The evolution of cardiovascular medicine is based soundly on a progressively advanced understanding of vascular biology, hemostasis, and thrombosis. Indeed, pharmacotherapies for the prevention and treatment of coronary atherothrombosis are the end results of several productive decades of investigation, highlighted by strong collaborative efforts between the cardiology, pathology, and hematology communities in response to several fundamental observations and clinically relevant questions that include the following: (1) What are the anatomic and physiologic effects of atherosclerotic vascular disease? (2) How does atherosclerosis influence the complex and delicate balance between thrombosis and thromboresistance? (3) Can intrinsic thrombotic potential in atherosclerotic vascular disease be selectively modulated pharmacologically without compromising protective hemostasis (and patient safety)? and (4) Are untapped opportunities available for translating an existing knowledge of congenital hemostatic disorders into the development of new and widely affordable treatments?

This chapter is designed to summarize the rapid evolution of cardiovascular medicine with particular emphasis on antithrombotic therapy, its evidence-based use in routine clinical practice, and the practical management of drug-induced hemostatic impairment.

SCOPE OF THE PROBLEM

According to recent studies conducted by the American Heart Association,¹ an estimated 1.2 million Americans will develop angina pectoris or experience an acute myocardial infarction in 2007. The cost of cardiovascular disease and stroke, projected to exceed \$403 billion, includes the direct costs of health care expenditures (e.g., physicians and other health care professionals, hospitals, rehabilitation programs and nursing home services, medications, and home health care) and indirect costs (loss of productivity as a result of morbidity and mortality).

HISTORICAL PERSPECTIVES IN CARDIOVASCULAR MEDICINE

The rapid transformation of fluid blood to a gel-like substance (clot) has been a topic of great interest since

the days of Plato and Aristotle.^{2,3} However, it was not until the early 18th century that blood clotting was recognized as a complex mechanism that could be used to stem blood loss after vascular injury.⁴

The microscope played a pivotal role in enhancing understanding of coagulation. In the mid-17th century, Marcello Malpighi separated the individual components of a blood clot into fibers, cells, and serum.⁵ Fibers were later found to be derived from a plasma precursor (fibrinogen) and were given the name fibrin.⁶ Further advances in the mid-19th century included the recognition of an enzyme (later called thrombin) that was capable of coagulating fibrinogen.⁷

In the latter half of the 19th century, the scientific community began to appreciate that thrombin could not be a constituent of normal plasma (otherwise, clotting would occur continuously and at random).⁸ This fundamental construct was vital to an understanding of coagulation, and it remains in situations in which inactive precursors are activated precisely where and when they are needed only to be quickly neutralized where and when they are not needed. It also introduced the possibility that blood contained many, if not all, of the necessary elements for intravascular coagulation and served as the template for the theory of intrinsic coagulation.

Coagulation Cascade: Past and Present

Scientists have long known that blood coagulates soon after it comes into contact with a foreign surface, and that some surfaces are more likely to precipitate clotting than others. This provided an early foundation for the study of hereditary disorders of coagulation.^{9,10} Our understanding of extrinsic coagulation followed the pioneering work of several preeminent scientists,^{11–14} all of whom described blood coagulation after infusion of tissue suspensions (tissue factor, thromboplastin). A revised theory of extrinsic coagulation suggested that exposed tissue surfaces (from damaged blood vessels) were capable of stimulating blood clot formation. Later discoveries included information on the direct contributions of calcium, phospholipid, and other essential components of the prothrombinase complex (factors Va, Xa) to blood coagulation.

Platelets

The contribution of platelets to blood coagulation can be traced back to Alfred Donné, who in 1842, described

circulating globules seen under the newly developed microscope lens.¹⁵ Despite his astute observations, the clinical importance of platelets in hemostasis was not appreciated until the end of the 19th century, when William Osler at age 25 first reported platelet aggregation,¹⁶ and Hayem proposed platelet plugs as a critical means of stemming blood loss after tissue injury.¹⁷

Electron microscopy subsequently provided direct evidence that platelets adhered to damaged blood vessels and could subsequently become “activated” by one or more biochemical (e.g., adenosine diphosphate, epinephrine, thrombin) or mechanical (e.g., shear stress) stimuli.

