are used.

Management of these two entities varies because VWF concentrates and DDAVP can worsen thrombocytopenia of platelet-type VWD because of the increased availability of VWF multimers and subsequent increased clearance of the patient's defective platelets.¹⁵² Platelet replacement is the treatment of choice for bleeding episodes in platelet-type VWD.

MYH9-Related Thrombocytopenia (May-Hegglin, Sebastian, Fechtner, and Epstein Syndromes)

MYH9-related disease refers to a spectrum of autosomal dominant syndromes characterized by macrothrombocytopenia and varying degrees of nephritis, hearing loss, and

cataracts. Previously, on the basis of their various clinical presentations, patients with MYH9-related disorders had been classified as having one of several different syndromes (May-Hegglin anomaly, Sebastian, Fechtner, and Epstein syndromes). The recent discovery of the causative gene for the May-Hegglin anomaly led to the recognition that these disorders are all the result of mutations within the same gene, MYH9.^{153–155} All individuals from families with a mutation in the MYH9 gene described to date exhibit some degree of macrothrombocytopenia (Figs. 10-8 and 10-9);

Figure 10-8 Low-magnification micrograph of platelets and leukocytes from a patient with May-Hegglin anomaly. Platelets appear normal, except for their large size. At least one platelet is larger than a polymorphonuclear leukocyte (PMN), and several are larger than a lymphocyte (Ly).

Figure 10-9 Thin section of a polymorphonuclear leukocyte (PMN) containing a spindle-shaped inclusion diagnostic of the May-Hegglin anomaly (MHA). Ribosomal (Ri) clusters are present on intermediate filaments (IF) in the long axis of the inclusion. The cell contains normal PMN organelles other than the MHA inclusion. Gr, granules.

however, the occurrence of other phenotypes is variable. In one study, families with 21 different causative mutations of *MYH9*-related disease were screened by audiology, urinalysis, and ophthalmologic evaluation. High-tone sensorineural hearing loss occurred in 83% of individuals with *MYH9* mutations. Of these individuals, 62% had some degree of nephritis, ranging from microscopic hematuria to renal failure, and ocular cataracts were observed in 23% of patients.¹⁵⁶ Other studies have reported a lower incidence of these manifestations. On close examination of the blood smear, polymorphonuclear inclusions called Döhle-like bodies can also be observed in almost all patients with *MYH9*-related disease (Fig. 10-10). Diagnosis of these disorders is dependent on the observation of macrothrombocytopenia in association with characteristic leukocyte inclusions.

The protein product of the *MYH9* gene is nonmuscle myosin heavy chain IIA, a component of nonmuscle myosin IIA. The precise biologic function of myosin IIA within the platelet is unknown, but it has been suggested that it serves as a molecular motor, facilitating changes in cell shape, phagocytosis, and organelle trafficking (for review, see Krendel and Mooseker¹⁵⁷). The universal finding of thrombocytopenia in these syndromes is most likely related to the fact that human platelets exclusively express myosin IIA, whereas other tissues express multiple isoforms of myosin II (IIA, IIB, and IIC).¹⁵⁸ Consistent with the role of myosin IIA in platelet cytoskeletal organization, defective localization of myosin, tubulin, and multiple intracellular signaling molecules is seen before and after platelet activation in patients with May-Hegglin syndrome.^{159,160}

Approximately 80% of identified myosin IIA mutations in patients with *MYH9*-related disorders are exclusively localized at five different amino acid residues of the 1961 amino acid protein.¹⁶¹ Evaluation of patients with these common mutations has allowed investigators to make reliable genotype/phenotype associations. For example, mutation of the site for amino acid R702 is closely related to hearing loss and nephritis, and individuals with a mutation of the C-terminal residue E1841 have no kidney or hearing manifestations.¹⁶¹

Although bleeding symptoms are usually mild, platelets from these patients have been reported to lack the platelet shape change typically observed in platelet aggregation studies. Otherwise, the platelet aggregation pattern is normal, with the exception of an increased frequency of individuals with a defective response to epinephrine.¹⁶⁰

GATA1-Related Thrombocytopenia

Mutations of the transcription factor *GATA1* have been described in several families who presented with X-linked macrothrombocytopenia and varying degrees of dyserythropoiesis or thalassemia.¹⁶² *GATA1* is a transcription factor critical for normal megakaryocytopoiesis, and several different causative mutations have been identified within the region encoding its N-terminal zinc finger domain.^{162,163} The N-terminal zinc finger functions as a DNA binding domain and in recruitment of the essential transcription cofactor *FOG1* to the promoter of platelet specific genes such as *ITGA2B* (which encodes for the IIb portion of the fibrinogen receptor GP-IIb/IIIa). Mutations within the N-terminal zinc finger domain that interfere with the DNA binding of *GATA1* or with its ability to interact with *FOG1* have been identified.¹⁶²

Patients with thrombocytopenia due to a *GATA1* mutation typically have a moderate bleeding diathesis with a greater than expected amount of bleeding relative to the observed platelet count. On close inspection, the platelets of patients with *GATA1* mutations are large and have a paucity of α granules; cytoplasmic clusters of smooth endoplasmic reticulum are often noted.¹⁶⁴ Platelet function studies show abnormalities in platelet shape change after platelet activation, as well as impaired platelet activation, particularly with collagen.^{165,166} The severity of the hematologic abnormalities associated with mutations in *GATA1* is highly variable; these abnormalities include thalassemia, mild marrow dyserythropoiesis, and transfusion dependent-anemia with marked anisocytosis and poikilocytosis.¹⁶²

Figure 10-10 May-Hegglin syndrome. In panel **A**, notice the two large platelets. In panel **B**, the neutrophil contains a pale blue inclusion body.

Gray Platelet Syndrome

Gray platelet syndrome (GPS) is a mild to moderate bleeding diathesis characterized by the presence of macrothrombocytopenia and gray-appearing platelets on peripheral blood smear (Fig. 10-11).¹⁶⁷ Electron microscopy shows the presence of α -granules that are virtually empty (Figs. 10-12 and 10-13). Analysis of platelet content reveals severely decreased levels of several α -granule proteins, including fibrinogen, thrombospondin, and factor V.^{167,168}

Figure 10-11 Gray platelet syndrome. There is a large ghost-like platelet near the middle. Its pale color is due to lack of stainable granules.

Figure 10-12 Thin section of a normal human platelet cut in the horizontal plane. A circumferential coil of microtubules (T) just under the cell membrane supports the discoid form. Numerous organelles, including α -granules (Gr), dense bodies (DB), and mitochondria (Mi), are randomly dispersed in the cytoplasm, which also contains single and masses of glycogen (Gly) particles. Two membrane systems are present, including the open canalicular system (OCS), continuous with the cell membrane, and the dense tubular system (DTS), derived from endoplasmic reticulum.

Figure 10-13 Single gray platelet syndrome (GPS) platelet. The absence of internal contents inside the α -granule vacuoles (V) is evident in this example. Glycogen (Gly), mitochondria (Mi), and other cytoplasmic contents are normal despite the large size of the GPS platelet.

Both autosomal recessive and dominant forms of GPS have been reported.^{169,170} In some patients, GPS has been associated with a mild to severe myelofibrosis that on occasions is associated with extramedullary hematopoiesis.¹⁷⁰ In another described pedigree, gray-appearing neutrophils with absent granules are also observed.¹⁷¹ These varying presentations and patterns of inheritance suggest locus heterogeneity, as seen in the Hermansky-Pudlak syndrome. To date, no gene has been assigned responsibility for GPS.

White Platelet Syndrome

This autosomal dominant macrothrombocytopenic syndrome was recently described in a large multigenerational pedigree from Minnesota.¹⁷² The α -granule content of platelets was decreased, giving some platelets a gray appearance. Different from GPS, uniquely large, fully developed Golgi complexes were noted in a minority of circulating platelets. Mild to moderate bleeding symptoms were reported in affected patients, and platelet aggregation to all agonists tested was blunted (Table 10-4).

TREATMENT OF PATIENTS WITH PLATELET-RELATED BLEEDING (GENERAL GUIDELINES)

Transfusion of donor platelets is the optimal treatment for significant bleeds in most patients with congenital or acquired platelet disorders. DDAVP is the treatment of choice for individuals with bleeding and platelet dysfunction secondary to uremia and may provide some benefit in select individuals with other platelet disorders with mild to moderate bleeds. DDAVP facilitates clot formation by causing the release of VWF and FVIII from endothelial cells, thereby enhancing platelet adhesion. The potential

effectiveness of DDAVP in minor bleeds may be assessed in select patients with use of the PFA-100. In patients with congenital or acquired platelet disorders and a prolonged PFA-100 closure time, shortening of closure time may suggest that DDAVP will be of some benefit. However, the correlation with clinical outcomes has yet to be determined.

rFVIIa has been used with some success in individuals with congenital platelet disorders and is of particular benefit in those patients who are refractory to transfused platelets.^{80,173} rFVIIa is believed to function by increasing thrombin generation at the site of vessel wall damage, thereby enhancing platelet recruitment and facilitating the use of alternate pathways for platelet aggregate formation.^{81,174,175}

As expected, each treatment option is associated with specific adverse effects and complications that must be considered. Patients who receive multiple platelet transfusions may become refractory to the administration of donor platelet because of immunity to platelet-specific or human leukocyte antigen (HLA)-related antigens. In Glanzmann thrombasthenia, which is characterized by the absence of the fibrinogen receptor GP-IIb/IIIa on the platelet surface, both GP-IIb/IIIa and HLA antigens on the surface of donor platelets have been linked to the development of antibodies that result in increased platelet clearance and platelet transfusion refractoriness.⁸⁰

Administration of DDAVP causes water retention, and appropriate precautions regarding fluid restriction must be taken to avoid possible serious electrolyte imbalance. Because of this complication, its use in children younger than 2 years of age should be approached with caution.¹⁷⁶ Tachyphylaxis to DDAVP will most likely develop if multiple successive doses of DDAVP are given.⁵⁸ It is important to mention that the use of aspirin and NSAIDs in patients with congenital platelet disorders should be avoided if possible because of the known effects of these drugs on platelet function.

The increasing off-label use of rFVIIa for acquired and congenital platelet conditions has triggered a large number of case reports and patient series.^{60,80,173} However, only carefully designed clinical trials will prove the efficacy of this hemostatic agent in various platelet disorders related to bleeding. With any of the previously mentioned treatment options, the potential exacerbation of an underlying thrombotic condition should be carefully considered before treatment is initiated.¹⁷⁷

CONCLUSIONS

Accurate diagnosis of congenital and acquired platelet disorders should have considerable impact on the care of patients

with clinical bleeding. Appropriate treatments that avoid undesired adverse effects may be implemented, and safeguards for procedures and surgeries determined. Also, understanding the mode of transmission of hereditary disorders allows medical personnel to provide family counseling.

Once the diagnosis has been made, the real challenge for the practicing hematologist is to identify patients at risk for clinical bleeding. No global test of platelet function has been able to predict the population at risk, and treatment decisions are usually made on the basis of bleeding history or previous hemostatic challenge (e.g., surgeries).

It is hoped that newly discovered modifier genes in the hemostatic and vascular systems will provide new insights into the variability observed in clinical presentations. However understanding the impact of these modifiers requires time and carefully designed clinical trials. Meanwhile, the hematologist should judiciously use the tools that are currently available to provide the best care for patients with platelet-related bleeding.

ACKNOWLEDGMENT

The authors thank Dr. James White of the University of Minnesota for kindly providing all the electron micrographs for this chapter.

Chapter 11

Purpura and Other Hematovascular Disorders

Marc Zumberg, MD • Craig S. Kitchens, MD

Confined to the vascular system, blood comes into contact only with endothelial cells, which line all macrovascular, microvascular, and sinusoidal systems. Disruption of this closed system leads to bleeding—either gross bleeding (characteristic of macrovascular hemorrhage) or extravasation into tissue or potential spaces (more typical of microvascular leakage). [Table 11-1](#) depicts the nature, causes, consequences, and therapeutic approaches to bleeding, and even the types of physicians who address these issues. Bleeding occurs chiefly via at least one of two possible mechanisms: trauma and physical disruption or hemostatic failure; neither is necessarily exclusive. This chapter focuses on hemorrhagic processes that are due to nontraumatic weakening of the vascular wall at the microvascular or macrovascular level. The hematologist is called to consult on such events. The primary goal of this chapter is to present a systematic approach to and differential diagnosis of hemorrhage and purpura. Discussion of treatment provided to patients with each disease is not feasible, and the reader is referred to more in-depth reviews of each disease. Central to the theme of this chapter is the normality of the hemostatic system yet the failure of vessels through which normal blood flows.

Sudden hemorrhage (characteristic of macrovascular disruption) leads to alterations in blood volume; patients often present with shock and usually with pain. Purpura, ecchymoses, and especially petechiae are not characteristic. In microvascular disruption, leakage of red cells from extravasated blood displayed as petechiae and purpura is characteristic, but alterations in blood volume and blood pressure from blood loss are generally not. Uncommonly, shock due to infectious causes of purpura may occur.

[Table 11-2](#) lists and defines multiple terms used in the discussion of various microvascular and macrovascular lesions.

Reports of purpura are common. During histories and physical examinations, up to 65% of healthy women and 25% of healthy men state that they bruise easily.¹ This is a common occurrence in general medical practice. Much of what is regarded by patients as excessive bleeding is actually mild day-to-day traumatic purpura. Defining characteristics of these benign “normal” lesions are that (1) they are never true (i.e., palpable) hematomas, (2) they number no more than four to six on the body at any one time, and (3) lesions are generally not larger than 3 cm in diameter.

Petechiae are pinpoint lesions that are brilliant “cayenne pepper red” when they first appear. Petechiae are usually

smaller than 3 mm in diameter with sharply demarcated margins. They soon fade to a salmon color in a few days, becoming less demarcated, and then finally become brownish spots caused by retention of hemosiderin from extravasated blood. A new crop may occur, with the process repeating itself.

Ecchymosis refers to large extravasations that result from coalescence of separate petechial lesions or, more commonly, a bleed from a slightly larger vessel.

Purpura occurs as the initial presentation of a variety of illnesses that are further discussed in the section on microvascular disruption. Any leakage of blood may well be due to or exacerbated by hematologic causes; therefore, the hematologist may be consulted. Often, no true hemostatic defect is apparent; therefore, the hematologist must have broad medical knowledge and interest. Establishing the diagnosis from a broad differential diagnosis and opening various therapeutic and prognostic windows are keys.

A modicum of hemostatic tests can be ordered and initiated when the consultation occurs. Results of these tests, combined with findings of history and physical examination, usually help to differentiate hematologic causes from other causes ([Table 11-3](#)). A thorough list of prescribed, nonprescribed, borrowed, and over-the-counter medications, including herbal and alternative medicines (see Chapter 33), should be elicited. Systemic symptoms such as weight loss, chills, fevers, night sweats, and malaise are frequently described. A thorough examination should include auscultation of the heart and examination for lymphadenopathy and splenomegaly.

MACROVASCULAR DISRUPTION

Macrovascular disruption most often occurs suddenly as the result of trauma or severe atherosclerotic processes, such as a ruptured abdominal aortic aneurysm. Whereas management of macrovascular hemorrhage is beyond the scope of this text, reference is made here to disease processes for which the hematologist may be asked to consult and assist.

Causes of macrovascular hemorrhage can be grouped into six broad categories ([Table 11-4](#)). The first two, trauma and atherosclerotic processes, are not further discussed in this chapter. The four broad categories that may be called primary vascular disorders of the macrocirculation include disorders of connective tissue, infiltration of

Table 11-1 Characteristics of Macrovascular and Microvascular Vessel Bleeding

	Large Vessel	Small Vessel
Vessel	Typically named	Typically unnamed
Nature of bleeding	Sudden gush	Slow ooze
Primary promoter	Vessel wall	Hemostatic system
Pathophysiology	Trauma, disruption	Hemostatic failure
Physician	Surgeon	Hematologist
Therapeutic approach	Ligature, cautery	Diagnose and treat cause

macrovascular vessels with amyloid, inflammatory processes involving the macrocirculation, and certain arteriovenous malformations. Designation of a particular disorder as microvascular or macrovascular in origin is imperfect in that some processes may fit into either niche.

TRUE DISORDERS OF CONNECTIVE TISSUE

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome (EDS) encompasses clinical manifestations associated with a true collagen vascular disease.² (This section does not include discussion of rheumatic

Table 11-2 Terminology Used in This Chapter

Purpura	General term for nonblanching, bluish-purple lesions due to extravasated blood, fading over time to greenish-yellow lesions as those extravasated cells deteriorate.
Petechiae	Specific type of purpura with macular pinpoint lesions (3 mm) and well-demarcated borders.
Ecchymosis	Specific type of purpura that is a larger macular purpuric lesion due to confluence of petechiae or, more commonly, a larger hemorrhagic lesion. Borders are not sharply defined.
Palpable purpura	Purpuric lesions that appear to be raised (i.e., papular) and palpable because of infiltration of lesions with leukocytes.
Bruise	Lay term without specific meaning; a frequent chief complaint.
Hematoma	Palpable 1-cm or larger mass usually due to bleeding into or between tissue planes.
Vasculitis	Palpable purpura due to infectious, inflammatory, or immunologic mechanisms with white cell infiltration.
Necrotizing vasculitis	Infarctive necrosis of the skin due to vasculitis. Subsequent to necrosis, lesions may turn from purple to "gun-metal gray" or black.
Erythema	Reddened skin due to increased cutaneous blood flow from vasodilatation secondary to fever, exercise, or emotional factors. Ill-defined borders. Readily blanchable.
Telangiectases	Plural term for 1- to 4-mm dark-red masses of capillaries without extravasation that blanch to pressure. May be macular or somewhat papular.
Cherry angiomas	Very papular 1- to 4-mm cherry red "hard" hemangiomas that compress only with difficulty. A normal finding in middle-aged and older persons, particularly in the lower chest and upper abdominal area.
Spiders	Appropriately named lesions with a central 1- to 2-mm visible arteriole ("body") with "legs" branching centrifugally for 1 to 3 cm. Gentle pressure on the body occludes the arteriole, and the legs rapidly disappear.
Livedo reticularis	Purplish, faint, ill-defined reticular network of small vessels on the legs and occasionally arms.
Purple (or blue) toes	Ischemic toes and extremities from arteriolar infarction due to arteriolar emboli, especially from cholesterol embolization or thrombosis in the setting of heparin-induced thrombocytopenia.
Warfarin skin necrosis	Ischemic skin over fatty tissue resulting from capillary and venular infarction due to fibrin deposition.

Table 11-3 Evaluation of the Patient With Petechiae, Purpura, or Ecchymosis

Following a complete history and physical examination, the following laboratory examinations should be considered:	
Always	Complete blood count and review of blood smear Partial thromboplastin time and prothrombin time
Additional tests to be considered if diagnosis not apparent	Thrombin time Fibrinogen level Analyses for fibrin degradation products and D-dimers
Additional tests to be considered in cases of cutaneous vasculitis	Skin biopsy Serologic tests for hepatitis B and C Antinuclear antibody (ANA) Antineutrophilic cytoplasmic antibody (ANCA) Rheumatoid factor (RF) Serum protein electrophoresis (SPEP) Complement Human immunodeficiency (HIV) antibodies
Additional tests to be considered in obscure cases	Blood cultures Viral studies Bone marrow aspirate/biopsy

 - D. Rheumatic disorders (RA, SLE, PAN, etc.)
 - E. Kawasaki disease
6. Arteriovenous malformations
 - A. Hemangiomas
 - B. Kaposiform hemangioendothelioma
 - C. Hereditary hemorrhagic telangiectasia

RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; PAN, polyarteritis nodosa.

diseases such as lupus erythematosus, which previously were regarded as “collagen vascular diseases.”) This clinically and genetically heterogeneous connective tissue disorder is characterized by abnormalities in genetic coding of various subtypes of collagen. Advances in our basic understanding of abnormalities of the various subtypes of EDS have been reviewed.^{3,4} In brief, nine subtypes have been identified, and each subtype is characterized by specific genetic abnormalities; six subtypes are considered to be primary clinical variants and three are viewed as primary biochemical variants.⁵

Several groups have studied kindreds with EDS by seeking disorders of the hemostatic system, yet no thematic defects have been discovered.^{6,7} Anstey and colleagues, in studying a group of 51 patients, found that only 8% exhibited any type of abnormal bleeding, and 82% of the group had normal findings on multiple plasma-based coagulation tests.⁷ Hemostatic laboratory abnormalities observed in the remaining 18% of these patients were deemed to lack clinical significance. Therefore, the general consensus is that bleeding is due to alterations in the structure of collagen that result in weakened collagen or collagen that does not adequately enhance hemostasis. Most of the “bleeding” that these patients exhibit occurs because of the general tendency for their skin to be weak and thin and to heal poorly, leading to tears with subcutaneous bruising. These abnormalities cause so-called “cigarette paper skin,” which is characteristic of patients with some EDS subtypes. Other problems noted in patients with this underlying connective tissue disorder include spontaneous dislocation of joints and the tendency to be “double jointed.”

Among several subtypes of EDS, type IV appears to be one of the rarest, yet it has the worst hemorrhagic potential with respect to arterial hemorrhage.^{8,9} The hematologist is most likely to encounter type IV EDS. Median survival appears to be 48 years for patients with this autosomal dominant subtype. The specific abnormality associated with type IV EDS is the production of abnormal type III collagen. This abnormality accounts for the structural compromise of these vessels, which, in turn, accounts for their tendency to rupture.

The primary cause of death in EDS is rupture of large intra-abdominal arteries. The secondary cause is colonic perforation. Freeman and colleagues¹⁰ reviewed 90 surgical procedures encountered over a 20-year period; 41 were performed for colonic perforation, 17 for repair of arterial aneurysm, and 17 for spontaneous hemorrhage from ruptured arteries. In this study, 23% of patients died from a gastrointestinal problem, and 30% died of vascular complications. Their review showed that treatment with fresh frozen plasma, cryoprecipitate, or any other hemostatic agent did not aid the patient. It was also noted that attempts to repair these large, muscular arteries with the use of vascular clamps were fraught with complications. Maltz and associates¹¹ concluded that hemorrhaging vessels should be ligated, and that none should be clamped. Other conservative methods, such as a great reluctance to operate, use of bed rest, and the generous and continued use of external compression, were advocated.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a true collagen-vascular disorder in which type I collagen is defective because of several flaws in the genes that encode for type I procollagen.¹² Type I collagen, which is found primarily in bone, ligaments, tendons, skin, sclerae, and dentin, is not a major component of blood vessels; therefore, disorders of type I collagen are not typically hemorrhagic in manifestation. Although OI is occasionally mentioned as a collagen-vascular disease characterized by hemorrhagic tendencies and purpuric lesions, bruising may be so minimal that it serves almost no diagnostic purpose in the management of OI. Indeed, modern reviews of this disorder fail to mention clinical hemostatic defects despite several surgical needs noted for patients with OI.^{12,13}

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum (PXE) is another disease that results from derangement of tensile strength in connective tissues and occasionally may be associated with subcutaneous evulsion of tissue, resulting in minimal purpura. Purpura and bleeding, however, are not cardinal manifestations of this disease. PXE appears to be due to homozygous (or double heterozygous) inheritance of mutations involving the *ABCC6* gene, leading to degeneration of elastic fibers in the skin, retina, and cardiovascular system. The primary arteries that rupture are those of the gastric mucosa; thus, gastrointestinal bleeding may occur. This disease has recently been reviewed.^{14,15}

Marfan Syndrome and Cystic Medial Degeneration

Marfan syndrome results from mutations in genes that encode for production of fibrillin-1, a component of normal connective tissue.¹⁶ This autosomal dominant syndrome has several defining features that include a marked tendency toward dissection of the aorta with aneurysmal formation, the chief cause of death in this syndrome. Bleeding or bruising of the skin is rare and hemostatic defects are not encountered, despite the frequent need for corrective cardiothoracic surgery in this disorder.¹⁷

The histologic lesion that is uniformly seen in the aortic wall of Marfan syndrome is called cystic medial degeneration. Many patients have the identical histologic lesion but do not share any of the other features of Marfan syndrome. Most often, these patients are older than those with Marfan syndrome and appear to have no familial pattern of inheritance. The cause of cystic medial degeneration of the aorta is unknown, but the effects on the aorta and resultant aneurysmal formation and treatment are the same as those for Marfan syndrome.

LARGE VESSEL INFILTRATION

Amyloidosis and its hemorrhagic manifestations are generally microvascular in nature but may involve the great vessels of the brain; thus, they are discussed here. Amyloidosis is not a single disorder, but a series of disorders, all which have in common the misfolding of any number of proteins, giving rise to beta-pleated sheets that reside beneath the basement membrane of multiple structures, including blood vessels. All of these proteins have in common the characteristic birefringent apple green color seen on staining of affected tissue with Congo red in polarized light, as well as a typical pattern of microfibrils on electron microscopy.¹⁸ Over 20 types of amyloid have been described, and each abnormality has subtle variations in its clinical manifestation.¹⁹ Vessel wall strength may be reduced; thus, simple mechanical stress or sheer force may result in bleeding, which is seen in 28% of patients with amyloidosis.²⁰ Purpura about the face (Fig. 11-1) seems especially common in amyloidosis and is discussed in greater detail in the Microvascular Purpura section of this chapter. Of interest, spontaneous rupture of the spleen has been described in amyloidosis and in fact may be the presenting symptom.²¹

A unique subtype of amyloidosis that clearly has hemorrhagic macrovascular ramifications is cerebral amyloid angiopathy (CAA), which has in the past been referred to as congophilic angiopathy. Subtypes of CAA may be sporadic or familial; all have as yet undetermined causes.^{22,23} In CAA, amyloid deposition of the cerebral arteries is characteristic. CAA is extremely common and may be present in nearly one half of all elderly individuals at autopsy. CAA is one of the leading causes of spontaneous cerebral

hemorrhage, accounting for about 10% to 15% of all such bleeds.²³ CAA has medical-legal implications, in that many older patients are given long-term anticoagulation therapy, which is often blamed for the hemorrhagic event, even though the true underlying cause is frequently CAA.²⁴ A peculiar and uncertain relationship has been noted between CAA and Alzheimer disease, in that cerebral vessels that contain amyloid are seen in 80% of patients with Alzheimer disease.²⁵

INFLAMMATORY PROCESSES

Any one of several inflammatory processes may involve large vessels and subsequently may lead to their rupture and hemorrhage.

Infectious causes have historically included syphilitic aortitis. Although this disorder is rarely seen now, in previous eras, it was the prevalent cause of aortic aneurysm. Tuberculous arteritis can conceivably affect any artery.²⁶ Mycotic aneurysms²⁷ may accompany almost any infection but are classically seen in subacute bacterial endocarditis²⁸; unfortunately, they may lead to hemorrhage, particularly in the central nervous system. Human immunodeficiency virus (HIV) infection has been implicated as a cause of inflammatory vasculitis resulting from large vessel damage.²⁹

Any of the classic inflammatory rheumatic diseases, such as rheumatoid arthritis, polyarteritis nodosa, relapsing polychondritis, Behçet syndrome,³⁰ giant cell arteritis,³¹ and systemic lupus erythematosus,³² occasionally involve large vessels characterized by inflammation, weakening, and eventual rupture and sudden hemorrhage. Probably, the best understood relation is with rheumatoid vasculitis,³³ which, paradoxically, may occur in older patients with quiescent “burned-out” arthritic manifestations, yet may perforate large arteries. Kawasaki disease involves an inflammatory process of the arteries that occurs in childhood; in a small number of patients, panvasculitis occurs, with particular reference to coronary vessels, which may lead to aneurysmal dilatation of these vessels.³⁴

ARTERIOVENOUS MALFORMATIONS/ HEMANGIOMAS

Recent discoveries have changed our knowledge and understanding of the pathogenesis of this anatomic disorder. Whereas in the past, most terms used to define these entities as separate diseases were based on epidemiology, clinical presentations, or even treatment, an explosion in our understanding of the basic science of vascular endothelial growth has already begun to change not only our understanding but even our classification of these disorders. Ultimately, no doubt, new treatments will be found as our level of knowledge increases. Accordingly, processes as diverse as Kaposi sarcoma, hereditary hemorrhagic telangiectasia, and diabetic retinopathy may have more in common than we would otherwise ever have imagined.³⁵

Many of these processes have at their core abnormal and sustained proliferation of endothelial cells caused by upregulation of growth-promoting factors or inhibition of growth-promoting apoptosis.³⁶ Indeed, in hereditary hemorrhagic telangiectasia (HHT), circulating levels of vascular

Figure 11-1 Spontaneous periorbital purpura in a patient with systemic amyloidosis.

endothelial cell growth factor (VEGF) are consistently higher than normal, and a tendency toward even higher levels has been noted among those patients with HHT who bleed more than other patients with HHT.³⁷ It is hypothesized that most features of HHT are due to persistence of the activation phase of angiogenesis caused by perturbations in VEGF.

Our understanding of these processes has realigned our thinking regarding hemangiomas, particularly those occurring in children.³⁸ The International Society for the Study of Vascular Anomalies has produced a new classification scheme that is based on whether the lesion is a tumor (i.e., due to vascular proliferation) or a malformation (i.e., due to structural abnormalities associated with slow endothelial cell turnover).³⁹ This group carefully dissected what were previously (and probably erroneously) considered to be two manifestations of the same process, namely, localized disseminated intravascular coagulation (DIC) and “cavernous hemangioma” (previously known as the Kasabach-Merritt syndrome). Students of this disease now argue that what up to this point has been called Kasabach-Merritt syndrome is actually a localized form of coagulation activation that produces thrombocytopenia and arguably DIC; however, most often, it is confined to a unique vascular anomaly, namely, kaposiform hemangioendothelioma (KHE).⁴⁰ Most vascular lesions, particularly the common hemangiomas of infancy, do not exhibit the Kasabach-Merritt phenomena, namely, localized DIC and DIC-like changes.

Mulliken and associates defined differences between KHE and otherwise benign infantile hemangioma.⁴¹ Vascular lesions, whether KHE or not, that exhibit the Kasabach-Merritt phenomenon, have recently been reviewed by Hall.⁴² These lesions were initially described by Kasabach and Merritt in 1940⁴³ and were believed to be seen in only about 1% of cases of hemangioma. Neither the site nor the size of the vascular lesion predicts the syndrome. The Kasabach-Merritt phenomenon is very serious, with a mortality rate of about 40%. Patients can “bleed into” these highly vascular tumors. Not many specimens undergo biopsy, but the vast majority of patients who have true Kasabach-Merritt phenomena actually have KHE—not benign hemangioma. Therapy includes arterial embolization and general support of the patient with fresh frozen plasma (FFP) or platelet infusion. Some have advocated the use of glucocorticosteroids, 2 to 3 mg/kg/day. It is hoped that breakthroughs in antiangiogenic sciences may result in therapies based on antiangiogenic strategies.

Hereditary Hemorrhagic Telangiectasia

Whereas most of the hemangiomas that appear in infancy spontaneously involute over the years, the lesions of HHT (Osler-Weber-Rendu syndrome [OWR]) slowly progress over decades. As has been mentioned, perturbations of VEGF are most certainly associated with the slow, continued hyperproliferation of microcirculatory endothelial cells, giving rise to characteristic telangiectasia. Because blood remains intravascular in HHT, the lesions are easily blanched by external pressure, a key feature distinguishing telangiectasia from purpura.

HHT remains arguably the most understood and most common of this group of vascular proliferative lesions.

Understanding of the molecular basis of this disease has resulted in division into two types of HHT, namely, HHT-1 and HHT-2. Disorders of endoglin, located on chromosome 9q33-34, are those which determine that a kindred has HHT-1, whereas genes encoding for the activin A receptor, which are encoded on chromosomes 12q13, account for those kindred that have HHT-2. Both of these genes are heavily expressed in endothelial cells, and most lesions have in common loss of function mutations.⁴⁴ Rapid growth in this field, as in other areas of human genetics, is documented by the cataloguing of at least 57 genetic defects that lead to HHT-1 and 50 that lead to HHT-2.⁴⁵ A mouse model for HHT-2 exists.⁴⁶ It appears that homozygosity for HHT is lethal in mice and man.⁴⁷

As experience with HHT has progressed, the poorly appreciated but long known interrelations between bothersome cutaneous otolaryngologic (ENT) lesions of HHT and systemic arterial venous malformations (AVMs) have been solidified. Jacobson⁴⁸ estimates that 70% of all patients with AVMs have as their root cause HHT, type 1 or type 2, as do 10% of all patients with central nervous system (CNS) AVMs.

Pulmonary AVMs in HHT can cause considerable morbidity and mortality, ranging from high cardiac output heart failure to massive intrathoracic hemorrhage.⁴⁹ These as well as other AVMs may worsen with pregnancy, especially given increased blood volume and cardiac output during pregnancy.⁵⁰ Diagnosis and management of this situation in pregnancy have been addressed, and it has been concluded that embolotherapy is effective and safe in pregnancy.⁵¹

Primary symptoms that lead to the diagnosis and treatment of HHT involve persistent ENT bleeding (Table 11-5). In a study of recalcitrant epistaxis, Shah and colleagues⁵² noted that among 76 patients, 66% had mild epistaxis (correlating with one or two short episodes of epistaxis per week), 21% had moderate epistaxis (meaning one or two brief episodes per day), and 13% had severe (daily bleeds longer than 30 minutes) epistaxis. Their perceived requirement for red cell transfusion among 76 patients with HHT mirrored the degree of bleeding; of those patients labeled as having mild epistaxis, none required transfusions; those labeled with moderate epistaxis required 1 to 10 transfusions per year, and those labeled severe required more than 10 units of blood per year.

Pathophysiology of HHT is explained by increased elaboration of VEGF, leading to enhanced microcirculatory

Table 11-5 Characteristics of Patients With HHT

Positive family history	70%–95%
Epistaxis	90%–95%
Cutaneous telangiectasia	70%–75%
Visceral involvement	20%–25%
Gastrointestinal involvement	12%–15%
Hepatic AVMs	8%–30%
Pulmonary AVMs	5%–20%
Central nervous system AVMs	4%–10%

HHT, hereditary hemorrhagic telangiectasia; AVM, arteriovenous malformation.
From Larson⁵⁹.

growth, which slowly increases over the decades, leading to AVMs that slowly grow into frank telangiectases characteristic of the disorder. The architecture of these AVMs is that of abnormally large capillaries, meaning that there is no smooth muscle investiture of these very large, even visible vessels that yet have the architectural makeup of capillaries. Hence, vasoconstriction to minimize bleeding is not anatomically possible.

Multiple methods for arresting epistaxis have been advocated⁵³; these include packing, electrocautery, cryosurgery, arterial embolization, arterial ligation, and hormonal manipulation. Various types of laser apparatus also may be used. Whereas each of these methods has its advocate, the fact that none of them has clearly been established as having precedence over the others is problematic. None of these treatments has been studied in an evidence-based format, and the preferences and resources of one's local otolaryngologists may well determine the approach taken until the best treatment for epistaxis of HHT is determined. Daily use of nasal lubricants and avoidance of low-humidity environments seem effective. Websites exist for North American (www.hht.org) and European (www.telangiectasia.co.uk) patients.

One group has developed diagnostic criteria for HHT. Each finding is given a score of 1. Findings include epistaxis, the presence of telangiectases, visceral AVMs, and a positive history of a first-degree relative with similar findings. A score of 2 leads to possible diagnosis of HHT, and a score of 3 or 4 is definitive.⁵⁴

Although ENT manifestations of this disease are most problematic, it is now becoming clear that systemic AVMs are equally serious. Primary causes of death in HHT consist of hemorrhage due to pulmonary and CNS AVMs. CNS AVMs in particular may become sites of abscess; therefore, prophylactic administration of antibiotics in a manner similar to that used in the prevention of endocarditis has been advocated by many for dental work and for gastrointestinal/genitourologic (GI/GU) procedures.^{55,56}

AVMs of HHT are cumulative and progressive. Abdalla and colleagues⁵⁷ noted that 26% of a cohort with HHT-1 developed visceral lesions upon screening for such, and 30% of kindred with HHT-2 had similar lesions.⁵⁷ Lesions of the liver can be sought by ultrasound. One group⁵⁸ found that if the diameter of the hepatic artery is greater than 7 mm, the probability of hepatic hypervascularity was high, whereas if the hepatic artery is smaller than 7 mm, such is not the case. The average size of the hepatic artery among patients with hepatic AVMs due to HHT was 11.3 mm, whereas lesions in controls measured 4.6 mm and in patients with cirrhosis, only 4.8 mm. Larson⁵⁹ found that 30% of patients with liver disease due to AVMs of HHT developed signs of high cardiac output congestive heart failure, portal hypertension, biliary ischemia, liver failure, and, in some cases, hepatic encephalopathy. Debate continues about whether embolization of large hepatic AVMs is less dangerous than liver transplantation in affected patients. Embolization of hepatic AVMs is associated with complications in up to 40% of patients who undergo the procedure.⁵⁹

Elsewhere in the gastrointestinal (GI) tract, telangiectases are common along the large and small intestines and are a frequent cause of persistent GI hemorrhage and iron deficiency. Longacre and colleagues⁶⁰ found a

correlation between the number of lesions seen in the GI tract on endoscopy and the number of transfusions needed per year. Those patients with fewer than 7 visible lesions required 9 units of blood per year, those with 7 to 19 lesions needed on average 13 units of blood per year, and patients with more than 20 lesions used an average of 28 units of blood per year. Neither estrogen therapy, danazol, ε-aminocaproic acid (EACA), nor any combination thereof yielded reproducible or dependable success; 50% of patients appeared to respond to any therapeutic maneuver. Standard of care remains elusive. Video capsule endoscopy has been successful in finding the cause (including HHT) of obscure chronic GI hemorrhage.⁶¹

Central nervous system lesions occur less frequently (5% to 10% of patients with HHT) and tend to occur later in life. Obviously, the seriousness of hemorrhage is great. It is estimated that mortality associated with a CNS bleed from an AVM is between 53% and 81%.⁶² It appears that males have approximately a four-times higher risk than females of developing a spontaneous CNS bleed, and the entire group has a 1.8% chance per year of developing this complication. HHT with large AVMs may involve the spinal cord.⁶³

These data have caused considerable debate in the literature regarding screening for CNS lesions. Studies of this disorder from the United Kingdom⁶⁴ strongly suggest that magnetic resonance imaging (MRI) should be used to screen even asymptomatic patients with HHT, whereas Maher and colleagues⁶⁵ in the United States, in their review of patients from the Mayo Clinic, found a low incidence (4%) of CNS AVMs in patients with HHT who had no symptoms. They argue that this figure is low and that outcomes after a CNS bleed may be not as bleak as was originally believed; therefore, they do not favor screening of asymptomatic patients. However, among a cadre of patients with HHT known to have pulmonary AVMs, 30% had experienced symptoms such as transient ischemic attacks (TIAs) or infarction of the brain; therefore, CNS screening of patients known to have pulmonary AVMs is rational.

Despite several excellent reviews on the management of HHT^{55,60,66} very little mention is made of aggressive replacement of iron through intravenous administration. Anemia of HHT is due to profound iron deficiency. Iron replacement in its least efficient form, namely, transfusion of blood is the prevalent method of treating patients with severe anemia. Given that the rate of maximal absorption from the GI tract of medicinal and/or food iron is sufficient only to make 8 to 12 ml. of blood each day, even in the most compliant of patients, it is understandable that oral replenishment of iron is sufficient only in the mildest cases of HHT. Because hemorrhagic loss from ENT and GI bleeding is lifelong and progressive, the routine administration of parenteral iron is rational yet grossly underused. At this institution, we follow patients' serum ferritin levels, and as soon as they begin to drop, yet before the development of microcytic anemia, we routinely infuse total replacement doses of iron in the form of 2 g of iron dextran, which is enough iron to generate the equivalent of 8 units of blood. Our average patient with HHT requires 1 to 2 such administrations per year, whereas some exceptional patients require 4 to 6 administrations per year.

When aggressive periodic iron infusion is used, it is the exception that patients with HHT require transfusions.⁶⁷ The rare patient who is intolerant of iron infusion may have to be given oral iron replacement, supplemented occasionally by transfusion. Given that patients will need such treatment over their lifetime, once one can establish that a patient is tolerant of intravenous iron, outpatient maintenance therapy becomes much more rational and acceptable to all parties involved. Additionally, blood-borne infections and multiple alloantibody formation are minimized.

MICROVASCULAR HEMORRHAGE

Purpura is a general term that describes either small punctate lesions called petechiae or larger lesions called ecchymoses (see Table 11-2 for terminology). *Purpura* is derived from the Latin term for purple—the color generated by the extravasation of red cells into the skin. Extravasation may result from coagulation disorders, physical trauma, or systemic conditions that lead to alterations in the microvasculature. Purpura, which is due to extravasation of blood from the microcirculation, consisting of the smallest arterioles, capillaries, and postcapillary venules, is thus a disorder of the microcirculation.

The hematologist may be consulted to evaluate patients with purpura because the differential diagnosis of disorders that may result in purpura includes many hematologic processes. Because purpuric disorders require careful consideration of hematologic and dermatologic causes, the hematologist should be familiar with hematologic purpura, as well as its imitators. One may wish to coconsult with a dermatologist for many patients. The differential diagnosis of disorders that lead to purpuric lesions encompasses a considerable range of processes, from mild chronic dermatologic disorders to rapidly progressive, life-threatening illnesses such as meningococemia with DIC.

Although HHT (also known as Osler-Weber-Rendu syndrome) is not truly a purpuric disorder because blood is not extravasated, discussion of HHT syndrome traditionally is placed among discussions of nonthrombocytopenic purpura. HHT also was discussed in the previous section because of its multiple macrovascular manifestations. Later in the chapter, we will address other hematovascular perturbations of skin that are included in the differential diagnosis of purpura.

HISTORICAL PERSPECTIVE

Because of their ready visibility, purpuric lesions have been described throughout history. Victims of the bubonic plague, which circled the globe in the Middle Ages, killing untold millions of people, often were purpuric (hence “Black Death”), which led to the rapid recognition of the affliction and banishment by others. Typhus is claimed to have killed more soldiers throughout history than all battles combined.⁶⁸ Scurvy, particularly the prevention of scurvy, which was appreciated and practiced by the British Navy, was highly instrumental in England’s defeat of Napoleon’s navy at Trafalgar because the French did not practice scurvy prevention. Before the adoption of antiscorbutic measures by the British Navy, 1500 patients with scurvy

were admitted to the main naval hospital in England each year. After antiscorbutic policies were initiated, scurvy was essentially eliminated from the British Navy, and extant records reveal only two cases in the 5-year period following Alfred Lord Nelson’s destruction of the French Navy in 1805. This story has been engagingly recounted in the medical literature.⁶⁹

Although purpura had been known for centuries, scientific interest in these lesions was established in the 18th century, when Werlhof, then serving as court physician to King George II of England, accurately described what is now called acute idiopathic thrombocytopenic purpura (ITP).⁷⁰ At the very beginning of the 19th century, Willan⁷¹ reviewed purpura and proposed five categories in the first rudimentary attempt to explain purpura as a rightfully circumscribed area of clinical science. The five subtypes of purpura that he described consisted of the following: (1) purpura simplex, (2) purpura hemorrhagica, (3) purpura urticans, (4) purpura senilis, and (5) purpura contagiosa. More likely than not, the five subtypes of purpura that he explained 200 years ago would now be regarded as, respectively, purpura simplex, acute ITP, Henoch-Schönlein purpura, senile purpura, and meningococemia, as well as other acute bacterial infections related to purpura. Approximately 100 years later, at the turn of the 19th century, purpura was reviewed by Austin Flint in his textbook.⁷² Scientists’ understanding of purpura had not substantially advanced since the time of Willan’s review. Flint clearly separated clinical purpura from hemophilia and traumatic hemorrhage. He preferred the term *purpura rheumatica* to *purpura urticans* and clearly described what we now refer to as Henoch-Schönlein purpura (HSP). He did not like Willan’s term, *purpura hemorrhagica*, because he recognized that all purpura was indeed hemorrhagic. He preferred to revert to the older European name for ITP, namely, *morbus maculosus Werlhofii*, or Werlhof disease. Although he did not use a separate descriptive category for scurvy, he correctly described the two primary differences between ITP and scurvy—gum swelling and bleeding characteristic of advanced scurvy but not of ITP—and that ITP did not respond to dietetic manipulation, as did scurvy. William Osler in a major textbook of medicine in that era (competing with that of Flint) gave a similar account of purpura.⁷³ He again clearly separated hemophilia from the purpuric disorders. Revealing his strength in observational medicine, he was the first to accurately describe petechiae, differentiating them from ecchymoses. He described cases of purpura following iodine administration, which were probably the result of iodine-induced cutaneous vasculitis. He preferred the term *cachectic purpura* to *senile purpura*. Osler also clearly distinguished HHT (now one of the several diseases bearing his name, OWR syndrome) from hemophilia, while recognizing that both were hereditary hemorrhagic diatheses.⁷⁴

That thrombocytopenia was causally related to the petechiae of ITP was recognized by the end of the 19th century. The existence of nonthrombocytopenic purpura received a large boost in credibility when Wolbach⁷⁵ in 1919 described that purpura in Rocky Mountain spotted fever was associated with the infestation of rickettsiae in the walls of microcirculatory vessels. In 1942, Wintrobe opined that although thrombocytopenia was characteristic in ITP, in many purpuric diseases, platelet counts were normal;

he therefore concluded that “some obscure change in the capillary endothelium” must account for at least some cases of nonthrombocytopenic purpura.⁷⁶ In 1948, Haden and colleagues⁷⁷ showed that cutaneous hemorrhage could occur with a normal platelet count and a normal clotting system. They promulgated the concept of “increased capillary fragility,” a term that by virtue of its accuracy, has continued to be used up to now. In 1952, Spaet,⁷⁸ and in 1953, Ackroyd⁷⁹ clearly, convincingly, and permanently established vascular damage as the primary cause of nonthrombocytopenic purpura. Study of the microcirculation and endothelial biology in particular became possible with electron microscopy, endothelial cell culture, and other modern biomedical techniques.

MICROVASCULAR STRUCTURE–FUNCTION INTERRELATIONS

Study of the fine structure of the microcirculation was pioneered by Majno.⁸⁰ The microcirculation is defined as terminal arterioles, capillaries, and postcapillary venules. [Figure 11-2](#) depicts a normal capillary, which will be used as the model of the basic microvascular structural unit. The primary anatomic difference between capillaries and arterioles, as well as postcapillary venules, is that both of the latter have an investiture of smooth muscle cells that control blood flow. The capillary, by anatomic definition, lacks smooth muscle investiture because its function is not to regulate traffic; rather, as the “business end” of the circulation, it is the site of unimpeded gas, fluid, and nutrient exchange. Accordingly, its structure is simple. The primary structural unit is a series of two to five endothelial cells that are joined by tight junctions. Endothelial cells are now known to be extremely influential, providing a great deal of secretory activity on both luminal and

abluminal surfaces and assuming, under appropriate stimulation, a neutral, antithrombotic, or prothrombotic stance (see Chapter 3). The subendothelial basement membrane is immediately beneath the closed circle of endothelial cells. This ill-defined material probably affords some degree of structural integrity but chiefly is highly procoagulant in the event that blood makes contact with it by virtue of a breach in the endothelial membrane. Liberally scattered both longitudinally and circumferentially around capillaries are collagen bundles, which offer resilience against mechanical stresses. Around capillaries are pericytes, whose function is probably largely one of support. Accordingly, the four chief functioning members of the structure of the capillary circulation that keep the circulatory system closed are (1) the endothelium; (2) the subendothelial basement membrane; (3) collagen; and (4) pericytes.

The histologic hallmark of purpura is extravasation of red blood cells from the microcirculation. [Figure 11-3](#) shows light microscopic examination of a biopsy specimen of a single petechia in which red cells have extravasated from a nearby capillary. In [Figure 11-4](#), extravasated red cells abound, with at least one phagocytized by a tissue macrophage. Iron from the heme of red blood cells remains in the skin, causing hemosiderin deposition characteristic of the extremities of patients who have had long-standing purpura.

PATHOPHYSIOLOGIC CATEGORIES OF PURPURA

[Table 11-6](#) presents a classification of purpura and hematovascular lesions.

Purpura Not Associated with Known Microvascular Pathology

Frequently, purpura is identified in which no known anatomic aberration of the microcirculation occurs. These conditions are truly purpuric in that if one chooses to biopsy such lesions, extravasated red cells are seen.

Figure 11-2 Electron micrograph of a normal capillary. This capillary consists of parts of five endothelial cells. A red cell is in the lumen. The thickness of the endothelium is approximately 2500 μm . Supporting tissue includes the basement membrane immediately on the abluminal side of the endothelium. Darker bands of collagen are seen longitudinally and circumferentially around the capillary. The two large nuclei are those of pericytes.

Figure 11-3 Light micrograph of a single petechia. Beneath the skin, one sees the longitudinal cut of a capillary from which innumerable red cells have extravasated and are trapped in the interstitial connective tissue. The diameter of the entire field is roughly that of a petechia, namely on the order of 1 mm.

Figure 11-4 Electron micrograph of a petechia. Two extravasated red cells are apparent. The one on the bottom left is in the interstitial space surrounded by bundles of collagen. The one on the right has been phagocytized by a macrophage and is being degraded. The cytoplasm of the macrophage contains residual material from previous red cell ingestion.

Table 11-6 Microvascular Disorders That May Lead to Hemorrhage

1. Purpura not associated with known microvascular pathology
 - A. Mechanical causes of purpura
 - B. Factitious and psychogenic purpura
 - C. Purpura simplex
 - D. Bruises and hematomas
 - E. Progressive pigmented purpuras (PPPs)
2. Purpura associated with abnormalities of platelets
 - A. Immune thrombocytopenic purpura (ITP)
 - B. Disorders of platelet function
3. Cutaneous vasculitis and leukocytoclastic vasculitis
4. Microbial endothelial damage
 - A. Rickettsial diseases
 - B. Leptospiral diseases
 - C. Parvovirus B19 infection
 - D. Viral hemorrhagic fevers
5. Decreased microvascular mechanical strength
 - A. Scurvy
 - B. Hypercortisolism
 - C. "Senile," "Atrophic," or "Actinic" purpura
 - D. Heritable disorders of connective tissue
 - E. Amyloidosis
 - F. Hereditary hemorrhagic telangiectasia
6. Purpura due to microthrombi
 - A. Disseminated intravascular coagulation (DIC)
 - B. Warfarin skin necrosis
 - C. Fat embolism
 - D. Myeloblastemia
 - E. Thrombotic thrombocytopenic purpura (TTP)
 - F. Heparin-induced thrombocytopenia (HIT)
 - G. Cholesterol emboli
7. Purpura associated with endothelial malignancies

Mechanical Purpura

The mechanical strength of the capillary unit is finite; thus, any pressure that exceeds that limit could well lead to extravasation of red cells. A vacuum of 200 mm Hg over normal skin will extravasate red cells.^{81,82} That the human mouth can generate this much suction is exemplified by lesions about the neck known as "hickeys." Petechiae on

the face and neck may result from increased venous pressure after vomiting or seizures, or even from prolonged hanging upside down by one's feet to alleviate back pain.⁸³ Purpura on the palms and soles of the feet may result from leisure activities such as weight-lifting or from traumatic blows from one's avocation or occupation.⁸⁴ Formation of petechiae may be seen following choking,⁸⁵ asphyxiation,⁸⁶ seizure,⁸⁷ barotrauma,⁸⁸ and electrocution,⁸⁹ and even a few may be seen on normal infants.⁹⁰ The chief diagnostic criterion is the history of activities prior to the appearance of purpura.

Factitious Purpura

When patients with purpura provide a history that is vague or not credible, one should suspect factitious purpura. A variety of suction devices have been applied to every imaginable part of the body to produce purpura for whatever gain the patient may seek. Figure 11-5 shows a pattern of purpura that clearly suggests that the patient raked reachable parts of his body with a gardening implement. Factitious purpura is more common than one may at first appreciate but can be suspected when the patient has been seen repeatedly by multiple physicians with no hemostatic or underlying medical conditions found. This purpura tends to be well circumscribed and is found chiefly in areas that can be readily reached by the patient.

Psychogenic Purpura

This is an unusual form of purpura that is increasingly regarded as factitious in origin.⁹¹⁻⁹³ It is indisputable that patients with this type of purpura harbor major deep emotional disturbances and a great deal of unresolved emotional conflict. Lesions of this type of purpura usually begin with bruises that are heralded after a variable lead time by a feeling of warmth, stinging, or swelling. Later, an ecchymotic lesion might appear. These bruises can vary from small to rather large. They have many of the features of factitious purpura in that they are often linear, have well-demarcated edges, and chiefly occur in areas that can

Figure 11-5 Factitious purpura. These long linear lesions with very sharply demarcated borders appear only in places that the patient can reach. All hemostatic tests were normal, and no evidence suggested an underlying medical disorder. These lesions were probably produced when the patient traumatized his skin with a gardening implement.

Figure 11-6 Factitious purpura. This patient has diffuse purpura on one leg without true hematoma formation; the other leg has no lesions at all. All hemostatic studies were normal. She had underlying psychological problems and later admitted to causing these lesions by beating her leg with a hairbrush.

be reached by the patient (Fig. 11-6). The relationship of this disorder to autoerythrocyte sensitization as described by Gardner and Diamond⁹⁴ is uncertain.

Purpura Simplex

This vascular phenomenon is a nonpathologic normal process. Many people have small bruises that are associated with trauma of daily living. Women bruise or report bruising more frequently than men.⁹⁵ Figure 11-7 shows an ecchymotic area on the lateral surface of the thigh. It is striking how frequently these bruises appear about 30 inches above the floor—the height of most furniture, cabinets, and tables about the house or at work. Purpura simplex may result from being pinched; such lesions are also referred to as “devil’s pinches” if an individual has no recall of being pinched. Because this purpura is not of pathologic origin, further evaluation is not necessary. Such patients may safely undergo surgery or invasive procedures.

Figure 11-7 Simple bruise due to day-to-day trauma. Such bruises are caused by encounters with objects on a daily basis. As shown, these lesions occur on the external surface of the thigh and are typically 30 inches above the ground, as this is the height of most American furniture, desks, and countertops.

Bruises and Hematomas

Bruises (including purpura simplex) are not palpable (i.e., not true hematomas) but are flat within the surface of the skin. Bruises result from trauma but of course can be exacerbated by platelet or coagulation defects to become larger bruises or even hematomas. Simple bruises have been somewhat arbitrarily defined as smaller than 3 cm in diameter and not palpable; they usually number no more than four to six over the body. “Normal bruising” has been quantified in healthy infants, of whom 13% may have up to four bruises up to 10-mm maximum diameter. Such bruises tend to occur over bony prominences and increase in frequency as the child’s mobility increases.⁹⁶ Bruises not confined to bony prominences or in unusual places (soles or palms) may raise questions of abuse. If bruises are larger and more numerous, consideration may be given to a hemostatic defect, especially if the masses are palpable (i.e., true hematomas). Figure 11-8 shows a large hematoma of the shin after an athletic incident that served as the diagnostic event for a teenager with heretofore undiagnosed mild hemophilia A with 7% of normal factor VIII activity. Large ecchymotic areas with hematoma formation (Fig. 11-9) provide the typical presentation of factor VIII inhibitors, as discussed in Chapter 6.

Progressive Pigmented Purpura

A variety of dermatologic diseases have no known underlying cause but are characterized by long periods of progressive crops of purpuric lesions about the legs. Dermatologists have subdivided these progressive pigmented purpuras (PPPs) into a variety of categories, such as progressive pigmented purpura

Figure 11-8 True hematoma in a previously undiagnosed hemophiliac. This 22-year-old college athlete developed a large hematoma over the external surface of his leg after a baseball game in which his leg was stepped on by another player. The patient was found to have 7% of normal factor VIII activity.

Figure 11-9 Extensive subcutaneous hemorrhage in a patient with acquired hemophilia. This patient's extrathoracic hematoma occurred following mild trauma to the skin over his left scapula. Over the next several days, he bled several units of blood and was found to have a high titer antibody against factor VIII.

of Schamberg, telangiectodes of Majocchi, lichen aureus, and Gougerot-Blum purpura.⁹⁷ These disorders are similar on skin biopsy, with specific absence of leukocytoclastic vasculitis, but many display mononuclear pericapillaritis. Results of laboratory examinations such as complete blood count (CBC) and immunologic tests are normal. Electron microscopic studies in these disorders have failed to show any abnormalities in the capillaries. These disorders have no major sequelae, and therapy is primarily cosmetic.

Purpura Associated With Abnormalities of Platelets

Thrombocytopenic purpura results most commonly from mild trauma with profound thrombocytopenia (20,000/ μ L or less) but may also be found in patients with qualitative platelet defects.

Thrombocytopenic Purpura

Spontaneous purpura and epistaxis are most frequently seen in severe thrombocytopenia (less than 10,000/dL) and, as such, sudden, spontaneous petechial hemorrhage is the clinical hallmark of acute ITP (see Chapter 9). Purpura probably results from two closely related but separate pathophysiologic events. Clearly, platelets serve a reparative function in the microcirculation, in that they are called on to bridge breaches in the endothelium through adhesion to disrupted endothelium and subendothelial tissues with subsequent aggregation. However, lack of this reparative process does not readily explain the concept of increased

capillary fragility. Petechiae, ecchymosis, and epistaxis occur during severe thrombocytopenia, even without trauma. Examples of capillary fragility include the ring of petechiae around the arm under a blood pressure cuff following blood pressure determination (Fig. 11-10) and petechiae that appear after one simply scratches oneself. This is likely due to intense capillary fragility resulting from severe thrombocytopenia. In experimental animals and humans with severe thrombocytopenia, the microvascular endothelium undergoes morphologic changes, including extreme thinning of the endothelium from its normal 2000 to 3000 μ m to 20 to 50 μ m, or even, in some places, to narrow fenestrations composed only of endothelial cell membranes (Fig. 11-11). Clearly, such endothelial lesions afford virtually no strength against mechanical stresses or pressure and, in fact, may spontaneously leak red cells. Of interest, capillary membrane thickness reverts toward normal even without quantitative improvement in platelets after administration of glucocorticosteroids.^{98,99}

Purpura Associated With Abnormal Platelet Function

Occasionally, platelets are sufficient in number but their quality is such that hemostatic failure manifested as purpura or epistaxis may occur. Theoretically, this can be seen with antiplatelet agents such as aspirin or any of the newer agents that are being increasingly used in the treatment of patients with ischemic heart disease.¹⁰⁰ Whether an accompanying endothelial morphologic disturbance occurs by virtue of qualitative platelet defects, as in quantitative defects, is not known. Congenital defects of platelet function that cause purpura, such as Bernard-Soulier syndrome or Glanzmann thrombasthenia, are discussed in Chapter 10. Chapter 33 discusses various over-the-counter and

Figure 11-10 Capillary fragility. This man developed petechiae on his upper arm in the area underneath a blood pressure cuff following determination of his blood pressure. His platelet count was found to be 5000/ μ L, and he was diagnosed as having idiopathic thrombocytopenic purpura (ITP).

Figure 11-11 Electron micrograph of capillaries in experimental thrombocytopenia. **(A)** A capillary from a nonthrombocytopenic control animal. The endothelial membrane has a thickness of approximately 2000 to 2500 μm . The arrow points to a normal vesicle. **(B)** The endothelium has been thinned (arrow) nearly to the same size as the normal vesicle. **(C)** Even further thinning is shown (arrows), to the point where the endothelium has become fenestrated, an anatomic finding not characteristic of cutaneous capillaries. The lumen of the capillary is oriented to the right in all three panels. (From Kitchens CS: Ameliorization of endothelial abnormalities by prednisone in experimental thrombocytopenia in the rabbit. *J Clin Invest* 60:1129–1134, 1977, with permission.)

complementary medicines that decrease platelet function and may result in purpuric lesions, especially when an underlying platelet defect coexists.

Cutaneous Vasculitis

Cutaneous vasculitis (CV) is one of the most common causes of nonthrombocytopenic purpura and, because of its frequent association with significant underlying medical disease, is of interest to the hematologist and the internist. That CV is often associated with diseases of rheumatic origin led early investigators such as William Osler and Austin Flint to refer to this as *purpura rheumatica*. We now frequently refer to CV also by its chief clinical attribute (*palpable purpura*) or its histologic hallmark (*leukocytoclastic vasculitis*). In leukocytoclastic vasculitis (LCV), the smallest vessels in the skin are encased by sheets of neutrophils in various stages of disintegration, often referred to as “nuclear dust” (Fig. 11-12). Heavy infiltration by leukocytes is what actually gives rise to the perception of palpability in palpable purpura (Fig. 11-13). It is hypothesized that this pathologic event results from leakage of immune complexes through the vessel wall into the sub-endothelial area. These complexes then induce the egress of leukocytes. Subsequently, the neutrophils disintegrate, releasing their proteolytic enzymes into the area around the adjacent vessel, causing digestion and disruption of the endothelial membrane, with subsequent egress of red cells (Fig. 11-14). When LCV is acutely severe, it is called *necrotizing vasculitis*.

Figure 11-12 Leukocytoclastic vasculitis. This photomicrograph shows a central capillary surrounded by extravasated red cells and neutrophils in varying grades of disintegration (“nuclear dust”). This infiltrative process gives rise to the notion of “palpable purpura.”

Figure 11-13 Palpable purpura. This man had an upper respiratory tract infection, received antibiotics, and several days later developed cutaneous vasculitis typical of palpable purpura.

Figure 11-14 Electron micrograph of leukocytoclastic vasculitis. **(A)** A capillary with an extravasated granulocyte (white blood cell [WBC]) at the lower pole. The endothelial cell (E) on the top has become ballooned and is nonviable. **(B)** A key, with RBC representing a red blood cell, L, the lumen, and the blackened areas representing electron-dense immune complexes.

The list of disorders associated with CV is long and varied (Table 11-7). These are best categorized as rheumatic in origin and are associated with requisite immune complexes. The predominance of CV in children is called *primary CV* because no obvious chronic underlying cause can be found. Most (89%) pediatric primary CV is associated with some combination of palpable purpura, arthralgia, colicky abdominal pain, and evidence of nephritis and is commonly referred to as Henoch-Schönlein purpura (HSP). In a large series,¹⁰¹ these findings occurred in 100%, 70%, 70%, and 50%, respectively, of patients who were deemed to have HSP. No chronic underlying disease occurs. The other 11% of pediatric cases represent acute hypersensitivity reactions. Only about 1% of CV in children and young adults is determined to result from some underlying and more serious chronic disease.

In adults, again, most cases (63%) are deemed primary CV, but two thirds are labeled acute hypersensitivity vasculitis, with only one third meeting the criteria for HSP. Hypersensitivity to drugs is a common cause of CV. Roughly one third of all adult CV is found to be secondary; in Table 11-7, the most common causes are lupus erythematosus, cryoglobulinemia,^{102,103} chronic hepatitis C,¹⁰⁴ Sjögren syndrome, polyarteritis nodosa, Churg-Strauss syndrome,¹⁰⁵ rheumatoid arthritis, and subacute bacterial endocarditis.¹⁰⁶

As was mentioned previously, CV is often referred to by its historical name of Henoch-Schönlein purpura when it is associated with any two or three of the following four cardinal features: symmetrical petechial process, abdominal pain, large joint arthralgia or swelling, and evidence of nephritis. Others have found that the diagnosis of HSP is facilitated by ultrasound of the abdomen, which can frequently show edematous bowel walls with visible blood flow.¹⁰⁷ Indeed, the line between the disease classically referred to as HSP, especially when adult and childhood variations are taken into account, and the increasingly used

term CV has blurred,¹⁰⁸ and in fact, some¹⁰⁹ have questioned why the term HSP continues to be used, as the distinction occasionally is arbitrary, especially if one uses preemptory criteria such as an age cutoff and whether or not microvascular deposition of immunoglobulin (Ig)A is found. If a specific chronic underlying disease is not encountered and the patient has arthralgia, nephritis, or abdominal pain, perhaps the more narrow term *HSP* is best. If no cause can be found and criteria for HSP are not met, *primary hypersensitivity vasculitis* is the term that is used, denoting a hypersensitivity reaction to some commonly occurring viral infection, medications used to treat such upper respiratory tract infections, or the use of other drugs.

Primary CV is indicated not only by the lack of an obvious underlying disease but also by normal results of almost all routine laboratory studies, with the exception of the sedimentation rate, which is greatly elevated in 69% of cases. Studies that return with normal results include CBC, coagulation profile, serum studies for cryoglobulins, serologic studies for antinuclear antibodies (ANAs), serum complement levels, and antineutrophil cytoplasmic antibodies (ANCA).¹¹⁰ A proposed guideline for the evaluation of palpable purpura¹⁰⁸ includes studies shown in Table 11-3. More specific studies are guided by one's clinical index of suspicion for a specific underlying disorder.

The diagnosis of secondary CV is not difficult to make when one notices palpable purpura in a patient known to have a disorder such as lupus erythematosus, subacute bacterial endocarditis, or other immune complex illness. On the other hand, evaluation of CV may lead to the discovery of an important underlying disease first manifested by palpable purpura.

The prognosis for primary CV is excellent; complete recovery occurs in 90% of cases in adults and children with primary CV. Frequently, especially in childhood, the process spontaneously resolves over weeks. Prognosis in the secondary types depends on the prognosis of the underlying disease, particularly the presence or absence of nephropathy, which determines the outcome in many adults.¹¹¹

One unusual and fairly rare cause of CV is benign hypergammaglobulinemic purpura of Waldenström.¹¹² This process is seen chiefly in women with episodic bursts of palpable purpura that are clearly dependent in distribution and exacerbated by prolonged standing or the wearing of tight clothes. As its name implies, the hallmark is a broad-based polyclonal increase in immunoglobulins that does not appear to be associated with any other known disease, and therefore, by definition, is negative for evidence of chronic viral hepatitis. ANA and other serologic tests for lupus may be positive, as may analysis for rheumatoid factor and ANCA. Treatment is rarely indicated, and the process is not known to progress to any other disease.

Golfer's vasculitis¹¹³ has been recently described in healthy men who play golf in hot environments. The lesions are those of CV on usual and histologic examination. Tests as outlined in Table 11-3 are negative, and vasculitis tends to spontaneously disappear within a week. This represents most likely the same process as that described by Ramelet¹¹⁴—exercise-induced purpura; the only exception is that Ramelet ascribed the purpuric disorder to "major muscular activity," a term hardly descriptive of golf.

Table 11-7 Disorders Associated With Cutaneous Vasculitis

Primary	Secondary
Idiopathic	Systemic lupus erythematosus
Hypersensitivity reaction*	Chronic hepatitis B
Upper respiratory tract infection, viral or bacterial	Chronic hepatitis C
Drugs	Cryoglobulinemia
Penicillin	Sjögren syndrome
Iodine	Polyarteritis nodosa
Aspirin	Rheumatoid arthritis
Antibiotics	Mixed connective tissue syndrome
Analgesics	Subacute bacterial endocarditis
NSAIDs	Wegener granulomatosis
Thiazides	Churg-Strauss syndrome
Colchicine	Hypergammaglobulinemic purpura of Waldenström
	Myelodysplastic syndromes
	Malignancies

*Hypersensitivity reactions frequently are called Henoch-Schönlein purpura (HSP) if the patient has colicky gastrointestinal symptoms, gastrointestinal bleeding, hematuria or other evidence of nephritis, and large joint arthralgias or swelling and is not on medication known to be associated with hypersensitivity vasculitis.

NSAIDs, nonsteroidal anti-inflammatory drugs.

Purpura Associated With Microbial Endothelial Damage

The endothelium may be the site of residence and proliferation of microorganisms, or it can be directly attacked by microorganisms. Either situation may lead to destruction of the endothelial membrane with resultant extravasation of red cells.

Rickettsial Disease

The best-studied rickettsial disease involving purpura is Rocky Mountain spotted fever (RMSF), due to *Rickettsia rickettsii*. This agent is an obligate endothelial cell organism, and its endothelial presence was shown as early as 1919 by Wolbach.⁷⁵ The petechial rash may be first detectable on the first day of illness but generally is not clearly manifest until the third or fourth day. These spots become larger than most petechiae, growing to 5 to 6 mm in diameter, and may have vague borders that blend into erythema. One unusual feature is that the spots also may appear on the palms and soles. The seriousness of the disease is enhanced by the invasion of the vasculature of all organs by the organism and an intense increase in vascular permeability brought about by destruction of endothelial cell integrity. This results in simultaneous edema and intravascular hypovolemia with characteristic increases in serum concentrations of blood urea nitrogen and creatinine. Although mild thrombocytopenia occurs, it is not believed to be the genesis of hemorrhage. True disseminated intravascular coagulation (DIC) is rare. The hematologist may be asked to consult for evaluation of mild thrombocytopenia in a febrile patient with multiorgan failure who is not improving despite antibiotics. The hematologist may be the first practitioner to suspect RMSF. Other rickettsial diseases may be associated with petechial rashes, but none as extensively as RMSF.

Leptospirosis

Leptospirosis is due to systemic invasion by the spirochete genus *Leptospira*. In its severe form, often known as Weil disease, nearly all tissues are invaded by this microbe. Endothelial damage gives rise to the vasculitis, capillary leak syndrome, and petechial rash that are characteristic of the disorder. Other hemorrhagic phenomena can be abetted by the modest thrombocytopenia and DIC that may occur. Penicillins are usually the antibiotic group of choice for therapy.

Parvovirus B19 Infection

This virus may cause a variety of hematologic disorders, such as pure red cell aplasia or hypoplastic pancytopenia. It is also the agent of “fifth disease.” Recently, it has been reported to cause a peculiar “socks and gloves” petechial rash that is self limited.^{115–117} On skin biopsy, no evidence for vasculitis is found, so endothelial damage is speculated to be the cause of blood extravasation.

Viral Hemorrhagic Fevers

Several viruses have been incriminated as destroying endothelial cells, resulting in various hemorrhagic fevers. Owing in part to the global distribution of these illnesses, typically in remote areas, detailed investigation into these diseases has been severely limited. Whereas bleeding may also be due in part to accompanying thrombocytopenia

or even DIC, petechial manifestations of these hemorrhagic fevers are believed to represent endothelial damage caused by direct invasion and destruction. These hemorrhagic fevers include Lassa fever, Rift Valley fever, dengue, yellow fever, and Marburg fever.^{117a} The mortality rate of these diseases varies from rather low to extremely high.^{118,119} A periodically discovered and rediscovered hemorrhagic fever with a mortality rate as high as 90% is Ebola hemorrhagic fever, which directly causes endothelial cell damage.¹²⁰ Hemorrhage in all these disorders not only is cutaneous in the way of purpura but also involves multiple organs, the dysfunction of which results from hemorrhage and ultimately causes death. Unfortunately, treatment is nonexistent. If any of these viral hemorrhagic diseases is seriously considered in the differential diagnosis, especially in persons who have recently been abroad, rapid consultation with infectious disease experts and the Centers for Disease Control and Prevention in Atlanta is mandatory.¹²¹

Purpura Associated With Decreased Microvascular Mechanical Strength

The following disorders have in common that the structural integrity of the microvascular unit, shown in [Figure 11-2](#), has been compromised. Many investigators have tried to ascribe platelet defects and mild coagulation disorders as causative or additive in this classification of purpura, but none of these theories has stood the test of time.

Scurvy

We have alluded to scurvy previously in the Historical Perspective section of this chapter. Scurvy was the first hemorrhagic disease to have a specific cure following Lind's study of this disabling bleeding disorder.⁶⁹ Scorbutic bleeding is characterized by perifollicular hemorrhage, large if not even huge, flat, platelike ecchymoses ([Fig. 11-15](#)), and hypertrophic spongy, bleeding gums. The disease is only rarely seen now because of improved dietary habits; severe chronic inveterate alcoholics with poor nutrition represent most current patients with scurvy. Scurvy, however, has been reported in pediatric populations¹²² and those on exceptionally low-carbohydrate diets.¹²³

The disease is diagnosed clinically by its appearance. One may send blood samples for vitamin C level determination in equivocal cases. The response to vitamin C administration either pharmacologically or dietarily is gratifying and rapid. The disorder is due to the inability to crosslink fibers of collagen at proline sites, as vitamin C is necessary to convert proline into hydroxyproline for participation in crosslinking of the helical structure of collagen. Microvascular strength and structure are enormously compromised by virtue of weakened collagen synthesis.

Hypocortisolism

Hypocortisolism, whether exogenous or endogenous, also results in decreased collagen strength. Cortisol is known to decrease collagen synthesis, and because collagen catabolism is not affected, collagen becomes scarce, resulting in capillary fragility. Purpura is seen primarily on the extensor surfaces of the forearms ([Fig. 11-16](#)). Purpura is a presenting sign in about 25% of cases.¹²⁴ The skin is thin, which accounts for the superficial appearance of extravasated

Figure 11-15 Scurvy. These large, platelike ecchymotic areas are characteristic of scurvy. They promptly resolved following resumption of a normal diet.

Figure 11-16 Hypercortisolism. Subcutaneous purpura is seen in this man's arm, as is slight edema consistent with his hypercortisolism due to long-term, high-dose glucocorticosteroid therapy.

blood. Treatment involves cessation of cortisone administration in exogenous hypercortisolism or correction, if possible, of endogenous sources, resulting in the increased production of cortisol. Vitamin C administration has not been shown to help in the management of these patients.

"Senile," "Atrophic," or "Actinic" Purpura

This type of purpura is common in older and debilitated patients, but it is hardly limited to the elderly, as any extremely ill patient who exhibits weight loss and negative nitrogen balance is subject to this process. It is also seen in fairly healthy patients who have excessive solar exposure,

which increases breakdown of collagen. Accordingly, the extensor surfaces of the forearms are characteristic locations of this purpura, particularly in those who work outdoors with short or no sleeves. The skin has the appearance on close examination of being extremely thin across the extensor surfaces of the arms and the backs of the hands (Fig. 11-17). Should the skin undergo biopsy, the dermal-epidermal junction is found to be thin, with characteristically flattened rete pegs. Patients often report that just the slightest trauma or stretching of the skin can cause the skin to physically rupture, with subcutaneous bleeding. No specific treatment is available. Vitamin C is not efficacious in this disorder. Hemostasis is normal.

Heritable Disorders of Connective Tissue

Rare inherited metabolic disorders of connective tissue may result in large vessel hemorrhage, as was discussed in the first section of this chapter. Subcutaneous hemorrhage may be encountered yet essentially is never of diagnostic importance in that these heritable disorders are usually quite obvious to all. Bleeding in these disorders usually is more likely to occur as the result of tearing of fragile subcutaneous tissues and skin than as the result of spontaneous purpuric lesions. No persistent coagulation or platelet abnormality has been elucidated. No specific treatment is available. Surgical hemostasis is normal, but healing is impaired.

Amyloidosis

Macrovascular hemorrhage due to amyloidosis was discussed in the first section of this chapter. Purpuric bleeding may very well be one of the initial findings that leads to the correct diagnosis. Purpuric bleeding was detected in 15% of all cases of amyloidosis in one large review.¹²⁵ Amyloid material is deposited between the endothelium and the basement membrane (Fig. 11-18) and therefore can be found in the vasculature of any organ. Amyloid not only leads to probable increased capillary fragility but also, for arterioles, impedes the ability of those vessels to constrict, thereby failing to limit regional flow and bleeding from injured vessels. Coagulation abnormalities are frequent,

Figure 11-17 Actinic or solar purpura. The skin of this man's forearm is very thin; the tendons of the hand are visible. The skin can easily be torn away. The purpura consists of sheets of extravasated red cells. It is not palpable.

Figure 11-18 Amyloidosis. This small vessel is encased in amorphous material between the endothelial wall and the basement membrane, resulting in increased capillary fragility.

multiple, and of varying patterns in amyloidosis^{126–128} which may confuse the diagnostician about the true cause of the purpura, which is the deposition of amyloid. The distribution of purpura is somewhat unusual in that it is not nearly as dependent as most purpuric lesions are but seems more likely to occur along pressure points, with a peculiar periorbital predilection (see Fig. 11-1).

Hereditary Hemorrhagic Telangiectasia

This disorder is also referred to as Osler-Weber-Rendu syndrome (OWR). HHT is an accurate term in that it describes key elements of the disease. HHT is not truly a purpuric disorder because no extravasation of red cells occurs; rather, they remain in the intravascular space until the lesions rupture. Because of this, telangiectases blanch easily on external pressure. Additionally, a telangiectatic lesion is typically 2 to 3 mm in diameter, slightly larger than a nonblanchable petechia. This disorder is discussed under Purpuric Diseases, as it is traditionally classified in reviews. The hemorrhagic component of the disorder is due to decreased mechanical strength of the microvasculature (Fig. 11-19). HHT was discussed in depth in the section on Macrovascular Hemorrhage.

Numerous attempts to identify coagulation defects have usually not borne out any consistent defect. Individual cases of concomitant von Willebrand disease and HHT syndrome have been reported.

A surgical approach to any problem should not be discounted for fear of bleeding, as HHT is not a primary hemostatic defect. Patients may undergo surgery for these AVMs or other procedures not related to their HHT without risk of excessive bleeding.

Telangiectases are not limited to HHT. Many otherwise normal persons have a few telangiectases while having no family history of characteristic hemorrhage. Lesions may become even more prominent during pregnancy. Telangiectases are seen in some other disorders, particularly as part of the CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) of scleroderma. They may also result from actinic damage or from therapeutic radiation.

Figure 11-19 Light microphotograph of Osler-Weber-Rendu syndrome. This section has been made through a telangiectasis. No extravasated red cells are observed. Red blood cells have been washed out of the lumina of these vessels during preparation. Toward the top and also on the right-hand edge are several normal capillaries. Toward the center are several larger vessels, and in the extreme lower left-hand corner, is the lumen of an even larger vessel. The walls of all these vessels are anatomically those of a capillary, that is, thin-walled consisting only of an endothelial cell. These anatomic characteristics give insufficient strength to vessels larger than capillaries, which leads to increased hemorrhage.

Purpura Associated With Microthrombi

The microcirculation may become obstructed by emboli, which may cause microinfarction and disruption of the endothelial membrane with subsequent extravasation of red cells. These dermal emboli cause purpuric lesions. In its most expressive form, the process is called *purpura fulminans*. Because microthrombi often simultaneously occur in other organs, end organ damage may occur, leading to multiorgan dysfunction syndrome (MODS).

Disseminated Intravascular Coagulation

Multiple causes give rise to the syndrome called *disseminated intravascular coagulation (DIC)*. Tissue samples or autopsy specimens frequently show occlusive deposition of fibrin, particularly in the microcirculation. These emboli lead to purpuric skin lesions and frank purpura fulminans. One of the foremost causes of the latter is meningococemia, which results in characteristic rapidly progressive necrotizing purpura fulminans (Figs. 11-20 and 11-21). Fibrin deposition is not limited to the skin; MODS is the most frequent cause of death in DIC. Recognition and treatment of disorders associated with DIC are more thoroughly discussed in Chapters 12 and 13. Morbidity and mortality in purpura fulminans are high, averaging about 50%.^{129,130} An underlying thrombophilic disorder such as factor V Leiden mutation may coexist in patients whose illness progresses to purpura fulminans.¹³¹

Warfarin Skin Necrosis

This is a special cause of fibrin deposition that appears limited to the dermal microcirculation.^{132,133} This process was previously believed to be due to an idiosyncratic toxic reaction to warfarin. It is now believed to be due to the precipitous drop in levels of protein C following initiation of warfarin administration. The half-life of protein C is only 4 to 5 hours; therefore, a rapid decrease in this

Figure 11-20 Meningococcal purpura. This young woman presented with fever and headache. Her early, bright red petechiae rapidly became darker; the characteristic “gun-metal gray” necrosis was apparent.

Figure 11-21 Meningococcal purpura. Skin biopsy shows several capillaries tensely engorged with fibrin deposition (disseminated intravascular coagulation [DIC]), which can lead to rupture of the microcirculation, as well as ischemic infarction of the skin.

anticoagulant occurs before a decrease is noted in procoagulant factors II, VII, IX, and X. This is believed to induce an early hypercoagulable state. Levels of protein C may already be low for genetic reasons or because of further consumption during the thrombotic process. A further decrease in protein C levels allows for relative localized hypercoagulability in the microcirculation, the site of the primary action of protein C. Because protein S is the cofactor of protein C, congenital or acquired protein S deficiency is also a risk factor for warfarin skin necrosis.

This process is normally heralded first by a stinging or burning sensation about 2 to 4 days after the initiation of warfarin therapy. The site becomes hemorrhagic a day or two later. For some reason, warfarin skin necrosis occurs more frequently in women than men (9:1 ratio) and usually develops in areas in which generous adipose tissue is found, such as the thighs, buttocks, or breasts. If the condition is not recognized and treated promptly, the site becomes necrotic and assumes the appearance of a large burn eschar, usually requiring subsequent skin grafting (Fig. 11-22). On biopsy, fibrin deposition is prominent in

Figure 11-22 Warfarin skin necrosis. This woman was administered warfarin and developed painful infarctive lesions a few days later; lesions are shown here as necrotic eschars.

the microcirculation. This process is not as common as it used to be when large doses of warfarin (up to 1 mg/kg) were used as a “loading dose.” It is best prevented by not loading patients with warfarin but starting with a dose that approximates the estimated maintenance dose. It may also be rarer now because patients with active thromboses are first aggressively administered heparin. If the diagnosis of warfarin skin necrosis is entertained, prompt initiation of heparin therapy and cessation of warfarin is considered the best treatment. Vitamin K should be administered intravenously. A similar pattern of unopposed decrease in protein C levels may be seen with intermittent stopping and restarting of warfarin and nearly certainly explains warfarin skin necrosis that occurs in patients reported to develop this syndrome during long-term warfarin therapy. Initiation of warfarin therapy should follow heparin therapy, and these should overlap for 4 to 5 days in patients known to have protein C or S deficiency or those with a personal or family history of warfarin skin necrosis. Warfarin skin necrosis is extremely unlikely following initiation of warfarin for treatment of patients with stroke or for prophylaxis in atrial fibrillation, because a large, fresh clot is not present, and this population is not believed to harbor patients with congenital deficiency of protein C or S. Accordingly, heparin therapy is not routinely given first to such patients unless the history suggests an underlying thrombophilia. Warfarin skin necrosis may also complicate warfarin therapy in patients with heparin-induced thrombocytopenia (see Chapter 25).

Fat Embolism Syndrome

Petechiae are characteristic of fat embolism syndrome. These petechiae have a fairly unusual distribution in that

they are scattered most often about the neck, shoulders, and especially the axillary folds in the upper chest area. They are occasionally seen on the conjunctivae. It is believed that this distribution may be due to the fact that these are counterdependent areas of the body. Thus, circulating fat particles may rise and embolize in this pattern. These petechiae rarely represent a problem in and of themselves, but their presence may serve to suggest or diagnose fat embolism syndrome.^{134–136}

Fat embolism is apparently much more common than fat embolism syndrome. If one looks for fat embolism particularly with the use of bronchoalveolar lavage (BAL) and staining of pulmonary macrophages for neutral fat, fat may be seen in as many as 60% of patients who undergo instrumentation of long bone fractures. Fat can also be seen traversing the cardiac circulation through transesophageal echocardiography performed at the time of long bone manipulation. Fat embolism may also be seen after liposuction.