Fibrinolysis

The inability of blood to remain clotted after death was observed as early as the days of Hippocrates.¹⁸ Pioneering work near the end of the 18th century described the process of fibrinolysis and a mechanism whereby a circulating precursor (plasminogen) generated an active enzyme (plasmin) capable of degrading clotted blood.^{19,20}

The era of fibrinolysis began with the work of Gratia, who observed in 1921 that clots could be dissolved by staphylococcal extracts.²¹ Tillett and Garner²² later found that bacteria-free filtrates of β -hemolytic streptococci contained a substance (streptokinase) capable of dissolving blood clots. Soon thereafter, the groundbreaking work of Sol Sherry and coworkers²³ highlighted the potential use of fibrinolytics in treating humans with thrombotic disorders.

Early Developments in Cardiovascular Medicine

Aspirin

The potential role of aspirin in the prevention and treatment of cardiovascular disease had been recognized by clinicians for decades; however, landmark observations made during the Second International Study of Infarct Survival (ISIS-2)²⁴ placed antithrombotic therapy with aspirin at the forefront of current management strategies for acute myocardial infarction (MI).

Myocardial Reperfusion

The recognition that sudden, complete coronary arterial occlusion was the proximate cause of acute ST segment elevation MI, coupled with the work of Reimer and Jennings highlighting the “wavefront phenomenon” of myocardial necrosis and the “time-dependent” effects of coronary perfusion in limiting myocardial damage, paved the way for pharmacologic (fibrinolysis) and mechanical (coronary angioplasty, bypass grafting) reperfusion strategies that currently represent standards of care.^{25–27} Efforts at the national level designed to reduce MI-related mortality have focused on education, early recognition, and prompt evidence-based intervention.

Low Molecular Weight Heparin

The contribution of coagulation proteins, including factor Xa and thrombin, to cardiovascular thrombosis stimulated interest in safe and effective antagonists. In acute coronary syndromes, as well as in acute venous thromboembolism, low molecular weight heparin (LMWH) has shown great promise and is rapidly becoming an accepted therapy.^{27–32}

Platelet Glycoprotein-IIb/IIIa Receptor Antagonists

Given that the platelet is a pivotal component of arterial thrombosis, and that a congenital disorder is characterized by the absence of a platelet surface receptor and a bleeding tendency (Glanzmann thrombasthenia), platelet glycoprotein (GP)-IIb/IIIa receptor antagonists have, through intense investigation, become a mainstay in the treatment of high-risk patients with acute coronary syndromes and those undergoing percutaneous coronary intervention.³³

Combination Pharmacotherapy

Astute observations made over the past two decades regarding thrombosis, fibrinolysis, anticoagulants, and platelet antagonists will undoubtedly lead to their combined administration in clinical practice.³⁴ This effort will focus on establishing doses that will attenuate thrombosis while maintaining vascular and hemostatic integrity.

CORONARY ATHEROGENESIS

After monocytes attach to the morphologically intact but dysfunctional vascular endothelium, a net directed migration of cells occurs through the endothelium to the subendothelial space, where they undergo differentiation. The phenomenon of “monocyte activation and differentiation” plays an important role in atherosclerosis, particularly with regard to plaque remodeling and lesion progression. This complex process proceeds through at least two mechanisms: (1) the generation of reactive oxygen species (free radicals); and (2) the phenotypic modulation and expression of a scavenger receptor or family of receptors. The chemical modification of low-density lipoprotein (LDL) results in its avid uptake by blood monocytes (now considered tissue macrophages) and subsequent transformation to foam cells. The specific receptor responsible for the uptake of modified LDL fails to effectively downregulate; as a result, a substantial amount of intracellular LDL cholesterol accumulates. When the influx of LDL particles exceeds the capacity of the macrophage scavenger receptors to remove them from the intracellular space, oxidized LDL particles accumulate within the arterial intima; this event irreversibly injures endothelial cells, smooth muscle cells, and macrophages. Disruption of relatively fragile macrophage-derived foam cells ensues, leading to the release of cytotoxic lipid material into the extracellular compartment of the intima and the formation of a cholesteryl ester-rich atheromatous core.^{35–37}

CORONARY ARTERIAL THROMBOGENESIS

The clinical expression of atherosclerotic vascular disease is determined by pathologic events that lead to coronary thrombosis (or thromboembolism). In this regard, two factors are key: (1) the propensity of plaques to rupture, and (2) the thrombogenicity of exposed plaque components.

The morphologic characteristics of plaques destined to rupture have been determined through careful analyses of lesions that exhibit disruption. Observational studies of necropsy and atherectomy tissue samples have shown

Figure 20-1 Vulnerable plaques are characterized by a prominent lipid core, a thin fibrous cap, and an active state of inflammation. In contrast, nonvulnerable plaques are fibrotic and are less likely to disrupt (provoking thrombosis).

convincingly that plaques associated with intraluminal thrombosis are rich in extracellular lipid, and that the lipid core of these “vulnerable or rupture-prone” plaques occupies a large proportion of the overall plaque volume. The degree of cross-sectional narrowing of the vessel lumen is typically less than 50%.³⁸ In addition to a large lipid core, vulnerable plaques are characterized by a thin fibrous cap and high macrophage density.³⁹ Whereas most individuals with atherosclerotic coronary artery disease exhibit a diversity of plaque types, most have a preponderance of one specific type (vulnerable or nonvulnerable) (Fig. 20-1). The genetic and acquired determinants of plaque type and predisposition to disruption are subjects of intense investigation.

Under normal physiologic conditions, cellular blood components interact with the vessel wall for the purpose of normal vascular repair. Exposure of circulating blood to disrupted or dysfunctional surfaces initiates a series of complex yet orderly steps that give rise to the rapid deposition of platelets, erythrocytes, leukocytes, and insoluble fibrin, which, if poorly regulated, establishes a mechanical barrier to blood flow (Fig. 20-2).

Thrombosis that occurs within the arterial circulatory system involves platelets and fibrin in a relatively small, tightly packed network. By contrast, venous thrombi consist of a more loosely woven, larger network of erythrocytes, leukocytes, and fibrin.

The process of vascular thrombosis, particularly in the coronary arterial bed, is dynamic, with clot formation and dissolution occurring almost simultaneously. The overall

extent of thrombosis and ensuing circulatory compromise is therefore determined by the predominant force that “shifts” the delicate balance in one direction or another. If local thrombotic stimuli exceed the vessel’s own thromboresistant capacity, thrombosis will occur. If, on the other hand, the stimulus is not particularly strong and the intrinsic defenses are intact, clot formation of clinical importance is unlikely. In many circumstances, systemic factors contribute to or “magnify” local prothrombotic factors, shifting the balance toward thrombosis.

Overall, the site, size, and composition of thrombi forming within the heart and arterial circulatory system are determined by the following:

- Alterations in blood flow
- Thrombogenicity of vascular and endocardial surfaces
- Concentration and reactivity of plasma cellular components
- Preservation and functional capability of physiologic protective mechanisms.

Platelet Deposition

Platelets that attach to disrupted vascular surfaces adhere, activate, and aggregate to form a rapidly enlarging platelet mass. Under physiologic conditions, this represents the first or primary step in hemostasis. In contrast, pathologic thrombosis is characterized by a poorly regulated response to vessel wall injury that escalates to the point of circulatory compromise.

The biology of platelet deposition involves several processes:

- Platelet attachment to collagen or exposed surface adhesive proteins
- Platelet activation and intracellular signaling
- Expression of platelet receptors for adhesive proteins
- Platelet aggregation
- Platelet recruitment mediated by thrombin, thromboxane A₂, and adenosine diphosphate, as well as other biochemical agents.