Among trauma cases, fat embolism syndrome is diagnosed in approximately 0.5%, if it is not actively sought; however, it is diagnosed in 10% to 20% of all trauma cases when evidence is prospectively sought, specifically, through close examination of patients with trauma and hypoxemia. Fat embolism syndrome is seen in up to 60% of autopsies involving blunt trauma.

This syndrome is characterized by petechiae in the characteristic distribution in 60% of cases, and by shortness of breath and hypoxia in 50%. Thirty percent of patients experience confusion or coma. Retinal changes may occur, and platelet count may drop slightly in 50% of cases. Fever is characteristic, and diagnosis hinges on recognition of the probability of this syndrome. Its peak incidence is between 24 and 72 hours after the traumatic event.

Treatment is believed to be nonspecific and supportive. Because of the apparent association (if it is not a precipitating factor) with hypovolemic shock, low blood pressure should be aggressively treated. Hypoxemia needs to be addressed. Putative treatments include steroids, heparin, or aspirin. Although all of these may have some efficacy, no evidence-based study has proved their efficacy.¹³⁷

Myeloblastemia

Leukostasis syndromes typically manifest through central nervous system dysfunction and hypoxia when cerebral and pulmonary capillary beds are involved.¹³⁸ Leukostasis is most typically seen with a large number of circulating myeloblasts and promyelocytes such as in blast crisis of chronic myelogenous leukemia. These large malignant myeloid cells may also embolize within the dermal microcirculation and cause infarctive lesions that are far in excess of the degree of thrombocytopenia that may accompany leukemia and its treatment. The most appropriate therapy is cytoreduction of malignant cells.

Thrombotic Thrombocytopenic Purpura (TTP)

This interesting disease is discussed thoroughly in Chapter 24. Although platelet aggregates induce thrombosis in many tissues, a paucity of cutaneous purpura is noted, despite its name. Nonetheless, petechial, purpuric, and infarctive lesions are occasionally present but are often overshadowed by other manifestations of this disorder.

Heparin-Induced Thrombocytopenia With Thrombosis (HIT)

Purpura and embolic ischemia but rarely petechiae are characteristic of this disorder. Ischemia of the extremities in patients who have received or are receiving heparin and in those who have become thrombocytopenic should alert the practitioner to this possibility. HIT is discussed in Chapter 25.

Blue Toe Syndrome, Purple Toe Syndrome, and Cholesterol Emboli Syndrome

These are different terms for what most likely are variations of the same process.^{133,139–141} Whether they occur during heparin administration, during warfarin administration, following abdominal trauma, following cardiac catheterization, or even spontaneously, the unifying points are (1) that all these patients have significant underlying atherosclerosis, and (2) that the histologic picture is one of cholesterol crystals in the arterioles of biopsied lesions.

In the past, the purple (or blue) discoloration of the toes that occurred when patients were administered an oral or a parenteral anticoagulant was believed to be a reaction to the anticoagulants. It is far more likely that these lesions are due to the underlying process for which the anticoagulants were indicated. Use of anticoagulants results in remodeling of the clots that commingle among large atherosclerotic plaques, allowing bleeding into the atherosclerotic plaques or freeing up of cholesterol crystals, which then embolize distally.

This process resembles livedo reticularis but differs in that it is usually significantly bluer and is quite painful because of the ischemia. This appears to be strictly an arteriolar embolization syndrome in that deposition of fibrin that one sees in the venules in warfarin skin necrosis is not encountered. The process may progress to involve not only purple or blue toes but through-and-through necrosis of the toes and feet, as well as significant parts of the soft tissue, usually of the legs and sometimes into the lower flank and back (Fig. 11-23).

Occasionally, the differential diagnosis is not straightforward and includes HIT, antiphospholipid syndrome (APLS), warfarin skin necrosis, and cholesterol emboli, which may be clarified if there is a recent history of manipulation or trauma of the arterial system. When it occurs spontaneously, one can often be led astray by many findings that suggest a vasculitis, including weight loss, anorexia, fever, anemia, eosinophilia, and a very high erythrocyte sedimentation rate. Calf muscle tenderness may coexist with elevations in serum creatine kinase level, both of which can broaden the differential diagnosis; however, this is believed to be due to an ischemic myositis from infarcts that are simultaneously taking place within the calf muscles.

Assessment should be focused on the arterial system. Echocardiography that includes the aortic arch is indicated, as is imaging of the entire aorta. Ankle-to-brachial pressure index may be helpful, but sometimes arterial pulses are palpable and half the time are even described as bounding. There is usually a very high probability that cholesterol crystal deposition will be found on skin biopsy of appropriate material.

These conditions are serious, not only because of the ischemia and the risk of amputation but because of the underlying atherosclerosis itself. Treatment probably is best

Figure 11-23 Cholesterol embolization. This man had severe peripheral vascular disease and had recently undergone cardiac catheterization. The lesions resemble livido reticularis but are painful and darker, and the margins are more easily delineated. Additionally, ischemic blisters are seen in this case, near the Achilles tendon.

provided by minimizing or totally avoiding additional invasive procedures of the arterial system; if catheterization studies are necessary, consideration should be given to use of the upper extremity.

Purpura Associated With Vascular Malignancy

Endothelial cells, similar to other cells, may become malignant. Although multiple rare endothelial malignancies exist, the prototypic and most common form is Kaposi sarcoma (KS).¹⁴² This disease in the past was very rare; however, it became more common in the 1980s because of its association with acquired immunodeficiency syndrome (AIDS).

The hematologist from time to time will be asked to see a patient with a purpuric lesion that proves to be KS (Fig. 11-24). KS typically starts as an ecchymotic-appearing macular lesion that progresses to a plaque or nodular lesion. KS has become more common in the AIDS pandemic and is believed to be due to the opportunistic coinfection of human immunodeficiency virus (HIV)-positive patients with Kaposi sarcoma herpes virus (KSHV), which is also known as human herpes virus type 8 (HHV8). Although KS is seen chiefly in homosexual men and at one time was the AIDS-defining illness in approximately one half of such patients, a dramatic decrease has occurred over the past decade, with KS being found in only about 15% of patients with AIDS and in 1% of newly diagnosed HIV-positive patients.¹⁴³ A variety of dermal processes are included in the differential diagnosis, but a very important clue, typical of all purpuric lesions, is that the early KS lesion does not blanch on external pressure. As lesions become larger, more plaque-like, and nodular, they are clearly distinguished from purpura. The diagnosis may ultimately depend on biopsy, which can be undertaken without excessive risk of hemorrhage despite the vascular nature of the tumor.

Research into this tumor has generated a wealth of information on angiogenesis.¹⁴⁴ The sarcomatous tissue

Figure 11-24 Kaposi sarcoma. These fleshy tumors are purpuric as a result of extravasated blood cells, yet they are most purpuric in their early stages.

produces vascular endothelial growth factor (VEGF), which greatly stimulates further proliferation of endothelial cells. This accounts for the massing of endothelial cells in an attempt to make channels, referred to as “vascular slits,” the histologic hallmark of this lesion. Also found is a swirling arrangement of spindle-shaped cells admixed with the angiogenic component. These spindle cells stain for smooth muscle actin, which suggests their relation to vascular cells. These cells also produce matrix metalloproteinase 2 (MMP-2), as well as a collagenase and other enzymes that tend to degrade the hemostatic membrane and may very well facilitate migration of endothelial cells among the growing lesion and extravasation of red cells.

The lesions rarely cause severe morbidity and mortality but often do cause cosmetic and other less life-threatening burdens. As KS progresses, an increased number of life-threatening lesions may occur, particularly in the respiratory tract, mouth, and gastrointestinal tract.¹⁴⁵

Other Hematovascular Findings of Hematologic Interest

For completeness, several disorders of interest that are germane to this topic and the differential diagnosis are presented here.

Livedo Reticularis

Livedo reticularis is commonly seen and, in the correct clinical setting, is indicative of APLS. Livedo reticularis has a dusky, ill-defined violaceous reticular pattern that is seen primarily on the legs and occasionally on the arms (Fig. 11-25). It vaguely resembles a pair of blue or purple fishnet stockings. It may be seen transiently in normal people, especially if they are in a cool environment. Anti-cardiolipin antibodies were found in roughly one half of

Figure 11-25 Livedo reticularis. This young woman with antiphospholipid syndrome exhibits the lacy, evanescent-appearing, weblike pattern characteristic of this skin disorder. A more advanced (but less typical) case is shown as “Images in Clinical Medicine,” *N Engl J Med* 356:284, 2007.

65 patients with livedo reticularis studied by Asherson and colleagues.¹⁴⁶ Livedo reticularis may also be seen in lupus without APLS and in other rheumatic disorders. Sneddon recognized the association of livedo reticularis with cerebrovascular accidents; this disorder was referred to as Sneddon syndrome although it now appears he was recording two manifestations of APLS.¹⁴⁷

Histopathologic samples of livedo reticularis show a slight endotheliitis, usually without necrotizing features. Should necrotic lesions be encountered, the process may be called *livedoid vasculitis*. Following necrotization, small cutaneous porcelain-white ulcerations, called *atrophie blanche*, result.¹⁴⁸

Livedo reticularis serves as one of the minor diagnostic criteria for APLS (see Chapter 19). Therapy other than the treatment of underlying disease is not indicated. Other dermal manifestations of APLS have been recently reviewed by Gibson and colleagues.¹⁴⁹

Urticarial Vasculitis

Whereas typical urticaria is commonplace and self limited, a subtype has been called *urticarial vasculitis*. These edematous lesions look like typical urticaria, except that their appearance includes a considerable vasculitic component. On biopsy, some degree of neutrophilic perivascular infiltrate is usually apparent. Clinically, this type of urticaria differs from common urticaria in that it usually lasts longer than 24 hours, is actually painful, and is sometimes described as burning; also, sometimes, when the lesions clear, a slight amount of residual purpura is seen. It is associated with hypocomplementemia. Some patients also have arthritis and abdominal pain.¹⁵⁰

Purpuric Contact Dermatitis

Contact dermatitis is a common skin disorder known to all practitioners. It is a small subtype of dermatitis, and lesions, particularly those that appear to be elicited by contact with various textile dyes in clothing, are purpuric. Extravasated red cells are seen on biopsy, but no vasculitis is apparent.¹⁵¹

Acute Hemorrhagic Edema of Infants

Dermatologists have described this as the alarmingly sudden onset of hemorrhagic edema in children that involves particularly the face. Onset is very rapid, but fortunately, the condition proves to be benign and usually goes away in about a week. On biopsy, intense leukocytoclastic vasculitis is seen. This appears to be different from Henoch-Schönlein purpura, in that the disease is more benign and sudden in its coming and going.^{152–154}

Hemangiomas

These soft bluish tumors are common in infancy and usually spontaneously regress.³⁸ Persistent huge cavernous hemangiomas have a worse prognosis and may require aggressive treatment. The Kasabach-Merritt syndrome is thrombocytopenic hemorrhage that results from DIC or hyperfibrinolysis, or both when it occurs in patients with a subtype of giant hemangioma that was recently renamed kaposiform hemangioendothelioma (KHE).^{40–42} The hemostatic defect is believed to result from activation of the coagulation and fibrinolytic systems through stagnation of blood creeping through the maze of entangled vessels in these large lesions.

Cherry Angiomas

These appear as cherry red, small, 1- to 3-mm domed papules over the upper abdomen and lower chest that occur in the second half of life. They consist of proliferated capillaries with vessels that are not as large as those in HHT syndrome; cherry angiomas do not blanch nearly as easily or completely as the telangiectases of HHT syndrome. At one time, they were also known as de Morgan spots and were believed to herald internal malignancy, but this is no longer held as true.

Spiders

These vascular lesions are noted by their 1- to 3-cm “legs” that radiate out from a 1- to 2-mm central body. The body of the spider angioma is a dermal arteriole with anastomoses to the legs. Gentle pressure on the head causes collapse of the spider and disappearance of the legs. Spiders are seen in aging, cirrhosis, and pregnancy and require no specific therapy. Vascular spiders are occasionally of cosmetic concern.

Erythema

A simple increased supply of blood to the skin dilates normal dermal vessels with resultant reddening of the skin, especially the skin of the face. Erythema has no clear-cut borders but blanches with pressure or application of cold to decrease cutaneous blood flow. Erythema may result from a hot environment, hyperthermia, fever, mild viral infection (“slapped cheeks” of fifth disease), or emotional phenomena.

CONSULTATION CONSIDERATIONS

In hospitalized patients with purpura, high probabilities exist for CV, DIC, amyloidosis, and livedo reticularis, as well as for the above-mentioned classic hemostatic diatheses. Essentially all patients in the category of purpura due to microthrombi will be hospitalized because of their underlying illness. In healthy ambulatory patients, the most

commonly encountered processes are senile purpura, purpura simplex, PPPs, OWR syndrome, CV, and factitious purpura.

Clues exist in the distribution of purpura. Postictal petechiae, petechiae secondary to fat embolization, telangiectases of OWR syndrome, and the purpura associated with amyloidosis occur about the head and face. Mouth bleeding from boggy gums should signal the possibility of scurvy. Body and trunk ecchymoses and purpura are seen with hemophilia, factor VIII inhibitors, concomitant anticoagulant use, amyloidosis, and even purpura simplex, especially when the patient's activities involve leaning over and bearing weight on the lower rib cage.

Dependent purpura is seen in acute and chronic ITP, PPPs, CV, and scurvy. Livedo reticularis is seen most commonly on the legs. Painful acral purpuric lesions are indicative of ischemia from emboli such as those seen in subacute bacterial endocarditis, cholesterol embolization, or cardioembolization from atrial myxoma or nonbacterial thrombotic emboli (marantic endocarditis).¹⁵⁵ The nearly mirror image, symmetrical involvement of the legs and trunk in the palpable purpura of CV is noteworthy. A high degree of asymmetry should increase the index of suspicion for a factitious process.

Acute-onset purpura generally has a worse prognosis than chronic purpura, and haste must be used to evaluate for and rule out infectious causes, DIC, cholesterol embolism, and other catastrophic processes such as TTP and DIC in the microthrombotic category. Long-standing purpuric lesions may well be HHT, PPPs, purpura simplex, purpura secondary to heritable connective tissue disorders, or chronic ITP. Hemosiderin deposits in the dependent portions of the legs connote chronicity due to accumulation of heme iron retained in the cutaneous macrophages. Both senile (atrophic or actinic) purpura and purpura secondary to hypercortisolism are essentially limited to the extensor surfaces of the forearms, a pattern that essentially is diagnostic for either of these disorders.

LABORATORY EVALUATION

The hematologist will nearly always order a CBC with a platelet count and differential white cell count, as well as a prothrombin time and a partial thromboplastin time for screening purposes. Such practice is both understandable and defensible. Otherwise, the laboratory should be used primarily to rule out or rule in other specific disorders in a manner not unlike those listed in [Table 11-3](#), which are used to specifically evaluate for secondary causes of CV.

The bleeding time or platelet function assay (PFA) is normal, except in qualitative and quantitative platelet disorders. Normal bleeding time is consistent with the fact that other purpuric disorders do not primarily interfere with platelet–endothelial interaction, as is tested by bleeding time.

Skin biopsy is frequently helpful and is usually ordered in collaboration with a dermatologist. It is particularly useful in establishing CV, PPPs, amyloidosis, KS, and senile purpura if these diagnostic considerations are not otherwise straightforward, thus justifying further testing.

COST CONTAINMENT

The modest laboratory evaluation just described will considerably curtail costs. A reasonable knowledge base of purpura and a good history and physical examination are typically all that are needed to establish the diagnosis in most patients with purpura. This approach leads to the accurate diagnosis of mechanical purpura, factitious purpura, purpura simplex, PPPs, many causes of CV, RMSF, scurvy, hypercortisolism, senile purpura, heritable disorders of connective tissue, OWR syndrome, DIC, warfarin skin necrosis, fat embolism syndrome, cholesterol emboli, and associated nonpurpuric hematovascular disorders such as livedo reticularis, angiomas, and spiders.

TREATMENT ISSUES

Clearly, treatment begins with a correct diagnosis. No hematologic treatment is necessary for many patients (e.g., purpura simplex, PPPs, primary CV), but hematologic treatment is indicated for others (e.g., ITP, TTP, DIC, HHT). Nonhematologic treatment is indicated for a third group (e.g., psychiatric evaluation in factitious purpura; rheumatologic evaluation in many cases of secondary CV; antibiotics for RMSF, subacute bacterial endocarditis, or meningococcemia; dietary management for scurvy). This review does not cover all treatment aspects for all causes of purpura.

With the obvious exceptions of patients with a qualitative or quantitative platelet defect, hemophilia, or an acquired coagulation factor inhibitor, and those on anticoagulants, purpuric patients do not harbor a systemic hemorrhagic diathesis. Accordingly, those patients with HHT, senile purpura, purpura simplex, PPPs, CV, scurvy, heritable disorders of connective tissue, and KS may undergo invasive and operative procedures without fear of hemostatic failure. Patients with amyloidosis fall between these two groups and may require special consideration before undergoing an elective invasive procedure.

MEDICAL-LEGAL CONSIDERATIONS

In patients with bruising and hematoma, consideration must always be given to the possibility of trauma due to abuse. Although abused patients may present with bruising as their sole problem, nonabused patients may be falsely accused of having been abused simply because of the presence of purpuric lesions. Parents who do not know that a child has von Willebrand disease or mild hemophilia may be accused of abuse.

Chapter 12

Disseminated Intravascular Coagulation

Carrie LaBelle, MD • Craig S. Kitchens, MD

An enormous amount has been written about disseminated intravascular coagulation (DIC). During the 1970s and 1980s, it was rather fashionable to report on yet another “cause” of DIC. Over the past three decades, however, it has become increasingly clear that DIC, rather than being a specific disease, really represents a pathophysiologic final common pathway of the coagulation system gone awry. That single understanding brings into focus that DIC is an “intermediary mechanism of disease”¹ and collapses the nearly infinite list of causes into an understandable and functional process. Less time is now spent on indexing new and unique causes of DIC, with the thrust toward recognizing the underlying and initiating process of DIC and directing therapy toward that cause. The central role of tissue factor and various cytokines in the initiation and continuation of coagulation up to and including DIC has been elucidated and will be the focus of Chapter 13.

Even the terminology has been controversial. DIC has been called *defibrination syndrome*, *acquired afibrinogenemia*, *consumptive coagulopathy*, and *consumptive thrombohemorrhagic disorder*. Although each term certainly has its advocates and rationale for use, the term *disseminated intravascular coagulation*, and “DIC” in particular, seems to be rooted in our medical vocabulary, and so DIC will be used in this chapter. Additionally, microvascular thrombosis appears to be a major pathologic mechanism, resulting in multiorgan dysfunction syndrome (MODS). MODS is the chief cause of death among patients experiencing processes that initiate DIC. Hence, an association between DIC and MODS has been identified.

HISTORICAL OVERVIEW

The end result of DIC has been long known. The “Black Death” refers to the intense peripheral gangrene and bleeding resulting from thrombosis and defibrination of the plague that scourged the earth over the second millennium. That fatal bleeding could occur with various obstetric emergencies has been known also for centuries.² In 1834, de Blainville³ was able to induce fatal massive intravascular thrombosis in animals through the rapid infusion of brain tissue. Nauyn,⁴ 40 years later, observed similar manifestations when animals were infused with hemolyzed red cells. In 1884, Foa and Pellacani⁵ elaborated on de Blainville’s experiment by showing that extracts of several organs when infused could cause both thrombosis and hemorrhage. In further studying de Blainville’s model, Wooldridge⁶ in 1893 infused brain tissue slowly rather than rapidly, as did de Blainville, and showed that the animals did not

die of massive intravascular thrombosis but rather, their blood became unclottable and, further, that after this state had been achieved, rapid infusions of more brain tissue did not cause any outward harm to the animal. It was Mills⁷ in 1921 who observed that the latter findings were in fact due to selective defibrination that occurred with slow infusion of brain tissue and that the secondary rapid infusion failed to cause thrombosis because the animal had been defibrinated. In 1957, Krevans and colleagues⁸ studied defibrination after hemolytic transfusion reactions in humans and made seminal observations regarding what we would now call DIC. At about that same time, Schneider⁹ infused placental tissue into rabbits and was able to induce hemorrhage in these animals, thus offering a peek into the mechanism of DIC characteristic of obstetric catastrophes. In the late 1960s, Merskey’s¹⁰ laboratory developed a test to detect serum fibrin degradation products (FDPs) and thus opened the door to laboratory investigation of DIC. Additional studies into the fate of fibrinogen and the mechanism of FDP production in DIC were conducted by Marder’s group.¹¹ Corrigan and colleagues¹² made rapid advances in the elucidation of DIC associated with septicemia, focusing on meningococcemia. McKay¹ catalogued the knowledge base regarding DIC in 1965, making it a distinct clinical entity. In 1968, microangiopathic hemolysis to include that seen in DIC was described.¹³ The rapid growth in experience and knowledge was again thoroughly reviewed by Colman in 1972.¹⁴ The notion of a pristine laboratory approach to diagnosing DIC was dismantled when Merskey¹⁵ pointed out that not everything that appears to be DIC by laboratory criteria may be DIC, whereas sometimes true DIC may not “fit” if the primary criteria are laboratory findings rather than the underlying illness and the overall clinical picture. Mant and King¹⁶ appropriately argued that DIC may be severe and acute, and Sack and colleagues¹⁷ clearly and accurately described chronic DIC associated with neoplasia. Causes of DIC are heterogeneous and signs and symptoms are varying.¹⁸

During the next 30 years and up to the present, innumerable papers have been written on the initiation and control of normal hemostasis and the pathologic end result, DIC. These discoveries are discussed in greater detail in the following pages.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Coagulation is initiated by interruption of the endothelial lining of the vascular system or by entry of tissue factor (TF) into the blood. With the former mechanism, the

intrinsic clotting system may be activated by interaction of blood with subendothelial tissue and collagen; with the latter, TF, which is within all or most cells with the exception of unperturbed endothelial and peripheral blood cells and is released with cellular disruption,¹⁹ causes activation of the tissue factor (extrinsic) clotting system. It appears that the extrinsic TF-driven system is the predominant force in hemostasis. Provided that the impetus is durable or protracted enough to sustain a procoagulant force, thrombin will be generated. During this cascade of activation, each step must pass through physiologic hurdles, be they potential inactivation of activated serine proteases (factors XIa, Xa, IXa, VIIa, and IIa) by antithrombin III (ATIII) or degradation of activated cofactors (factors Va and VIIIa) by the protein C system. Should thrombin be eventually generated, it must continue to evade ATIII as well as endothelial-bound thrombomodulin (TM) to finally convert fibrinogen to fibrin. All of this is quite physiologic following a surgical incision or other event for which hemostasis is regarded as desirable. When a breach in the circulatory system has been corrected, it is then appropriate for any remaining procoagulants, but especially thrombin, to be neutralized by these physiologic inhibitors. By virtue of the fact that a clot begets its own dissolution by incorporation of plasminogen, which is then activated by the fibrinolytic system, the clot remains in place for a while until it eventually is cleared by the action of plasmin. Any excess plasmin is neutralized by its inhibitor, α_2 -plasmin inhibitor (α_2 -PI). This all physiologically happens continually. One could arguably claim that events that could lead to DIC occur every day, but DIC does not routinely happen because these are tightly regulated events.

What separates the pathophysiologic process of DIC from physiologic clotting is the combination of nonphysiologic, sustained, and excessive initiation of coagulation (obstetric catastrophes, sepsis, cancer, trauma) and the eventual inability to neutralize circulating activated products of coagulation because of deficiencies in the inhibitory system (congenital deficiencies, hepatic insufficiency, or impaired circulation), such that the initiating stimulus for coagulation is not neutralized. If the stimulus is massive, sustained, and/or not neutralized, the resultant procoagulant wave soon inundates physiologic inhibitors, resulting in free, circulating, unopposed thrombin and plasmin, the two key agents responsible for DIC. Table 12-1 lists the inhibitors that are overcome in the genesis of DIC. Each inhibitor system is in place to neutralize a key hemostatic force listed on the left, each of which is key in the initiation and sustainment of DIC. Any attempt by their individual inhibitors to hold these in check will be overwhelmed by

the continued amassing of procoagulants. The pathologic consequence of overwhelming the inhibitors is listed to the right. In fact, the clinical and laboratory manifestations of DIC can be explained by pathologic circulation of thrombin and plasmin. Thrombin will result in the pathologic intravascular clotting of fibrinogen, especially in the microcirculation, and deposition of platelets in nonphysiologic areas and consumption of coagulation factors; plasmin degrades fibrinogen, fibrin, and multiple coagulation factors, thus generating FDPs and D-dimer characteristic of DIC (Fig. 12-1). Of interest in profound DIC is that circulating levels of plasminogen activator inhibitor-1 (PAI-1) paradoxically increase by virtue of being an acute phase reactant greatly intensified by cytokines.²⁰ This increase in PAI-1 efficiently downregulates the fibrinolytic system, which correlates with more massive thrombosis, MODS, and death.²¹ During infusion of *Escherichia coli* endotoxin into normal human subjects, circulating levels of tissue plasminogen activator (tPA) initially increase and fibrinolysis is promoted; however, with continual infusion, levels of PAI-1 greatly increase, resulting in a total loss of tPA functional activity.²² D-dimer is the specific FDP generated by plasmin lysis of two γ -chain fragments of fibrin that have been crosslinked by the action of activated factor XIII. Because factor XIII activation requires the presence of thrombin and the only initiator of fibrinolysis is plasmin, this D-dimer complex serves as a “footprint,” proving

Figure 12-1 Electron micrograph of a capillary in experimental disseminated intravascular coagulation (DIC). The intact capillary contains a network of fibrin (F) and an occluded platelet (P) ($\times 13,000$).

Table 12-1 Hemostatic Consequences of Loss of Inhibitors in Disseminated Intravascular Coagulation

Key Hemostatic Forces	Inhibitor	Consequence of Loss of Inhibitor
Tissue factor (TF)	Tissue factor pathway inhibitor (TFPI)	Enhanced thrombin generation
Activated factors V and VIII	Protein C and protein S	Enhanced thrombin generation
Activated coagulation factors, especially thrombin	Antithrombin III (ATIII)	Enhanced fibrin formation and platelet activation
Tissue plasminogen activator (tPA)	Plasminogen activator inhibitor, type 1 (PAI-1)	Enhanced fibrinolytic activation with decrease in PAI-1 and enhanced thrombosis with increase in PAI-1 (see text)
Plasmin	α_2 -plasmin inhibitor (α_2 -PI)	Unopposed fibrinolysis

the prior dual existence of thrombin and plasmin in the circulation.^{23,24}

CAUSES OF DISSEMINATED INTRAVASCULAR COAGULATION

Whereas DIC was previously regarded as a specific disorder, it is now held that DIC, much as fever, hyponatremia, or abdominal pain, is a manifestation of a pathologic process. These are all abnormalities but are not recognized diseases. Rather, they are always due to some underlying cause. Accordingly, recognizing DIC in a patient implies that an underlying process is becoming such a burden on the patient's hemostatic system that the patient's situation is becoming increasingly unstable. DIC should be regarded as an indicator of a severe disease process or injury that is blatantly obvious (e.g., burns, trauma, cardiopulmonary collapse, carcinomatosis, sepsis), yet occasionally DIC serves as part of the original diagnosis, which may help to establish the presence of an underlying process. Common examples include recognition of DIC as distinguishing meningococcemia from viral headache and fever in a young healthy patient, establishing acute promyelocytic leukemia (APL) in a previously uncertain type of leukemia, and differentiating an obstetric catastrophe such as abruptio placentae or placenta previa from an otherwise mildly complicated labor and delivery. Table 12-2 lists several processes that may induce DIC.

INITIATION OF DISSEMINATED INTRAVASCULAR COAGULATION

Following is a brief outline of the physiologic activation of coagulation that may help to explain how continued and

unchecked activation results in the clinical syndrome known as DIC.

Figure 12-2 is a crude attempt to illustrate key events in DIC. Any graphic attempting to exhaustively demonstrate all the on-going reactions, interactions, and counteractions would be functionally unfathomable; accordingly, this chart admittedly greatly simplifies the seminal points of DIC. For instance, the direct infusion of substances (snake venoms) that activate directly either prothrombin or factor X²⁵ is not portrayed by this simplification. The key role of the liver in holding in check DIC by the clearance of activated factors is also not satisfactorily addressed. The importance of the liver was revealed by the pioneering works of Deykin.²⁶ Key inhibitors of coagulation are represented by letters at proposed control points, although they too are greatly simplified. For example, Sandset and colleagues²⁷ showed that elimination of the TF pathway inhibitor (TFPI) from experimental animals proved that TFPI was an important governor of experimental DIC.

Nonetheless, Figure 12-2 does depict the general flow of events. Effects of vascular injuries that occur are not as neatly divided into activation of the extrinsic (TF-driven) clotting system or the intrinsic (contact system–driven) system as was previously held. Accordingly, in the box on the left, initiation by tissue damage, endothelial injury, and exposure of blood to bacterial products, necrotic cells, and subendothelial tissue is probably correctly depicted as activating both the intrinsic and extrinsic systems. However, the role of the intrinsic system appears to actually be less important than that of the TF-driven extrinsic system in initiating DIC.^{28,29} Endotoxin and other bacterial products can activate the contact system.³⁰ Those systems result in the generation of thrombin, which is absolutely essential to normal or perturbed hemostasis. Thrombin then activates platelets, clots fibrinogen, and activates factors V, VIII, and XIII. All of these create a profound prothrombotic force. When their inhibitors as depicted by A (TFPI) and B (ATIII) are overwhelmed, thrombin generation becomes pathologic and DIC starts.

Circulating thrombin binds to TM. When thrombin binds to TM to make a thrombin:TM complex, thrombin metamorphoses from a powerful procoagulant to a powerful anticoagulant by virtue of it activating proteins C and S, which, in turn, enhance the fibrinolytic system by neutralizing PAI-1. The product of the fibrinolytic system is the conversion of plasminogen to circulating plasmin. Other enhancers of fibrinolysis include endotoxin, interleukin-1 (IL-1), IL-6, factor XIIa, and fibrin, as well as tumor necrosis factor (TNF), which releases endothelial tPA and u-PA (urokinase-type plasminogen activator). Just as important as the keystone role of thrombin in DIC is the role of plasmin, as it causes degradation not only of fibrin but also of fibrinogen and factors V, VIII, and XIII. Degradation of fibrinogen and fibrin results in the characteristic “footprints” of circulating FDPs and D-dimer. Attempting to check plasminogen activation is PAI-1, whose concentration is greatly increased in the inflammatory reaction. If levels of PAI-1 greatly increase, the fibrinolytic system totally shuts down, potentiating catastrophic thrombosis. The inhibitor of plasmin, α_2 -PI, also attempts to keep plasmin activity under control but is overwhelmed in DIC.

DIC may be characterized along three different axes, representing tempo, extent, and clinical manifestation

Table 12-2 Processes that May Induce Disseminated Intravascular Coagulation

Tissue Damage	Infection
Trauma	Gram-positive bacteria
Crush injuries	Gram-negative bacteria
Central nervous system injuries	Spirochetes
Heatstroke	Rickettsiae
Burns	Protozoa
Hemolytic transfusion reaction	Fungi
Acute transplant rejection	Viruses
Neoplasia	Obstetric Conditions
Cancers	Abruptio placentae
Leukemias	Placenta previa, accreta, and percreta
Cancer chemotherapy	Retained dead fetus syndrome
Tumor lysis syndrome	Amniotic fluid embolism
Miscellaneous	Uterine atony
Shock	Therapeutic abortion
Cardiac arrest	Toxemia of pregnancy
Near drowning, especially in fresh water	
Fat embolism	
Aortic aneurysm	
Giant hemangiomas	
Bites by certain snakes	

Figure 12-2 A brief overview outlining forces initiating coagulation that could lead to disseminated intravascular coagulation (DIC). Key to the generation of DIC is circulating thrombin and plasmin free of physiologic inhibition.

(Table 12-3). It is acknowledged that this simplistic approach may represent some degree of overlap; however, it offers a glimpse into the multiple and varied ways that DIC can manifest. The tempo axis distinguishes DIC as acute or chronic. The classic diseases representing acute DIC include most of the sepsis syndromes, DIC secondary to trauma, and cardiopulmonary collapse. Chronic DIC is represented by the retained dead fetus syndrome, large intra-abdominal aortic aneurysms, and Trousseau syndrome.

Regarding extent, localized causes of DIC include abdominal aortic aneurysm (AAA), an empyema or necrotic gallbladder, or an obstetric catastrophe such as

placenta previa or abruptio placentae. Systemic causes include most leukemias and lymphomas, carcinomatosis, sepsis, heatstroke, and burns.

The third axis for consideration is clinical manifestation, which can be thrombotic, hemorrhagic, or, occasionally, both. An example of the thrombotic arm is Trousseau syndrome, whereas examples of almost pure hemorrhagic DIC would include abruptio placentae or hemolytic transfusion reaction.

FIVE ILLUSTRATIVE CAUSES OF DISSEMINATED INTRAVASCULAR COAGULATION

Closed Head Injury

Closed head injury is a model for acute, severe DIC.³¹ In experimental head injury in rats, fixed amounts of head trauma result in reproducible amounts of fibrin deposition in the microcirculation.³² The same investigators³³ found that among patients with head injury, a correlation could be made between extent of head injury, hemostatic defects, and worsening clinical outcome. Olson and associates³⁴ confirmed these findings in a large series of patients with head injuries. Head injuries not only lead to neurologic damage, paralysis, and venous stasis, they also cause coagulation activation because damaged brain tissue serves as the source of tissue thromboplastin released into the circulation. Selladurai and colleagues³⁵ prospectively studied

Table 12-3 The Three Axes of Disseminated Intravascular Coagulation, with Clinical Examples

Axis	Example
Tempo	
Acute	Meningococcemia
Chronic	Retained dead fetus syndrome
Extent	
Localized	Abdominal aortic aneurysm
Systemic	Acute promyelocytic leukemia
Manifestation	
Hemorrhagic	Abruptio placentae
Thrombotic	Trousseau syndrome

204 patients with acute closed head injury using readily available coagulation tests and found that 38% had moderate or severe alterations of such global tests, thus supporting the diagnosis of DIC. They noticed an increasing incidence of DIC with decreasing Glasgow coma scores ($P < .0001$). Patients whose laboratory data suggested DIC had worse overall outcomes than those without such findings. Fujii and associates³⁶ pointed out that for these hemostatic manifestations to occur, the damaged neural tissue had to transverse from the parenchyma into the circulation via the subarachnoid space. DIC associated with closed head injury is usually rather brisk and self limited because the spillage of brain tissue into the circulation usually ceases. On the other hand, closed head injury often has such a high mortality rate that the patient may expire from the primary injury.

Abdominal Aortic Aneurysm

Abdominal aortic aneurysm (AAA) serves as a model for chronic compensated DIC in that the platelet count can be low, high, or normal, as can the fibrinogen concentration. Most frequently, DIC in AAA is recognized when the platelet count is somewhat low, in the 40,000 to 80,000/ μ L range, and analysis for serum FDP is positive. It is believed that the rough saccular nature of the aneurysm allows pockets of clotting to take place, and therefore, some degree of localized DIC occurs. Of interest, microangiopathic hemolytic anemia changes in red cells may be seen, as well as laboratory evidence of intravascular hemolysis, including decreased levels of serum haptoglobin and the presence of urine hemosiderin. Low-dose heparin, such as 5000 units administered subcutaneously twice daily, or low molecular weight heparin (LMWH) has been advocated to attenuate chronic DIC and allow the platelet count to increase, so the patient may be a better surgical candidate.³⁷ The platelet count may increase yet fluctuate on its own. Oba and colleagues³⁸ opine that because the cause of the DIC is the aneurysm itself, rather than spending days to weeks administering heparin to such patients and waiting for improvement, the clinician should surgically approach the aneurysm as soon as possible. Aboulafia and Aboulafia³⁹ reportedly found evidence of such chronic DIC in 2 of 67 consecutive cases of AAA. They reviewed reports of 34 cases of DIC associated with AAA and concluded that DIC was a variable process and that often the platelet count improved whether heparin was administered or not. They also suggested that the best approach was surgical correction of the AAA. It is not clear whether the presence of DIC added to the overall surgical morbidity of AAA.

Acute Bilateral Renal Cortical Necrosis

Acute bilateral renal cortical necrosis (BRCN) is a rare cause of acute renal failure (ARF) and may represent acute DIC with preponderance of impact on the renal microvasculature. Two lines of evidence suggest that this process may well be a limited form of DIC.^{40,41} The first is that the list of precipitating illnesses is the same as the list for DIC with special reference to all manner of obstetric emergencies,^{42,43} sepsis,⁴⁴ and shock.⁴⁰ Second, extreme deposition of fibrin is frequently seen in the renal microcirculation,

particularly if renal biopsy is done early in the process, although this event does not happen frequently, given the laboratory perturbations of DIC. This finding sets BRCN apart from the more common acute tubular necrosis (ATN), also seen in many similarly ill patients. Because hypotension and hypoperfusion are common in both BRCN and ATN, differentiation by clinical means is frequently difficult.

The histologic pattern is extremely reminiscent of those found in the generalized Shwartzman reaction seen in laboratory animals that have been administered repeated doses of endotoxin.⁴⁵ Whereas in DIC of unknown cause, fibrin deposition can be seen in any organ, in BRCN, the renal vasculature is disproportionately involved. Whether local "second hits" (renal endothelial damage, or unknown host effects) destine this vascular bed is a matter of conjecture. The initial clinical picture of nearly all cases of BRCN is characterized by hypotension, suggesting that hypoperfusion to the point of overcoming renal autoregulatory defense mechanisms may well be a major contributing factor. Additionally, experimental models show that the high levels of PAI-1 seen in BRCN play an important antifibrinolytic role,⁴⁶ and that PAI-1 can be blocked by anti-PAI-1 antibodies, which results in marked histologic reduction of renal fibrin deposition.⁴⁷

The pattern of ischemic necrosis is unusual in that sparing of a thin rim of perfused viable tissue immediately under the renal capsule and at the corticomedullary junction can be seen, thus causing the brunt of the thwarted circulation to be directed at the interlobular and afferent arterioles. Clinically, this is important in that magnetic resonance imaging (MRI) showing such a pattern might be the prime or even sole early suggestion of BRCN.⁴⁸

BRCN has become less common with improved obstetric intensive care and the use of high-risk teams providing prepartum care for those patients who might otherwise be at risk for this disorder. Similar arguments can be made regarding nonobstetric causes because of improved interventional and intensive care.

Treatment hinges on prompt diagnosis, correction of hypoperfusion, and measures taken to address other contributory factors. Renal failure is extremely common, and usually, renal replacement therapy is required. Whether anticoagulant therapy is efficacious is unclear but, on the basis of the histologic deposition of fibrin, one is tempted to use it.

Placental Abnormalities

Placental abnormalities are a rare yet significant cause of obstetric DIC morbidity and mortality. Placenta previa (the implantation of the placenta in such a position as to occlude the cervical canal) is most common, occurring in 10% of women who had a previous caesarean section. This abnormality is not discussed further here. A subtype of placenta previa is placenta accreta, which may occur in about 1% of women who have undergone caesarean section; rarer yet is placenta percreta, which occurs in about 1 in 10,000 pregnancies.^{49–51} The term *placenta accreta* implies the pathologic implantation of the placenta deep into the myometrium. *Placenta percreta* implies dissection of the placenta with the use of its proteolytic and coagulation proteins through the uterine wall along the line of a previous injury

such as a caesarean section.⁵² Once in the peritoneal cavity, the placenta may implant itself ectopically onto the bladder or any other available tissues. Although all these placental abnormalities are fairly rare, without question they are becoming more common as the rate of caesarean section increases. When the pregnancy is otherwise normal, whether the fetus survives is a function of its success in establishing an adequate vascular supply. If inadequate, the fetus may not survive; if adequate, gestation may progress normally, yet at parturition, the placenta fails to be delivered because it is extrauterine.

Diagnosis can be made prepartum by imaging,^{50,53,54} especially in women with a high index of suspicion, such as those with multiple prior caesarean sections. The density of abnormal vasculature with vascular spaces represents the diagnostic criteria (sometimes called “Swiss cheese appearance”) and the source of characteristic hemorrhage, which may occur prematurely or at parturition because these vessels are large and multiple. Management of this event is largely handled surgically with liberal use of fluid and blood products, as well as internal uterine artery ligation or coil embolization.^{50,51,54}

The failed third stage of labor presents the question of whether one should leave the placenta in situ or pursue the retained ectopic placenta; both of these approaches have been advocated. In situations in which it is left in, the placenta sometimes undergoes spontaneous involution.^{55,56} Leaving the placenta in place can be associated with a delayed DIC–hyperfibrinolysis situation, probably caused by the necrosing retained products of conception. Methotrexate has been administered to hasten involution or to otherwise curtail the hemorrhagic picture, with both good⁵⁷ and poor results reported.⁵⁸

In the diagnosis and management of such cases, the hematologist should be aware of these rare conditions, particularly in the rare patient with retained implanted placenta of placenta percreta.

Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APL) represents a particular leukemic subtype that is highly associated with DIC and hyperfibrinolysis. It is mentioned here because advances in its treatment have resulted in substantial improvement in survival. Prior to the availability of all-transretinoic acid (ATRA) induction therapy, patients with APL had rates of extreme and frequently lethal hemorrhage as high as 50%.⁵⁹ Now, with the routine availability of ATRA therapy, the hemorrhagic rate is much lower, although still about 3% of patients die of hemorrhage before therapy is started, and another 3% die of hemorrhage during the first week of induction with ATRA. Another 2% to 3% die after the first week.⁶⁰ Because it appears that early therapy is associated with a less intense and/or an abbreviated coagulopathy, experts in APL therapy recommend that ATRA be administered as early as possible to control hemorrhage, even if this means not awaiting results of sophisticated genetic confirmation of the diagnosis. The malignant cells of APL cause increased generation of thrombin associated with brisk fibrinolysis, which may be part of the DIC; others have believed that it may be an event that is primarily induced by APL malignant cells.⁶¹ With early and aggressive ATRA therapy

combined with aggressive supportive therapy, up to 90% of patients may achieve remission, and an estimated 70% are curable.⁶² Supportive therapy is aimed primarily at anticipation and early diagnosis of hemorrhagic complications, which may very well be the acute presentation of APL. Fibrinogen sources are often suggested in quantities sufficient to keep the fibrinogen level at approximately 150 mg/dL and platelet counts higher than 30,000/ μ L during induction with ATRA.⁶⁰ The role of heparin therapy with or without antifibrinolytic therapy, given to prevent the development of the coagulopathy or to ameliorate it once it has started, has never been established in a controlled study.

DIAGNOSIS OF DISSEMINATED INTRAVASCULAR COAGULATION

The most common clinical manifestations of DIC are bleeding, thrombosis, and concomitant bleeding and thrombosis, often with resultant dysfunction of one or many organs. This is what the clinician sees. Bleeding occurs from all incisions, mildly traumatized mucosal membranes, and intravenous (IV) sites, and in the urine. Occasionally, thrombosis is the first clinical observation. This can occur in the form of ecchymoses, which may rapidly progress to purpura fulminans (the manifestation of subdermal microthrombosis with skin necrosis), a cold pulseless limb, or sudden loss of vision or some other neurologic catastrophe resulting from thrombosis.

The diagnosis of DIC is, indeed, a clinical diagnosis (Table 12-4).¹⁶ Because such patients are already at such high clinical suspicion for DIC, only a few simple and readily available laboratory tests are necessary to confirm the diagnosis. These include prothrombin time (PT), partial thromboplastin time (PTT), thrombin time (TT), platelet count, FDP level, and blood smear. PT and PTT, in clinically severe and life-threatening DIC, are prolonged in approximately 50% to 75% of cases by virtue of consumption of many coagulation factors. TT is significantly prolonged in approximately 70% to 80% of cases because levels of fibrinogen may be low whereas FDPs may be high, both of which serve to prolong the TT. The platelet count is moderately reduced, or at least lower than seen on previous pre-DIC observations, about 80% to 90% of the time. Usually, the initial platelet count is not lower than 30,000 to 40,000/ μ L. Analysis for FDPs yields abnormal findings 95% of the time (i.e., high sensitivity); when FDPs are

Table 12-4 Clinical Diagnostic Criteria for Disseminated Intravascular Coagulation

- Patient bleeding, thrombosing, or both, typically with progressive organ dysfunction
- An underlying illness or process that may cause tissue damage, cell death, or production/release of tissue factor
- Usually some perturbation exists of simple, readily available tests such as thrombin time (TT), prothrombin time (PT), partial thromboplastin time (PTT), fibrin degradation products (FDP)/D-dimer, and platelet count. These values may markedly change as the clinical situation changes.

increased and D-dimers (i.e., high specificity) are concomitantly present in patients for whom the clinical suspicion for DIC is high, virtually 100% will indeed have DIC.²³ Examination of the blood smear confirms the thrombocytopenia and reveals schistocytic hemolysis in about one half of cases.

Some have written extensively on more detailed laboratory evaluations of DIC. Because various factors are consumed, measurement of any of the classic coagulation factors may reveal reduced levels, as well as reduced levels of ATIII, plasminogen, and α_2 -PI. The difficulties associated with a pure laboratory approach are several (Table 12-5). First, this approach implies that consideration of a diagnosis of DIC should begin in the laboratory, whereas, in fact, this occurs at the bedside. Second, DIC presents an extremely dynamic situation in which its initiation may be extremely brisk, yet brief, such as occurs with intermittent sepsis from a necrotic gallbladder, empyema, or abscess. This initiating force for DIC may be so rapid that by the time the clinical manifestations of DIC are observed, laboratory parameters may already have been righted by reparative mechanisms before the tests are ordered, samples collected, tests performed, and results reported and interpreted. These more sophisticated tests require a considerable amount of time, laboratory expertise, and expense and, in the authors' opinion, are unlikely to yield more clinically useful information than is provided by the simple tests described.

Others^{21,63,64} have advocated more aggressive incorporation of laboratory data to support a diagnosis of DIC. Bick⁶³ has evaluated and ranked more than 20 tests that may be used in formulating such a diagnosis. These tests arguably are frequently but not always altered in DIC. One might object that availability of many of these tests is much more restricted compared with tests that we have favored, which are readily available in almost any clinical setting. Using elaborate laboratory data, Reister and colleagues⁶⁴ formulated four different levels of DIC (DIC I to DIC IV), claiming that progression of DIC through these phases is supported by progressive perturbations of 11 laboratory tests. Gando and colleagues²¹ established a score using four laboratory tests and three clinical situations. They also stated that by following this score, they were able to separate patients into survivors (those whose scores decreased over the next 5 days) and nonsurvivors (those whose scores remained high for the 5-day period). They noted that higher scores correlated not only with clinical deterioration of the patient but with progressive organ failure until MODS developed. Gando's report²¹

parenthetically noted that an increase in PAI-1 level was the best predictor for lethality of DIC, whereas Wada and colleagues⁶⁵ found no such correlation between PAI-1 levels and the prediction of patient outcomes. Not only are laboratory data in DIC potentially confusing, but results may show trends in opposing directions when acute DIC is compared with chronic DIC or when compensated and decompensated DIC are compared.⁶⁶ Accordingly, unless and until such interesting laboratory findings prove more predictive and cost effective, the conservative use of inexpensive and rapidly available tests seems most prudent. The International Society of Thrombosis and Haemostasis (ISTH) Subcommittee on DIC published a scoring grid in 2001 in order to facilitate laboratory diagnosis of DIC and validated the utility of this simplified approach in 2007.^{67,67a}

DIFFERENTIAL DIAGNOSIS OF DISSEMINATED INTRAVASCULAR COAGULATION

Several situations should be considered in the differential diagnosis of DIC because clinical manifestations or laboratory abnormalities of other disorders may mimic DIC. Most common among these is severe hepatic cirrhosis, whose laboratory coagulation abnormalities mimic DIC (see Chapter 39). In patients with hepatic cirrhosis, decreased levels of hemostatic factors, including fibrinogen, ATIII, protein C, protein S, and plasminogen, are due to impaired production and not usually to enhanced activation, as would be found in DIC.⁶⁸ Because the liver clears the small quantity of FDPs as the result of physiologic production, decreased clearance with hepatic disease results in an accumulation of FDPs in the blood. Portal hypertension with hypersplenism is also characteristic of advanced cirrhosis, hence thrombocytopenia is frequently encountered. Bleeding varices and gastritis in these patients are due not to DIC but to hepatic failure and portal hypertension.

Dilutional coagulopathy may cause diagnostic confusion with DIC or may coexist with DIC, but it does not cause DIC in the sense of a pathologic overproduction of thrombin. One working definition for dilutional coagulopathy is the result of infusion of blood, blood products, or crystalloid fluids infused at a volume to compensate for the loss of blood equal to the total blood volume of a patient within a 24-hour period. Because packed red cells, platelet concentrates, plasma, and crystalloid fluids, separately or together, are not equal to native blood in any respect, one must appreciate that any test, such as platelet count, PT, or PTT, cannot emulate the results of a stable patient. Troubles arise when one tries to make clinical decisions that are based on the results of static tests in the midst of a most dynamic emergency, using tests that were neither designed nor able to do this.⁶⁹

As are depicted in Table 12-6, the results of such basic coagulation tests cannot help the clinician to discriminate between DIC, dilutional coagulopathy, and severe hepatic failure. Regarding Table 12-6, assume that Case 1 represents a 55-year-old patient with severe alcoholic cirrhosis who is presently stable but has splenomegaly, ascites, jaundice, and severely deranged hepatic synthetic function. Case 2 could be considered a 40-year-old healthy woman

Table 12-5 Reasons Why Laboratory Findings are of Secondary Importance in the Diagnosis of Disseminated Intravascular Coagulation

- There is always an underlying problem that presents its own varied perturbations of many tests.
- Tests represent static "snapshots" of a highly dynamic situation.
- Special tests frequently are esoteric, and results arrive long after the dynamic situation has changed.
- Diagnostic test results rarely direct or redirect therapy and may confuse the clinical picture.

Table 12-6 Laboratory Testing is Limited in Discriminating Among Three Clinical Situations

	Case #1* Chronic, Stable, Severe Hepatic Insufficiency		Case #2* Dilutional Coagulopathy		Case #3* Disseminated Intravascular Coagulation	
	<i>Level</i>	<i>Score</i>	<i>Level</i>	<i>Score</i>	<i>Level</i>	<i>Score</i>
ISTH DIC TESTS						
Platelet count/ μ L	80,000	1	70,000	1	60,000	1
D-dimer, μ g/mL	2	2	2	2	3	2
PT, seconds prolonged	6	2	7	2	6	2
Fibrinogen, mg/dL	85	1	70	1	90	1

†These levels represent ranges typically encountered within such patient scenarios.

undergoing an elective hysterectomy during which ligation of an artery was incomplete and, because of postoperative hemorrhage, she became hypotensive, during which time she was resuscitated with 6 liters of saline, 6 units of FFP, and 6 units of blood. Consider the third case to be an example of classic DIC involving a healthy 47-year-old man with gallstones, who suddenly became febrile, septic, and hypotensive, and whose blood cultures subsequently grew out Gram-negative rods. Changes in the patient's clinical condition, whether or not blood or volume replacement was administered, were more important than changes in hemostatic test results.⁷⁰ Improvement seen on tests of a deteriorating patient is not as desirable as those noted in an improving patient with distorted laboratory tests. Dilutional coagulopathy is thoroughly discussed in Chapter 46, but it is mentioned here because of its association and confusion with DIC. They may coexist. In simple terms, two primary clinical situations may eventuate dilutional coagulopathy. The first is elective surgery in which unexpected massive hemorrhage (such as from a ruptured major artery or a ligature failure) results in massive blood and fluid infusion to the extent that it represents a rather pure form of dilutional coagulopathy. The second is the trauma patient who not only is experiencing severe hemorrhage, but also has multiple fractures or punctures of various organs with concomitant sepsis, hypovolemia, and shock with acidosis, which would represent dilutional coagulopathy coexisting with DIC. Indeed, it is the massive production of tissue factor and other cytokines within the trauma patient that initiates DIC, distinguishing that situation from the relatively controlled situation of events in an elective surgery patient. Both hypothermia and acidosis are appreciated as limiting physiologic coagulation (i.e.,

thrombin generation) and enhancing the fibrinolytic system, both of which may exacerbate clinical bleeding.⁷¹ Following therapeutic phereses in which volume is replaced with albumin administration, fibrinogen level, PT, and PTT, and platelet count due to this dilutional coagulopathy may be considerably altered, but microvascular hemorrhage is rarely encountered. Considerable surgical and critical care debate is ongoing regarding whether, when, and with what the massively injured trauma patient should be infused.⁷² As is discussed in Chapter 46, prompt exploration to minimize hemorrhage, thereby minimizing dilutional coagulopathy in the first place, is becoming the accepted trauma surgery standard.

Measurable decreases in plasma fibrinogen (typically elevated in pregnancy) and increases in serum FDP are found during the immediate postpartum period, even in uncomplicated deliveries. These measurable changes should be viewed not as pathologic but as physiologic. However, in an appropriate clinical setting such as massive hemorrhage, these changes may support a diagnosis of DIC.

The differential diagnosis of DIC may include the HELLP (Hemolysis, Elevated Liver function tests, and Low Platelets) syndrome, which is discussed thoroughly in Chapter 35.⁷³ Indeed, distinguishing among DIC, acute fatty liver of pregnancy, preeclampsia, eclampsia, massive thrombosis, thrombotic thrombocytopenic purpura (TTP), and the HELLP syndrome^{74,75} can present a challenge. Table 12-7 lists some differences among these presentations. Treatment for patients with the HELLP syndrome centers around delivery of the child and placenta as soon as is feasible. Delivery is timed closely with the obstetrician. If possible, waiting a few extra days will enhance

Table 12-7 Differential Diagnosis of Disseminated Intravascular Coagulation

Feature	Acute DIC (e.g., sepsis)	Chronic DIC (e.g., Trousseau syndrome)	Thrombotic Storm	HELLP	TTP	Primary Hyperfibrinolysis
Patient population	Patients with severe obstetric, medical, or surgical illness	Patients with cancer	Patients with hypercoagulability	Pregnant patients	Usually otherwise healthy	Prostate cancer, post CAB
Mechanism	Tissue damage and release of thromboplastins and cytokines	Tumor cell release of procoagulants or cell death	Uncontrolled hypercoagulability	Placental factors?	Platelet microthrombi	Direct plasminogen activation
Course Thrombosis*	Usually acute Usually microcirculation	Subacute/chronic Arteries, veins, and microcirculation	Subacute Multiple veins and arteries	Subacute Nil	Acute Microvascular	Acute Nil
Hemorrhage Coagulation parameters	Frequent Usually abnormal	Nil Usually normal	Nil Normal	Nil Normal	Microvascular Normal	Massive Abnormal
Platelet count	Low	Variable	Normal	Low	Low	Normal
Response to heparin	Nil	Fair	Good	NA	NA	NA
Response to warfarin after heparin	Nil	Nil	Good	NA	NA	NA
Prognosis with aggressive therapy	Good if underlying cause corrected	Poor	Good	Improved after delivery	Improved with plasma therapy	May be self limited; consider EACA
Hemolysis	Microangiopathic	Microangiopathic	None	Microangiopathic	Microangiopathic	None

DIC, disseminated intravascular coagulation; HELLP, Hemolysis, Elevated Liver function tests, and Low Platelets) syndrome; TTP, thrombotic thrombocytopenic purpura; CAB, coronary artery bypass; NA, not applicable; EACA, ε-aminocaproic acid.

*Without anticoagulant therapy.

the viability of the fetus, as this syndrome often comes to light at the beginning of the third trimester.⁷⁶ Paradoxically, the HELLP syndrome frequently deteriorates 2 to 4 days before or after delivery. One must be on guard at that time for the possibility of overt thrombosis. In fact, one can justify prophylactic administration of heparin immediately postpartum if the platelet count is not less than 20,000/ μ L. Distinguishing between the HELLP syndrome and DIC can be difficult or impossible, as it is clear that the HELLP syndrome can degenerate to DIC. Van Dam and colleagues⁷⁶ and De Boer and associates⁷⁷ studied this transition and found that laboratory manifestations heralding a worsening of the HELLP syndrome into probable DIC included progression of the PT and PTT from normal to abnormal, the progressive appearance of serum FDPs, and a decrease in the plasma ATIII level.

Although TTP (discussed in Chapter 24) is clearly a thrombotic process with major organ damage resulting from pathologic intravascular deposition of large aggregates of platelets, it is not regarded as representative of DIC. The PT, PTT, TT, and FDP level are nearly always normal. Microangiopathic hemolysis is a hallmark.

A thrombin-like enzyme, crotalase, found in the venom of the Eastern diamondback rattlesnake (*Crotalus adamantus*), partially clots fibrinogen.²⁵ However, it does not activate platelets or bind to ATIII, which distinguishes its actions from those of thrombin. Although laboratory findings after envenomation by the Eastern diamondback rattlesnake are highly reminiscent of DIC, neither thrombotic nor hemorrhagic complications usually occur.

It has been long known that there is an association between thromboembolic disease and carcinoma. If thromboembolism occurs as described by Trousseau over 100 years ago,⁷⁸ the process is appropriately known as Trousseau syndrome. The approximate two- to threefold incidence of bland deep venous thrombosis (DVT) found in patients with cancer is not usually regarded as Trousseau syndrome. Rather, Trousseau syndrome is a subset of the hypercoagulability associated with carcinoma and is recognized by specific characteristics (Table 12-8). Trousseau syndrome is now regarded as chronic DIC, as elaborated by Sack and colleagues.¹⁷ The syndrome is particularly associated with

adenocarcinoma, and frequently, the tumor is occult.⁷⁹ It is believed to be due to the release of procoagulant products from tumors, one of which is TF.^{79,80} Indeed, these authors showed an association between malignant tissue TF concentrations and hypercoagulability. The metastatic potential of a tumor may be related to TF expression in or on the malignant cells.^{79,81}

Many studies have been undertaken to find laboratory abnormalities that would be sensitive and specific enough to establish the diagnosis of Trousseau syndrome, but these variables have not gained much popularity because of their inherent variability. Situations such as Trousseau syndrome have been referred to as *chronic compensated DIC* by Mammen,⁶⁶ who observed that the simplest tests such as platelet count, PT, partial thromboplastin time (PTT), and fibrinogen level can yield results that are low, normal, or high. Typically, but not always, the ATIII level is decreased and the concentration of FDP increased in Trousseau syndrome.

Trousseau syndrome is recognized by its features, as listed in Table 12-8. A particularly useful diagnostic criterion is the recurrent nature of DVT, which is usually controlled by heparin but then recurs almost as soon as heparin therapy is withdrawn after initiation of warfarin therapy, regardless of the international normalized ratio (INR) achieved.⁷⁹ The vessels involved may be veins, particularly those in unusual places such as superficial veins in the thorax and abdomen, subclavian veins, and especially cerebral veins.^{82,83} Arterial thromboses also occur and may be sudden, catastrophic, life-threatening, or fatal.^{17,84} Therapy is challenging. Warfarin therapy fails.^{79,85} Heparin, often given in very large doses, is required to keep the PTT at target levels, or at least to maintain the heparin concentration at therapeutic levels, such as 0.3 to 0.8 U/mL, which can be achieved with large doses of standard unfractionated heparin, even on an outpatient basis. Some have resorted to continuous infusion of heparin to avoid peaks and troughs of heparin levels.⁸⁵ Whether LMWH is more efficacious than standard heparin in this situation is not certain.⁸⁶ However, if one does use LMWH, measurement of LMWH levels by anti-Xa activity to validate sufficient concentrations for long-term ambulatory therapy appears rational. At least one patient who developed heparin-induced thrombocytopenia was treated on a long-term basis with lepirudin.⁸⁷ The patient may succumb to uncontrolled venous and arterial thrombosis of Trousseau syndrome or to therapy, as metastases may hemorrhage. The thrombohemorrhagic syndrome is as lethal as the primary tumor.^{88,89} The prognosis is poor owing to the nature of the malignancy and its thrombohemorrhagic manifestations.^{84,86}

The fibrinolytic system may be activated independent of the coagulation system. Activation of the fibrinolytic system in the overwhelming majority of cases of DIC is the secondary physiologic result of thrombosis. In some circumstances, the fibrinolytic system may be activated in a primary fashion. The existence of primary hyperfibrinolysis has been debated for some time, and it probably does exist in select instances. In this situation, bleeding may be significant, but thrombosis is not a feature. Primary hyperfibrinolysis may result in some cases of carcinoma⁹⁰ or acute promyelocytic leukemia, as such cells may elaborate plasminogen activators.⁹¹ Late phases of cardiopulmonary bypass (rewarming) and orthotopic liver transplant

Table 12-8 Features of Trousseau Syndrome	
Clinical	
Recurrent migratory thrombophlebitis	
Unusual sites of thrombosis: axillary/subclavian veins; superficial veins of the neck, thorax, or abdomen; visceral or cerebral veins	
Failure to respond clinically to warfarin	
Usually respond clinically to heparin but may relapse immediately after discontinuation	
May simultaneously experience arterial thrombosis and hemorrhage	
Associated with nonbacterial thrombotic endocarditis	
Tumor typically small or occult adenocarcinoma	
Laboratory	
No laboratory test sensitive or specific	
Platelets and antithrombin III (ATIII) levels are usually decreased	
Red blood cells may show changes consistent with microangiopathic hemolysis	

(washout of the donor liver) also are associated with a brisk release of endogenous tPA, resulting in probably the most common cause of bleeding after cardiopulmonary bypass and liver transplantation.^{92,93} In keeping with this hypothesis, the use of antifibrinolytic agents is associated with decreased hemorrhage during such procedures. Obviously, infusion of pharmacologic plasminogen activators, such as streptokinase or tPA, causes a primary hyperfibrinolytic state. Hemorrhage may be brisk but often is self limited, especially after cardiovascular surgery or liver transplantation. Coagulation tests, which reflect the very low fibrinogen level and high level of FDP, include prolonged TT, PT, and PTT. Platelet count and ATIII level are normal or near normal, and microangiopathic hemolytic anemia is conspicuously absent. If the condition is not self limited and DIC (thrombosis) can be excluded, treatment with antifibrinolytic agents such as ε-aminocaproic acid (EACA) or tranexamic acid may be carefully attempted.

CONSEQUENCES OF DISSEMINATED INTRAVASCULAR COAGULATION

The consequences, often life-threatening or fatal, of DIC involve multiorgan failure, resulting in what is now called *multiorgan dysfunction syndrome* (MODS) (Table 12-9). At autopsy, target organs are found to be damaged and rendered ineffective by hemorrhage into the organ and thromboses. Both events tend to occur more often at the microcirculatory level than at the macrocirculatory level. Liver function test results may deteriorate at an alarming rate. This may be due not only to hemorrhage and infarction of the organ, but also to circulatory collapse with so-called shock liver. Clearly, preexisting liver disease makes this syndrome worse.²⁶ Because of the liver's key role in clearance of activated factors and its role in synthesis of hemostatic factors, sustained liver function is key to survival. Additionally, the liver has been shown to be central to the host's survival in sepsis.

Cardiac abnormalities are revealed by the appearance of elevated levels of serum cardiac enzymes, such as creatine kinase (CK), or cardiac rhythm disturbances due to destruction of the cardiac conduction system. Central nervous system abnormalities include seizures, mental status alterations, and behavioral abnormalities that may appear to be psychiatric in origin. Decreased renal function often occurs because of microinfarction of the filtering and collecting tubular apparatus. Usually, oliguria is the harbinger

of renal insufficiency and is quickly followed by elevation of serum creatinine and/or blood urea nitrogen (BUN). Adult respiratory distress syndrome (ARDS) is a very common and frequently lethal manifestation of sepsis with shock; it occurs most often in situations severe enough to result in DIC. Gastrointestinal manifestations appear chiefly as mucosal ulcerations with subsequent bleeding. Adrenal glands may infarct and then necrose, leaving the patient adrenally insufficient. Skin manifestations include petechiae from bleeding and infarctive necrosis, with the prime example being purpura fulminans (see Chapter 11). The onset of MODS, especially with progressive and sequential organ failure despite therapeutic efforts, accurately forecasts lethality.

A probable role of the von Willebrand factor cleaving protease (ADAMTS13) in DIC has recently been suggested. Low levels of plasma ADAMTS13 have been detected in patients with DIC. Crawley and colleagues^{96a} have demonstrated that plasmin and thrombin can proteolytically inactivate ADAMTS13. As both thrombin and plasmin circulate in DIC, it is plausible that ADAMTS13 reductions encountered in DIC are explained, at least in part, by these discoveries. Ono and colleagues^{96b} demonstrated that patients with DIC with plasma ADAMTS13 levels lower than 20% of normal were three times more likely to experience renal failure than patients with DIC with levels higher than 20% of normal. The finding of increased levels of unusually large von Willebrand factor multimers in patients with ADAMTS13 levels lower than 20% suggested a causal relationship with renal failure.

It is impossible to accurately predict lethality of DIC for two reasons. The first is that by its very definition, DIC may include a range of patients, from those who will have no immediate mortality (those with liver disease presenting with laboratory data mimicking DIC) to those who have long-range mortality (those with AAA or chronic DIC from neoplasia), to those with a relatively high acute mortality (those with acute leukemias, crush injuries, and shock), and finally, to those with exceedingly high mortality (those with septic shock or meningococcemia). Second, each initiating process is recognized and treated in a different fashion, and the overall approach to the patient and his or her morbidity hinges on those processes. The process of DIC is less important regarding lethality than are the host, the disease, and its treatment. Mant and King¹⁶ showed that 85% of patients with acute, severe DIC expired. Most expired, in their opinion, from the underlying disease and not from DIC itself. Wada and colleagues⁶⁵ showed that of 395 patients with DIC, a total of 25% died. Study patients comprised 154 with leukemia (of whom 21% died) and 241 who did not have leukemia but had cancer, sepsis, or other infectious diseases (of whom 28% died).

Predictors of death based on laboratory criteria are even more difficult to establish. Some have claimed that specific laboratory data did²¹ or did not⁶⁵ predict death. Of interest and seemingly paradoxically, higher plasma fibrinogen levels predicted a higher rate of MODS and eventual death. Higher fibrinogen levels connote higher levels of fibrinolytic inhibition (presumably from higher levels of PAI-1), resulting in more microinfarction-enhancing MODS.⁹⁴ The more often laboratory abnormalities manifest and the greater the degree of alteration that occurs, the more likely the patient is to expire. Additionally, hepatic insufficiency is as an effective

Table 12-9 Multiorgan Dysfunction Syndrome as a Consequence of Disseminated Intravascular Coagulation

Oliguria
Decreased renal function
Acute respiratory distress syndrome (ARDS)
Gastrointestinal tract mucosal ulceration with bleeding
Adrenal insufficiency
Purpura fulminans

predictor of mortality as is shock. At autopsy, many patients who die of DIC have ARDS and MODS. Multiple interrelationships exist between DIC, ARDS, MODS, and systemic inflammatory response syndrome (SIRS).⁹⁵ These may be separate factors that reveal a very ill patient with processes that are progressively killing the patient or, more likely, they may all be different manifestations of an evolving fatal process.^{21,27,66,95,96} From a clinical point of view, one may predict at least a 25% to 50% mortality rate if the presenting syndrome of a very ill patient is DIC, MODS, ARDS, or SIRS, and the patient fails to rapidly improve. The mortality rate is even higher if the presenting syndrome is conjoined by or progresses to include another of the DIC, MODS, SIRS, or ARDS consortium.

TREATMENT OF PATIENTS WITH DISSEMINATED INTRAVASCULAR COAGULATION

Because DIC is a grave consequence of a serious underlying disease, it would seem reasonable that primary treatment should be directed at control of that disease. Such has become increasingly accepted, although stating this fact is easier than accomplishing it. This approach is so successful that, when it can be accomplished, identification of DIC in a patient sanctions the use of aggressive therapy directed toward the primary process. The author knows of no clinical setting in which this is more successful than in a case of DIC that results from an obstetric emergency. Women may present in labor with massive bleeding and all the laboratory and clinical manifestations of DIC. The appropriate treatment is now recognized by obstetricians to be evacuation of the uterus. Time should not be spent in studying or trying to analyze in great depth the individual parameters of DIC; rather, the patient should be taken to the delivery suite, with resuscitation of blood pressure and volume by appropriate fluids, and the uterus evacuated. It is remarkable that a patient who is severely hemorrhaging can become hemostatically normal within a few hours of evacuation of the uterus. The success of this situation additionally underscores the marked restorative ability of an otherwise healthy person with normal hepatic function and a normal circulatory system to rectify these hemostatic abnormalities.

DIC may result from bacterial sepsis that occurs as a complication of an empyema, necrotic gallbladder, or

other abscess. Again, time should not be spent analyzing various patterns and parameters of laboratory data in attempts to stratify, stage, or correct the DIC; rather, this situation is a medical and surgical emergency, neither of which will get better until the abscess is drained. Too frequently, surgical colleagues request "correction of the coagulopathy" before the abscess is drained, when it is precisely drainage of the abscess that will lead to correction of the coagulopathy. It is far more likely that the patient will die from bleeding and/or thrombosis from the DIC while one vainly attempts to correct the DIC, rather than from the minimal amount of bleeding that may occur with prompt drainage of the abscess to which the DIC will respond.

Table 12-10 presents a treatment schema for DIC. First, treating the underlying cause is the mainstay of treatment for patients with DIC. Second, and almost equally important, is resuscitation of the patient's circulatory system. It would be difficult to overestimate the value of the liver in neutralizing activated coagulation products and reconstituting normal procoagulant and inhibitory proteins.⁹⁷ Hepatic circulation will not be maximal and hence correction of blood abnormalities will not be maximal until hepatic perfusion is normalized by correction of volume, electrolyte, pH, temperature, and blood pressure abnormalities. Failure to correct the initiating process and pre-existing hepatic hypoperfusion are harbingers of a bad outcome.

The role of fresh frozen plasma (FFP) and/or platelet transfusion appears to be simultaneously uncertain yet necessary. For thrombocytopenia to be a key potentiator of hemorrhage in patients, the platelet count is usually substantially below 50,000/ μ L. Similarly, if depletion of fibrinogen and other coagulation factors is to be clinically significant, levels must be below approximately 50 to 60 mg/dL and below 25% of normal levels, respectively. Otherwise, administration of fibrinogen, FFP, or platelet transfusions is not indicated because these perturbations are the result of DIC and not the cause of bleeding. However, if the patient is hemorrhaging and the platelet count is less than 50,000/ μ L, transfusing platelets to keep the platelet count in the range of 50,000 to 75,000/ μ L seems reasonable. Equally, in a patient who is bleeding with a fibrinogen concentration of less than 50 to 60 mg/dL, fibrinogen may be infused in the form of FFP or, preferably, cryoprecipitate in amounts needed to raise the fibrinogen level to that minimal level. Usually 10 "units" of

Table 12-10 Treatment of Disseminated Intravascular Coagulation

Treatment	Example	Rationale
Treat underlying cause	Abruptio placentae	Interrupt cause of DIC
Resuscitation	Maintain blood pressure, correct acid/base balance	Maximize blood flow from areas of activation to clearance by liver
Replacement	Fresh frozen plasma and platelet transfusions	Provide enough procoagulant materials to control hemostasis
Antithrombin III	Severe liver disease with concomitant DIC	Replace severely decreased levels of ATIII
Heparin therapy	Trousseau syndrome, purpura fulminans, abdominal aortic aneurysm	May decrease ongoing thrombosis
Antifibrinolytic therapy	Kasabach-Merritt syndrome, prostate cancer	Occasionally used to control fibrinolysis, but only after administration of heparin

DIC, disseminated intravascular coagulation; ATIII, antithrombin III.

cryoprecipitate (each containing about 200 mg of fibrinogen) will suffice. Rarely are other blood coagulation factor levels lower than 25% of normal; accordingly, FFP is rarely recommended for the replacement of other coagulation factors.

If ATIII is considered to be the primary inhibitor of circulating thrombin, it would seem that ATIII infusion would be efficacious in treating DIC. ATIII is available in FFP but has more recently become available as a purified concentrate. Infusion in DIC has not been rigorously established, but its use certainly is rational. In experimental models, ATIII infusions blunt lethality, DIC, and SIRS in response to infusion of lethal amounts of *E. coli*.⁹⁸ Preliminary studies^{99,100} have proved the safety and efficacy of ATIII concentrates, particularly in septic shock syndromes and in patients whose liver insufficiency is such that an acquired ATIII deficiency state exists. ATIII may be administered in amounts sufficient to support the ATIII level in the range of 100% of normal. This may be approximated by the infusion of 100 units of ATIII per kilogram of body weight. This formula is complicated by the variable and often brief half-life of ATIII in DIC. For clinical purposes, ATIII in otherwise normal patients has an overall half-life of approximately 24 hours; in DIC, it may be as brief as 3 or 4 hours. Should ATIII concentrates be employed, frequent measurement of ATIII levels is indicated to help regulate the infusion. At this time, infusion of ATIII concentrates generally is not recommended.¹⁰¹

Activated protein C infusion has shown some initial success in decreasing mortality in patients with severe sepsis¹⁰² and is discussed further in Chapter 13.

Direct thrombin inhibitors such as hirudin have the theoretical advantage of neutralizing thrombin, a key participant in DIC, while not acting as a direct anticoagulant. In preliminary human DIC studies, several laboratory markers improved, but overall survival was uncertain when this evolving treatment modality was used.¹⁰³

Heparin therapy remains extremely controversial. In some studies, the infusion of heparin has seemed to increase not only death, but particularly, hemorrhagic death.¹⁶ It is intellectually attractive to administer heparin to decrease thrombotic events; its use may be even more reasonable when the clinical axis of thrombosis versus hemorrhage is more toward the thrombotic end. Accordingly, its use in Trousseau syndrome has been established as not only rational but lifesaving.⁸⁸ It may also be useful in purpura fulminans, APL, and AAA, each of which represents a subacute thrombotic form of DIC. When heparin is used in situations in which coagulation test results are abnormal, one cannot monitor it with the usual coagulation tests, so it must be given empirically. One commonly recommended method is to administer approximately 8 to 10 U/kg of standard heparin per hour by constant intravenous infusion. In more chronic DIC such as Trousseau syndrome, one may monitor heparin administration by PTT or plasma heparin levels.

Antifibrinolytic inhibitors such as EACA are occasionally advocated in patients who are on the extreme hemorrhagic end of the thrombotic-hemorrhagic axis. Such agents are very effective in blocking fibrinolysis and therefore must be used with caution. Patients with massive fibrinolysis may be considered candidates for EACA therapy;

however, EACA should not be administered unless heparin has previously been infused to block the prothrombotic arm of DIC before the antifibrinolytic arm is blocked. A 4-g intravenous loading dose followed by 1 g every 2 hours intravenously for 24 hours may be tried. If bleeding does not decrease within 24 hours, it is unlikely to do so later.

Recombinant factor VIIa (discussed extensively in Chapter 27) has been used in select cases of DIC associated with obstetric emergencies,¹⁰⁴ malignancies,¹⁰⁵ and cerebral injuries.¹⁰⁶ Whereas thus far in these few cases, factor VIIa was administered after all other methods failed, the efficacy of factor VIIa seemed impressive, and the feared complication of thrombosis was not frequently reported. Further work is anticipated.

CONSULTATION CONSIDERATIONS

Patients who are consulted on usually fall into the following two groups: (1) those with rather typical severe acute DIC in which bleeding, hypotension, and organ failure generate the consultation; or (2) stable patients whose laboratory data make the referring practitioner consider the possibility of DIC.

Promptness in consultation is in order. Because of the great usefulness of readily available and inexpensive global tests such as PT, PTT, TT, FDP level, and complete blood count (CBC), it is strongly advisable that these tests should be repeated immediately in one's preparation to see the patient. One should insist that blood samples be drawn through a fresh venipuncture and not through intra-arterial or intravenous lines that may contain blood, saline, or heparin. Very frequently, one finds that a new, fresh, reliable set of data is of more use than a set that may have been obtained 1 or 2 days in the past, let alone any disinformation generated from an incorrectly obtained sample. The consultant should have an open dialogue with the coagulation laboratory technicians because discussion heightens the hematology technician's involvement in the patient's problem. The technician's expertise frequently generates data or observations not immediately available to the consultant that may be helpful. The laboratory technician may be the first to observe schistocytes on the blood smear, signifying microangiopathic hemolysis; vacuolization of white cells, signifying sepsis; or spontaneous lysis of a test tube clot, signifying high levels of plasmin activity.

During the consultation, one must think extremely broadly as an internist rather than just as a subspecialist—a comment justified by the extraordinarily broad range of differential diagnoses and initiating processes involved in DIC. The consultant may be the first to recognize petechiae on a febrile patient, thus securing a working diagnosis of meningococcemia and justifying rapid, aggressive antibiotic treatment, or the peripheral stigmata of chronic liver disease, which, heretofore not appreciated, would indicate that the patient's laboratory data are more consistent with chronic liver insufficiency than with acute DIC.

Should it be determined that an invasive procedure such as drainage of an abscess or evacuation of the uterus may be needed, the surgeon, obstetrician, or invasive radiologist must appreciate that the necessity of the procedure overrides concern regarding "coagulopathy," because the cure for the coagulopathy is the procedure itself.

COST CONTAINMENT ISSUES

Patients with DIC are typically so ill that they are usually cared for in an intensive care unit, so hospital costs are truly considerable. Blood replacement costs can escalate if one does elect to use large quantities of FFP or platelet transfusions. Blood products should be used in moderation, perhaps, as indicated earlier in this chapter, with the aim of keeping the platelet count higher than 25,000 to 50,000/ μ L and/or the fibrinogen level higher than 50 mg/dL with active bleeding. Most practitioners would not transfuse platelets or FFP unless such critical levels are reached; transfusion at levels above these cutoffs has not been shown to improve clinical outcomes.

Perhaps the most important area for cost containment in DIC is the use of the laboratory. The routine laboratory tests advocated in this chapter such as CBC, TT, PT, PTT, and FDP level are generally available and are useful to the clinician in making a diagnosis in the current clinical setting.^{67a} Their rapid turnaround and low cost justify their use. Select tests such as ATIII, D-dimer, and fibrinogen levels may be of intermittent use. Not only are most of the other tests that some have advocated extremely expensive, but also, because of their relative nonavailability, more often than not, test results are returned to the practitioner too late to be of clear use in daily bedside decision making.

MEDICAL-LEGAL CONSIDERATIONS

One might expect medical-legal concerns to arise periodically because DIC may be difficult to diagnose, it is typically associated with a wide variety of dire clinical circumstances, and it is known to have a high rate of mortality. On the other hand, no clear standards of care or practice guidelines have been established for the recognition or treatment of DIC. Physicians are held to practice in a manner consistent with good medical care and are required to approach the patient as any reasonable and prudent physician would do. As in any dire clinical situation, frank and open discussion with the patient and family is in order.

Potential areas of controversy include failure to obtain a sufficiently detailed history or physical examination, documentation of facts, and interpretation of the myriad of laboratory data. This may be another reason to limit laboratory data and focus on those tests that one is accustomed to ordering, reviewing, and interpreting. Treatment is sharply focused on the initiating cause of DIC; therefore, treatment for DIC itself would hardly be expected to be a standard of care issue, as it is anecdotal and controversial. It has not even been established whether one should use heparin, or how much FFP or platelet transfusion support patients require. Use of antifibrinolytics is extremely controversial, and one should probably not employ those agents unless heparin or some other antithrombotic agent is first administered.

The Cross-Talk of Inflammation and Coagulation in Infectious Disease and Their Roles in Disseminated Intravascular Coagulation

Eefje Jong, MD • Eric C.M. van Gorp, MD • Marcel Levi, MD • Hugo ten Cate, MD

Viral, bacterial, fungal, and parasitic infections may all cause disturbances in hemostasis, which can eventually lead to thrombohemorrhagic complications such as disseminated intravascular coagulation (DIC), hemolytic-uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), or even vasculitis. Symptoms and signs may be absent in cases of subclinical activation of the coagulation cascade, or they may be overt in cases of bleeding, thrombosis, or both.¹ None of the clinical signs and symptoms is pathogen specific, and in general, signs and symptoms depend on the severity of the infection and the response of the host. In this chapter, we discuss general aspects and pathogen-specific aspects of the cross-talk between coagulation and inflammation. We focus on the pathophysiology of Gram-negative sepsis as a prototypic model of an inflammation-coagulation-regulated syndrome. In addition, we discuss recently developed and clinically tested anticoagulants designed to intervene in DIC and sepsis.

DIC is associated with a high rate of mortality in both bacterial and nonbacterial disease; for this reason, the acronym has been referred to as “Death Is Coming.”^{2,3} According to criteria developed by the International Society for Thrombosis and Haemostasis (ISTH), DIC (see Chapter 12) is “an acquired syndrome characterised by the intravascular activation of coagulation with loss of localisation arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction.”⁴ One consequence of DIC may indeed be fibrinous occlusion of small and midsize vessels, contributing to multiorgan failure (MOF). Because of consumption of coagulation factors and activation of the fibrinolytic system, life-threatening hemorrhage may occur. The severity of bleeding ranges from localized oozing from arterial or venous puncture sites to more systemic complications, such as petechiae, purpura, ecchymosis, intestinal bleeding such as hemoptysis, or frank hematuria. Purpura fulminans is observed in the course of bacterial infection with meningococci and pneumococci, as well as in other bacterial and viral infections.⁵ The typical thrombohemorrhagic syndrome described by Waterhouse and Friderichsen in 1911 includes

fever, cyanosis, a purpuric rash, and circulatory collapse. Internal bleeding within organs may be confined and asymptomatic but can also cause systemic circulatory failure when localized in critical organs such as the adrenals.

Often, a patient with DIC has microvascular fibrin formation and bleeding at the same time, which hampers the clinician’s choice of appropriate treatment.^{2,6} Local thromboembolic disease, that is, deep venous thrombosis and pulmonary embolism, may theoretically occur in viral and bacterial infections, particularly in bedridden patients with comorbidity. In a thromboembolism prevention study of low-dose subcutaneous standard heparin for hospitalized patients with infectious diseases, morbidity due to thromboembolic disease was significantly reduced in the heparin group compared with the group that was given no prophylaxis. However, no beneficial effect of prophylaxis was noted on mortality due to thromboembolic complications.⁷

HUS and TTP are regarded as variants of a single syndrome characterized by thrombocytopenia, hemolytic anemia, fever, renal abnormalities, and neurologic disturbances. For a discussion of TTP and HUS, the reader is referred to Chapter 24. Vasculitis is characterized by local or more generalized vascular changes, resulting from ischemia caused by luminal occluding of thrombi of small blood vessels in the upper part of the dermis or bleeding due to local tissue damage (see Chapters 11 and 16).^{6,8}

GENERAL ASPECTS OF PRIMARY HEMOSTASIS, COAGULATION, AND FIBRINOLYSIS

The hemostatic mechanism consists of primary hemostasis and coagulation on the one hand, and natural anticoagulant mechanisms and fibrinolysis on the other hand. Under physiologic conditions, these mechanisms are balanced. The tissue factor (TF) pathway is considered to be the main route for activation of the coagulation cascade in sepsis. Initiating factors comprise the membrane-bound glycoprotein TF and plasma protein factor VIIa.^{9,10} TF is induced

by proinflammatory mediators, including cytokines, C-reactive protein, and advanced glycosylated end products in circulating blood cells and on microparticle fragments.^{11–13} On expression at the cell surface, TF interacts with factor VII in its zymogen or activated form, and the catalytic complex activates factors IX and X, resulting in the generation of thrombin and subsequently fibrin (Fig. 13-1).¹⁴ In contrast to current hypotheses, a recent study indicates that factor XII is not irrelevant for procoagulant activity because platelet-dependent thrombosis is reduced in factor XII-deficient mice.¹⁵ However, in patients with sepsis and other infections, a significant contribution of factor XII in generating fibrin has not yet been proved. A more prominent role of the kinin-kallikrein system relates to regulation of vascular tone and permeability, also through interactions with the complement system.¹⁶ In addition, factor XII is an activator of fibrinolysis, which also may be relevant in infectious disease, but not much is known yet about its particular functions.¹⁷

Coagulation is balanced by different inhibitory mechanisms. The first mechanism is made up of circulating inhibitors of blood coagulation (e.g., antithrombin III [ATIII], proteins C [PC] and S, and the TF pathway inhibitor [TFPI]). A second inhibitory mechanism consists of the glycocalyx-associated glycosaminoglycans such as heparan sulfate, endothelial protein C receptor (EPCR), and thrombomodulin (TM), all of which facilitate the inhibitory activity of ATIII and activated protein C (APC).¹⁸ The third mechanism, fibrinolysis, may be activated primarily and thus independently of activation of the coagulation cascade, or secondarily in response to fibrin formation. It is activated by tissue plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA) after their synthesis and release from the endothelial cell. These activators initiate the conversion of plasminogen to plasmin, which hydrolyzes polymerized fibrin strands into soluble fibrin degradation products. An important inhibitor of this

system is plasminogen activator inhibitor-1 (PAI-1). Severe infections result in an imbalance between primary hemostasis and coagulation with anticoagulant mechanisms and fibrinolysis, as is explained later.¹⁹ During these events, endothelial cells at the tissue–blood interface become of crucial importance.

ENDOTHELIAL ACTIVATION AND ITS EFFECTS ON COAGULATION DURING INFLAMMATION

Vascular endothelial cells play a central role in all mechanisms that contribute to inflammation-induced activation of coagulation. During acute infection, the endothelium is activated by pathogens or indirectly via inflammatory mediators, and the major regulatory antithrombotic properties become inactivated (Fig. 13-2).^{18,20,21} Proinflammatory cytokines, including interleukin (IL)-1,^{22,23} tumor necrosis factor (TNF)- α and IL-6,²⁴ induce TF within endothelial cells, which may be shed in part as soluble TF.²⁵ Shedding of soluble TF may perhaps explain why it has been difficult to detect endothelial TF by immunohistochemistry in animal studies.²⁶ The same proinflammatory cytokines appear to downregulate the anticoagulant receptors TM and EPCR, as well as cellular glycosaminoglycans.²⁷ Proteolytic cleavage of the receptors TM and EPCR may also occur owing to enzymes such as elastase, which are secreted by activated neutrophils. Soluble TF probably does not activate clotting,²⁸ and soluble TM may continue to function as a cofactor for activation of thrombin-activatable fibrinolysis inhibitor (TAFI), which would slow down fibrinolysis and worsen DIC.²⁹ Given interactions with inflammation (see later), it is also most likely that loss of TM and EPCR from the cell surface, such as has been demonstrated in the microvasculature of patients with sepsis,³⁰ leads to enhanced inflammatory

Figure 13-1 The core of the coagulation cascade related to fibrin formation and the three major natural anticoagulant pathways (dotted ovals).

Figure 13–2 Endothelial cell and infection. Under normal conditions, endothelial cells (EC) contain anticoagulant agents, such as thrombomodulin, heparan sulfate (HP), and plasminogen activator. Stimulation by pathogens and/or cytokines activates endothelial cells (EPCR, endothelial protein C receptor). Tissue factor (TF) and von Willebrand factor (VWF) are expressed. Subsequently, the coagulation cascade is activated through the TF pathway, as described in Figure 13-1. Furthermore, normal antithrombotic properties are lost, such as antithrombin III (ATIII), activated protein C (APC), and fibrinolysis. Activation of endothelial cells produces a procoagulant state.²⁹

responses in vivo. The net effect of these changes in endothelial cell function likely is of a procoagulant and proinflammatory nature.

TFPI is synthesized and stored in endothelial cells. However, no evidence suggests that depletion or dysfunction of TFPI occurs as part of an infectious disease such as sepsis, and its clinical role in inflammation and infection must be further substantiated.^{31–33}

Studies have shown that the PC system is critically important in inflammation and infection.^{34,35} On binding, thrombin TM catalyzes PC activation, and APC appears to be a modifer of inflammation, apoptosis, and wound healing,^{36–41} although its precise anti-inflammatory actions in vivo remain unclear.⁴²

The TM molecule has two properties that differentiate it from PC. First, the lectin-like domain of TM has direct anti-inflammatory properties in mice,⁴³ not only as an integral part of TM but also as a soluble molecule. Second, TM sequesters high-mobility group B-1 (HMGB-1), providing another anti-inflammatory defense mechanism.⁴⁴ EPCR, by its sequence homology with major histocompatibility complex class I (MHC I) CD1, may also play a role in inflammation, but details of this remain unknown.³⁴ Overexpression of EPCR enhances the level of APC in vivo; such mice are also protected against lipopolysaccharide (LPS).⁴⁵

ATIII directly mediates cellular responses through anti-inflammatory effects that are partly antagonized by heparin (which may explain why patients with sepsis given ATIII did worse in cases of heparin comedication).³⁴ In septic baboons, high doses of ATIII markedly attenuated proinflammatory activity.⁴⁶

Another important endothelial cell mechanism is provided by cellular protease activated receptors (PARs). These receptors are widely distributed among different cell types, but PAR-1 and PAR-2 are present on endothelial cells.^{47,48} Here, these receptors are linked to cell signaling functions that modulate endothelium-dependent relaxation and contraction, angiogenesis, vascular permeability, and expression of P-selectin, intercellular adhesion molecule (ICAM), and vascular cell adhesion molecule (VCAM) on stimulation. Phosphorylation of cellular proteins turns down the expression of the receptor, thus maintaining a regulated level of activity. Thrombin, trypsin, and

APC are agonists of PAR-1,^{47,48} and PAR-2 is activated mainly by factors Xa and VIIa (in competition with binding to TF, which also drives cell signaling functions).⁴⁹ A recent study comparing the kinetics of PAR-1 cleavage on endothelial cells by APC or thrombin indicates that APC can indeed cleave and activate PAR-1, but it is ≈ 104 -fold less potent than thrombin, and the concentrations required are substantially higher than endogenous APC concentrations in vivo.⁵⁰ From this perspective, thrombin seems the preferred agonist of PAR-1 on endothelial cells, potentially regulating a range of cellular functions.⁵¹ Specifically, the activated coagulation system, especially thrombin, can stimulate endothelial cells to express proinflammatory cytokines, such as IL-6, IL-8, and monocyte chemoattractant protein-1 (MCP-1).^{19,20} Endothelial cells are also able to express adhesion molecules and growth factors that may not only promote the inflammatory response but also increase the coagulation response. Interactions between platelets and endothelial cells, as well as between platelets and neutrophils, are important links in the onset of inflammation. In endothelial cells, the Weibel-Palade body secretes von Willebrand factor and P-selectin, which support platelet rolling. Inflamed endothelium supports leukocyte rolling, and activated platelets in contact with leukocytes and endothelial cells release a number of mediators of the inflammatory response.⁵² Such mediators include CD40-ligand, lipoxygenases, prostaglandins, and so forth.

Of potential procoagulant importance are microparticles that are released on activation and apoptosis of cells and that originate from virtually any blood cell.⁵³ These microparticles have shown procoagulant activity by carrying TF or other enzymes in a number of disease states, including meningococcal sepsis.¹³

COAGULATION AND INFLAMMATORY DISORDERS ASSOCIATED WITH VARIOUS PATHOGENS

Inflammatory Networks in Gram-Negative Sepsis

By definition, sepsis is a systemic inflammatory response syndrome that occurs in a patient with a documented or

highly suspected infection (based on culture or Gram stain and/or focus of infection).⁵⁴ Although nowadays, most cases of bacterial sepsis are due to Gram-positive microorganisms, most studies of the pathophysiology of infection in relation to coagulation have focused on Gram-negative bacteria. Gram-negative bacteria make and shed an endotoxin, an LPS component of the membrane, which is in large part responsible for the sepsis syndrome. Experimental models of live bacteria or purified LPS have been extensively applied in the study of the mechanisms of sepsis and of the patterns of release of cytokines, coagulation, and fibrinolytic proteins and peptides. Before addressing the relevant outcomes of such model studies, we briefly discuss here the mechanisms involved in Gram-negative sepsis in humans. More extensive reviews on this subject have been recently published.^{54–57}

Common Gram-negative bacteria that cause septic shock include opportunistic normal flora of the intestines or genitourinary system such as *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, and *Proteus* species. Other opportunistic Gram-negative pathogens are *Neisseria* species and *Pseudomonas aeruginosa*.^{58,59}

Endotoxin plays a pivotal role in development of the sepsis syndrome.^{60,61} It can be detected in the blood of patients with Gram-negative sepsis, although this remains technically challenging. In some cases, such as meningococemia, but also in more “common” infections, a reasonable correlation between plasma levels of endotoxin and outcomes has been described.^{62,63}

The introduction of Gram-negative bacteria and LPS into the bloodstream induces a host response through binding of LPS to LPS-binding protein (LBP) that is interacting with the opsonic receptor CD14, which exists in membrane-bound and soluble forms. Cells that do not express CD14 may respond to LPS through the soluble CD14 molecule.⁵⁵ The LPS–CD14 complex triggers one of the family of Toll-like receptors (TLRs), of which TLR-4 is most relevant for inducing an array of host response effects. The innate immune response includes the release of inflammation-modulating cytokines (e.g., IL-1, IL-6, IL-8, TNF- α , interferon- β , and IL-10) from activated monocytes and macrophages.

In general, the host response serves to counteract infection; thus, an adequate initial proinflammatory response is critical in combating all infections. Indeed, attempts to counteract specific proinflammatory cytokines such as IL-1 or TNF- α (pneumonia, peritonitis) have been generally disappointing in clinical trials.^{57,64} During the recovery phase, anti-inflammatory cytokines are important in limiting inflammatory damage to the host. Hence, the balance between proinflammatory and anti-inflammatory response signals (including cytokine release) is critical to the clinical outcomes of patients with infection.

In sepsis, the early cytokine storm appears within 30 to 90 minutes after LPS exposure. The next phase consists of activation of neutrophils and nitrous oxide, further cytokine release, and the formation of kinins, complement products, and lipid mediators,^{55,57} and the tissue response to infection is initiated by the expression of cellular adhesion molecules. An increase in HMGB-1 appears about 24 hours after LPS stimulation and is considered an important “late” mediator of severe sepsis but not of septic shock.⁶⁵ This notion raises another important issue, that is, the

difference in immunology between sepsis and septic shock.⁵⁴ Sepsis follows a protracted course over several days, and HMGB-1 may have a profound impact on its pathogenesis, contributing to epithelial cell barrier dysfunction and acute cardiac arrest, but without overt pathologic sequelae. In contrast, septic shock is the typical picture dominated by TNF- α , with features of hemorrhagic necrosis in the bowel, inflammation in the kidneys and lungs, and adrenal necrosis. Serum concentrations of TNF- α and HMGB-1 may help to distinguish these features.

Early Events in Sepsis in Relation to Blood Coagulation: LPS Studies

The above scenario of inflammatory response to sepsis is important in appreciating the effects on blood coagulation, which is an evolutionary conserved element of the innate immune system.³⁴ This means that in cases of invading organisms, whether these are bacteria or viruses, an immediate coagulation response occurs that should assist in limiting morbidity.

Early events after infection are probably mimicked well by the infusion of LPS in volunteers or animals, particularly primates. A single dose of 2 to 4 ng/kg LPS elicits a symptomatic inflammatory and an asymptomatic procoagulant response, the latter characterized by immediate generation of TF mRNA in blood leukocytes (likely mononuclear cells)⁶⁶ and exposure of TF to trigger factor (F) X conversion to Xa.⁶⁷ Early rises in TNF- α and IL-6 occur at between 30 and 90 minutes, and the early procoagulant response, including generation of FXa, follows the same time course. This phase is followed by a slower, more sustained generation of thrombin, indicated by a rise in prothrombin fragments 1 and 2 (F1+2) and thrombin: ATIII (TAT) complexes in plasma, with a peak at 4 to 6 hours after LPS. A fibrinolytic response also follows a biphasic course, with an early rise in tPA and a subsequent rise in PAI-1, which shuts off fibrinolytic activity in blood. The net result of these reactions contributes to DIC in patients with sepsis.⁶⁸ Studies by Taylor and colleagues⁶⁹ have further indicated that after a single LPS injection, a sustained response reflecting neutrophil activation (elastase release) and damage of other cell types follows, indicated by increases in soluble fibrin, soluble TM, and soluble TF, and even a rise in lactate that reflects microvascular perturbation during a 48-hour period.⁶⁹

Early and Late Effects Merge in Models of Sepsis and DIC

Animal models have been used to study the kinetics of early hyperinflammatory responses in humans and primates challenged with LPS. To mimic sepsis in a disease-like way, other models are required that more thoroughly reflect the condition wherein bacteria remain present in the circulation for a longer time, or a disease process remains active (such as in models of cecal ligation and puncture, peritonitis, local infection, etc.). Here, we focus on the sepsis model in baboons because this model has been fundamental in the development of the inhibitors APC, TFPI, and ATIII for testing in clinical trials.

In the model originally developed by Hinshaw,⁷⁰ live *E. coli* are injected intravenously, targeting reversible

(sublethal) or irreversible (lethal) sepsis in a dose-dependent way. In sublethal concentrations, four stages can be distinguished: an inflammatory stage (0–2 hours), a coagulopathic stage (2–6 hours), a cell injury stage (6–10 hours), and a cell degeneration stage (>10 hours).⁷¹ In a lethal (LD100) inoculation of *E. coli*, the four phases tend to merge in an overwhelming sepsis.

In the baboon model, inhibitors of the TF system (TFPI, anti-TF, FVIIai), PC, and APC, as well as ATIII, each successfully prevented death from sepsis associated with a marked attenuation of systemic inflammation and coagulopathy.^{72–74} These studies were fundamental in elucidating the concept that coagulation and its inhibitors are of major importance in coagulation-inflammation cross-talk, as well as in survival from sepsis. Although the limited clinical efficacy of APC appears to support the animal data, other major phase 3 trials with TFPI and ATIII have been disappointing (see later). These negative clinical data also cast doubt on the value of primate models in the study of human sepsis; however, these doubts should not diminish the importance of the fundamental pathways and interactions that have emerged from these animal studies. As outlined by Esmon,⁷⁵ a variety of factors differentiate sepsis models in primates from patients with sepsis; the absence of underlying morbidity or comorbidity may be one of the most relevant differences. Although healthy baboons behave similarly to healthy volunteers in showing a hyper-immune response to bacterial challenge, patients often are older with a number of significant comorbid conditions like diabetes, heart failure, and atherosclerosis that may alter the inflammatory response. Another major difference concerns the timing of the intervention in the disease process. Anticoagulant agents with potential anti-inflammatory effects (like APC, ATIII, and TFPI) may benefit patients only during a particular phase of the disease and may even harm those whose inflammatory system should not be impaired.

In this regard, it is also fundamentally important to recognize the fact that many, if not all, coagulation enzymes and inhibitors have a number of often counteracting properties, for instance, thrombin is a potent anticoagulant under normal conditions but also is the most powerful procoagulant in thrombosis. These considerations are vital in a determination of the appropriate timing of interventions in the individual patient; however, at this time, proper laboratory predictors for guiding individual treatment are not available.

GRAM-POSITIVE BACTERIA

The role of Gram-positive bacterial pathogens in the pathogenesis of sepsis has received little attention because these organisms were believed to be quantitatively less important than Gram-negative bacteria. However, recent data indicate that Gram-positive pathogens are increasing in prevalence in septic patients.^{54,76–78} Common Gram-positive bacteria that may cause septic shock include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Enterococcus* species that make up the normal flora of the intestines, and *Streptococcus pyogenes*. These organisms arise from skin, wounds, or soft tissue structures and catheter sites rather than from enteric or genitourinary sites.

One of the fundamental differences between Gram-positive and Gram-negative bacteria is the way in which they initiate disease. Endotoxin, the *sine qua non* of Gram-negative bacteria, is not present in Gram-positive bacteria, although the cell wall contains specific components that are able to mimic some of the properties of endotoxin-inducing proinflammatory cytokines from mononuclear cells.⁷⁹ It is important to note that Gram-positive bacteria produce exotoxins. Some toxins act locally to help bacteria survive by killing nearby white blood cells. Other toxins help organisms to disseminate in host tissues by degrading the proteins of the connective tissue matrix. Still other toxins diffuse far from the site where they are synthesized.⁸⁰

The mode of action of exotoxin from the clostridial species (gas gangrene, antibiotic-associated colitis), diphtheria (*Corynebacterium diphtheriae*), food poisoning (*Bacillus cereus*, *S. aureus*), and anthrax (*Bacillus anthracis*) is highly specific and well understood. For Gram-positive bacteria associated with septic shock, however, toxins of a different type seem to be involved. Cases of menstruation-associated staphylococcal infection in healthy women (the staphylococcal toxic shock syndrome) were associated with the production of toxic shock syndrome toxin-1, a so-called superantigen.^{81,82} Superantigens do not require previous processing and highly specific presentation by antigen-presenting cells. They are able to activate more lymphocytes than conventionally processed antigens. The peak response to these cytokines occurs 50 to 75 hours after the challenge, in contrast to the 1- to 5-hour response to endotoxin.⁸³

Staphylococcal infections usually are localized infections like an abscess, as occurs in furuncles. If the staphylococci spread to the subcutaneous and submucosal tissue, cellulitis may develop. If bacteria sustain the host immune response, they may cause metastatic abscesses in highly vascularized organs like bones, lungs, and kidneys. More severe staphylococcal infections are associated with the production of superantigens. These superantigens may cause purpura fulminans and DIC⁸⁴; a possible mechanism involves the induction of spontaneous platelet aggregation by staphylococcal peptidoglycan.⁸⁵ Only rare cases of HUS or TTP associated with staphylococcal infection have been described.⁸⁶

In infection with *S. pneumoniae*, the main virulence factor and principal antigen is a capsular polysaccharide rather than an exotoxin. The classic manifestation is pneumococcal pneumonia in which bacteremia can be shown in 25% of patients and is indicative of more severe illness. DIC and purpura fulminans have been described in a few case reports.⁸⁷ Certain other respiratory pathogens, especially *Haemophilus influenzae* type b and *Klebsiella pneumoniae*, also have similar polysaccharide capsular antigens and do not produce exotoxins. Activation of inflammation and coagulation by these organisms also appears to occur through the CD14 mechanism, but less is known about the signal transduction pathways.⁸³ The tempo of cytokine response is much slower than in Gram-negative infection.⁸⁸

Leptospirosis, especially in those with Weil syndrome, may present with hemoptysis, epistaxis, intestinal bleeding, adrenal hemorrhage, hematuria, and even subarachnoid hemorrhage.⁸⁹ The pathogenesis may be primary activation of coagulation or diffuse vasculitis, resulting in bleeding or ischemia of the vascularized tissue.^{90,91} TTP, with bleeding

as the presenting symptom, may also occur in the course of Weil syndrome.⁹²

VIRAL INFECTIONS

Viruses may influence the coagulation system in various ways; one general route of entry for a number of viruses may be provided by invasion of endothelial cells. This has been shown to occur for herpes simplex virus (HSV),^{24,93} adenovirus, (para-)influenzavirus, poliovirus, echovirus, measles virus, mumps virus, cytomegalovirus (CMV),^{94–98} and human immunodeficiency virus (HIV). Infection of endothelial cells has also been shown for hemorrhagic fever (HF) caused by dengue, Marburg, Ebola, Hantaan, and Lassa HF viruses, which increases the possibility that hemorrhage occurs as the result of endothelial cell activation and enhanced permeation to blood cells, particularly in combination with thrombocytopenia. A procoagulant response may be caused by increased expression of TF and secretion of PAI-1.

Severe coagulation disorders occur in HF.¹ Among the viral HFs, dengue,^{90–92} Marburg,^{99,100} and Ebola^{101–103} are the most prominent, and dengue is the most prevalent. Dengue fever (DF) is a self-limited, non-specific illness characterized by fever, headache, myalgia, and constitutional symptoms caused by the dengue virus (serotypes 1–4). The cardinal feature that differentiates dengue hemorrhagic fever (DHF) from DF is not hemorrhage but increased vascular permeability that results from capillary leakage.^{104–106} The underlying mechanisms responsible for bleeding in dengue infection remain poorly understood. Thrombocytopenia is universal in DHF. Platelet function is abnormal with impaired platelet aggregation. Through the capillary leak, plasma levels of coagulation proteins are decreased. Some evidence suggests specific activation of the endothelial cells by dengue virus, which liberates TF, PAI-1, and TM.^{107,108} Dengue virus isolates can bind to and activate plasminogen directly and activate fibrinolysis.¹⁰⁹ The plasmin generated can specifically degrade both fibrin and fibrinogen. A possible scenario for the coagulation disorders associated with dengue infection may be that dengue virus primarily activates fibrinolysis in the absence of a thrombotic stimulus, degrading fibrinogen directly and prompting secondary activation of various procoagulant mechanisms. Bleeding in patients with dengue infection may result from a combination of thrombocytopenia, dysfunctional platelets, and increased fibrinolysis.¹⁰⁸ DIC is not frequently encountered in other viral infections but has been found in cases of rotavirus,^{110,111} varicella,^{112,113} rubella, rubeola, and influenza infections.^{113–118}

HIV is associated with both venous and arterial disease.¹¹⁹ In epidemiologic studies on the occurrence of venous thrombotic disease in HIV-infected patients, the overall risk of venous thrombotic disease may be roughly 2- to 10-fold higher in comparison with a healthy population of similar age. Important risk factors for the development of venous thrombosis in these patients could be severity of HIV infection and the therapeutic introduction of protease inhibitors. Changes in procoagulant and anticoagulant factors, including acquired defects in ATIII and the protein C and S systems, may contribute to a

hypercoagulable state in blood and may explain the apparently increased risk of venous thrombotic disease. Infection with HIV leads to activation of endothelial cells and subsequent expression of TF. Another triggering factor of the coagulation cascade in patients with HIV could be stimulation of microvesicles, small cellular remnants originating from platelets, endothelial cells, and CD4 lymphocytes.^{120–129} DIC is only sporadically associated with HIV. HIV infection may also be accompanied by vasculitis syndromes such as polyarteritis nodosa, Henoch-Schönlein purpura, and leukocytoclastic vasculitis.^{130–136} Thrombotic microangiopathy, for example, TTP and HUS, has been described in HIV infection.^{137–139} Bleeding disorders may occur as the result of thrombocytopenia, a common hematologic complication of HIV infection. The most common cause is now known to be immune thrombocytopenic purpura (ITP).¹⁴⁰ Decreased production owing to megakaryocyte infection is also suggested, as is marrow infiltration by infectious organisms or neoplasms.¹⁴¹ Adverse drug effects may cause impaired platelet function and thrombocytopenia.¹⁴² The hemophagocytic syndrome is an uncommon complication of HIV infection.^{143–145}

Vasculitis is well documented in CMV infection,^{146,147} occurring predominantly in the vasculature of the gastrointestinal tract where it causes colitis,^{148,149} the central nervous system where it causes cerebral infarction,^{150,151} and the skin where it results in petechiae, papular purpura, localized ulcers, or a diffuse maculopapular eruption.^{1,152} Hepatitis B and C infections may cause polyarteritis-like vasculitis.^{153–155} Parvovirus B19 has been suggested to be associated with vasculitis-like syndromes, including Kawasaki disease, polyarteritis nodosa, and Wegener granulomatosis.^{156–158} These associations are also discussed in Chapter 11.

FUNGAL AND PARASITIC INFECTIONS

Data on fungal and parasitic infections are scarce and are limited to smaller studies and case reports. Fungal infections such as systemic candidiasis or aspergillosis are a common major clinical complication in immunocompromised patients and may lead to DIC and the development of MOF.^{159,160} The mechanism of activation of the coagulation cascade works through a complex network of proinflammatory and anti-inflammatory cytokines, resulting in deficiencies of ATIII, PC and protein S (PS), and TFPI. Additional inhibition of the fibrinolytic system by elevated plasma concentrations of PAI-1 ultimately may lead to DIC and the development of MOF. Subsequent depletion of clotting factors and platelets also can result in severe hemorrhage.^{161–165} *Candida albicans*-derived substances lead to arteritis in an animal model of coronary arteritis.¹⁶⁶

DIC is seen in less than 5% of patients with severe falciparum malaria.¹⁶⁷ It tends to occur more commonly in patients with cerebral malaria, pregnancy, and secondary bacterial infection. DIC may aggravate the other complications of malaria, including cerebral malaria, renal failure, pulmonary edema, and hemorrhage, and predicts a worse outcome.^{168–170}

The presence of low-grade DIC has been described in patients with advanced hepatosplenic schistosomiasis and trypanosomiasis.^{171,172}

TREATMENT OF PATIENTS WITH DISSEMINATED INTRAVASCULAR COAGULATION AND INFECTION

The cornerstone in the treatment of patients with hemostatic abnormalities and severe infection, such as sepsis, is the specific use of appropriate antibiotics and control of the infectious source. However, in many cases, additional supportive treatment, aimed at circulatory and respiratory support and replacement of organ function, is required. Coagulation abnormalities may proceed, even after proper treatment has been initiated. In those cases, supportive measures taken to manage the coagulation disorder may be considered and may positively affect morbidity and mortality.¹⁷³ Increased insight into the various mechanisms that play roles in the coagulation abnormalities associated with infection has indeed been helpful in the development of such supportive management strategies.

Plasma and Platelet Substitution Therapy

Low levels of platelets and coagulation factors may increase the risk of bleeding. However, plasma or platelet substitution therapy should not be instituted on the basis of laboratory results alone; it is indicated only in patients with active bleeding and in those requiring an invasive procedure or otherwise at risk for bleeding complications.¹⁷⁴ The suggestion that administration of blood components might “add fuel to the fire” has in fact never been proved in clinical or experimental studies. The presumed efficacy of treatment with plasma, fibrinogen, cryoprecipitate, or platelets is not based on randomized controlled trials but appears to represent rational therapy in bleeding patients or in those at risk for bleeding with a significant depletion of these hemostatic factors.¹⁷⁵ It may be necessary to use large volumes of plasma to improve the coagulation defect. Coagulation factor concentrates, such as prothrombin complex concentrate, may overcome this obstacle, but these compounds may lack essential factors, such as factor V. Moreover, in the older literature, caution is advocated with the use of prothrombin complex concentrates in DIC because these may worsen coagulopathy through traces of activated factors in the concentrate. It is, however, not clear whether this is relevant for the concentrates that are currently in use. Specific deficiencies in coagulation factors may be corrected by administration of purified coagulation factor concentrates or, in the case of fibrinogen, cryoprecipitate.

Anticoagulants

Experimental studies have shown that heparin can at least partially inhibit the activation of coagulation in sepsis.¹⁷⁶ Uncontrolled case series in patients with sepsis and DIC have claimed to be successful. However, a beneficial effect of heparin on clinically important outcome events in patients with DIC has never been demonstrated in controlled clinical trials.¹⁷⁷ Also, the safety of heparin treatment is debatable in patients with DIC, who are prone to bleeding. Therapeutic doses of heparin are rational in patients with clinically overt thromboembolism or extensive fibrin deposition, as occurs in purpura fulminans or

acral ischemia. Patients with sepsis may benefit from prophylaxis to prevent venous thromboembolism, which may not be achieved with standard low-dose subcutaneous heparin.¹⁷⁸ Theoretically, the most logical anticoagulant agent for use in DIC is directed against TF activity. Potential agents include recombinant TFPI, active site-inhibited factor VIIa, and recombinant NAPc2, a potent and specific inhibitor of the ternary complex between tissue factor/factor VIIa and factor Xa.¹⁷⁹ Phase 2 trials of recombinant TFPI in patients with sepsis showed promising results,¹⁸⁰ but a recently completed phase 3 trial did not show an overall survival benefit in patients who were treated with TFPI.¹⁸¹ It is interesting to note that in an a priori defined subgroup of patients with an international normalized ratio (INR) <1.2, TFPI treatment was associated with more favorable outcomes.

Restoration of Anticoagulant Pathways

In view of the deficient state of physiologic anticoagulant pathways in patients with sepsis, restoration of these inhibitors may offer a rational approach.¹⁸² Because ATIII is one of the most important physiologic inhibitors of coagulation, and because preclinical results have been successful, the use of ATIII concentrates in patients with DIC has been studied relatively intensively. Most randomized, controlled trials consisted of patients with sepsis, septic shock, or both. All trials showed some beneficial effect in terms of improved laboratory parameters, shortening of the duration of DIC, or even improvement in organ function.¹⁸³ In more recent clinical trials, very high doses of ATIII concentrate were used to attain supraphysiologic plasma levels. A series of relatively small trials showed a modest reduction in mortality in ATIII-treated patients^{184–186}; however, this effect did not reach statistical significance in any of the trials. A large-scale, multicenter, randomized controlled trial conducted to directly address this issue showed no significant reduction in the mortality of patients with sepsis who were treated with ATIII concentrate.¹⁸⁷ It is interesting to note that post hoc subgroup analyses revealed some benefit in patients who did not receive concomitant heparin, but this observation needs prospective validation.

On the basis of the notion that depression of the protein C system may significantly contribute to the pathophysiology of DIC, supplementation of APC might be beneficial.¹⁸⁸ A beneficial effect of recombinant human APC was shown in two randomized controlled trials. First, in a dose-ranging clinical trial, 131 patients with sepsis were enrolled.¹⁸⁹ Included patients received APC by continuous infusion at doses ranging from 12 µg/kg/hr to 30 µg/kg/hr, or they were given placebo. In accordance with D-dimer plasma levels, the optimal dose of recombinant human APC was determined to be 24 µg/kg/hr. A clear trend toward lower mortality was noted in patients who received higher doses of APC. In these patients, a 40% reduction in relative risk of mortality was shown, although this was not statistically significant (because of the size of the trial). The potential benefit of APC was shown for duration of mechanical ventilation, shock, and length of intensive care unit (ICU) stay, as well as for days free of systemic inflammatory response. A subsequent phase 3 trial of APC concentrate in patients with sepsis was prematurely stopped

because of its efficacy in reducing mortality in these patients.¹⁹⁰ All-cause mortality at 28 days after inclusion was 24.7% in the APC group versus 30.8% in the control group (19.4% relative risk reduction). Administration of APC was shown to cause amelioration of coagulation abnormalities; APC-treated patients also had less organ failure.¹⁹¹ In view of the previously described effects that APC has on inflammation, part of the success may have been caused by a beneficial effect on inflammatory pathways.¹⁹²

A recent analysis of this trial showed that patients who met criteria for DIC, according to the DIC scoring system of the ISTH, received a relatively greater benefit with APC treatment than did patients who did not have overt DIC.¹⁹³ Relative risk reduction in mortality of patients with sepsis and DIC who received APC was 38%, in comparison with a relative risk reduction of 18% in patients with sepsis who did not have DIC. This seems to underscore the importance of the coagulation derangement in the pathogenesis of sepsis and the point of impact that restoration of microvascular anticoagulant pathways may provide in the treatment of sepsis. Recombinant human APC has been licensed in most countries for the treatment of patients with severe sepsis and two or more failing organs. The most frequently encountered adverse effect of APC is bleeding. In a phase 3 study conducted in patients with severe sepsis, the incidence of major bleeding (i.e., bleeding reported as a serious adverse event) during the infusion period was 2.4% in the APC group as compared with 1.0% in the control group ($P = .02$).¹⁹⁰ During the 28-day study period, the incidence of major bleeding was 3.5% in the APC group and 2.0% in the placebo group ($P = .06$). Gastrointestinal bleeding was the most frequent bleeding complication in both groups. Most bleeding episodes were procedure related or occurred in patients with a severely deranged coagulation system (partial thromboplastin time [PTT] > 120 sec or INR > 3.0), whereas spontaneous bleeding was rare. Of note, severe thrombocytopenia (i.e., platelet count <50,000/ μ L) was an exclusion criterion for the trial, but patients with lower platelet counts appeared to benefit more from the administration of APC compared with patients with higher platelet counts. Ongoing studies focus on the concomitant use of heparin in patients given APC and the efficacy of APC in patients with less severe sepsis. Recent data indicate that recombinant APC in patients with severe sepsis but with a low risk of dying (APACHE [Acute Physiology And Chronic Health Evaluation] score <25 or single organ failure) provides no survival benefit over placebo but increases the risk of serious bleeding.¹⁹⁴ Therefore, APC should be considered only in patients with severe sepsis who are also at increased risk of death.

Part III

Thrombotic Processes

Thrombophilia: Clinical and Laboratory Assessment and Management

John A. Heit, MD

INTRODUCTION

Symptomatic thrombosis is due to dysregulation of the normal hemostatic response to vessel wall “injury” that occurs with exposure to a clinical risk factor (e.g., surgery, trauma, inflammation, hospitalization for acute medical illness). Vessel wall injury may be anatomic (e.g., venous endothelial microtears within vein valve cusps due to stasis, rupture of a lipid-rich atherosclerotic plaque)^{1–3} or “nonanatomic” (e.g., cytokine-mediated endothelial expression of adhesion molecules, downregulation of thrombomodulin expression, related to the “acute inflammatory response”).^{4,5} However, the vast majority of individuals who are exposed to a clinical risk factor do not develop symptomatic thrombosis. We now recognize that clinical thrombosis is a multifactorial (complex) disease that becomes manifest when a person with an underlying predisposition to thrombosis (e.g., a thrombophilia) is exposed to additional risk factors. Emerging evidence suggests that individual variation in the regulation of the procoagulant, anticoagulant, fibrinolytic, and acute inflammation/innate immunity pathways likely accounts for those exposed individuals who actually develop clinical thrombosis.

Thrombophilia is defined as a predisposition or susceptibility to thrombosis. Thrombophilia is not a disease per se, but it may be associated with a disease (e.g., cancer), drug exposure (e.g., oral contraceptives), or a medical condition (e.g., pregnancy, postpartum; “acquired thrombophilia”; Table 14-1); thrombophilia may also be inherited (Table 14-2). This concept is important because disease susceptibility does not imply an absolute requirement for primary or secondary prevention, or for treatment. Most persons with a thrombophilia do not develop thrombosis. Thus, a thrombophilia must be considered in the context of other risk factors for incident thrombosis or predictors of recurrent thrombosis when the need for primary or secondary prophylaxis, respectively, is estimated. With rare exceptions, therapy for acute thrombosis is no different for those with versus those without a recognized thrombophilia.

Thrombophilia may manifest clinically as one or more of several thrombotic disorders (“phenotypes”; Table 14-3). The predominant clinical manifestation of thrombophilia is venous thromboembolism (VTE), the chief components of which are deep vein thrombosis (DVT) and pulmonary embolism (PE).^{6,7} Consequently, this chapter focuses on the role of thrombophilia in VTE. In particular, this chapter describes recent comprehensive studies of the epidemiology

of VTE that reported racial demography and included the full spectrum of disease that occurred within a well-defined geographic area over time, separated by event type, incident versus recurrent event, and level of diagnostic certainty, as well as studies of VTE recurrence that included a relevant duration of follow-up.

Thrombophilia may also rarely present as purpura fulminans (i.e., neonatalis or adult)⁸ or as warfarin-induced skin necrosis.^{9–12} Although it is biologically plausible to hypothesize that patients with atherosclerotic arterial occlusive disease and an underlying thrombophilia who experience an atherosclerotic plaque rupture are more likely to develop a symptomatic thrombosis,¹³ most clinical studies have failed to show a consistent association between thrombophilia and myocardial infarction or stroke.^{14–19} Thrombophilia may also manifest as (recurrent) fetal loss,^{20–23} and possibly as stillbirth and complications of pregnancy^{24,25} (e.g., intra-uterine growth restriction,^{26,27} severe preeclampsia,²⁸ abruptio placentae) (see Chapter 36).

Unfortunately, no single laboratory assay or simple set of assays will identify all thrombophilias. Consequently, a battery of complex and potentially expensive assays is usually required. Many of these laboratory analytes are affected by other conditions (e.g., warfarin reduces protein C and S levels) such that the correct interpretation of results may be complicated and always requires clinical correlation. This chapter addresses several fundamental questions that all clinicians must answer when faced with the task of assessing a person or a patient for a possible thrombophilia. In addition, this chapter addresses how the results of such testing should be interpreted, and how results might alter primary prophylaxis, acute therapy, or secondary prevention of thrombosis. Detailed descriptions of the known thrombophilias are appended, including information on special coagulation laboratory interpretation. Most likely, several thrombophilic disorders have yet to be discovered.

INDICATIONS FOR THROMBOPHILIA TESTING: WHY SHOULD I TEST FOR THROMBOPHILIA?

No absolute indications for clinical diagnostic thrombophilia testing have been determined. Potential relative indications may include general population screening, selected screening of populations that are potentially “enriched” for a thrombophilia(s) (e.g., asymptomatic or symptomatic

Table 14-1 Acquired or Secondary Thrombophilia

Strongly supportive data
Active malignant neoplasm
Chemotherapy (L-asparaginase, thalidomide, antiangiogenesis therapy)
Myeloproliferative disorders
Heparin-induced thrombocytopenia and thrombosis (HIT)
Nephrotic syndrome
Intravascular coagulation and fibrinolysis/disseminated intravascular coagulation (ICF/DIC)
Thrombotic thrombocytopenic purpura (TTP)
Oral contraceptives
Estrogen therapy
Pregnancy/postpartum state
Tamoxifen and raloxifene therapy (selective estrogen receptor modulator [SERM])
Antiphospholipid antibodies (lupus anticoagulant, anticardiolipin antibody, anti- β_2 -glycoprotein I antibody)
Paroxysmal nocturnal hemoglobinuria (PNH)
Wegener granulomatosis
Supportive data
Inflammatory bowel disease
Thromboangiitis obliterans (Buerger disease)
Behçet syndrome
Varicose veins
Systemic lupus erythematosus
Venous vascular anomalies (e.g., Klippel-Trénaunay syndrome)
Progesterone therapy
Infertility "therapy"
Hyperhomocysteinemia
Human immunodeficiency virus (HIV) infection
Dehydration
Inappropriate use of erythropoietin

Table 14-3 Thrombophilia: Clinical Manifestations

Purpura fulminans (neonatalis or adult)
Superficial or deep vein thrombosis, pulmonary embolism
Thrombosis of "unusual" venous circulations (e.g., cerebral, hepatic, mesenteric, and renal veins; possibly arm, portal, and ovarian veins)
Warfarin-induced skin necrosis
Possibly arterial thrombosis (e.g., stroke, acute myocardial infarction)
(Recurrent) fetal loss
Possibly intrauterine growth restriction
Possibly stillbirth
Possibly severe gestational hypertension (preeclampsia)
Possibly abruptio placentae

family members of patients with a known familial thrombophilia, especially first-degree relatives) or populations at increased risk for thrombosis (e.g., prior to pregnancy, oral contraception or estrogen therapy, high-risk surgery, chemotherapy with angiogenesis inhibitors), testing of symptomatic patients with an incident thrombotic event (e.g., incident VTE, stillbirth or another complication of pregnancy, incident arterial thrombosis in a young person without other arterial disease), or testing of symptomatic patients with recurrent thrombosis, "idiopathic" thrombosis, thrombosis at a young age (e.g., ≤ 45 years for venous thrombosis, ≤ 55 years for arterial thrombosis), or thrombosis in unusual vascular territories (e.g., cerebral vein, portal vein, hepatic vein, mesenteric vein or artery, renal vein) (see Chapter 16). With the exception of general population screening (which is not recommended), all of these potential indications are controversial and must be considered in the context of the clinical presentation.

Table 14-2 Hereditary (Familial or Primary) Thrombophilia

Strongly supportive data
Antithrombin III deficiency
Protein C deficiency
Protein S deficiency
Activated protein C (APC) resistance
Factor V Leiden
Prothrombin 20210
Homocystinuria
Supportive data
Increased plasma factors I (fibrinogen), II (prothrombin), VIII, IX, and XI
Hyperhomocysteinemia
Dysfibrinogenemia
Hypoplasminogenemia and dysplasminogenemia
Hypofibrinolysis
Reduced protein Z and Z-dependent protease inhibitor (ZPI)
Reduced tissue factor pathway inhibitor (TFPI)
Sickle cell disease
Weakly supportive data
Tissue plasminogen activator (tPA) deficiency
Increased plasminogen activator inhibitor (PAI-1) levels
Methylene tetrahydrofolate reductase (MTHFR) polymorphisms
Factor XIII polymorphisms
Increased thrombin-activatable fibrinolysis inhibitor (TAFI)

Counseling and Screening Asymptomatic Family Members

Thrombophilia testing, and especially genetic testing, of asymptomatic family members should be done with caution. Family members (and patients) should first receive genetic counseling and are most appropriately tested only after consent is obtained. Counseling should include the reasons for testing, such as the potential for avoiding clinical thrombosis by risk factor modification or prophylaxis (for the family member and for his or her children), and the reasons for not testing, such as stigmatization and mental anguish,²⁹ the potential effect on obtaining personal health insurance or employment, and the possibility of nonpaternity.

Thrombophilia testing should be done if the results are likely to change medical management. The risk of idiopathic ("unprovoked") thrombosis associated with thrombophilia, although increased, is still insufficient to warrant chronic primary prophylaxis (e.g., warfarin anticoagulation), even for thrombophilias with high penetrance (e.g., antithrombin III deficiency, homozygous factor V Leiden carriers), with the possible exception of paroxysmal nocturnal hemoglobinuria.³⁰ Thus, primary "prophylaxis" typically involves avoidance or modification of risk exposure, or prophylaxis when such exposures are unavoidable.

Figure 14-1 Annual incidence of venous thromboembolism by age and sex. Silverstein M, Heit J, Mohr D, et al: Trends in the incidence of deep vein thrombosis and pulmonary embolism: A 25-year population-based, cohort study. *Arch Intern Med* 158:585–593, 1998.

When counseling a family member (or patient) regarding the risk of thrombosis associated with a thrombophilia, it is most useful to provide the “absolute” risk (e.g., incidence) of thrombosis among persons with that particular thrombophilia. For example, the relative risk of VTE among heterozygous factor V Leiden carriers who receive oral contraceptives is increased about 30-fold; however, the incidence is only about 300 per 100,000 woman-years, or about 0.3% per woman-year.^{31,32} Thus, the absolute risk provides information on both the baseline risk of VTE (e.g., about 10 to 46 per 100,000 woman-years for women of reproductive age^{31,33}) and the relative risk (e.g., relative risk [RR] of 30 for women who are factor V Leiden carriers and are taking oral contraceptives).

When the absolute risk of thrombosis is estimated, it is especially important to factor in the effects of age on the baseline incidence of VTE. For example, among women of potentially perimenopausal age (i.e., ages 50 to 54 years), the incidence of VTE is 123 per 100,000 woman-years,³⁴ and this incidence increases exponentially thereafter (Fig. 14-1). Among women who are factor V Leiden carriers of perimenopausal age, the relative risk of VTE associated with hormone therapy may be increased 7- to 15-fold.^{32,35–38} However, although the relative risk for VTE is less with hormone therapy than with oral contraceptives, the absolute risk is substantially higher (e.g., ~900 to 1800 per 100,000 woman-years, or ~1% to 2% per woman-year) because of the increased baseline incidence associated with age. Given recent studies questioning the benefit of postmenopausal hormone therapy,³⁹ most women likely would choose to avoid such therapy if they were known to be carriers of thrombophilia. Thus, it may be relatively cost-effective to perform thrombophilia screening for an asymptomatic perimenopausal or postmenopausal woman with a known history of familial thrombophilia who is considering hormone therapy.⁴⁰

Primary Prevention of Incident Venous Thromboembolism

VTE is a major health problem, with at least 300,000 first-lifetime cases per year reported in the United States.^{34,41} Observed survival after VTE is significantly less than expected, especially after PE.⁴² For about one quarter of patients with acute PE, the initial clinical presentation is sudden death.

Figure 14-2 Annual incidence of all venous thromboembolism, deep vein thrombosis (DVT) alone, and pulmonary embolism with or without DVT (PE ± DVT) by age. Silverstein M, Heit J, Mohr D, et al: Trends in the incidence of deep vein thrombosis and pulmonary embolism: A 25-year population-based, cohort study. *Arch Intern Med* 158:585–593, 1998.

After controlling for other comorbid diseases, survival is significantly reduced for up to 3 months after PE. PE accounts for an increasing proportion of VTE, with increasing age for each sex (Fig. 14-2).³⁴ Hence, as the average U.S. population age increases, the total number of incident VTE events per year will increase, and an increasing number of these events will be PE. Because of markedly reduced survival after PE, the number of U.S. deaths due to VTE per year also will increase. In addition to reduced survival, VTE and its common complication, namely, venous stasis syndrome, significantly reduce quality of life.⁴³ VTE patients have a 17-fold increased risk of U.S. venous stasis syndrome.⁴⁴ The 20-year cumulative incidence rates of venous stasis syndrome after venous VTE and after proximal deep vein thrombosis are about 25% and 40%, respectively (see Chapter 17).^{45,46} Primary prevention of VTE, by risk factor modification or by appropriate prophylaxis of U.S. patients at risk, is essential for improving survival and preventing complications. However, despite improved prophylaxis regimens and more widespread use of prophylaxis, the overall incidence of VTE has been relatively constant at about 1 per 1000 since 1979.^{34,41,44,47}

To avoid or modify risk, or appropriately target prophylaxis, patients at risk for VTE must first be identified. In the absence of a central venous catheter or active cancer, the incidence of VTE among children and adolescents is very low (<1 per 100,000 for ages 15 years and younger), and the incidence increases exponentially after age 50 to 55 years to about 1000 per 100,000 for persons who are 85 years of age or older.^{34,48–50} The incidence of VTE increases significantly with age for both idiopathic and secondary VTE, suggesting that the risk associated with advancing age may be due to the biology of aging rather than simply to an increased exposure to risk factors due to advancing age.^{34,47,51–54} The incidence is slightly higher for women during childbearing years and higher for men after age 50 to 55 years. The incidence of VTE also varies by race. Compared with white Americans, African Americans have a 30% higher incidence, and Asian and Native Americans have up to a 70% lower incidence; Hispanics have an incidence that is intermediate between that of whites and Asian Americans.^{51,55–59}

Additional independent risk factors for VTE, as well as the magnitude of risk associated with each, are shown in Table 14-4.⁶⁰⁻⁶⁵ Compared with residents in the community, hospitalized residents have a greater than 150-fold increased incidence of acute VTE.⁴⁴ Hospitalized and nursing home residents together account for almost 60% of all incident VTE events that occur in the community.⁶¹ Thus, hospital confinement provides an important opportunity to significantly reduce VTE incidence. Of note, hospitalization for medical illness and for surgery accounts for almost equal proportions of VTE (22% and 24%, respectively), emphasizing the need to provide prophylaxis to both of these risk groups.

The risk among surgery patients can be further stratified on the basis of patient age, type of surgery, and presence of active cancer.^{66,67} The incidence of postoperative VTE is increased for surgical patients who are 65 years of age or older. High-risk surgical procedures include neurosurgery; major orthopaedic surgery of the leg; thoracic, abdominal, or pelvic surgery for malignancy; renal transplantation; and cardiovascular surgery.⁶⁷ After controlling for age, type of surgery and type of cancer, additional independent risk factors for incident VTE after major surgery include increasing body mass index, intensive care unit confinement for longer than 6 days, immobility, infection, and varicose veins.^{41,68} The risk from surgery may be reduced with neuraxial (spinal or epidural) anesthesia compared with general anesthesia.⁶⁹

Independent risk factors for incident VTE among patients hospitalized for acute medical illness include increasing age and body mass index, active cancer, neurologic disease with extremity paresis, immobility, fracture, and prior superficial vein thrombosis.^{41,70,71} Active cancer accounts for almost 20% of incident VTE events that occur in the community.⁶¹ VTE risk among patients with active cancer can be further stratified by tumor site, presence of distant metastases, and whether active chemotherapy is being provided. Although

all patients with active cancer are at risk, this risk appears to be greater with pancreatic cancer, lymphoma, malignant brain tumor, cancer of the liver, leukemia, and colorectal and other digestive cancers,⁷²⁻⁷⁴ and in patients with distant metastases.⁷⁵ Patients with cancer who are given immunosuppressive or cytotoxic chemotherapy are at even higher risk for VTE,^{60,75} including therapy with L-asparaginase,⁷⁶ thalidomide⁷⁷ and other angiogenesis inhibitors,⁷⁸ tamoxifen,^{79,80} and erythropoietin.⁸¹

A central venous catheter or transvenous pacemaker now accounts for about 9% of incident VTE.⁶¹ Unfortunately, neither warfarin nor low molecular weight heparin (LMWH) prophylaxis is effective in preventing catheter-induced thrombosis, and therefore are not recommended.⁶⁶ Prior superficial vein thrombosis is an independent risk factor for subsequent DVT or PE remote from the episode of superficial thrombophlebitis (Table 14-4).⁶⁰ The risk of DVT imparted by varicose veins is uncertain and appears to be higher among persons younger than 40 years of age.⁶⁰ Long haul (>6 hours) air travel is associated with a slightly increased risk for VTE that is preventable with elastic stockings.^{82,83} Studies regarding the protective effects of coenzyme A reductase inhibitor (statin) therapy against VTE have provided conflicting results.^{84,85} In addition, the risk associated with atherosclerosis or other risk factors for atherosclerosis (e.g., diabetes mellitus) remains uncertain.⁸⁶⁻⁸⁹ Body mass index, current or past tobacco smoking, chronic obstructive pulmonary disease, and renal failure are not independent risk factors for VTE.⁶⁰ The risk associated with congestive heart failure, independent of hospitalization, is low.^{60,64}

Among women, additional risk factors for VTE include oral contraceptive use and hormone therapy,^{90,91} pregnancy, and the postpartum period.^{33,63} The greatest risk may occur during early use of oral contraceptives⁹² and hormone therapy.⁹¹ This risk may be less with second-generation oral contraceptives or progesterone alone compared with first- or third-generation oral contraceptives (see Chapter 34).^{93,90} For women with disabling perimenopausal symptoms that cannot be controlled with nonestrogen therapy,^{35,39,94} esterified oral estrogen or transdermal estrogen therapy may confer less risk than oral conjugated equine estrogen therapy.⁹⁵⁻⁹⁷ Although VTE can occur at any time during pregnancy,⁹⁸ the highest incidence has been noted during the first two postpartum weeks, especially for older mothers.⁹⁹ Independent risk factors for pregnancy-associated VTE include tobacco smoking and prior superficial vein thrombosis.¹⁰⁰ Women who are given therapy with the selective estrogen receptor modulators, tamoxifen^{80,101-104} and raloxifene,^{105,106} also are at increased risk for VTE.

Other conditions associated with VTE include heparin-induced thrombocytopenia, myeloproliferative disorders (especially uncontrolled polycythemia rubra vera and essential thrombocythemia),^{80,107,108} intravascular coagulation and fibrinolysis/disseminated intravascular coagulation (ICF/DIC), nephrotic syndrome,¹⁰⁹ paroxysmal nocturnal hemoglobinuria,³⁰ thromboangiitis obliterans (Buerger disease), plasma exchange for thrombotic thrombocytopenic purpura,¹¹⁰ Behçet syndrome, systemic lupus erythematosus,¹¹¹ Wegener granulomatosis,¹¹² inflammatory bowel disease,¹¹³ homocystinuria,¹¹⁴ and possibly, hyperhomocysteinemia.¹¹⁵⁻¹¹⁷

Table 14-4 Independent Risk Factors for Deep Vein Thrombosis or Pulmonary Embolism⁶⁰

Baseline Characteristic	Odds Ratio	95% CI
Hospitalization		
Hospitalization for acute medical illness	7.98	4.49, 14.18
Hospitalization for major surgery	21.72	9.44, 49.93

Heit J, Silverstein M, Mohr D, et al: Risk factors for deep vein thrombosis and pulmonary embolism: A population-based case-control study. *Arch Intern Med* 160:809-815, 2000.

Recent family-based studies indicate that VTE is highly heritable and follows a complex mode of inheritance involving environmental interaction.^{118–120} Inherited reductions in plasma natural anticoagulants (e.g., antithrombin III, protein C, protein S) have long been recognized as uncommon but potent risk factors for VTE.^{121–124} More recent discoveries of additional reduced natural anticoagulants^{125–130} or anticoagulant cofactors,¹³¹ impaired downregulation of the procoagulant system (e.g., activated protein C resistance, factor V Leiden),^{19,99,132,133} increased plasma concentrations of procoagulant factors (e.g., factors I [fibrinogen], II [prothrombin], VIII, IX, and XI)^{134–144} and increased basal procoagulant activity,^{145–147} impaired fibrinolysis,¹⁴⁸ and increased basal innate immunity activity and reactivity^{149,150} have added new paradigms to the list of inherited or acquired disorders that predispose to thrombosis (thrombophilia). These plasma hemostasis-related factors or markers of coagulation activation correlate with increased thrombotic risk and are highly heritable.^{118,151–154} Inherited thrombophilias interact with such clinical risk factors (e.g., environmental exposures) as oral contraceptives,^{31,92,155} pregnancy,¹⁵⁶ hormone therapy,^{36–38} surgery,^{157,158} and cancer¹⁵⁹ to compound the risks associated with incident VTE. Similarly, genetic interaction increases the risk of incident venous thromboembolism.¹⁶⁰ Thus, it may be reasonable to consider thrombophilia testing of asymptomatic male and female family members with a known family history of familial thrombophilia.

Secondary Prevention of Recurrent VTE

VTE recurs frequently; about 30% of patients develop recurrence within the next 10 years (Table 14-5).¹⁶¹ A recent modeling study suggested that more than 900,000 incident or recurrent VTE events occurred in the United States in 2002.¹⁶² The hazard ratio varies with time since the incident event and is highest within the first 6 to 12 months (Fig. 14-3).^{161,163} Additional independent predictors of recurrence and the hazard ratio associated with each are

shown in Table 14-6; these include male sex,^{161,163–165} increasing patient age and body mass index, neurologic disease with extremity paresis, and active malignancy.^{45,47,161,166,167} Other predictors of recurrence include “idiopathic” (as opposed to provoked) VTE,^{163,168–170} a persistent lupus anticoagulant and/or high-titer antiphospholipid antibody,^{168,171} antithrombin III, protein C or protein S deficiency,^{124,172} compound heterozygous carriers for more than one familial thrombophilia (e.g., heterozygous for the factor V Leiden and prothrombin 20210 mutations) or homozygous carriers,^{173–181} possibly increased procoagulant factor VIII¹⁸² and factor IX¹⁷⁶ levels, decreased tissue factor pathway inhibitor (TFPI) levels,¹⁷⁹ and persistent residual DVT.¹⁸³

Data regarding the risk of recurrent VTE among isolated heterozygous carriers for the factor V Leiden or the prothrombin 20210 mutation are conflicting.¹⁹ In a recent meta-analysis, pooled results from 10 studies involving 3104 patients with incident VTE revealed that the factor V Leiden mutation was present in 21.4% of patients and was associated with a 1.41-fold increased risk for recurrent

Figure 14-3 Cumulative incidence of first venous thromboembolism recurrence (—) and the hazard of first recurrence per 1000 person-days (---). VTE (95% confidence interval [CI], 1.14 to 1.75).¹⁸⁴ Similarly, pooled results from nine studies involving 2903 patients revealed that the prothrombin 20210 mutation was present in 9.7% and was associated with a 1.72-fold increased risk of recurrence (95% CI, 1.27 to 2.31). The estimated population-attributable risks for recurrence were 9.0% and 6.7% for the factor V Leiden and prothrombin 20210 mutations, respectively.

An increased D-dimer measured at least one month after warfarin therapy was stopped may be a predictor of DVT recurrence independent of residual venous obstruction.^{185,186} Secondary prophylaxis with anticoagulation therapy should be considered for patients with these characteristics. Although the incident event type (DVT vs PE) is not a predictor of recurrence, patients with recurrence are significantly more likely to recur with the same event type as the incident event type.^{187,188} Because the 7-day case fatality rate is significantly higher for recurrent PE (34%) than for recurrent DVT alone (4%),^{188,189} secondary prophylaxis should be considered for incident PE, especially for patients with chronically reduced cardiopulmonary functional reserve.

DIAGNOSTIC THROMBOPHILIA TESTING: WHO SHOULD BE TESTED?

Current Recommendations

Currently recommended indications for thrombophilia testing include idiopathic or recurrent venous thromboembolism; a first episode of venous thromboembolism at a “young” age (e.g., ≤ 45 years); a family history of venous thromboembolism (in particular, a first-degree relative with thrombosis at a young age); venous thrombosis in an unusual vascular territory (e.g., cerebral, hepatic, mesenteric, or renal vein thrombosis) (see Chapter 16); and neonatal purpura fulminans or warfarin-induced skin necrosis (see Chapter 11).^{17,190–192} When two or more of these thrombosis characteristics are present, the prevalence of at least one of antithrombin III, protein C, or protein S deficiency, as well as the factor V Leiden and prothrombin 20210 mutations, is increased.^{193–196} Consequently, a “complete” laboratory investigation (*vide infra*) is recommended for patients who meet these criteria, and more selective testing (e.g., activated protein C resistance/factor V Leiden, prothrombin 20210 mutation) is recommended for other patients (Table 14-7).¹⁹¹

However, the prevalence of hereditary thrombophilia (e.g., activated protein C [APC] resistance, factor V Leiden) is substantial among patients with a first-lifetime VTE (Table 14-8). Because knowledge of a hereditary thrombophilia may be important for estimating the risk of VTE recurrence,^{184,197} testing for a hereditary thrombophilia should be considered for patients with a first-lifetime thrombosis and should not be limited to patients with recurrent VTE. Moreover, although patients with idiopathic or recurrent VTE may have a higher prevalence of a recognized thrombophilia, these patients should be considered for secondary prophylaxis regardless of the results of thrombophilia testing. In addition, the prevalence of hereditary thrombophilia (e.g., APC resistance) is substantial among patients with a first-lifetime episode of VTE at an older

age (see Table 14-8). Therefore, testing for a hereditary thrombophilia should not be limited to patients with a first-lifetime episode of VTE prior to age 40 to 50 years. Although persons with a deficiency of antithrombin III, protein C, or protein S are more likely to experience thrombosis at a younger age,²⁰ genetic interaction (e.g., factor V Leiden or prothrombin 20210 mutations combined with antithrombin III, protein C, or protein S deficiency) compounds the risk of thrombosis.^{160,198–201} such that testing among patients with a first thrombosis after age 45 years should not be limited to APC resistance (factor V Leiden) or the prothrombin 20210 mutation.²⁰²

Recent evidence suggests that a family history of VTE does not increase the likelihood that a recognized familial thrombophilia will be identified.²⁰³ The cumulative lifetime incidence (penetrance) of thrombosis among carriers of the most common familial thrombophilia (factor V Leiden) is only about 10%.⁹⁹ Therefore, many patients with VTE with an inherited thrombophilia do not have a family history of thrombosis. Consequently, thrombophilia testing should not be limited to symptomatic patients with a family history of VTE.

The most common manifestation of familial thrombophilia consists of DVT of the leg veins and PE.⁷ Except for catheter-induced thrombosis, all VTE is likely associated with an underlying thrombophilia. Therefore, limiting testing to patients with thrombosis in unusual vascular territories will cause most patients with an identifiable familial (or acquired) thrombophilia to be missed.

Several additional issues should be considered when one is addressing the question of whether to perform testing for a possible thrombophilia. For example, the prevalence of hereditary thrombophilia (e.g., factor V Leiden, prothrombin 20210) among patients with VTE differs substantially by race.^{204–208} However, the question of whether testing should be modified on the basis of race has not been directly addressed. Factor V Leiden and prothrombin 20210 mutation carrier frequency among asymptomatic African Americans, Asian Americans, and Native Americans, as well as among African Americans with VTE, is extremely low,²⁰⁷ such that test selection for hereditary thrombophilia likely should be tailored to patient race. The risk of VTE during pregnancy or the postpartum period and the risk of recurrent fetal loss are increased among patients with acquired or hereditary thrombophilia. Women with these obstetric disorders should be tested. Recent evidence suggests that patients who develop acute VTE in the presence of active malignancy are also more likely to have an underlying thrombophilia.¹⁵⁹ Nevertheless, thrombophilia testing for patients with thrombosis associated with active cancer or another risk exposure (e.g., surgery, hospitalization for acute medical illness, trauma, neurologic disease with extremity paresis, upper extremity thrombosis in the presence of a central venous catheter or transvenous pacemaker) is controversial.

Suggested Revised Recommendations

All patients with VTE, regardless of age, sex, race, location of venous thrombosis, initial or recurrent event, or family history of VTE, should be considered for testing for an acquired or hereditary thrombophilia. Women with recurrent fetal loss or complications of pregnancy and patients

Table 14-7 Laboratory Evaluation for Suspected Familial or Acquired Thrombophilia

(Suggested tests to be performed selectively on the basis of clinical judgment)

General

Blood: CBC, peripheral smear, ESR, chemistries, PSA, β -HCG, CA-125, ANA (dsDNA, RF, ENA)
 PA/lateral CXR, UA, mammogram
 Colon imaging, especially if no prior screening (proctosigmoidoscopy, colonoscopy)
 Chest imaging for smokers (CT, MRI)
 ENT consultation, especially for smokers
 UGI/upper endoscopy
 Abdominal imaging (CT, MRI, ultrasound)
 Angiography

Special Coagulation Laboratory Testing**Platelets**

HIT testing: plasma anti-PF4/glycosaminoglycan (heparin) antibodies ELISA; platelet ^{14}C -serotonin release assay; heparin-dependent platelet aggregation

Plasma Coagulation

Prothrombin time, PTT (with phospholipid "mixing" procedure if inhibited)
 Thrombin time/reptilase time
 Dilute Russell's viper venom time (with confirmatory procedures)
 Mixing studies (inhibitors)
 Specific factor assays (as indicated)

Fibrinolytic System

Fibrinogen
 Plasma fibrin D-dimer
 Soluble fibrin monomer complex (SFMC)

Natural Anticoagulant System

Antithrombin III (activity, antigen)
 Protein C (activity, antigen)
 Protein S (activity, total and free antigen)
 Activated protein C (APC) resistance ratio (second generation; factor V-deficient plasma mixing study)

Direct Genomic DNA Mutation Testing

Factor V Leiden gene (depending on the result of the APC resistance ratio)
 Prothrombin 20210

Additional General Testing

Anticardiolipin (antiphospholipid) antibodies (immunoglobulin [Ig]G and IgM isotypes); anti- β_2 -glycoprotein I antibodies
 Plasma homocysteine (basal, postmethionine load)

Additional Selective Testing

Flow cytometry for PNH
 Plasma ADAMTS13 activity
 Plasminogen (activity)

CBC, complete blood count; ESR, erythrocyte sedimentation rate; PSA, prostate-specific antigen; β -HCG, β -human chorionic gonadotropin; CA-125, cancer antigen 125; ANA, antinuclear antibody; dsDNA, double-stranded DNA; RF, rheumatoid factor; ENA, extractable nuclear antigen; PA, posteroanterior; CXR, chest x-ray; UA, urinalysis; CT, computed tomography; MRI, magnetic resonance imaging; ENT, ear, nose, and throat; UGI, upper gastrointestinal; HIT, heparin-induced thrombocytopenia; ELISA, enzyme-linked immunosorbent assay; PTT, partial thromboplastin time; PNH, paroxysmal nocturnal hemoglobinuria; ADAMTS13, a disintegrin and metalloproteinase with thrombospondin subunits.

with unexplained arterial thrombosis also most likely should be tested. These recommendations are controversial and are not universally accepted.

DIAGNOSTIC THROMBOPHILIA TESTING: FOR WHAT SHOULD I TEST?

A complete history and physical examination is mandatory in the evaluation of individuals with a recent or remote history of thrombosis, with special attention given to age at onset, location of prior thromboses, and results of objective diagnostic studies undertaken to document thrombotic episodes. An inquiry regarding interval imaging to establish a new baseline is particularly important when recurrent thrombosis is diagnosed in the same vascular territory as a previous thrombosis. For patients with an

uncorroborated history of DVT, noninvasive venous vascular laboratory or venous duplex ultrasound evidence of venous outflow obstruction (e.g., residual vein thrombosis) or (possibly) venous valvular incompetence may be helpful in corroborating the clinical history.

Patients should be questioned carefully about diseases, exposures, conditions, or drugs that are associated with thrombosis (see [Tables 14-1 and 14-4](#)). A family history of thrombosis may provide insight for a potential familial thrombophilia, especially in first-degree relatives. Thrombosis may be the initial manifestation of a malignancy, so a complete review of systems directed at symptoms of (occult) malignancy is important, including whether indicated screening tests for normal health maintenance (e.g., mammography, colon imaging) are current. Ethnic background should be considered, given the extremely low prevalence of factor V Leiden and prothrombin 20210 mutations in

Table 14-8 Familial or Acquired Thrombophilia: Estimated Prevalence by Population, and Incidence and Relative Risk of Incident or Recurrent Venous Thromboembolism by Thrombophilia

Thrombophilia	Prevalence (Whites, %)			Incident VTE		Recurrent VTE	
	Normal	Incident VTE	Recurrent VTE	Incidence* (95% CI)	Relative Risk (95% CI)	Incidence* (95% CI)	Relative Risk (95% CI)
Antithrombin III deficiency	0.02–0.04	1–2	2–5	500 (320, 730)	17.5 (9.1, 33.8)	10,500 (3800, 23,000)	2.5

VTE, venous thromboembolism; CI, confidence interval; Ab, antibody.

individuals of African American, Asian American, and Native American ancestries.^{204–207,209}

The physical examination should include a careful peripheral pulse examination and examination of the extremities for signs of superficial thrombosis or DVT and vascular anomalies, as well as a skin examination for venous stasis syndrome (e.g., leg swelling, stasis pigmentation and/or dermatitis, stasis ulcer), varicose veins, livedo reticularis, skin infarction, or other evidence of microcirculatory occlusive disease. Given the strong association of thrombosis with active cancer, a careful examination for lymphadenopathy, hepatosplenomegaly, and abdominal or rectal mass should be performed, along with breast and pelvic examinations for women and testicular and prostate examinations for men (see Chapter 23).

Laboratory evaluation for individuals with thrombosis should be selective and based on the history and physical examination (see Table 14-7); assessment may include a complete blood count with peripheral smear, serum protein electrophoresis, serum chemistries for electrolytes and liver and renal function, prostate-specific antigen, carcinoembryonic antigen, α -fetoprotein, β -human chorionic gonadotropin (HCG), cancer antigen ([CA]-125), antinuclear antibody (ANA) (double-stranded DNA [dsDNA], rheumatoid factor [RF], extractable nuclear antigen [AUA]), and urinalysis. Elevations in hematocrit or platelet count may indicate the presence of a myeloproliferative disorder, which can be associated with venous or arterial thrombosis. Secondary polycythemia may also provide evidence of an underlying occult malignancy. Leukopenia and thrombocytopenia can be found in paroxysmal nocturnal hemoglobinuria, which is characterized by intravascular hemolysis and thrombotic sequelae. The development of thrombosis and thrombocytopenia concurrent with heparin administration should always prompt consideration of heparin-induced thrombocytopenia (see Chapter 25). The peripheral smear should be reviewed for evidence of red cell fragmentation that would indicate microangiopathic hemolytic anemia, such as occurs with ICF/DIC (see Chapter 12). In individuals with malignancy, chronic ICF/DIC may result in venous or arterial thrombosis. A leukoerythroblastic picture with nucleated red cells or immature white cells suggests the possibility of marrow infiltration by tumor.

A chest x-ray should be performed. More detailed imaging (e.g., chest, abdominal, or pelvic computed tomography [CT] or magnetic resonance imaging [MRI]; angiography) should be performed only if there are other independent reasons to suspect an occult malignancy or other arterial disease (in the case of arterial thrombosis). Routine screening for occult cancer in patients who present with idiopathic VTE has not been shown to improve cancer-related survival and is not warranted in the absence of clinical features and abnormal basic laboratory findings suggestive of underlying malignancy.^{210,211} Sputum cytology, an ear, nose, and throat (ENT) examination, and upper gastrointestinal (GI) endoscopy should be considered for tobacco smokers or others at risk for esophageal or gastric cancer. In addition to a Papanicolaou (Pap) smear, endometrial sampling should be considered for women at risk for endometrial cancer.

Recommended assays for initial and reflex special coagulation testing for a familial or acquired condition are

provided in Table 14-7. Detailed discussions regarding the interpretation and nuances of specific assays are provided at the end of this chapter, along with a description of the biochemistry, molecular biology, and epidemiology of each thrombophilia.

Arterial Thrombosis

Aside from antiphospholipid antibodies (e.g., lupus anticoagulant, anticardiolipin antibody, anti- β_2 -glycoprotein I antibodies), heparin-induced thrombocytopenia, myeloproliferative disorders, homocystinuria, and possibly, hyperhomocysteinemia, a familial or acquired thrombophilia appears to be an unusual cause of stroke, myocardial infarction, or other organ or skin infarction.^{17,192} A young patient with organ or skin infarction in the absence of one of the previously mentioned disorders, or with no risk factors for atherosclerosis (e.g., diabetes mellitus, hypertension, hyperlipidemia, cocaine or tobacco exposure) or cardioembolism (e.g., cardiac arrhythmia, patent foramen ovale), should be carefully evaluated for “esoteric” or occult arterial disease (Table 14-9). One should not conclude that organ infarction must be due to a “hypercoagulable disorder” simply because the patient is young or lacks common risk factors for atherosclerosis or arterial thromboembolism. A detailed inquiry into constitutional or specific symptoms of vasculitis (primary or secondary), infection (systemic [e.g., endocarditis] or local [e.g., infected aneurysm with artery-to-artery embolism]), atheroembolism, trauma (accidental, thermal, or occupational), dissection, vasospasm, or vascular anomaly is required. In addition to a careful pulse examination (including examination for aneurysmal disease), evidence of microcirculatory

Table 14-9 “Esoteric” Causes of Arterial Thrombosis

Cardioembolism (e.g., atrial fibrillation, left ventricular or atrial septal aneurysm, endocarditis [infectious or noninfectious], atrial septal defect [ASD] or patent foramen ovale [PFO] with “paradoxical” embolism, cardiac tumors)
Artery-to-artery embolism (thromboembolism, cholesterol, tumor, infection)
Arterial dissection (large and small vessels)
Fibromuscular dysplasia (cervical and renal arteries)
Cystic adventitial disease
Arterial aneurysmal disease with thrombosis in situ
Trauma
Arterial entrapment (e.g., thoracic outlet syndrome, popliteal entrapment, common femoral entrapment at the inguinal ligament)
Vasculitis (primary or secondary)
Thromboangiitis obliterans
Arterial wall infection
Vasospasm
Vascular tumors
Vascular anomalies
Thermal injury (erythromelalgia, pernio [chilblains], frostbite)
Occupational trauma (e.g., hypothenar hammer hand syndrome)
Hyperviscosity syndromes
Cold agglutinins
Cryoglobulinemia
Cocaine abuse

occlusive disease of the hand (e.g., livedo, skin or nail bed infarction, ulcer) should prompt a search for endocarditis (infectious and noninfectious), thoracic outlet syndrome, or other causes of repetitive arterial trauma (e.g., hypothenar hammer hand syndrome, “jackhammer” or “volleyball” hand), atheroembolism, and thermal injury. Such physical findings in the foot should involve a similar search plus an evaluation for abdominal aortic or popliteal artery aneurysmal disease with atherothromboembolism or thromboembolism. Fibromuscular disease typically affects the carotid and renal arteries and may manifest as stroke or renal infarct due to carotid and renal artery dissection or embolism, respectively. Because the vascular supply to the organs cannot be directly palpated or observed, arteriography is required to evaluate organ infarction.

In general, duplex ultrasonography and CT or MRI angiography do not provide sufficient resolution to exclude these arteriopathies, with the exception of carotid artery disease. Contrast arteriography should be performed by a vascular physician (i.e., vascular radiologist, vascular surgeon, vascular medicine/cardiologist) who is experienced in diagnosing occult vascular disease, including careful and detailed selective arteriography of the involved and upstream vascular territory with selective vasodilator injection and magnified views, where appropriate.

TIMING OF DIAGNOSTIC THROMBOPHILIA TESTING: WHEN SHOULD I TEST?

Many of the natural anticoagulant and procoagulant plasma proteins are acute phase reactants. Acute thrombosis can transiently reduce levels of antithrombin III and occasionally proteins C and S. Consequently, testing should not be performed during the acute phase of thrombosis or during pregnancy. A delay of at least 6 weeks after the acute thrombosis, or after delivery, usually allows sufficient time for acute phase reactant proteins to return to baseline. Heparin therapy can lower antithrombin III activity and antigen levels and may impair interpretation of clot-based assays for a lupus anticoagulant. A delay of at least 5 days after heparin is stopped prior to testing²¹² is usually feasible. Warfarin therapy reduces the activity and antigen levels of vitamin K–dependent factors, including proteins C and S. Rarely, warfarin has also been shown to elevate antithrombin III levels into the lower normal range in individuals with a hereditary deficiency.²¹³ Many authorities recommend delaying testing until the effects of warfarin therapy also have resolved. In those in whom temporary discontinuation of anticoagulation is not practical, heparin can be substituted for warfarin. However, the effects of warfarin on protein S levels may not resolve for up to 6 weeks. Moreover, the clinical decision regarding secondary prophylaxis may depend on the results of special coagulation testing. For these patients, testing for protein C or S deficiency may be done during stable warfarin anticoagulation, with adjustment of protein C and S levels for the warfarin effect by comparison with the levels of other vitamin K–dependent proteins with similar plasma half-lives (e.g., factors VII and II [prothrombin], respectively). If levels of protein C or S are within the normal range, then

the diagnosis of deficiency may be reliably excluded. However, any abnormal result should be confirmed after the patient has been taken off warfarin therapy for a sufficient amount of time to allow warfarin effects to resolve (if possible), or through testing of a first-degree family member. Direct leukocyte genomic DNA testing for factor V Leiden and prothrombin 20210 mutations is unaffected by anticoagulation therapy; such testing can be performed at any time.

DIAGNOSTIC THROMBOPHILIA TESTING: HOW DO I MANAGE PATIENTS WITH THROMBOPHILIA?

Primary Prophylaxis

All patients should receive appropriate antithrombotic prophylaxis when exposed to thrombotic risk factors (e.g., surgery, trauma, hospitalization for acute medical illness; see Table 14-4).⁶⁶ Despite accumulating evidence that an underlying thrombophilia increases the risk of clinical thrombosis among individuals exposed to a clinical risk factor, thrombophilia screening for such persons in the absence of a known family history of familial thrombophilia is not recommended at this time.³² Current recommendations regarding VTE prophylaxis for surgery or hospitalization for medical illness are based solely on clinical characteristics⁶⁶; in general, prophylactic regimens are not altered on the basis of a known inherited or acquired thrombophilia. However, given emerging evidence that a thrombophilia does increase the risk of symptomatic VTE after high-risk surgery,^{157,158} in the absence of contraindications, such patients should be considered for a longer duration (e.g., “out-of-hospital”) of prophylaxis.²¹⁴

At present, general screening of asymptomatic women for a thrombophilia prior to initiation of oral contraceptive therapy or prior to conception is not recommended. However, it may be appropriate to screen asymptomatic women family members of a proband with a known familial thrombophilia. Anticoagulant prophylaxis is recommended for asymptomatic women with antithrombin III deficiency or homozygosity/double heterozygosity for factor V Leiden and/or prothrombin 20210 mutations during pregnancy and the puerperium (see Chapter 36).

Acute Therapy

In general, patients with a familial or acquired thrombophilia and a first-lifetime VTE should be managed in standard fashion with intravenous unfractionated heparin at doses sufficient to prolong the partial thromboplastin time (PTT) into the laboratory-specific therapeutic range, as referenced to plasma heparin levels (0.2 to 0.4 U/mL using protamine sulfate titration, or 0.3 to 0.7 anti-Xa IU/mL) or with LMWH or fondaparinux (see Chapter 15).^{215,216} Among patients with impaired renal function (e.g., creatinine clearance of ≤ 30 mL/minute), peak LMWH levels (obtained 3 hours after subcutaneous injection) should be monitored and the dose adjusted to maintain a LMWH (anti-Xa activity) level of 0.5 to 1.0 anti-Xa IU/mL. Fondaparinux is not approved for use among patients with renal insufficiency.

Patients with a prolonged baseline PTT due to a lupus anticoagulant likely should be treated with LMWH rather than unfractionated heparin (UFH) because of difficulties associated with use of the PTT for monitoring and adjusting the UFH dose. Patients with acute DVT may be managed as outpatients. However, a brief hospitalization may be appropriate for edema reduction, along with fitting of a 30- to 40-mm Hg calf-high graduated compression stocking for patients with severe edema. Compared with patients with DVT alone, those with PE have significantly worse survival rates. Such patients may need to be hospitalized at least briefly to ensure that they are hemodynamically stable. Hemodynamically stable patients with PE who have normal cardiopulmonary functional reserve may be managed as outpatients with the use of LMWH therapy. Subsequent oral anticoagulation should be adjusted to prolong the international normalized ratio (INR) to a target of 2.5, with a therapeutic range of 2.0 to 3.0. Heparin and oral anticoagulation therapy should be overlapped by at least 5 days (regardless of the INR) and until the INR has been within the therapeutic range for at least two consecutive days. Warfarin therapy for lupus anticoagulant patients should not be monitored with INR point-of-care devices.

Special attention may be required for patients with deficiencies of antithrombin III or protein C. Some patients with antithrombin III deficiency are heparin resistant and may require larger doses of unfractionated heparin to obtain an adequate anticoagulant effect, as measured by the PTT. Antithrombin III concentrate can be used in special circumstances, such as with recurrent thrombosis despite adequate anticoagulation, unusually severe thrombosis, or difficulty achieving adequate anticoagulation.²¹⁷ It is also reasonable to treat antithrombin III-deficient patients with concentrate before major surgeries or in unusual obstetric situations when the risks of bleeding from anticoagulation are unacceptable.²¹⁸ Antithrombin III concentrate appears to have a low risk of transmitting blood-borne infection and is supplied as 500 IU per 10 mL or 1000 IU per 20 mL. An initial loading dose should be calculated to increase the antithrombin III level to 120%, assuming an expected rise of 1.4%/IU/per kilogram transfused over the baseline antithrombin III level. For example, for a patient with a baseline antithrombin III level of 57%, the calculated dose is $(120 - 57) 1.4 = 45$ IU per kilogram. The dose should be administered over 10 to 20 minutes, and a 20-minute postinfusion antithrombin III level should be measured. In general, plasma antithrombin levels of 80% to 120% can be maintained by administration of 60% of the initial loading dose every 24 hours.

Hereditary protein C deficiency may be associated with warfarin-induced skin necrosis due to a transient hypercoagulable state. Initiation of warfarin at standard doses leads to a decrease in protein C anticoagulant activity to approximately 50% of baseline within the first day. Consequently, treatment with warfarin should be started only after the individual is receiving full therapeutic doses of heparin, and the dose of warfarin should be increased gradually, after starting from a relatively low dose (e.g., 2 mg). Individuals with a history of warfarin-induced skin necrosis may be anticoagulated after receiving a source of exogenous protein C via fresh frozen plasma or an investigational protein C concentrate. This offers a bridge until a stable level of anticoagulation can be achieved.

The total duration of anticoagulation for acute therapy should be individualized in accordance with the circumstances of the thrombotic event. In general, a duration of 3 months appears to be adequate for thrombosis related to transient risk factors,^{168,219} and patients with persistent risk factors require at least 3 to 6 months.^{168,215,216,219,220}

Secondary Prophylaxis

It is important to make a distinction between acute therapy and secondary prophylaxis. Acute therapy aims to prevent extension or embolism of an acute thrombosis, and it must continue for a sufficient duration of time and intensity to ensure that the acute thrombus has lysed or become organized and the “activated” acute inflammatory/innate immunity system has returned to baseline.²²¹ As discussed earlier, the most appropriate duration of acute therapy varies among individual patients but probably is between 3 and 6 months.

Beyond about 6 months, the aim of continued anticoagulation is not to prevent acute thrombus extension or embolism but instead to prevent recurrent thrombosis (e.g., secondary prophylaxis). VTE is now viewed as a chronic disease (likely because all such patients have an underlying, if not recognized, thrombophilia) with episodic recurrences.^{41,222} All randomized clinical trials that tested different durations of anticoagulation showed that as soon as anticoagulation is stopped, VTE begins to recur.^{168,169,219,220,223–227} Thus, anticoagulation therapy does not “cure” VTE.²²⁸ When the full spectrum of venous thromboembolic disease is considered, the rate of recurrence after acute therapy is stopped differs according to the duration of anticoagulation, but this is so because the rate of recurrence varies (decreases, yet the risk curve never becomes “flat”) according to (increasing) time since the incident event—not the duration of anticoagulation.^{161,166,226}

The decision regarding a recommendation for secondary prophylaxis is complex and depends on estimates of the risk of unprovoked VTE recurrence while the patient is not receiving secondary prophylaxis, the risk of anticoagulant-related bleeding, and the consequences of both, as well as the patient’s individual preference.²²⁹ Clinical predictors of VTE recurrence and the hazard ratios associated with each are presented above and in Table 14-6.¹⁶¹ In addition, a meta-analysis of the relative risks of recurrence associated with a familial or acquired thrombophilia is presented in Table 14-8.²³⁰

Secondary prophylaxis after a first episode of VTE is controversial and should be recommended only after careful consideration of the risks and benefits. In general, secondary prophylaxis is not recommended after a first-lifetime episode, especially if the event was provoked by a transient (e.g., surgery, hospitalization for acute medical illness, trauma, oral contraceptive use, pregnancy, the puerperium) clinical risk factor.