Activation of Coagulation Factors

Thrombin is generated rapidly in response to vascular injury. It also plays a central role in platelet recruitment and formation of an insoluble fibrin network. The thrombotic process is localized, amplified, and modulated by a series

Figure 20-2 The initiating step in arterial thrombosis is both tissue factor and platelet dependent.

Figure 20-3 The growth phase of arterial thrombosis is coagulation protein dependent.

of biochemical reactions that are driven by the reversible binding of circulating proteins (coagulation factors) to damaged vascular cells, elements of exposed subendothelial connective tissue (especially collagen), platelets (which also express receptor sites for coagulation factors), and macrophages. These events lead to an assembly of enzyme complexes that increase local concentrations of procoagulant material; in this way, a relatively minor initiating stimulus can be greatly amplified to yield a thrombus (Fig. 20-3).

Fibrin Formation

The final phase of arterial thrombosis involves the generation of a stable fibrin network, which provides a structural scaffold for circulating cellular elements and vascular remodeling. In this pivotal process, thrombin cleaves two peptides, fibrinopeptide A and fibrinopeptide B, to form fibrin monomers, which, in turn, polymerize to form soluble fibrin strands. Orderly assembly and branching and lateral association of fibrillar strands follow, terminating with factor XIII-mediated covalent crosslinking to form a cohesive fibrin network or a mature thrombus.

ESTABLISHING A UNIFIED PLATFORM FOR THE DIAGNOSIS AND MANAGEMENT OF CARDIOVASCULAR THROMBOTIC DISORDERS

Cell-Based Model of Coagulation

The “waterfall” or “cascade” model of coagulation, proposed almost simultaneously by McFarland, Davie, and Ratnoff,⁴⁰ provided a biochemical basis for an understanding of coagulation reactions. However, its separation into intrinsic and extrinsic pathways and the omission of platelets (and other cellular elements) from the overall working framework limited the model’s direct application to in vivo hemostasis and thrombosis.

Initiation takes place on cells or specialized particles (monocytes, macrophages, neutrophils, activated endothelial cells, smooth muscle cells, apoptotic cells, platelet particles, circulating vesicles) that bear the transmembrane glycoprotein

tissue factor (TF).⁴¹ Exposed tissue factor binds and fully activates coagulation factor VII (FVIIa); subsequently, both FIX and FX are activated (which then activates FV), generating a small amount of thrombin from prothrombin (FII). In the amplification phase that follows, the small amount of generated thrombin activates platelets (causing release of α -granule contents) and factors V, XI, and VIII (cleaving the latter from von Willebrand factor [VWF]). FXIa generates additional FIXa (whose action is accelerated by FVIIIa), whereas FVa accelerates the enzymatic action of FXa. During the propagation phase, FIXa binds to activated platelets, causing further activation of FX. Complexing of FXa and FVa to membrane surfaces leads to a “burst” of thrombin generation. Major hemostatic roles of thrombin include conversion of soluble fibrinogen to a tri-dimensional network of fibrin (coagulation), activation of platelets through at least two different G-protein-coupled protease-activated receptors (PARs),⁴² and nonphysiologic constriction of structurally or functionally impaired (at the endothelial level) vessels.

Thrombus growth in rapidly flowing blood is closely linked to the presence of soluble and surface-bound VWF.⁴³ This multimeric protein not only acts as a bridge for the initial tethering and translocation of platelets to subendothelial collagen (via platelet GP-Ib), it also induces the surface expression of platelet GP-IIb/IIIa (also referred to as $\alpha_{IIb}\beta_3$), leading to stable adhesion and subsequent aggregation of activated platelets.⁴⁴

Idling Coagulation: Setting the Stage for Thrombotic Events

Traditional models of coagulation, although they underemphasize the functionality of cellular surfaces for determining biochemical and physiologic events, have underscored the importance of enzymatic amplification potential as a mechanism for “responsive coagulation.”⁴⁵ “Idling coagulation systems,” characterized by low circulating levels of active clotting proteins, require constant regulation to prevent activation thresholds from being reached. Under normal circumstances, modest stimuli do not activate coagulation, whereas strong stimuli provoke a full response. The “idling model” emphasizes the regulatory properties of enzymatic cofactors, such as

FVIII- and FIXa-mediated generation of FXa. The FIXa: VIIIa complex loses its activity through FVIIIa decay and inactivation by activated protein C. TF is regulated by tissue factor pathway inhibitor (TFPI). Thus, the functionality of both pivotal coagulation proteases is determined by their cofactors (and their varying inhibition kinetics).