Secondary prophylaxis may be recommended for idiopathic, recurrent, or life-threatening VTE (e.g., PE, especially in association with persistently reduced cardiopulmonary functional reserve due to chronic cardiopulmonary disease; phlegmasia with threatened venous gangrene; purpura fulminans); persistent clinical risk factors (e.g., active cancer, chronic neurologic disease with extremity paresis, other persistent secondary causes of thrombophilia

[see Table 14-1]]^{161,163}; a persistent lupus anticoagulant and/or high-titer anticardiolipin or anti- β_2 -glycoprotein I antibody^{168,171,231}; antithrombin III, protein C, or protein S deficiency^{7,124,172,232}; increased basal factor VIII activity¹⁸² or substantial hyperhomocysteinemia²³³; compound heterozygous carriers for more than one familial thrombophilia (e.g., heterozygous for factor V Leiden and prothrombin 20210 mutations) or homozygous carriers^{173-179,181}; and possibly, a persistently increased plasma fibrin D-dimer¹⁸⁶ or residual posttreatment venous obstruction.^{183,234} The risk of recurrence among isolated heterozygous carriers for the factor V Leiden or prothrombin 20210 mutations is relatively low and is likely insufficient to warrant secondary prophylaxis after a first-lifetime thrombotic event in the absence of other independent predictors of recurrence.¹⁸⁴ A family history of VTE is not a predictor of an increased risk for VTE recurrence²³⁵ and should not influence the decision regarding secondary prophylaxis. However, the quality of anticoagulation (i.e., time within the therapeutic INR range) during acute therapy is a predictor of the long-term risk of recurrence.^{236,237} Because of the high risk of recurrent VTE due to warfarin failure among patients with active cancer, the most recent American College of Chest Physicians (ACCP) Consensus Conference on Antithrombotic and Thrombolytic Therapy recommended LMWH as secondary prophylaxis as long as the cancer remains active.^{238,239}

The risks of recurrent VTE must be weighed against the risks of bleeding from anticoagulant (warfarin)-based secondary prophylaxis. The relative risk of major bleeding is increased about 1.5-fold for every 10-year increase in age,^{226,230,240-242} and about twofold for patients with active cancer.^{167,226,230,238-240} Additional risk factors for bleeding include a history of prior gastrointestinal bleeding or stroke, or one or more comorbid conditions, including recent myocardial infarction, anemia (hematocrit <30%), impaired renal function (serum creatinine >1.5 mg per deciliter),^{243,244} impaired liver function, and thrombocytopenia. Moreover, the ability to perform activities of daily living should be considered because of the increased risk of bleeding associated with falls. The patient's prior anticoagulation experience during acute therapy should also be considered; patients with unexplained wide variations in the INR and noncompliant patients likely should not receive secondary prophylaxis. Finally, the method by which the anticoagulation effect of secondary prophylaxis with warfarin will be monitored and the warfarin dose adjusted should be considered; the efficacy and safety of such care, when rendered through an "anticoagulation clinic" or when "self-managed" at home, are superior to those associated with usual medical care.²⁴⁵⁻²⁴⁷ With appropriate patient selection and management, the risk of major bleeding can be reduced to 1% per year, or less.²⁴⁸⁻²⁵⁰

Because the risk of VTE recurrence decreases over time since the incident event,¹⁶¹ because the risk of anticoagulant-related bleeding also may vary over time,²⁴² and because our knowledge base changes, the indications for secondary prophylaxis must be continually reevaluated; it is inappropriate to simply recommend "lifelong" or "indefinite" anticoagulation therapy.

Common myths and misunderstandings regarding thrombophilia are presented in Table 14-10.

Table 14-10 Thrombophilia Myths and Misunderstandings

In clinical decision making, the presence of an acquired or familial thrombophilia "outweighs" clinical risk factors.
"Negative thrombophilia testing" excludes the presence of an acquired or familial thrombophilia.
Oral contraceptives are contraindicated for women with thrombophilia.
Acute therapy for thrombosis is always different for patients with thrombophilia.
Heparin or warfarin "resistance" must indicate a "hypercoagulable disorder."
Symptomatic patients with thrombophilia require lifelong anticoagulation.
Cerebral, retinal, myocardial, hepatic, splenic, bowel, or renal arterial infarction at a young age must represent a hypercoagulable disorder.

SPECIFIC THROMBOPHILIAS: PRIMARY OR FAMILIAL

Impaired "Natural" Anticoagulant Pathway

Antithrombin III Deficiency

Antithrombin III is a single-chain plasma glycoprotein (432 amino acids; molecular weight [M_r], 58 kDa; plasma concentration, 2.5 μ M) that is synthesized in the liver.²⁵¹ Antithrombin III is a serine protease inhibitor (SERPIN) that acts as a pseudosubstrate to inhibit factors IIa (thrombin), IXa, Xa, XIa, and XIIa, and kallikrein and plasmin, through covalent binding of Arg393 within the antithrombin III reactive site loop to the serine protease active site. Antithrombin III inhibitory activity is increased approximately 1000-fold by the catalyst, glycosaminoglycan (e.g., heparin). The antithrombin III plasma half-life is 60 to 70 hours, and the thrombin:antithrombin (TAT) complex is cleared by the liver.²⁵²

The antithrombin III gene is located on the long arm of chromosome 1 (1q23-q25); it contains seven exons (1, 2, 3A, 3B, 4, 5, and 6) that span 13.5 kilobases (kb). Congenital antithrombin III deficiency is inherited as an autosomal dominant disorder, with an estimated prevalence of 70 to 160 per 100,000. Antithrombin III has two major active functional sites: the reactive site and the heparin-binding site located at the amino terminus of the molecule. Congenital antithrombin III deficiency can be classified into two general categories. Type I deficiency is characterized by a concordant reduction in antithrombin III function (activity) and protein (antigen) levels to about 50% of normal plasma. Over 80 point mutations, and 9 whole or partial gene deletions (>30 bp) have been described in individuals with type I deficiency.²⁵³ Type II deficiency is characterized by a normal antithrombin III antigen level with reduced activity due to a dysfunctional protein. This category has been further subdivided into three subtypes, depending on the genetic defect: type IIa mutations affect the antithrombin III active site; type IIb mutations involve the heparin-binding site; and type IIc includes a pleiotropic group of 11 distinct mutations near the antithrombin III "reactive loop." Homozygous types I and IIa mutations are embryonically lethal and heterozygous types I and IIa mutations have a higher prevalence of thrombosis

compared with heterozygous type IIb mutations. However, homozygous type IIb mutations are not embryonically lethal and may be associated with venous and arterial thromboses.²⁵⁴ Type IIc mutations also have reduced plasma antigen levels, possibly caused by reduced synthesis and secretion, and increased catabolism.

Functional antithrombin III activity assays use a synthetic peptide that mimics the natural substrate of thrombin, to which is attached a “reporter” group (e.g., para-nitroaniline) that forms a “chromogenic substrate.” Cleavage of the specific synthetic peptide by thrombin releases the reporter group, which emits a color (yellow) at a specific light wavelength (405 nm). In this assay, patient plasma (the source of antithrombin III) is incubated with an excess of thrombin and heparin. During the first phase of the reaction, heparin catalyzes the patient antithrombin III to bind and inhibit thrombin in a 1:1 stoichiometry. The remaining “free” thrombin, which is inversely proportionate to the patient plasma antithrombin III, is then quantitated through cleavage of the chromogenic substrate. Some assays use inhibition of factor Xa rather than thrombin to decrease potential confounding by heparin cofactor II (which inhibits thrombin but not factor Xa).²⁵⁵ More recent commercial assays minimize the effects of nonspecific substrate cleavage by other proteases (e.g., plasmin) or the effects of heparin cofactor II by the addition of protease inhibitors (e.g., aprotinin) and the use of bovine thrombin (which is not inhibited by heparin cofactor II), respectively. Antithrombin III antigen levels are typically tested by enzyme-linked immunosorbent assay (ELISA) or latex immunoassay (LIA). The antithrombin III activity and antigen level reference range is about 80% to 130%,²⁵⁶ although each laboratory should determine its own laboratory-specific reference range according to the methods and equipment used in the laboratory. The typical interassay coefficient of variation (CV) ranges from 3% to 5%, and possibly up to 10%.

Both assays may be affected by such preanalytic variables as hemolysis, lipemia, high hematocrit (>55%), or a clotted sample (as are all “clot-based” coagulation assays). LIAs may be spuriously increased in the presence of high levels of rheumatoid factor or dysproteinemia. Normal antithrombin III activity and antigen levels are unaffected by sex or tobacco use. However, antithrombin III levels are lower in neonates and approach adult levels by about age 1 year; after 1 year of age, levels may be slightly higher than those of adults until about age 16 years.²⁵⁷ Modest reductions are also found in women on oral contraceptives or estrogen therapy,^{258,259} and warfarin therapy may tend to normalize reduced antithrombin III levels.²¹³ Acquired causes of decreased antithrombin III levels include impaired synthesis (liver disease, malnutrition, premature infancy, inflammatory bowel disease, and burns) and increased consumption (acute thrombosis, heparin therapy, intravascular coagulation and fibrinolysis [ICF/DIC], sepsis, hemolytic transfusion reaction, malignancy, L-asparaginase therapy, and urinary protein loss [nephrotic syndrome]).^{260,261} Patients with low antithrombin III levels should have this finding confirmed on a subsequent sample after acquired causes have been excluded. Family studies may also be useful in confirming a diagnosis of congenital antithrombin III deficiency.

Heterozygosity for antithrombin III deficiency can be found in approximately 4% of families with inherited thrombophilia and in 1% of consecutive patients with an initial episode of deep VTE.^{6,262} The incidence and relative risk of a first-lifetime (incident) and recurrent venous thromboembolism are presented in Table 14-8.

Protein C Deficiency

Protein C is a vitamin K-dependent plasma glycoprotein that is synthesized in the liver as a single-chain molecule (M_r , 62 kDa).²⁵¹ However, most plasma protein C consists of a two-chain molecule (light- and heavy-chain) that results from cleavage at Arg157-Thr158 prior to secretion. The protein C plasma concentration (65 nM) is about 100-fold lower than the antithrombin III plasma concentration (2.5 μ M). The protein C plasma half-life is 6 to 7 hours.

Protein C is the zymogen precursor to the serine protease—activated protein C. Protein C is cleaved at Arg169-Leu170 by the thrombin:thrombomodulin complex on the endothelial cell surface (facilitated by endothelial protein C receptor) to form activated protein C. Activated protein C (along with phospholipid, calcium, and its cofactor, protein S) acts as a potent anticoagulant through cleavage/inactivation of factors VIIIa and Va; it thus down-regulates the rate of thrombin generation by a huge factor. The protein C aminoterminal light chain (155 amino acids; M_r , 21 kDa) functions in calcium and phospholipid binding, protein C activation, and interaction with protein S; it contains the γ -carboxyglutamic acid (Gla)-rich domain and two epidermal growth factor (EGF)-like domains. The carboxyterminal heavy chain (250 amino acids; M_r , 41 kDa) contains the serine protease catalytic domain. Activated protein C is inhibited by an α_1 -proteinase inhibitor (protein C inhibitor-1) and α_2 -macroglobulin.

The protein C (PROC) gene is located on the long arm of chromosome 2 (2q13-q14) and contains 9 exons that span 11 kb. Congenital protein C deficiency is inherited as an autosomal dominant disorder but with variable penetrance; more than 160 unique mutations spread throughout the PROC gene have been identified. The estimated prevalence of protein C deficiency ranges from 200 to 400 per 100,000 (see Table 14-8).^{263,264} Congenital protein C deficiency is classified as two types. Type I deficiency consists of concordant reduction in protein C activity and antigen level; it accounts for about 75% of all congenital protein C deficiencies. Approximately 60% of type I deficiency mutations are missense mutations that likely cause decreased protein synthesis or intracellular protein degradation. However, type I deficiency also is caused by promoter and 5'-untranslated region mutations that disrupt binding of transcription factors, as well as splice junction and small insertion/deletion mutations that cause premature stop codons. Type II deficiencies are due to missense mutations that cause synthesis of dysfunctional protein C; functional plasma protein C activity is reduced, yet protein C antigen levels are normal. Examples include mutation within the catalytic active site, the Gla domain, and the propeptide cleavage site.

Functional protein C assays may be clot-based or amidolytic; both use the protein C activator, Protac, from the venom of the Southern Copperhead snake (*Agkistrodon contortrix contortrix*) to activate patient protein C. Clot-based assays may be modified PTT- or prothrombin time

(PT)-based, and they determine the patient's (activated) protein C level by measuring prolongation of the clotting time. In contrast, amidolytic assays determine the patient's (activated) protein C level by measuring color from a reporter group (para-nitroaniline) released by cleavage of a synthetic ("chromogenic") peptide substrate. Clot-based protein C activity assays have the potential to detect abnormalities due to mutation within several different protein C domains, as well as factors VIII and V; amidolytic assays detect only mutations within the catalytic active site.²⁶⁵ However, interfering substances that prolong the baseline clotting time (e.g., heparin, direct thrombin inhibitors, lupus anticoagulant, uremia²⁶⁶) may preclude interpretation of clot-based assays, and high factor VIII levels (as occurs with an acute phase reaction) may cause underestimation of protein C activity when measured by PTT-based assays. Finally, most clot-based assays require predilution of the patient's plasma in protein C-deficient plasma to correct for possible protein S deficiency. Neither clot-based nor amidolytic assays measure all functional aspects of protein C, such as the ability of protein C to interact with thrombin, thrombomodulin, phospholipids, or endothelial cell protein C receptor. Consequently, although clot-based assays may have the highest sensitivity in screening patients for hereditary protein C deficiency,²⁶² most laboratories use an amidolytic assay because it is more reproducible and less susceptible to interfering substances.²⁶⁷ Rarely, however, some type II protein C deficiencies may have normal amidolytic functional activity and antigen levels but abnormal clot-based functional activity and may be missed.²⁶⁸ Protein C antigen levels are determined by ELISA, which typically is performed only when protein C activity is reduced.

The normal adult protein C plasma level ranges from about 70% to 140%, but each laboratory must determine its own laboratory-specific reference range. Levels of protein C antigen in the heterozygous deficiency state overlap with those in the normal population, thus making it difficult to define the diagnosis in some patients. In general, antigen levels of 60% to 70% represent borderline values and warrant repeat testing. Protein C antigen levels may also vary according to age. Protein C levels in newborns are 20% to 40% of normal adult levels,²⁶⁹ and preterm infants have even lower levels.²⁷⁰ Neonates with significant perinatal thrombosis may have levels suggestive of homozygous deficiency.²⁷¹ In adults, protein C levels typically increase by 4% per decade.²⁶⁴ Adult levels are independent of age and sex but may be higher in postmenopausal women. Acquired reduction in protein C occurs because of decreased synthesis/posttranslational modification (e.g., liver disease, vitamin K deficiency, warfarin therapy) or increased turnover (e.g., acute thrombosis, ICF/DIC, sepsis, impaired renal function, postoperative state, adult respiratory distress syndrome [ARDS], plasma exchange, breast cancer, massive hemorrhage).²¹² A particularly severe form of acquired protein C deficiency has been reported in association with purpura fulminans and ICF/DIC in individuals with acute meningococcal infection.^{8,272} In contrast to antithrombin III, antigenic concentrations of vitamin K-dependent plasma proteins, including protein C, are often increased in individuals with nephrotic syndrome.²⁷³ Patients with low protein C levels should have this finding confirmed on a subsequent sample after acquired causes have been excluded. Family studies may also be useful in

confirming a diagnosis of congenital protein C deficiency. Warfarin therapy reduces functional and, to a lesser extent, antigenic measurements of protein C, thus complicating diagnosis of the deficiency state.²⁶⁸ For patients who are stably anticoagulated on warfarin, a suspicion of congenital protein C deficiency may be raised when protein C activity is discordantly reduced compared with factor VII activity, a vitamin K-dependent zymogen with a similar plasma half-life.²⁷⁴ However, definitive diagnosis requires repeated measurements after the patient has been off warfarin therapy for at least 1 week, preferably longer. If it is not possible to discontinue warfarin therapy because of the severity of the thrombotic diathesis, such individuals may be studied while receiving heparin therapy, which does not alter plasma protein C levels. In addition, family studies may be helpful. The incidence and relative risk of first-lifetime (incident) and recurrent VTE are presented in Table 14-8.

Protein S Deficiency

Protein S is a vitamin K-dependent plasma glycoprotein (635 amino acids; M_r , 70 kDa) that is predominantly synthesized in the liver but also in the endothelial cells, megakaryocytes, and Leydig cells of the testis.²⁷⁵ Protein S is a nonenzymatic cofactor for APC-mediated inactivation of factors VIIIa and Va. In addition, protein S may exhibit APC-independent anticoagulant activity by directly binding and inhibiting factor VIIIa in the tenase complex, as well as factors Va and Xa in the prothrombinase complex. The aminoterminal end of the molecule consists of a Gla domain, an aromatic ring amino acid domain, a thrombin-sensitive region, and four EGF-like domains; the carboxyterminal end includes a sex hormone-binding globulin-like domain rather than a serine protease domain. Approximately 60% to 70% of total plasma protein S circulates noncovalently bound in 1:1 stoichiometry to a complement regulatory protein, C4b-binding protein (C4BP β), and is inactive. The remainder circulates as "free" protein S (plasma concentration, 150 nM) with a plasma half-life of 96 hours.

The protein S (PROS, PSa) gene is located on the short arm of chromosome 3 (3p11.1–3p11.2) and consists of 15 exons that span 80 kb. In addition, a protein S pseudogene (PS β) with 96.5% homology to PSa is located within 4 centimorgans (cM) of the PROS gene. Congenital protein S deficiency is inherited as an autosomal dominant disorder with variable penetrance. The prevalence of protein S deficiency in the normal population is about 200 per 100,000 (see Table 14-8).

Of the known congenital deficiencies that may lead to thrombophilia, testing and interpretation are most difficult for protein S deficiency. On the basis of total and free plasma protein S antigen levels, protein S deficiency was initially categorized into three phenotypes; all three have reduced protein S activity. Type I protein S deficiency consists of reduced total and free protein S antigen levels,^{276,277} type II is made up of normal total and free protein S antigen levels, and type III comprises normal total protein S antigen levels but reduced free protein S antigen. However, mutations have been identified in only 44% of individuals with a type III phenotype, raising the possibility that some of these cases represent acquired abnormalities.²⁷⁸ More recent studies show that many patients with type III deficiency have the same molecular defect as those with type I deficiency, and that the

age-related increase in C4BP β but not protein S leads to the type III phenotype.^{200,275} About two thirds of protein S-deficient patients have a type I phenotype, and one third have a type III phenotype; the type II phenotype is rare. However, because most laboratories previously screened for protein S deficiency with a free protein S antigen assay, and because of our inability to measure all protein S anticoagulant activities, the true prevalence of type II protein S deficiency is unknown.

Plasma protein S (e.g., APC cofactor) activity assays are modified PTT- or PT-based assays in which patient protein S levels are directly proportionate to protein S cofactor activity in APC-mediated prolongation of the clotting time. In the PTT-based functional protein S assay, patient plasma is diluted in protein S-deficient plasma; fixed amounts of APC and factor Va are added, and the clotting time is measured. PT-based assays are performed similarly, or the patient's native protein C may be activated to APC by the addition of Protac. Early-generation assays yielded falsely low protein S activity in the presence of APC resistance, the factor V Leiden mutation, or increased factor II (prothrombin), VII, or VIII activities. In addition, prolongation of baseline PTT due to heparin or a lupus anticoagulant rendered the assay uninterpretable. More recent generation assays are less susceptible to such interference because of greater dilution of patient plasma in protein S-deficient plasma, addition of an increased amount of factor Va, and inclusion of polybrene to neutralize any heparin effect. However, increased factor VIII activity (as occurs with acute thrombosis or any other cause of an acute phase reaction) still may cause falsely low protein S activity with PTT-based assays.

Early assays of plasma protein S protein levels typically measured total protein S antigen by ELISA. Free protein S antigen levels were measured in the plasma supernatant after precipitation of protein S:C4b-binding protein complexes with 3.75% polyethylene glycol (PEG) 6000. More recent assays measure free protein S antigen directly and without the need for PEG precipitation with the use of a monoclonal antibody ELISA that is specific for free protein S antigen.

Assays for protein S activity or free protein S antigen level may be used for initial testing for protein S deficiency.²⁷⁵ A screening assay for protein S activity may identify type II protein S deficiency that would be missed with a free protein S antigen assay. However, protein S activity assays are subject to potential interference and should be used with caution as initial testing. A low protein S activity should be confirmed with an assay for free protein S antigen. If the initial protein S test result is low with either method, the result should be confirmed on a different sample collected after it has been ensured that all potentially acquired causes of protein S deficiency have been excluded or corrected. Routine testing of total protein S antigen levels is unnecessary but may be useful if the free protein S antigen level and/or protein S activity is low.

Neonatal protein S levels are approximately 35% and approach adult levels by about 1 year of age.²⁷⁵ Protein S levels are generally lower among premenopausal than among postmenopausal women, and levels increase with age for both men and women. Levels are reduced by vitamin K deficiency, oral (vitamin K antagonist) anticoagulants, liver disease, acute thrombosis,²⁷⁹ sepsis, ICF/DIC, human immunodeficiency virus (HIV) infection,²⁸⁰ and

L-asparaginase therapy, and among women, by oral contraceptives, pregnancy, and estrogen therapy. Although total protein S antigen measurements are generally increased in individuals with nephrotic syndrome, free protein S antigen levels and protein S activity may be reduced because of the loss of free protein S in the urine and elevations in C4b-binding protein levels.²⁷³ For patients who are stably anticoagulated on warfarin, a suspicion of congenital protein S deficiency may be raised when protein S activity is discordantly reduced compared with factor II (prothrombin) activity, a vitamin K-dependent zymogen with a similar plasma half-life. However, definitive diagnosis requires repeated measurements after the patient has been off warfarin therapy for at least 4 to 6 weeks, preferably longer. If it is not possible to discontinue warfarin because of the severity of the thrombotic diathesis, such individuals can be studied while receiving heparin therapy, which does not alter free protein S antigen levels. Family studies may also be useful in confirming a diagnosis of congenital protein S deficiency. The incidence and relative risk of first-lifetime (incident) and recurrent VTE are presented in Table 14-8.

Deficiencies of Other Natural Anticoagulants (TFPI, Protein Z, Z-Dependent Protease Inhibitor, and Heparin Cofactor II)

Tissue factor pathway inhibitor (TFPI) is a 32 kDa (276 amino acid) plasma protein and a Kunitz-type protease inhibitor of factor Xa and tissue factor:factor VIIa catalytic activity.^{281,282} The TFPI gene is located on the short arm of chromosome 2 (q32) and consists of 9 exons that span 70 kb. TFPI has a complex intravascular distribution. A major proportion (60% to 80%) of intravascular TFPI is normally bound to the vascular endothelium; this pool is mobilized to circulating blood after the injection of heparins.²⁸³ Plasma contains only a minor fraction (20% to 30%) of intravascular TFPI, which is largely associated with lipoproteins.²⁸⁴ Consequently, measurement of TFPI is difficult. Moreover, international standards for calibration of TFPI assays are not yet available. Several studies have reported that TFPI increases somewhat with age, possibly in relation to hormonal state.^{285,286} Plasma TFPI levels are lowest in women on oral contraceptives, and premenopausal women have lower levels compared with postmenopausal women and men.²⁸⁶⁻²⁸⁸ Postmenopausal women who receive hormone therapy also have lower TFPI levels.²⁸⁹

TFPI knockout mice die in utero from thrombosis.²⁹⁰ Immunodepletion of TFPI in rabbits lowers the threshold for tissue factor-induced thrombosis,^{291,292} and exogenous recombinant TFPI protects against DIC²⁹³ and VTE.^{294,295} Hormone therapy reduces plasma TFPI levels by 30% to 50% and may contribute to the risk of thrombosis associated with exogenous estrogen therapy.²⁸⁹ Plasma TFPI levels below the 10th percentile are a weak risk factor for DVT (odds ratio [OR], 1.1 to 1.7),²⁸⁶ and patients with DVT may have slightly lower mean TFPI levels compared with controls.^{125,296-298}

Protein Z is a 62-kDa vitamin K-dependent plasma protein that circulates in blood almost entirely as a noncovalent complex with a protein Z-dependent protease inhibitor (ZPI) with a plasma concentration of 2.6 ± 1 μ g per milliliter.^{128,129,299,300} The ZPI plasma concentration is 3.8 μ g per milliliter (53 nM). Protein Z catalyzes the inhibition of factor Xa by ZPI by 1000-fold. Protein Z

increases rapidly during the first months of life, and adult levels are reached during puberty.^{264,301} Protein Z deficiency compounds the risk of thrombosis among carriers of the factor V Leiden mutation.³⁰² Reduced protein Z levels may increase the risk of an adverse pregnancy outcome.³⁰³ Low plasma protein Z levels have also been reported in patients with antiphospholipid antibodies.³⁰⁴ Studies undertaken to test for an association between ischemic stroke and protein Z deficiency have reached contradictory conclusions.^{305,306}

Heparin cofactor II is a serine protease inhibitor (SERPIN) synthesized in the liver that circulates in blood at a plasma concentration of $\approx 1 \mu\text{M}$.³⁰⁷ Heparin cofactor II solely inhibits thrombin, and the rate of thrombin inhibition is increased more than 1000-fold by heparin, heparan sulfate, or dermatan sulfate. The physiologic function of heparin cofactor II is unknown. Heparin cofactor II knockout mice undergo normal fetal development, are born at the expected mendelian frequency, and have subsequent normal growth and survival with no increased rate of spontaneous thrombosis. However, such mice have a shorter time to thrombosis in an arterial injury model. At least 15 families with heparin cofactor II deficiency have been reported. Data from these families suggest that heparin cofactor II deficiency is a weak risk factor for VTE; usually, the risk for thrombosis is compounded when it is combined with other thrombophilias.³⁰⁷

These data suggest that deficiency of TFPI, protein Z and/or ZPI, and heparin cofactor II may be important risk factors for thrombosis, but current data are insufficient to support routine assay of these analytes as part of a diagnostic thrombophilia evaluation.

Enhanced Procoagulant Pathway: Increased Plasma Procoagulant Levels

Increased Fibrinogen (Factor I) Level

Fibrinogen (factor I) is a 340-kDa soluble glycoprotein that is synthesized in the liver.³⁰⁸ Thrombin cleaves fibrinogen, yielding fibrinopeptides A and B and fibrin monomers. Fibrin monomers self-assemble to form soluble fibrin polymers that are crosslinked by factor XIIIa to form insoluble (crosslinked) fibrin. Increased fibrinogen levels may enhance thrombus formation by altering the kinetics of coagulation, augmenting platelet interaction due to increased binding to the platelet glycoprotein-IIb/IIIa ($\alpha_{IIb}\beta_3$) receptor, and increasing plasma viscosity, and through formation of less porous fibrin networks, leading to impaired fibrinolysis.³⁰⁹

An increased fibrinogen level is epidemiologically strongly associated with myocardial infarction, stroke, and peripheral vascular disease.^{310–317} A plasma fibrinogen level $>500 \text{ mg/dL}$ combined with thrombosis has been associated with incident DVT in two studies.^{318,319} However, an increased fibrinogen level was not significantly associated with VTE in other studies and did not compound the risk for thrombosis among factor V Leiden carriers.^{320,321} Fibrinogen levels increase with age, which may, in part, explain the increased risk of VTE that is associated with increasing age.¹³⁵

Routine measurement of fibrinogen to assess individual thrombotic risk is controversial.³⁰⁸ No threshold measurement for defining hyperfibrinogenemia has been determined,

and no universal standardization system has been developed for the fibrinogen assay. Moreover, significant intra-individual variation in fibrinogen levels has been noted over time, suggesting the need for serial determinations before diagnosing hyperfibrinogenemia.

Increased Prothrombin (Factor II) Level/Prothrombin 20210 Mutation

Prothrombin (factor II) is a vitamin K–dependent plasma protein that is synthesized in the liver. In the final common coagulation pathway, factor Xa within the prothrombinase complex (factors Va and phospholipid) cleaves an activation peptide (prothrombin fragment 1.2) from prothrombin, yielding thrombin that cleaves fibrinogen to yield fibrin, and activates platelets and factors V, VIII, XI, and XIII to form an insoluble hemostatic plug. Plasma prothrombin activity ranges from about 70% to 130%, and the amount of thrombin formed is directly proportionate to the plasma prothrombin concentration.³²²

In a population-based, candidate gene, case-controlled study from the Netherlands, a common variation within the 3′-untranslated region (UTR) of the prothrombin gene (prothrombin 20210) was associated with a threefold increased risk of VTE.^{137,196} The prothrombin 20210 carrier frequency among VTE cases was 6.2% compared with 2.3% (1.2% allele frequency) among healthy controls. These findings have been confirmed in populations from Brazil, Italy, Sweden, and the United Kingdom, with VTE relative risks ranging from 2.8 to 11.5.^{137,323}

The prothrombin gene is located on chromosome 11 and consists of 14 exons and 13 introns that span 21 kb. The prothrombin 20210 mutation is located at the 3′-UTR polyadenylation cleavage site and is a gain of function mutation leading to increased plasma prothrombin levels.^{324–326} The incidence and relative risk of first-lifetime (incident) and recurrent VTEs are presented in Table 14-8. In the initial study, 87% of prothrombin 20210 carriers were in the highest quartile of plasma prothrombin levels.¹⁹⁶ Prothrombin 20210 carriers have indirect evidence of increased thrombin generation.³²⁷ The prothrombin 20210 polymorphism is a founder mutation that arose 20,000 to 30,000 years ago.³⁸⁸ The carrier frequency is highest among persons of Southern European ancestry (3%), and the carrier frequency in Northern Europeans is lower (1.7%).¹³⁷ The prothrombin 20210 allele is uncommon among Asians and African Americans (carrier frequency, 0.4%), and it accounts for $<0.5\%$ of VTE cases in the latter population.^{206,207}

Depending on the population, about 3% to 8% of patients with incident VTE and 15% to 20% of those with recurrent VTE will be prothrombin 20210 carriers (see Table 14-8). VTE risk among prothrombin 20210 carriers is compounded by concomitant deficiency of antithrombin III, protein C or protein S, or factor V Leiden, as well as other exposures, such as oral contraceptives, pregnancy, or hormone therapy.^{137,328} The prothrombin 20210 mutation has also been associated with recurrent fetal loss and complications of pregnancy.²¹ The prothrombin 20210 mutation generally is not associated with myocardial infarction or stroke in older populations, but it may interact with other exposures (e.g., tobacco smoking, hormone therapy) to increase the risk of arterial thrombosis in younger populations.^{137,329}

Identification of prothrombin 20210 mutation carriers requires direct DNA-based genotyping assays; the plasma prothrombin activity is not sufficiently sensitive for carrier testing.¹³⁷

Increased Factors VII, VIII, IX, X, and XI, and von Willebrand Factor

Factor VII is a 50-kDa, vitamin K–dependent zymogen synthesized by the liver that is critical for initiation of tissue factor–induced coagulation (extrinsic pathway).³⁰⁸ The tissue factor–factor VIIa pathway is believed to be the major mechanism for initiating thrombin generation. Increased factor VII levels are seen in patients who use certain types of oral contraceptives³³⁰ and in those who are pregnant³³¹ or have hyperlipidemia,³³² as well as during obesity and aging.³⁰⁸ In the Northwick Park Heart Study, increased basal factor VII levels were significantly associated with subsequent death from ischemic heart disease.³³³ However, in more recent studies, an increased factor VII level was not an independent risk factor for arterial^{311,315,334–336} or venous thrombosis.³¹⁸

Factor VIII is a 330-kDa glycoprotein that is synthesized in nonhepatocyte liver cells and endothelium, and that circulates in blood bound to von Willebrand factor (VWF) at a mean plasma concentration of 0.1 ng per milliliter (0.6 nM).³⁰⁸ Thrombin (or factor Xa) activates factor VIII to factor VIIIa. Factor VIIIa is the cofactor for intrinsic system activation of factor X by factor IXa in the presence of phospholipids and calcium. Factor VIII activity is an acute phase reactant that increases with acute stress, chronic inflammation, and exogenous estrogen administration. Factor VIII levels also vary with ABO blood type; factor VIII activity is about 15% lower for those with type O blood group compared with type A or B. In addition, factor VIII activity is labile and may be decreased by 10% to 20% with improper sample collection and processing, including freeze-thaw. Increased basal factor VIII activity is, in part, heritable.^{141,337–339} The level of plasma VWF and ABO blood type account for about one third of the population variability of factor VIII.³⁴⁰

Increased factor VIII activity was first associated with thrombosis more than 40 years ago.³⁴¹ Subsequent studies have shown that basal factor VIII activity >150% confers about a five- to sevenfold increased risk for incident^{139,141,319,342,343} and recurrent VTE.^{141,182} Combined increased factor IX and factor VIII antigen levels are associated with an eightfold relative risk of VTE.¹⁴³ In addition, increased factor VIII activity interacts with the factor V Leiden mutation to compound the risk for thrombosis.^{342,344} Increased factor VIII activity also confers a 1.5- to twofold increased risk for arterial thrombosis (see Table 14-8).^{345–348} In a recent case-controlled study, the risk of VTE associated with increased factor VIII activity (>270%) was increased almost ninefold, but risk varied by patient age.¹³⁶ Factor VIII cutoffs for a 95% specificity by age were 238% for subjects <40 years of age, 248% for ages 40 to 55 years, 261% for ages 56 to 70 years, and 313% for ages >70 years. The upper limit of normal (150%) for factor VIII was not of clinical use, and a much higher cutoff (>270%) was proposed. In addition, age-specific cutoffs were recommended for clinical use.

Factor VIII activity typically is measured with a PTT-based one-stage clotting assay. Although a factor VIII

activity assay is available in many laboratories, the reported reference range may vary by more than threefold (e.g., 55% to 205%).³⁴⁹ Immunoassays (e.g., ELISA) are commercially available for use in measuring factor VIII antigen levels.³³⁹ In general, ELISAs show narrower coefficients of variation than clotting assays and are not influenced by spurious factors, such as partial clotting activation during blood drawing. Most other commercially available immunoassays are limited in their ability to bind to factor VIII in plasma.³⁰⁸

Factor IX is a 57-kDa vitamin K–dependent zymogen that is synthesized in the liver. Factor IX is activated by factor VIIa or factor XIa.³⁰⁸ In turn, factor IXa together with factor VIIIa activates factor X. Factor IX levels increase with age and with the use of oral contraceptives.³⁵⁰ After correction for age, sex, oral contraceptive use, factor VIII, factor XI, and other vitamin K–dependent clotting factors, increased plasma factor IX (antigen level >129%, or activity level >150%) is associated with a two- to 2.3-fold (95% CI, 1.3 to 3.2) increased risk for incident VTE.^{143,351}

Factor X is a 59-kDa vitamin K–dependent zymogen that is synthesized by the liver. Factor X is activated to factor Xa by the tissue factor–factor VIIa (extrinsic) pathway or by the factor IXa–factor VIIIa (intrinsic) pathway.³⁰⁸ In conjunction with the cofactor, factor Va, factor Xa catalyzes the conversion of prothrombin to thrombin. Increased factor X levels have been reported in users of oral contraceptives and during pregnancy.³³¹ In univariate analyses, increased factor X antigen levels were associated with a 1.6-fold increased risk of VTE.³⁵² However, after adjusting for other vitamin K–dependent coagulation factor levels, factor X was not an independent risk factor for VTE. Similarly, increased factor X activity is not an independent risk factor for myocardial infarction.³³⁴

Factor XI is a 143-kDa zymogen that is synthesized in the liver and megakaryocytes, and that circulates in blood at a plasma concentration of 4 to 6 µg per milliliter (≈30 nM).³⁰⁸ Factor XI is activated to the serine protease, factor XIa, by factor XIIa (as part of the contact activation or intrinsic coagulation pathway) or by thrombin (as part of “feedback” activation).³⁵³ After adjusting for inherited risk factors, age, sex, and oral contraceptives, factor XI antigen levels above the 90th percentile (>121%) are associated with a 2.2-fold (95% CI, 1.5 to 3.2) increased risk of VTE.¹⁴⁴ Factor XIa formed by thrombin creates positive feedback, leading to even higher levels of thrombin that can activate thrombin-activatable fibrinolysis inhibitor.³⁵⁴ Inhibition of fibrinolysis may account for an association of factor XI levels with VTE.

VWF is a large multimeric protein that is synthesized in endothelial cells and megakaryocytes. VWF functions as a ligand to tether platelets to the site of a blood vessel injury and as a carrier protein for plasma factor VIII.³⁰⁸ VWF is stored within endothelial cell Weibel-Palade bodies and platelet α granules. VWF levels vary with blood type. Individuals with type O blood have the lowest levels, those with type AB have the highest levels, and those with types A and B have intermediate levels. VWF levels increase with age and may be higher in women than in men.^{355,356} VWF is an acute phase reactant that is rapidly released from endothelial cells in response to a variety of agonists, including epinephrine, bradykinin, and vasopressin and its analogues (1-deamino-8-D-arginine vasopressin [DDAVP]).

The concentration in blood can increase chronically in response to inflammation, infection, cancer, trauma, female hormones, sepsis, and other stimuli.

Univariate analyses from prospective studies have shown that an increased basal VWF antigen level is associated with a 1.2-fold increased risk of coronary heart disease and stroke.^{311,317} However, VWF was not an independent risk factor after adjustments were made for smoking, hypertension, diabetes, and lipid profile. In contrast, in the ECAT (European Concerted Action on Thrombosis) Angina Pectoris study, an increased VWF antigen level was significantly associated with an increased risk of myocardial infarction or sudden cardiac death in patients with a history of angina pectoris after adjusting for age, field center, and other risk factors (RR > 1.24).³⁵⁶ Other studies have shown a significant association between VWF antigen level and ischemic heart disease after adjusting for age, sex, and other risk factors³⁵⁷; a significant association with acute myocardial infarction,³⁵⁸ recurrent myocardial infarction,³⁵⁹ stroke,³⁶⁰ and peripheral arterial disease³¹⁶ after adjusting for age and sex, but not after adjustment for other risk factors; an association with fatal ischemic heart disease but not all ischemic heart disease after adjusting for blood group³⁴⁷; and no association between VWF levels and stroke.³¹⁵ An increased VWF level was not an independent risk factor for VTE after adjusting for factor VIII activity.¹³⁹ Therefore, an increased VWF level does not appear to be an independent predictor of thrombotic risk but is part of a larger complex of hemostatic alterations associated with inflammation, atherosclerosis, and arterial thrombosis.

Current procoagulant factor activity assays were developed to identify factor deficiencies among patients with clinical bleeding disorders; however, extant tests have not been established to precisely measure excesses among patients with thrombotic presentations. In general, factor activities of 35% to 40% or higher are associated with normal or near normal hemostasis. In contrast, an increase in factor activity as small as 15% may be associated with a significant risk for thrombosis. International standards for procoagulant factors are neither widely available nor routinely used to calibrate most assays.³⁰⁸ In a recent College of American Pathologists survey,

plasma laboratories were asked to assay several procoagulant factor activities. The between-laboratory coefficient of variation for a sample with an approximately normal level of factor ranged from 11.6% for factor X activity to 20.4% for factor IX activity. Because of the lack of widely used calibrators and the imprecision of individual assay methods, a single cutoff value for risk that will apply to all methods has not yet been defined. Consequently, routine assays of procoagulant factor activities to assess individual thrombosis risk are not recommended at this time.³⁰⁸

Increased Homocysteine (Homocystinuria; Hyperhomocysteinemia)/Methylene-Tetrahydrofolate Reductase (MTHFR)

Homocysteine is a sulfhydryl amino acid that is an intermediary between methionine and cysteine. Homocysteine cycles to methionine in an intracellular demethylation/remethylation pathway, where dietary methionine is demethylated to form homocysteine, and homocysteine is subsequently remethylated to form methionine (Fig. 14-4).¹¹⁵ The remethylation pathway requires inclusion of the enzyme, methionine synthase, and the essential cofactor, cobalamin (vitamin B₁₂). In this reaction, methyltetrahydrofolate “donates” a methyl group to “remethylate” homocysteine to form methionine. Methyltetrahydrofolate is derived through reduction of 5,10-methylenetetrahydrofolate in a reaction catalyzed by the enzyme, methylenetetrahydrofolate reductase (MTHFR). When methionine is present in excess or cysteine synthesis is required, homocysteine cycles to cysteine in a transsulfuration pathway. In the transsulfuration pathway, homocysteine is condensed with serine to form cystathionine in a reaction that requires the enzyme, cystathionine β-synthase (CBS), and the essential cofactor, pyridoxal 5'-phosphate (vitamin B₆; see Fig. 14-4). Cystathionine is subsequently hydrolyzed to cysteine and α-ketobutyrate. The remethylation pathway is primarily responsible for regulating fasting plasma homocysteine levels (e.g., dependent on folate, vitamin B₁₂, MTHFR); the resulfuration pathway mainly regulates higher plasma homocysteine levels, as occurs in the postprandial state or after a methionine load (e.g., dependent on vitamin B₆, CBS).¹¹⁵

Figure 14-4 Homocysteine remethylation and transsulfuration pathways.

The initial association of one or more childhood features of mental retardation, ectopia lentis, marfanoid habitus, premature atherosclerosis, and VTE with homocystinuria was noted longer than 40 years ago.^{361,362} As opposed to “normal” fasting plasma homocysteine levels of 5 to 15 μmol per liter, homocystinuric individuals have levels in the range of 100 to 400 μmol per liter. Plasma homocysteine reference ranges may vary according to population characteristics, including dietary intake of methionine and vitamins B₆ and B₁₂ or folic acid. In about 90% to 95% of cases, homocystinuria is due to an inherited deficiency of CBS; the remainder of cases are due to a deficiency in the remethylation pathway (e.g., severe deficiency of methionine synthase or MTHFR). The CBS gene is located on the long arm of chromosome 21 (q22). The most frequent CBS mutations leading to homocystinuria include homozygosity for T833C, G919A, and A1224C; the population carrier frequency for these mutations is 0.3% to 1.0%.¹¹⁵ Heterozygotes may have normal fasting homocysteine levels but increased levels within 4 to 8 hours after methionine loading. However, abnormal results from loading tests are not specific for heterozygous CBS deficiencies.³⁶³

The observation of arterial and venous thrombosis due to severe hyperhomocysteinemia suggested the hypothesis that mild (15 to 30 μmol per liter) or moderate (31 to 100 μmol per liter) hyperhomocysteinemia might be associated with incident or recurrent thrombosis at an older age.¹¹⁴ This hypothesis has been tested in case-controlled and prospective cohort study designs with conflicting conclusions. A meta-analysis of 27 case-controlled studies determined that the risk for coronary, cerebrovascular, and peripheral arterial disease was increased 1.6-, 1.5- and 6.8-fold, respectively, per 5 μmol per liter increase in total plasma homocysteine.³⁶⁴ Compared with the lowest four quintiles, a large case-controlled study found that patients in the top plasma homocysteine quintile had a 2.2-fold (95% CI, 1.6 to 2.9) increased risk for vascular disease.³⁶⁵ Single case-controlled studies and meta-analyses of these studies have detected a similar risk for incident and recurrent VTE, with about a 2.5- to threefold increased risk.^{115,117,233,366–368}

Case-controlled studies, however, cannot establish causality. Previous studies have shown that homocysteine levels may increase for an unknown duration after an acute thrombotic event, suggesting that hyperhomocysteinemia may be an effect of thrombosis rather than a cause.^{115,368} In support of this hypothesis, prospective cohort studies found no increase in relative risk, or only a weakly increased risk, of arterial vascular disease or incident VTE with hyperhomocysteinemia.^{115,116,368–372} One study found an increased risk for idiopathic but not secondary VTE,²⁰⁵ and several studies found an increased risk for recurrent VTE.^{116,233,373} Hyperhomocysteinemia may interact with other risk factors (e.g., factor V Leiden) to compound the risk for VTE.^{205,374} However, prospective clinical trials of homocysteine-lowering (vitamin) therapy have failed to show a benefit in reducing recurrent stroke, myocardial infarction, or VTE.^{373,375–377} Taken together, these findings question the benefit of measuring basal or post-methionine load plasma homocysteine levels. Nevertheless, hyperhomocysteinemia, whether causal or a marker for some other

cause, appears to be a consistent predictor of increased risk for recurrent VTE. Consequently, homocysteine levels may be useful in assessing the need for secondary prophylaxis with oral vitamin K inhibitors (e.g., warfarin).

Hyperhomocysteinemia may be due to inherited or acquired disorders. Deficiencies of vitamins B₆, B₁₂, or folic acid are common acquired causes. Two common polymorphisms within the MTHFR gene (C677T and A1298C) increase the risk of hyperhomocysteinemia among homozygous carriers who become deficient in folic acid or vitamin B₁₂.¹¹⁵ The MTHFR C677T polymorphism encodes for substitution of valine for alanine, and the A1298C polymorphism encodes for a glutamic acid-to-alanine substitution. Both polymorphisms are associated with reduced in vitro MTHFR enzymatic activity, and both are quite common, with a minor allele carrier frequency approaching 40%; about 10% of the U.S. white population are homozygous carriers. These MTHFR polymorphisms are uncommon among African Americans.³⁷⁸ Combined heterozygotes may have a mildly increased risk for hyperhomocysteinemia with a deficiency of vitamin B₁₂ or folic acid. However, in the absence of hyperhomocysteinemia, homozygous or combined heterozygous carriers are not at increased risk for arterial or venous thrombosis.^{115,363,368} In a recent meta-analysis of 40 case-controlled studies, individuals with the MTHFR C677T genotype had a 16% increased risk for coronary heart disease, but significant heterogeneity was seen between studies of European and American populations, suggesting an interaction with folate status.³⁷⁹ Consequently, routine genotyping for these polymorphisms is neither useful nor recommended.¹¹⁵

Other common acquired causes for hyperhomocysteinemia include impaired renal or liver function, hypothyroidism, psoriasis, inflammatory bowel disease, rheumatoid arthritis, organ transplantation, and drugs (e.g., anticonvulsants, levodopa, niacin, bile acid sequestrants, methotrexate, thiazides, cyclosporin A).¹¹⁵ Social (e.g., physical inactivity, tobacco smoking, coffee consumption) and demographic (increasing age, postmenopausal status, male sex) characteristics also may cause mild hyperhomocysteinemia. Exogenous estrogens (e.g., oral contraceptives, hormone therapy) may decrease plasma homocysteine levels.

About 70% of homocysteine in plasma circulates while bound to albumin; about 30% is oxidized to disulfides and 2% or less as free homocysteine.¹¹⁵ Total plasma homocysteine is usually assayed with high-pressure liquid chromatography or immunoassay after reduction of all homocysteine moieties to homocysteine. Basal plasma homocysteine levels are usually measured on a fasting blood sample. A post-methionine load sample is usually collected 3 to 6 hours after oral ingestion of 0.1 g of L-methionine per kilogram of body weight. About 25% to 45% of patients with a normal basal homocysteine level will exhibit hyperhomocysteinemia after methionine loading. Blood samples collected in ethylenediaminetetraacetic acid (EDTA) must remain on ice until the plasma can be separated as homocysteine is produced and exported by blood cells. Laboratories should develop local population- and sex-specific reference ranges. As noted previously, homocysteine levels may remain elevated for several months after an acute thrombotic event, such that measurement of plasma homocysteine levels should be delayed accordingly.

Enhanced Procoagulant Pathway: Impaired Downregulation of Procoagulant Activity

Activated Protein C Resistance/Factor V Leiden

Protein C is a plasma protein zymogen (pre-enzyme) that is activated by the thrombin:thrombomodulin complex on the endothelial cell membrane luminal surface to activated protein C (APC), a serine protease that cleaves and inactivates procoagulant factors VIIIa and Va, thus downregulating further thrombin generation. When added to plasma *ex vivo*, APC causes progressive prolongation of the clotting time (e.g., PTT, PT) in a dose-dependent manner. In 1993, Dahlbäck and coworkers³⁸⁰ reported three apparently unrelated patients with idiopathic recurrent VTE whose plasma was resistant to the anticoagulant effect of exogenous addition of activated protein C, called APC resistance. With the use of a simple assay for APC resistance that consisted of the ratio of PTT after the addition of a fixed amount of APC (sufficient to prolong the PTT about twofold) divided by the baseline PTT (e.g., normal APC ratio, 2), APC resistance (defined as APC ratio <2) was noted to segregate in families with a mendelian autosomal dominant inheritance pattern, and it was found to be associated with VTE.^{194,381}

Procoagulant factors V and VIII are large (300+ kDa) template proteins that catalyze assembly of the prothrombinase and “tenase” complexes, respectively, on negatively charged phospholipid (e.g., activated platelet surface membrane). Factors V and VIII are “activated” (FVa, FVIIIa) by proteolytic cleavage of an activation peptide (B domain) by thrombin. FVa and FVIIIa markedly accelerate the rate of activation of prothrombin to thrombin and thus are key regulatory points for downregulation of procoagulant activity. Activated protein C inactivates FVa and FVIIIa via cleavage of FVa at three different amino acid positions (R[arginine]306, R506, and R679), and at two FVIIIa positions (R336 and R562), within the heavy chains of each. Initial APC cleavage at the R506 position is required for optimal exposure and subsequent rapid inactivation of FVa by APC cleavage at positions R306 and R679.³⁸²

The factor V gene is located on the long arm of chromosome 1 (1q21–1q25) and is closely linked to the antithrombin gene. FVa isolated from APC-R patient plasma was noted to be resistant to inactivation by APC.³⁸³ Subsequent work identified a single point mutation (guanine to adenine) at the 1691 position of the heavy chain of factor V that encodes for substitution of a glutamine (Q) for arginine (R) at amino acid position 506, now called factor V Leiden.³⁸⁴ Carriers of the factor V Leiden mutation have normal factor V procoagulant activity but impaired downregulation of this activity, as shown by increased basal prothrombin fragment 1.2 (an activation fragment generated when prothrombin is converted to thrombin), consistent with increased basal thrombin production.³⁸⁵ Factor V Leiden carriers also have reduced rates of thrombolysis, possibly caused by increased activity of thrombin-activated fibrinolysis inhibitor (TAFI).^{386,387}

The first-generation PTT-based APC resistance (ratio) assay could not be interpreted in the presence of an abnormal baseline PTT (i.e., as may occur with a lupus anticoagulant, or heparin or oral anticoagulation) and was only

85% to 95% sensitive for the factor V Leiden mutation. Assay results were sensitive to the choice of reagents (PTT reagent and APC and calcium chloride concentration), instrument (mechanical, photo-optical), preanalytic conditions (centrifugation, storage, fresh or frozen samples), and several patient-related factors (e.g., pregnancy, oral contraceptive therapy, factor VIII and prothrombin activities). Residual platelets in frozen/thawed samples could falsely lower the APC resistance ratio. Prolonged centrifugation, double centrifugation, or postcentrifugation plasma filtration was required prior to sample freezing.

Alternative (non-PTT-based) assays, including assays based on PT, factor Xa-clotting time, Russell's viper venom time, and Textarin time, have been developed. The major advantage of all these assays is insensitivity to FVIII activity. “Second-generation” PT- or PTT-based assays with predilution (1:10) in factor V-deficient plasma (immunodepleted) have been developed to normalize all other factors that might affect the APC resistance ratio (e.g., FVIII, prothrombin, protein S, other vitamin K dependent factors reduced in oral anticoagulation therapy) and possibly prevent interference by heparin or the presence of a lupus-like anticoagulant. These assays are 100% sensitive for the factor V Leiden mutation but are insensitive to other causes of APC resistance (e.g., oral contraceptives, pregnancy). Nevertheless, a second-generation APC resistance assay is recommended for screening for APC resistance.

APC resistance is associated with VTE. Depending on the assay used, 95% to 100% of patients with APC resistance are factor V Leiden carriers. Factor V Leiden is common among white populations of Northern European ancestry.¹⁹ Factor V Leiden is a founder mutation that occurred 30,000 years ago.³⁸⁸ No survival disadvantage is evident among factor V Leiden carriers.⁹⁹ About 10% of factor V Leiden carriers develop VTE over their lifetime.⁹⁹ The risk of VTE among factor V Leiden carriers increases with age; most events occur in carriers older than 50 to 55 years of age (Table 14-11).^{99,133} Homozygous factor V Leiden carriers have an 80-fold increased risk of thrombosis, and environmental exposures or other genetic risk factors may compound that risk.^{389,390} Penetrance of the thrombosis phenotype is increased among patients with multiple genetic defects (e.g., concomitant antithrombin III, protein C, or protein S deficiency).¹⁹ Thrombosis phenotype penetrance is dependent on clinical risk factor exposure (genetic/environmental interaction), such as oral contraceptives, pregnancy, or surgery. The reported risk of recurrent VTE among factor V Leiden carriers varies.¹⁹ The risk of recurrence is increased among homozygous factor V Leiden carriers, and among combined heterozygous factor V Leiden and prothrombin 20210 carriers. In a recent meta-analysis, pooled results from 10 studies involving 3104 patients with incident VTE revealed that the factor V Leiden mutation was present in 21.4% of patients and was associated with a 1.41-fold increased risk for recurrent VTE (95% CI, 1.14 to 1.75).¹⁸⁴ Factor V Leiden (along with other hereditary thrombophilias) is associated with increased fetal loss. Factor V Leiden does not appear to be associated with arterial events such as acute myocardial infarction, coronary artery disease, or stroke.¹⁹

[†]Compared to patients without factor V Leiden.

Impaired Fibrinolysis Pathway

With the use of an assay for global clot lysis, hypofibrinolysis (as reflected by a prolonged clot lysis time) was associated with a 1.6-fold increased risk of VTE.¹⁴⁸ In this assay, the clot lysis time is at least partially dependent on plasma levels of the proteins involved in fibrinolysis, including plasminogen, α_2 -plasmin inhibitor, and plasminogen activator inhibitor-1 (PAI-1).

Plasminogen Deficiency

Plasminogen is a 92-kDa protein that is present in blood as the inactive precursor of the serine protease, plasmin.^{391,392} Plasminogen is converted to plasmin by cleavage at the Arg561-Val562 peptide bond by tissue-type or urokinase-type plasminogen activator (tPA and uPA, respectively). Activation of plasminogen by tPA is the major physiologic pathway that leads to lysis of fibrin clots. The interaction between tPA and plasminogen is relatively slow. Annexin II is a cofactor on endothelial cells that binds plasminogen and tPA and catalyzes activation of plasminogen by tPA. The other major protein cofactor for the activation of plasminogen by tPA is fibrin. Both plasminogen and tPA have a relatively high affinity for fibrin (but not fibrinogen) and are incorporated into the fibrin clot that is forming. Coordinated binding of plasminogen and tPA to fibrin localizes activation of plasmin to the matrix of the clot, where tPA and plasmin are relatively protected from inhibition by PAI-1 and α_2 -plasmin inhibitor, respectively. Plasmin progressively lyses the fibrin clot, releasing multiple varying degradation products, including a specific degradation product, D-dimer. The rate and extent of fibrinolysis are affected by the activity of factor XIIIa; the more the fibrin clot is crosslinked, the more resistant it is to lysis.

Homozygous plasminogen deficiency is associated with ligneous conjunctivitis, characterized by the formation of proliferative pseudomembranes on the conjunctiva and other mucous membranes.^{393,394} However, the clinical importance of plasminogen deficiency as a risk factor for thrombosis is uncertain.

In family studies, thrombosis does not segregate with plasminogen deficiency.³⁹² Moreover, no consistent clinical

evidence of an association between homozygous plasminogen deficiency or decreased tPA and risk of thrombosis is apparent. Consequently, determination of plasminogen or tPA concentration (activity or antigen) should not be part of the routine evaluation of patients with thrombophilia. In addition, no indication for routine assessment of genetic abnormalities or polymorphisms of plasminogen or tPA has been identified in the evaluation of risk for VTE or arterial thrombosis.³⁹²

Increased PAI-1/Reduced Plasminogen Activator

PAI-1 is a 52-kDa single-chain plasma glycoprotein that is synthesized in the liver and endothelial cells; its synthesis is regulated by several physiologic mediators, including endotoxin, interleukin-1, fibroblast growth factor-2, and lipids.³⁹⁵ Plasma levels increase after surgery is performed. PAI-1 is a member of the SERPIN family and the primary inhibitor of tPA. Plasma PAI-1 is stabilized in its active form through interaction with vitronectin in plasma. Although increased plasma PAI-1 activity theoretically may become prothrombotic through downregulation of intravascular thrombolysis clearance, the results of studies that tested for an association of venous or arterial thrombosis with increased PAI-1 level or PAI-1 polymorphisms are conflicting.³⁹⁵ The predictive value of PAI-1 plasma concentrations is uncertain, and several important physiologic covariates are involved in the regulation of plasma levels. Common polymorphisms in the PAI-1 gene may affect plasma concentrations. However, currently available data do not support the routine measurement of PAI-1 plasma levels or genotype in the evaluation of thrombophilia.

Increased Factor XIII Activity/Factor XIII Polymorphisms

Plasma factor XIII is zymogen that circulates as a tetramer of two pairs of nonidentical A and B subunits.³⁹⁶ Factor XIII is activated to factor XIIIa by thrombin cleavage of an activation peptide from the two A subunits, which then dissociate from the B chains in the presence of calcium ions to form the active enzyme. Factor XIII is also found in the soluble fraction of platelets, but platelet factor XIII is composed only of α -chain dimers.

Factor XIIIa is a transamidase that catalyzes the formation of intermolecular (γ -glutamyl)-lysine covalent crosslinks in fibrin. One set of crosslinks forms rapidly between two fibrin α chains of adjacent fibrin monomers with reciprocal antiparallel bonding between Lys and Gln residues near the carboxylterminus of the chain. Factor XIIIa also crosslinks the fibrin α chain in a more complex pattern, ultimately resulting in large crosslinked fibrin polymers. α -Chain crosslinking proceeds more slowly than γ -chain crosslinking, and other plasma proteins, including α_2 -plasmin inhibitor, fibronectin, and VWF, are also crosslinked to the α chain.

Crosslinking increases fibrin strength and imparts resistance to lysis by plasmin, contributing to the stability of fibrin clots. Factor XIIIa also participates in other physiologic processes, including clot retraction, cell migration, and wound healing.

Factor XIII deficiency (see Chapter 5) results in a bleeding disorder that is inherited as an autosomal recessive trait with variable severity. Mutations of the A and B subunits have been associated with a bleeding tendency, and a large number of different mutations have been identified.

Four common polymorphisms are found within the factor XIII gene; these may produce amino acid changes at Val34Leu, Pro564Leu, Val650Ile, and Glu651Gln. The common Val34Leu mutation in the factor XIII A subunit is located only three amino acids away from the thrombin cleavage site (Arg37-Gly38). Thrombin activates factor XIII 34Leu more rapidly and at lower concentration than 34Val.³⁹⁷⁻³⁹⁹ Early activation of factor XIII leads to early crosslinking of fibrin, which inhibits lateral aggregation of the fibrin fibers such that the fibers are thinner and the fibrin clot is less porous. Thin fibrin fibers are relatively resistant to plasmin degradation,⁴⁰⁰ suggesting that factor XIII 34Val could be a risk factor for symptomatic thrombosis by producing a thrombus that is less susceptible to clearance by fibrinolysis.

However, contradictory to what would be predicted from fibrin structure, studies that determined the risk of VTE among factor XIII 34Leu carriers relative to noncarriers have reported a protective effect or no effect on risk.⁴⁰¹⁻⁴⁰⁶ Recent studies suggest a complex interaction between the factor XIII 34Leu mutation and plasma fibrinogen levels. Similar to the factor XIII 34Leu variant, high fibrinogen levels lead to a less porous and therefore less permeable fibrin clot with thin fibers, which would predict less susceptibility to fibrinolysis and an increased risk for thrombosis. Indeed, high fibrinogen levels are associated with an increased risk of myocardial infarction and premature coronary artery disease^{407,408} and VTE.^{135,318} However, at high fibrinogen concentrations, clot permeability is increased among factor XIII 34Leu homozygotes.⁴⁰⁹ This interaction would predict a protective effect of 34Leu at high fibrinogen levels. A recent study did report a reduced risk of VTE among factor XIII 34Leu carriers with high fibrinogen levels,¹²³ although the protective effect was limited to men. Similarly, case-controlled studies have reported that factor XIII 34Leu is protective from coronary artery disease and stroke,^{17,410} although the 34Leu polymorphism has also been associated with resistance to fibrinolytic therapy for acute myocardial infarction.⁴¹¹

Clearly, additional studies are needed to resolve the complex interaction between factor XIII activity and

genotype, fibrinogen concentration and fibrin structure, and risk of thrombosis. The data are insufficient at this time to warrant routine assay of factor XIII activity or genotyping for common factor XIII polymorphisms as part of a diagnostic evaluation of thrombophilia.³⁹⁶

Dysfibrinogenemia

The dysfibrinogenemias are a heterogeneous group of disorders that may cause alterations in the conversion of fibrinogen to fibrin. Approximately 300 abnormal fibrinogens have been reported with a wide variation in phenotypic expression, ranging from asymptomatic to a bleeding diathesis to recurrent VTE.⁴¹² Fewer than 20 cases of variant fibrinogens have been reported to be associated with thrombotic complications.

Increased Thrombin-Activatable Fibrinolytic Inhibitor

Thrombin-activatable fibrinolytic inhibitor (TAFI) is a 55-kDa carboxypeptidase B-like proenzyme that is synthesized in the liver and circulates in blood at a plasma concentration of 4 to 15 μ g per milliliter (70 to 275 nM).⁴¹²⁻⁴¹⁸ TAFI is activated by thrombin cleavage at Arg93 to form the active enzyme, carboxypeptidase U (also called TAFIa); thrombomodulin accelerates thrombin-mediated activation of TAFI by 1250-fold.⁴¹³ Thrombin-mediated activation of factor XI generates large amounts of additional thrombin via the intrinsic pathway, which results in TAFI-dependent downregulation of fibrinolysis.^{417,419,420} TAFIa inhibits fibrinolysis by removing carboxyterminal lysine residues from partially degraded fibrin polymers and preventing the binding of the fibrinolytic components, plasminogen and tPA, thereby limiting plasmin formation.⁴¹⁴ Plasma TAFI antigen levels appear to be lower among premenopausal women but otherwise do not appear to vary by age or sex.⁴²¹⁻⁴²³ An assay for functional TAFI has been developed that is based on (1) activation of TAFI with thrombin:thrombomodulin and (2) the amount of TAFIa activity generated.⁴¹⁵

Increased plasma TAFI levels and/or increased generation of TAFIa theoretically may be prothrombotic, and single studies have shown that increased plasma TAFI levels are weak risk factors for incident⁴²⁴ and recurrent¹⁸⁹ VTE. High TAFI levels have also been associated with incident stroke,⁴²⁵ although the association with coronary artery disease is less certain.⁴²⁶ However, the data are insufficient at this time to warrant routine assay of TAFI activity as part of a diagnostic evaluation of thrombophilia.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Paroxysmal nocturnal hemoglobinuria (PNH) manifests as hemolytic anemia, bone marrow failure, and thrombophilia, and is due to nonmalignant clonal expansion of one or more hematopoietic stem cells that have acquired a somatic mutation in the X-linked PIG-A gene, resulting in deficiency of glycosyl phosphatidylinositol (GPI)-anchored proteins such as the complement regulatory proteins, CD55 and CD59.⁴²⁷ Despite its rarity, PNH has served as a diagnostic dilemma, as an unusual but highly virulent form of thrombophilia, and as an example of a

unique clinical profile because of its thrombotic manifestations. Whereas DVT and PE are reported in PNH, an unusual overrepresentation of hepatic vein thrombosis (HVT), mesenteric vein thrombosis (MVT), cerebral vein thrombosis (CVT), and excess morbidity and mortality has been observed during pregnancy.^{427a} In their review of 125 patients with PNH, Ray and colleagues⁴²⁸ reported that DVTs and PEs together accounted for only 34% of all thromboses, and HVT alone constituted 29% and CVT 20% of all thrombotic events.

The disorder is rare and usually affects adults. It seems to have a common but not totally understood relationship with prior bone marrow problems, aplastic anemia in particular. It occurs in about 1 to 10 individuals per million and appears to be worldwide in its distribution. Its three primary manifestations consist of (1) thrombotic events (discussed here), (2) paroxysmal episodes of hemolysis with hemoglobinemia, and (3) hematopoietic marrow failure that manifests as any mixture of pancytopenia, myelodysplastic syndrome, and, within this population, a tendency toward evolution into acute leukemia.⁴²⁹ Hemolysis and hematopoietic failure are not further addressed in this chapter.

The median age of patients at the time of diagnosis was 42 years, and median survival was reported to be 10 years in a 1995 review.⁴³⁰ A leading, if not *the* leading, cause of death was venous thrombosis. In this review, 40% of patients experienced various thrombotic episodes during their illness. Of interest, spontaneous and lasting remissions of PNH may recur. Long-term anticoagulant therapy enhanced overall survival.^{427,430} A 2004 review⁴³¹ reported a longer survival, which may mean additional diagnoses of subtle, less virulent PNH categories and/or improvement in therapy. Investigators reported that patients of European ancestry experience more thrombotic events than Asians, and those Western patients' current survival appears to be on the order of 20 years, whereas in those of Asian extraction with fewer thrombotic events, survival is as long as 30 years. Asian patients appear to have more difficulty than Western patients with bone marrow aplasia. An additional risk for thrombosis is evident in African American and Latin American patients with PNH.⁴³²

Laboratory diagnosis historically involved the sucrose hemolysis test and the Ham acidified hemolysis test, but recently, these tests have been supplanted by flow cytometric detection of CD59-negative cells.⁴³³ As tests become more sensitive, one can expect that more patients with CD59-negative cells will be identified. Of interest, the finding of CD59-negative cells is not specific for PNH as patients with myeloproliferative disorders (especially essential thrombocythemia) and aplastic anemia may harbor small clones of CD59-deficient cells.^{434,435}

The red cell defect can be quantified through determination of the number of polymorphonuclear white cells that are negative for the CD59 antigen.⁴³¹ Patients who have a larger CD59-negative clone seem to have the worst symptoms, particularly thrombotic symptoms. Those with smaller PNH clones seem to express fewer thromboses but are more prone to bone marrow failure. Patients with shrinkage of their PNH clone may be especially subject to marrow failure. No patients with a PNH clone <60% in one series were found to have experienced thrombosis, whereas at least half of all patients with PNH clones $\geq$ 60% manifested

thrombosis. It was estimated that for each 10% increase in PNH clone, the odds ratio for risk of thrombosis increased by 1.64.⁴³⁶ These facts must be used in calculating the risks of anticoagulant therapy in patients who have not yet had a thrombotic manifestation.

One group that studied 56 patients with PNH sought evidence for additional thrombophilic risk factors to determine whether risks were additive. It was surprising that among 56 patients, no increase in the frequency of factor V Leiden mutation was noted.⁴³⁷ It remains to be seen whether these data can be duplicated for other thrombophilic disorders among patients with PNH.

Despite the relative rarity of PNH, all investigators have been intrigued by the strong proclivity among these patients to present with HVT or CVT. Among reviews of patients with HVT, the density of those who have PNH is noteworthy. PNH also seems to be overrepresented in CVT.

Louwes and colleagues⁴³⁸ detected shortened platelet survival, as well as decreased platelet production, among patients with PNH. Using kinetic studies, investigators identified enhanced uptake of platelets within abdominal vessels and hypothesized increased adherence of platelets to the endothelium within abdominal vessels in patients with PNH. This may explain, in part, the tendency of patients with PNH to experience intra-abdominal thromboses.

An increase in circulating procoagulant microparticles (MPs) has been detected in the plasma of patients with PNH.^{439,440,441} Hugel⁴³⁹ found increased circulating MPs seemingly of platelet origin in the plasma of patients with PNH, and they argued that these could serve as procoagulant phospholipid platforms in the plasma of such patients. Others⁴⁴⁰ detected increased platelet activation and platelet MP formation, as well as laboratory evidence for increased hypercoagulability (positive plasma thrombin:antithrombin III complexes as well as D-dimers) and markedly elevated levels of tissue factor (TF).

Given the frequency of thrombotic manifestations of PNH, all reviews suggest that anticoagulation is indicated and is usually effective.^{427,430,433,442,443} Antithrombotic therapy, probably provided for an indefinite period, appears to be indicated for nearly all patients who have had prior thrombosis. The use of anticoagulants for primary prevention of thromboembolic phenomena is controversial but certainly seems rational in patients with PNH clones greater than 50% to 60%⁴³⁶ and perhaps is less indicated in patients of Asian ancestry.⁴³¹

PNH is particularly virulent among pregnant patients. Ray and colleagues⁴²⁸ reviewed the literature regarding pregnancy in patients with PNH. They studied 20 reports involving 33 pregnancies and found a thrombosis rate of 12%. It also appears that some patients progress to thrombosis despite seemingly aggressive and adequate prophylaxis.^{440,444} The all-cause mortality rate was 21%. Half of patients were delivered before they reached term. A 9% perinatal mortality rate was reported.

In their review of PNH and pregnancy, Ray and associates⁴²⁸ recommended heparin (7500 to 10,000 units twice daily) or enoxaparin (75 to 100 anti-Xa units per kilogram once daily) for thromboprophylaxis, beginning early in the first trimester and continuing for at least 4 to 6 weeks postpartum. In patients with PNH who have concomitant thrombocytopenia with a platelet count of less than

50,000/ μ L, such therapy may be trying. Because of the extreme degree of hypercoagulability at term, one should be cautious regarding the usual lowering or cessation of thromboprophylaxis at the time of delivery, as this action seems to be frequently associated with a thrombotic event. Careful discussion with the obstetrician is warranted.

Chapter 15

Deep Vein Thrombosis and Pulmonary Embolism

Samuel Z. Goldhaber, MD

Venous thromboembolism (VTE) comprises deep vein thrombosis (DVT) and pulmonary embolism (PE). VTE constitutes the third most common cardiovascular disease, after acute coronary syndrome and stroke.¹ DVT and PE afflict individuals over a wide age range, from teenagers to the elderly. This illness strikes all socioeconomic groups in developed Western countries. Because the morbidity and mortality of VTE are favorably affected by modern therapy, accurate and prompt diagnosis is very important.

The diagnosis of VTE is often elusive. The greatest challenge for the clinician is to have sufficient clinical suspicion to consider the diagnosis. DVT and PE often manifest without classic symptoms or signs. DVT often mimics a harmless muscle cramp. In a multicentered VTE registry at 70 North American medical centers, 170 of 808 patients (21%) were given diagnoses more than 1 week after symptom onset, and 40 of 808 (5%) received diagnoses more than 3 weeks after symptom onset. On average, 80% of the delay in diagnosis occurred between symptom onset and medical evaluation.²

PE is notoriously difficult to diagnose and has earned the description of “the Great Masquerader.” However, attention to the clinical setting, risk factors, and differential diagnosis, coupled with ordering the appropriate imaging tests, often result in an accurate and timely diagnosis.

DIAGNOSIS

Deep Vein Thrombosis

Clinical Considerations

Figure 15-1 is an algorithm for DVT diagnosis. The most commonly reported symptom is a cramp or “charley horse” in the lower calf that gets worse with walking, that does not abate, and that gradually worsens after several days. The discomfort begins as a transient, nagging sensation, but it may eventually become persistent.

Edema may develop. Swelling is usually most prominent in the calf but can be limited to the ankle or even the foot. When thigh edema occurs because of DVT, one should consider the possibility of pelvic vein thrombosis. If the leg is diffusely edematous, DVT is less unlikely. Much more common is an acute exacerbation of venous insufficiency due to postphlebotic syndrome. Occasionally, erythema accompanies leg edema. Erythema may signify concomitant

superficial phlebitis with saphenous vein involvement or coexisting cellulitis.

The differential diagnosis (Table 15-1) includes ruptured Baker cyst, often manifested by sudden, excruciating calf discomfort. Fever and chills usually suggest cellulitis rather than DVT, although DVT may occur concomitantly. The clinical probability of DVT can be estimated with the use of the formal Wells DVT Scoring System,³ yet this approach is rarely used. I have never witnessed its use firsthand. Likelihood is usually estimated by *gestalt*.

Some favor stopping the DVT workup and not ordering a venous ultrasound if the clinical probability is low and a D-dimer enzyme-linked immunosorbent assay (ELISA) is normal. However, the prevailing approach is to image virtually all patients suspected of having DVT. The terminology of the ultrasound report may cause miscommunication. The distal portion of the deep femoral vein is called the *superficial femoral vein*. Despite the use of the term *superficial*, this is a large deep vein, and patients with superficial femoral vein thrombosis should be treated for DVT. Patients should not be discharged with the mistaken diagnosis of superficial thrombophlebitis.⁴

With upper extremity venous thrombosis, asymmetry may be noted in the supraclavicular fossae or in the girth of the upper arms.^{5,6} Also, a prominent superficial venous pattern may be seen over the anterior chest wall. This condition occurs most commonly (1) as a complication of a chronic indwelling central venous catheter, or (2) in otherwise healthy individuals who have been overexerting themselves with activities such as weightlifting (see Chapter 16).

Venous Ultrasonography

Usually, the venous ultrasound examination definitively detects or excludes symptomatic DVT. It is safe to withhold anticoagulation after negative results have been obtained on comprehensive duplex ultrasonography.⁷ However, new or progressive symptoms should prompt further testing. Occasionally, imaging test results are equivocal because of the patient’s body habitus, recent leg trauma or surgery, or profound edema that limits compression of vascular structures. Under these circumstances, one should consider using other imaging modalities such as computed tomography (CT) venography, magnetic resonance venography, or invasive contrast venography.⁸

Venous ultrasound is less reliable for screening asymptomatic patients. In a meta-analysis of asymptomatic

Figure 15-1 Diagnosis of deep vein thrombosis (DVT).

5. Varicose veins
6. Erythema nodosum

patients after orthopaedic surgery, when venous ultrasound was compared with invasive contrast venography as the gold standard, ultrasonography had a sensitivity of 62%, a specificity of 97%, and a positive predictive value of 66% in detecting proximal DVT.⁹ Of 100 consecutive patients who had undergone craniotomy, 13 had proximal DVT with contrast venography, and only 38% of these had concomitant abnormalities on ultrasound evaluation. Overall, ultrasound identified only 13 of 26 patients with proximal or isolated calf DVT.¹⁰ Should one leg be found to harbor a DVT, it is advisable for the clinician to study the other leg, even if it is presently asymptomatic.

Magnetic Resonance Venography

Magnetic resonance venography is especially useful for assessing pelvic vein and upper extremity thrombosis and for defining the extent of upper extremity vein thrombosis. Magnetic resonance imaging (MRI) can also be used to estimate the age of thrombus on the basis of “spin” characteristics of the image. Among patients with normal venous ultrasound examination findings, a substantial proportion of the DVTs that are responsible for PE originate in the pelvic veins.¹¹ For leg DVT diagnosis, MRI agrees closely with contrast venography.¹²

Catheter-Based Venography

Invasive contrast venography¹³ is rarely performed as a diagnostic test. However, for catheter-based intervention, contrast venography is the first step when one is considering thrombolysis, suction embolectomy, angioplasty, or stenting.

Pulmonary Embolism

Clinical Evaluation

The most important step involved in successfully diagnosing PE is simply to include PE in the differential diagnosis

when the symptoms, signs, and clinical setting suggest this condition. If PE is considered, one should pay careful attention to the chest x-ray (Table 15-2) and electrocardiogram (Table 15-3) to determine whether they are consistent with PE, or if they point toward another diagnosis, such as pneumonia or acute myocardial infarction. Too often, PE is overlooked because it mimics so many other illnesses (Table 15-4).

After the diagnosis is considered as a possibility, the next step for the clinician is to consider the likelihood of PE. This can be done in a formal model or by *gestalt*. With clinical *gestalt*, accurate determination of pretest probability appears to increase with clinical experience. In a study at the Brigham and Women’s Hospital’s emergency department, a trend was observed toward increasing accuracy with increasing experience, with respect to true-positive assessments, true-negative assessments, and likelihood ratios.¹⁴

When the clinician assesses for possible PE, the clinical context and the patient’s symptoms are the two most helpful findings. The clinician should ask whether the patient was predisposed to PE. Regarding symptoms, the most important clue is the presence of otherwise unexplained shortness of breath. Pleuritic chest pain usually occurs with small peripheral PE near the pleural lining, where nerve innervation is plentiful. Ironically, PE associated with dyspnea but no chest pain tends to be anatomically large and at times massive, whereas painful pleuritic PE tends to be anatomically small.

Table 15-2 Chest X-Ray Findings

Dilated pulmonary arteries, especially the right descending pulmonary artery
 Pulmonary infarction (Hampton hump)
 Lack of pulmonary vascularity (Westermark sign)
 Dilated azygous vein (indicating tricuspid regurgitation due to right ventricular dysfunction)

Table 15-3 Electrocardiographic Findings

Tachycardia (often absent in previously healthy younger patients)
 S in lead I; Q in lead III; inverted T in lead III
 Right bundle branch block (sometimes incomplete right bundle branch block)
 New atrial fibrillation or atrial flutter
 Rightward QRS axis

Table 15-4 Illnesses That Mimic Pulmonary Embolism

Anxiety/hyperventilation
 Pleurisy/acute viral illness
 Pneumonia
 Myocardial infarction
 Dissection of the aorta
 Pericardial tamponade

Small PE in the distal pulmonary vasculature may cause pulmonary infarction. This infarction is usually small but painful. It can cause so much pain that splinting of the chest and resulting atelectasis lead to secondary pneumonia. Pulmonary infarction is characterized by low-grade fever, tachypnea, and pain with inspiration or changing position. Hemoptysis is frequent in infarction and less common in PE without infarction. The pain may not respond to high-dose narcotics but usually abates with the use of nonsteroidal anti-inflammatory agents.

Use of a formal clinical scoring model is becoming more widely accepted as an accurate, efficient, and inexpensive way to triage patients according to the clinical probability of PE. The best known model is the Wells DVT Scoring System, which continues to be revised and modified.¹⁵ In 1998, Wells¹⁵ tested a clinical model in a prospective cohort study of 1239 inpatients and outpatients with suspected PE. These investigators showed that by using a clinical scoring system, they could stratify patients into 3 groups: low probability in 734 patients (3.4% with PE), moderate in 403 patients (28% with PE), and high in 102 patients (78% with PE).

The Wells criteria have been modified into a decision rule that dichotomizes patients according to PE unlikely with 4 or fewer score points versus PE likely with more than 4 score points (Table 15-5). This modified simple clinical decision rule can be used by the clinician as the first step in deciding whether to pursue blood test screening with D-dimer, or to go directly to imaging with chest CT scanning.¹⁶

Regardless of whether *gestalt* or Wells criteria are used to assess PE likelihood, it is important for the consultant to perform a directed history (Table 15-6) and physical examination (Table 15-7). Pertinent positive and negative findings are useful when one is predicting the clinical likelihood of PE, and they rapidly assist the consultant in understanding specific circumstances relevant to the patient who is being evaluated.

Screening With Blood Tests

Room air arterial blood gas analysis was the classic screening blood test used to triage patients with suspected PE. However, in the Prospective Investigation of PE Diagnosis (PIOPED) study, hypoxemia did not discriminate well between patients suspected of PE who actually had PE at pulmonary angiography and those whose pulmonary

Table 15-6 A “Directed” History for Suspected Pulmonary Embolism

“What did you notice that made you think you needed medical attention?”
 “Did you have breathlessness?”
 “Did you have chest pain? If so, did it occur with taking a deep breath or changing position?”
 “Have you had a prior DVT or PE?”
 “Is there a family history of DVT or PE?”
 “What do you think might predispose you to DVT or PE? Surgery? Trauma? Cancer? Birth control pills or hormone replacement? Immobility? Stress?”
 “Do you smoke cigarettes?”
 “What is your exercise routine?”

DVT, deep vein thrombosis; PE, pulmonary embolism.

Table 15-7 A “Directed” Physical Examination for Suspected Pulmonary Embolism

General appearance: Ill or healthy-looking? Anxious or calm?
 Respiratory rate and whether respirations are shallow, deep, or labored
 Neck vein distention
 Lung auscultation: Is there dullness at the base? Is there a pleural rub?
 Cardiac examination: Is there a right ventricular heave (manifested by a left parasternal lift)? Is S2 accentuated? Is there a distinct P2? Is there a murmur of tricuspid regurgitation (often a II/VI systolic murmur best heard at the left lower sternal border that increases to III/VI with inspiration)?
 Abdomen: Is there hepatjugular reflux?
 Legs: Is there leg or calf swelling or tenderness? Unilateral? Bilateral?

angiograms were normal.¹⁷ Normal values for the alveolar-arterial oxygen gradient also failed to exclude the diagnosis of PE in this study.¹⁸

Plasma D-dimer is the most useful screening test for patients with suspected PE. Even in the presence of PE, endogenous albeit ineffective fibrinolysis causes plasmin to digest some of the fibrin clot from the PE. The digested portion circulates as D-dimers that can be recognized by commercially available high-sensitivity monoclonal antibody kits. An elevated D-dimer is sensitive but not specific for PE.¹⁹ Other causes of D-dimer elevation include conditions that mimic PE and even those conditions predisposing to PE (Table 15-8).

Not all D-dimer testing is the same. Quantitative rapid ELISA D-dimer testing appears to provide the most reliable results for exclusion of DVT and PE.²⁰ In the emergency department of Brigham and Women’s Hospital, investigators mandated during a single calendar year that physicians order D-dimer ELISA tests on all patients suspected of acute PE. Of 1106 D-dimer assays, 559 were elevated, and 547 were normal. Only 2 of 547 had PE despite a normal D-dimer. The sensitivity of the D-dimer ELISA for acute PE was 96%. A high negative predictive value is the most important feature of an excellent screening test. In this study, the negative predictive value was 99.6%. Thus, with ruling out of PE by D-dimer testing, fewer chest CT scans

Table 15-5 Pulmonary Embolism Clinical Decision Rule

PE is unlikely with ≤ 4 score points.
 PE is likely with > 4 score points.

Variable	Points
Signs, symptoms of DVT	3.0
Alternative diagnosis less likely than PE	3.0
Heart rate > 100 /minute	1.5
Immobilization or surgery within 4 weeks	1.5
Prior PE or DVT	1.5
Hemoptysis	1.0
Cancer	1.0

Second or third trimester of pregnancy

and lung scans were required.²¹ The safety of D-dimer testing in ruling out PE and halting evaluation for PE in those patients with a high clinical probability of PE has not been firmly established.²²

Lung Scans

If clinical probability and D-dimer testing do not exclude suspected PE, the next major step is to order an imaging test. Lung scanning is rarely diagnostic²³ and has therefore fallen out of favor. By 2001, in the United States, a higher proportion of PE imaging tests were performed with chest CT than with lung scans.²⁴ Nowadays, lung scans are done only for patients with renal insufficiency, those with severe intravenous contrast reactions, and pregnant women (to minimize radiation).

Chest CT Scans

The introduction of the chest CT scan changed my professional life as a PE consulting doctor.²⁵ Before CT scanning became available, the most frequently posed question was: "Does this patient have a PE?" Most consult questions focused on interpretations of lung scans, which were usually reported as nondiagnostic. However, some consultant cases involved queries about patients with low-probability lung scans but high clinical suspicion. As a practical matter, PE consultants could not from a practical standpoint recommend diagnostic pulmonary angiography on every patient who had been evaluated with an equivocal lung scan. One has to practice the art and the science of medicine. After the patient had been exhaustively examined, with review of every detail of history and attempts to elicit every possible physical sign that would clarify the likelihood of PE, one had only three options: (1) Treat empirically for PE, (2) declare "no PE," or (3) recommend invasive pulmonary angiography. Nowadays, with the advent of chest CT scans, the consultant is less haunted by the possibility of excessive diagnosis or underdiagnosis of PE.

Multislice CT for PE diagnosis is a technological marvel. Multiple generations of CT scanners are used, but even first-generation machines deliver images that are dramatic in clarity, rapidly acquired, and accurate in delineating the proximal pulmonary arterial tree.²⁶ A 16-slice scanner can image the entire chest with submillimeter resolution and a breath-hold of less than 10 seconds.²⁷ The latest generation of scanners can image sixth-order vessels and visualize thrombi so small that their clinical importance is uncertain.²⁸

The chest CT scan can first make the "yes" or "no" diagnosis of PE. If PE is present, the CT will provide information

on size and location that is crucial to planning the management strategy. A central, saddle PE is readily seen and is amenable to surgical or catheter embolectomy. Multiple small peripheral PEs exclude a mechanical approach.

The chest CT scan can provide "one stop" access to diagnostic and prognostic information (Table 15-9). CT scan of the chest includes the central upper extremity veins and can be extended to the pelvic and deep leg veins, often pinpointing the location of the DVT that served as the source of the PE. In addition, careful review of the right ventricular size in relation to the left ventricular size can provide clues regarding the presence of pulmonary hypertension and the likelihood of right heart failure. These observations are important because they signify that the CT scan can be used as a prognostic tool and as a diagnostic tool.

If no PE is present, CT can often provide another plausible explanation for symptoms such as dyspnea that led to the PE workup. Most common is a pneumonia that is not well visualized on chest x-ray. At times, important incidental findings are noted that can be lifesaving, such as an early lung carcinoma causing no symptoms whatsoever.

A single-center study²⁹ and two overviews^{30,31} recently analyzed the reliability of CT scanning as the primary diagnostic test performed to exclude PE. All three studies required a minimum of 3 months of patient follow-up. Chest CT scanning was found to be at least as reliable as traditional invasive contrast pulmonary angiography. With normal CT scans that excluded PE, it was safe to withhold anticoagulation. CT scanning certainly avoids the myriad of complications that can occur with invasive pulmonary angiography,³² including cardiac perforation, pericardial tamponade, precipitation of ventricular tachycardia or fibrillation, and development of pseudoaneurysm or infection at the vascular access site.

Echocardiography

Transthoracic echocardiography is usually normal in patients with PE. The thrombus itself is difficult to visualize. Interpretation of the echocardiogram depends on indirect clues, such as right ventricular dilatation and hypokinesis, septal flattening and paradoxical septal

Table 15-9 Information to be Gleaned from the Chest Computed Tomography Scan

Is PE present or excluded? If PE is excluded, is there CT evidence for dissection of the aorta or pericardial effusion or tamponade?
If PE is present, what are the locations of the emboli? Are they central and accessible to surgical or catheter therapy?
Are there concomitant pulmonary parenchymal problems, such as pulmonary infarction, atelectasis, or pneumonia?
What is the diameter of the right ventricle compared with the left ventricle? Is the interventricular septum displaced toward the left ventricle?
Is thrombus visualized in the pelvic, leg, or arm veins?
Is thrombus visualized in any arterial vessel (thereby suggesting paradoxical embolism in the presence of PE)?

PE, pulmonary embolism; CT, computed tomography.

motion, and diastolic left ventricular impairment. These findings are often absent in patients with PE of small to moderate size. If present, they are especially useful in patients with PE that has been confirmed directly by chest CT. Right ventricular dysfunction on echocardiogram is far more useful for prognosis than for diagnosis.³³ Transesophageal echocardiography facilitates direct visualization of PE in the right or left main pulmonary artery. It provides a tool for prompt decision making in patients with hemodynamic compromise, in whom confirmation of the diagnosis is essential before thrombolysis or embolectomy is performed.³⁴

Magnetic Resonance Angiography

This modality is especially useful for patients with renal insufficiency or contrast allergy. In addition to direct thrombus imaging, lung perfusion-ventilation MRI is under development.³⁵ Beware that the FDA issued an alert in December 2006 that gadolinium, the contrast agent for MRI, is associated with development of a rare form of kidney disease.

Integrated Diagnostic Approach

Disparate clinical assessment tools and imaging modalities may overwhelm both the clinician who seeks consultation and the consultant. It is important to choose carefully from the array of diagnostic options and to select those tests that will be most helpful in a particular circumstance.

The most fundamental question is whether the patient has a PE. A systematic approach to assessment with an accepted and validated diagnostic protocol maximizes efficiency and success (Fig. 15-2). If the workup is negative, the consultant should try to find an alternative explanation for the symptoms and signs that suggested the diagnosis. If the workup reveals PE, the consultant should determine whether the PE is acute, subacute, or chronic. The consultant should then proceed with risk stratification and recommendations for therapy, as discussed in the remainder of this chapter.

Figure 15-2 Diagnosis of pulmonary embolism (PE).

RISK STRATIFICATION

Risk stratification is the key to successful treatment of patients with DVT and PE (Table 15-10). Low-risk patients have excellent outcomes with anticoagulation alone. Higher risk PE patients may benefit from consideration for more aggressive therapy with thrombolysis or embolectomy.

Clinical evaluation and fundamental parameters such as general appearance, respiratory rate, oxygen saturation level, heart rate, and blood pressure constitute the foundation for PE risk assessment. However, patients who have been previously healthy will often maintain normal vital signs despite anatomically large PE. Thus, contemporary risk assessment moves beyond the classic clinical evaluation and adds key elements, including measurement of cardiac biomarkers and determination of right ventricular size and function.

Cardiac Biomarkers

Cardiac troponins and NT-pro brain natriuretic peptide (NT-proBNP) and brain natriuretic peptide (BNP) have emerged as promising tools for risk stratification.³⁶ Elevated troponin levels in patients with PE are transient and small, compared with those in patients with acute coronary syndrome. In acute PE, troponin levels correlate with extent of right ventricular dysfunction.^{37–41} Myocardial ischemia due to alterations in oxygen supply and demand of the failing right ventricle play major roles in the pathogenesis of troponin level elevation.⁴²

The stimulus for natriuretic synthesis and secretion is cardiomyocyte stretch. Elevations in BNP and NT-proBNP are associated with right ventricular dysfunction in acute PE.^{43–48} Normal levels of natriuretic peptides imply low risk for patients with PE.

Elevated cardiac biomarker levels indicate that further risk stratification is warranted owing to limited specificity of the assays for predicting right ventricular dysfunction. In patients with PE who have normal biomarker levels, echocardiography is unlikely to provide additional prognostic information.⁴⁹

Echocardiography

Right ventricular dysfunction on echocardiography (Table 15-11) is an independent predictor of mortality in patients with PE.^{50,51} Among 1035 patients in the International Cooperative PE Registry (ICOPER) who presented

Table 15-10 Risk Stratification

Clinical assessment (Hemodynamically stable? Ill or healthy appearing?)
Anatomic size of clot
Oxygen saturation?
Elevation of cardiac biomarkers (e.g., troponin or BNP)?
Right ventricular enlargement (on chest CT or echo)
Right ventricular dysfunction (on echo)
Pulmonary hypertension (estimated on echo)

BNP, brain natriuretic peptide; CT, computed tomography; echo, echocardiography.

Table 15-11 Echocardiographic Abnormalities in Pulmonary Embolism

Abnormality	Comments
Right ventricular dilatation	Right-to-left ventricular diameter ratio >0.9 in the apical four-chamber view
Reduced ($<50\%$) respiratory variability of dilated (>2 cm) inferior vena cava	Suggests increased central venous pressure
Flattening or paradoxical motion of the interventricular septum	Suggests pulmonary hypertension
Tricuspid regurgitation jet velocity >2.6 mL/sec	Indicates pulmonary arterial systolic hypertension
Right ventricular systolic hypokinesis	Indicates right ventricular dysfunction
McConnell sign: Hypokinesis of the free wall but preserved apical motion	Specific for pulmonary embolism
Pulmonary artery thrombi	Rarely seen with transthoracic echo; more commonly observed with transesophageal echo
Right atrial or ventricular thrombi	Usually free floating
Patent foramen ovale; atrial septal defect	Seen with color duplex interrogation or echo "bubble" study

echo, echocardiography.

with systolic blood pressure ≥ 90 mm Hg and who underwent echocardiography within 24 hours of diagnosis, 405 had right ventricular hypokinesis, and 630 had preserved right ventricular function.⁵² The 30-day survival rates were 83.7% and 90.6%, respectively ($P < .001$).

Detection on echocardiography of a patent foramen ovale or an atrial septal defect is an ominous prognostic sign.⁵³ Another adverse prognostic finding is free floating right heart thrombus. In ICOPER, patients with right heart thrombus had increased mortality, primarily within the subgroup that was treated conservatively with only heparin (24% vs 8%).⁵⁴

Combined Troponin Elevation Plus Right Ventricular Enlargement

In a series of 141 patients with PE for whom both echocardiographic and troponin data were reported, those with both elevated troponin levels and right ventricular enlargement were at significantly greater risk of death after PE than those with only one or no adverse prognostic marker. The 30-day mortality rates were 5% for normal troponin and normal echocardiography, 9% for right ventricular dilatation alone, 23% for elevated troponin alone, and 38% for the lethal combination of right ventricular enlargement and elevated troponin. The adjusted hazard ratio for death within 30 days associated with right ventricular enlargement on echocardiogram and normal troponin was 2.2. For elevated troponin and no right ventricular enlargement on echocardiogram, the hazard ratio was 4.9. With the combination of troponin and right ventricular enlargement, the hazard ratio was 7.2.⁵⁵

Chest CT

Chest CT can be used to risk stratify and diagnose PE. With multislice CT scanners, standardized cardiac views provide valuable information about the size of the right ventricle compared with the left ventricle. In 63 patients with acute PE, the presence of right ventricular enlargement on the reconstructed CT four-chamber view correlated with the presence of right ventricular dysfunction on echocardiogram.⁵⁶

Right ventricular enlargement on chest CT helps the clinician to identify patients with PE who are at especially high risk of death. In 431 consecutive patients with acute PE, right ventricular enlargement on the reconstructed CT four-chamber view was an independent predictor of 30-day mortality (hazard ratio, 5.2).⁵⁷

PARENTERAL ANTICOAGULATION

Rapidly initiated, adequately dosed parenteral anticoagulation provides the foundation of treatment for DVT and PE. Initial treatment with oral anticoagulation alone leads to paradoxical thrombosis and triples the rate of recurrent VTE compared with the standard approach.⁵⁸ The mechanism is probably acute depletion of protein C, which causes rebound thrombosis.

Unfractionated Heparin

Bolus followed by continuous intravenous infusion of unfractionated heparin remains the most widely employed strategy for the initial management of acute PE. The heparin dose is titrated to the partial thromboplastin time (PTT), usually with the use of a target of 60 to 80 seconds. Many nomograms are available for heparin dosing.⁵⁹ In the United States, the most popular nomogram is the Raschke nomogram, which boluses initially with 80 U/kg, immediately followed by an infusion of 18 U/kg/hr.⁶⁰

Although continuous intravenous unfractionated heparin has been used for about 40 years, it is the most frequent cause of medication errors associated with anticoagulant therapy in the hospital. The root of these errors is most often related to the infusion device and to parenteral delivery problems. More advanced infusion devices with drug libraries, dosing guardrails, bar code readers, and dose calculators are being introduced.⁶¹

Subcutaneously administered anticoagulation has become increasingly popular in avoiding intravenous parenteral anticoagulation. Adjusted-dose subcutaneous heparin can be given safely and effectively to treat patients with DVT.^{62,63} However, this approach requires that PTTs be obtained and is cumbersome when used to maintain the target therapeutic range.

Low Molecular Weight Heparin

Subcutaneously administered low molecular weight heparin (LMWH) has become the first-line anticoagulant in the treatment of patients with DVT. A meta-analysis suggests that LMWH reduces the mortality rate compared with unfractionated heparin, with no increase in major bleeding complications.⁶⁴ LMWH also appears to be highly cost

effective, even for inpatient management of DVT.⁶⁵ However, proponents of unfractionated heparin argue that previous studies with unfractionated heparin used subtherapeutic ranges for the PTT target and dispute that LMWH is superior to unfractionated heparin.⁶⁶ Nevertheless, the ability to provide fixed, weight-based dosing without laboratory coagulation monitoring and the ability to avoid intravenous therapy have influenced most practitioners to favor LMWH.

For treatment of patients with DVT with LMWH, the most widely used regimen is enoxaparin 1.0 mg/kg twice daily.⁶⁷ An alternative dosing regimen is enoxaparin 1.5 mg/kg once daily.⁶⁸ A head-to-head comparison of tinzaparin versus dalteparin showed no differences with respect to efficacy and safety in a randomized trial for outpatient treatment of VTE.⁶⁹ The LMWH reviparin, appears more effective than unfractionated heparin in reducing the size of DVT. It is also more effective than unfractionated heparin for preventing recurrent DVT.⁷⁰

Because of success in managing DVT with LMWH, interest in the use of LMWH to treat patients with acute PE has been increasing. A study in which subcutaneous tinzaparin was compared with intravenous unfractionated heparin found that tinzaparin appeared to be as effective and safe in patients with acute PE.⁷¹ An individual patient data meta-analysis showed that the efficacy and safety of enoxaparin versus unfractionated heparin for DVT treatment are not modified by the presence of symptomatic PE.⁷² Another meta-analysis found that fixed-dose LMWH appears to be as effective and safe as dose-adjusted intravenous unfractionated heparin for the initial treatment of nonmassive PE.⁷³

In patients with cancer and VTE, a randomized trial of 672 patients compared dalteparin as a bridge to oral anticoagulation with dalteparin as monotherapy without oral anticoagulation. During the 6-month study period, a 52% reduction in recurrent VTE occurred in the dalteparin monotherapy group, without any difference in the bleeding complication rate.⁷⁴ It also appears that enoxaparin can be given as monotherapy to patients with acute PE with no differences in efficacy or safety compared with a strategy that “bridges” to warfarin.^{75,76}

Fondaparinux

Fondaparinux is a synthetic and selective inhibitor of factor Xa. It is FDA approved as a “bridge” to warfarin therapy in patients with acute DVT or PE. Its pharmacokinetic properties allow a simple, fixed-dose, once-daily subcutaneous injection that is weight based and that does not require laboratory coagulation monitoring. In a trial of 2205 patients with symptomatic acute DVT, fixed-dose fondaparinux (5.0 mg for <50 kg, 7.5 mg for 50–100 kg, and 10.0 mg for >100 kg) was at least as effective and safe as twice-daily weight-adjusted enoxaparin.⁷⁷ In a separate trial of 2213 patients with symptomatic acute PE, fondaparinux given in the same once-daily subcutaneous dosing regimen was at least as effective and safe as adjusted-dose continuous infusion intravenous unfractionated heparin.⁷⁸

THROMBOLYSIS

Thrombolytic therapy as an adjunct to parenteral anticoagulation should be considered for patients with painful

iliofemoral DVT or for those with PE with adverse prognostic factors such as elevated cardiac biomarkers, moderate or severe right ventricular enlargement, or moderate or severe right ventricular hypokinesis.

The Management Strategies and Prognosis in Pulmonary Embolism Trial-3 (MAPPET-3) is the largest single randomized, controlled PE trial of thrombolysis plus heparin versus heparin alone. Alteplase, the thrombolytic agent, was administered as a peripheral intravenous infusion of 100 mg over 2 hours. The primary end point was in-hospital death or clinical deterioration requiring escalation of treatment, defined as catecholamine infusion, repeat thrombolysis, mechanical ventilation, cardiopulmonary resuscitation, or embolectomy. The end point of escalation of therapy was higher in the heparin alone group (25% vs 10% in the heparin plus alteplase group). However, the difference was driven primarily by the administration of thrombolysis, which was considered a “soft” and controversial part of the composite end point.⁷⁹ A meta-analysis of randomized trials found that a benefit was suggested in those with hemodynamically unstable PE who were at highest risk of recurrence or death.⁸⁰

The indications for PE thrombolysis continue to generate controversy. A recent analysis from ICOPER found no benefit for thrombolysis among patients with massive PE, defined as those presenting with a systolic arterial pressure lower than 90 mm Hg.⁸¹

Lytic therapy administered systemically or (“catheter-directed”) regionally may have a role in the treatment of patients with acute DVT. The rationale for lytic therapy is that if clot lysis was rapidly successful, then decompression of the extremity would occur faster and perhaps would be limb saving in cases of impending venous gangrene, resulting in less venous valvular destruction and, over the long term, less chronic venous insufficiency.^{82–85} Despite years of use, none of these hypotheses has been adequately addressed, let alone answered, by appropriate randomized control trials (RCTs). Registries of catheter-directed lytic therapy documenting prompt efficacy do not prove superiority over systemically administered thrombolytic therapy or adequate heparin-based anticoagulant therapy. Evidence favoring catheter-directed thrombolytic therapy is strongest in cases of acute impending venous gangrene.^{86,87} Thrombolysis is frequently used to treat large, fresh thromboses of the veins of the arm and iliofemoral veins, especially in younger, otherwise healthy patients who are expected to have a low hemorrhagic risk and a long lifetime of less troublesome postphlebotic syndrome.

EMBOLECTOMY

Pulmonary embolectomy should be considered for patients with PE who are at high risk of death or major nonfatal complications and who cannot safely receive treatment with thrombolysis because of a prohibitively high bleeding risk. At Brigham and Women’s Hospital, we perform about one pulmonary embolectomy per month and 30-day survival exceeds 90%. Our success is based in part on an integrated medical-surgical thrombosis service that rapidly consults on high-risk PE patients. The objectives are (1) to refer patients to surgery on the basis of risk stratification, and (2) to make a disposition prior to the onset of irreversible cardiogenic

shock and multisystem organ failure.⁸⁸ At certain centers, surgical pulmonary embolectomy, which had been virtually abandoned, is making a successful renaissance.^{89,90}

Catheter embolectomy promises to be a less invasive approach for patients with PE who have a poor prognosis and contraindications to thrombolysis.⁹¹ Integration of catheter thrombectomy into the therapeutic armamentarium has been hampered by technical problems, including poor steerability, mechanical hemolysis, and distal embolization of the thrombus. A novel catheter is under development that aspirates, macerates, and removes the thrombus through an aspiration port.⁹²

INFERIOR VENA CAVAL FILTERS

Two major indications for inferior vena caval (IVC) filters are as follows: (1) inability of the patient to tolerate anticoagulation because of major bleeding, and (2) recurrent PE despite adequate anticoagulation. However, filter insertion has increased for “softer” indications such as prophylaxis in high-risk or trauma patients, anatomically large DVT, or “free-floating” DVTs.⁹³

Over a 20-year period in the United States, the frequency of IVC filter insertion has increased by more than 20-fold.⁹⁴ The most recent trend has been to insert retrievable IVC filters.⁹⁵ In a prospective DVT registry of 5451 patients with ultrasound-confirmed DVT from 183 U.S. study sites, 781 (14%) received IVC filters.⁹⁶ IVC filters, used in both short-term⁹⁷ and long-term follow-up,⁹⁸ appear to reduce the risk of PE but increase the risk of DVT, with no effect on overall survival. Patients with IVC filters have a higher rate of rehospitalization for VTE than do those with DVT who are not given IVC filters⁹⁹ (see Chapter 31).

INTEGRATED APPROACH TO INITIAL MANAGEMENT

Acute DVT

Most patients with small or moderate leg DVT are at low risk of complications and receive LMWH as a “bridge” to oral anticoagulation with warfarin (Fig. 15-3). An alternative and equally effective strategy is to prescribe fondapar-

influx as a “bridge” to warfarin. Symptomatic patients with isolated calf DVT should receive anticoagulation and should not be subjected to a strategy of “observe and rescans for proximal propagation.”

A pivotal management issue is whether patients should be treated at home or in the hospital. Although home treatment is becoming more popular, certain caveats should be kept in mind. Table 15-12 lists contraindications to home treatment of DVT.

For patients with large or massive DVT, a decision must be made as to whether catheter-directed thrombolysis is appropriate.¹⁰⁰ Massive DVT with purplish skin discoloration is called phlegmasia cerulea dolens. This term refers to a spectrum of large DVT, ranging from iliofemoral thrombosis to venous gangrene and necrosis. Venous engorgement with increased pressure in the capillaries leads to massive leg edema and potential arterial inflow compromise. Patients should be followed for possible progression to a compartment syndrome, for which urgent fasciotomy may be required if arterial flow becomes impaired.

For those patients with DVT who have active bleeding or a tendency to bleed, insertion of an IVC filter should be considered. When the duration of bleeding is believed to be short, placement of a retrievable filter is preferable to use of a permanent filter.

Patients with septic thrombophlebitis should receive broad coverage antibiotics plus full anticoagulation, usually with continuous intravenous unfractionated heparin. They should remain hospitalized until the fever subsides and the pain and erythema caused by the phlebitis have abated.

Patients with only an initial superficial thrombophlebitis may respond to conservative measures such as nonsteroidal anti-inflammatory agents. If superficial phlebitis persists, a 1-month course of half-dose anticoagulation, such as with enoxaparin 1 mg/kg once daily as monotherapy without warfarin, is often highly effective.

Acute PE

The key to successful management is rapid and accurate risk stratification (Fig. 15-4). Low-risk patients have excellent outcomes with anticoagulation alone. However, thrombolysis or embolectomy should be considered, in addition to anticoagulation, for high-risk patients.¹⁰¹ Rapid institution of definitive therapy usually improves the acutely decompensated right ventricle.¹⁰²

Figure 15-3 Treatment for deep vein thrombosis (DVT).

Table 15-12 Contraindications to Home Treatment of Patients With Deep Vein Thrombosis

The patient has leg pain or is unable to walk comfortably. Massive thigh or calf swelling has been noted. Pelvic vein thrombosis occurs, in addition to leg DVT. The upper arm is markedly swollen. Thrombolysis, catheter embolectomy, or IVC filter placement has been planned. Low likelihood of compliance with prescribed treatment. Homeless. Phoneless.

DVT, deep vein thrombosis; IVC, inferior vena caval.

Figure 15-4 Risk stratification for pulmonary embolism (PE).

Massive PE with hemodynamic compromise warrants special consideration. The clinician may use high-dose unfractionated heparin in larger than usual doses. A minimum bolus of 10,000 units followed by a continuous infusion of at least 1250 units per hour serves as a cornerstone of therapy. Empirical observation reveals that standard doses of heparin often fail to achieve therapeutic levels of anticoagulation. Although rapid administration of 500 mL of normal saline is acceptable for restoring adequate blood pressure, fluids should be used with extreme caution. In right ventricular failure, fluid administration exacerbates right ventricular wall stress, intensifies right ventricular ischemia, and causes further interventricular septal shift toward the left ventricle, thereby worsening left ventricular compliance and filling. Therefore, the clinician should have a low threshold for initiating pressors, such as dopamine or dobutamine.¹⁰³ A temporary improvement in hemodynamics facilitates more definitive therapy with thrombolysis or embolectomy.

Acute PE can lead to chronic thromboembolic pulmonary hypertension¹⁰⁴ (see Chapter 45). Previously considered a rare event, the incidence is high and seems progressive: 1.0% at 6 months, 3.1% at 1 year, and 3.8% at 2 years.¹⁰⁴ The best therapy for established chronic thromboembolic pulmonary hypertension is pulmonary thromboendarterectomy, a complex operation that can restore normal cardiopulmonary function.¹⁰⁵ For nonsurgical candidates, balloon pulmonary angioplasty may be considered.¹⁰⁶

LONG-TERM ANTICOAGULATION

Warfarin anticoagulation provides the foundation for long-term prevention of recurrent DVT and PE. Warfarin, patented in 1948 and introduced commercially in 1954, is the 20th most frequently prescribed drug in the United States, with more than 24,000,000 prescriptions written annually in the United States alone.

For the initial treatment of patients with DVT or PE, the target international normalized ratio (INR) is usually between 2.0 and 3.0. An overview of bleeding complications revealed that the rate of intracranial bleeding was 1.15 per 100 patient-years, and the case fatality rate of

major bleeding was 13%.¹⁰⁷ Centralized telephone-based anticoagulation services can improve safety.¹⁰⁸ Self-monitoring of INR and learning how to self-dose warfarin, analogous to the common practice among patients with insulin-dependent diabetes of blood sugar testing and self-dosing, can lower the complication rate even further¹⁰⁹ (see Chapter 40). Rapid turnaround genetic testing may personalize warfarin dosing and eliminate much of the “guess work” in prescribing the initial dose.

Risk of Recurrence After Warfarin is Discontinued

Clinical and thrombophilic risk factors for recurrent DVT and PE are present after warfarin is discontinued. In general, clinical risk factors are more predictive than is laboratory thrombophilia evaluation. Patients with provoked DVT or PE after surgery, trauma, pregnancy, or hormone replacement therapy are ordinarily at low risk of recurrence, as long as these specific risk factors are negated and further avoided.

Patients with a first symptomatic PE have a higher risk of recurrent VTE than do those who originally present with DVT without symptoms of PE. In a study from Vienna, Austria, the relative risk of recurrence was more than twice as high in patients who initially presented with PE.¹¹⁰ The risk that patients may have a PE rather than a DVT as the recurrent event was 4 times higher compared with the risk in patients who presented originally with DVT and no symptoms of PE.¹¹⁰ For unknown reasons, men have a higher risk of recurrence than women.^{111,112}

Impact of Thrombophilia

The Leiden Thrombophilia Study enrolled and followed 474 patients with VTE for a mean of 7 years; complete follow-up was provided in 94%. The incidence rate of recurrence was highest during the first 2 years after the event. The risk of thrombotic event recurrence was twice as high among patients whose initial event was idiopathic. Prothrombotic laboratory abnormalities did not appear to play an important role in the risk of recurrent VTE.¹¹³ However, other studies found that prothrombin gene mutation,¹¹⁴ hyperhomocysteinemia,¹¹⁵ and antiphospholipid antibody syndrome¹¹⁶ increased the risk of recurrent events. Whether factor V Leiden increases the risk of recurrence remains controversial^{117,118} (see Chapter 14).

Optimal Duration of Anticoagulation

It is clear that 6 months of anticoagulation halves the recurrent VTE rate compared with 6 weeks of therapy.¹¹⁹ It is also evident that indefinite anticoagulation should be instituted after a second episode of VTE has occurred.¹²⁰ A meta-analysis indicates that with lifelong therapy, one needs to treat about nine patients to prevent a single episode of VTE. The long-term bleeding risk in the population that has successfully received anticoagulation for 6 months is very low.¹²¹

For patients with idiopathic VTE, indefinite duration anticoagulation was shown to be superior to 3 to 6 months of anticoagulation in three separate randomized, controlled

trials of the extended treatment strategy. A Canadian study¹²² investigated warfarin given in the standard therapeutic INR range of 2.0 to 3.0. An American study¹²³ examined warfarin in the low-intensity INR range of 1.5 to 2.0. A European study¹²⁴ examined ximelagatran, an oral direct thrombin inhibitor, as the therapeutic anticoagulant agent. All three extended treatment strategies were successful.

Another approach to determining duration of therapy in patients with DVT used residual venous thrombosis visualized on venous ultrasound examination. Patients with residual disease at 3 months underwent serial ultrasound examinations until their studies normalized, or until they had undergone 36 months of follow-up. At 3 months, only 39% of patients had normal ultrasound examinations. By 36 months, 74% of patients had normal studies. The likelihood of recurrent DVT was 2.4 times higher among patients whose ultrasound results showed residual venous thrombosis.¹²⁵

Another alternative strategy involves measuring D-dimer levels 1 month after anticoagulation is discontinued. In an Italian study, VTE recurrence was 2.4 times greater among patients whose D-dimer levels failed to normalize.¹²⁶ A study from Vienna found that the recurrence rate was 40% lower with D-dimer levels between 250 and 500 ng/mL (the upper portion of the normal range) and 70% lower for levels below 250 ng/mL.¹²⁷

Venous Thromboses at Unusual Sites

Marc Zumberg, MD • Craig S. Kitchens, MD

Deep venous thrombosis (DVT) and its associated condition, pulmonary embolism (PE), represent the most commonly encountered examples of venous thromboembolism (VTE). DVT and PE were discussed thoroughly in Chapter 15. VTE that occurs at unusual locations, for example, in the intracerebral or intra-abdominal venous circulation, is being diagnosed with increasing frequency. In this chapter, we discuss VTEs at unusual sites. These events are associated with acquired and congenital hypercoagulable disorders and, although less frequently encountered than DVT, they account for a disproportionate amount of morbidity and mortality. Modern radiographic imaging and improved clinical understanding have resulted in more timely diagnosis and institution of effective treatment. In fact, owing to the sensitivity of modern radiographic imaging, these VTEs may be detected in asymptomatic individuals as incidental findings on studies done for other purposes, thus leading to difficult management decisions. Whereas in the past these unusual VTEs were autopsy suite curiosities, we now have the opportunity to deal with them in life, thus minimizing morbidity and mortality.

HISTORICAL ASPECTS

Many founders of what we now call internal medicine complemented their vast clinical practice through precise observations made at the autopsy table. Both William Osler¹ and Austin Flint,² in their textbooks written a century ago, discussed unusual sites of VTE. They both recognized that these conditions were characterized by vague and often subacute symptoms, and that diagnosis was only rarely made in life and was more often noted at autopsy. These observations pertained to thromboses of the hepatic veins, cerebral veins and sinuses, portal vein, and renal veins. Although Virchow³ speculated 30 years before the Osler and Flint textbooks were written that abnormalities would be found in blood, in addition to inflammation and impaired circulation (thus creating Virchow's triad), neither Osler nor Flint referenced his theory. Rather, they resorted to pathophysiologic theories that we now regard as somewhat unusual. For instance, the known association of cerebral venous and sinus thrombosis with the puerperium was explained by propagation of clots from pelvic veins up through venous complexes along the spinal column and into the brain. They also speculated that renal vein thrombosis was caused by DVTs of the legs that embolized to a renal vein. Those pathogenic mechanisms are no longer embraced. We now hold that these clots are formed in situ, yet they may also coexist with VTE at other locations—an association that early investigators did not appreciate. These great observational

clinicians believed that most of these events were idiopathic, although an association was made with marantic conditions and chronic infections.

Progress in our knowledge of this area of medicine has been exciting and intellectually satisfying as we have witnessed the replacement of theory, dogma, and the unknown by scientific discovery. Idiopathic causes are dwindling and have been replaced by more specific diagnoses (Table 16-1).⁴ The tempo of knowledge acquisition has been rapid if one recalls that antithrombin III (ATIII) deficiency, the first thrombophilic disease discovered (which vindicated Virchow), was described in 1965, followed by protein C deficiency in 1981 and protein S deficiency in 1984. The factor V Leiden mutation and the prothrombin 20210 mutation were described in 1994 and 1996, respectively. Other acquired hematologic conditions such as the antiphospholipid antibody syndrome (APLS), paroxysmal nocturnal hemoglobinuria (PNH), and heparin-induced thrombocytopenia (HIT) have also been associated with thrombosis at unusual sites.^{5–8} Undiscovered disorders will no doubt be found in ensuing years. Not only has the idiopathic category been eroded, but pathogenic mechanisms have given way to more reasonable concepts. Most thrombotic events are still best explained by a “double hit,” in which an underlying hypercoagulable condition exists, yet an additional provocation such as pregnancy, surgery, infection, travel, or some other condition tips the hemostatic scales in favor of thrombosis. Contributing provocations may be revealed in approximately 50% of cases of thrombosis through a thorough history, with the remaining one half of cases remaining seemingly spontaneous and idiopathic.⁹

The role of diagnostic imaging in the 21st century is nowhere better exemplified than in the use of modern radiology to elucidate thromboses at unusual sites. Computed tomography (CT) is limited in some aspects, particularly in detecting cerebral vein and sinus thromboses, but it is excellent for imaging visceral thromboses. Ultrasonography with Doppler flow has also been extremely useful in the diagnosis of visceral thromboses. In many cases, magnetic resonance imaging/angiography (MRI/MRA) is the most sensitive and specific tool used by clinicians to diagnose thromboses at unusual sites.^{10,11}

IMPORTANCE TO THE PATIENT AND THE CLINICIAN

DVT and PE remain the *sine qua non* of hypercoagulability. With the use of ATIII deficiency as the prototypic hypercoagulable disease, data are available to show that 25% of all

Table 16-1 Inherited and Acquired Hypercoagulable Conditions Associated with Thromboses at Unusual Sites**Congenital**

Antithrombin III deficiency
 Protein C deficiency
 Protein S deficiency
 Factor V Leiden mutation/activated protein C resistance
 Prothrombin 20210 gene mutation
 Hyperhomocysteinemia

Acquired

Cancer
 Myeloproliferative disease
 Polycythemia vera rubra
 Essential thrombocythosis
 Antiphospholipid antibody syndrome
 Heparin-induced thrombocytopenia
 Paroxysmal nocturnal hemoglobinuria (PNH)

patients with ATIII deficiency will at some time manifest their thrombophilia as thrombosis at an unusual site (Table 16-2).¹²⁻¹⁵ Thromboses may occur as the initial presentation of thrombophilia, may coexist with DVT/PE, or may arise later in the course, once the diagnosis of hypercoagulability has been established in patients or their kindred. A clue to the correct diagnosis of a thrombosis at an unusual site often is found in a past personal or family history of thromboembolism. Data presented by DeStefano and associates⁹ substantiate the role of a heightened index of suspicion in the thrombophilic patient when the differential diagnosis of vague subacute symptoms is considered. Whereas such symptoms may signify uncertain meaning in patients without hypercoagulability, these same symptoms in a thrombophilic patient may very well prompt a diagnosis of cerebral or visceral thrombosis.

One could charge that the hematology community has been somewhat passive in the diagnosis, management, and follow-up of these patients, instead yielding to organ-specific physicians such as the hepatologist to treat a patient with hepatic vein thrombosis, the nephrologist for the patient with renal thrombosis, and the neurologist for the patient with cerebral vein thrombosis. It is obvious

Table 16-2 Thromboses at Unusual Sites and the Role of Hypercoagulability**Established**

Table 16-3 Facts Regarding Patients with Thromboses at Unusual Sites

- Thrombophilia will account for 75% of these unusual and rare conditions.
- Twenty-five percent of thrombophilic patients will experience at least one of these conditions in their lifetime.
- These conditions cause considerable degrees of morbidity and mortality if not diagnosed and treated aggressively.
- Familiarity with hypercoagulable patients allows the hematologist to maintain a high index of suspicion for these rare conditions.
- Anticoagulation or antifibrinolytic therapy is the mainstay of treatment in most thrombophilic conditions.

that the pathophysiologic link among these three examples is hypercoagulability, and that the affected organ is primarily an “innocent bystander.” A single organ that manifests a thrombosis in no way protects other organs or sites from thrombosis in patients with hypercoagulability. By virtue of their experience with a cohort of hypercoagulable patients, hematologists are in a unique position to make a prompt and preemptive diagnosis, guide initial treatment, and make long-term management decisions (Table 16-3).

INTRA-ABDOMINAL THROMBOSIS

The hepatic, portal, and mesenteric venous systems are sites of unusual thrombosis that can manifest with dramatic clinical and radiologic findings. Recognition of the anatomy of this region is imperative for the consultant hematologist who wishes to make effective treatment recommendations.

Mesenteric Venous Thrombosis**Overview**

Mesenteric venous thrombosis (Table 16-4) is distinct and is much less common than mesenteric arterial thrombosis.¹⁶ Although rare, it ranks as the third most common site of venous thrombosis behind the lungs and the limbs.¹⁷ Mesenteric arterial thrombosis is usually seen in older, hypertensive, and often diabetic patients who present with an acute abdominal catastrophic event that rapidly leads to ischemia and death of the abdominal organs supplied

Table 16-4 Mesenteric Venous Thrombosis: Clinical Vignettes

Vague abdominal pain is insidious in onset.
 Pain is out of proportion to physical findings.
 Kidney, ureter, and bladder (KUB) findings are nondiagnostic.
 Computed tomographic scanning with contrast or magnetic resonance imaging with gadolinium is necessary for proper diagnosis.
 Frank gastrointestinal bleeding is rare.
 If left untreated, it will evolve into a surgical abdomen.
 Primary preinfarctive treatment consists of anticoagulant or thrombolytic therapy.

Figure 16-1 Mesenteric vein thrombosis. This computed tomographic scan with contrast shows an engorged superior mesenteric vein (arrow) that is distended with clot and outlined by a thin rim of dye.

by the superior mesenteric artery. A detailed description of mesenteric artery thrombosis is outside the scope of this chapter but is provided in other sources.¹⁸ As compared with mesenteric artery occlusion, thrombosis of the superior and inferior mesenteric veins is less common and less precipitous; it is often subacute in nature. Superior mesenteric vein thrombosis has historically been difficult to diagnose because less sophisticated radiographic images, such as flat plates and upright views of the abdomen, as well as various barium studies, are nonspecific and often do not lead to the diagnosis. Diagnosis of mesenteric vein thrombosis is now more readily made, even if accidentally, by CT with vascular contrast. The thrombosed superior mesenteric vein is seen as a large, distended vessel that does not fill appropriately with contrast (Fig. 16-1). The bowel wall may be thick and edematous. We have observed several cases of a “misty mesentery”¹⁹ on abdominal CT, caused by inflammation and edema from mesenteric vein thrombosis (Fig. 16-2). This finding totally resolves with successful treatment of the thrombosis.

Two adjacent articles in *Annals of Surgery* in 1895 provided seminal insight into mesenteric vein thrombosis. Delatour²⁰ described a fatal case of mesenteric infarction that occurred after an enlarged spleen had been electively removed to treat a patient with what was most likely a myeloproliferative disorder. He opined that the hematologic condition “so changed her blood that coagulation was easily induced.” Elliot²¹ was able to remove infarcted bowel in a living patient yet noted that the patient concomitantly had bilateral femoral vein and portal vein thrombosis, thus suggesting an underlying hypercoagulable condition.

Causes

Causes of mesenteric vein thrombosis are multiple. One must cautiously read older reviews of mesenteric vein thrombosis that garnered patients before the modern era of hypercoagulability because, by definition, causes could not include the thrombophilic diseases that had yet to be described. In one study, mesenteric vein thrombosis accounted for 0.01% of all surgical admissions and surgical autopsies,²² and in another study, 0.06% of all surgical admissions.²³ Clearly, this is a rare disease. On the other

Figure 16-2 “Misty mesentery.” This computed tomographic scan with contrast shows the mesentery as strands in a weblike configuration caused by edema and inflammation. This situation may have several causes, but in this case, mesenteric vein thrombosis is most likely due to leakage of bacteria and bacterial products from the compromised ischemic small bowel. After successful treatment was provided, follow-up images were normal.

hand, in a cross-sectional study, mesenteric vein thrombosis was found to have occurred in 3% of patients who were known to have a deficiency of ATIII, protein C, or protein S⁹; in another cross-sectional study, mesenteric vein thrombosis was found in 10% of patients with ATIII deficiency, in 6% of those with protein C deficiency, and in 4% of patients with protein S deficiency. One can estimate that the incidence of mesenteric vein thrombosis is increased at least 100-fold in patients who have an identified deficiency of one of these anticoagulant proteins. Pabinger and Schneider reported that 80% of patients who had thrombophilia and mesenteric vein thrombosis had a prior history of a previous DVT or PE.¹⁵ Recent studies of patients with mesenteric vein thrombosis have discovered prothrombotic disorders in 45% to 82% of cases.^{17,24,25} In these studies, factor V Leiden was found in 18% to 25% of cases, and the prothrombin 20210 mutation in 25% to 45% of cases.^{17,24} Combined defects were seen in more than one third of cases.^{17,24} Recently, the JAK2 mutation has been detected in 17% of patients with splanchnic venous thrombosis; most had no evidence of myeloproliferation at the time of the thrombosis.^{25a}

Whereas mesenteric vein thrombosis may appear to occur spontaneously in patients with thrombophilia, an additional provocation may be detected in about one half of cases. This fact more likely than not accounts for older reviews that include such “causes” of mesenteric vein thrombosis as cirrhosis, heart failure, intra-abdominal malignancy, peritonitis, intra-abdominal abscess, abdominal trauma, and abdominal surgery.²⁶ Although these provocations may well induce thrombosis in hypercoagulable patients, they prove to be the sole cause in only a minority of cases.²⁷ Synergy between an underlying hypercoagulable disorder and a provocation is frequent. For example, we have seen several patients with APLS whose long-term oral anticoagulant therapy had unwisely been held in preparation for colonoscopy with polypectomy; they developed

abdominal pain several days later and were subsequently given a diagnosis of mesenteric vein thrombosis. The unopposed hypercoagulable disorder coupled with inflammation and bacterial showering from the biopsy site may have provoked thrombosis in these high-risk patients.

Signs and Symptoms

Symptoms of mesenteric vein thrombosis are vague and nonspecific.^{4,28} Abdominal pain is usually of insidious onset. The patient cannot find a position or maneuver that makes the pain disappear. In contrast to most abdominal catastrophes, bowel movements continue, and frequently, the patient continues to eat. Nausea is seen in less than one half of cases. Typically, the pain continues for days to weeks, and several evaluations may yield no diagnosis. When transmural ischemia occurs, gastrointestinal bleeding, perforation, and peritonitis may ensue. Hematochezia, hematemesis, or melena occurs in only 15% of patients, although occult blood may be detected in one half of cases.²⁷ When intra-abdominal disease is the main underlying cause, thrombosis usually occurs in proximal large vessels and then extends distally; however, the reverse is often true when underlying thrombophilia is the main cause.²⁷

Abdominal pain appears to be far worse than one can account for on the basis of physical examination findings. Rebound tenderness is not present unless the bowel is infarcted. Laboratory data show hemoconcentration and white cell count usually in the 15,000 to 30,000/ μ L range. Routine abdominal radiographs are nearly always normal. The natural history of the process is such that if a diagnosis is not made after 10 to 20 days, the intestines undergo ischemic infarction. At that time, the symptoms evolve into those of a classic surgical abdomen, with rebound tenderness, rigidity, and increased morbidity and mortality due to venous infarction of the intestine.

Diagnosis

Diagnosis is best made by helical CT scan or CT angiography, which confirms the diagnosis in 90% of cases.^{11,27} Doppler ultrasonography is also accurate but is operator dependent and may be limited by bowel gas.¹¹ MRI with gadolinium and MRA are also highly accurate but may be less readily available.²⁵ Helical CT has remained our diagnostic test of choice.

If the patient undergoes surgery before the correct diagnosis has been made, the surgeon usually finds a dusky but not frankly gangrenous intestinal wall (unless through-and-through infarction has taken place) and bounding mesenteric arterial pulses. When ischemia or infarction is present, viability is not as clearly demarcated as in cases of acute arterial infarction. Second-look laparotomy has been advocated as an approach that is useful for minimizing the amount of resected bowel during the initial operation.^{29,30} When the bowel wall is transected, tiny wormlike clots extrude from engorged veins at the edge of the resected bowel in a peculiar but pathognomonic way. Histologic examination shows extensive hyperemia and hemorrhage, and the degree of infarction is determined by the duration of ischemia.

Treatment

Surgery is to be avoided as the primary diagnostic method unless an acute surgical abdomen and obvious bowel

infarction are detected. A thickened or edematous bowel wall on imaging itself does not imply infarction. Surgical exploration has been replaced by radiologic exploration. Once the thrombotic cause of the disorder has been discovered, it should be approached vigorously with aggressive anticoagulant therapy, even in the face of hemodynamically stable active gastrointestinal bleeding. Thrombolytic therapy has also been used with success.³¹ We have employed systemic thrombolysis with excellent results without excessive hemorrhage. Some clinicians have advocated catheter-directed thrombolytic therapy, but this is not a universally accepted approach.^{25,32} Early surgical series that were reported before anticoagulant therapy or modern radiologic imaging became available described a mortality rate of about 65%, which was an improvement over the initial natural history of the disease treated with only supportive care, for which mortality was estimated to be 95%. If the diagnosis is made at surgery and is followed promptly by anticoagulant therapy, observed mortality drops to approximately 35%. If the diagnosis is made radiographically and patients are treated promptly with anticoagulants with no surgical intervention, mortality averages about 10%.⁴

Because the pathogenesis of this abdominal catastrophe is thrombosis, it is appropriate that therapy should be directed toward minimizing thrombotic potential. Such an approach is appropriate and additionally targets, even if inadvertently, thromboses at other sites that the patient may harbor and of which the practitioner may be unaware. Modern reviews advocate early diagnosis and prompt aggressive anticoagulant or thrombolytic therapy.^{25–27} Mesenteric vein thrombosis has a high rate of recurrence, which usually occurs within 30 days of presentation and typically at the anastomotic site in patients who have undergone surgery, further supporting the need for early and adequate anticoagulation.²⁷

Because of the seriousness of this event and the fact that most patients have already sustained a previous DVT or PE, unless a definitive precipitant event (e.g., use of oral contraceptives) is found and reversed, we favor indefinite anticoagulant therapy with warfarin, even in the face of esophageal varices, to maintain an international normalized ratio (INR) in the range of 2.0 to 3.0.^{27a}

Splenic Vein Thrombosis

Overview

Splenic vein thrombosis (Table 16-5) is often subtle and is rarely recognized at the time of initial thrombosis. However, vague acute abdominal pain and new-onset splenomegaly may lead to imaging studies that show acute splenic vein

Table 16-5 Splenic Vein Thrombosis: Clinical Vignettes

Vague abdominal pain, new-onset splenomegaly, or variceal bleeding may be noted.
Significant cytopenias are rare.
Liver function test results remain normal, and hepatomegaly is not typically seen.
The condition is often associated with intra-abdominal disease or surgery.
Splenectomy is recommended for recurrent variceal bleeding.

thrombosis. More often, splenic vein thrombosis is discovered during the evaluation of a patient with vague chronic abdominal pain or chronic splenomegaly or thrombocytopenia, or it may be detected serendipitously during the evaluation of pancreatitis or pancreatic carcinoma. Splenic vein thrombosis may complicate sclerotherapy for esophageal varices.³³

Causes

Splenic vein thrombosis has been described in all types of hypercoagulable disorders, whether congenital or acquired. In this disorder, however, local intra-abdominal events, whether or not they are accompanied by hypercoagulable disorders, directly lead to a significant percentage of splenic vein thromboses. The chief offenders are pancreatitis and pancreatic carcinoma because of the intimate contact of the splenic vein with the pancreas. Pancreatitis is found to be the initiating event that leads to discovery of isolated splenic vein thrombosis in up to 65% of cases.³⁴ Splenic vein thrombosis has also been described in abdominal trauma and after abdominal surgery. It complicates 11% of all splenectomies but occurs at a much higher rate among patients who have had their spleens removed for hematologic indications.³⁵ Thus, the condition that warrants splenectomy (such as a myeloproliferative disorder) probably is more “hypercoagulable” than the operation per se. Splenic vein thrombosis has been related historically to splenectomy for immune thrombocytopenic purpura (ITP). That connection now is most likely due to the association of ITP with APLS, which explains both the ITP and the splenic vein thrombosis.³⁶

Signs and Symptoms

A common presentation for chronic splenic vein thrombosis is variceal bleeding, especially from the stomach and lower esophagus. Varices develop in 17% to 55% of patients with isolated splenic vein thrombosis.³⁴ When varices occur in the setting of normal serum liver function test results and no hepatomegaly but isolated splenomegaly, the diagnosis of splenic vein thrombosis should be strongly considered.³⁷ This syndrome has been referred to as “left-sided portal hypertension.” Up to 71% of patients with splenic vein thrombosis develop splenomegaly, although few develop significant cytopenias.^{34,38} Because removal of the spleen relieves venous collateral outflow, splenectomy cures the portal hypertensive gastropathy, and esophageal hemorrhage usually ceases at this time as well.^{34,37,39} Splenectomy remains a treatment choice when variceal bleeding is frequent, but it is controversial as a means of prophylaxis in the face of nonbleeding varices.³⁴

Diagnosis

The signs and symptoms of splenic vein thrombosis are nonspecific. The diagnosis is most commonly made through ultrasonography, CT, or MRI.³⁵

Treatment

Should the diagnosis of acute splenic vein thrombosis be made, anticoagulation is indicated not only to stop the process but also to limit potential propagation of thrombosis into the mesenteric and portal veins.³⁵ Long-term anticoagulant therapy is indicated, particularly if the patient has an

Table 16-6 Portal Vein Thrombosis: Clinical Vignettes

Painless splenomegaly with ascites is a common presentation. Normal hepatic function is noted in extrahepatic thrombosis. Thrombosis related to hepatic cirrhosis usually results in abnormal test findings. Anticoagulation is recommended if underlying thrombophilia is suspected. Anticoagulation is controversial if cirrhosis is the underlying cause.

underlying hypercoagulable condition. Most practitioners would maintain an INR at 2.0 to 3.0 with continued use of warfarin. Continued follow-up by the hematologist is also appropriate because a significant number of patients with idiopathic splenic vein thrombosis who do not currently have manifestations of a myeloproliferative disorder do develop them over time.⁴⁰

Portal Vein Thrombosis

Overview

Similar to splenic vein thrombosis, portal vein thrombosis (Table 16-6) usually is not recognized in its acute phase. It is characterized by relatively painless increasing splenomegaly and ascites without concomitant worsening of hepatic function. Portal vein thrombosis appears to have been described first by Belfour and Stewart in 1869.⁴¹ Portal vein thrombosis has been described in the recent literature in association with most of the acquired or congenital hypercoagulable disorders.⁴² However, it also continues to be seen in patients with common variety portal hypertension, especially when due to hepatic cirrhosis. A recent review by Amitrano and colleagues⁴³ revealed an 11% incidence of portal vein thrombosis in 701 cirrhotic patients examined on Doppler ultrasound.

Causes/Signs and Symptoms

Almost one half of patients in whom portal vein thrombosis was detected remained asymptomatic.⁴³ It remains to be seen whether these two risk factors, namely, hypercoagulability and portal hypertension, are synergistic in the genesis of portal vein thrombosis.⁴⁴ Because proteins C and S and ATIII levels are low in patients with liver disease, it is likely that deficiencies in these clotting factors, especially if all are depressed, represent a secondary phenomenon.^{45,46} A congenital or acquired thrombophilic condition was detected in 37% of patients with portal vein thrombosis in a recent case-controlled multicenter trial.⁴⁷ In other series, approximately 70% of patients with portal vein thrombosis were noted to have thrombophilic mutations.^{43–45} In a recent study of cirrhotic patients, 13% and 35% of patients with portal vein thrombosis harbored the factor V Leiden or prothrombin 20210 gene mutation, respectively, compared with 8% and 2.5% of cirrhotic patients without portal vein thrombosis (PVT).⁴⁴ On the contrary, in a recent review by Pinto and coworkers,⁴⁸ hereditary thrombophilia did not seem to play a significant role in children and adolescents with PVT. However, in an Egyptian study, El-Karaksy⁴⁹ identified hereditary thrombophilia in 62% of 40 children investigated at a single center. Factor V Leiden (30%),

protein C deficiency (28%), and the prothrombin 20210 gene mutation (15%) were the most common conditions diagnosed. Other clinicians argue that even in cirrhotic patients, thrombophilia likely plays a contributing role and should be investigated.⁴⁵

Other causes of portal vein thrombosis include intra-abdominal neoplasia, especially carcinoma of the pancreas; infection, with particular reference to spontaneous bacterial peritonitis; and abdominal trauma, including surgery. Additionally, sclerotherapy for esophageal varices has been implicated in several cases. Portal vein thrombosis may complicate neonatal umbilical vein catheterization but is not further discussed here. Hypercoagulability should be considered strongly in patients who have no history of hepatic disease, intra-abdominal infection, or an inflammatory or neoplastic process. As with splenic vein thromboses, the myeloproliferative disorders (acquired causes of hypercoagulability) are notoriously common, particularly when patients are followed long enough to manifest a previously occult myeloproliferative disorder.⁵⁰ When splenectomy is performed in patients with myeloproliferative disorders, the incidence of portal vein and mesenteric vein thromboses is approximately 30% for patients not given prophylactic anticoagulation.^{51,52} Accordingly, when splenectomy is performed in patients with a known hypercoagulable or myeloproliferative disease, antithrombotic prophylaxis is strongly indicated.

Diagnosis

The diagnosis of portal vein thrombosis is usually made through noninvasive radiologic methods.⁵⁰ With color Doppler techniques, the direction of portal vein blood flow can be determined reliably. Contrast CT and MRI/MRA are equally powerful but somewhat more expensive (Fig. 16-3).

Figure 16-3 Portal vein thrombosis. This computed tomographic scan with contrast shows a distended portal vein that is partially occluded; the thrombus (arrow) is outlined by a rim of contrast material.

Treatment

Management of portal vein thrombosis depends on the manifestations of the process. If the process produces acute variceal hemorrhage, attention should be paid to that disorder. Discussion of the treatment of patients with variceal esophageal hemorrhage is not within the scope of this chapter; however, patients with pure portal vein thrombosis who do not have liver disease (so-called extrahepatic thrombosis) generally survive acute upper gastrointestinal hemorrhage far better than those who have liver disease. If portal vein thrombosis is believed to be secondary to an intra-abdominal process such as infection, neoplasia, or other inflammation, therapy should be directed toward those problems. Chronic portal hypertension due to chronic portal vein thrombosis is occasionally treated surgically through various decompressive mechanisms, but long-term anticoagulant therapy is increasingly considered.^{27a,45,50}

The role of anticoagulant therapy has been somewhat controversial, but as more patients have presented and more proof has accrued that this disorder is frequently a manifestation of hypercoagulability, anticoagulant therapy has become more attractive.^{45,53,54} This therapeutic option is particularly appealing for those patients who do not have prior portal hypertension on the basis of intrinsic liver disease but who have experienced spontaneous thrombosis due to a hypercoagulable disorder. In these conditions, it is rational to initiate acute anticoagulant therapy so as not only to reverse the thrombotic process but to minimize further progression of the thrombosis into the splenic or mesenteric veins.^{45,54} In fact, in a small study by Sheen and associates,⁵⁵ resolution of thrombosis was noted in 5 of 9 patients who were treated with heparin followed by oral anticoagulant therapy.⁵⁵ Anticoagulant therapy is also strongly indicated in patients who have undergone a shunt procedure for decompression of chronic portal hypertension due to chronic portal vein thrombosis. In this situation, the patient's well-being is dependent on the shunt remaining patent; therefore, anticoagulant therapy, particularly for an identified underlying hypercoagulable disorder, is the treatment of choice. Concern about increased bleeding in patients with esophageal varices treated with concomitant anticoagulant therapy is always raised but may be more theoretical than based on actual experience; ironically, because anticoagulant therapy addresses the underlying pathophysiology, bleeding over time seems better controlled.^{27a,45,54} In fact, recent reviews have suggested that anticoagulant therapy in the treatment of patients with portal vein thrombosis increased neither the risk nor the severity of gastrointestinal bleeding, and no deaths occurred on anticoagulant therapy.⁴⁵ We treat those patients with esophageal varices from portal hypertension due solely to hypercoagulable disorders with long-term warfarin therapy, while maintaining an INR of 2.0 to 3.0. Patients treated with long-term oral anticoagulant therapy have been described who have recanalized their portal veins, thereby reversing portal hypertension.⁵⁰ Thrombolytic therapy has been tried in a small number of cases with encouraging results; use of thrombolytic therapy is most attractive when thrombosis is fairly acute.⁵⁶ Data are limited on whether and how treatment should be provided for asymptomatic cirrhotic patients who were incidentally found to have portal vein thrombosis on imaging done

Table 16-7 Renal Vein Thrombosis: Clinical Vignettes

The classic triad of acute flank pain, hematuria, and sudden deterioration of renal function is seen in only a minority of cases.
 Worsening renal insufficiency with peripheral edema is an increasingly common presentation.
 Nephrotic syndrome, especially when due to glomerulonephritis, is a major risk factor.
 Anticoagulant and thrombolytic therapies are the treatments of choice.
 Often associated with thrombooses at other sites.

for unrelated reasons. Patients with grade 2 to 4 portal vein thrombosis who require liver transplantation have a worse prognosis, a greater number of in-hospital complications, and greater mortality than those given transplants without portal vein thrombosis.⁵⁷

Renal Vein Thrombosis

Overview

The association of renal vein thrombosis (Table 16-7) with renal disease, with particular reference to the nephrotic syndrome, has been known since 1840.⁵⁸ Previous debate focused on whether renal vein thrombosis caused the nephrotic syndrome or vice versa; it is now appreciated that the nephrotic syndrome is the preexistent problem, and the hypercoagulability of the nephrotic syndrome gives rise to thrombosis not only of renal veins but also of veins throughout the body, and frequently to pulmonary embolism.^{59,60} One putative mechanism for this hypercoagulability is that of decreased plasma levels of ATIII resulting from urinary loss of this small plasma protein, paralleling the degree of albuminuria. Others have described a decrease in free protein S explained by urinary loss or by excessive binding to increased levels of C4b-binding protein characteristic of nephrotic syndrome.^{61,62} The latter mechanism is especially attractive for APLS, which is increasingly recognized as one of the most common conditions associated with the nephrotic syndrome.^{63–65}

Renal vein thrombosis may also occur in neonates during periods of acute dehydration. Whether these sporadic cases of renal vein thrombosis are associated with an underlying hypercoagulable disorder is currently unknown. Recent articles have reported on the association of hereditary thrombophilia with neonatal renal vein thrombosis. Mitchell noted a 50% incidence of prothrombotic abnormalities in patients screened, but these usually occurred in association with other known risk factors such as prematurity, central venous catheterization, or a diabetic mother.⁶⁶ A separate multicenter case-controlled study showed an odds ratio of 10.9 for thrombophilia in neonates and infants with renal vein thrombosis.⁶⁷ A 10-year follow-up study noted a risk for in utero renal vein thrombosis in patients with the factor V Leiden mutation.⁶⁸

The classic syndrome of acute renal vein thrombosis, namely, acute flank pain, hematuria, and sudden deterioration of renal function, is seen in only about 10% to 20% of all adults with renal vein thrombosis. Remaining patients have a more chronic variety that is usually detected by subtle worsening of renal insufficiency, progressive

proteinuria, and edema, usually without pain or hematuria. Nephrotic syndrome in adults appears to be more thrombogenic than in children, and nephrotic syndrome due to membranous nephropathy appears to be more thrombogenic than nephrotic syndrome related to diabetes.⁶⁹

Causes

The chronic form of renal vein thrombosis occurs much more commonly than is appreciated and, accordingly, if one waits for symptoms, the disorder will be underdiagnosed. Cross-sectional studies have shown that as many as 30% to 50% of all patients with chronic nephrotic syndrome have evidence of renal vein thrombosis.^{69,70} Renal vein thrombosis has also been noted to be an important cause of graft loss following transplantation, and the potential role of thrombophilia has been explored.⁷¹ Functional renal vein thrombosis with acute worsening of renal function may be seen in patients in whom a suprarenal inferior vena cava (IVC) filter has been deployed, which subsequently fills with clots.

Thrombosis resulting from hypercoagulability with renal vein thrombosis may be self-perpetuating.⁷² Concurrent PE is seen in 20% to 30% of patients in whom renal vein thrombosis has been diagnosed. Among these patients with PE, only 5% are symptomatic.^{69,73} Renal vein thrombosis is bilateral in half of cases. Clots protrude from the renal vein into the IVC in 40% of cases. Anticoagulant therapy is the hallmark of successful treatment, although increasingly, systemic thrombolytic therapy is advocated; the few available case reports in which the use of thrombolytic therapy is reported describe gratifying results in acute situations.^{73,74} Etoh and colleagues⁷⁵ have described several patients with the nephrotic syndrome who experienced multiple concomitant thrombooses of the renal, portal, and splenic veins. The general systemic nature of such hypercoagulability and the potential involvement of multiple sites warrant systemic rather than catheter-directed therapy. Systemic thrombolytic therapy should be considered, especially in those patients with acute renal failure, bilateral renal vein thrombosis, or concomitant thrombooses at other sites.⁶⁵

Diagnosis

The diagnosis is aided by a high index of suspicion in the occasional patient with preexisting acute or chronic renal insufficiency who then develops flank pain, hematuria, and sudden worsening of renal failure or, more commonly, unexplained worsening renal insufficiency, as well as in the azotemic patient who has an increase in proteinuria and peripheral edema. Renal vein thrombosis is also known to occur in patients without renal disease who have other hypercoagulable disorders. Regardless of presentation, the diagnosis is best confirmed by imaging on ultrasonography with Doppler flow or on MRI/MRA after discussion with the radiologist of one's suspicion of renal vein thrombosis (Fig. 16-4).⁷⁶

Treatment

The role of long-term anticoagulation with warfarin is debatable, but such therapy appears to be efficacious in the prevention of recurrent thrombosis of the renal vein or elsewhere. It is not known whether long-term oral anticoagulant therapy will help preserve renal function, given the

Figure 16-4 Renal vein thrombosis. This magnetic resonance angiography scan shows a large clot in the right renal vein that is extending (arrow) as a large mass into the suprarenal inferior vena cava.

natural slow deterioration of renal function in patients with ongoing renal disease. However, rapid return of renal function to the patient's long-term baseline level is expected with successful treatment in the acute syndrome.⁷³

Hepatic Venous Thrombosis

Overview

Hepatic venous thrombosis (Table 16-8), previously known as Budd-Chiari syndrome, has been an area of semantic confusion since it was first described.⁷⁷ The history of this disorder has been detailed by Wang and Jones.⁷⁸ The English internist Budd described a case of thrombotic occlusion of the hepatic veins in 1845, and the Austrian pathologist Chiari reported on autopsies of 10 patients who had intrahepatic venous thrombosis. Osler⁷⁹ described a case of obliteration of the IVC by fibrotic stenosis at the orifices of the hepatic veins. It has become increasingly

Table 16-8 Hepatic Venous Thrombosis: Clinical Vignettes

Acute abdominal pain with hepatomegaly, rapid-onset ascites, and grossly elevated transaminases is a common presentation.

It is commonly associated with an underlying hereditary or acquired thrombophilia, such as polycythemia vera, essential thrombocythosis, antiphospholipid antibody syndrome, and paroxysmal nocturnal hemoglobinuria.

Prognosis is much improved through early anticoagulation or thrombolytic therapy, as compared with surgery and transplantation, as provided in historic controls.

Vascular decompression/shunting procedures are treatment options that should be considered if evidence of portal hypertension is found. Timing of these procedures remains controversial.

clear that two entities that initially appeared to be similar are now regarded as two distinct disorders. These two entities differ in locality, tempo, lethality, and other manifestations. It is interesting that most scholars believe that obliterative hepatocavopathy (which is seen in Africa, India, and Asia) is the end result of thrombosis, resulting in formation of webs and intravascular diaphragms or scarring and obliteration of the vessels, as described by Osler. Whether both the Eastern and Western types of this syndrome are due to thrombosis, and, if so, why it would manifest as an acute veno-occlusive disease in the Western world and a chronic fibrosing disease in Africa, India, and Asia, are not known.

Many clinicians advocate use of the term *hepatic venous thrombosis* for the Western disease and the cumbersome term *obliterative hepatocavopathy* for the Eastern type.⁸⁰⁻⁸³ The remainder of this discussion centers around the more acute thrombotic disease, for which we will use the term *hepatic venous thrombosis*, which includes hepatic outflow obstruction at the level of the main hepatic veins to the distal venules. *Veno-occlusive disease* refers to a nonthrombotic obstruction of sinusoids or central hepatic veins due to injury of the sinusoidal wall and seen most commonly as a complication of bone marrow transplantation; this condition is not discussed further here.⁷⁷

Our understanding of hepatic vein thrombosis has been changed by rapid diagnosis, which is possible because of advances in radiographic imaging and in therapeutic options (Figs. 16-5 and 16-6). It is believed that this disease has an excellent prognosis when it is detected early and is limited to only the peripheral smaller hepatic veins. If larger veins are partially occluded, morbidity is about 30%, and in cases with total obstruction of the major hepatic vessels and suprahepatic IVC, mortality is 67%.^{84,85} The current overall 10-year survival is estimated at 75%.⁵

Causes

Hepatic venous thrombosis is due principally to hypercoagulable disorders yet is exacerbated frequently by provocations such as pregnancy, use of estrogen-containing birth control pills, and infection. The syndrome is acute and is

Figure 16-5 Hepatic venous thrombosis. This computed tomographic scan with contrast shows an enlarged, tense liver with a heterogeneous perfusion pattern. At this level, the hepatic veins should be clearly outlined by contrast media as they enter the contrast-filled inferior vena cava (arrow). They are not visualized because of total thrombosis of the hepatic veins.

Figure 16-6 Obliteration of the inferior vena cava (IVC) with extensive collateral flow. In this case of chronic hepatic vein thrombosis, the IVC is obliterated. The aorta (*right black arrow*) and the azygos vein (*left black arrow*) are seen. Multiple large subcutaneous collaterals are apparent in the abdominal wall (*white arrows*).

recognized clinically by the triad of acute painful abdomen, sudden enlargement of the liver, and ascites, with these symptoms noted in 82%, 86%, and 100% of cases, respectively.⁸³ In acute cases of hepatic venous thrombosis, a lag of 1 or 2 days in elevation of standard liver function tests results may initially obscure the diagnosis.⁸⁶

Diagnosis

Diagnosis can also be made through liver biopsy,⁸⁷ which may reveal the early phase of the disease when thrombosis is limited to the smaller hepatic veins. Sinusoidal congestion, loss of hepatocytes, centrilobular fibrosis, hepatic outflow obstruction, and venous engorgement are often seen. Lack of visualization of thrombosis does not rule out the syndrome, and thrombosis may not always be apparent in biopsy specimens.⁵ Constrictive pericarditis and congestive heart failure remain in the differential, and similar findings may be revealed on liver biopsy. The disease may also have a more insidious course, with more extensive microscopic changes observed on liver biopsy (i.e., fibrosis) than might be predicted from the apparently short clinical course.⁷⁷

Before recent descriptions of the factor V Leiden mutation and the prothrombin 20210 mutation, Valla and Benhamou⁸² opined that approximately 30% of cases were due to myeloproliferative disorders (notoriously polycythemia vera), and about 10% of all cases were due to PNH alone. Given the rarity of PNH, the penetrance of hepatic venous thrombosis in that rare disease is exceptional.^{87a} It has been estimated that hepatic vein thrombosis is observed in 1% of patients with myeloproliferative disorders and 12% of patients with PNH.⁵ As Valla and Benhamou⁸² have shown, acute hepatic venous thrombosis may be the initial presentation of myeloproliferative disorder, and occasionally, these hematologic disorders may not become clinically apparent until after years of follow-up. The newly described somatic mutation *JAK2* is believed to be rather sensitive and specific in detecting myeloproliferative disorder even years prior to usual laboratory manifestations. Patel and colleagues^{87b} report positive assays for *JAK2* in 59% of patients with hepatic venous thrombosis, thus representing the largest single group of disorders associated with hepatic venous thrombosis.

JAK2 should be tested for in patients with hepatic and other splanchnic venous thrombosis.^{25a,87c} More recent reviews indicate that APLS is the second most common cause of the disease,^{6,88} accounting for approximately 30% of cases, and congenital thrombophilic disorders account for up to another 30% of cases.^{42,89} Acquired and congenital thrombophilic conditions and other risk factors can now be detected in at least 75% of patients.⁹⁰ In a recent review, factor V Leiden accounted for 25% to 30% of cases, and protein C deficiency 20% of cases; a combined thrombophilic defect was seen in 25% of cases of hepatic vein thrombosis. Fifty-five percent of those afflicted by hepatic vein thrombosis were oral contraceptive users compared with the expected prevalence of 25% in the general female population.⁵ Other recent reviews have shown similar results, and the odds ratio for hepatic venous thrombosis has been estimated to be 11 for the factor V Leiden mutation, 7 for protein C deficiency, and 2 for the prothrombin gene mutation.^{91,92} Interpretation of low protein C, protein S, and antithrombin III levels must be made with caution in the face of liver disease; therefore, their contribution to hepatic vein thrombosis remains uncertain.

With the advent of modern radiographic imaging, the diagnosis of hepatic vein thrombosis is made increasingly early. Imaging now is very effective; ultrasonography combined with Doppler flow yields the diagnosis very rapidly in 85% of cases. Using the combination of ultrasonography, MRI/MRA, and occasional angiography, Valla and Benhamou⁸² confirmed the diagnosis rapidly in more than 90% of cases. The initial goal in the management of hepatic vein occlusion is to relieve hepatic outflow obstruction.⁹³ The natural history of this disease has therefore improved since the introduction of anticoagulation, although no randomized trials exist.⁵ Many experts favor early initiation of heparin,^{5,77,82,83,94} and others advocate an early, aggressive role of thrombolytic therapy, whether it is given systematically or by local infusion.^{78,95,95a} If short segment thrombosis is noted or ascites cannot be controlled, some reports favor angioplasty and wall stenting.⁷⁷ Patency rates of 80% to 90% have been noted with this approach.⁵ The success of the early use of thrombolytic therapy coupled with anticoagulants has resulted in the use of orthotopic liver transplantation as the therapy of last resort for those patients who have not benefited from thrombolytic therapy, or for those who present late with fulminant hepatic failure and coma.^{83,85,89} Long-term management should include long-term anticoagulant therapy provided to prevent local recurrence of thrombus and systemic manifestations of any underlying hypercoagulable disorder.^{78,83,88,96}

Treatment

If symptomatic portal hypertension persists and if vascular decompressive procedures are indicated, various types of decompressive surgery are available; these have been reviewed elsewhere.^{78,81} Some argue for earlier surgical decompression.⁹⁷ The goal of these shunting procedures is to convert the portal vein into a venous outflow tract of the liver. Transjugular intrahepatic portosystemic shunts (TIPS) are minimally invasive and have been found to be beneficial in controlling ascites in chronic hepatic vein thrombosis, but stenosis requiring revision has been noted in up to 50% of cases in some series.^{93,98–100} Other types of surgical portosystemic shunts have been described that have proved to be beneficial in controlling refractory ascites.^{5,90,101}

Others argue that surgical decompression should be the initial treatment of choice, and, if thrombophilic conditions are found, anticoagulation should follow the surgical procedure.⁹⁷ If patients develop end-stage liver disease or if shunts fail, liver transplantation remains a viable option for many, with 5-year survival reported as high as 95%.^{90,100}

CEREBRAL VENOUS THROMBOSIS

Overview

Cerebral venous thrombosis (Table 16-9) refers to thrombosis of the superficial or deep cerebral veins and of the dural venous sinuses. Blood from the brain drains through small cerebral veins into larger veins, which empty into the dural sinuses; these are themselves drained by the internal jugular veins.¹⁰² The main cerebral venous sinuses affected by thrombosis are the superior sagittal sinus (72%) and the lateral sinuses (70%).¹⁰ This condition, similar to most conditions discussed in this chapter, is diagnosed more frequently because of increased knowledge of its existence and increased ease of diagnosis through modern imaging techniques. Cerebral vein thrombosis remains rare, with an estimated annual incidence of 3 to 7 cases per million.¹⁰³

Gates and Barnett have reviewed the history of cerebral venous thrombosis,¹⁰⁴ noting that Ribes first described cerebral venous thrombosis in 1825 in a man with disseminated carcinoma. Three years later, Abercrombe described cerebral venous thrombosis in a woman in her puerperium. In 1873, Parrot described neonatal cerebral venous thrombosis. Gowers in 1888 associated cerebral venous thrombosis with both congestive heart failure and cachexia. In 1904, Nonne first used the term *pseudotumor cerebri*. In an important neurosurgical review in 1966,¹⁰⁵ Krabenbuhl clearly separated infectious from noninfectious causes of cerebral venous thrombosis. He was prescient in stating that neurosurgery had a limited and decreasing role in the treatment of this disease, and that anticoagulant therapy was the treatment of choice. He further correctly pointed out that as opposed to other ischemic brain syndromes, central nervous system dysfunction due to cerebral venous thrombosis has an outstanding recovery rate, often with no permanent sequelae if treated aggressively and appropriately.^{106,107}

Table 16-9 Cerebral Venous/Sinus Thrombosis: Clinical Vignettes

Headaches (75%), papilledema (49%), fevers (45%), seizures (37%), and altered mental status (30%) are frequent, yet subacute, presentations.
It is important to differentiate infectious from idiopathic risk factors.
High-estrogen states are significant risk factors.
Hereditary thrombophilias are significant risk factors, especially in combination with high-estrogen states.
Magnetic resonance imaging/venography is the imaging study of choice; computed tomographic scans may be falsely negative.
Anticoagulation is recommended with noninfectious causes.
Most patients have good clinical recovery.

*Data from Ameri A, Bousser MG: Cerebral venous thrombosis. *Neurol Clin* 10:87–111, 1992.

A recent international study of 624 patients with cerebral vein thrombosis revealed that 79% of patients had a full recovery or minimal residual symptoms.¹⁰⁶ In the Venous Thrombosis Portuguese Collaborative Study Group (VENOPORT) study, 82% of patients followed prospectively recovered completely.¹⁰⁷ The prognosis may be worse in the elderly, however.¹⁰⁸

Causes

In the preantibiotic era, the most common causes of thrombophlebitis in the skull and its contents were chronic suppurative infection due to inner ear infection, skull osteomyelitis, and erysipelas. Infectious causes have been thoroughly reviewed.¹⁰⁹

The puerperium represents a strong provocation for hypercoagulability and particularly thrombosis at unusual sites; however, this association is nowhere more apparent than in cerebral venous thrombosis. The reason for these repeated observations is unknown. Cerebral venous thrombosis appears to be the only thrombosis at an unusual site that has a strong sex predilection, with a 3:1 ratio favoring women; the difference is explained by the puerperium and/or the use of oral contraceptive agents.^{110–113} Although cerebral vein thrombosis is often related to pregnancy, the recurrence rate appears to be low, and subsequent pregnancy is not thought to be contraindicated.¹¹⁴ Cerebral venous thrombosis has been associated with all known hypercoagulable disorders, both congenital and acquired. A prothrombotic risk factor or direct cause for cerebral vein thrombosis is identified in up to 85% of affected patients.¹⁰³ Hereditary thrombophilia can be found in 20% to 30% of these cases.^{114,115} Recent series have also documented a relative risk for cerebral venous thrombosis of 6 to 10 among patients having factor V Leiden mutation and a relative risk of 10 to 21 caused by the prothrombin 20210 mutation.^{110–112,116,117,117a} Data document that risk factors are not simply additive: A relative risk for cerebral venous thrombosis of 8 to 22 exists in patients who use birth control pills, and a relative risk of 10 has been noted in women who have the prothrombin 20210 mutation; the relative risk factor escalates to 150 among women with the prothrombin 20210 mutation who also use oral contraceptives.¹¹⁰ A fourfold increase in cerebral vein thrombosis was recently noted in patients with hyperhomocysteinemia in one study, and a sevenfold increase in another.^{117,118} A recent pediatric study found at least 1 prothrombotic risk factor in 55% of patients with cerebral vein thrombosis as compared with 21% of controls.¹¹⁹

Diagnosis

As dangerous as the disease is, the diagnosis is often delayed because of its nonspecific and nonsensitive subacute presentation and fairly broad differential diagnosis. It is believed that symptoms are caused by increased intracranial pressure due to venous congestion and by local inflammation due to phlebitis.¹¹⁷ Headaches are experienced in the vast majority of cases. Papilledema occurs in approximately half of cases. When headache and papilledema occur without focal neurologic signs, the term *pseudotumor cerebri* may be used.¹²⁰ Although pseudotumor cerebri has several sources of origin besides cerebral venous thrombosis, this condition remains one of its more important causes. Typically, the headache progresses over several days and is followed by confusion, stupor, and finally,

Figure 16-7 Cerebral venous thrombosis. This oblique magnetic resonance image shows a contrast-outlined superior sagittal sinus and both transverse sinuses. A large clot occupies the torcular Herophili, which is not visualized because contrast medium was not used (arrow).

coma, if the process is not interrupted. Seizures occur much more commonly than in arterial stroke.¹¹⁴ A recent review has suggested that patients older than 65 years of age may present differently with fewer symptoms, suggestive of isolated intracranial hypertension, but with an increased frequency of depressed levels of consciousness and mental status changes.¹⁰⁸ Conspicuously absent are sensory loss and motor weakness. Examination of the cerebrospinal fluid and electroencephalogram shows nonspecific findings that do not support other entries within the differential diagnosis. CT has usually been performed by this time in the evaluation but is notoriously nonspecific, if not even misleading. The classic “empty delta sign” is seen in only 21% of cases.^{10,102,114} A normal CT scan is found in 25% to 30% of cases and should never be used to exclude this important diagnosis.¹¹⁴ The diagnosis is best established by MRI/MRV (Fig. 16-7),^{103,121–123} which has essentially replaced standard four-vessel angiography and is sensitive for diagnosing the subtype known as deep cerebral venous thrombosis; this includes thrombosis of the internal cerebral veins and/or the great vein of Galen.^{122–124} Once the diagnosis has been made, prompt and aggressive therapy is indicated to avoid or reverse cerebral herniation. The lingering fear of hemorrhage with anticoagulant therapy is probably based on older reports of the natural history of cerebral venous thrombosis that terminates in intracerebral hemorrhage because of infarctive ischemia. Both historical¹²⁵ and level 1¹²⁶ studies have shown that patients who are treated with heparin achieve approximately 80% full recovery, with only 15% to 20% having any sequelae. A very small number or no patients die when administered heparin. Conversely, as shown in Table 16-10, of patients who do not receive heparin, approximately 25% die and 50% survive but with sequelae, with only 25% experiencing complete recovery. A recently published study in which low molecular weight heparin was used showed a nonstatistically significant trend toward benefit in the treatment group (Table 16-11).^{127,128}

Table 16-10 Outcomes of Cerebral Venous Thrombosis With and Without Heparin Therapy

	Historical Study*		Level 1 Study†	
	Heparin	No Heparin	Heparin	No Heparin
Complete recovery	85%	53%	80%	10%
Some sequelae	15%	20%	20%	60%
Died	0%	27%	0%	30%

Table 16-11 Outcomes of Cerebral Venous Thrombosis With and Without Nadroparin

	Nadroparin	Placebo
Poor Outcome or Barthel Index of Activity of Daily Living Score <13		
3 weeks	20%	24%
12 weeks	13%	21%

Data from DeBruijn STFM, Stam J, for the Cerebral Venous Thrombosis Study Group: Randomized placebo-controlled trial of anticoagulant treatment with low molecular-weight heparin for cerebral sinus thrombosis. *Stroke* 30:484–488, 1999.

A meta-analysis of these data revealed an absolute risk reduction for mortality by 14% and death or dependency by 15%, although these findings were not statistically significant because of the small sample size (79 patients in the two studies combined). An increased rate of intracranial hemorrhage was not seen in these trials. Although these findings are not statistically significant, because of the trend in favor of anticoagulation, we and other physicians have adopted the use of early anticoagulation in the treatment plans of patients with cerebral vein thrombosis.^{10,102,103,106,114,127,129,130,130a}

Treatment

Improvement with heparin therapy has been noted as early as the second or third day of therapy,¹²⁶ even in patients who have evidence of some “petechial” hemorrhage on imaging. Evidence for hemorrhage should no longer be viewed as an absolute contraindication to heparin therapy.^{124,126} In a study involving small numbers of patients with the rarer subtype of deep cerebral venous thrombosis, none of 7 patients receiving heparin therapy died, and all 10 patients who did not receive heparin therapy died.¹²² Most reviews of the subject agree that vigorous heparin therapy followed by warfarin is the treatment of choice.^{10,102,103,112–114,120–122} However, in cases of cerebral vein thrombosis due to obvious underlying intracranial infection, the role of anticoagulation remains uncertain.

A growing number of patients have been treated successfully with thrombolytic agents without experiencing undue bleeding. Thrombolytic therapy cannot be routinely recommended at this time but should be given consider-

ation because of its uniformly high efficacy. The safety of thrombolytic therapy compared with standard heparin therapy has not been evaluated rigorously, and a recent Cochrane Database review showed that no randomized trials have been performed.¹³¹ A recent literature review of thrombolytic therapy reported a 17% incidence of intracranial hemorrhage, a 21% incidence of extracranial hemorrhage, and a 12% incidence of death or dependency.¹³² It has been suggested that thrombolytic therapy may be reserved for use as initial therapy in those with significant CNS compromise, especially in those who are comatose.^{106,114,132} Patients should be maintained on long-term warfarin in doses sufficient to keep the INR at 2.0 to 3.0 for at least 3 to 6 months, with consideration for indefinite therapy if a reversible cause is not corrected.¹⁰

RETINAL VEIN/ARTERY THROMBOSIS

Overview

The history of our knowledge of retinal vein occlusion (Table 16-12), which is often divided into branch retinal vein occlusion (BRVO) and central retinal vein occlusion (CRVO), has been reviewed by Williamson.¹³³

Previous reviews and indeed some recent reviews in the ophthalmology literature continue to focus on the time-honored observation of an apparent correlation between retinal artery occlusion, BRVO, and CRVO and increased plasma fibrinogen level, age, dyslipidemia, diabetes mellitus, hypertension, hyperviscosity, and decreased exercise.^{133–138} It is curious that none of these reviews addresses the possibility of an association with hypercoagulable disorders, and one¹³³ minimizes the role of anticoagulant therapy in afflicted patients.