Blood-Borne Propensity for Arterial, Venous, and Microcirculatory Thromboses

TF exists at high concentrations within atherosclerotic plaques, activated endothelial cells, fibroblasts, macrophages, and vascular smooth muscle cells; however, TF antigen can also be identified within the circulating blood of patients with coronary artery disease.⁴⁶ TF-containing neutrophils, monocytes, and microparticles circulating in peripheral blood can be delivered to sites of vascular injury, where they contribute directly to the initiation of thrombus formation and its subsequent propagation.^{41,43} Adherent leukocytes enhance fibrin deposition through CD18-dependent capture of fibrin protofibrils that are flowing in plasma and through FXII-dependent thrombin generation. They also activate platelets, providing a fully functional platform for fibrin formation under flow conditions.⁴⁷

A blood-borne propensity for thrombosis that is not entirely dependent on vascular disease provides a biologic explanation for the observed disparities between “degree” or “extent” of atherosclerosis and risk of thrombotic events in the arterial vascular bed,⁴⁸ as well as for the propensity toward venous thrombosis noted with malignancy and after trauma or major surgery.

Cellular Interfacing in Cardiovascular Thrombosis

Several traditionally held views that warrant reconsideration for a fuller appreciation of the dynamic environment that characterizes vascular bed-specific thrombosis include

the following: (1) circulating platelets adhere to exposed subendothelial tissues solely to prevent bleeding, (2) leukocytes respond to inflammatory stimuli solely to facilitate tissue repair, and (3) these two preceding events occur independently of one another.⁴³

An emerging model of importance for an understanding of atherosclerosis and other thrombosis-prone disease states involves platelet and leukocyte adhesion to activated endothelial cells, leukocyte adhesion to activated platelets, and multicellular interactions among platelets, leukocytes, and endothelial cells on vascular surfaces.⁴³ Each event is supported by the engagement of cell surface receptors (selectins and integrins) with soluble or membrane-anchored ligands, which include VWF, fibrinogen, collagen, fibronectin, P-selectin, CD40 ligand, GP-Ib-IX-V complex, GP-IIb/IIIa, GP- $\alpha_2\beta_1$ and GP- $\alpha_5\beta_1$, P-selectin, GP ligand-1, neutrophil Mac-1, CD40, and a variety of other intercellular and vascular adhesion molecules.⁴⁹

ATHEROTHROMBOTIC VASCULAR DISEASE: CLINICAL PRACTICE

Management of atherothrombotic vascular disease involving the coronary, cerebral, and peripheral vascular beds includes an increasingly complex array of fibrinolytic and antithrombotic agents. It is important for the hematology consultant to become familiar with these commonly used agents, along with their mechanisms of action, pharmacology, and potential impact on hemostasis (Table 20-1, Figs. 20-4 and 20-5).^{50,51}

PLATELET-DIRECTED THERAPIES

The pivotal role of platelets in atherothrombosis provides a biology-based platform for targeted approaches to drug development, clinical trial testing, and employment in patient care.⁵²

Table 20-1 Antithrombotic Agents Used in Treating Atherothrombotic Cardiovascular Disease

Oral Antiplatelet Therapy

Aspirin	Initial dose of 162–325 mg nonenteric formulation is followed by 75–325 mg/day of an enteric formulation.
Clopidogrel (Plavix)	75 mg/day; a loading dose of 4–8 tablets (300–600 mg) is frequently administered to initiate treatment.
Ticlopidine (Ticlid)	250 mg twice daily; a loading dose of 500 mg can be used when rapid onset of inhibition is required; assessment of platelet and white cell counts during treatment is required. Rarely used now.