A renaissance of investigation into retinal vein thrombosis began in the 1990s and continues to this day.¹³⁴ Although reported results of several studies are seemingly mutually incompatible, several groups have noted an association between the presence of antiphospholipid antibodies and retinal vein occlusion, as well as other retinal disorders.^{135–137} In a recent review of 40 patients with retinal thrombosis, 22.5% had evidence of antiphospholipid antibodies compared with 5% in a reference population.¹³⁸ Case reports include an association with APLS in a young woman who had depressed levels of free protein S.¹³⁹ Glueck and associates¹⁴⁰ noted that 43% of their patients had laboratory evidence consistent with APLS, but only 3% in a control group had such laboratory evidence. In one study in Saudi Arabia,¹⁴¹ 50% of patients with retinal venous occlusion had laboratory evidence of APLS. In a recent review of

thrombophilia in retinal vein occlusion, the odds ratio for retinal vein occlusion was estimated to be 3.9 for those with anticardiolipin antibodies as compared with those without detected antibodies.¹³⁷ A sixfold increase was noted in patients who harbored the factor V Leiden mutation in a single study¹⁴⁰; another study group reported a twofold increase in factor V Leiden,¹⁴² a third group¹⁴³ described an eightfold increase, and in a fourth group, a threefold increase was seen.¹⁴⁴ In a single report, 8.3% of patients with retinal vein occlusion tested positive for the prothrombin 20210 mutation compared with 0% in a control group.¹⁴⁵ Multiple other studies^{137,146–152} failed to find an increased incidence of factor V Leiden mutation, but some have found evidence of resistance to activated protein C at a rate 5 times higher than that of controls.

One group reported that resistance to activated protein C was the most common cause of retinal vein occlusion in the young,¹⁵⁴ and another¹⁵³ found that it was the most common (25%) laboratory-identified risk factor among patients with CRVO. Of interest, the same investigator¹⁵⁴ a year later was unable to duplicate those findings when he reported that among 55 patients with retinal vein occlusion, the incidence of resistance to activated protein C was precisely the same as in his control group. A recent review comparing patients with CRVO with a normal cohort found that in only 2 of 9 studies was the incidence of resistance to activated protein C and/or factor V Leiden mutation significantly increased.¹⁵⁵ Gottlieb and colleagues¹⁵⁶ were unable to find any evidence of increased resistance to activated protein C or factor V Leiden mutation in 21 of their patients, and Delahousse¹⁵⁷ determined that the incidence of prothrombin 20210 mutation was precisely the same (3.6%) in his patients with retinal vein occlusion as in a control group.

Greiner and coworkers¹⁵⁸ reported an incidence of factor V Leiden of 27% among patients with CRVO. In a pooled analysis of 232 patients with CRVO, only 7 patients with the prothrombin 20210 mutation were identified—a number similar to that expected in the Caucasian population at large.¹⁵⁵ The incidence of factor V Leiden or prothrombin 20210 mutation was not increased in a recent study of 136 patients with retinal artery occlusion.¹⁵⁹ Compelling evidence appears to link elevated homocysteine levels to retinal vascular events,^{137,160} although not all study findings have been positive.^{161,162} One study found a 60% incidence of hyperhomocysteinemia in patients with ocular venous occlusion.¹⁶³ Several recent studies have shown higher risks of retinal artery and vein occlusion in patients with elevated homocysteine levels,^{164–168} although others have not confirmed this association.^{150,169} In one recent study, hyperhomocysteinemia was found to have an odds ratio of 8.9 for retinal vein occlusion—the highest ratio among all thrombotic risk factors that were investigated.¹³⁷

Causes

A causative role of abnormalities in the fibrinolytic system has been suggested by some clinicians, as summarized by Fegan, but this remains controversial.^{155,165} It is difficult to resolve these differing data, but recent evidence published over the past several years suggests the possibility of an underlying disorder such as factor V Leiden mutation, prothrombin 20210 mutation, resistance to activated protein C, hyperhomocysteinemia, and particularly, APLS in patients with retinal vein thrombosis.^{137,170–172,172a} Some

Table 16-12 Retinal Vein Thrombosis: Clinical Vignettes
Painless loss of vision is a typical presentation. Risk factors for retinal artery thrombosis also apply to retinal vein thrombosis. The role of inherited thrombophilia is controversial. Data on antiphospholipid antibody syndrome are the most convincing. The role of anticoagulant or thrombolytic therapy is controversial.

editorialists^{141,155,170,171,173} urge an open mind and indicate that larger studies need to be done; others argue against an association of thrombophilia with retinal vascular occlusion.^{174,175} They also note that much as with hypercoagulability and thrombosis in other sites, it may take a combination of a hypercoagulable disorder and a second provocation, such as age, diabetes, hypertension, and hyperfibrinogenemia in cases of CRVO, for the process to become manifest.

Diagnosis

Other matters to consider include the unique anatomy of the optic sheath, through which both the retinal vein and the retinal artery travel. Accordingly, perturbations of the retinal artery due to hypertension, diabetes, or aging may encroach upon the adjacent retinal vein. Thus, in contrast to other venous thrombotic disorders, typical risk factors for arterial thrombosis are significant and likely are more important than or, at a minimum, synergistic with the aforementioned hereditary thrombophilic states. Giorgi and colleagues¹⁷⁶ recommended long-term warfarin therapy in patients with retinal vein occlusion believed to be due to a thrombotic process.¹⁷⁶ Although oral anticoagulant therapy has been successfully used by others,^{177,178} studies have yet to be done to establish the best therapy. One author strongly recommends against anticoagulation and states that it is contraindicated in patients with an increased bleeding risk.¹⁷⁵

Treatment

Given our referral pattern of patients who are likely to have hereditary thrombophilia, along with the variable and poor prognosis with recent and recurrent retinal vessel thrombosis, we tend to anticoagulate patients with retinal vein occlusion, especially the young.¹⁷⁹ In older patients with retinal artery occlusion and other obvious risk factors, decisions are made on a case-by-case basis, but recommendations often include therapy aimed at improving atherosclerotic risk factors and the use of antiplatelet agents.

Some centers^{180,181} have administered systemic intravenous thrombolytic therapy in both acute and subacute retinal vein occlusion and have reported very good results. In fact, vision in half of patients significantly improved, even though therapy was provided weeks after the occlusion occurred. Recent reports of local catheter-directed lytic therapy and of intravitreal infusion of tissue plasminogen activator (tPA) have shown variable success.^{182–184}

Patients with this disorder should be monitored, and consideration should be given to thrombolytic therapy in an acute or subacute phase, depending on the level of visual impairment and the expertise of local interventional radiologists. Long-term oral anticoagulant therapy in doses designed to maintain an INR of 2.0 to 3.0 seems reasonable, especially if no obvious underlying disorder is found.

UPPER EXTREMITY THROMBOSIS

Overview

The prevalence of thrombosis of the vessels of the upper extremity (UE) (Table 16-13) is reported to be 2 per

Table 16-13 Upper Extremity Thrombosis: Clinical Vignettes

Swelling of a unilateral extremity, chest wall, or the face is a common presentation that is dependent on which specific vein is thrombosed.
It is less commonly associated with clinically significant pulmonary embolism as compared with lower extremity thrombosis.
Intravenous catheters or devices are a significant risk factor. Anatomic abnormalities need to be evaluated and ruled out. Recent data do not support routine primary prophylactic anticoagulation for central venous access devices.
Initial treatment includes anticoagulation and consideration of removal of intravenous devices, if present.
Surgical decompression is warranted in the presence of thoracic outlet syndrome.

100,000 patient-years but appears to be increasing, probably because of the combination of increased ease of diagnosis through modern imaging and increased use of intravascular devices such as indwelling catheters that are placed into those vessels.¹⁸⁵ The superficial veins of the upper extremities include the cephalic, basilic, and cubital veins, which drain into the deep system. The axillary vein is the first named deep vessel. It is joined by the brachial and cephalic veins, which continue into the chest as the subclavian vein. The subclavian and internal jugular veins form the brachiocephalic vein, which drains into the superior vena cava (SVC).

Causes

Although the incidence and causes of thrombosis of these vessels vary according to the perspective of the physician and the clinic reporting them, roughly one third are found to be due to so-called primary or effort thrombosis, often associated with an anatomic abnormality (Paget-Schroetter syndrome), at least one third are due to the presence of indwelling catheters, and the remaining one third appear to be more or less idiopathic, including those due to hypercoagulable situations. Concomitant use of oral birth control pills may increase the risk because of other factors. Of course, any of these causes may be additive, as Virchow would have predicted. A recent single institution study showed that in 60% of cases of upper extremity DVT, a catheter had been inserted into the thrombosed vessel, and in 46%, cancer was the underlying diagnosis.¹⁸⁶ Only 29% had no apparent cause. Thrombophilic situations, including ATIII deficiency, have been associated with axillary and subclavian vein thromboses. However, the inherited hypercoagulable disorders may play a lesser role in arm venous thrombosis than in deep¹⁸⁷ or superficial¹⁸⁸ vein thrombosis of the leg, in that a large quantity of the data is observational, with varying results.¹⁸⁹ APLS and Trousseau syndrome are common among the acquired causes of hypercoagulability.^{190–192} In one study, 25% of patients who presented with idiopathic UE DVT were found to have a malignancy within the subsequent year.¹⁸⁹ The occurrence of thrombophilic defects in patients with UE DVT ranges from 8% to 61% in the literature, much of which is retrospective and descriptive of few patients.^{185,193} A recent review documented at least one thrombophilic defect in 61% of patients examined; factor V Leiden (12.9%), prothrombin 20210 gene mutation (20%), and

elevated homocysteine levels (16%) were the most prevalent.¹⁸⁵ In another study, the odds ratio for UE DVT was 6.2 for factor V Leiden, 5.0 for the prothrombin 20210 gene mutation, and 4.9 for anticoagulant protein deficiencies.¹⁹⁴ However, the prevalence of factor V Leiden and of the prothrombin 20210 gene mutation was not increased in a separate study by Leebeek and colleagues.¹⁹⁵ Catheter-related UE DVT may be present in as many as 72% of cases of catheter placement, if they are prospectively radiographically investigated.¹⁹⁶ In an epidemiologic study, the presence of a catheter was the strongest risk factor for thrombosis, with an odds ratio greater than 7.¹⁹⁷ In patients with idiopathic UE DVT, the odds ratio for a hypercoagulable condition was 4.1 as compared with those with effort-related thrombosis.¹⁹⁸

UE DVT accounts for only about 1% to 4% of all DVTs.¹⁹³ The subclavian vein, the internal jugular vein, and the axillary veins seem to be the most commonly thrombosed deep veins of the UE, possibly because of the frequency of catheterization of these vessels.¹⁹⁹ A male/female predilection of about 2:1 has been reported, largely due to effort thrombosis, which is seen most often among younger males. UE DVT occurs bilaterally about 10% of the time, especially with effort thrombosis.

Signs and Symptoms

Signs and symptoms of the disorder include swelling (100%), venous engorgement (82%), pain (73%), mild cyanosis of the involved arm (55%), and a palpable cord (26%).²⁰⁰ The palpable cord often is appreciated only in the very dome of the axilla, where the enlarged, tender, inflamed subclavian vein may be palpated. Fortunately, UE venous gangrene occurs in only about 1% of all cases.²⁰⁰ Death from embolism-related pulmonary hypertension has been rarely reported. Debate is ongoing about the frequency of PE that originates from axillary or subclavian vein thrombosis; rates of 7% to 9% are frequently quoted.¹⁸⁶ More recent reviews quote rates as high as 33%.²⁰¹ Such emboli, however, are often asymptomatic and are only infrequently of sufficient size to cause circulatory compromise, which is characteristic of the large emboli originating from the legs.^{186,191}

Effort thrombosis (Paget-Schroetter syndrome) may result from prolonged heavy use of the arms, particularly when the arms are maintained in somewhat less than usual positions. Examples include prolonged weightlifting, pole vaulting, painting ceilings, playing racquet sports, and taking rifle practice. A subset of patients with effort vein thrombosis is found to have some type of thoracic outlet obstruction, including anatomic abnormalities of the veins coursing under the first rib or the scalene muscle (Fig. 16-8). This fact is often discovered on follow-up venography of a previously thrombosed vessel. The degree of venous obstruction is best appreciated when the arm is raised above the head during venography. The rate of postphlebotic syndrome is uncertain but has been approximated as high as 90% in some series.²⁰¹

The use of various indwelling catheters into veins of the arm, the subclavian vein, and the internal jugular vein is a frequent trigger for UE vein thrombosis (see Chapter 32). In a prospective study of patients admitted to intensive care units, Timsit and colleagues²⁰² found that 33% of internal jugular vein catheter placements and 10% of subclavian vein catheter placements were associated with thromboses of

Figure 16-8 Thoracic outlet syndrome. Left upper extremity venogram shows large, contorted collateral veins arising from the axillary vein, rather than diving through the thoracic cage as the left subclavian vein. Removal of the first rib may relieve the pathologic obstruction. Narrowing of the subclavian vein is apparent, along with obliteration of normal flow (arrow).

those contiguous vessels when in place for 9 ± 5 days. A positive correlation was noted between older patients and those who were not receiving thromboprophylaxis with heparin. Catheter-related thrombosis also resulted in a 2.6-fold increase in risk for catheter-related sepsis. It is unknown whether catheter-related thrombosis is associated with underlying thrombophilic conditions.

Diagnosis

The subclavian and axillary veins may be associated with tumors that are caused (1) by resultant hypercoagulability associated with the tumor (including Trousseau syndrome), or (2) by direct pressure from a tumor mass, most commonly lung cancer and lymphoma.

Thrombosis of these vessels is best documented through the use of imaging techniques, typically starting with ultrasonography. These thromboses may be found serendipitously on imaging of the thorax for other reasons. The index of suspicion should be heightened in anyone with a newly swollen, tender arm with increased, engorged surface veins. A concern is cephalad propagation of thromboses up into the internal jugular and even into the cerebral venous drainage system; this is manifested by signs and symptoms of cerebral venous thrombosis, notably headache and papilledema.²⁰³

Treatment

Once the diagnosis has been made, most experts recommend anticoagulant therapy, although it is often underused.^{189,197} Withholding anticoagulant therapy has not led to good outcomes; the result has often been a chronically swollen, heavy, and disfigured arm. Accordingly, treatment with anticoagulants and thrombolytic therapy have been proposed, whether they are given systemically or, in the case of thrombolytics, are site directed.^{185,189,199,204–209} Anticoagulation has supplanted the indication for acute

thrombectomy.^{209,209a} Thrombolytic therapy was shown by one group¹⁹⁹ to result in a 50% reduction in residual signs and symptoms of UE postphlebotic syndrome. Thrombolytic therapy should be considered seriously for the rare person who presents with UE venous gangrene.²⁰⁷ If anticoagulation is absolutely contraindicated in a patient with severe underlying lung disease, such that even a small pulmonary embolism may be considered life threatening, then an SVC filter could be considered. The efficacy and safety of SVC filters remain unproved, however.¹⁸⁹

If a patient is subsequently found to have thoracic outlet obstruction, surgery is indicated, with selected use of first rib resection with or without scalenectomy, and appears to improve long-term results. Otherwise, an approximately 50% relapse rate is reported in these patients who do not undergo anatomic relief of their obstruction.^{208,209} Others have recently recorded a more favorable long-term prognosis with conservative therapy alone.²¹⁰

Previous studies have suggested that unmonitored prophylactic use of low-dose (1 mg daily) warfarin²¹¹ or low-dose low molecular weight heparin²¹² decreases the risk of UE DVT in patients with long-term catheter or central venous line placement. A study comparing these two treatment modalities in a prospective fashion showed no difference in efficacy.²¹³ However, more recent trials do not support these data, and recent recommendations from the American College of Chest Physicians (ACCP) recommend against routine prophylaxis in patients with cancer with central venous catheters.^{214,215}

LEMIERRE SYNDROME

Overview

In 1936, Lemierre²¹⁶ described a rather rare syndrome that still bears his name. This consists of the triad of pharyngitis, thrombosis of the internal jugular vein (IJV), and severe metastatic infection, particularly to the lungs and large joints. Because this description was provided during the preantibiotic era, his observations were essentially those of the natural history of this aggressive course caused by the Gram-negative anaerobe *Fusobacterium necrophorum*, a normal oral cavity inhabitant. Indeed, 18 of his 20 patients died from this unique type and location of septic thrombophlebitis.

Now, with the broad use of antibiotics, the defining criteria employed by Lemierre have become blurred and modified, so one might expect the disorder to not unfold as originally defined.²¹⁷ Indeed, to some purists, if the triad is not as described, a patient does not have the true syndrome as described by Lemierre. Therefore, the characteristics and even the use of the eponym have been modified, and it is often now referred to as postanginal sepsis. Unfortunately, the disease is recognized and diagnosed less often than it should be; it is a dangerous condition if it remains unidentified and untreated.²¹⁸

Diagnosis

Realizing the alteration of the natural history, Chirinos and coworkers²¹⁸ more recently described the evolution of the manifestations of Lemierre syndrome. Their diagnostic criteria consisted of pharyngitis plus thrombosis of the IJV

and/or culture positive for *Fusobacterium necrophorum*. Now that aggressive antibiotic therapy is available, the mortality rate in this review has dropped to only 5%, and, although pulmonary infiltrates are common, pulmonary cavitation is now rare.²¹⁸ Investigators described that the chief clinical clue leading to correct diagnosis in 70% of cases was a culture (usually of blood) that was positive for *Fusobacterium necrophorum*.²¹⁸ Additionally, detection of an IJV thrombosis was the deciding factor in 16% of cases, most of which did not involve positive blood culture findings. Most often, the IJV thrombosis was stumbled upon through imaging, typically by ultrasound, during evaluation of a tender swollen neck, particularly when it occurred parallel to the sternocleidomastoid muscle.

The reason to include this diagnosis in this chapter is that the hematologist may well be asked to consult on what otherwise may appear to be an isolated IJV thrombosis. This is especially true now that cases are typically diagnosed earlier and without an advanced inflammatory presentation, as had been initially described.

Treatment

The role of anticoagulant therapy in septic thrombophlebitis is uncertain. Most patients with Lemierre syndrome respond to antibiotic therapy, especially when the extent of the IJV thrombosis is limited. However, use of anticoagulant therapy seems justified, should the thrombotic process extend farther down into the great vessels of the chest and arm or, especially, cephalad into the vessels draining the head.²¹⁹

Cutaneous Microvascular Thrombosis (Purpura Fulminans)

Overview

Thrombosis of the dermal microvasculature results in discoloration and infarction of the skin and subcutaneous tissues. In its most dramatic and florid state, this process is referred to as *purpura fulminans* (Table 16-14).^{220,221} Although it is not limited to disseminated intravascular coagulation (DIC), purpura fulminans is characteristically seen in this condition; the reader is referred to Chapters 11 (purpura) and 12 (DIC) for additional details.

Causes

The leading category of causes of purpura fulminans is infectious disease,²²² which can be viral, bacterial, rickettsial, or protozoan. Key to the pathophysiology of infectious purpura fulminans are unchecked thrombin production

Table 16-14 Cutaneous Microvascular Thrombosis: Clinical Vignettes

Causes are often infectious.
In the neonate it is associated with homozygous protein C or protein S deficiency.
The roles of other inherited thrombophilic conditions are uncertain.
Treatment should include activated protein C concentrates used in inherited deficiency states.

and collapse of the fibrinolytic system, primarily through gross reductions in protein C and protein S and a concomitant increase in plasminogen activator inhibitor-1 (PAI-1).²²³ In at least one case, transient severe depression of protein S was due to transient autoantibodies directed against protein S.²²³

Symptoms

Dermal necrosis related to capillary infarction is the hallmark of warfarin skin necrosis, which is discussed in Chapter 11. Warfarin skin necrosis may occur in patients who have congenital or acquired deficiency of protein C or protein S,^{224–228} and occasionally, in patients with PNH.^{229,230}

Skin necrosis occurs spontaneously in newborns who are homozygous for protein S or protein C deficiency.^{231,232} In these situations, consanguinity may be encountered. Neonatal purpura fulminans has also been described in patients doubly heterozygous for protein C deficiency²³³ or protein S deficiency.²³⁴

Diagnosis

Some investigators have questioned why only some patients with diseases such as meningococcemia develop purpura fulminans, but other patients with the same illness do not.²²¹ They speculate that these patients also might harbor an underlying thrombophilia that may aid and abet microcirculatory thrombosis or that large increases in PAI-1 levels seen in patients with purpura fulminans may be restricted to unique hyperreactors. An increasing number of reports^{235–241} have involved patients ranging in age from infancy through adolescence to full adulthood who have had infectious disease associated with excessive purpura fulminans, all of whom were found to be heterozygous for the factor V Leiden mutation. In another report,²⁴² seven children with purpura fulminans from varicella infection were all found to have strong lupus anticoagulants and transient severe deficiency of protein S. These findings have led some^{239,243} to recommend routine screening for congenital thrombophilic disorders in patients who exhibit purpura fulminans. On the other hand, Westendorp and colleagues²⁴⁴ analyzed blood from patients who survived meningococcemia and from the parents of those patients who died. Although they found evidence for congenital thrombophilia in 7 of 50 consecutive patients, they determined that this incidence was the same as that in the general population. This question is an interesting point that has not yet been resolved.

Treatment

Therapy depends on prompt diagnosis and, in cases associated with DIC, therapy should be directed toward any treatable underlying cause. Treatment of patients with warfarin skin necrosis is discussed in Chapter 11. Owing to the central role of depletion of protein C, many have advocated infusion with activated protein C concentrates,²²¹ and limited case reports have shown a hint of efficacy (see Chapter 13). A therapeutic trial has been advocated by some,^{245,246} and others²⁴⁷ have proposed the use of tPA therapy. Because of extensive skin loss, these patients are best treated in a burn unit.²⁴⁸

Long-term replacement therapy with protein C has been advocated for the rare unfortunate children with homozygous

deficiency of protein C. This has been administered intravenously²⁴⁹ or, more recently, subcutaneously.²⁵⁰

OVARIAN VEIN THROMBOSIS

Overview

Thrombosis of the ovarian veins (Table 16-15) occurs almost exclusively during the postpartum period.²⁵¹ It occurs rarely (≈ 1 in every 2000 deliveries), although in an extensive prospective study, Witlin and colleagues²⁵² found only 11 cases out of 77,000 deliveries over a 10-year period, representing an incidence of less than 0.01%. It is interesting to note that all these cases were associated with vaginal delivery, but in other series, the incidence was much higher after cesarean section, accounting for 87% of cases.²⁵³ In Witlin's review,²⁵² investigators were unable to find features peculiar to or unusual about the nature of the pregnancy or the delivery predisposing to thrombosis. The typical patient was admitted 7 to 13 days postpartum, usually for the combination of fever, right pelvic pain, and leukocytosis. The admitting diagnosis was endometritis in three quarters of cases, and in the other one quarter, pyelonephritis; no patient was suspected to have postpartum ovarian vein thrombosis. Patients are regarded as clinically infected and are typically treated with antibiotics.

Symptoms

Two different forms of pelvic thrombophlebitis have been described. Ovarian vein thrombosis, as discussed in this chapter, typically manifests with fever and abdominal pain and is amenable to diagnosis on CT. The second form, deep septic thrombophlebitis, more commonly begins with high spiking fevers despite antibiotic therapy, but the patient feels well and comfortable between fevers. The condition is difficult to diagnosis on imaging. These two conditions are often discussed separately in the literature.

Diagnosis

Because of the overwhelming predominance of ovarian vein thrombosis occurring in the right pelvic vein as opposed to the left pelvic vein by virtue of the unique drainage of the right ovary, appendicitis is often included in the differential diagnosis. When patients' symptoms fail

Table 16-15 Ovarian Vein Thrombosis: Clinical Vignettes

Fever, right-sided abdominal pain, or leukocytosis unresponsive to antibiotic therapy is the most common presentation.
This is likely a complication of septic thrombophlebitis. This is seen almost exclusively postpartum; less commonly, it occurs following gynecologic surgery.
Ultrasound, computed tomographic scanning, and magnetic resonance imaging are imaging studies of choice.
Heparin is recommended for initial treatment until symptoms resolve, but the role for extended anticoagulation is uncertain.
Few adverse long-term sequelae have been reported.

to respond to antibiotic therapy, deeper diagnostic consideration is required. The correct diagnosis is almost always made on the basis of the combination of failure to respond to antibiotics and visualization of abdominal and pelvic contents on modern imaging. One group found that MRI, CT, and ultrasonography had sensitivities and specificities as follows: 92% and 100%, 100% and 99%, and 50% and 99%, respectively. Imaging led to correct diagnosis in 76 consecutive cases of postpartum fever refractory to antibiotic therapy.²⁵⁴ The thrombosed postpartum ovarian vein may be surprisingly large.

Treatment

Therapeutic efforts initially consist of antibiotics and are directed toward anticoagulation once the diagnosis has been made. Most experts recommend the initial use of heparin in the treatment of patients with ovarian vein thrombosis on the basis of rapid resolution of clinical symptoms in treated patients.²⁵⁵ Whereas it is often cited in the obstetric literature that defervescence of fever in response to heparin therapy occurs characteristically within 24 to 48 hours, Witlin and colleagues²⁵² found in their study that the response usually requires 3 to 4 days. A recent series has questioned the need for anticoagulation. These authors randomly assigned 15 patients to antimicrobials, plus or minus heparin, and found no difference in the number of days of fever and hospitalization.²⁵⁶ Our group favors initial anticoagulant therapy but does not necessarily prescribe anticoagulation with warfarin for longer than 3 to 6 months unless an underlying thrombophilic mutation is identified, because this unique DVT is always associated with the provocation of pregnancy or gynecologic surgery.

Ovarian vein thrombosis is believed to be due to septic thrombophlebitis.^{257,258} Because modern imaging yields the correct diagnosis, surgical exploration is no longer required. Taking advantage of cases found at surgery in premodern imaging days, however, Munsick and Gillanders²⁵⁸ cultured the clots excised from thrombosed ovarian veins and found that in six of seven cases, they were able to culture bacteria, thereby solidifying the theory that this is in fact septic thrombophlebitis. The postpartum state is already one of increased thrombotic risk, given hypercoagulability, but the dilated ovarian vein with slow flow further increases the risk. Minimal evidence suggests that this condition is associated with congenital thrombophilia. One case of protein C²⁵⁹ deficiency, one case of protein S deficiency, and two cases of antiphospholipid antibody syndrome have been implicated.^{260,261} A recent review, however, found that 11 of 22 patients with ovarian vein thrombosis had a thrombophilic condition with negative personal and family histories of prior VTE.²⁶² These experts suggested that warfarin may be administered for several months after the diagnosis has been established and initial heparin therapy provided. They were not certain about the role of antibiotics but noted that almost all patients had already completed a course of antibiotics prior to discharge. Although it is known that thrombi from the ovarian vein may protrude into the IVC or veins of the legs, clinically significant PE is very rare, and no cases of death due to PE have been reported in patients with ovarian vein thrombosis. The absence of adverse long-term sequelae has been noted with ovarian vein thrombosis, and the relapse rate with subsequent pregnancy is low.^{252,253} Excellent

imaging studies of postpartum ovarian vein thrombosis have been published.²⁶¹ A smaller version of ovarian vein thrombosis has also been found in nonpregnant women, usually incidentally when clinicians are staging an oncologic disorder. Those having ovarian vein thromboses associated with malignancy have a worse prognosis, accounting for all the deaths in one series.^{261a} Patients with these asymptomatic thromboses of the ovarian veins probably do not need to be treated with heparin, but the argument could be made for serial monitoring of the process.²⁶²

OTHER SITES OF THROMBOSES

Adrenal Gland

It is now believed that adrenal gland hemorrhage is (Table 16-16) initiated by thrombosis of the adrenal veins. The unique anatomy of the adrenal vein, with its rich arterial supply but only a single draining vein, may predispose this site to thrombosis.⁷ Thrombosis is followed by infarction and subsequent hemorrhage²⁶³ into this highly vascular organ. Adrenal vein hemorrhage occurs in stressful situations and is increasingly recognized in association with lupus anticoagulant syndrome, APLS, heparin-induced thrombocytopenia with thrombosis,²⁶⁴ and purpura fulminans. In fact, in recent reviews, it has been noted that 10% to 26% of patients with catastrophic antiphospholipid antibody syndrome (CAPS) have adrenal failure, which may be the first clinical sign of CAPS in more than one third of cases.⁸ Whereas, traditionally, adrenal gland hemorrhage had been detected at autopsy, it is now often recognized in life in patients who are in stressful situations and develop fever, hypotension, and abdominal or back pain of uncertain cause. Routine laboratory evaluation is not helpful in the acute situation, and therapy should hinge on clinical suspicion—not on laboratory results. Enlargement and hemorrhage of the gland subsequently are observed when abdominal exploration is performed by CT scanning (Fig. 16-9).²⁶⁵ Despite secondary hemorrhage, initial management of the condition often involves anticoagulation, given the underlying thrombosis, especially in known hypercoagulable conditions.^{7,8} Treatment of patients with adrenal insufficiency with mineralocorticosteroids is of paramount importance.

Table 16-16 Adrenal Infarction with Secondary Hemorrhage: Clinical Vignettes

Typical clinical presentation includes vague abdominal or back pain with hypotension requiring pressor support, especially in stressful situations.
It is commonly associated with antiphospholipid antibody syndrome.
Computed tomographic imaging is the diagnostic modality of choice.
Adrenal hormone studies are of little diagnostic value in the acute setting.
Anticoagulation is recommended despite overt hemorrhage.
Empirical replacement therapy of patients with adrenal insufficiency should be strongly considered.

Figure 16-9 Adrenal gland hemorrhage. This computed tomographic scan with contrast shows bilateral adrenal hemorrhage (arrows) that is more advanced on the left.

Pituitary Gland

Hemorrhagic infarction related to thrombosis of the pituitary gland has been described as a cause of hypopituitarism in patients with APLS.²⁶⁶ This diagnosis may be entertained in the appropriate clinical setting in patients who exhibit evidence of hypopituitarism.

Placenta

Antiphospholipid antibody syndrome^{267–269} has long been regarded as a major cause of infarctive placental dysfunction (Table 16-17), but other hypercoagulable disorders are now also implicated through the systematic evaluation of women who have experienced late fetal loss and stillbirth.^{267,270} The role of inherited thrombophilia as a cause of intrauterine growth retardation (IUGR), preeclampsia, and placental abruption remain controversial.^{267,269} Pathologic evaluation of the placenta in cases of recurrent fetal loss also supports the causative role of thrombophilia.^{267,269} Thrombotic changes and infarcts of the placental circulation are seen in a significant proportion of cases. Placental thrombotic infarcts may be maternal or fetal.²⁶⁹ However, the frequent finding of thrombosis on the maternal side, in conjunction with the fact that heparin can prevent fetal loss but does not cross the placental circulation, argues that thrombosis on the maternal side of the placental circulation is of primary

importance.²⁶⁹ Kupferminc and colleagues²⁷¹ found that among 110 women with complications of pregnancy associated with abnormal placenta vasculature, 71 (65%) had laboratory evidence of thrombophilia compared with 18% among controls ($P < .001$).²⁷¹

A complete review of the role of thrombophilia in pregnancy-related complications is beyond the scope of this chapter (see Chapter 36), but an increasing number of studies and reviews on this topic have been published.^{267–270,272–274} A meta-analysis has recently shown that factor V Leiden and the prothrombin 20210 mutation were associated with early and late fetal loss (odds ratio, 2 to 8).²⁷² A recent review of the European Prospective Cohort on Thrombophilia (EPCOT) showed only a small increase in fetal loss among carriers of thrombophilic mutations (odds ratio, 1.4 to 1.6, depending on the mutation).²⁷³ Brenner and colleagues²⁷⁵ found factor V Leiden mutation in 32% of patients with fetal loss compared with only 10% in controls ($P < .001$). Gris and coworkers²⁷⁶ identified similar defects in 21% of women with late fetal loss or stillbirth compared with 4% in controls. These last two reports additionally confirmed that those harboring more than one hypercoagulable defect had a higher rate of fetal wastage (increasing from 7% with one abnormality to 23% with more than one), consistent with the synergism of risk factors described for thromboses at other sites.²⁷⁷ Martinelli and colleagues²⁷⁸ calculated a relative risk of late fetal loss of 3.0 for women heterozygous for the factor V Leiden or prothrombin 20210 mutation. Among women known to have a deficiency of protein S, protein C, or ATIII, fetal loss was experienced in 22% of pregnancies when the women were not prophylactically treated with anticoagulants; among control women without these deficiencies, 11% experienced fetal loss.²⁷⁹ Although positive and negative data exist for most of the mutations studied, recent reviews suggest roles of factor V Leiden, antiphospholipid antibody syndrome, hyperhomocysteinemia, and the prothrombin gene mutation in recurrent pregnancy loss.^{271,272,274} Although deficiencies of ATIII, protein C, and protein S are much less common and their significance is therefore more difficult to prove, data suggest that these mutations also increase the risk of fetal loss.²⁷⁴ Although less information is available on congenital hypercoagulable disorders compared with APLS (see Chapter 36), recent data suggest that it may be prudent to administer anticoagulant therapy to such women throughout pregnancy and the puerperium, to increase the chances for a live birth.^{270,280,281} Newer data have supported the efficacy of low molecular weight heparin in increasing the chances of a viable pregnancy in women with recurrent fetal loss.²⁷⁰ In a study by Brenner and associates,²⁸² doses of enoxaparin ranging from 40 to 80 mg per day (determined by the number of underlying thrombophilic risk factors) resulted in a live birth in 75% of gestations compared with 20% in previous pregnancies.²⁸²

Table 16-17 Infarctive Placental Dysfunction: Clinical Vignettes

Inherited and acquired thrombophilia may play a role in diverse fetal complications, especially with recurrent or second or third trimester miscarriage.
Recent data have shown the safety and efficacy of low molecular weight heparin in preventing fetal loss.
This topic is covered in greater detail in Chapter 36.

CONSULTATION CONSIDERATIONS

The consultant hematologist will be asked to see patients with thromboses at unusual sites through differing pathways. First, the patient with an established hypercoagulable history may develop nonspecific yet serious signs and

symptoms that defy diagnosis. However, the knowledgeable physician is justified in elevating to very high on the list thrombosis at an unusual site from a rarity buried in the differential diagnosis, when the patient is known to be thrombophilic. Second, the consulting hematologist could (and should) be asked to make anticoagulation recommendations in thrombophilic patients before the time of a planned or urgent surgical procedure, or after it has been performed. In a third instance, the hematologist will be asked to evaluate a patient who develops an unusual thrombosis for an underlying hypercoagulable disorder.

As in all internal medicine, the history and physical examination are fundamental. One should search aggressively for clues in the past history for signs or symptoms of a previous thrombosis. Subtle signs include varicose veins, hemosiderin deposition in the skin of the legs, and chronic edema. Family history should be combed for evidence of members with unexplained sudden death or a thrombophilic history, or who are on long-term warfarin therapy.

It is important to work closely with other specialists to plan for long-term management. Thrombosis is the unifying pathologic event in the genesis of syndromes with expressions as varied as abnormal liver function test results from hepatic vein thrombosis to altered mental status from cerebral venous thrombosis. Physicians who may not have received training or whose interest may not be attuned to thromboembolism may need special guidance and assistance in therapeutic maneuvers, especially ophthalmologists and obstetricians/gynecologists. Radiologists are essential in the diagnostic pursuit, in that special techniques, special contrasts, and special timing are all needed when modern expensive imaging studies are performed.

LABORATORY EVALUATION

It is ironic that laboratory evaluation is best *not* carried out during the acute part of a VTE because thrombosis itself and treatment thereof may affect levels of protein C, protein S, and ATIII, and possibly, detection of anticardiolipin antibodies. DNA-based testing through polymerase chain reaction (PCR) analyses, such as detection of the factor V Leiden mutation or the prothrombin 20210 mutation, will not be affected by these events, but results will usually be delayed by several days. It is important to query family members who visit the patient because frequently, a family member will have a history of a previous thrombosis. It should be noted that the presence or absence of thrombophilia will not change immediate management decisions; therefore, evaluation is likely best delayed until after the acute event, when a hematologist can guide, monitor, and interpret the results of ordered tests.

COST CONTAINMENT ISSUES

Frequently, the consulting physician will have already ordered an expensive battery of tests for hypercoagulability in a patient who has had an acute VTE and is under therapy. These will be difficult to interpret and, if abnormal, the results may have been altered by the acute condition or by therapy. Although these funds will have already been spent,

it is important to clarify in the medical record for future reference the clinical condition and medications the patient was receiving at the time the test samples were drawn. An incorrect diagnosis on a discharge summary is extremely difficult to undo. Frequently, a significant delay or even discharge may occur before results are returned, and many parties will have long forgotten these details. Cost containment is also favorably affected by rapid diagnosis of the thrombosis and rapid therapy, even if it includes expensive thrombolytic agents, because these may significantly decrease hospital stay, morbidity and mortality, and, frequently, the occurrence of extremely expensive procedures such as orthotopic liver transplantation in cases of hepatic vein thrombosis.

Prevention, Diagnosis, and Treatment of the Postphlebotic Syndrome

Reagan W. Quan, MD • David L. Gillespie, MD

INTRODUCTION/EPIDEMIOLOGY

The incidence of deep venous thrombosis (DVT) of the lower extremity is 250,000 cases per year, or 1 of 1000 persons in the United States annually.¹ The postphlebotic syndrome, consisting of persistent pain, edema, hyperpigmentation, induration of the skin, and stasis ulceration,² is a well-recognized complication of acute DVT, estimated to affect up to 4% of the general population.³ The most likely cause of the postphlebotic syndrome is venous hypertension that results from outflow obstruction and venous reflux, causing damage to venous valves. This venous hypertension is then transmitted to the skin microcirculation, leading to tissue hypoxia and lymphatic obstruction.⁴ Two thirds of patients with postphlebotic symptoms have evidence of a clinically or phlebographically proven DVT.⁵ Five to ten years may be required for the postphlebotic syndrome to become evident, although in some studies, most cases were recognized within the first 2 years of the acute thrombotic event.⁴ In one study of patients with acute DVT, 17% showed symptoms the first week after the acute episode; this increased to 37% after the first month and 69% after the first year.⁵ Approximately 25% to 33% of individuals with a history of DVT remain asymptomatic over the long term.^{3,6} Studies have reported that 67% to 80% of patients have symptoms and abnormal venous hemodynamics^{7,8} after DVT.

The presence of abnormal venous hemodynamics, with incompetent valves and reflux on a chronic basis, constitutes chronic venous insufficiency (CVI). Over time, CVI may lead to the symptom complex that we know as postphlebotic syndrome. The terms *chronic venous insufficiency* and *postphlebotic syndrome* are often used interchangeably. However, the former term represents the pathophysiologic situation, and the latter is a complex of resultant symptoms.

The postphlebotic syndrome varies from mild edema with minimal discomfort to incapacitating limb swelling with pain and ulceration. Mild postphlebotic skin changes and hyperpigmentation are observed in 15% to 30%,^{3,9} and severe signs of postphlebotic syndrome and marked trophic skin changes progressing to ulceration are observed in 2% to 10% of patients from 5 to 10 years after their DVT,^{3,6,8,9} regardless of the initial site of thrombosis. Severe CVI can be highly debilitating and frustrating to patient and physician. Successful treatment is fraught with difficulty, patient noncompliance, and recurrence, despite

the initial success of the treatment.¹⁰ The incidence of severe CVI appears to increase with age.¹¹

Retrospective studies report that in more than 80% of affected limbs, cutaneous ulceration resulted 10 years after a DVT. Recent studies suggest a lower incidence of severe changes after an episode of DVT.³ Some studies suggest that the aggressive use of heparin may have reduced the incidence of serious long-term changes in the postphlebotic syndrome,¹² but other studies have reported that even with adequate laboratory control of anticoagulation, up to 30% of patients will show extension of their DVT.³

Most studies have shown that patients who develop venous reflux after DVT have incompetence of the deep venous system, whereas about 15% have reflux of the superficial venous system alone.⁵ Venous thrombosis results in destruction of the delicate bicuspid venous valves that promote antegrade flow of blood from the leg. During the process of walking, with each step, the gastrocnemius muscle complex compresses lower extremity veins and propels the column of blood toward the heart. With the destruction of the venous valves, however, blood is free to reflux into the distal extremity. This results in a persistently elevated ambulatory venous pressure (AVP). The combination of a persistently elevated AVP and other factors yet to be fully elucidated results in the chronic skin changes of the lower extremity that we recognize as evidence of CVI, or the postphlebotic syndrome. Although some data suggest that this is most closely associated with the development of incompetent venous valves, the mechanism by which incompetence occurs, as well as its time course, is not completely understood.² For example, 15% of normal people have some degree of venous reflux, most often in the superficial veins.⁵

PATHOPHYSIOLOGY

The venous system of the lower extremity comprises three anatomic components: the superficial, perforator, and deep venous systems. The postphlebotic syndrome may be the result of abnormalities in one or more of these systems. CVI may be primary or secondary. Primary CVI, or idiopathic CVI, is usually due to primary valvular insufficiency. Secondary CVI is acquired and is typically a postphlebotic event.^{11,13} In primary valvular insufficiency, all symptoms of typical CVI are identified, yet patients have no prior history or imaging evidence of previous thrombosis. Patients with secondary CVI experience the consequences of the

two major sequelae of DVT: obstruction to outflow due to the presence of residual thrombus, and reflux due to valvular damage.^{3,5,14} Obstructive symptoms are most commonly associated with acute thrombosis, which usually improves with recanalization of the vessel¹¹ and collateral formation around an area of occlusion.^{2,15} Residual obstruction to outflow results from failure to recanalize the major deep veins of the leg. It is believed that reflux results from irreversible valve destruction. This results in valvular insufficiency that prevents efficient function of the calf muscle pump. Distal venous hypertension develops equal to the hydraulic pressure of the vertical column of blood extending without impedance from the heart to the ankle in the standing position.^{3,16} A common dilemma is whether valvular incompetence or venous outflow obstruction is the more important factor in the development of symptoms.¹⁵ Although it is likely a combination of both, reflux is usually believed to be the primary pathologic problem. As such, symptoms are more closely associated with valvular incompetence than with residual obstruction.^{2,7,11,13} Many patients with severe reflux have only mild symptoms; additional factors must therefore contribute to the development of severe postphlebotic syndrome.¹⁷ Chronic venous obstruction plays at least a secondary role in the sequelae of postphlebotic syndrome.⁷ It has been proposed that primary deep venous insufficiency in the thigh may play a role in the development of distal DVT by allowing reflux, which induces stasis. Valve destruction by DVT then appears to increase reflux, although this has not been proved in any prospective studies.^{12,18}

After DVT occurs, recanalization commences. In one study of patients treated with heparin, lysis of thrombi with recanalization was present in 44% of cases at 7 days, 94% at 30 days, and 100% at 90 days. This is not, however, a simple straightforward sequence, because many patients showed extension of thrombus despite therapeutic doses of anticoagulants. Some patients showed extension of thrombus as early as 7 days into their course, and some as late as between 30 and 180 days.² Incomplete recanalization or inadequate formation of collaterals may leave residual obstruction, resulting in venous hypertension. In the process of recanalization, however, some damage occurs to the venous valves, which ultimately results in valvular incompetence, reflux, and venous hypertension. Several mechanisms play a role in the recanalization of the thrombus; these include retraction of the thrombus, peripheral fragmentation, central softening of the thrombus, and spontaneous fibrinolysis.^{2,7} Lytic clefts form around the valve cusps; this has been attributed to local fibrinolytic activity that may be greater on the valve cusps than in the surrounding endothelium. This fibrinolytic activity appears to be more efficient in small veins, suggesting a higher concentration of fibrinolytic activity at these sites. Such increased efficiency may contribute to valve preservation. It also appears that very large and very small thrombi are more likely to recanalize rapidly and that certain veins, such as the posterior tibial vein, which has a large number of valves, may have a decreased incidence of reflux. Analysis of lysis times of the thrombi in vivo suggests that early recanalization is important in preserving valve integrity.^{2,7} It has been postulated that rapid resolution of the thrombus may preserve valvular function and decrease the incidence of postphlebotic syndrome. In one study, early lysis

with the use of fibrinolytic agents resulted in a better clinical outcome after DVT than did stabilization of the thrombus with heparin.² The theory that early and complete lysis reduces the incidence of the postphlebotic syndrome has been the basis for the use of early, aggressive thrombolysis in selected patients with acute DVT.

Factors that contribute to the development of valvular incompetence are not completely understood. After thrombosis has resolved, changes in the vein walls and valve degeneration occur within a few months, leading to postphlebotic reflux.¹⁹ A strong association has long been established between severe postphlebotic syndrome and venous reflux, which is probably the major pathophysiologic component of ulceration.^{17,18} The valve cusps rarely are involved through fibrocellular organization.⁷ However, because of the surrounding inflammatory processes, loss of elasticity results in impairment of venous wall compliance.¹⁸ The development of reflux, which coincides with or is preceded by complete clot lysis within a venous segment, has been reported as early as 7 days after onset of the DVT.² Some patients have transient reflux associated with recanalization. Because of incomplete clot lysis, valves are prevented from closing completely. With complete lysis, these valves eventually become functional again.⁷ In other cases, venous valvular incompetence develops much later than recanalization. Doppler data suggest that incompetence occurs between 2 and 5 months after a DVT.² Van Bemmelen and coworkers²⁰ proposed that the development of venous incompetence is a two-stage process. Initially, the vein dilates in response to proximal venous obstruction. Valvular incompetence occurs because the cusps of the valves are not large enough to coapt with the increased venous diameter.²⁰ At this stage, which occurs between the first and second months, the incompetence is reversible. By approximately the sixth month, the valves are completely destroyed and thus permanently incompetent.⁷ Therefore, the presence of thrombus may not be the primary factor responsible for the development of valvular incompetence. These studies suggest that long-term permanent destruction may be related to the development of venous hypertension.² Investigators have attempted to document the chronologic changes of venous physiology that occur after major thromboses. Akesson and coworkers²¹ studied 20 patients for longer than 5 years after an acute iliofemoral thrombosis was treated with conventional anticoagulation. Radionuclide angiography showed that 70% of patients had obstructive lesions of the iliac vein, with only minor changes occurring from 6 months to 5 years. Despite this, plethysmographic evaluation showed that venous outflow improved over time. Venous reflux, however, worsened with time. The authors concluded that, although venous outflow continually improves after iliofemoral thromboses, valvular competence and muscle pump function continually deteriorate.²¹

Obstruction to outflow, although not the primary cause of the postphlebotic syndrome, may be more common than has been realized, and may in fact be present in as many as one third of patients with severe symptoms.^{3,15} It seems that collaterals may be sufficient sometimes to accommodate resting but not ambulatory flow.^{2,15} Duplex abnormalities consistent with previous DVT often suggest the coexistence of reflux and chronic obstruction.¹¹ Venous obstruction, particularly of the proximal veins, is more

often implicated as the cause of the uncommon symptom of venous claudication, defined as pain in the limb while walking. This symptom is due to venous hypertension that results from occlusion of the proximal veins.⁵

Increasing severity of the postphlebotic syndrome seems to be related to the site and extent of the DVT.^{5,11,22} Residual venous abnormalities in the popliteal and tibial veins are associated with an increased likelihood that an individual will develop the postphlebotic syndrome.^{14,22} Isolated disease of the superficial system is most frequently responsible for the development of CVI, which occurs in 18% to 30% of patients. Isolated perforator vein incompetence is uncommon and occurs in less than 5% of individuals. Most individuals with severe CVI have combined abnormalities that involve all three venous systems.¹¹ In another study, in which the incidence of symptoms was correlated with the site of disease, swelling was increased by distal reflux or a combination of proximal and distal reflux, regardless of which system was involved. Absence of superficial reflux was associated with a low incidence of ulceration, even in the presence of deep venous insufficiency.⁵

It has been suggested that vena caval filters have an association with the postphlebotic syndrome by virtue of the associated incidence of inferior vena caval thrombosis. In a recent comprehensive review of all the literature related to vena caval filters, however, the incidence of postphlebotic syndrome after vena caval interruption ranged from 14% to 41%, according to the type of filter used,²³ whereas the incidence of postphlebotic syndrome after DVT is recognized to be as high as 80%.^{7,8} Further study would be required, therefore, before we can say that vena caval filters are associated with an increased incidence of postphlebotic syndrome. The relatively low incidence of postphlebotic syndrome associated with the filters is likely to be a reflection of relatively short follow-up.

At the microscopic level, cutaneous blood flow regulation is disturbed in severe CVI. The feedback system between the transmural pressure in the postcapillary venules and the precapillary resistance that regulates arterioles is altered. Postural feedback remains disturbed and upregulated even after a venous ulcer has healed.²⁴ Skin biopsy specimens from patients affected by CVI show marked structural derangements. These include collapsed, thickened, and reduplicated basement membranes of the blood vessels, numerous and complex interdigitations between contiguous endothelial cells, and a lack of open junctions, as well as extensive fibrosis in the connective tissue matrix. As a consequence, the capacity for fluid exchange is reduced in CVI.²⁵

Four major areas of basic science in the development of lipodermatosclerosis (defined as thickening and induration of the skin) and ulceration associated with the postphlebotic syndrome have been investigated: (1) the role of cellular apoptosis, (2) the regulation of tissue fibrosis by transforming growth factor (TGF)- β , (3) leukocyte activation in the microcirculation of the skin, and (4) the role of matrix metalloproteinases in tissue remodeling.

Mendez and coworkers²⁶ have shown that wound fibroblasts grown from biopsy specimens of venous ulcers show an abnormally high rate of apoptosis as compared with fibroblasts from normal tissue. They also found that growth rates of wound fibroblasts were significantly lower in all patients than were those of normal fibroblasts.

Pappas and coworkers²⁷ have shown increased levels of TGF- β in dermal biopsy specimens of patients with advanced CVI as compared with normal tissue biopsy specimens. They showed that pathologic dermal degeneration in patients with CVI seems to be associated with increased production of TGF- β in patients with skin induration, hyperpigmentation, and lipodermatosclerosis. In addition, they found significantly increased production of TGF- β in the skin of patients with lipodermatosclerosis and active ulcers as compared with healthy skin. Finally, they were also able to show significantly increased production of TGF- β in lower calf skin biopsy specimens as compared with lower thigh skin biopsy specimens from the same patient.

Saharay and coworkers²⁸ have shown that venous hypertension results in sequestration of activated neutrophils and monocytes in the microcirculation of the leg in patients with venous disease. They postulate that these cells bind to the endothelium and release L-selectin.²⁸ Shoab and coworkers²⁹ reported on the efficacy of treating patients with CVI with oral micronized flavonoid fraction. In this study, they demonstrated decreased surface expression of L-selectin by neutrophils and monocytes, as well as reduction of endothelial activity of intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM) with the administration of oral flavonoid 500 mg twice daily for 60 days.²⁹ The clinical significance of their findings is yet to be determined.³⁰

Increased proteolytic activity by proteases, particularly matrix metalloproteinases (MMPs), is a key feature in venous leg ulcer formation. It is believed that the proteolytic effect of MMPs initiates an elevated turnover of the extracellular matrix, with breakdown of the matrix resulting in venous ulceration.^{31,32} Further research is needed before we will understand the role of MMPs in venous stasis ulcer formation.

SYMPTOMS

Clinical features of the postphlebotic syndrome include pain, edema, pigment deposition resulting in hyperpigmentation, and, ultimately, ulceration.^{5,16,33} In one fifth of patients, however, no evidence of antecedent deep venous occlusion is apparent.³⁴ Typically, unilateral lower leg swelling occurs. In milder cases, symptoms consist of pain and edema. The early edema that follows a DVT is secondary to residual obstruction, and the late edema that forms part of the postphlebotic syndrome is related to valvular insufficiency.² The pain is more often described as an ache, throb, or heaviness that worsens with prolonged standing and as the day progresses. Earlier in the course, the edema is pitting and may resolve with appropriate compression. It also worsens with prolonged standing and as the day progresses. As the disease progresses, the skin becomes chronically thickened and permanently indurated (lipodermatosclerosis) (Fig. 17-1), and subdermal scarring occurs.¹¹ It is not uncommon to see evidence of previously healed ulcers. Areas of hyperpigmentation are usually located in the anteromedial lower leg and appear as clusters of multiple brownish spots. Over time, these may coalesce and appear as a single large area of hyperpigmentation that involves the entire anteromedial mid to distal leg, or gaiter zone. Ulceration, when present, classically appears in the medial aspect of the mid to distal leg.

Figure 17-1 Postphlebotic syndrome. Note areas of hyperpigmentation and healed and healing ulcers.

Ulcers are usually painless. Any significant pain or tenderness should raise the suspicion of infection. Ulcers are often moist and covered by exudate.

The CEAP (Clinical, Etiologic, Anatomic, and Pathophysiologic) classification is used to categorize the severity of CVI.³⁵ CEAP is therefore a clinical classification. A numeric value can be assigned to each of the four categories; in practice, the clinical, or “C,” category is most frequently used. The higher the number, the worse is the process. A “C” value of 0 indicates symptoms only with no identified venous disease. C1 indicates telangiectasias, reticular veins, or malleolar flares; C2 indicates the presence of varicose veins; C3 indicates edema without skin changes; C4 indicates the presence of skin changes, including brawny edema, venous eczema, thickening, pigmentation, and lipodermatosclerosis; C5 indicates a history of a previously healed ulcer; and C6 indicates the presence of an active ulceration^{10,11} (Table 17-1). This classification is useful in providing a guide on how likely it is that a more complex form of therapy will be required in a particular patient. It also facilitates interinstitutional studies.³⁶

DIFFERENTIAL DIAGNOSIS

In considering the diagnosis of postphlebotic syndrome, as in any other condition, a differential diagnosis should be entertained. The conditions to be considered will vary, depending on the stage and severity of the disease. In patients who have leg edema only, conditions that cause peripheral edema should be considered. Most prominent in the differential are lymphedema (primary or secondary, or hereditary in cases of Milroy disease), congestive heart failure, cirrhosis, nephrotic syndrome and other conditions associated with hypoproteinemia, and possibly hypothyroidism and hyperthyroidism.

In patients who present with an ulcer, the differential diagnosis includes arterial insufficiency, vasculitis, hypertensive (or Martorell) ulcer, pyoderma gangrenosum, squamous cell carcinoma, calciphylaxis, and other less common conditions.

A history of DVT and the presence of findings associated with venous insufficiency, such as hyperpigmentation and lipodermatosclerosis, assist in the diagnosis. Venous stasis ulcers are often located in the medial malleolar area and, unless infected, are not painful. Most often, the correct diagnosis can be established on the basis of history and physical examination alone.

RISK FACTORS

Multiple risk factors for the development of postphlebotic syndrome have been identified. Trauma to the venous wall, venous stasis, and hypercoagulability are the most common risk factors. Generally, we associate the development of postphlebotic syndrome with the previous occurrence of DVT, which is true in about 80% of patients.³⁴ The remaining 20% of patients, with no antecedent history of DVT, experience primary venous insufficiency, or, equally possible, a subclinical DVT. Some reports suggest that this number may be even higher. In a study in which ascending venography was performed on 51 limbs with postphlebotic syndrome, 32 had no radiologic evidence of recent or old thrombophlebitis. Instead, they had normal-appearing veins, which suggested primary incompetence of the deep and/or perforating venous valves rather than thrombophlebitis as the cause.³⁶ Older age, male sex, and obesity are also strongly associated with the development of CVI.³⁷ Somewhat less common associations consist of malignancy, superficial varicosities, family history of DVT, recent travel involving sitting for longer than 6 hours, cardiac failure, and pregnancy.² Some patients also essentially

Table 17-1 Clinical, Etiologic, Anatomic, and Pathophysiologic (CEAP) Classification of Venous Insufficiency

CEAP Classification		
Class	Clinical Characteristics	Clinical Significance
C0	No identified venous disease	Minimally symptomatic disease; not generally considered candidates for perforating vein surgery, although superficial ablation is appropriate for C2 or greater
C1	Telangiectasia	
C2	Varicose veins	
C3	Edema	C4-6 are considered candidates for perforating vein surgery
C4	Skin changes: Brawny edema, venous eczema, thickening, pigmentation, and lipodermatosclerosis	
C5	Previously healed ulcer	
C6	Active ulceration	

exist in a sitting position while eating, watching television, and even sleeping while sitting in a chair or recliner with their legs dependent all night. This activity can and should be avoided.

Deficiencies of the fibrinolytic system have been well documented in patients with the postphlebotic syndrome.⁷ Those with inherited or acquired hypercoagulable states are also at risk for postphlebotic syndrome.³⁸ For example, the prevalence of antithrombin III (ATIII)-deficient patients among those with the postphlebotic syndrome is reported at between 2% and 3%. Conversely, postphlebotic syndrome may be an initial presentation of ATIII deficiency.³⁹ Diagnosis and treatment of the disorder with long-term warfarin therapy are indicated to reduce the incidence of recurrent venous thrombosis and the risk of pulmonary embolism.⁴⁰ Patients with DVT also may have lower levels of tissue plasminogen activator (tPA) or higher levels of plasminogen activator inhibitor (PAI-1).²

Other miscellaneous causes of lower extremity DVT include compression of the iliac vein, which was described by Thurner and May⁴¹ and is now known as May-Thurner syndrome. In these patients, the left common iliac vein is compressed against the vertebral column by the overlying right common iliac artery. This results in constant pulsation, which causes reactive changes in the vein and luminal narrowing with subsequent stasis and DVT.⁴²

DIAGNOSIS

The postphlebotic syndrome is most often a clinical diagnosis that is based on the typical signs and symptoms of pain, edema, hyperpigmentation and induration of the skin, and ulceration. More specific information is sometimes needed to differentiate the syndrome from DVT, or when surgical intervention is under consideration. As many as two thirds of patients who present with new symptoms after documented DVT actually have postphlebotic syndrome, which can often mimic or coexist with acute DVT. A skin biopsy, however, is neither necessary nor indicated to make the diagnosis of postphlebotic syndrome.

Duplex Scanning

Duplex scanning is the most common modality used to diagnose a DVT. Venous obstruction is indicated by the absence of spontaneous, augmentable, and phasic flow on pulsed-wave Doppler. Additional observations include the presence of thrombus visualized on B-mode ultrasonography and incompressibility of the vein in transverse section under probe pressure.⁴³ Absence of flow is considered the best method by which total occlusion of a venous segment can be determined.^{2,3,44} To assist in the diagnosis of postphlebotic syndrome, duplex scanning can be used to diagnose chronic venous changes, indicated by the presence of incompetent valves and reflux, or to differentiate old from fresh clot on the basis of sonographic appearance of the thrombus.⁴³ Color flow Duplex scanning is the diagnostic test of choice for identifying the presence of reflux in the superficial, deep, and perforator systems. Competency of the saphenofemoral and saphenopopliteal junctions, the common femoral vein, and the origins of the deep and superficial femoral veins should be documented. Reflux should be evaluated with the patient in the standing posi-

tion. Reflux of the lower leg is elicited by manual compression of the calf with sudden release or with the use of a rapid cuff deflator.²⁰

Incompetency of the tibioperoneal veins is best evaluated with the patient sitting with the foot at rest supported off the floor. Duplex criteria for reflux within the deep system consist of retrograde flow that persists for longer than 0.5 second. Visualization of a venous lumen that directly connects a superficial and a deep vein is diagnostic of perforator vein incompetence.^{2,5,11,33} Most surgically significant incompetent perforating veins are located on the medial calf. Medial calf-perforating veins generally link the posterior tibial vein with tributaries of the saphenous system, most commonly the posterior arch vein. The two clusters corresponding to Cockett II and III are the most commonly involved and are located between 7 and 9 cm and 10 and 12 cm proximal to the inferior border of the medial malleolus.

Air Plethysmography

Air plethysmography (APG) is a noninvasive test that provides reproducible information about degree of venous outflow obstruction, and reflux and efficiency of the calf pump.^{45,46} An air-filled plastic bladder placed around the proximal calf is used to measure changes in the volume of the leg. These changes and the rates of these changes after certain maneuvers designed to fill or empty the venous system reflect the degree of venous obstruction. These maneuvers are done when the patient is supine, upright, or exercising. A series of measurements is obtained during the APG to assess the patient (Table 17-2). Immediately after a DVT appears, the venous outflow fraction (OF) is reduced because of obstruction. However, as recanalization and collateralization progress, OF gradually returns to normal and can become completely normal in a patient with evident postphlebotic syndrome. As the degree of reflux worsens, an increase in venous filling index and residual volume fraction (RVF) is observed. These changes are characteristic of valvular incompetence.^{5,11}

Ambulatory Venous Pressure

An elevated AVP is the hallmark of chronic venous insufficiency and the postphlebotic syndrome. To measure the AVP, a catheter is inserted into a vein in the dorsum of the foot of the affected extremity, and the venous pressure is transduced while the patient is ambulating on a treadmill. This is cumbersome and invasive, and for these reasons, it is not frequently done. Investigations have shown that the RVF measurement during APG correlates directly with increased AVP.⁴⁷ However, because various operations have recently been proposed to correct or bypass malfunctioning valves, precise demonstration of pathologic change is required for selection of the appropriate procedure and evaluation of results.³⁶ Other tests, such as magnetic resonance imaging and radionuclide scintigraphy, may be useful in selected patients.⁴⁸

Intravascular Ultrasound

A newer but more invasive form of ultrasound imaging is intravascular ultrasound (IVUS). With the use of percutaneous venous access, a guidewire-based catheter ultrasound

Table 17-2 Measurements Used to Assess Severity of Venous Obstruction and Insufficiency

Air Plethysmography (APG)			
Ejection fraction	EF	Fraction of the blood volume expelled by the calf pump after a single tiptoe maneuver	Evaluates calf pump function
Maximal venous volume	MVV	Maximum volume reached by the extremity, compared with baseline, when dependent and not weight bearing	Evaluates obstruction
Residual volume fraction	RVF	Fraction of blood volume remaining after 10 tiptoe maneuvers, which are designed to completely empty the extremity	Evaluates calf pump function
Venous filling index	VFI	Rate of filling of the venous system when going from supine with the leg elevated to an upright position	Evaluates reflux
Venous outflow	VO	Volume of blood passively expelled from the elevated extremity by the action of gravity	Evaluates obstruction

device is inserted into the vein lumen. Intraluminal imaging allows for visualization of the thrombus or stricture and measuring of the luminal diameter or vessel wall. This also enables users to verify that wire access is intraluminal versus subluminal or extraluminal. In areas where traditional color flow Duplex is limited, such as in the pelvic or truncal central veins, with obesity, and with significant scarring or fibrosis from a reoperative field, IVUS offers distinct advantages. In cases where exact sizing of the vein diameter is needed for angioplasty or stenting, measuring with IVUS may aid in prevention of vessel fracture.

Computed Tomography Venography

For arterial imaging, many studies have shown that computed tomography (CT) angiography is equivalent to digital subtraction angiography. Although conventional digital subtraction venography remains the gold standard, CT venography (CTV) offers contrast and spatial resolution, along with extraluminal information and multiplanar differentiation of venous and arterial structures.

In body cavities where the venous system is tortuous, such as in the thorax and the pelvis, venous imaging does not conform well to any single 2-dimensional (2D) plane.⁴⁹ Luminal diameters and stenotic vein segments are distorted by 2D venography. Similar to CT angiography for use in preoperative planning for aortic stent grafting, CT venography may be helpful for venous stenting.

Magnetic Resonance Venography

Magnetic resonance venography (MRV) is another modality that may be used to diagnose and stage central venous obstruction. It can reliably predict sites for central venous access. As an alternative to carbon dioxide venography or contrast venography for patients with contraindications to intravenous contrast, MRV can define patent and occluded veins, especially in the chest.

With the use of 2D time-of-flight MRV, slow or partial occlusion of the vessels may be detected. This modality is helpful in the evaluation of axillary-subclavian venous obstruction or thrombophlebitis. In a study by Muller and Triller,⁵⁰ 19 patients with malignant central vein obstruction were evaluated by digital subtraction venography and MRV for stent placement planning. MRV was found to be superior.

Venography

Venography may be used to show level of reflux and degree of venous obstruction. In ascending venography, a vein of the foot is cannulated and contrast is administered in an antegrade fashion. As contrast fills the veins from below, venous anatomy and any obstruction to venous outflow become evident (Fig. 17-2). Ascending venography may, however, fail to reveal the most proximal anatomy. Ascending venography may also be used to show perforator incompetence. With the use of tourniquets placed to obstruct the greater saphenous vein, contrast injected into a dorsal foot vein should reveal only the deep system. If perforator vein flow from the deep to the superficial system is shown, those perforator veins are seen to be incompetent.

In descending venography, a more proximal vein, such as the contralateral common femoral vein, is accessed, and contrast is injected in a retrograde fashion into the desired system. As contrast fills and distends the veins from above, the venous valves and their ability or inability to prevent reflux become evident. Descending venography cannot reveal distal disease in the presence of a competent

Figure 17-2 Ascending venography. **Solid arrow** shows obstruction. **Broken arrow** indicates valvular anatomy.

proximal femoral valve because the valve prevents contrast from filling the most distal vein.³

PREVENTION

Prevention of the postphlebitic syndrome centers on prevention of venous valvular damage and reduction of AVP. For the vast majority of patients, this means preventing DVT, or, once a DVT has occurred, minimizing damage to the venous valves with aggressive, adequate therapy. Healthcare professionals are responsible not only for recognizing and treating thromboembolic disorders, but also for taking all possible measures needed to prevent recurrences. Individuals who have developed a venous thromboembolism remain at an elevated risk of recurrence; this rate is about 3% to 6% during the first 3 months, and although it is lower from then on, it remains elevated for years (see Chapter 14). This possibility is greater in patients with permanent risk factors such as inherited abnormalities of hemostasis than in those with posttraumatic or postoperative venous thrombosis.^{6,51} Hospitalized individuals are at increased risk of DVT because of immobility, trauma, and underlying conditions that promote a hypercoagulable state. These patients should be assessed for the need for a prophylactic regimen such as compression devices that prevent stasis of blood in the extremities and/or the use of anticoagulants. Once a DVT has occurred, prompt resolution is probably the best measure that could be taken to minimize long-term impact. Clinically suspected DVT should be confirmed by objective tests because further evaluation often reveals a different diagnosis.⁴³

Although anticoagulation is critical for stabilizing the thrombus and reducing the incidence of pulmonary embolism after a DVT, anticoagulants may not prevent the sequelae of postphlebitic syndrome.⁵² Unfortunately, no validated method is capable of predicting its occurrence.⁵³ The failure of anticoagulants to prevent postphlebitic syndrome probably stems from their failure to clear the thrombus.⁵³

The long-term clinical implications regarding the development of postphlebitic syndrome after isolated calf DVT, which has been estimated to occur in 5% to 33% of all patients with DVT, are not clear. If not treated with anticoagulation, at least 8% of patients will have propagation of the thrombus proximally. The incidence of postphlebitic syndrome in this population has been reported to range between 3% and 37%. The incidence of ulceration, however, is extremely low.⁵⁴ On the basis of this information, a patient with DVT localized to the calf should be treated for 3 to 6 months with anticoagulation. Prior to discontinuation of anticoagulation, a follow-up Duplex ultrasound study should be performed to monitor for clot propagation; if the clot has propagated, then continued anticoagulation therapy is required. The use of compression stockings, although perhaps not as critical, given the low incidence of ulceration, is probably still advisable to reduce the incidence of some of the less severe sequelae of postphlebitic syndrome.

The use of thrombolytic agents to treat patients with acute DVT is believed to reduce the sequelae of postphlebitic syndrome by affecting valve preservation. Although this has not been proved definitively, several studies suggest

that this is true. Because of large differences in the reported incidence of late postphlebitic syndrome after DVT, it has been suggested, however, that a minimal reopening rate is required to be of clinical value to the individual patient.⁵³ Thrombolytic therapy is most effective when initiated within 14 days of the onset of DVT. Thrombolytic therapy, however, has a higher incidence of hemorrhagic complications (≈5% to 15%) (see Chapter 28). Until conclusive evidence proves its benefits, it should probably be reserved for those patients with massive DVT or DVT associated with relevant clinical signs, most often, for those with iliofemoral thrombosis.^{1,55} The rationale of venous valve preservation is more attractive in young, healthy patients (e.g., postpartum patients) than in patients with short survival (e.g., patients with cancer). It should also be considered in patients who have failed to respond to standard therapy, and in those with a renal allograft on the same side as the DVT, in whom extension to the renal vein could result in loss of the transplant. The use of an inferior vena caval filter to prevent embolization during thrombolytic treatment is not necessary.¹ The use of catheter-directed thrombolysis may reduce the incidence of systemic complications and provide more complete lysis,⁵⁶ although this approach ignores the fact that 30% to 40% of such patients also have a coexisting pulmonary embolus or undetected DVT elsewhere. Although a large portion of the literature on thrombolysis has been based on urokinase therapy, because of its variable availability on the market, the more frequent choice has been tPA. Anticoagulation therapy, instead of thrombolysis, will probably continue to be the mainstay of therapy because of aspects such as limited extent of thrombolysis, absence of tissue loss, complications associated with thrombolysis, and, unfortunately, delay in referral for treatment beyond the 7 days or so when thrombolysis is most effective.⁵⁷

Open venous thrombectomy is rarely indicated and is not frequently used in modern medicine. It should be considered only in instances of DVT involving the iliofemoral venous segment, and when the age of the clot is believed to be less than 72 hours.^{58,59} It is particularly indicated in the patient with phlegmasia cerulea dolens (see Chapter 14), in whom the inherent delay associated with thrombolytic therapy would be unacceptable because rapid results are necessary to save the limb and possibly the patient's life. Even if vascular patency is restored in a good percentage of cases, it is not particularly effective in preventing postphlebitic syndrome.⁵² Open thrombectomy for venous thrombosis below the inguinal ligament has not been consistently beneficial. In the setting of widespread metastatic disease, rethrombosis rates are too high to justify thrombectomy in some patients.⁵⁸ Alternatively, aggressive anticoagulant therapy is indicated.

Following management of acute DVT, compression is probably the most important form of management for preventing the more debilitating form of CVI, which is ulceration. It has been suggested that early application of external compression in patients with acute DVT may prevent the sequelae of postphlebitic syndrome. A randomized trial that compared the use of stockings with the use of no stockings after a first episode of DVT showed reduced development of postphlebitic syndrome by 50% at 2 years in patients who wore the stockings when compared with those who did not

wear the stockings.⁴ Patients who have no symptoms often will not wear the stockings, even though they have been prescribed.³ Although the precise mechanism is unknown, it is believed that they stimulate the development of collaterals, reduce transcapillary filtration, increase fibrinolytic activity, and reduce overdistention of the venous system.^{4,7} It is recommended that the use of appropriately sized, graded compression stockings should be initiated within 2 to 3 weeks from the time of initial diagnosis, and they should be used for at least two⁴ and perhaps up to five years.⁹

TREATMENT

Pharmacologic Treatment

The role of pharmacology in the treatment of patients with postphlebotic syndrome has been very limited. Although several products have been suggested to provide benefit, none has been established as routine clinical practice. Pentoxifylline is reported to improve the healing rate of venous leg ulcers. The mechanism of action of pentoxifylline is believed to be a downregulating effect in leukocyte activation. This in turn reduces leukocyte-derived free radicals, proteolytic enzymes, cytokines, and a number of other noxious mediators.⁶⁰ Another product is venostat, an herbal medicine commercially available as Venostat (Boehringer Ingelheim Corporation, Ingelheim, Germany). It is marketed for the treatment of patients with varicose veins and venous stasis among other conditions. As is the case with many herbal medicines, minimal or no scientific literature is available regarding its effectiveness.

Medical Therapy

The mainstay of treatment for patients with postphlebotic syndrome is compression. Graded compression stockings are used to mechanically reduce ambulatory venous pressure. Stockings are typically available in three degrees of compression: moderate compression provides 15 to 20 mmHg, firm compression, 20 to 30 mmHg, and extra firm compression, 30 to 40 mmHg. No firm data favor the use of knee-high stockings rather than thigh-high stockings, but compliance seems better with the knee-high devices. For the patient with minimal symptoms, moderate compression and even leg elevation at the end of the day are reasonable alternatives. For the patient with mild to moderate symptoms of heaviness, achiness, and edema, firm compression is a reasonable starting point. To prevent recurrence, compression stockings should be used continually in the patient who has experienced previous ulcer formation; in the compliant patient, most limbs are adequately controlled with graded compression stockings.³ It is recommended that the patient put the stocking on in the morning when edema is at its least, before ambulating, and wear it all day. Stockings can be removed at night when the patient sleeps in the supine position and venous pressure is reduced to 0 mm Hg. Because of loss of their elasticity, stockings should be replaced approximately every 6 months. For patients who have previously had an ulcer, conservative treatment has initial treatment failure and recurrence rates at 1 to 3 years that range from 54% to 69%. In a study in which compliance with the use of

stockings was compared with noncompliance, the compliant group had a recurrence rate of 29%, but the noncompliant group had a 100% recurrence rate, at 3 years. If the data were recalculated, the recurrence rate would be closer to 30% in the first year.¹⁰

Patients with advanced CVI (CEAP 6) require daily care of their venous ulcer, in addition to compression therapy. The ulcer should be cleaned properly with saline, and a gentle detergent solution should be followed by adequate debridement. Various wound dressing alternatives are commercially available. The Unna boot is probably the best known. The dressing contains zinc oxide as the active ingredient, combined with a semirigid compression dressing. The goal is to apply the dressing with the use of the model of graded compression, in which the highest degree of compression is present at the foot, beginning just proximal to the toes, and the least compression is noted proximally, immediately below the knee. After application, “boots” are kept in place for 3 to 7 days, depending on the amount of wound drainage and dressing soilage that are present. A sponge dressing may be added to the Unna boot to absorb wound exudate.

Duoderm (ConvaTec, Princeton, NJ) is an example of this type of dressing. The use of a sponge dressing by itself does not improve healing rate, but in combination with compression, it has been shown to result in faster healing rates than the Unna boot alone.⁶¹ A second type of non-elastic stocking is the CircAid (Metro Medical, Nashville, Tenn) legging. It consists of multiple pliable yet unyielding adjustable layers that are attached with the use of Velcro. This device is considered by some providers to be easier to apply than stockings.⁶² This inelastic device has been shown to maintain limb size and reduce venous volume better than stockings.⁶³ A trial of sequential compression pump therapy is worthwhile for patients with severe postphlebotic syndrome. A sustained beneficial response can be expected in 80% of patients; this is slightly decreased to 75% with long-term continued use.⁶⁴ Pump therapy increases the transcutaneous pressure of oxygen; this is associated with a rise in skin temperature and a decrease in edema.⁶⁵

Surgical Treatment

Various surgical alternatives have been developed over the years in an attempt to deal with the late sequelae of postphlebotic syndrome. Some procedures attempt to eliminate venous hypertension in the superficial system by eliminating diseased portions of the superficial system and by ligating incompetent perforating veins. Other procedures are aimed at reducing reflux and venous hypertension by restoring or reconstructing the valvular system. In any particular patient, surgery should be directed at the affected component, as identified by the proper preoperative studies.

Ligation and Stripping and Flush Ligation

Surgical treatment of patients with postphlebotic syndrome should be guided by preoperative venous testing.⁶⁶ In an effort to preserve the great saphenous vein (GSV) for potential later use for coronary artery bypass graft or lower extremity bypass, surgical ablation of varicose veins should be selective and guided by preoperative color flow Duplex and/or APG or continuous-wave Doppler.

Radiofrequency Ablation

As an alternative to conventional vein stripping, radiofrequency ablation (RFA) of the GSV has emerged as one of the earliest forms of minimally invasive endovenous treatments for saphenous vein incompetence. This approach uses a percutaneous technique, whereby radiofrequency energy is delivered through a catheter to achieve heat-induced venous endothelial injury that results in venous spasm and luminal shrinkage. Through the Seldinger technique, the distal GSV is entered with a vascular sheath. Under ultrasound guidance, a tumescent solution (50 mL of 1% lidocaine and 1 mL of epinephrine [1:1000] diluted in 1 L of 0.9% saline solution) is injected around the vein from the knee to the groin. The Closure System (VNUS Medical Technologies Inc., San Jose, Calif) treats 3-mm-diameter to 12-mm-diameter incompetent saphenous varicose veins. The RFA catheter tip is inserted into the vascular sheath and is advanced in an ascending fashion toward the saphenofemoral venous junction. The temperature of the RFA catheter tip is maintained between 82°C and 90°C. The advancement of the catheter, at a rate of 2 to 3 cm per second, is guided by ultrasound to prevent entry into and subsequent ablation of the femoral vein, snagging against valve leaflets, and accidental entry into venous side branches. After vein ablation has been completed, the leg is wrapped with a Kerlex (Kendall Co., Mansfield, Mass) inner layer and an ACE bandage (Becton Dickinson, Franklin, NJ) outer layer. RFA endovenous ablation has been shown to be comparable with vein ligation and stripping. The venous occlusion rate has been reported between 83% and 100%.^{67,68} The complication rate ranges between 4% and 23%.^{69,70} Complications include leg edema, cellulitis, thrombophlebitis, skin color changes, thermal injury, nerve injury, and femoral vein thrombosis or injury.

Endovenous Laser Treatment

Instead of using radiofrequency energy to obliterate the vein lumen, endovenous laser treatment (EVLT) uses laser-derived thermal energy to cause localized endothelial venous damage. Similar to RFA ablation, the vein is injected with tumescent solution under ultrasound guidance. The distal GSV is cannulated with a 5 Fr vascular sheath. Through an over-the-wire technique, a 810-nm laser diode catheter is advanced toward the saphenofemoral junction; this is verified by ultrasound. With the laser delivering continuous energy of 12 to 15 W, the catheter tip is withdrawn toward the knee at a rate of 1 cm per 2 sec until the catheter tip is located 2 cm proximal to the medial femoral condyle. Again, after the procedure has been completed, the leg is wrapped in a two-layered compressive dressing, as described for RFA ablation. Both RFA and EVLT have high rates of venous obliteration, with slightly higher rates for EVLT ranging from 98% to 100%.^{71,72} Complications for EVLT range up to 10%⁷² and are similar to those for RFA. In a direct comparison of early efficacy and complications, both techniques yielded >90% GSV occlusion at 1 month (94.4% for EVLT vs 90.9% for RFA). In three of 54 patients (6%) treated with EVLT, a common femoral vein (CFV) thrombus developed, with one patient requiring an inferior vena cava (IVC) filter for a free-floating thrombus.⁸³

Subfascial Endoscopic Perforator Surgery

The first report from the NASEPS (North American Subfascial Endoscopic Perforator Surgery) registry emphasized the importance of superficial reflux as a cause of venous ulceration.⁷⁴ Perforator interruption, however, has remained a controversial issue.¹⁰ The superficial system is managed by removal of the incompetent branches after these have been identified and marked. The perforator system has recently been the object of renewed interest with the advent of subfascial endoscopic perforator surgery (SEPS). Patients are not generally considered candidates for this type of procedure unless their CVI is rated CEAP 4 or higher. This procedure recreates in a minimally invasive fashion what previous procedures such as the Linton operation did, namely, ligation and interruption of communication between the superficial and deep venous systems of the lower extremity—the perforating veins. The recurrence rate of ulceration after a Linton flap operation of the lower extremities is 14.5% at 6 months to 10 years follow-up.⁷⁵ However, the Linton operation was associated with a high wound complication rate and required an extensive incision in the leg. The success rate of the SEPS procedure is very similar to that of the Linton operation, with about 84% of ulcers healed in one study at a median time of 54 days. The recurrence rate, in the same study, was 28% at 2 years. The wound complication rate, however, was 6%, which is lower than for open procedures. A very high failure rate was noted in patients with residual venous occlusion. In four of nine patients, the ulcer failed to heal, and the other five had recurrence. A clear association has also been found to exist between missed or recurrent perforators and ulcer recurrence.¹⁰

Valve Reconstruction

Various operations have been designed with the purpose of recreating a normal valvular system. Options include valve transposition, reconstruction, and transplantation.^{76–78} In valve transposition, a normal segment of vein is swung into position to replace the diseased segment. In valve reconstruction, the wall of the vein may be folded and sutured in place to recreate valve function. In valve transplantation, a normal segment of vein from a distant position is removed and interposed in the area of disease.

Surgical repair of an incompetent femoral vein as an adjunct to conventional stripping of varices and subfascial interruption of perforating veins is associated with a 90% success rate.⁷⁹ Isolated disease of the more proximal (iliofemoral) valves does not seem to correlate with disease severity, yet distal incompetence, or combined distal and proximal incompetence, does appear to correlate with disease severity. Thus, the value of proximal vein reconstruction is uncertain.⁴⁰ Furthermore, venous pressure measurements do not always return to normal after surgery.⁷⁷ Failure of venous pressure to normalize in the presence of an otherwise successful operation may sometimes be explained by the presence of residual obstruction in association with reflux.³

Surgical Treatment for Patients with Venous Obstruction

Surgical alternatives are available for the rare patient who presents with symptoms associated with the presence of

clinically significant chronic venous obstruction. The principal goal of these alternatives is to bypass the obstructed area. Various options have been described; these include the use of autologous or prosthetic material. Described configurations include saphenofemoral venous crossover,⁸⁰ femorofemoral crossover with expanded polytetrafluoroethylene (ePTFE),⁸¹ cross-pubic bypass, and saphenopopliteal bypass.⁸² Recently, percutaneous angioplasty and stenting have been used for the treatment of May-Thurner syndrome and more extensive ilio caval thrombosis.⁸³

Catheter-Directed Thrombolysis, Thrombectomy, and Stenting

Systemic anticoagulation is the standard of care for the treatment of patients with acute DVT or pulmonary embolism (PE). This mode of treatment prevents propagation of the thrombus but does not protect against valvular incompetence and venous outflow obstruction, which may lead to the development of postthrombotic syndrome.⁸⁴ Catheter-directed thrombolysis and/or thrombectomy with selective endovascular stenting has been shown to be an effective alternative to systemic anticoagulation for the treatment of patients with acute DVT.⁸⁵

Indications for thrombolysis treatment include acute symptoms lasting ≤ 14 days, thrombosis of two or more major deep venous segments, ambulatory capacity, and no contraindications to thrombolysis, such as allergy to thrombolytic agents, coagulopathy, recent surgery, previous stroke, brain lesions, recent gastrointestinal bleeding, severe hypertension, pregnancy, bacterial endocarditis, severe hypertension, and recent severe trauma. Catheter-directed thrombolysis has also been used in chronic DVT (symptoms >14 days), acute-on-chronic DVT, and recurrent DVT. However, the response rate and patency rates are significantly lower.

After DVT has been diagnosed by Duplex ultrasound, venographic examination is performed from the popliteal vein to the IVC. In our practice, an ascending venogram is performed from the ipsilateral ankle or foot to access the distal extent of the thrombus. This is followed by a descending venogram with sheath access from the contralateral common femoral vein, crossing over the IVC bifurcation into the ipsilateral iliac vein. From the contralateral side, a hydrophilic, pliable wire (under catheter guidance) is passed through the entire length of the thrombosed vein segments.

If the thrombus is soft, as evidenced by easy passage of the pliable wire, a pulsed mechanical thrombectomy is performed prior to thrombolysis. Through debulking of the thrombus, the surface area of the residual thrombus is increased for improved thrombolysis. We use an Angiojet Thrombectomy System (Possis Medical Inc., Minneapolis, Minn), which is a catheter-based impeller at the distal tip that produces a pulsed jet vortex. Another mechanical thrombectomy device is the Amplatx device (Microvena Corp., White Bear Lake, Minn). The clot is mascerated into subcapillary-sized particles, which are then aspirated into the suction catheter.

Thrombolysis is performed through a Cragg-McNamara infusion catheter, with tissue tPA provided at 1 to 2 mg per hour after a 2-mg bolus. Additionally, through the side port of the sheath, unfractionated heparin is infused at 500 U per hour to prevent thrombosis at the access site. After 12 to 24 hours, the patient returns for repeat venography. If residual thrombus remains, tPA is continued for another

24 hours. If the thrombus has resolved but flow-limiting stenosis is observed in a vein segment, then selective endovascular stenting is performed with a balloon expandable stent. After the intervention has been completed, patients are treated with oral anticoagulation with or without clopidogrel.

The efficacy of catheter-directed thrombolysis for lower extremity deep venous thrombosis has been reported by Mewissen and associates in a review of a national multicenter registry.⁸⁶ In this study, 221 patients with iliofemoral DVT and 79 patients with femoropopliteal DVT were treated with catheter-directed urokinase infusion. After thrombolysis was performed, endovascular stenting was completed in 99 iliac veins and five femoral veins. The 1-year primary patency rate was 60%. In another study by Jackson and colleagues,⁸⁵ mechanical thrombectomy was added to catheter-directed thrombolysis and stenting. In this series of 28 patients, 15.5-month follow-up revealed 80% long-term patency.

Percutaneous Angioplasty and Stenting

Endovascular surgery has emerged as a new modality for the treatment of patients with CVI and central venous stricture or obstruction from complications of lower extremity deep vein thrombosis. For some patients, IVC and/or iliac vein stenosis may be the cause of lower extremity edema or stasis dermatitis with or without skin ulceration, despite prior GSV stripping and stab avulsion. In a series by Raju and coworkers,⁸⁷ balloon angioplasty and stent placement were performed in 304 limbs with symptomatic CVI.⁸⁷ At 24 months, primary and secondary stent patency rates were 71% and 90%, respectively. Limb swelling decreased from 88% before stenting to 53% after stenting. The incidence of a pain-free limb increased from 51% to 71%. Cumulative recurrence for ulcer healing was 62% at 2 years after stenting.

The left common iliac vein is sometimes compressed by the overlying right common iliac artery. In May-Thurner syndrome, flow through the left common iliac vein is severely impeded because of external compression between the artery and the pelvic brim, as well as intraluminal web formation (venous spur) from within the vein. The acquired venous stenosis may result in left leg pain, edema, and ileofemoral DVT. When a DVT is found in this syndrome, the patient should be treated with catheter-directed thrombolysis, as was described previously. Otherwise, endoluminal stenting with self-expanding stents and balloon angioplasty, or balloon expandable stents have yielded high patency rates with low morbidity in multiple, small case series with up to 1 year of follow-up.

Retroperitoneal fibrosis is an uncommon condition. Its origin is uncertain but has been correlated with the ingestion of methysergide and now is believed to be associated with ergotamine, hydralazine, methyl dopa, and β blockers. Classically, the disease involves encasement of the ureters. In more uncommon circumstances, ilio caval stenosis or occlusion may occur. Surgical exploration and ilio caval lysis have been disappointing. Endovenous stenting has been used with success.⁸⁸

Venous Bypass Procedures

Currently, most cases of ilio caval stenosis or occlusion can be effectively treated with percutaneous stenting with or

without angioplasty. In patients with unilateral iliac vein or inferior vena cava occlusion who have failed endovenous treatment, surgical therapy may be indicated.

In patients who have failed endovenous stenting of a unilateral iliac venous occlusion, a Palma-Dale operation or an interposition spiral vein graft may be performed. The contralateral GSV is harvested, and a crossover saphenous vein transposition is performed to create a femorofemoral venous bypass. In addition, a distal arteriovenous fistula is created on the side of the venous obstruction, to improve graft patency. The 4-year primary and secondary patency rates of 18 saphenous vein crossover grafts were 77% and 83%, respectively.⁸⁹ However, cross-femoral venous ePTFE grafts, even with an arteriovenous fistula, are associated with early graft thrombosis. Alternatively, an occluded iliac vein segment may be resected and reconstructed with a spiral vein graft. The 10-month patency for spiral grafts is 67%.

In the case of concomitant iliac and vena caval occlusion, ilioacaval or femorocaval bypass with ePTFE may be used. Primary and secondary patency rates at 2 years for five ilioacaval and eight femorocaval prosthetic bypass grafts were 38% and 54%, respectively.⁸⁹

CONSULTATION CONSIDERATIONS

Prevention of the postphlebotic syndrome should be the goal of every practitioner who manages DVT. Prevention should begin with the prescription of compression stockings; these can be ordered by physicians of any practice specialty. In cases of iliofemoral thrombosis, preventive measures might involve thrombolysis, and consultation with a vascular surgeon should be considered.

Patients with evidence of established postphlebotic syndrome with active ulcers, new or recurrent, who continue to show evidence of progression despite compression therapy or who have associated varicose veins should be evaluated by a vascular surgeon.

Surgeons and hematologists can work best together if they communicate with each other within their particular institutions to gain an understanding of each other's practices in the management of postphlebotic syndrome.

CONCLUSIONS

Postphlebotic syndrome occurs as dermatologic destruction of the microscopic lymphatics, caused by persistent lower extremity venous hypertension. It is usually caused by valvular destruction after DVT. The mainstay of therapy is prevention through DVT prevention. Early venous thrombolysis decreases the incidence of the disorder. The goal of treatment of patients with the postphlebotic syndrome is to reduce venous hypertension associated with ambulation. Reduction in venous hypertension helps to prevent advanced CVI with ulceration (CEAP 6). Most patients with CVI may be treated with skin emollients and compression stockings. Surgical therapy for the postphlebotic syndrome is aimed at eliminating venous reflux through ligation or stripping of varicose veins, or valve reconstruction.

Unfortunately, reduction in ambulatory venous hypertension does not restore skin affected by lipodermatosclerosis to its healthy state. Patients require lifelong

compression therapy and skin care. Ultimately, understanding and prevention of the postphlebotic syndrome will occur when investigators gain a better understanding of its cause.

Thrombocytosis: Essential Thrombocythemia and Reactive Causes

Craig M. Kessler, MD • Jan Jacques Michiels, MD, PhD

INTRODUCTION

Thrombocytosis is defined as a platelet count above 350,000 to 400,000/ μ L, which is the upper limit of the normal reference range. Thrombocytosis may be categorized as familial, reactive, or secondary nonclonal processes (reactive thrombocytosis [RT]), or as the manifestation of a primary myeloproliferative disorder (MPD)—usually an autonomous and clonal process. This differentiation between RT- and MPD-associated thrombocytosis is critical because the clinical and laboratory features, as well as recommendations for management, are altogether different for each entity.¹ Thrombocytosis, when it is autonomous and clonal in origin, is designated as essential thrombocythemia (ET), a myeloproliferative disorder characterized by predominant megakaryocytic hyperplasia. However, thrombocytosis can also complicate any of the chronic MPDs, including polycythemia vera (PV), chronic myeloid leukemia (CML), myeloid metaplasia with myelofibrosis (MMM) (representing the transformation of these other MPDs), and de novo primary myelofibrosis.

REACTIVE THROMBOCYTOSIS

RT is caused by increased megakaryocyte production of platelets mediated by a physiologically normal megakaryocyte response to elevated circulating levels of cytokines. Megakaryocyte development is stimulated by various growth factors and cytokines, including thrombopoietin (TPO), interleukin (IL)-1, IL-3, IL-6, IL-11, granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, and stem cell factor. Elevated levels of IL-1, IL-6, IL-4, and C-reactive protein are found in patients with RT, whereas normal levels are observed in individuals with primary thrombocythemia.^{2–4} Controversy is ongoing as to whether the degree of elevation of endogenous plasma levels of TPO can be used to distinguish a clonal process from RT. In those studies in which TPO levels were found to be significantly higher in patients with primary thrombocytosis versus those with RT (whose levels were essentially equal to those of normal healthy individuals), the difference was attributed to defective platelet- and megakaryocyte-dependent TPO clearance due to a reduced number of TPO receptors on ET platelets.

In general, RT is a much more common cause of elevated platelet counts than ET or thrombocythemia due to var-

ious MPDs (Fig. 18-1). RT is a common epiphenomenon of inflammatory (e.g., rheumatoid arthritis, inflammatory bowel disease) and neoplastic disease states, iron deficiency, and acute blood loss (Table 18-1). Secondary thrombocytosis is much more commonly encountered in clinical practice than is the primary process.^{5,6} In one study of 280 patients with extreme thrombocytosis (platelet count, $\geq 1,000,000/\mu$ L), 82% were found to have secondary causes of thrombocytosis, and only 14% had MPDs that produced elevated platelet counts.⁵ In another study, the causes of thrombocytosis in 732 patients included ET and the thrombocythemia associated with various MPDs in 12.3% and RT in 87.7%. RT was the result of tissue damage, infection, malignancy, and other rare or miscellaneous diseases (see Fig. 18-1). Therefore, a careful history and physical examination should be done and relevant laboratory data obtained to exclude causes of RT. Elevated levels of C-reactive protein, IL-6, erythrocyte sedimentation rate, and plasma fibrinogen suggest the presence of RT.³ ET is considered a distinct entity, and its diagnosis is based on exclusion of reactive causes of elevated platelet count or on demonstration on bone marrow biopsy of increased numbers of large megakaryocytes.^{7,8} Detection of the JAK2-V617F tyrosine kinase mutation is consistent with the diagnosis of ET but not with the presence of RT. Table 18-2 lists important clinical and laboratory features that may help the clinician to differentiate between diagnoses of ET and RT. RT is typically asymptomatic and is not associated with the thrombohemorrhagic complications seen in many patients with ET. Management of any secondary thrombocytosis basically involves treatment for the underlying condition that is responsible for the elevated platelet count.

FAMILIAL OR HEREDITARY THROMBOCYTOSIS

Familial thrombocytosis is a very rare condition in which extremely high platelet counts have been observed in multiple individuals in successive generations; it affects both sexes and is usually transmitted through an autosomal dominant inheritance mode.^{9–13} This disorder appears to be mediated by heterogeneous gene mutations, which, in several well-defined families, have resulted in gain of function for the TPO gene^{14–16} and the c-MPL receptor gene.¹⁷ Each gain of function mutation in the TPO gene is associated

Figure 18-1 Causes of thrombocytosis in 732 patients. (From Griesshammer M, Bangerter M, Sauer T, et al: Aetiology and clinical significance of thrombocytosis: Analysis of 732 patients with an elevated platelet count. *J Intern Med* 245:295–300, 1999.)

Table 18-1 Causes of Thrombocytosis

- Pseudothrombocytosis
- Primary thrombocytosis
 - Chronic myeloproliferative disorders: essential thrombocythemia, polycythemia vera, chronic myelogenous leukemia, agnogenic myeloid metaplasia/myelofibrosis
 - Myelodysplastic syndromes: 5q- syndrome, idiopathic acquired sideroblastic anemia
 - Hereditary or familial thrombocytosis
- Reactive or secondary thrombocytosis
 - Bacterial infections and tuberculosis
 - Inflammatory diseases
 - Advanced malignancies
 - Acute blood loss and hemolytic anemias
 - Postsplenectomy or asplenia (congenital or functional)
 - Rebound after chemotherapy-induced thrombocytopenia
 - Iron deficiency

with overexpression of mRNA, causing TPO overproduction with increased plasma levels of TPO and increased platelet counts. Nevertheless, other mechanisms must be responsible for the development of hereditary thrombocythemia because in many other families, no mutations have been detected in the genes that code for TPO or its receptor, c-MPL.^{18,19} Familial thrombocytosis due to a gain of function mutation in the TPO gene or in

c-MPL is polyclonal and lacks the JAK2-V617F mutation. Clinical and laboratory features of familial thrombocythemia are similar to those of acquired ET, in which no TPO gene or c-MPL receptor gene mutation has yet been recognized. A TPO-independent mechanism has also been invoked for the extreme thrombocytosis observed in some African Americans, who are homozygous positive for the K39N missense mutation in the c-MPL gene.²⁰

ESSENTIAL THROMBOCYTHEMIA

Although the ability of clinicians to establish disease clonality, to detect JAK2-V617F gene polymorphism, and to monitor elevated levels of TPO may suggest that ET can be distinguished easily from other phenotypically similar conditions associated with thrombocytosis, diagnosis of ET continues to rely heavily on exclusion of the secondary causes of elevated platelet counts (see Table 18-1 and Fig. 18-1).^{1,5,6} For instance, through careful examination of the peripheral blood smear, the clinician can confirm or exclude the presence of “pseudothrombocytosis,” an artefactual epiphenomenon generated by automated complete blood cell count analyzers, which frequently misidentify as platelets basophilic amorphous deposits of cryoglobulins, erythrocyte or white cell fragments, or cellular inclusions. This is most likely to occur in patients with chronic lymphocytic

Table 18-2 Laboratory and Clinical Characteristics of Essential Thrombocythemia and Reactive Thrombocytosis

Feature	Essential Thrombocythemia	Reactive Thrombocytosis
Thrombosis or hemorrhage	Present	Absent
Splenomegaly	Occasionally present	Typically absent
Abnormal platelet morphology and platelet aggregates on peripheral blood smear	Present	Absent
Bone marrow reticulum/fibrosis	Present	Absent
Clusters of dysplastic megakaryocytes in bone marrow	Present	Absent
Increased acute phase reactants (IL-6, C-reactive protein)	Absent	Present
Spontaneous colony formation in in-vitro cell cultures	Present	Absent
Abnormal cytogenetics	Occasionally present	Absent
Suboptimal platelet aggregation responses in in-vitro/spontaneous platelet aggregation	Present	Absent
JAK2 mutation	Frequently present	Absent

leukemia and extreme leukocytosis, in those with thrombotic thrombocytopenic purpura or massive burn injury with brisk intravascular hemolysis, and in postsplenectomy individuals with microspherocytosis in whom the presence of Howell-Jolly bodies is detected. Large numbers of giant platelets or so-called megakaryocytic fragments on the peripheral blood smear are very consistent with thrombocytosis due to an MPD rather than to a reactive process. Thus, the diagnostic workup of ET should also include cytogenetic screening for the Philadelphia chromosome (or the *bcr/abl* gene rearrangement) and other chromosome abnormalities because thrombocytosis and megakaryocytic hyperplasia, particularly the del(5q) syndrome, may be prominent presenting features of chronic myelogenous leukemia and myelodysplastic syndrome (MDS). Coexistence of thrombocytosis and ringed sideroblasts within the bone marrow aspirate should suggest the possibility of MDS (refractory anemia with ringed sideroblasts), but the presence of grade 3 to 4 myelofibrosis in the marrow would be more consistent with MPD.

MPD-associated thrombocythemia (polycythemia rubra vera, agnogenic myeloid metaplasia, idiopathic myeloid metaplasia, or ET) is characterized by the autonomous proliferation of platelets by megakaryocytes that reside in an abnormal marrow microenvironment and/or perhaps by megakaryocytes that are intrinsically hypersensitive to TPO stimulation.^{1,21} Spontaneous megakaryocyte and/or erythroid colony formation in *in vitro* cell cultures is seen in 80% of patients with ET.¹ This type of abnormal growth is not observed in reactive or secondary thrombocytosis; therefore, this test, if available, may provide a useful means of distinguishing between benign and myeloproliferative causes of thrombocytosis.¹

Although ET is the most common of the MPDs, it is a relatively uncommon disease state with an undetermined true incidence. For ET, reported annual incidence rates have ranged from 0.59 to 2.53 per 100,000 inhabitants (Table 18-3).^{21–27} Prevalence is approximately 30 per 100,000 inhabitants. The Olmstead County study estimated that the annual incidence of ET is approximately 2.38 patients per 100,000 population²⁴; however, the increasing use of automated blood counters has led to the detection of a significant number of incidental asymptomatic cases of ET. This is reflected in a 3.2-fold increase in the annual incidence of ET diagnosis in Denmark; diagnosis of this condition increased from 0.31 per 100,000 population in 1977 to 1.00 per 100,000 by 1998.²⁵ Two additional published studies have confirmed this recent phenomenon.^{22,23}

Also, the incidence of ET is approximately twofold higher in females than in males.^{23–25}

Pathogenesis of Essential Thrombocythemia

In 1981, ET was first recognized as a disease that arises from clonal platelet expansion by pluripotent stem cells. With the use of X-chromosome-linked gene probes, such as those used for glucose-6-phosphate dehydrogenase (G6PD), phosphoglycerate kinase, hypoxanthine phosphoribosyl transferase, and later, human androgen receptor (HUMARA) and reverse transcriptase polymerase chain reaction (RT-PCR) analysis of RNA transcripts from genes for iduronate-2-sulphatase (IDS), palmitoylated membrane protein p55, and G6PD, the study of larger populations of patients with ET became possible.^{28–31}

TPO, as the primary regulator of platelet production, stimulates the growth and differentiation of megakaryocyte progenitor cells *in vitro* and *in vivo*. TPO binds to c-MPL receptors (the product of the c-MPL proto-oncogene) on the platelet membrane surface and is subsequently internalized and degraded.³² Plasma TPO levels are regulated normally by total platelet and megakaryocyte mass, and are highly elevated in patients with aplastic anemia. It is interesting to note that TPO levels are normal or slightly elevated in ET despite an expanded megakaryocyte and platelet mass.³³ Dysregulation of the TPO–c-MPL system in ET is suggested. In fact, patients with ET have markedly decreased expression of c-MPL protein on their platelet membranes (and decreased mRNA expression), resulting in reduced TPO-binding capacity, impaired uptake and catabolism of TPO, and decreased clearance of TPO from the circulation. These findings explain the normal or slightly increased plasma TPO levels that occur in ET^{34–36} and suggest that megakaryocytes in ET may be hypersensitive to the stimulatory effects of TPO on production of platelets *in vivo*.⁶ It has not yet been determined how reliable the detection of reduced expression of c-MPL would be as a diagnostic marker for ET and primary thrombocytosis versus secondary causes for elevated platelet counts. Because TPO levels may be elevated in reactive and clonal thrombocytosis, TPO assays available to date cannot reliably be used to differentiate between these two conditions.^{37–39}

Since the time that the JAK2-V617F mutation was discovered to be the cause of trilinear MPD, including ET, PV, and myelofibrosis, clinicians have come to appreciate that ET is pathogenetically heterogeneous, and that

Table 18-3 Incidences of Essential Thrombocythemia from Five Different Population-Based Studies, Adjusted to a Standard Population²⁷

clonal thrombopoiesis is frequent.^{40–44} Combined results of clonality assays and a PCR test for the JAK2-V617F mutation have shown that clonal proliferation occurs in up to 90% of patients with ET.^{45,46} Half of these and most patients with PV have the JAK2-V617F mutation.^{47–49} No consistent gene or chromosomal defect or causal gene association for ET has been identified to date.

Criteria for the Diagnosis of Essential Thrombocythemia

In 1923, Minot and Buckman⁵⁰ recognized the occurrence of multiple hemorrhagic episodes, along with very high platelet counts, in a patient with MPD. In 1934, Epstein and Goedel,⁵¹ two Austrian hematologists, introduced the term *hemorrhagic thrombocythemia* for the association of recurrent hemorrhages with extreme thrombocytosis (vasculärer Schrumpfmilz) that had persisted for longer than 10 years. In 1960, Gunz⁵² refined the definition of hemorrhagic thrombocythemia to a clinical syndrome of recurrent spontaneous hemorrhage, often preceded by thromboses, and extremely high platelet counts, usually in excess of 1,000,000/ μ L, that is frequently accompanied by splenomegaly and hypochromic anemia and a tendency to develop erythrocytosis (PV) between hemorrhagic episodes. In 1975, this entity was designated ET by the Polycythemia Vera Study Group (PVSG),⁵³ which at that time established the diagnostic criteria for ET as (1) platelet counts in excess of 1,000,000/ μ L, (2) bone marrow characterized by marked megakaryocytic hyperplasia, and (3) absence of PV, the Ph1 chromosome, and significant myelofibrosis.⁵⁴ These parameters were intended to exclude RT and other clonal causes of thrombocytosis (CML, PV, and the hypercellular stage of idiopathic myelofibrosis), which currently are more specifically excluded through PCR assays that detect the *bcr/abl* gene rearrangement when the Ph1 chromosome is absent and cytogenetic studies undertaken to detect del (5q), which is associated with a type of MDS that often manifests as thrombocytosis.^{64–66}

In the late 1970s and early 1980s, several reports^{55–61} showed that symptomatic patients with ET usually presented with microvascular peripheral or cerebral circulation disturbances when platelet counts ranged between 400,000 and 1,000,000/ μ L. This prompted the PVSG to

lower the platelet count criterion for the diagnosis of ET to an arbitrary minimum of 600,000/ μ L⁶² (Table 18-4). In addition, the PVSG endorsed the presence of a normal serum ferritin level concurrent with normal red blood cell MCV as sufficient evidence to exclude both reactive thrombocytosis caused by iron deficiency and PV masked by iron deficiency as the causes of thrombocytosis (see Table 18-4).⁶³

The most prominent and consistent laboratory abnormality seen in ET, as defined by PVSG criteria, is a platelet count elevated to more than 600,000/ μ L.^{61,62} In most studies, average platelet count at diagnosis is around 1,000,000/ μ L.^{67,68} Hematocrit is usually normal unless the clinical course is complicated by bleeding or iron deficiency. Mild leukocytosis (range, 10,000 to 20,000/ μ L) is commonly seen and may be associated with myeloid immaturity and left shift in the differential count. Basophilia and/or eosinophilia may be present, as it is in other MPDs. Serum potassium levels may be spuriously elevated because of the very high platelet count observed in the presence of normal renal function (pseudohyperkalemia, i.e., increased serum yet normal plasma potassium levels).^{61,69–71} This pseudohyperkalemia is explained by the release of potassium from platelets during in vitro coagulation and clot retraction.^{70,71} Measurement of plasma potassium provides a more accurate assessment. One fourth of patients may have elevated serum lactate dehydrogenase and uric acid levels. Leukocyte alkaline phosphatase is normal in most patients, although abnormally increased or reduced levels are not uncommon.^{67,72}

Assays for formation of spontaneous endogenous erythroid colonies (EECs) and spontaneous megakaryocytic colonies (EMCs) may be useful in distinguishing between ET and RT.⁷³ In one study, EEC had a diagnostic sensitivity of 65% for ET, and only one of 88 RT cases was EEC positive.⁷³ EEC-positive ET actually represents latent PV or PV masked by bleeding or chemotherapy.^{74,75} In two representative studies of patients with ET^{76,77} (n = 204) and RT (n = 59), the frequency of EMC in ET was modest (sensitivity, 63% and 69%; specificity, 100%), and diagnostic sensitivities rose to 77% and 92% when EMC results were combined with EEC data.⁷³ Although such in vitro assays are meaningful from a pathophysiologic perspective, they are difficult and expensive to perform and are reserved primarily for use in clinical research efforts.

A retrospective analysis of 143 patients with ET revealed that early ET can exist with platelet counts ranging from slightly above normal to 600,000/ μ L, despite the fact that PVSG diagnostic criteria for ET are not met. Bone marrow biopsies showed an increased number of loosely clustered large and giant megakaryocytes with mature cytoplasm and hyperploid multilobulated nuclei, consistent with ET.^{61,65,78–86} In the overall population of patients with ET in this study,⁷⁸ bone marrow morphology in biopsy material showed normal cellularity in 52%, consistent with ET, and increased cellularity in 48%, which was attributed to erythroid hyperplasia in 17% (consistent with early PV that mimics ET) and myeloid hyperplasia in 45% (consistent with early or overt PV or prefibrotic chronic idiopathic myelofibrosis [CIMF-0]) (Table 18-5).⁷⁹

In 2001, World Health Organization (WHO) bone marrow criteria attempted to differentiate between true ET, early PV mimicking ET, and extreme thrombocytosis, the latter of which is the presenting prominent feature in more than 90%

Table 18-4 Polycythemia Vera Study Group Criteria for Diagnosis of Essential Thrombocythosis

- Platelet count >600,000/ μ L
- Hematocrit <40%, or normal red cell mass (males <36mL/kg, females <32mL/kg)
- No cause for reactive thrombocytosis
- Absence of iron deficiency documented by stainable iron in marrow or normal serum ferritin or normal RBC mean corpuscular volume
- Absence of Philadelphia chromosome and *bcr/abl* gene rearrangement
- Absence of collagen fibrosis of marrow or, if present, it should be less than one third biopsy area without marked splenomegaly and without leukoerythroblastic reaction
- No cytogenetic or morphologic evidence of myelodysplastic syndrome

Table 18-5 Grading of Bone Marrow Fibrosis in Chronic Idiopathic Myelofibrosis (CIMF)

CIMF Classification	Characteristics
CIMF-0	Scattered linear reticulin with no intersections corresponding to normal bone marrow
CIMF-1	Loose network of reticulin with many intersections, particularly in perivascular areas
CIMF-2	Diffuse and dense increase in reticulin with extensive intersections, occasionally with focal bundles of collagen and/or osteosclerosis
CIMF-3	Diffuse and dense increase in reticulin with extensive intersections and coarse bundles of collagen, often associated with osteosclerosis.

Barosi G, Bordessoule D, Briere J, et al: Response criteria for myelofibrosis with myeloid metaplasia: Results of an initiative of the European Myelofibrosis Network (EUMNET). *Blood* 106:2849–2853, 2005.

of cases of prefibrotic CIMF (Table 18-6).^{79–83} CIMF-0 is characterized by hypercellular bone marrow caused by a dual proliferation of megakaryocytes and myeloid precursors,

along with relatively decreased erythropoiesis. Dense clusters of atypical immature megakaryocytes contain irregular “cloudlike nuclei,” which are almost never seen in ET and PV (see Table 18-6).^{79–83}

When WHO bone marrow criteria were applied retrospectively to 539 patients who had previously been diagnosed with ET according to PVSG criteria (platelet counts >600,000/ μ L),^{79,91–93} true ET was corroborated in 21%, CIMF-0 in 27%, CIMF-1 in 40%, and CIMF-2 in 13%.⁹²

According to PVSG criteria, approximately 50% of patients with ET present with spontaneous EEC^{73–75} and increased polycythemia rubra vera (PRV)-1 expression,^{74,87,88} together with low serum erythropoietin (EPO) levels.^{87,89} EEC+/PRV-1+ ET is associated with higher risks for microvascular and major thrombotic complications as compared with EEC–/PRV-1– ET.^{87,88} PRV-1– positive ET may represent a pathobiologically distinct subgroup of ET in which patients are at increased risk for the development of thrombotic complications and for eventual emergence of PV (Table 18-7).⁸⁸ The JAK2-V617F mutation has been strongly correlated with PRV-1 overexpression and the ability to form spontaneous EEC in all three subtypes of MPD.⁹⁰ Comparison of the laboratory features of JAK2-V617F positivity with those of JAK2 wild-type ET clearly shows that JAK2-V617F–positive ET is

Table 18-6 Clinical Peripheral Blood Criteria and World Health Organization (WHO) Bone Marrow Criteria for the Diagnosis of Essential Thrombocythemia (ET), Early-Stage Polycythemia Vera (PV) Mimicking ET, and Thrombocythemia as the Presenting Features of Prefibrotic Chronic Idiopathic Myelofibrosis (CIMF-0) Mimicking ET

Clinical Peripheral Blood Criteria of ET	Pathologic Criteria for ET, PV, and CIMF; WHO Bone Marrow Criteria
A1 Persistent increase in platelet count: in excess of 400,000/μL; grade I, 400,000–1,000,000/μL, and grade II, >1,000,000/μL A2 Normal spleen or only minor splenomegaly on ultrasound A3 Normal or increased leukocyte alkaline phosphatase (LAP) score, normal erythrocyte sedimentation rate (ESR) and increased mean platelet volume (MPV; some large platelets) A4 Spontaneous megakaryocyte colony formation (CFU-Meg) or spontaneous endogenous erythroid colony formation (EEC) A5 Normal or slightly increased hemoglobin (male <18.5 g/dL, female <16.5 g/dL) and hematocrit (male <51%, female <48%) A6 Low serum erythropoietin (EPO) level (early PV mimicking ET) A7 JAK2-V617F mutation (polymerase chain reaction [PCR] test) A8 No signs or causes of reactive thrombocytosis (RT) A9 No leukoerythroblastosis and no teardrop erythrocytes A10 No preceding or other allied subtypes of chronic myeloid leukemia (CML), CIMF, or myelodysplastic syndrome (MDS) and absence of the Philadelphia chromosome (<i>bcr/abl</i> gene)	True ET Predominant proliferation of enlarged megakaryocytes with hyperlobulated nuclei and mature cytoplasm, lacking conspicuous cytologic abnormalities. No proliferation or immaturity of granulopoiesis or erythropoiesis; no or only borderline increase in reticulin Early PV mimicking ET Increased cellularity with trilineage myeloproliferation (i.e., panmyelosis). Proliferation and clustering of small to giant (pleomorphic) megakaryocytes; no pronounced inflammatory reaction (plasmacytosis, cellular debris). Absence of bone marrow features consistent with congenital polycythemia and secondary erythrocytosis; no or only borderline increase in reticulin Prefibrotic CIMF mimicking (false) ET Megakaryocytic and granulocytic myeloproliferation and relative reduction of erythroid precursors; abnormal clustering and increase in atypical giant to medium-sized megakaryocytes containing clumpy (cloudlike) lobulated nuclei and definitive maturation defects; no or only borderline increase in reticulin

EEC, endogenous erythroid colony formation.

characterized by increased levels of hemoglobin and hematocrit, elevated neutrophil counts, and higher leukocyte alkaline phosphatase (LAP) scores, but by lower values for serum EPO, serum ferritin, and mean corpuscular volume (MCV); increased cellularity of the bone marrow is seen in biopsy material. These properties indicate that JAK2-V617F-positive ET probably represents a “forme fruste of PV” that is consistent with early PV that mimics ET (see Table 18-7).³⁷ In contrast, patients with JAK2 wild-type ET have significantly higher platelet counts and usually show a clinical picture of true ET with normal serum EPO levels, normal PRV-1 expression, and normal LAP scores.³⁷

Life expectancy in true ET is normal when transformation or progression to myelofibrosis does not occur but is compromised in those with prefibrotic CIMF-0 or early fibrotic CIMF-1 mimicking ET (false ET). This is due to an increased tendency of patients to develop worsening myelofibrosis and splenomegaly during long-term follow-up.^{91,93} In one large study, 10-year relative (age-adjusted) survival rates were $99.1\% \pm 7.8\%$ for true ET, $80.8\% \pm 11.7\%$ for CIMF-0, and $67.3\% \pm 17.8\%$ for CIMF-1.⁹³

Coagulation Laboratory Features of Essential Thrombocythemia: The Paradox of In Vivo Platelet Activation and Impaired Platelet Function

Elevated levels of plasma β -thromboglobulin, increased generation of thromboxane B_2 , and enhanced expression of P-selectin (CD62P) and thrombospondin on platelet surface membranes have been observed in patients with ET.^{94–98} These findings suggest that enhanced in vivo platelet activation occurs in patients with ET and may predispose them to hypercoagulable complications.^{94–98} These laboratory changes are not detected in patients with RT.^{94,95} A recent study of patients with ET and thrombocythemia associated with PV revealed that markers of in vivo platelet activation (CD62P [P-selectin] and CD63 antigens measured by flow cytometry) were significantly

more elevated in those who experienced arterial thromboses or erythromelalgia⁹⁹ than in healthy controls and those thrombocythemic patients without thrombotic events. Individuals with arterial thromboses and/or erythromelalgia also exhibited evidence of endothelial cell activation (increased levels of plasma soluble vascular cell adhesion molecule-1 [sVCAM-1]).⁹⁹ Cause/effect relationships were not obvious in this cohort because laboratory markers for platelet and endothelial cell activation remained elevated after cytoreductive therapy was provided. A possible pathophysiologic link was suggested by the observation that patients with ET had higher percentages of circulating platelet/neutrophil and platelet/monocyte complexes in conjunction with higher monocyte tissue factor (mTF) expression as compared with healthy controls.¹⁰⁰ Enhanced platelet–leukocyte interaction is known to facilitate leukocyte adhesion and activation, as well as tissue factor (TF) transfer between monocytes and platelets. These events may modulate activation of coagulation by release of TF and formation of circulating microparticles rich in TF and may mediate damage to the endothelium. Consistent with this hypothesis is that monocyte activation (CD11b expression) and mTF expression were significantly higher in patients with ET who had a history of thrombosis than in patients without thrombosis.¹⁰⁰ Aspirin inhibits platelet–granulocyte interactions^{101–103}; this inhibition provides a rationale for aspirin use to reduce the intrinsic hypercoagulability associated with ET and PV.^{104,105} In toto, these data support the concept that spontaneous platelet activation and subsequent platelet–neutrophil and platelet–monocyte aggregation precipitate or exacerbate inflammatory responses and thrombogenesis in the end-arterial circulation of patients with ET (Fig. 18-2).^{61,106,107} Thus, patients with ET and PV along with microvascular ischemic or thrombotic complications have shortened platelet survival; increased plasma levels of β -thromboglobulin (β -TG), platelet factor 4 (PF4), and thrombomodulin (TM); and increased urinary excretion of thromboxane B_2 (Tx B_2).^{108–110} Subsequent inhibition of platelet cyclo-oxygenase (COX-1) by aspirin is followed by symptomatic relief of microvascular ischemic and throm-

Figure 18-2 The clinical spectrum of microvascular circulation disturbances, including erythromelalgic ischemic complications, atypical transient ischemic cerebral attacks (TIAs), ocular manifestations, and coronary artery disease, is caused by platelet-mediated thrombotic processes in the peripheral, cerebral, and coronary microvascular circulation. The paradox of *in vivo* platelet activation and impaired platelet aggregation tests can readily be explained by recirculation of exhausted platelets with secondary storage pool disease. At increasing platelet counts, large von Willebrand factor (VWF) multimers are proteolyzed, leading to prolonged platelet function analyzer (PFA)-100 closure times (CTs) and bleeding times.

botic complications; reversal of shortened platelet survival; reduction of increased β -TG, PF4, and TM plasma levels; and normalization of increased TxB_2 excretion.^{106–110}

Contrary to evidence of *in vivo* platelet activation, *in vitro* platelet aggregation responses in patients with ET are usually suboptimal after agonists are added.^{111,112} Spontaneous platelet aggregation or hyperaggregability is variably observed.^{56,67,68} Platelet function tests that characteristically differentiate ET from RT include (1) absent second wave of platelet aggregation after addition of epinephrine to platelet-rich plasma from patients with ET; (2) increased adenosine diphosphate (ADP) aggregation threshold in ET; and (3) reduced secretion of dense body products from ET platelets (e.g., serotonin during arachidonic acid or collagen-induced aggregation).^{111,112} Bleeding time is usually normal at platelet counts between 400,000 and 1,000,000/ μL .¹¹¹ Platelets in ET are characterized by acquired storage pool disease; by defects in the structure and function of surface membrane glycoproteins (GPs) and receptors, very likely due to downregulated adrenergic GP-Ib-IX and GP-IIb/IIIa receptors on activated platelets; and by their ability to form aggregates with activated leukocytes.^{111,112}

Findings of *ex vivo* traditional platelet aggregation studies in which platelet-rich plasma from 55 patients with ET was used have been compared with simultaneous results obtained with platelet function analyzer (PFA)-100 closure times.¹¹³ Aggregation results were abnormal in 75% of patients with ET; impaired responses to epinephrine were

noted in 58%, to collagen in 38%, and to ADP in 11%. Analysis of the whole group revealed a statistically significantly decreased response to epinephrine and collagen as compared with 26 normal controls. PFA-100 closure times were prolonged in 74% (41 of 55) of patients with ET: 38 with the collagen/epinephrine cartridge and 23 with the collagen/ADP cartridge (some with defects using both cartridges).¹¹³ This study did not attempt to correlate abnormal PFA-100 closure times with occurrence of clinical bleeding.

The paradox that *in vivo* platelet activation and impaired platelet function may coexist in ET can be explained by the fact that ET platelets are “hypersensitive” and can be activated spontaneously by high shear stress in the arterial microvasculature. This causes platelets to secrete their granular contents to promote the formation of von Willebrand factor (VWF) protein-mediated platelet aggregates. These aggregates transiently plug the microcirculation; eventually, the platelets disaggregate and recirculate as “exhausted” or “spent” platelets, which are functionally deficient by virtue of their acquired “secondary” storage pool disease. This pattern is apparent on *in vitro* platelet function assays (see Fig. 18-2).^{94–113}

From the clinical perspective, when VWF-mediated platelet aggregates plug the microcirculation, they release into the local milieu potent vasoactive and inflammatory secretion products, which, in turn, may precipitate vasomotor symptoms, such as erythromelalgia, acroparesthesia, migraine-like headaches, and atypical transient ischemic attacks (TIAs)

(see Fig. 18-2). Paresis, visual disturbances, and epileptic seizures have also been reported.^{114–118} VWF-rich platelet thrombi have been observed in skin punch biopsy specimens of erythromelalgic lesions in untreated patients with ET¹⁰⁸; they probably also occur in the cerebral, ocular, coronary, and abdominal microcirculation, if left untreated (see Fig. 18-2).^{94–113} Erythromelalgia and atypical and typical cerebral or ocular migraine-like TIAs in ET rapidly and dramatically resolve after administration of aspirin, which reveals an additional compelling indication of the critical role of platelet activation *in vivo* and the contribution of prostaglandin endoperoxides to induced thrombotic complications in ET.^{56–61,106–110,115–117}

Clinical Features and Thrombohemorrhagic Complications

ET was originally classified as a hemorrhagic disease associated with thrombocytosis.^{51–54} More recent observations indicate that thrombotic episodes, particularly microvascular episodes, occur far more frequently in ET than do hemorrhagic complications. This may reflect increased awareness and the earlier age of ET diagnosis when thrombocytosis is detected on routine complete blood count (CBC). When extreme thrombocytosis complicates other MPDs, differences are noted in patterns of clinical hemostatic manifestations as compared with ET.¹¹¹ For instance, bleeding and thrombosis occur very infrequently in individuals with CML, despite the presence of extreme thrombocytosis. Idiopathic myelofibrosis associated with extreme thrombocytosis is rarely complicated by hypercoagulable thrombotic events. Patients with PV and thrombocytosis are more prone to thrombotic episodes, particularly when their hematocrit levels are elevated (see later), although bleeding complications may occur concurrently. Despite these generalized observations, the literature has failed to show a clear correlation between platelet count and incidences of hemorrhage or thrombosis in patients with MPD with uncontrolled thrombocytosis.¹¹⁹

Patients with ET with platelet counts above 1,000,000/ μ L present with high incidences of bleeding and thrombotic complications.⁵⁴ Symptomatic manifestations related to the arterial microcirculation, especially in peripheral and cerebral regions, constitute the most frequent clinical complications in ET.^{55,60,111} Patients may present with paresthesias and erythromelalgia, characterized by warm, markedly erythematous, and congested extremities and an intensely painful burning sensation over the fingers, soles, and toes. If left untreated, erythromelalgia can lead to acrocyanosis or gangrene of the fingers and toes. Other associated complications may include migraine-like headaches, atypical and typical TIAs, ocular ischemic manifestations, and peripheral arterial occlusive disease of the lower extremities.^{56–61,65,72,114–117} These symptoms are most likely due to platelet activation in the microcirculation and microthrombi formation, which are so promptly relieved by low doses of aspirin (81 mg) that the response serves as a diagnostic criterion (see Fig. 18-2).

The published incidence of major thrombosis has ranged from about 25% to 30% in unselected individuals with ET.^{67,68,120–127} An analysis of 11 retrospective clinical studies comprising 809 patients with ET¹²⁸ reported the overall incidence of thromboembolic complications

as 58% and of overall bleeding events as 17%; thromboembolic events without concurrent bleeding occurred in 42%, bleeding without thrombosis was reported in 1.4%, and absence of bleeding or thrombotic symptoms was noted in 36%.¹²⁸ The incidence of deep venous thrombosis, including portal and splenic vein thrombosis, was reportedly 4%, but the incidence of Budd-Chiari syndrome was not recorded.¹²⁸ Arterial thrombotic problems in this cohort of 809 patients with ET were described as microcirculatory in 41%, with 24% involving upper and lower extremities and 17% involving the cerebral circulation.

The literature is imprecise as to the frequency of thrombohemorrhagic complications at time of presentation of ET. Of 809 patients with ET in 11 retrospective studies analyzed, between 31% and 83% presented with minor and/or major arterial complications. Significantly, 27% to 70% of these patients had end-arterial microvascular signs and symptoms, reported as acroparesthesias, burning red or blue toes or fingers (erythromelalgia), peripheral ischemia, poorly localized neurologic symptoms, and blurred vision or headache.¹²⁸ Four percent to 38% of patients with ET presented with bleeding complications.¹²⁸ This variability in manifestations and longitudinal symptoms probably reflects the heterogeneity of the patient population studied and differences in the definition of thrombohemorrhagic complications; however, age at diagnosis of ET also is very important in this regard because major thrombohemorrhagic manifestations are less frequent before the age of 60 years. Analysis of the overall patient population with ET indicates that the median age at presentation is approximately 60 years, with only 10% to 25% of patients presenting when younger than 40 years old. In addition, one third of ET diagnoses are established in asymptomatic individuals.^{67,68,120,121,124,128} At ages younger than 60 years, ET is more common among females, but thereafter, no sex predilection is known. The annual incidence of major thrombotic complications in ET is significantly greater in those older than 60 years of age (15%) compared with those younger than 40 years of age (2%).¹²⁵ Thrombosis-free survival (TFS) was noted to be normal in those diagnosed when younger than 60 years and without a prior history of venous or arterial thromboembolic episodes.^{122,125} Most major thrombotic events in ET occur in those with prior hypercoagulable histories and cardiovascular risk factors. The potential contribution of the hereditary hypercoagulable state (factor V Leiden, prothrombin gene mutation, deficiency of antithrombin III, protein S, or protein C) to the incidence of thrombotic complications in patients with ET has not yet been established.¹³¹

A thrombocythemic patient with ET or PV may “shift” from being primarily thrombosis prone to becoming a “bleeder,” as the disease progresses and platelet counts increase during long-term follow-up.^{51,52,118} Major hemorrhagic complications usually affect the gastrointestinal tract and are frequently associated with, precipitated by, and exacerbated by concurrent use of antiplatelet-aggregating medications.^{118,134–138} Large hematomas, hemarthroses, and intraocular, posttraumatic, or postsurgical bleeding rarely occur. Uncontrolled thrombocytosis is also a definite risk factor for these major bleeding events.^{118,119} Minor bleeding is characteristic among those with qualitative or quantitative platelet disorders or VWD (Fig. 18-3)¹¹¹;

Figure 18-3 Correlation between clinical signs and symptoms and platelet counts in essential thrombocythemia (ET) and polycythemia vera (PV). The concept of platelet-mediated microvascular thrombosis and bleeding in thrombocythemia and the relationship between platelet counts and functional von Willebrand factor (VWF) levels (VWF ristocetin cofactor activity [VWF:RCo] and VWF collagen binding activity [VWF:CB]) in patients with erythromelagic thrombotic thrombocythemia (ETT) and hemorrhagic thrombocythemia (HT) are shown here. Note the progressive decrease in VWF:RCo and VWF:CB that occurs at increasing platelet counts. As the platelet count rises, risks of bleeding increase because of reduced VWF protein activities. Erythromelagic symptoms are an indication for aspirin, but loss of VWF protein activity is a relative contraindication for the use of aspirin in thrombocythemic patients (ET and PV). (From Schafer AI: Bleeding and thrombosis in the myeloproliferative disorders. *Blood* 64:1–12, 1984.)

mucosal hemorrhagic manifestations, such as epistaxis, ecchymoses, and gingival bleeding, predominate.

In a study of 100 consecutive case histories of MPD-associated hemorrhagic thrombocythemia, 50 had gastrointestinal blood loss (melena and/or hematemesis or chronic occult blood loss), 34 had manifestations of cutaneous bleeding (subcutaneous hematomas and ecchymoses), 33 had episodes of epistaxis, 15 experienced gingival bleeding, and 29 had bleeds related to trauma or surgery.¹¹⁸ Petechiae were never seen. Bleeding symptoms occurred at a mean platelet count of greater than 2,000,000/ μ L (compared with thrombotic complications, which occurred at a mean platelet count of approximately 1,100,000/ μ L)¹¹⁸ and often were associated with the development of acquired VWD (Figs. 18-3 and 18-4).

Decreases in VWF protein function (ristocetin cofactor activity; VWF:RCo) and in ability to bind to collagen (VWF:CB) and the loss of large VWF multimers are significantly correlated in ET and other MPDs with extremely increased platelet counts (see Fig. 18-4).^{134–138} At platelet counts in excess of 1,000,000/ μ L, the absolute

values of VWF antigen (VWF:Ag) and factor VIII:C usually remain normal as VWF:RCo and VWF:CB decrease. This results in decreased ratios of VWF:RCo/VWF:Ag and VWF:CB/VWF:Ag, consistent with acquired variant type 2A von Willebrand disease. Also, plasma concentration of the large VWF multimers is decreased (confirmed on sodium dodecyl sulfate [SDS] chromatography of VWF protein) through their increased adsorption to platelet surfaces as platelet counts rise (see Fig. 18-4).^{134–138} Reduction of the platelet count to <1,000,000/ μ L usually restores the multimeric integrity of the VWF protein with reversal of bleeding tendencies.^{134–136} Deficient VWF:RCo and VWF:CB may also be corrected to low normal levels.^{133–138} Altered VWF structure and function and qualitative platelet defects are not features of RT; thus, clinical bleeding is typically not observed in that condition.¹³⁷

Physical examination is usually unremarkable in early ET. Some patients may have moderate or progressive splenomegaly and/or hepatomegaly indicative of CIMF,^{61,67,68} particularly as the disease progresses to MMM.^{61,67,68,129}

Figure 18-4 Platelet counts related to von Willebrand factor (VWF) multimeric analysis with medium-resolution agarose gel in four patients with essential thrombocythemia. Medium-resolution agarose gel separates each oligomer into at least three bands—one main and two satellite bands—the so-called triplet structure, which is typically pronounced because of proteolysis of large VWF in von Willebrand disease types 2A and 2B and is also seen in the three patients with ET and high platelet counts. Absence of large VWF at platelet counts of approximately 2,000,000/ μ L is associated with increased VWF degradation bands (176 and 140 kDa), reappearance of large VWF multimers after 1-deamino-8-D-arginine vasopressin (DDAVP), and correction of the VWF multimeric pattern to nearly normal at platelet counts of 348,000/ μ L and 545,000/ μ L. (Modified from Budde U, Scharf RE, Franke P, et al: Elevated platelet count as a cause of abnormal von-Willebrand factor multimer distribution in plasma. *Blood* 82:1749–1757, 1993.)

However, the prevalence of splenomegaly in ET is much less than the 70% incidence observed in PV.¹³⁰

The natural history and life expectancy of individuals with ET have been difficult to ascertain in an accurate manner. Most clinical studies of ET have been retrospective in nature with limited follow-up times, small sample sizes, and a predominance of young women. A large longitudinal study of 187 consecutive patients with ET reported that those diagnosed before 55 years of age had a significantly shorter life expectancy than did healthy age-matched controls.¹²⁴ In this study, arterial thromboses occurred more frequently in ET than did venous thrombotic events (ratio, 3.1:1).¹²⁴ About 60% of venous thromboses were noted to involve splanchnic veins and cerebral venous sinuses.^{60,124} ET is not associated with significant risks for thromboembolism. Life expectancy for patients with ET has recently been redefined through a retrospective analysis of a substantial cohort of 322 individuals followed for a median of longer than 13

years.¹³² In this cohort, with a median age of 54 years (82.9% treated with cytoreductive therapy, 62.4% treated with aspirin), median survival time was 18.9 years, and survival during the first decade of disease was similar to that in a normal, healthy control group. On the other hand, as disease progressed over time, survival statistics worsened for patients with ET. At 20 years after diagnosis of ET, median survival was approximately 50% compared with 70% for controls.¹³² Age at diagnosis of ET (> 60 years), leukocytosis, smoking, and diabetes mellitus were independent predictors of decreased survival and adverse thrombotic complications.¹³² Short-term life expectancy has not been affected substantially by the rare progression of ET into acute leukemia or transformation of ET into MMM. In older studies, overall progression of ET to acute leukemia or development of MMM has been observed in 3% to 5% of cases, with acute leukemia occurring predominantly in older patients and in those who previously received treatment with radiophosphorus or

alkylating agents.^{67,68,129} The Mayo Clinic cohort recorded a relatively low incidence of leukemic or myeloid disease transformation over the first 10 years of the disease (1.4% and 9.1%, respectively) with substantially increased incidences of acute leukemia to 24% and 58.8%, respectively, with myeloid disease transformation during the third decade of ET.¹³²

Similar trends in the natural history and life expectancy of ET were reported in a recent retrospective study of 231 consecutive Chinese patients with ET,¹³³ all of whom received hydroxyurea at diagnosis or during follow-up. Age over 60 years was the sole prognostic factor for overall survival and was a predominant risk factor for nonfatal major thrombosis with a TFS of 60% after 10 years as compared with a TFS of 90% at age younger than 60 years.¹³³ However, thrombosis was not a risk factor for survival, in that only 2 of 231 patients with ET (0.9%) died from thrombosis. Of 20 deaths in this cohort, 5 patients died between 62 and 90 years of age from acute myelogenous leukemia (AML)/MDS/MF, 2 died as a result of major thrombosis, 2 died because of severe bleeding, 3 died from carcinoma, and 8 died from pneumonia or chronic obstructive respiratory disease unrelated to ET.¹³³

Prognostic Indicators for Thrombosis and Hemorrhage in ET

Numerous risk factors that predispose patients with ET to thrombotic and hemorrhagic complications have been identified and used to develop risk stratification paradigms for treatment planning. Age and prior history of cardiovascular disease and/or thromboembolic events have emerged as primary prognostic factors for future or recurrent thrombotic complications in ET. Age older than 60 years is associated with an annual incidence of thrombosis of almost 15%, compared with 6.7% at age 40 to 60 years, and less than 2% in those younger than 40 years of age.¹²² The likelihood of thrombosis during follow-up was tenfold greater in those not on aspirin with a prior history of major thrombosis, irrespective of age (3.4% incidence per patient-year for those without and 31.4% per patient-year for those with a history of major thrombosis).¹²² When aspirin is administered to patients with ET, TFS approaches normal and age is eliminated as a risk factor for such complications.¹³⁹

Other risk factors besides age and history of prior thrombotic events may contribute to thrombotic tendencies. In a series of young women with ET, Tefferi¹⁴⁰ reported recurrent thrombosis in 45% of those with and 13% of those without a history of prior thrombosis. The contributions of obesity, oral estrogen contraceptive use, and smoking must be clarified in this population. The role of hypercholesterolemia in the development of thrombosis in ET is also unclear. Although one study reported a 59.5% incidence of thrombosis among patients with ET with hypercholesterolemia,¹²³ no increased risk has been noted by others.^{122,124} Furthermore, no increased risks for thrombosis in ET were observed with other vascular risk factors, such as diabetes, essential hypertension,^{78,122–124} and sex.^{121,124} Cigarette smoking was linked to an increased incidence of ischemic complications in one study⁶¹ but not in others.^{78,122–124} Leukocytosis ($>15,000/\mu\text{L}$) also has recently been recognized as an independent predictor of major thrombotic events.¹³²

In general, platelet count is *not* a reliable predictor for development of thromboses in individual patients with ET.^{68,120–123,126} Although most thrombotic events are associated with platelet counts higher than 500,000 to 600,000/ μL ,^{120,124} even while patients are on aspirin, it is not uncommon for thrombotic, neurologic, or peripheral vascular symptoms to be diagnosed at lower platelet counts.¹²⁷ Extreme thrombocytosis (1,000,000 to 1,500,000/ μL) appears to increase the risk of spontaneous bleeding events, particularly from the gastrointestinal tract, with concomitant use of aspirin or other antiplatelet aggregation agents.^{68,118,120,135,139}

Analysis of risk factors is important in determining which patients need cytoreductive therapy and when treatment should begin. Stratification of patients into low-, intermediate-, and high-risk categories for thrombohemorrhagic complications is recommended to establish the risk:benefit ratio for treatment because some cytoreductive medications have significant adverse effects and potentially are leukemogenic.^{122,141–143} Patients of any age with a prior history of thrombosis, extreme thrombocytosis, and/or thrombotic or hemorrhagic symptoms should be classified as high risk. Those older than 60 years of age with platelet counts above 450,000/ μL are also classified as high risk by most physicians, but in the absence of previous thrombosis and vascular risk factors, they are better labeled as intermediate risk.¹³⁹ Healthy patients with ET who are older than 60 to 65 years and have no vascular risk factors, no symptoms while on low-dose aspirin, and platelet counts lower than 1,000,000/ μL are not at high risk for major thrombosis and therefore should not be treated with anagrelide or hydroxyurea.^{139,142,143} Individuals of any age with extreme thrombocytosis ($>1,500,000/\mu\text{L}$) but without active thrombohemorrhagic symptoms are considered to be at intermediate risk.^{122,140} It is unclear whether cardiovascular risk factors (e.g., diabetes mellitus, hypertension, hyperlipidemia) contribute to mortality or morbidity in ET, but clearly, these risk factors should be addressed. Patients with ET who are younger than 60 years of age, asymptomatic, and without a previous history of thrombosis and cardiovascular risks but who have an elevated platelet count (in excess of 1,000,000/ μL and less than 1,500,000/ μL) have been designated as at low risk for major thromboembolic or hemorrhagic events.^{122,140} However, it remains unclear whether low-risk individuals with ET should be treated. Most clinicians advocate a “wait and watch” policy. Careful monitoring of bleeding time, PFA-100 closure times, and VWF parameters seems warranted for symptomatic patients with ET with platelet counts between 1,000,000/ μL and 1,500,000/ μL while on low-dose aspirin, because they are at increased risk of bleeding complications.^{142,143} These considerations suggest that more aggressive cytoreductive therapy with newer nonleukemogenic agents, like anagrelide or interferon (IFN)- α , should be considered in patients with ET with platelet counts in excess of 1,000,000/ μL , irrespective of age, to maintain platelet counts lower than 600,000 to 400,000/ μL .

Treatment of Patients with Essential Thrombocythemia

In patients with ET, the occurrence of thrombotic complications is related to increased platelet count and enhanced function but is not exclusively dependent on degree of platelet elevation.¹⁴⁴

Reducing the platelet count to normal ($<400,000/\mu\text{L}$) in *symptomatic* patients with ET through the use of cytoreductive medications is clearly associated with a significant reduction in the frequency of minor and major venous and cerebral arterial thrombotic events. In fact, recurrent thromboses are unusual, even without aspirin use, as long as platelet counts are maintained within the normal range.^{115–117,139,142–146} In patients with ET with a platelet count greater than $600,000/\mu\text{L}$ (uncontrolled thrombocytosis), the incidence of cerebral arterial thrombosis was 180 times higher than the epidemiologic expected rate in a normal population.¹⁴⁷ In this controlled, prospective study of 100 consecutive patients with ET, 63% of arterial cerebral ischemic attacks were associated with platelet counts higher than $1,000,000/\mu\text{L}$. After busulfan therapy had been administered to reduce platelet counts, the subsequent incidence of cerebral ischemic events was reduced to 37% when platelet count ranged from $650,000$ to $990,000/\mu\text{L}$, and no events occurred at counts lower than $650,000/\mu\text{L}$.¹⁴⁷ In another prospective trial, 114 high-risk patients with ET were randomly assigned to receive no myelosuppressive therapy or hydroxyurea to maintain platelet counts lower than $600,000/\mu\text{L}$.¹⁴⁸ After a median follow-up of 27 months, 2 (3.6%) patients in the hydroxyurea arm (one with stroke and one with deep vein thrombosis) versus 14 (24%) in the untreated group (one with cerebrovascular accident [CVA]; 12 with minor microvascular thrombotic events, including TIAs in five and peripheral digital ischemia in five; one with deep vein thrombosis [DVT]; and two with superficial thrombophlebitis) experienced thrombotic complications of ET.¹⁴⁸ Although this striking difference ($P < .003$) suggests at first glance that cytoreduction of platelet counts is the primary means of preventing thrombosis in high-risk patients with ET, another possible explanation for these observations may be the fact that 10 of 14 symptomatic patients in the control group were not receiving treatment with platelet-inhibiting medications (aspirin or ticlopidine) at the time of their thrombotic events.¹⁴⁸ This could also account for the unusually high incidence of microvascular arterial events reported in the control arm as compared with the hydroxyurea arm.^{139,146}

Important hints for the optimal treatment of patients with ET have been provided by the British Medical Research Council's primary thrombocythemia (PT-1) study, in which 809 high-risk patients with ET were randomly assigned to receive hydroxyurea (an antineoplastic agent with nonspecific myelosuppressive properties acquired through inhibition of DNA synthesis) combined with aspirin (75 mg per day) or anagrelide (a specific inhibitor of megakaryocytopoiesis and thrombopoiesis) combined with aspirin.¹⁴⁹ No statistically significant differences in the incidence of specific major arterial thrombotic events (CVA, angina, or myocardial infarction), pulmonary embolism, or death due to thrombosis or hemorrhage were reported between the two arms of the study.¹⁴⁹ However, when composite end points were considered, anagrelide plus aspirin was associated with increased risk for the development of all types of arterial thromboses ($P = .004$), primarily those attributable to a greater than fivefold enhanced incidence of TIAs ($P < .001$), compared with hydroxyurea combined with low-dose aspirin. This is difficult to explain because the extent of reduction in platelet counts was equivalent between the two treatment arms,

and because aspirin has been shown to effectively prevent atypical and typical TIAs in ET.^{115–117} Thus, control of platelet count alone should not be regarded as the exclusive surrogate end point by which the efficacy of a treatment strategy for ET should be judged. A more likely explanation for the apparent superiority of hydroxyurea over anagrelide in the PT-1 study lies in the observation that hydroxyurea, in contrast to the specific effects of anagrelide on platelet counts, conveys broader myelosuppressive activity that also affects platelets, leukocytes, and erythrocytes. Growing evidence suggests that leukocytes may play an important role in the pathogenesis of thrombosis in ET.¹³² Perhaps counterintuitive to this discussion is the fact that a significantly decreased rate of venous thromboembolism (VTE) (pulmonary embolism and DVT) was seen in the anagrelide cohort compared with the hydroxyurea group ($P = .006$). Evidence suggests that the JAK2-V617F gene mutation is associated with predisposition to VTE as opposed to arterial events in patients with ET.⁴⁷

Traditionally, the decision to initiate treatment for ET has been based on clinical symptoms and signs and risk factor analysis, and not merely on diagnosis, platelet number, or function (Table 18-8). It remains unclear whether young (younger than 60 years old), asymptomatic (low-risk) patients should receive treatment. In a prospective study of 65 untreated patients with ET who were younger than 65 years of age, had no history of thrombosis or hemorrhage, and had platelet counts lower than $1,500,000/\mu\text{L}$, the incidence of thrombosis was 1.91 cases per 100 patient-years versus 1.5 cases of thrombosis in a normal, age- and sex-matched control population after a median follow-up of 4.1 years.¹⁴⁰ This was not statistically significant, but 25 of these patients (38%) needed low-dose aspirin to control ET-related microvascular symptoms.¹⁴⁰ Pregnancy and surgery were not associated with an increased incidence of thrombosis in these patients with ET. In contrast, cytoreductive therapy is clearly indicated for those patients with ET who have symptoms or who have risk factors for thrombosis or hemorrhage, including age older than 60 years, prior history of major thrombosis, or extreme thrombocytosis (platelet count $>1,000,000/\mu\text{L}$).^{122,142,143,148} Hydroxyurea administration is the preferred treatment modality for patients with ET who are older than 60 to 65 years of age; anagrelide or IFN- α should be considered for the treatment of patients with ET who are younger than 60 to 65 years of age.¹³¹ Patients should be advised to cease smoking, to avoid taking estrogen-containing medications, and to seek proper management of hypertension and diabetes, each of which is an independent risk factor for hypercoagulability and major thrombosis. Treatment options designed to reduce platelet counts in ET are listed in Table 18-8.

Hydroxyurea Therapy

Hydroxyurea is a nonalkylating S-phase-specific myelosuppressive agent with a mechanism of action that is not platelet specific. It inhibits ribonucleotide diphosphate reductase, the enzyme that catalyzes the conversion of ribonucleotide diphosphates to corresponding deoxyribose forms. Clinical experiments indicate that hydroxyurea treatment reduces hematopoietic progenitor growth and CD34-positive cells in PV and ET.¹⁵¹ It is administered

Table 18-8 Risk Stratification and Management Guidelines for Essential Thrombocythemia

Age, years	Platelet count, $\times 10^3/\mu\text{L}$	Microvascular Symptoms	Prior History of Major Thrombosis or Bleeding	Vascular Risk	Risk of ET	Guideline
18–90	>1500	–	–	–	High	Platelet reduction to below 1000, and add aspirin
18–90	>400	–	Yes	–	High	Platelet reduction plus aspirin
18–90	<1000	Yes	No	No	Low	Low-dose aspirin
<60	<1500	No	No	No	Low	Wait and see, aspirin uncertain
<60	>1000 but <1500	Yes	No	No	Moderate	Platelet reduction to below 1000 plus aspirin
>60–65	<1000	Yes/no	No	No	Moderate	Low-dose aspirin
>60–65	<1000	Yes/no	No	Yes	High	Platelet reduction plus low-dose aspirin
>60–65	>1000	–	–	–	High	Platelet reduction plus low-dose aspirin

For all patients, manage cardiovascular risk factors; advise against smoking.

May consider low-dose aspirin in asymptomatic patients if no other contraindications are present and platelet counts are $<1500 \times 10^3/\mu\text{L}$.

Consider continuation of aspirin after platelet reduction is attained in patients with high-risk ET, if no contraindications are present.

Consider anagrelide as first-line therapy in patients younger than 65 years of age with no cardiac disease.¹⁵⁰

Consider pegylated interferon- α as an alternative first-line nonleukemogenic agent in patients younger than 65 years of age.

Consider hydroxyurea as first-line therapy for patients 60 to 65 years of age or older.

Consider low-dose aspirin and pegylated interferon- α , if indicated, in pregnancy.

orally and appears to have good bioavailability. Hydroxyurea is predominantly used to treat patients with MPDs, in CML to control leukocytosis, in ET to reduce platelet counts, and in PV to reduce red cell mass and elevated platelet counts. The starting dose is 15 to 20 mg/kg/day orally, taken as a single dose. Subsequent dosing traditionally has been titrated to maintain platelet counts lower than 600,000 per microliter without excessive lowering of neutrophil counts. Recent data suggest that patients with ET may benefit further from platelet counts reduced to lower than 400,000/ μL and maintained at that level. Dose modifications should be considered for patients with renal insufficiency. Continuous treatment with hydroxyurea has been shown to reduce platelet counts to lower than 500,000/ μL within the first 8 weeks in 80% of patients.^{152–154} Advantages of hydroxyurea include its convenience, efficacy, and low level of toxicity. Major short-term adverse effects include reversible myelosuppression manifested as neutropenia and macrocytic anemia. Other adverse effects include nausea, vomiting, diarrhea, skin changes and ulceration (including severe painful ankle ulceration), and, rarely, drug fever. Sudden withdrawal is associated with rebound elevations in platelet count.^{155–157}

In the 1970s and 1980s, hydroxyurea was considered the drug of choice for reducing platelet counts in ET because of the significant risk that secondary acute leukemias may be associated with the administration of alkylating agents or radioactive phosphorus (^{32}P). Hydroxyurea is definitely effective in reducing the incidence of thrombotic complications in high-risk patients with ET.^{148,149} A recent update of the data generated by the original prospective, randomized, controlled study continues to show a significantly better TFS in the hydroxyurea-treated ET cohort after a median follow-up of 73 months. Thrombotic complications occurred in 45% of patients in the untreated high-risk group with ET versus 9% of patients in the hydroxyurea treatment cohort.¹⁵⁸ In the PT-1 study, TFS was sig-

nificantly superior in the hydroxyurea/aspirin arm in JAK2-V617F-positive ET compared with the anagrelide/aspirin arm. TFS was equal in both treatment arms in JAK2-V617F-negative ET.⁴⁷ This suggests that hydroxyurea combined with low-dose aspirin should become the first-line treatment option in patients with JAK2-V617F-positive ET. Prospective, randomized studies are needed to confirm this premise.

Considerable concern that administration of hydroxyurea in ET accelerates the transformation of ET into AML has been prompted by the observation that leukemia-free survival appears significantly reduced in patients with ET who were given treatment with hydroxyurea plus busulfan (some patients had received busulphan prior to randomization) versus an untreated ET control group; however, cancer-free survival was equivalent between the hydroxyurea alone group and the untreated control group.⁷⁴

Numerous other studies have challenged the relative leukemogenic safety of hydroxyurea.^{152–154,159–162} All incidence data must be interpreted carefully because a natural, albeit low, progression of untreated ET to AML is apparent. The rate of background transformation to AML has been difficult to quantitate because most data were collected before PCR assays were available to exclude the presence of the *bcr/abl* gene. Furthermore, 17p chromosome deletions in patients with ET¹⁵⁹ have been associated with a higher risk of AML and suggest that some cohorts of patients with ET may be particularly susceptible and heretofore were not stratified in clinical studies. The incidence of transformation to AML is estimated to be approximately 3.5% at a median follow-up of 8.2 years when hydroxyurea is used alone.¹⁵⁹ This risk increases to 14% when hydroxyurea is combined with other agents, in this study, pipobroman. A high proportion of leukemia cases (41%) possessed deletions of the 17p chromosome, which were accompanied by morphologic evidence of dysgranulopoiesis and the presence of p53 mutations.¹⁵⁹ Thus, it appears that hydroxyurea adminis-

tered as single-agent therapy carries an intrinsically small but definite genotoxic and mutagenic risk of inducing secondary malignancy. This risk increases significantly when hydroxyurea is administered in combination with other chemotherapy agents. Nevertheless, it is reasonable to continue to consider hydroxyurea the drug of choice for elderly patients (over 60 to 65 years of age) who have not received prior chemotherapy because its cost:benefit ratio, tolerability, and safety profile are superior to those of anagrelide, IFN- α , and the alkylating agents (Table 18-9).^{148,149,163} In younger patients at high risk of thrombosis or hemorrhage, or in those given prior chemotherapy, anagrelide or IFN- α should be considered as the initial treatment choice.¹³¹ Administration of hydroxyurea may be a particularly effective and rapid means of shrinking spleen size over 2 to 3 months in those patients with ET who have massive splenomegaly.

Anagrelide Therapy

Anagrelide is an imidazo (2-1-b) quinazolin-2-1 compound that was originally developed as an antithrombotic agent because of its powerful antiaggregating effect on platelets. It inhibits cyclic nucleotide phosphodiesterase and the release of arachidonic acid from phospholipase, possibly by inhibiting phospholipase A2. When anagrelide was first administered to humans, it had a potent thrombocytopenic effect, which had not been observed previously in any animal model system. Because anagrelide produces thrombocytopenia at doses significantly lower than those required to inhibit platelet aggregation, the potential risk that clinically important hemorrhagic complications may be precipitated is miniscule. Anagrelide has little or no immediate effect on myelopoiesis or erythropoiesis, but its long-term use has been associated with a 5% to 10% reduction in hemoglobin concentration in approximately one third of patients with ET.^{164,165} This latter effect of anagrelide is probably mediated by an effect on EPO levels because it can be readily reversed in vivo by the administration of therapeutic doses of recombinant EPO.

The specific mechanism by which anagrelide induces thrombocytopenia remains unclear. The seminal clinical study, published by Silverstein and coworkers,¹⁶⁴ showed that anagrelide does not alter the cellularity of bone marrow, the number of megakaryocytes in the bone marrow, or the survival of circulating platelets.¹⁶⁴ Anagrelide does

not inhibit the proliferation of megakaryocytic-committed progenitor cells (colony forming units-megakaryocyte [CFU-M]) in vivo, although suprapharmacologic concentrations may inhibit megakaryocyte colony expansion in cell culture systems. Therefore, anagrelide-induced thrombocytopenia does not arise as the result of direct stem cell toxicity or from direct inhibition of megakaryocytopoiesis.¹⁶⁶ Anagrelide alters the maturation of megakaryocytes and thereby decreases their size and affects their morphology.¹⁶⁷ A left shift is observed in the distribution of morphologic stages and decreased ploidy. The intracellular processes influenced by anagrelide have not been elucidated. In addition, it is not known whether anagrelide or a metabolite of the drug possesses the primary platelet-lowering property (see Table 18-9). Anagrelide in large concentrations can inhibit platelet aggregation in vitro; however, this mechanism is independent of its effects on thrombopoiesis and is rarely a significant issue from the clinical perspective.

The elimination half-life of anagrelide from the circulation is 76 hours. Seventy-five percent of the administered dose is excreted in the urine over 6 days, and 10% is excreted in feces. The recommended initial dose of anagrelide is 0.5 mg two or four times daily. This dose should be increased by a maximum of 0.5 mg/d/wk until the desired reduction in platelet count is achieved. The ideal maximum dose of anagrelide should not exceed 10 mg per day or 3 mg per dose.¹⁶⁸ Dose adjustments may be necessary if renal failure occurs.

Anagrelide is licensed for use in the United States and Europe for the treatment of patients with thrombocythemia associated with all MPDs. The broadest experience with anagrelide has been generated by the multicenter phase 2 clinical trial conducted by the Anagrelide Study Group.¹⁶⁵ Of 577 patients with primary thrombocythemia (median platelet count, 990,000/ μ L), a 94% response rate (defined as reduction in platelet count by 50%, or maintenance at levels lower than 600,000/ μ L for at least 4 weeks) was reported in individuals with ET who were treated with anagrelide. Patients initially received 1 mg anagrelide orally every 6 hours, which was later reduced to 0.5 mg four times a day, with increases of 0.5 mg per day every 5 to 7 days, depending on platelet count response. The median time to maximal response was 11 days and the dose needed to achieve a response ranged from 0.5 to 9.0 mg/day. However, 95% of patients responded to a dose of 4 mg per day or less.¹⁶⁵

Table 18-9 Comparisons of HU, IFN- α and Anagrelide¹³¹

	HU	IFN- α	Anagrelide
Route of administration	PO	SC	PO
Selectivity of platelet reduction	No	No	Yes
Leukemogenicity	Yes	No	No
Hematologic side effects	++	++	+
Tolerability	Very good	Fair/poor	Good/fair
Possibility to induce remission	No	Yes	No
Use in pregnancy	No	Yes	No
Regression of splenomegaly	Yes	Yes	No
Price	Low (1500 mg/d)	Moderate (3 MIU/d)	High (2.0 mg/d)

HU = hydroxyurea; IFN- α = interferon alpha. (Modified from Schwarz J, Pytlík R, Doubek M, et al: Analysis of risk factors: The rationale of the guidelines of the Czech Hematological Society for the diagnosis and treatment of Philadelphia-chromosome negative myeloproliferative disorders with thrombocythemia. *Sem Thromb Hemostas*; 32:231-245, 2006.)

The rapid and effective control of thrombocythemia by anagrelide would be expected to substantially reduce the incidence and severity of thrombotic and hemorrhagic complications in ET. In fact, the number of adverse events appears to be reduced proportionately to the decrease in platelet counts, but as indicated in the original nonrandomized studies that examined anagrelide use, the relationship was not linear. This suggests that other variables, such as total leukocyte counts, leukocyte properties, or intrinsic biochemical or physiologic characteristics of affected individuals with ET, may influence its clinical course (e.g., inherited hypercoagulability). Similar findings have been observed when hydroxyurea was used to control thrombocythemia. It is possible that markedly decreasing the elevated platelet counts in ET, no matter by what means or medications, is more critical than how they are reduced. One possible advantage that anagrelide has over hydroxyurea is that the “picket fence” or “peak-valley” pattern of platelet count reduction and rebound can be avoided. Fluctuating doses of hydroxyurea, necessitated by its effects on white blood cells, lead to a peak-valley effect on platelet counts compared with the stable plateau of platelet count reduction produced by anagrelide. Consistent control of platelet counts may reduce the risk of thrombosis; only randomized, controlled, appropriately prolonged studies with both of these medications will reveal whether this is a real or theoretical advantage for anagrelide therapy in ET.

Major adverse effects noted with anagrelide administration are neurologic, gastrointestinal, and cardiac in nature (Table 18-10). These may be severe enough to cause patients to discontinue the medication. Petit and coworkers¹⁶⁹ reported a 13% dropout rate in studies of anagrelide. Most neurologic and gastrointestinal adverse effects develop during the first 2 weeks of therapy and resolve on average within 2 weeks. Postural hypotension may be produced at higher dosing levels. In most cases, diuretics can control the fluid retention and peripheral edema induced by anagrelide use over time. Substantial normocytic and normochromic anemia is seen in about 25% of patients. Birgegard¹⁷⁰ recently reviewed the use of anagrelide in thrombocythemic (ET and PV) patients (Table 18-11). Platelet-lowering efficacy in seven studies was 70% to 80% in thrombocythemia, and response was rapid, with most patients reaching treatment goals within a few weeks.^{169,171–176} Some studies do not give separate response

results for ET and PV, and response criteria vary between studies. Adverse effects, which are common and are caused primarily by the vascular effects, include palpitations, headache, loose stools/diarrhea, and edema. Some adverse effects are time limited, but late dropout from therapy is not uncommon; the total dropout rate in prospective studies is 30% to 50%. Cardiac insufficiency may be worsened in patients with previous heart failure, and special caution is warranted in such patients.

In Europe, anagrelide was registered as a second-line therapy for thrombocythemia due to any MPD after a randomized, controlled, prospective study undertaken to compare the safety and efficacy of anagrelide with hydroxyurea revealed considerably more selective platelet-lowering effects compared with hydroxyurea.¹⁴⁹ In ET, anagrelide is often used as first-line therapy, especially in younger patients, because of concern about increased risk of leukemia with cytotoxic, potentially leukemogenic agents, such as hydroxyurea.¹³¹ Given that dose escalation of anagrelide or hydroxyurea may be problematic in some patients because of adverse effects associated with either agent, combination of the two medications in lower doses is a

Table 18-10 Major Adverse Effects and Their Relative Frequencies Associated with Anagrelide Use

Cardiovascular
Fluid retention or edema (24%)
Congestive heart failure (2.5%)
Palpitations and tachycardia (36%)
Irregular pulse (2.5%)
New or worsening angina (0.9%)
Neurologic
Headache (30%)

*CR criterion: Platelets <450,000/μL. If <600,000/μL is used to define CR, the response rate is 77%.

ET, essential thrombocythemia; PV, polycythemia vera; CR, complete remission.

(From Birgegard G: Anagrelide treatment in myeloproliferative disorders. *Sem Thromb Hemostas* 32:260–266, 2006.)

practical option that is already used by many clinicians yet without basis in any published study.

Cardiac adverse effects are observed in more than one third of patients during anagrelide use, and it may be contraindicated in those with uncontrolled arrhythmia.^{165,169,170} Many individuals report frequent anxiety-provoking palpitations that are dose related and temporally related to caffeine ingestion. Restriction of caffeine intake and/or dose reduction often relieves or eliminates symptomatic palpitations; occasionally, β -blocker medication may be necessary. Vasodilatory effects on the peripheral vasculature and potent inotropic properties of anagrelide may induce cardiac symptoms. Rarely, a cardiomyopathy may occur. This may be particularly problematic in elderly individuals but may respond to, or be reversed by, the use of diuretics.^{165,169,170} Severe headaches are reported in approximately one third of patients and are often described as “vascular” or “migraine-like.” These are probably the result of the peripheral vasodilatory effects of anagrelide and may lead to intolerance of the medication in a substantial number of patients. Those with a history of migraine may be particularly susceptible to this effect. Reduction of caffeine intake may be helpful. Finally, anagrelide is contraindicated in pregnancy because it crosses the placental barrier and may lead to fetal thrombocytopenia.^{169,170}

Observations from this randomized clinical trial in which hydroxyurea was compared with anagrelide (patients in both arms also received low-dose aspirin [75 mg]) confirmed the expected high incidence of anagrelide-induced adverse effects (37%).¹⁴⁹ This implies that about 60% of high-risk patients with ET do very well without adverse effects and with no leukemic risk during long-term use of anagrelide. In contrast, 18% of the hydroxyurea cohort also withdrew because of adverse effects and for other reasons over short-term follow-up (2.5 years); this is a higher proportion than clinicians would have expected. Of concern was the higher incidence of transformation to myelofibrosis ($P = .01$) in the anagrelide plus aspirin group, which suggested some fibrogenic predisposition of this regimen.¹⁴⁹ However, on follow-up examination of bone marrow (BM) specimens from another group of patients administered anagrelide, the platelet-lowering medication failed to show stimulation of myelofibrosis in ET.¹⁷⁷ Long-term follow-up study of hydroxyurea compared with anagrelide in patients with ET to assess survival, major thrombosis, serious skin toxicity, transformation to acute leukemia and myelodysplasia, and potential fibrogenic potential is warranted.

Recombinant Interferon- α

Recombinant IFN- α was first studied as alternative therapy for the treatment of patients with PV; it was noted to reduce thrombocytosis and erythrocytosis in approximately two thirds of patients.¹⁷⁸ Occasionally, massive splenomegaly disappeared and intense pruritus was ameliorated. Recombinant IFN- α administration significantly reduced the platelet count in approximately 85% of patients with ET and had beneficial effects on spleen size in about one third of recipients.¹⁷⁸ Numerous clinical trials have assessed the efficacy of IFN- α in reducing platelet count in MPDs.^{179–188} IFN- α was found to suppress the proliferation of pluripotent and lineage-committed hematopoietic progenitors and to

inhibit the growth of megakaryocyte progenitors in vivo and in vitro.^{189–192} IFN- α also reduces thrombopoiesis and causes modest shortening of platelet mean life span.¹⁹³ IFN- α does not cross the placenta¹⁹⁴ and is not known to be teratogenic; it has been used safely in pregnant women with CML and is the drug of choice for the treatment of pregnant patients with ET. IFN- α administration circumvents theoretical concerns about the potential risks of teratogenicity with hydroxyurea and anagrelide. IFN- α is nonleukemogenic and nongonadotoxic, yet it controls thrombocytopenia very efficiently.

Recombinant IFN- α is administered usually at doses of 3 million U given subcutaneously three times weekly. The response rate with regard to thrombocytopenia approaches 90%, and after initial cytorreduction is achieved, the interferon dose usually can be reduced. Discontinuation results in rapid relapse of thrombocytopenia, which usually responds to the resumption of interferon therapy.^{178–180,184,185} Sustained remissions have been documented in some patients after IFN- α therapy, suggesting that IFN- α has an antiproliferative effect on the neoplastic clone.^{179,181,182,195} One clinical study demonstrated decelerated proliferation of the neoplastic clone in five of seven patients who were given IFN- α for ET.¹⁹⁵ IFN- α also antagonizes the action of platelet-derived growth factor (PDGF), a product of megakaryopoiesis, which initiates fibroblast proliferation. IFN- α may reduce inherent risks of progressive myelofibrosis and leukemogenesis in ET and other MPDs through its antiproliferative and immunomodulatory effects. No randomized studies have yet compared the safety, efficacy, leukemia-free survival, and thrombohemorrhagic event-free survival of recombinant IFN- α with hydroxyurea or anagrelide in ET.

Major disadvantages of recombinant IFN- α in ET include its associated adverse effects and its high cost.¹⁹⁶ Almost all patients experience an influenza-like syndrome during induction with fever, chills, myalgias, headache, and arthralgias. These symptoms are frequently controlled with acetaminophen. Long-term treatment may result in fatigue, anorexia, weight loss, alopecia, and autoimmune disease, including autoimmune thyroiditis, autoimmune hemolytic anemia, autoimmune thrombocytopenia, and symmetrical polyarthropathy. Patients may also develop clinically significant neuropsychiatric symptoms, including altered mentation, confusion, and deep depression.^{178,184,196} The treating physician must be aware of suicidal ideation in those with prior personal and/or family history of depression. Neutralizing antibodies to recombinant IFN- α therapy may develop, leading to a rise in platelet count. Therapy with leukocyte IFN- α has been tried in such situations with excellent response.¹⁹⁷ In a review of 273 cases, IFN- α therapy was terminated in 25% of patients. The most common reasons for withdrawal were interferon-related adverse effects in 55% and patient refusal in 10%.¹⁹⁶ Many adverse effects dissipate over time with continued administration of the drug. Recombinant IFN- α is a very attractive therapeutic option for ET because it can (1) suppress the neoplastic clone, (2) efficiently lower platelet counts, (3) reduce and reverse massive splenomegaly and progression of myelofibrosis, and (4) circumvent potential teratogenicity of anagrelide, hydroxyurea, and alkylating agents, as well as leukemogenicity of hydroxyurea and alkylating agents. Nevertheless, IFN- α remains underutilized in this

disease, perhaps because of its price and its spectrum of adverse effects. It has been reserved primarily for use in patients with ET who are pregnant or who have massive splenomegaly.