Parenteral Anticoagulants

Dalteparin (Fragmin)	120 IU per kilogram subcutaneously every 12 hours (maximum, 10,000 IU twice daily)
Enoxaparin (Lovenox)	1 mg per kilogram SC every 12 hours; the first dose may be preceded by a 30-mg IV bolus (in ST segment elevation myocardial infarction [MI])
Heparin, unfractionated (UFH)	Bolus 60–70 U per kilogram (maximum, 4000 U) IV followed by infusion of 12–15 U/kg/hr (maximum, 1000 U per hour) titrated to partial thromboplastin time (PTT) 1.5–2.5 $\times$ that of control
Fondaparinux (Arixtra)	2.5 mg subcutaneously every 24 hours

Intravenous Antiplatelet Therapy

Abciximab (ReoPro)	0.25 mg per kilogram bolus followed by infusion of 0.125 μ g/kg/min (maximum, 10 μ g per minute) for 12 hours
Eptifibatide (Integrilin)	180 μ g per kilogram bolus $\times$ 2 followed by infusion of 2.0 μ g/kg/min for 18 hours*
Tirofiban (Aggrastat)	0.4 μ g per kilogram $\times$ 30 min, followed by infusion of 0.1 μ g/kg/min for 12–24 hours

*Different dose regimens were tested in recent clinical trials before percutaneous interventions were provided.

Figure 20-4 Management algorithm for patients with non-ST-segment elevation acute coronary syndrome (ACS). This information is based on Class I recommendations from the American College of Cardiology (ACC)/American Heart Association (AHA) 2002 Guideline Update for the Management of Patients with Unstable Angina and Non-ST-Segment-Elevation Myocardial Infarction. (From Braunwald E, Antman EM, Beasley JW, et al: ACC/AHA guidelines for the management of patients with unstable angina and non-ST-segment elevation myocardial infarction: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients with Unstable Angina). J Am Coll Cardiol 2000;36:970–1062. Reproduced with permission.)

Figure 20-5 Management pathway for patients at high risk for myocardial infarction and cardiovascular death. An early aggressive approach is recommended for most patients. (From Boden WE, Pepine CJ: Introduction to "optimizing management of non-ST-segment elevation acute coronary syndromes." Harmonizing advances in mechanical and pharmacologic intervention. J Am Coll Cardiol 41:S1–S6, 2003. Reproduced with permission.)

Aspirin

Aspirin has been available for more than a century and represents a mainstay in the prevention and treatment of vascular events, including stroke, MI, peripheral vascular occlusion, and sudden death. Accordingly, most patients with atherosclerotic vascular disease will receive aspirin.

Mechanism of Action

Aspirin irreversibly acetylates cyclo-oxygenase (COX), impairing prostaglandin metabolism and synthesis of thromboxane A_2 (TxA_2). As a result, platelet aggregation in response to collagen, adenosine diphosphate (ADP), thrombin (in low concentrations), and TxA_2 is attenuated⁵³ (Fig. 20-6).

Because aspirin more selectively inhibits COX-1 activity (found predominantly in platelets) than COX-2 activity

(expressed in tissues after an inflammatory stimulus), its ability to prevent platelet aggregation is achieved with relatively low doses, in contrast to the drug's potential anti-inflammatory effects, which require much higher doses.⁵⁴

Pharmacokinetics

Aspirin is rapidly absorbed in the proximal gastrointestinal (GI) tract (stomach, duodenum), achieving peak serum levels within 15 to 20 minutes and significant platelet inhibition within 40 to 60 minutes. Enteric-coated preparations are less well absorbed, causing an observed delay in peak serum levels and significant platelet inhibition after 60 and 90 minutes, respectively. The antiplatelet effect occurs even before acetylsalicylic acid is detectable in peripheral blood, probably as a result of platelet exposure in the portal circulation.