Pegylated (PEG)-IFN- α is a chemically modified IFN- α that is produced by covalently attaching polymers of ethylene glycol (PEG) of varying average molecular weights, endowing PEG-IFN- α with a superior pharmacokinetic and pharmacodynamic profile, thus yielding a drug that can be given weekly. For this reason, PEG-IFN- α has proved to be a potential therapeutic agent in clinical trials of patients with *bcr/abl*-negative thrombocythemia, including ET and PV. PEG-IFN- α is probably more effective and better tolerated than other treatments and can be considered as a nonleukemogenic alternative cytoreductive therapy in younger patients with ET. Two large phase 3 trials in which the activity and toxicity profiles of two slightly different recombinant PEG-IFN- α molecules were compared with those of two standard recombinant IFN- α molecules in patients with chronic phase CML showed a clear superiority of PEG-IFN- α over standard IFN- α in terms of both efficacy and tolerability.^{198,199} In a phase 2 study of 36 high-risk patients with ET, sustained treatment with PEG-IFN- α -2b was effective and safe in reducing platelet counts and had a toxicity comparable with that of conventional interferon.²⁰⁰ The complete remission rate at 1 year was 67%, and 23 of 36 patients with ET (64%) remained on long-term PEG-IFN- α -2b.²⁰¹ In a phase 2 study conducted by the Nordic MPD Study Group, PEG-IFN- α -2b given at an initial dose of 0.5 μ g per kilogram once weekly was administered to patients with PV ($n = 22$) and ET ($n = 20$).²⁰¹ Fifteen patients had previously received cytoreductive therapy. Four (10%) patients discontinued therapy initially because of toxicity, and 9 more were taken off study at 6 months because of adverse effects or insufficient response. At 12 months, 20 (48%) patients remained in complete remission, but 22 (52%) had discontinued therapy, primarily because of side effects—a higher rate than in previous trials.²⁰¹ The Italian GIMEMA Cooperative Group similarly reported on a large multicenter phase 2 study designed to evaluate the safety and tolerability of 2 years of treatment with PEG-IFN- α -2b.^{202,203} Ninety patients with high-risk ET (30 men, 60 women) were included, of whom 60% had been previously treated with cytoreductive agents. During the first year of therapy, PEG-IFN- α -2b was given at 25 μ g weekly with escalation up to 100 μ g weekly until a platelet count of $<500,000/\mu$ L was reached. After 12 months of therapy, 79% of patients were still receiving PEG-IFN- α -2b (at a mean value of 50 ± 22 μ g weekly), and 64 (71%) had achieved the target platelet count. At 24 months, reduced platelet count had been sustained in 75%, and the prevalence of splenomegaly had decreased from 22% to 6%.²⁰² According to the bone marrow criteria proposed by WHO (see Table 18-6), two thirds of ET cases at baseline were categorized as having true ET (23%), CIMF-0 (pre-MF, 17%), CIMF-1 (early MF, 40%), CIMF-2/3 (classic MF, 3%), and MPD-Unclassified (17%).²⁰³ No patient with true ET showed bone marrow evolution while on PEG-IFN- α -2b treatment, whereas those with CIMF-1/2/3 experienced an increase in marrow fibrosis. More important, the rate of complete hematologic remission at the end of the first year was higher with true ET (93%) than

in CIMF-0 (60%) and CIMF-1/2 (71%) patients.²⁰³ Overall, these data suggest that evolution (natural history) to myelofibrosis is very rare among patients with true ET, and that these patients achieve significantly higher response rates with PEG-IFN- α -2b therapy than are attained by those with thrombocythemia associated with prefibrotic CIMF-0 or early fibrotic CIMF-1 (false ET).

Alkylating Agents and Radiophosphorus

The use of alkylating chemotherapeutic agents, such as busulfan, melphalan, and chlorambucil, was considered for the treatment of patients with ET after these agents had been successful in reducing and controlling the thrombocythemia associated with PV in PVSG protocols. Similar good to excellent platelet responses also have been observed in ET; however, 11.3% and 3.5% incidences of secondary acute leukemia associated with administration of chlorambucil and busulfan, respectively, have led to abandonment of their widespread use in both ET and PV. The risk that acute leukemias may develop in patients given chlorambucil was 2.3 times that in patients given radioactive phosphorus and 13 times that in patients who were treated by phlebotomy alone.²⁰⁴

Radiophosphorus (^{32}P) was equally successful in controlling thrombocythemic states; however, this agent also has been generally avoided, except in exceptional clinical situations, because of its inherent oncogenesis. The incidence of acute leukemia was 9.6% at 10 years post administration in the PVSG protocol, and the expected number of gastrointestinal tract and skin cancers had doubled, beginning 2 to 3 years after ^{32}P administration.²⁰⁵

At this time, the availability of relatively safer cytoreductive drugs, such as hydroxyurea, anagrelide, and IFN- α , has resulted in the use of busulfan and ^{32}P only in high-risk patients with ET who cannot tolerate other medications, and whose life expectancy is considered to be less than 10 years. Busulfan 2 to 4 mg may be given orally daily with careful monitoring of platelet and whole blood counts. After initial control of platelet count is achieved, only intermittent courses of the drug are required. This limits the adverse effects experienced with use of the drug; these include bone marrow aplasia, skin pigmentation, amenorrhea, and pulmonary fibrosis.^{152,206}

^{32}P is a pure β emitter isotope with a half-life of 14.3 days and a maximum tissue range of 8 mm. Both oral and intravenous forms have been used to control thrombocythemia associated with ET or PV.^{207–209} In one study, normalization of full blood count was achieved in 50% of patients after a single administration of ^{32}P and in 73% after two treatments. Because oral ^{32}P may be more leukemogenic than the intravenous form, ^{32}P is usually administered intravenously at 2.3 mCi per meter squared (capped at 5 mCi per meter squared). Repeat dosing (possibly escalated by 25% with a cap of 7 mCi per meter squared) should be delayed for at least 3 months and should be administered only if adequate platelet control has not been achieved.

Pipobroman is a piperazine derivative that is structurally similar to alkylating agents but appears to act as a metabolic competitor of pyrimidine bases.^{108,112} Most experience with this medication has been derived from its wide use in France and Italy for the treatment of

patients with ET and PV.^{210–214} It is not licensed for use in the United States. A randomized prospective study of hydroxyurea and pipobroman in 292 patients with PV revealed equal efficacy for both in disease control and an equal risk of leukemogenesis of approximately 10% at 13 years.²²¹ Gastrointestinal toxicity, the predominant adverse effect, was sufficiently severe to cause discontinuation of pipobroman in 5.6%. In contrast, hydroxyurea toxicity was essentially limited to mucocutaneous adverse effects that included acne, oral aphthous ulcers (20%), and especially leg ulcers (9%). These mucocutaneous adverse effects generally appear late, 5 years or longer after initial treatment. Leg ulcers healed only when hydroxyurea was stopped and was replaced by pipobroman.²²¹

The incidence of AML/MDS has ranged between 0% and 16% in clinical studies that compared pipobroman with hydroxyurea in PV.^{159,215,216,222} In patients with PV who were younger than 65 years, rates of AML/MDS were 12% and 19% in the hydroxyurea and pipobroman groups, respectively, with median time to transformation of 10.5 years.^{215,216} In both groups, 40% of observed cases of AML/MDS occurred after the twelfth year of follow-up. Half of patients who developed AML/MDS in the hydroxyurea group had received more than one cytoreductive drug, whereas in the pipobroman group, 85% of patients with AML/MDS had been given only pipobroman.²¹⁶

Pipobroman has not been used widely in ET. In two uncontrolled studies involving 21 and 24 patients, hematologic remission and platelet control were attained in 86% and 92% of cases, respectively, with no observed secondary leukemia; however, the follow-up duration was relatively short in these studies.^{223,224}

A registry of consecutive patients in whom high-risk ET was newly diagnosed and patients were treated with hydroxyurea as first-line therapy and were prospectively followed has revealed a 9.3% incidence of AML after a median duration of 8 years of hydroxyurea administration.²¹⁶ Transformation to AML was the major cause of death (22%). Cytogenetics at diagnosis was the only parameter associated with evolution to AML: 28% of patients who developed AML had an abnormal karyotype, compared with 8% in the overall population.

Aspirin

The rationale for administration of aspirin in low doses (81 mg per day) in patients with ET is based on its irreversible inhibition of platelet cyclo-oxygenase (COX) activity and its excellent therapeutic and prophylactic profile in the control of platelet-mediated microcirculatory thrombotic disturbances.^{56,60,61,72,106–111,115–117,139,143} Similar benefits, although of briefer duration, may be observed with the use of nonsteroidal anti-inflammatory drugs (NSAIDs), which may be used as an alternative in cases of aspirin allergy. Aspirin is particularly useful in the treatment of patients with erythromelalgia and acral cyanosis^{56,60,61,106–110} (see Figs. 18-2 and 18-3) and in the prevention of thrombotic complications (i.e., TIAs, amaurosis fugax, and unstable angina).^{115–117,139} These benefits are observed even when platelet counts remain elevated. Low-dose aspirin (75 to 100 mg per day) is very effective in preventing or reversing potential platelet microthromboembolic complications associated with the

in vitro phenomenon of spontaneous platelet aggregation in patients with thrombocythemia (ET or PV).²¹⁷ High doses of aspirin (more than 325 mg/day) or aspirin used in combination with other medications with antiplatelet aggregation properties (such as dipyridamole or NSAIDs) should be avoided in ET because of the significantly increased incidence of gastrointestinal bleeding that has been reported. Fortunately, the incidence of serious bleeding, generally, and specifically associated with the use of aspirin, is much lower in ET than in PV. Care should be taken when aspirin is administered in the presence of qualitative platelet defects (as determined by platelet aggregation studies). Aspirin exacerbates bleeding episodes in patients with ET at platelet counts in excess of $1,000,000 \pm 100,000/\mu\text{L}$ because of acquired VWD, which results from loss of the highest-molecular-weight multimers of circulating VWF protein.^{72,134–138,143} Other medications with anticoagulant or antiplatelet activities, such as warfarin, sulfapyrazone, dipyridamole, and ticlopidine, do not convey the same salutary effects in ET as are conferred by aspirin.^{111,130,142,218}

Plateletpheresis in Essential Thrombocythemia

Rapid reduction in extremely elevated platelet counts (usually $>1,000,000/\mu\text{L}$) in ET is necessitated when emergent symptomatic or life-threatening thromboembolic and hemorrhagic complications occur. Cytoreductive agents may be initiated concurrently for long-term control; however, in certain clinical situations, such as pregnancy, the use of anagrelide and myelosuppressive medications may be contraindicated. Therefore, plateletpheresis, accomplished via the physical removal of platelets with an automated apheresis apparatus, can provide immediate and efficient benefits (see Chapter 30). Plateletpheresis is only a temporary measure, however, and other cytoreductive strategies will be needed.^{219–221} RT is not symptomatic and does not require plateletpheresis.

PREGNANCY AND ESSENTIAL THROMBOCYTHEMIA

Pregnancy may be complicated by spontaneous abortion, premature delivery, or abruptio placentae caused by placental infarcts. Pregnancy is a special clinical circumstance in ET because approximately 50% of such pregnancies are complicated by spontaneous miscarriage, intrauterine fetal death, abruptio placentae, intrauterine growth retardation, premature delivery, and preeclampsia. This rate is considerably higher than that observed in the general population and may be due to placental vessel thrombosis and subsequent infarction. Spontaneous miscarriage occurs most commonly during the first trimester and is unrelated to the degree of thrombocytosis or the type of treatment (including no treatment) given to the patient with ET.^{222,223} According to the observations of Beressi and coworkers,²²⁴ pregnancies that persist until term are not usually complicated by thrombohemorrhagic events or catastrophes at delivery. Smoking should be avoided particularly during pregnancy because it may precipitate potential hypercoagulability or platelet hyperaggregability. Hemor-

rhagic complications are uncommon in pregnancy. In some cases, decreased platelet count and even spontaneous remission of thrombocytosis have been noted to occur during pregnancy, perhaps as the result of hemodilution effects. Pregnancy is usually successful in such individuals.²²⁵

In a recent review of the literature, it was discerned that about 300 cases of pregnancy have been reported in patients with ET, and fewer than 50 pregnancies have been reported in patients with PV.²²⁶ Live birth rates are approximately 60% in ET and 58% in PV. Spontaneous abortion during the first trimester is the most frequent fetal complication, occurring in 31% of ET pregnancies and in 22% of PV pregnancies, respectively.²²⁶ Major maternal complications are more frequent in PV than in ET (44.4% vs 7.7%).²²⁶ Treatment of patients with ET with low-dose aspirin during pregnancy seems to reduce complications; this approach also seems beneficial during pregnancy in patients with PV. In high-risk pregnancies, the additional use of low molecular weight heparin and/or IFN- α should be considered.²²⁶

Management options during pregnancy should be tailored according to the perceived risk of thrombohemorrhagic complications. Low-risk (platelet count lower than 1,000,000/ μ L, asymptomatic, and no prior history of thrombosis) and intermediate-risk (platelet count higher than 1,000,000/ μ L, asymptomatic, and no history of thrombosis) pregnant women with ET or PV can usually be treated through careful observation alone with administration of low-dose aspirin. A successful pregnancy retention and delivery rate of 75% has been reported in association with aspirin administration compared with 43% in untreated women.¹²¹ Moderate-dose aspirin (325 mg or less per day) is preferred to minimize bleeding risks and to minimize blood loss during delivery. Some have advocated that aspirin be stopped at least 1 week prior to delivery and then resumed postpartum.^{226,227}

For women with ET (i.e., not RT) with high-risk pregnancy or those anticipated to be at high risk when pregnant (any high platelet count associated with prior miscarriage, neurovascular symptoms, prior thrombosis, hypertension, smoking, obesity, etc.), low-dose aspirin use should be combined with aggressive reduction of platelet counts. Cyto-reduction can be achieved effectively with IFN- α , which does not cross the placenta and is unlikely to be teratogenic. No birth defects have been associated with the use of IFN- α during pregnancies complicated by ET or CML.^{222,227-230} Nevertheless, package inserts list pregnancy as a contraindication for use. The adverse effects of IFN- α may be difficult to tolerate during pregnancy, and the cost is considerable.

Hydroxyurea has been used successfully and safely in pregnant patients with ET, CML, and sickle cell disease, despite its theoretical teratogenicity. Its initiation is often delayed until the second trimester. Currently, anagrelide is avoided during pregnancy because of its potential to cause fetal hemorrhage and teratogenicity.^{169,170,226} Additional experience is needed before the safety of anagrelide use during pregnancy can be established. This may occur with monitoring of administration of anagrelide in pregnant women who are intolerant of IFN- α or hydroxyurea. Alkylating chemotherapeutic drugs like busulfan should not be prescribed because of their increased risks of teratogenicity, although they have been used safely during pregnancies

that occurred in association with Hodgkin disease and non-Hodgkin lymphomas. With the availability of these other options, there is no reason for clinicians to administer ³²P for platelet reduction in pregnant patients with ET. Plateletpheresis decreases platelet counts rapidly and safely, but its benefits are only temporizing until a more permanent solution to thrombocythemia can be implemented.

SUMMARY: TREATMENT STRATEGIES FOR PATIENTS WITH ESSENTIAL THROMBOCYTHEMIA

Treatment of patients with ET should be individualized, based on stratification of risk, and modified according to extenuating clinical circumstances (e.g., pregnancy). The treatment of high-risk individuals is very straightforward. Treatment decisions regarding low- and intermediate-risk patients with ET are considerably more difficult because of a dearth of properly performed, adequately sized, randomized, controlled, prospective studies. In the United States, treatment of these individuals generally has been more aggressive than the available literature would support; however, this has occurred in response to numerous medical-legal claims that arise when one of these individuals develops a life-threatening or fatal thrombohemorrhagic event. Complications are very infrequent in low- and intermediate-risk patients, and the risk:benefit ratio of cytoreductive therapies remains to be established.

Chapter 19

The Antiphospholipid Syndrome: Clinical Presentation, Diagnosis, and Patient Management

Jacob H. Rand, MD • Miles B. Levin, MD • Barbara M. Alving, MD

INTRODUCTION AND HISTORICAL COMMENTS

Although the antiphospholipid *syndrome* (APLS) was first described as a distinct entity about 20 years ago, antibodies to phospholipid-binding proteins—(antiphospholipid–protein *antibodies* [APLA])—were observed more than 30 years earlier. They were initially recognized as “circulating anticoagulants” because of their interference in phospholipid-dependent coagulation reactions and by their causing a biologic false-positive syphilis test due to antibody-mediated recognition of cardiolipins.^{1,2} These *in vitro* anticoagulants became known as lupus anticoagulants (LAs)—a misnomer that persists to the present—because they were often detected in patients with underlying systemic lupus erythematosus (SLE). Forty years ago, Bowie and colleagues³ recognized their association with thrombotic events in patients with SLE. Recognition of APLS⁴ followed the development of quantitative immunoassays for APLA and the awareness that elevated levels of these antibodies were, in some patients, associated with thrombosis, fetal loss, and thrombocytopenia. During the past 20 years, sensitive quantitative tests for antibody detection have become available,⁵ and over the past 15 years, plasma proteins that serve as antigens for these antibodies have been identified.^{6–8}

The progressive elucidation of APLS has resulted in several different terms for the tests, target antigens, and related proteins; these are summarized in the glossary (Table 19-1). Individuals may have immunoglobulin (Ig)G, IgM, or IgA APLA. Approximately 90% of patients who test positive for LA also test positive for anticardiolipin antibodies (ACAs), which are actually antibodies against phospholipid-binding proteins.⁹ However, no direct correlation has been made between the potency of LA activity and the titers of ACA as determined through enzyme-linked immunosorbent assays (ELISA); this may reflect the heterogeneity of the APLA.^{4,9,10} Despite difficulties inherent in comparisons of studies in which only a single test for LA or only an ELISA has been used, associations between well-defined clinical conditions and the presence of APLA have emerged. This chapter describes the immunology, clinical presentations, and approaches to the diagnosis and management of treatment as they relate to patients who will generally be referred for consultation.

IMMUNOLOGY AND PATHOPHYSIOLOGY OF ANTIPHOSPHOLIPID ANTIBODIES

In the context of APLS, the term “antiphospholipid antibodies” is a misnomer that refers to a heterogeneous family of autoimmune immunoglobulins that are directed not against phospholipids, but against plasma proteins (also referred to as “cofactors”) that bind to anionic phospholipids. Although β_2 -glycoprotein I (β_2 GPI) is believed to be the major target of the antibodies, several other phospholipid-binding cofactors have been identified; among these are prothrombin, protein C, protein S, and annexin A5. APLA detected in ELISA are directed against these proteins, which are bound to anionic phospholipids that coat the plastic microtiter plates.^{7,11–14} The anionic phospholipid that is involved in this reaction *in vivo* is believed to be phosphatidylserine; however, the most widely used assays contain cardiolipin as the anionic phospholipid, with β_2 GPI and prothrombin as cofactors.^{13,15}

β_2 -Glycoprotein I (β_2 GPI)

β_2 GPI, or apoprotein H, is a 50-kDa proline-rich glycoprotein that is present in plasma at a concentration of approximately 150 to 200 μ g/mL. The protein is composed of five repeating stretches of ≈ 60 amino acid domains that bear homology to other members of the complement control protein superfamily (Fig. 19-1).^{14,16,17} The fifth short chain consensus repeat (SCR) domain deviates structurally from domains I through IV in that its carboxyterminus bears hydrophobic and cationic amino acids. The affinity of this protein for anionic phospholipid membrane arises through the attraction of the cationic domain for the polar heads of the phospholipids and the insertion of the flexible hydrophobic loop into the hydrophobic portion of the bilayer.^{16,18}

Recent evidence has defined an epitope that is recognized by thrombogenic APLA to domain I of β_2 GPI and has localized it to Gly40–Arg43.^{19,20} In a study of 198 patients with SLE, APLS, and “lupus-like” disease, investigators found that plasmas with detectable anti- β_2 GPI antibodies that had Gly40–Arg43 specificity correlated highly with LA activity and with a history of thrombosis (odds ratio, 18.9 vs 1.1). In contrast, plasmas with anti- β_2 GPI

Table 19-1 Glossary of Terms Used in Discussion of Antiphospholipid Antibodies

Antiphospholipid syndrome (APLS): Characterized by venous and/or arterial thrombosis, thrombocytopenia, or recurrent fetal loss in association with demonstrable antiphospholipid-protein antibodies.

Antiphospholipid-protein antibodies (APLA) or antiphospholipid antibodies: Immunoglobulin (Ig)G, IgM, or IgA antibodies directed against proteins such as prothrombin or β_2 -glycoprotein I (β_2 GPI) that bind to phospholipids. APLA may be described as lupus anticoagulant (LA) activity or by the particular immunoassay procedure used for their detection.

Lupus anticoagulant (LA): Antibody against a phospholipid-binding protein such as prothrombin or β_2 GPI that induces prolongation of an in vitro phospholipid-dependent clotting assay. These may be detected by several different methods, including but not limited to dilute Russell's viper venom time, partial thromboplastin time (PTT), tissue thromboplastin inhibition time, kaolin clotting time, and textarin/ecarin time. Results of these various LA tests do not correlate well with each other.

Anticardiolipin antibodies (ACA): Antibodies against β_2 GPI that have been detected in an enzyme-linked immunosorbent assay (ELISA) containing cardiolipin as the phospholipid-binding β_2 GPI (which is present in the assay).

Antiphosphatidylserine antibodies: Antibodies against β_2 GPI that have been detected in an ELISA that contains phosphatidylserine as the phospholipid-binding β_2 GPI.

Anti- β_2 GPI antibodies: Antibodies against β_2 GPI that are detected in an ELISA that contains this phospholipid-binding protein adsorbed to the surfaces of microtiter plate wells.

antibodies that did not recognize the Gly40-Arg43 domain did not correlate with a history of thrombosis or with LA activity.²⁰ These findings of two different types of β_2 GPI antibodies were followed by a retrospective study that showed an odds ratio for thrombosis of 42.3 for patients with β_2 GPI-dependent lupus anticoagulant activity compared with 1.6 for those with LA activity independent of β_2 GPI antibodies.²¹ These findings contrast with those from prior studies that showed only modest increases in thrombogenic

risk in patients who tested positive for LA and ACA compared with those who tested positive in only one of the two tests.²²⁻²⁴ Accumulating evidence for the role of a specific epitope in the APLA disease process may explain the suboptimal specificity of current clinical APLA tests (see "Laboratory Diagnosis of APLA"). Conversely, some anti- β_2 GPI antibodies as currently detected are nonpathogenic, and some APLS-related thrombotic episodes may be due to different populations of autoantibodies (e.g., antiprothrombin).

Investigation into disease mechanism(s) in APLS has been especially challenging. A major problem is that APLA exhibit diverse effects in vitro because of the many biologic processes that involve phospholipids and phospholipid membranes. The heterogeneity of APLA, even in individual patients, as shown on clonal analysis,²⁵ adds to the difficulty of defining the pathogenesis of APLS. Some of the main hypotheses that have been proposed to account for the pathogenic mechanisms in APLS are listed in Table 19-2.²⁶⁻⁵¹

The physiologic function of β_2 GPI has not yet been established; the protein may play a scavenging role for anionic phospholipids after apoptosis.^{52,53} Deficiencies of β_2 GPI in humans have not been associated with any disorders, including thrombosis,⁵⁴ and do not appear to affect coagulation reactions.⁵⁵ β_2 GPI-null mice do not manifest any obvious significant abnormalities.⁵⁶ Transgenic mice have impaired thrombin generation, and the offspring of heterozygous mice contained fewer than the expected percentage of homozygotes for β_2 GPI-null disrupted alleles.⁵⁶ The latter observation suggests that β_2 GPI may play an undefined role in the reproductive process.

Data from animal studies indicate that APLA may play a causal role in the development of thrombosis and that they are not simply an epiphenomenon. Mice immunized against β_2 GPI develop APLA and pregnancy wastage.^{37,57} Furthermore, mice that have been passively immunized with β_2 GPI or that have received human antibodies to β_2 GPI develop fetal wastage and susceptibility to thrombosis.⁵⁸⁻⁶¹

Several possible causes of thrombosis have been postulated; however, none has gained exclusive acceptance. Anti-endothelial cell antibodies, which are a common aspect of APLS, may cause endothelial injury, thereby inducing tissue factor

Figure 19-1 Structure of β_2 -glycoprotein I (left) and mechanism of binding of β_2 -glycoprotein I to the phospholipid surface. (From de Groot PG, Bouma B, Lutters BC, et al: J Autoimmunity 15:87-89, 2000; reprinted with permission from Elsevier.)

Table 19-2 Proposed Mechanisms for the Antiphospholipid Syndrome

Injury to endothelium²⁶
 Induction of receptors for cell adhesion molecules on endothelium^{27,28}
 Induction of tissue factor expression on monocytes and on endothelial cells^{29,30}
 Inhibition of heparin:antithrombin III complexes^{31–33}
 Interference with protein C pathway^{34–36}
 Complement activation^{37,38}
 Platelet activation^{39–42}
 Disruption of annexin A5 shield⁴³
 Induction of apoptosis^{44,45}
 Altered eicosanoid synthesis⁴⁶
 Increase in plasminogen activator inhibitor-1⁴⁷
 Cross-reactivity to oxidized low-density lipoprotein^{48,49}
 Impairment in autoactivation of factor XII and reduced fibrinolysis^{50,51}

(TF) production and exposure of membrane phospholipid.⁶² Circulating β_2 GPI could then bind to the phospholipids, and the APLA could in turn bind to the complex, thus inducing further damage.⁶² Other investigators have shown that APLA can recognize heparin or heparin bound to β_2 GPI, thereby inhibiting the interaction of heparin with antithrombin III.^{31–33} Several in vitro studies have suggested that APLA promote thromboses by inhibiting the ability of protein C to inactivate factors Va and VIIIa.^{34–36} Complement activation also appears to play a role in the thrombotic process in APLS.^{37,63}

Conflicting evidence has been gathered on the effects of APLA on platelets. APLA may activate platelets,^{42,64} but at least two groups have reported that APLA can bind directly to circulating platelets without inducing platelet activation or aggregation.^{40,65} Others have shown that APLA can bind to activated platelets, although this binding does not affect the release reaction or aggregation.⁶⁶ Most human hybridoma LAs do not bind to resting platelets in vitro.⁶⁷ Galli and coworkers⁶⁸ reported that 40% of patients with APLS and thrombocytopenia had antibodies against glycoprotein (GP)-IIb/IIIa and/or GP-Ib/IX, and that APLA did not bind to resting platelets.

Increasing evidence supports the concept that APLA and, in particular, β_2 GPI:anti- β_2 GPI complexes, may displace the potent anticoagulant, annexin A5 (previously known as annexin V) from anionic procoagulant phospholipid surfaces. Annexin A5 is derived from a family of proteins with a canonical structure consisting of repetitive homologous domains of about 70 amino acids. This protein clusters on exposed phospholipid membrane surfaces, forming a two-dimensional crystalline array^{43,69–71} that shields the phospholipids for availability from phospholipid-dependent coagulation reactions.⁷⁰ It has recently been shown with atomic force microscopy that APLA can displace annexin A5 from procoagulant surfaces, thereby accelerating coagulation reactions.⁷¹ Furthermore, annexin displacement is dependent on anti- β_2 GPI antibodies. These antibodies have been reported to correlate with clinical manifestations of thrombosis in patients with APLA.⁷²

Annexin A5 may play an antithrombotic role in physiologic conditions such as those present in the placental circulation, where it is expressed by trophoblasts whose apical surfaces are covered by a layer of annexin A5.⁷³ When mice were infused with anti-annexin A5 antibodies,

Table 19-3 Phospholipid-Dependent Coagulation Reactions

1. Tissue factor–factor VII/VIIIa-mediated activation of factors X and IX
2. Factor IXa and factor VIIIa activation of factor X to factor Xa
3. Factor Xa and factor Va activation of prothrombin to thrombin

varying degrees of fetal wastage occurred, including thrombosis and necrosis.⁷⁴ In one study, infusion of pregnant mice with APLA from patients with APLS reduced annexin A5 levels and accelerated the coagulation of plasma on cultured trophoblasts, endothelial cells,⁷⁵ and platelets.^{76,77} Thus, annexin A5 may have an antithrombotic effect on the surfaces of cells lining the placenta and in the systemic vasculature, which can be disrupted by APLA.

LA Effects Explained

For most APLA, immune recognition requires antigen binding to a suitable anionic phospholipid surface.^{11,12,78,79} Engagement of the F(ab) portions of an IgG APLA with two adjacent antigen molecules such as β_2 GPI or prothrombin at the anionic surface enhances the binding of the complex to the surface.^{11,12,78,79} Because most reactions that control the process of blood coagulation occur at the phospholipid surface, (Table 19-3) these stable trimolecular complexes of IgG and two phospholipid-binding protein molecules block the proper assembly of the phospholipid-dependent coagulation system, thereby producing the LA effect. Thus, in the confirmatory LA tests described later, this sequestering effect is overcome by the addition of excess phospholipids, which allow the coagulation reaction to proceed unhindered.

The paradox of why lupus anticoagulants promote thrombosis may be explained by the fact that APLA/ β_2 GPI complexes disrupt the ordered crystallization of the two-dimensional annexin A5 shield over phospholipid bilayers (Fig. 19-2). Consequently, the antibody/ β_2 GPI complexes expose a substantially greater quantity of phospholipids by disrupting the annexin A5 shield than they block by direct binding.^{76,80,81}

Triggers for Hematologic Consultation

The diverse clinical presentation of APLS results in a variety of avenues through which patients are referred for consultation. Common subjects for consultation are young patients, without other known risk factors, who have sustained a stroke or who have had unexplained venous thromboembolism (VTE) (Table 19-4). Other patients are referred with a previous diagnosis of APLS and the need to confirm the diagnosis. Obstetricians send women with multiple pregnancy losses. Patients with lupus are referred for evaluation because of known association with APLS.

However, other conduits for consultation exist for which little is known about appropriate treatment. Patients with a prior diagnosis of APLS who have been without symptoms for several years may wish to discuss potential changes in therapy. Surgeons send patients for an elevated partial thromboplastin time (PTT) found incidentally on preoperative testing. Some obstetricians test for APLA

Figure 19-2 Proposed model for the “lupus anticoagulant effect” paradox and for a “lupus procoagulant effect.” **A**, Anionic phospholipids (negative charges), when exposed on the apical surface of the cell membrane bilayer, serve as potent cofactors for the assembly of three different coagulation complexes—the tissue factor (TF):VIIa complex, the IXa:VIIIa complex, and the Xa:Va complex—and thereby accelerate blood coagulation. TF complexes yield factor IXa or factor Xa, the IXa complex yields factor Xa, and the Xa formed from both of these reactions is the active enzyme in the prothrombinase complex that yields factor IIa (thrombin), which, in turn, cleaves fibrinogen to form fibrin. **B**, Annexin A5, in the absence of antiphospholipid antibodies (APLA), serves as a potent anticoagulant by forming a crystal lattice over the anionic phospholipid surface, shielding it from availability for assembly of the phospholipid-dependent coagulation complexes. **C**, In the absence of annexin A5, APLA:β₂GPI complexes prolong coagulation times, compared with control antibodies. This occurs via antibody recognition of domain I on the β₂GPI, which results in dimers and pentamers of antibody:β₂GPI complexes that have high affinity for phospholipid via domain V. These high-affinity complexes reduce the quantity of anionic phospholipids available for binding of coagulation factors. This results in a “lupus anticoagulant” effect in conditions with limited quantities of anionic phospholipids. **D**, In the presence of annexin A5, antiphospholipid antibodies, via interaction with β₂GPI, disrupt the ability of annexin A5 to form ordered crystals on the phospholipid surface. This results in a net increase in the amount of anionic phospholipid available for promoting coagulation reactions. APLA:β₂GPI complexes expose significantly more phospholipids by disrupting the annexin A5 shield than they block by direct binding. This manifests in the net acceleration of coagulation in vitro (i.e., a “lupus procoagulant effect”) and in vivo (i.e., in thrombophilia). (Reprinted with permission from Rand JH: Molecular pathogenesis of the antiphospholipid syndrome. *Circ Res* 90:29–37, 2002.)

Table 19-4 Common Indications for Testing for Antiphospholipid Syndrome

Clinical

Venous thromboembolism (deep venous thrombosis, pulmonary embolism, and thrombosis in less common sites)
 Peripheral arterial thrombosis
 Myocardial infarction
 Stroke or transient ischemic attack (<55 years old without other risk factors)
 Pregnancy complications, including recurrent fetal loss, intrauterine growth retardation, preeclampsia, and HELLP (hemolytic anemia, elevated liver enzymes, low platelets) syndrome
 SLE (systemic lupus erythematosus)

in women who have not had recurrent miscarriages. Patients with neurologic deficits or ophthalmic manifestations with serologic evidence for APLA must be differentiated from patients with multiple sclerosis and other neurologic conditions.

This is only a sampling of the reasons for which patients are referred for consultation. This chapter focuses on the patient population in the former paragraph and, where appropriate, suggests guidelines that may be helpful to the consultant.

ANTIPHOSPHOLIPID SYNDROME: CLINICAL DIAGNOSIS

APLS should be considered in patients who present with one or more of the following clinical conditions: VTE, arterial thrombosis (stroke, myocardial infarction), or recurrent pregnancy loss,^{82–84} particularly in the absence of other thrombophilic risk factors. Associated conditions, particularly in patients with SLE or other autoimmune disorders, include thrombocytopenia, vasculitic rash, transient ischemic attack, arthralgia, dermal necrosis of digits, livedo reticularis, valvular heart disease, and pulmonary hypertension (Table 19-5).⁸⁵ The diagnosis is confirmed if the patient tests

Table 19-5 Clinical Manifestations of the Antiphospholipid Syndrome

Venous or arterial thromboembolism in typical or atypical locations
Multiple pregnancy losses
Thrombocytopenia
Stroke
Livedo reticularis, necrotizing skin vasculitis, skin ulcers
Cardiac valvular lesions
Coronary artery disease
Arthralgia, arthritis
Hemolytic anemia
Pulmonary hypertension, acute respiratory distress syndrome
Atherosclerosis, peripheral artery disease
Retinal disease
Adrenal failure, hemorrhagic adrenal infarction
Gastrointestinal manifestations: Budd-Chiari syndrome, mesenteric and portal vein obstructions, hepatic infarction, esophageal necrosis, gastric and colonic ulceration, gallbladder necrosis
Catastrophic antiphospholipid syndrome (CAPS) with microangiopathy

positive for autoantibodies that are detected in phospholipid-dependent clotting assays as LA, or as ACA in ELISA that contain cardiolipin, along with β_2 -glycoprotein I (β_2 GPI). Patients should be tested with both types of assay (immunologic and coagulation), and more than one negative test for LA is needed to rule out the diagnosis of APLS in a patient with a clinical presentation consistent with this disorder. Research criteria for diagnosing APLS, which have recently been updated in Sydney, Australia, require that tests should be positive for LA or for moderate to high levels of ACA (IgG, IgM, or anti- β_2 GPI) on two occasions at least 12 weeks apart (Table 19-6).⁸⁴⁻⁸⁹ The requirement for sustained positivity for APLA is given because results may be positive only transiently and may be unrelated to clinical symptoms.⁹⁰

The syndrome is known as secondary APLS if it occurs in patients who have another identifiable autoimmune connective tissue disorder, usually SLE. In this patient group, the female/male ratio for development of APLS is 7:1, similar to the sex ratio for SLE (9:1 to 10:1).^{91,92} The prevalence of ACA in patients with SLE is variable; frequencies range from 16% to 39%,⁹³⁻¹⁰³ although incidences as high as 86% have been reported.¹⁰⁴ LA is also commonly detected in patients with SLE; frequencies range from 11% to 30%,^{96,99,105} and significant overlap is seen in ACA detected in LA-positive plasma.

In the absence of SLE or other autoimmune connective tissue disorders, APLS is considered a primary APLS.⁹¹ The multicentered Euro-Phospholipid Project gathered clinical and immunologic data from 1000 unselected patients who met proposed preliminary criteria for the classification of definite APLS⁸³; investigators found that 53% of the cohort had primary APLS and 41% had APLS with SLE or lupus-like conditions.⁹¹ They also calculated a female/male ratio of 3.5:1 for primary APLS ($P < .005$) compared with a 5:1 ratio overall.⁹¹ The age of onset was between 15 and 50 years in 85% of patients. Patients who developed APLS after the age of 50 ($n = 127$; 12.7%) were most often male (34% vs 16%). In a retrospective analysis, it was noted that most patients with APLS did not progress to SLE.¹⁰⁶ Regardless, management of primary and secondary APLS is the same and the prognosis does not appear to

be different; some advocate eliminating the primary/secondary designation altogether.^{84,107}

An accelerated subentity of APLS that consists of disseminated macrovascular and microvascular occlusions resulting in multiorgan failure is known as the catastrophic antiphospholipid syndrome (CAPS). This disorder, which is reported in less than 1% of all patients with APLS, is defined by thrombotic occlusions in at least three organs/tissues that occur within a week ("thrombotic storm"), along with laboratory confirmation of APLA. Histologically, small vessel occlusion predominates, in contrast to the large vessel thromboses that are common in standard APLS.¹⁰⁸ The differential diagnosis in some circumstances may include other microangiopathic syndromes such as thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, and heparin-induced thrombocytopenia. In addition, many critically ill patients have false-positive results on LA assays¹⁰⁹ (e.g., from coagulation factor deficiencies, caused by heparin administration) that further complicate the diagnosis. Although the cause of CAPS is unknown, infection is associated as a triggering factor in up to 20% of patients.¹⁰⁸ Because of tissue necrosis and the resultant "cytokine storm," many patients go on to develop acute respiratory distress syndrome and require mechanical ventilation. Even with optimal treatment, the mortality rate is approximately 48%.^{108,110}

Neurologic Manifestations of Antiphospholipid Syndrome

Neurologic manifestations of APLS include single or recurrent cerebral infarct, severe vascular headache, transient ischemic attack, and visual disturbance (Table 19-7).¹¹¹ Recurrent strokes are more likely in patients with APLS who also have hypertension or other risk factors for cerebrovascular disease, such as cigarette smoking and hyperlipidemia.¹¹¹ As many as 80% of patients with primary APLS have at least one of these additional risk factors. Cerebral angiography performed on such patients shows large vessel occlusion with "cutoffs" or stenosis, without evidence of vasculitis and generally without systemic atherosclerosis.

Although arterial events are less frequent than venous events in APLS, ischemic stroke and transient ischemic attacks account for 50% of all arterial manifestations.^{91,112} Such an event, particularly in a young adult, warrants an APLA investigation. In one prospective study, 18% of adults (aged 15 to 44 years) who had sustained ischemic stroke or a transient ischemic attack tested positive for ACA. Patients with ACA had a higher probability of recurrent events than those who did not have the antibody.¹¹³

Among older populations, one large study showed no association between stroke and the presence of ACA. In the nested, case-controlled Physicians' Health Study, which was composed of men aged 40 to 84 years, IgG ACA levels in 61 participants with ischemic stroke were not significantly different from those of controls ($P > .2$), and there was no evidence to suggest increased risk for stroke in those with higher APLA levels.¹¹⁴ The Antiphospholipid Antibodies and Stroke Study (APASS) group recently completed the first prospective study of the role of APLA in recurrent ischemic stroke in collaboration with the Warfarin versus Aspirin Recurrent Stroke Study (WARSS) group.²³ The WARSS group was a controlled and blinded study that

Table 19-6 Sydney Consensus Statement on Classification Criteria for the Antiphospholipid Syndrome⁸⁴

Antiphospholipid antibody syndrome (APLS) is present if at least one of the clinical criteria and one of the laboratory criteria that follow are met.*

Clinical criteria:1. Vascular thromboses:[†]

One or more clinical episodes[‡] of arterial, venous, or small vessel thrombosis[§] in any tissue or organ. Thrombosis must be confirmed by objective validated criteria (i.e., unequivocal findings of appropriate imaging studies or histopathology). For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.

2. Pregnancy morbidity:

- (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or
 - (b) One or more premature births of a morphologically normal neonate before the 34th week of gestation because of (i) eclampsia or severe preeclampsia defined according to standard definitions, or (ii) recognized features of placental insufficiency,[¶] or
 - (c) Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.
- In studies of populations of patients who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of subjects according to a, b, or c above.

Laboratory criteria:**

- 1. Lupus anticoagulant (LA) present in plasma on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Haemostasis (Scientific Subcommittee on LAs/Phospholipid-Dependent Antibodies).⁸⁶
- 2. Anticardiolipin antibody (ACA) of immunoglobulin (Ig)G and/or IgM isotype in serum or plasma, present in medium or high titer (i.e., >40 GPL [1 µg of IgG antiphospholipid antibody {APLA}] or MPL [1 µg of IgM APLA], or >the 99th percentile), on two or more occasions, at least 12 weeks apart, measured by a standardized enzyme-linked immunosorbent assay (ELISA).^{87,88}
- 3. Anti-β₂-glycoprotein I antibody of IgG and/or IgM isotype in serum or plasma (in titer >the 99th percentile), present on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA, according to recommended procedures.⁸⁹

*Classification of APLS should be avoided if less than 12 weeks or more than 5 years separate the positive APLA test from the clinical manifestation.

[†]Coexisting inherited or acquired factors for thrombosis are not reasons for excluding patients from APLS trials. However, two subgroups of APS patients should be recognized, according to (a) the presence, or (b) the absence of additional risk factors for thrombosis. Indicative (but not exhaustive) causes include age (>55 in men, and >65 in women) and the presence of any established risk factors for cardiovascular disease (hypertension, diabetes mellitus, elevated low-density lipoprotein [LDL] or low high-density lipoprotein [HDL] cholesterol, cigarette smoking, family history of premature cardiovascular disease, body mass index ≥ 30 kg/m², microalbuminuria, estimated glomerular filtration rate [GFR] <60 mL min⁻¹), inherited thrombophilias, oral contraceptive use, nephrotic syndrome, malignancy, immobilization, and surgery. Thus, patients who fulfill criteria should be stratified according to contributing causes of thrombosis.

[‡]A thrombotic episode in the past could be regarded as a clinical criterion, provided that thrombosis is proved by appropriate diagnostic means and that no alternative diagnosis or cause of thrombosis is found.

[§]Superficial venous thrombosis is not included in the clinical criteria.

[¶]Generally accepted features of placental insufficiency include (1) abnormal or nonreassuring fetal surveillance test(s) (e.g., a nonreactive nonstress test, suggestive of fetal hypoxemia), (2) abnormal Doppler flow velocimetry waveform analysis suggestive of fetal hypoxemia (e.g., absent end-diastolic flow in the umbilical artery), (3) oligohydramnios (e.g., an amniotic fluid index ≤ 5 cm), or (4) a postnatal birth weight lower than the 10th percentile for gestational age.

**Investigators are strongly advised to classify patients with APLS into one of the following categories: I, more than one laboratory criterion present (any combination); IIa, LA alone present; IIb, ACA alone present; IIc, anti-β₂GPI antibody alone present.

(Reprinted with permission from Miyakis S, Lockshin MD, Atsumi T, et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome [APS]. *J Thromb Haemost* 4:295–306, 2006.)

sought to compare the risk of recurrent ischemic stroke in patients randomly assigned to aspirin (325 mg/day) or warfarin (target International Normalized Ratio [INR], 2.2; range, 1.4 to 2.8). The APASS trial included 890 patients on warfarin and 882 patients on aspirin; no increase was found in the rates of recurrent thrombotic events associated with baseline APLA status as measured at the time of initial stroke. Since this study began, before the Sydney and Sapporo⁸³ clinical criteria were formalized for APLS diagnosis, APLA-positive patients were not formally retested, which may account for the surprisingly high percentage of participants with APLA positivity (41%). It is interesting to note that the 7% of patients with baseline positivity for both LA and ACA tended to have a higher rate of recurrence than did those who were negative on both antibodies (32% vs 24%; RR, 1.36; 95% CI, 0.97–1.92; *P* = .07).

In a prospective case-controlled study that included whites, African Americans, and Hispanic patients, APLA

was found to be an independent stroke risk factor in all groups, causing a fourfold increase in risk for ischemic stroke.¹¹⁵ Although this point has not yet been clarified, data suggest that for patients who have transient ischemic attacks at a young age, or for those who have these events in association with other features of APLS, testing for ACA and LA appears to be warranted. However, indiscriminate testing of an otherwise general patient population with cerebrovascular events is not indicated.¹¹⁶

Antiphospholipid Antibodies and Cardiac Dysfunction

An increased incidence of cardiac valvular lesions and myocardial dysfunction occurs in patients with both primary and secondary APLS, as well as in patients with SLE alone.^{117–121} Prospective studies that used two-dimensional echocardiography to detect cardiac abnormalities in

Sneddon syndrome

patients with primary and secondary APLS have found significant associations with valvular lesions. A study from Mexico found valvular lesions in 17 of 29 (71%) consecutive patients with APLS.¹²² A prospective study in London identified valvular lesions in 38% of 55 patients with recently diagnosed APLS, and only in 4% in a control group of 55 healthy volunteers.¹²³ Studies have shown that at least one half of patients with cardiac lesions have other features of APLS.^{91,117,122} Serial studies in these patients have indicated that hemodynamically significant cardiac valvular disease can develop over time,^{119,122,123} and that these patients may be at increased risk for cerebroembolic events.^{122,124–126} Intramural cardiac thrombosis occurs rarely.¹²⁷ These studies emphasize the value of echocardiographic screening for all patients with APLS.^{123,128}

Sterile valvular lesions, known as Libman-Sacks endocarditis, are similar to those that occur in patients with SLE; they consist mainly of superficial or intravalvular fibrin deposits at various stages of fibroblastic organization and neovascularization, sometimes accompanied by mononuclear cell infiltration.^{129,130} Echocardiographic findings include generally diffuse and symmetrical valve thickening; when localized thickening is noted, it involves the leaflet midportion or base (Fig. 19-3). In contrast to rheumatic heart disease, chordal thickening, fusion, and calcification are rarely seen and, when present, are not prominent.^{129,131} The lesions, which appear as small clusters, most frequently affect the mitral valve, then the aortic valve; they may produce no symptoms, or they may cause valvular insufficiency or stenosis if significant thickening occurs.^{117–121,129–135}

Evidence suggests an immunologic origin, with APLA deposition initiating the valvular damage. This leads to superficial thrombosis, subendocardial mononuclear cell infiltration, and eventually, fibrosis or calcification.^{122,129} Histologically, most studies suggest that fibrin deposits are the major findings with minimum inflammation.^{130,131} A role for corticosteroid therapy remains unclear in the absence of significant underlying inflammation. Although administration of steroids may dramatically reduce an inflammatory condition and may facilitate healing of valvular vegetations, this treatment may result in marked scarring and deformity of the valve, thereby leading to valve dysfunction.¹³⁵

Nevertheless, clinical and hemodynamic responses have been reported in some cases, suggesting that a moderate inflammatory process is present.¹³⁶ Therefore, it is recommended that a short course of high-dose corticosteroids

be given, with echocardiographic follow-up¹²⁸ and appropriate anticoagulation treatment. Although case reports have described valvular improvement with anticoagulation, most studies cited earlier found that no benefit was derived from the use of anticoagulation.^{122,130,135}

APLA have been associated with myocardial microvasculopathy that is sufficiently severe to induce myocardial infarction, even in patients with normal coronary arteries.¹³³ In the multicentered Euro-Phospholipid Project of 1000 patients with APLS (described previously), 2.8% of patients initially presented with a myocardial infarction (MI), and 5.5% had an MI in the course of their disease.⁹¹ This suggests a possible role for screening for APLA in patients at low risk for coronary artery disease. However, in a different cohort study of the survivors of MI divided into those younger or older than 51 years of age, ACA (measured as both IgG and IgM isotypes) was not an independent risk factor for overall mortality, reinfarction, or thrombotic stroke.¹²⁴ The multivariate analysis was adjusted for age and high-density lipoprotein (HDL) cholesterol. The more recent Hopkins Lupus Cohort¹³⁷ study, which prospectively followed 380 patients with SLE (92% female; mean age, 46±12 years), evaluated whether APLA were predictive of atherosclerosis and/or coronary artery disease. Patients with LA were more likely to have an MI than those who tested negative for LA (22% vs 9%); however, elevated ACA levels also were not associated with an increased risk for MI. These findings are consistent with other studies that show the LA to be a stronger risk factor for thrombosis than ACA in the APLS.^{13,79,138} Many studies have reported mixed results when investigating APLA as an independent risk factor for mortality, reinfarction, or nonhemorrhagic stroke.¹³⁰ In general, screening of all patients who develop an MI for the presence of APLA is not cost effective.

Dermatologic Manifestations

Dermatologic manifestations are common; they occur in up to 40% to 50% of patients with APLS and as the presenting symptoms in 29% to 40% of patients.^{91,139–141} Cutaneous manifestations are diverse, ranging from minor signs to life-threatening conditions such as widespread cutaneous necrosis (Table 19-8). The most frequently encountered skin lesions are livedo reticularis and skin ulcers.

Livedo reticularis is observed in 25% of patients with APLS^{91,139}; it is characterized by a mottled purple reticular pattern that involves the upper and lower limbs and often the trunk and buttocks (see Fig. 11-25 in Chapter 11). The pattern is generally disseminated, with incomplete circular segments of irregular fine or wide ramifications. Microscopically, skin biopsy specimens do not usually reveal histopathologic changes, and they rarely contain thrombi, unless the patient has catastrophic APLS.^{139,142,143} The arterial subset of APLS^{139,144} may be related to Sneddon syndrome. First described in 1965, Sneddon syndrome is characterized by widespread livedo reticularis and recurrent ischemic cerebrovascular events with variable APLA positivity (0% to 85%).¹⁴⁵ Livedo may be observed in otherwise healthy patients, especially women after cold exposure; livedo may also be noted in patients with vasculitic and infectious conditions (e.g., syphilis, tuberculosis).¹⁴³

Other APLS-related cutaneous manifestations include subungual hemorrhage, necrotizing vasculitis, thrombophlebitis, anetoderma, pseudovasculitic lesions, skin ulcerations, and digital gangrene. In the latter conditions, noninflammatory thromboses in small arteries and veins throughout the dermis and subcutaneous fat tissue are the primary histologic findings.¹⁴² The presence of IgA ACA has been independently associated with skin ulcers, chilblain lupus, and vasculitis.¹⁴⁶ Treatments have included anticoagulation, immunosuppression,¹⁴⁷ and local measures such as autologous skin transplantation.¹⁴⁸

Fetal Loss and Antiphospholipid Syndrome

Please see Chapter 36, “Management of Thrombophilia and APLS During Pregnancy.”

Bleeding Complications and Antiphospholipid Syndrome

Although APLS is generally associated with thrombotic manifestations, bleeding complications may occasionally be encountered. Consultants should consider the following

differential diagnosis in appropriate patients who have laboratory or clinical evidence of a bleeding disorder: prothrombin deficiency, presence of antibody inhibitor to coagulation factors, acquired von Willebrand disease, acquired platelet function abnormalities, and thrombocytopenia. The recognition that prothrombin time (PT) prolongation may, in some patients, be partially due to the LA effect should prompt the use of prothrombin assays insensitive to the LA. As always, when patients with APLS and concurrent bleeding diatheses are treated, the clinician cannot rely solely on laboratory results as a prognosticator for bleeding risk. A recent study found significantly prolonged bleeding times in 21 of 27 consecutive patients with consistent LA, normal von Willebrand factor (VWF), and normal platelet function, who were not exposed to aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs).¹⁴⁹

Thrombocytopenia is frequently present in APLS and is usually mild. Two studies, including the Euro-Phospholipid Project group study of 1000 patients with APLS, found that 30% of patients had episodes of thrombocytopenia (<100,000 platelets/ μ L).^{91,150} When patients with idiopathic autoimmune thrombocytopenia (ITP) were examined in the absence of other autoimmune disease, elevated levels of ACA were noted in 15% to 66% of patients.^{151–153} One recent study¹⁵³ showed elevated ACA in the acute exacerbation or relapse of ITP, with subsequent decline to undetectable levels on remission. More specifically, this study found ACA IgG to be more prevalent in the acute stage, and IgM more prevalent in stable disease. However, LA was negative in all patients, and β_2 GPI was the least common target antigen. Although another study correlated thrombocytopenia in patients with APLS with higher rates of epilepsy, arthritis, livedo reticularis, skin ulceration, and cardiac valve thickening and dysfunction,¹⁵⁰ overall, the presence of APLA does not appear to affect outcome.

Patients who have LA may have slight prolongation of PT, depending on the sensitivity of the thromboplastin reagent used. However, patients who have significant prolongation of the PT (>2 to 3 seconds above the upper limit of normal) should be evaluated for a true acquired deficiency of factor II (prothrombin). In a study of patients with LA, SLE, and/or other autoimmune connective tissue disorders, most had IgG antibodies to prothrombin; only 30% of patients with antibodies had a detectable prothrombin deficiency.¹⁵⁴ Prothrombin deficiency, when it does occur in patients with LA, appears to be due to the binding of the antibody to prothrombin in vivo, which results in increased clearance.

An acquired deficiency of prothrombin with clinical symptoms of bleeding may be the initial presenting feature in a patient who will later develop other manifestations of APLS (and possibly SLE as well). Autoimmune-based prothrombin deficiency may also be suspected in a patient who is receiving warfarin as treatment for thrombotic complications of APLS, and who develops a gradually increasing INR for no apparent reason. Evaluation includes measurement of coagulation factor levels (II, V, VII, and X) in the extrinsic system and possible alterations in warfarin dose.

Multiple case reports of other factor deficiencies and antibody inhibitors have been found among patients with APLS, particularly those with inhibitors to factor VIII.¹⁵⁵ Caution is warranted in that the LA effect may be potent enough to cause apparent factor deficiencies in the assay

system. When this is suspected, PTT reagents that are insensitive to the LA effect may be used for more accurate results.

Antibody production can be suppressed by administration of corticosteroids and azathioprine, as was demonstrated in one patient in whom PT was normal 7 days after treatment had been initiated.¹⁵⁶ In another study, the use of corticosteroid therapy alone increased the prothrombin level, even when prothrombin/antibody complexes were still detectable.¹⁵⁷

More recently, several reports have indicated efficacy for rituximab, a chimeric anti-CD20 monoclonal antibody, in the treatment of patients with autoimmune disorders such as ITP, autoimmune hemolytic anemia (AIHA), SLE, and vasculitides.^{109,158–160} B-cell depletion in autoimmune disease may lower the pathogenic autoantibody levels associated with these syndromes, including APLS. One report described a marked response in a patient with ITP with LA and ACA who was refractory to steroids and azathioprine. Soon after initiation of rituximab, platelet counts returned to normal; within 14 months, ACA IgG levels became negative and anti- β_2 GPI was markedly lowered.¹⁶⁰

Laboratory Diagnosis of APLA

It is currently accepted that the detection of ACA for the diagnosis of APLS should be dependent on β_2 GPI. Also, prolongation of clotting assays for the LA effect should be confirmed by neutralization with excess phospholipids. Despite these generally accepted principles, the sensitivities and specificities of these methods vary widely, and no single test is sufficient for diagnosis. Therefore, when the disorder is suspected, a battery of available tests (Table 19-9) is required. Conversely, no array of negative results can conclusively exclude the diagnosis.

Lupus Anticoagulant

Currently, the detection of LA appears to be more specific for APLS than the ACA assay. In two recent studies in which antibody profiles for the diagnosis of APLS were analyzed, a positive LA test was independently associated

with VTE and arterial thrombosis with odds ratios of 4.4 and 3.6, respectively. When LA was also associated with ELISA-based tests, the odds ratios increased to 10.1 and 33, respectively.^{24,54} This is consistent with previous studies; in a meta-analysis of the risk of VTE in patients with APLA, with exclusion of patients with SLE, the mean odds ratio for LA was 11.0.¹⁶¹ More recently, in a systematic literature review, five of five studies reported a significant association of LA with thrombosis, with odds ratios ranging from 5.7 to 9.4 (Fig. 19-4).¹³ A positive LA is consistently associated with increased risks for arterial and venous events and is more predictive than ELISA-based assays.

In general, a lupus anticoagulant is suspected when one of several screening assays, such as PTT, is prolonged. A suspected LA is further evaluated by means of an inhibitor screen, such as a mixing study, to rule out factor-specific inhibitors. LA usually prolongs the coagulation time of test plasma and normal plasma, immediately after mixing. Conversely, demonstration of a factor VIII inhibitor usually requires incubation after mixing, before the PTT becomes

prolonged. The phospholipid-dependent nature of LA is then confirmed by correction of the LA effect through the addition of excess phospholipid. Also, the clinician should check to see whether PTT becomes normalized when an LA-insensitive PTT reagent is used (Fig. 19-5).⁸⁶

Coagulation factor levels are measured for the purpose of excluding a true factor deficiency or the presence of another inhibitor. If patient plasma has a prolonged PTT and a normal PT, factors VIII, IX, XI, and XII, as well as high molecular weight kininogen and prekallikrein, are measured. Frequently, LA is sufficiently potent to effect an apparent decrease in these coagulation factors. These apparent decreases in activity of the “contact factors” (factors XI and XII, as well as prekallikrein and high molecular weight kininogen) due to LA may provide the foundation for anecdotal reports in which contact factor deficiencies are associated with hypercoagulability.¹⁶²

Factor activity should increase toward the true value when measured in serial dilutions of patient plasma (i.e., because results among various dilutions are inconsistent, often referred to in the laboratory literature as inhibitory kinetics, or the “crossing lines” artifact). Progressive dilution of plasma also dilutes the inhibitory activity of LA and allows for more accurate determination of factor activity. Another option is to use PTT reagents that are relatively insensitive to LA. If the patient has a true factor inhibitor, determination of the factor level will not be influenced by the dilution at which the plasma is tested. If PT is also prolonged, then measurement of factors VII, X, V, and II should be included. Occasionally, in plasma with LA, the PT may also be slightly prolonged in the absence of a true factor deficiency.^{163,164} The most common true factor deficiency associated with the LA is prothrombin deficiency, as described earlier.

A major limitation of the clinical usefulness of LA results is the often considerable variation among laboratories, assays, and reagents used. Of available assays, none is 100% sensitive or specific. A recent compilation of quality assurance surveys

from several international agencies over the past decade found an overall intermediate interlaboratory coefficient of variation (generally <20%).¹⁶⁵ However, multiple studies have shown that LA activity is predictive and specific for the occurrence of thrombosis and pregnancy loss, even more so than the ACA and the anti- β_2 GPI ELISA assays.^{54,79,166} Furthermore, despite interlaboratory variations among individual assays, the surveys discussed earlier found that the use of LA test panels yields an overall error rate <5%.¹⁶⁵

Other considerations regarding laboratory diagnosis of LA include the heterogeneous nature of the target protein antigens that produce the LA effect and the frequent interlaboratory disagreements encountered when plasmas known to have weak LA activity are analyzed. Also, the effect of LA on phospholipid-dependent coagulation assays depends on the depletion of platelets and platelet fragments from plasma. A normal PTT alone is insufficient to exclude LA, and additional screening assays such as dilute Russell's viper venom time or kaolin clotting time should be used before the diagnosis is ruled out. Alternatively, a patient with an equivocal LA result should be evaluated for concurrent deficiencies of specific coagulation factors, especially if symptoms of a bleeding diathesis are present.

Immunoassays

The other arm for APLS diagnosis is the identification of ACA, antiphosphatidylserine, anti- β_2 GPI, and antiprothrombin antibodies. The first of these to be developed, the anticardiolipin test, was initially encountered as a biologic false-positive Venereal Disease Research Laboratory (VDRL) test for syphilis. Cardiolipin is an intracellular membrane phospholipid that is recognized by antibodies produced in response to syphilitic infection. In contrast to APLA, syphilitic anticardiolipins are not phospholipid dependent and can recognize cardiolipin epitopes directly.¹⁶⁷ Also, the conventional ACA assay is nonspecific in that it can detect a range of antibodies, including anti-human β_2 GPI, antibodies to bovine β_2 GPI, and direct ACA, to name a few.

These assays are designed to measure the level of APLA in patient sera in a quantitative fashion, with the use of microtiter plates coated with cardiolipin or another negatively charged phospholipid and containing β_2 GPI.^{5,168,169} After an incubation period has passed, plates are washed and antibodies are detected with the use of labeled antihuman IgG or IgM. Test results are expressed in units of MPL or GPL (1 MPL is equal to 1 μ g of IgM APLA, and 1 GPL is equal to 1 μ g of IgG APLA). Antibody concentrations are described qualitatively as high positive, moderately positive, low positive, or negative.^{170–172} Appropriate reference ranges must be validated for each laboratory and patient population. Elevated levels of IgA ACA alone are rare, and the clinical relevance of this test has been debated. However, occasionally, IgA ACA positivity is found and is shown to be associated with the major clinical manifestations of APLS, thus making it clinically useful.^{173,174}

ACA as risk factors for thrombosis are not as strong as LA, and studies have shown that only 50% of their associations with thrombosis reached statistical significance.¹³ In a systemic literature review, only 15 of 28 studies showed significant associations between ACA and thrombosis. Statistical significance improved depending on the type of thrombosis; ACA were associated more with cerebral stroke and myocardial infarction than with VTE (Fig. 19-6). In all

Figure 19-6 Anticardiolipin antibodies and thrombosis: Analysis of 11 cross-sectional, case-control, and ambispective studies on 1883 cases and 2469 controls. Odds ratios with 95% confidence intervals (CIs) are grouped according to site and type of thrombosis and antibody isotype. (Modified from Galli M, Luciani D, Bertolini G, et al: Lupus anticoagulants are stronger risk factors of thrombosis than anticardiolipin antibodies in the antiphospholipid syndrome: A systematic review of the literature. *Blood* 101:1827–1832, 2003. Reprinted with permission from the publisher).

studies, a correlation was noted between higher antibody titers and increased odds ratios for thrombosis. This is consistent with the Sydney consensus classification criteria,⁸³ which use only medium to high ACA and/or anti- β_2 GPI antibody titers in evaluation of APLS.

Although β_2 GPI is believed to be the major protein cofactor for APLA, most studies find that ACA is more predictive of thrombosis, both arterial and venous. In a systemic literature review, 34 of 60 studies (none prospective) showed significant associations between anti- β_2 GPI and thrombosis, but with greater odds ratios for ACA associations.⁷⁹ In two subsequent studies, the odds ratios for β_2 GPI-associated thrombosis were 2.4 and 2.7 when tests were performed independently of other APLA assays.^{24,54} In a recent prospective study in which 194 consecutive patients who tested positive for LA and/or ACA were followed, the rate of thrombosis was 7.3% per patient-year among patients with APLA with anti- β_2 GPI and/or antiprothrombin antibodies, as compared with 2.2% among those who tested negative.²² This study further supports the association of greater relative risk for thrombosis in patients with antibodies against more than one phospholipid-binding protein.

Prothrombin is considered to be the second major cofactor for APLA. However, in a systemic literature review, only 17 of 46 studies were noted to have found a significant statistical association with thrombosis, irrespective of antibody type.⁷⁹ Thus, the clinical usefulness of detection in practice has yet to be established.

ACA and anti- β_2 GPI immunoassays appear to be less well controlled and reliable compared with LA testing. In a recent multilaboratory quality assurance program, high interlaboratory variation in numeric results was found in 12 serum samples tested for ACA IgG, ACA IgM, and IgG β_2 GPI. In semiquantitative reporting, a 100% consensus was reached on only 4 of 36 occasions (11%). General consensus (i.e., >90% of participating laboratories agreed

that a given serum sample gave a result of either positive or negative) was attained on only 13 of 36 occasions.¹⁷⁵

Attempts have been made to standardize ACA testing.^{87,176} The first international workshop defined GPL and MPL units as 1 μ g of affinity-purified immunoglobulin (Ig)G and IgM antibody; this information was distributed to participating laboratories. However, secondary standards, calibrated against initial sera, from individual laboratories and companies are composed of a heterogeneous mix of polyclonal IgG and IgM antibodies. Consequently, these antibodies have differing ranges of binding avidity from batch to batch, and they behave differently when standard curves are constructed. This explains the development of semiquantitative reporting (i.e., low, medium, high) of ACA results.⁸⁸

Of the wide selection of APLA tests currently available for clinical use, only LA is consistently associated with thrombosis. Results of studies on ACA and anti- β_2 GPI antibodies are less convincing and partially controversial. An explanation may be that phospholipid-dependent clotting assays measure a functional capability of APLA, rather than providing a quantitative measurement of a heterogeneous population of antibodies with uncertain thrombogenic properties.^{13,79,165} With the recent identification of a subpopulation of β_2 GPI antibodies that have a high correlation for thrombosis and LA positivity, newer assays targeted to detect antibodies against the specific Gly40-Arg43 portion of β_2 GPI may prove to be the most specific and sensitive method of APLA testing.

APLA Presenting as a Laboratory Abnormality

The prevalence of LA and ACA in normal populations has been reported in several studies. ACA and LA in normal control populations are found at rates from 1.0% to 5.6% and from 1.0% to 3.6%, respectively^{24,103,177}; they show seasonal variability with increased prevalence during the

winter months.¹⁷⁸ These frequencies are similar in normal pregnant women.¹⁷⁹ In the “frail” elderly group, ACA have been reported to be significantly more prevalent, particularly after cerebrovascular events, than in normal controls, including older individuals (>63 years) without chronic illness.¹⁸⁰ Contradicting the latter finding of no relative increase in ACA among the healthy elderly compared with the general population was a study of 89 healthy women, with a mean age of 86 years (range, 75 to 102 years).¹⁸¹ ACA and β_2 GPI antibodies were elevated in 64% and 32%, respectively, of participants, suggesting that the prevalence of elevated ACA increases with age. The latter study is particularly important given the overall higher occurrence of thrombotic events in elderly patients. A prospective, nested, case-control study of 317 patients with elevated ACA and 655 control patients from the Longitudinal Investigation of Thromboembolism Etiology (LITE) cohort of 20,000 disease-free participants, found no association between elevated titers of ACA and VTE.¹⁸² Odds ratios comparing IgG and IgM ACA above the 95th percentile and within quintiles were not statistically significant. The conclusion of investigators was that this population does not require anticoagulation on the basis of an elevated ACA alone.

LA is frequently found in patients hospitalized for a wide variety of disorders; it is a common cause of unexplained prolongation of the PTT in patients referred for consultation.¹⁸³ In a prospective study of 177 patients with elevated PTT admitted to an acute care general hospital, 53% of cases were attributed to an LA.¹⁸⁴

Specific conditions other than APLS that are associated with APLA include carcinoma, infection, end-stage renal disease, and autoimmune disorders such as rheumatoid arthritis and Sjögren syndrome.^{185–190} The use of drugs such as procainamide, hydralazine, chlorpromazine, quinidine, isoniazid, and methyldopa, which are also associated with the development of SLE, has been implicated as well.^{191–196} LA activity associated with the IgG or IgM isotype may be detected months after drugs such as procainamide have been discontinued.^{195,197} Although thromboembolic events have been described in several patients who developed LA in association with procainamide, reports of such events appear to be uncommon.^{194,195,198–200} One study reported moderate to high APLA in 21% (14 of 66) of cardiac patients taking procainamide compared with no APLA elevations in 30 control cardiac patients. Overall, a frequent history of noncardiac thrombi was reported in the procainamide group (25.7%); however, no association with APLA positivity was found.²⁰¹

Among patients given chlorpromazine, APLA (detected as LA or in ELISA) developed in approximately 40%; this may occur as early as 3 months after initiation of treatment.^{192,193} One group reported that phenothiazines other than chlorpromazine did not induce LA; however, LA that occurred in patients on chlorpromazine persisted when patients were switched to other phenothiazines.¹⁹² Other investigators have found APLA in 27% of patients given phenothiazines other than chlorpromazine.¹⁹³ Patients with detected APLA may express it as LA only or as ACA, which is usually of the IgM isotype.^{191,193} Additional frequent immunologic abnormalities include positive tests for antinuclear antibodies (ANA)^{192,202} and antibodies to native DNA.²⁰² It is unlikely that LA positiv-

ity is a risk factor for thrombosis in these patients. Only 3 of 96 patients given phenothiazines who had LA or ACA developed thrombosis over a median 5-year follow-up period.¹⁹¹

Another significant drawback to many anticardiolipin immunoassays is that they cannot distinguish “autoimmune” from “infectious” antibodies. Because the latter are not typically associated with thrombotic complications, these immunoassays as a group may underrate the true value of anticardiolipin antibodies for diagnosing APLS.

In a study of patients with hepatitis C, 37.3% of infected patients were positive for ACA (IgG and/or IgM); however, mean titers of each isotype were significantly lower than those found in the APLS group. Furthermore, no thrombotic events occurred among ACA-positive patients with hepatitis C.²⁰³ In a study of patients with APLS with and without HCV, the HCV-positive group had a lower frequency of the more typical features of APLS, such as peripheral thrombosis and neurologic features, and a higher prevalence of atypical features of APLS, such as myocardial infarction and intra-abdominal thrombotic events.²⁰⁴

In the autoimmune variety of hepatitis (AIH), elevated levels of ACA were reported in 51% of patients with AIH. ACA were associated with more severe hepatic disease, including cirrhosis, with no APLS symptoms.²⁰⁵ Patients with end-stage renal disease are also known to have elevated ACA (up to 1 in 5 patients tested).^{186,190,206} Although no thrombotic risks are associated with these patients post transplantation, high titers of ACA may represent a risk factor for thrombosis.²⁰⁶

Elevated levels of ACA have been measured in patients with human immunodeficiency virus (HIV),^{207–211} Lyme disease,²¹² ornithosis, adenovirus, rubella, and chickenpox, as well as in those who have undergone vaccination against smallpox,²¹³ or who have syphilis. The presence of LA does not appear to increase the risk for thrombosis in these patients. In a study by McNally and colleagues,²¹⁴ sera from 114 patients with infection (syphilis, tuberculosis, and *Klebsiella* infection) were tested for IgG antibodies against β_2 GPI and cardiolipin. All patients tested negative for antibodies to β_2 GPI; the incidence of ACA in these patients according to their underlying infection was as follows: tuberculosis, 6%; *Klebsiella* infection, 5%; and syphilis, 64%. Similar results were found in HIV-positive patients who had low titers of β_2 GPI antibodies after findings of elevated ACA.^{208,215} In a retrospective analysis of 28 men with AIDS, 90% of whom were receiving highly active antiretroviral therapy (HAART), only two tested positive for LA, although 34 thrombotic events occurred during a 42-month period.²¹⁶ Although thrombotic complications may occur in patients with HIV,²¹⁷ specifically in patients with CD4 counts <200/mm³, APLS with its manifestations is infrequent in patients with HIV, and APLA screening is not warranted.^{210,215,218,219}

Treatment of Patients Who Have the Antiphospholipid Syndrome

Major issues in the management of patients with APLS and thrombosis are the intensity of anticoagulation that should be given, the duration of anticoagulation, and the appropriate method of monitoring. One goal is to reduce other

risk factors for thrombosis, such as uncontrolled hypertension, smoking, and use of oral contraceptives.²²⁰ Treatment of asymptomatic patients with LA or with moderate or high titers of ACA in the absence of SLE is controversial (see later). Some studies recommend protection with low-dose aspirin (80 mg/day) and/or hydroxychloroquine supplemented by anticoagulation with warfarin or heparin at times of increased risk for thrombosis.²²⁰ It is anticipated that clinical trials currently in progress will address this issue.^{221,222} At the present time, screening for APLA in asymptomatic patients should be discouraged.

Patients with SLE who have persistent elevation of ACA have a significantly increased odds ratio (5.4) for a peripheral thromboembolic event compared with those patients with SLE who test positive for APLA on only one occasion.⁹² The Hopkins Lupus Cohort study, which prospectively followed 380 patients, found that 20 years after SLE had been diagnosed, patients with LA had a 50% chance of having had a VTE.¹³⁷ These patients should be considered on an individual basis for prophylactic anticoagulation.

Patients with APLS may present with an initial thrombotic event followed by additional thrombotic episodes, leading to severe morbidity or death if adequate anticoagulation is not promptly achieved.²²³ Thus, before any other interventions such as placement of vena caval filters or plasmapheresis are considered, consultants should be convinced that anticoagulation has been maximized. This may also require consideration of thrombolytic therapy for select patients.

Oral Anticoagulation Intensity

The optimum intensity of oral anticoagulation therapy has been a matter of debate since it became clear that anticoagulation was effective in the prevention of recurrent thrombosis in patients with APLS.^{224–228} This subject has recently been systematically reviewed.²²⁹ Two of these studies retrospectively studied 70²²⁶ and 147²²⁷ patients with APLS and found a lower rate of recurrent thrombosis when the INR was maintained at higher than 3.0. Obvious concerns are that the high-intensity regimen (INR >3.0) has been shown to be associated with a high risk (20%) of clinically important bleeding in a series of 3 randomized trials^{230–232} and in more recent studies.²³³ A more recent retrospective study,²²⁴ which included 66 patients with APLS treated to a target INR of 3.5, concluded that risks of intracranial and fatal bleeding were similar to those in groups of patients treated to standard anticoagulation target INR (2.0 to 3.0).

To help resolve this debate, the Warfarin in the Anti-Phospholipid Syndrome (WAPS) trial from Europe²³⁴ and a similar Canadian study²³⁵ conducted independent prospective trials of 114 and 109 patients with APLS, respectively. Patients were randomly assigned to receive warfarin with a target INR of 2.0 to 3.0 (moderate intensity) or 3.0 to 4.0 (high intensity), to determine whether high-intensity anticoagulation was superior in preventing recurrent thrombosis without significantly increasing bleeding risks. In the Canadian study, recurrent thrombosis occurred in 2 of 58 patients (3.4%) given conventional therapy and in 6 of 56 patients (10.7%) who received high-intensity therapy (hazard ratio, 3.1; 95% confidence interval [CI], 0.6 to 15). The WAPS trial reported similar

results, with recurrent thrombosis in 3 of 55 patients (5.5%) given conventional therapy and in 6 of 54 patients (11.1%) receiving high-intensity warfarin treatment (hazard ratio, 1.97; 95% CI, 0.49 to 7.89). Although investigators in both studies recognized the limited statistical power, both concluded that high-intensity warfarin therapy was not superior to standard treatment for thromboprophylaxis. The WAPS study reported an increased rate of minor hemorrhagic complications in the high-intensity treatment cohort. On the basis of these results, the 2004 edition of the *ACCP Conference on Antithrombotic and Thrombolytic Therapy: Evidence-Based Guidelines*²¹¹ recommends a target INR of 2.0 to 3.0 in the treatment of patients with DVT and APLS; however, some patients may warrant higher INR targets or treatment with low molecular weight heparin to prevent recurrent thromboses.

In considering treatment recommendations based on these trials, the consultant should be aware of limitations that were noted.^{236,237} Most of the patients included in these two studies had VTE. Furthermore, neither trial reached the expected sample size, and both excluded large numbers of patients because they had already experienced recurrent events while receiving oral anticoagulation treatment. The Canadian study also excluded patients with recent strokes, so that 76% of participants in this study had previous VTE only. Additionally, patients in the high-intensity group from this study had subtherapeutic levels of anticoagulation 43% of the time, which contributed to 6 of 8 recurrent thrombotic events in which INR was between 2.0 and 3.0.

Although this debate focuses on the intensity of warfarin treatment in the prevention of venous and arterial thrombosis, the situation may be different for patients with APLA and stroke. Recent results of the prospective, randomized, double-blinded APASS and WARSS trials indicate that aspirin is as efficacious as warfarin given at standard intensity in the prevention of recurrent thrombo-occlusive events, regardless of APLA status.²³ The Sydney criteria for the diagnosis of APLS⁸⁴ include retesting after 12 weeks for an APLS diagnosis; the APASS study recommended APLA testing only at the time of stroke. The high rate of APLA in this cohort (41%) likely indicated transient APLA—not definitive APLS. If the outcome had remained unchanged (i.e., with use of the Sydney criteria), these results would have been more conclusive.

This discussion focuses on the desire of clinicians to minimize levels of anticoagulation and associated risks of bleeding. However, published data have not shown increased frequency or severity of bleeding complications in patients with APLS treated with oral anticoagulation, even with high-intensity therapy (INR >3.0), when compared with cohorts of patients treated to a lower target INR.^{224,234,235} Perhaps this may be partially attributed to the lower average age of this population compared with patients with atrial fibrillation.²³⁷

Case reports have been published describing patients with cerebral APLS who develop symptoms such as headache, dysarthria, confusion, and so forth, when their target INR of high-intensity treatment drops to below 3.0.^{238,239} Given that cerebrovascular disease in APLS has greater morbidity and mortality with a greater number of disabling sequelae, many would argue that the risks of bleeding are outweighed by the potential benefits in patients with APLS.

Figure 19-7 Recommended oral anticoagulation intensity for first antiphospholipid syndrome (APLS) thromboembolic events and recurrent thromboemboli that are refractory to conventional anticoagulant therapy.

Patients with APLS and VTE are at high risk for recurrence if anticoagulation is discontinued after a first episode of VTE.^{226,227,240} In a retrospective study of patients with primary and secondary APLS, discontinuation of warfarin resulted in recurrent thrombotic events in nearly 70% over a median follow-up of 82 months (range, 12 to 258 months); rate of recurrence was highest during the first 6 months. In contrast, continuation of warfarin (INR, 2.5 to 4.0) resulted in a 90% rate of freedom from thrombosis over a 5-year period.²²⁷

In summary, it is recommended that patients with APLS should be treated with standard-intensity anticoagulation after the first VTE, and with high-intensity anticoagulation after a recurrence of VTE while on standard therapy. High-intensity anticoagulation is recommended after the first arterial event, provided that no contraindications are noted (Fig. 19-7). Furthermore, anticoagulation should be continued on an indefinite basis as long as the risks and consequences of bleeding are lower than the risk of thrombosis.²²⁴ Low-dose aspirin may be added, depending on whether or not thrombotic manifestations such as superficial thrombophlebitis persist.

Monitoring of the International Normalized Ratio

One report has described variability in INR results for patients with LA who also had an increased baseline PT; this may result in underusage of warfarin.²⁴¹ However, two other studies have shown that the INR is not artificially prolonged in such patients.^{242,243} In one study, variability in INR measurements was greatly increased when a recombinant tissue factor was used as the PT reagent.²⁴²

Secondary Therapies

Several studies have indicated that the antimalarial drug hydroxychloroquine (HCQ) might reduce platelet aggregation and blood viscosity.^{244,245} In the 1980s and early 1990s, retrospective studies reported that patients with SLE who were treated with HCQ had fewer thrombotic events.^{246,247} In a mouse model, APLA-induced thrombus formation was reduced in animals given HCQ.^{59,248} These findings and proposed thrombotic mechanisms were supported by an in vitro study that showed that HCQ suppressed the activation of platelets by APLA primed with low doses of thrombin agonist receptor peptide (TRAP).²⁴⁹ A longitudinal cohort study was performed in 272 Chinese patients with APLS who were administered the following treatments: hydroxychloroquine (152), warfarin (17), prednisolone (203), azathioprine (112), and aspirin (38). Investigators reported fewer thrombotic complications among

patients taking HCQ compared with those not receiving the drug (odds ratio, 0.17; 95% CI, 0.07 to 0.44; $P < .0001$).²⁵⁰

Unresolved issues of HCQ administration involve adverse effects and safety during pregnancy. For the latter, HCQ is recommended only for malaria, but recent studies support its continued use in patients with SLE because no increase in the rate of birth defects has been reported.²⁵¹ In other populations, the primary serious adverse effect involves retinal pigment epithelium from HCQ, which can lead to retinal toxicity. Debate has focused on the optimum ophthalmologic screening, the reversibility of early effects, and whether a risk even exists at low HCQ doses.^{252,253} Overall, it is conceivable that HCQ may be of benefit in patients who cannot tolerate high-intensity oral anticoagulation.

The role of corticosteroids or plasmapheresis has not been well documented for patients with APLS without CAPS or pregnancy. Case reports from transplant recipients have suggested that immunosuppressive regimens are inadequate for providing protection against thrombotic events, including graft rejection, in patients with APLS.^{190,254} Even at the risk of bleeding, many prefer continued anticoagulation perioperatively rather than risking allograft thrombosis.¹⁹⁰ Immunosuppressive treatments are generally reserved for patients with CAPS. Asherson and colleagues^{108–110,255} have documented more than 230 cases since 1992 and recommends intravenous (IV) heparin and corticosteroids as first-line treatments. Intravenous immunoglobulin (IVIg)^{108,255} and plasmapheresis^{108–110} are appropriate second-line therapies for removal of pathogenic antibodies. Fresh frozen plasma may also be added to help replenish diminished clotting factors. Third-line therapies such as cyclophosphamide have not been very effective. However, because trigger factors such as infection have been identified in 20% of Asherson's cases, any infection must be rigorously treated with appropriate antibiotics. As mentioned previously, rituximab (anti-CD20), which is used to treat B-cell non-Hodgkin lymphoma, has been used with some success in the treatment of patients with autoimmune disorders; subsequent declines in APLA titers have been noted.^{158,160,256}

Despite seemingly adequate therapy, the mortality rate for CAPS is approximately 50%.¹⁰⁸ Once recovery ensues, patients usually have a stable course but require continued anticoagulant therapy. One paper reported that 66% of patients with CAPS who survived the initial catastrophic event remained symptom free over an average follow-up of 63 months. However, 26% of survivors experienced additional APLS-related events—not of the CAPS variety.²⁵⁷

COST CONTAINMENT AND MEDICAL-LEGAL ASPECTS OF TESTING FOR LUPUS ANTICOAGULANT AND ANTIPHOSPHOLIPID SYNDROME

LA testing is ordered primarily (1) to evaluate an unexplained (and unexpected) prolongation of the PTT, and (2) to assess an individual who presents with clinical features suggestive of APLS. In the first case, in which testing is done for prolonged PTT, at the present time, if the patient does not have a history of thrombosis, embolism, pregnancy loss, or SLE, the finding of LA does not mean that additional tests for ACA or cofactors must be performed. It is recommended that patients

who have prolonged PTT and LA should also be tested for appropriate coagulation factor activities, especially if they are about to undergo a major invasive procedure.

Plasma from patients may show artefactually low levels of factor VIII activity if a potent LA is present. However, in this case, the factor VIII activity will increase as the plasma sample is diluted, thus reducing the potency of the LA effect and allowing more adequate assessment of factor activity. For patients with a specific factor VIII-inhibiting antibody, factor VIII activity is truly decreased, and the same level of activity is achieved at all plasma dilutions in the test system. Testing factor activities provide a safeguard against missing a possible factor deficiency. For example, a factor VIII deficiency due to an inhibitor antibody might be present in combination with LA, or an antibody against factor VIII might be mistakenly described as an LA. At a clinical level, patients with true factor VIII deficiency will have bleeds, especially ecchymoses, whereas those patients with artefactual factor VIII deficiency will not.

Laboratory confirmation of APLS is expensive and should be performed thoroughly once initiated. If testing commences for the evaluation of possible APLS, at least two different tests for LA should be performed, as well as the ELISA for ACA, to establish or exclude the diagnosis. If a test is positive, then the evaluation should be repeated in 12 weeks to confirm the persistence of the abnormality. Once the diagnosis has been established, no evidence currently suggests that subsequent changes in APLA positivity would modify treatment. Patients with a history of thrombosis who are given a diagnosis of APLS are at high risk for recurrent thrombotic events. These patients may be candidates for the use of home monitoring devices to measure INR, given that continued and adequate anticoagulation is essential (see Chapter 40).

The consultant should be wary of ordering tests in the absence of clinical manifestations or without a history of SLE because of the uncertainty of treatment based exclusively on a positive APLA assay. Administration of warfarin places patients at risk for bleeding; withholding treatment makes patients at pre-APLS stage more susceptible to thrombosis.

CONCLUSION

Although the pathophysiology of APLS has not been established, it is clear that APLS is a major cause of human morbidity and mortality, both of which are ameliorated by anticoagulant therapy. The specificity of autoantibodies is now becoming better defined, and diagnostic testing and criteria for establishing the diagnosis have been greatly refined. A major issue is that of treatment²²⁸; the optimum type, duration, and intensity of anticoagulation still have not been completely specified, but with the development of cooperative international clinical trials, some of these issues may soon be resolved. APLS is a disorder that encompasses many specialties: hematology, neurology, obstetrics, and rheumatology. Thus, the approach to patients with this disorder must be truly interdisciplinary.