Figure 20-6 Aspirin is a potent, irreversible inhibitor of platelet cyclo-oxygenase (COX-1), reducing platelet activation and recruitment.

The plasma concentration of aspirin decays rapidly with a circulating half-life of approximately 20 minutes. Despite the drug's rapid clearance, platelet inhibition persists for the life span of the platelet (7 ± 2 days) because of aspirin's irreversible inactivation of COX-1. Because 10% of circulating platelets are replaced every 24 hours, platelet activity (primary hemostasis) returns toward normal ($\geq 50\%$ of normal activity) within 5 to 6 days of the last aspirin dose.⁵⁵

Adverse Effects

The adverse effect profile of aspirin in general and its associated risk for major hemorrhage in particular are determined largely by dose, duration of administration, associated structural defects (peptic ulcer disease, *Helicobacter pylori* infection), hemostatic abnormalities (inherited, acquired), and concomitant use of other antithrombotic agents.

Enteric coating of aspirin has *not* been shown to reduce the likelihood of adverse effects involving the GI tract. Patients with gastric erosions or peptic ulcer disease who require treat-

ment with aspirin should concomitantly receive a proton pump inhibitor to minimize the risk of hemorrhage.

Aspirin Administration in Clinical Practice

The beneficial effects of aspirin are determined largely by the absolute risk of vascular events. Patients at low risk (healthy individuals without predisposing risk factors for vascular disease) derive minimal benefit, and those at high risk (unstable angina, prior MI, stroke) derive considerable benefit.⁵⁶ A risk-based approach to aspirin administration is recommended to avoid subjecting individuals who are unlikely to benefit from aspirin administration to its potential adverse effects.

PRIMARY PREVENTION OF VASCULAR EVENTS

Aspirin was tested in three primary prevention trials involving more than 30,000 healthy individuals.^{57–59} Collective available data show strongly that aspirin reduces the risk of vascular events (Fig. 20-7).⁵⁴

The Women's Health Study⁶⁰ randomly assigned 39,876 healthy women 45 years of age or older to receive 100 mg of aspirin on alternate days or placebo and followed them for 10 years. A 9% risk reduction in major cardiovascular events was reported among those who took aspirin. Women older than 65 years of age enjoyed the greatest benefit. The greatest overall impact was noted in the reduction of ischemic stroke (relative risk, 0.76). GI bleeding requiring transfusion was increased by 40% with aspirin.

SECONDARY PREVENTION OF VASCULAR EVENTS

The Antiplatelet Trialists' Collaboration,⁶¹ which is based on a comprehensive evaluation of existing data, provides convincing evidence in support of aspirin's ability to prevent vascular events (vascular death, nonfatal MI, nonfatal stroke) in a wide variety of high-risk patients; overall, antiplatelet therapy (predominantly aspirin therapy) reduces nonfatal MI by one third, nonfatal stroke by one third, and vascular death by one quarter.

Figure 20-7 Benefits and risks of low-dose aspirin in primary prevention trials. The numbers of vascular events avoided and episodes of major bleeding caused per 1000 patients treated with aspirin per year are plotted from the results of individual placebo-controlled trials of aspirin in different patient populations characterized by varying degrees of cardiovascular risk, as noted on the abscissa. WHS denotes Women's Health Study; PHS, Physicians' Health Study; PPP, Primary Prevention Project; HOT, Hypertension Optimal Treatment study; BOT, British Doctors Trial; TPT, Thrombosis Prevention Trial; SAPAT, Swedish Angina Pectoris Aspirin Trial. (From Patrono C: Aspirin as an antiplatelet drug. *N Engl J Med* 330:1287–1294, 1994. Reproduced with permission.)

Aspirin Dosing

An updated meta-analysis of the Antiplatelet Trialists' Collaboration provides additional information on the effects of various doses of aspirin.⁶¹ Overall, among 3570 patients included in three trials that directly compared doses of aspirin (≥ 75 mg daily vs < 75 mg daily), significant differences in vascular events were observed (two trials compared 75 to 325 mg aspirin daily vs < 75 mg daily, and one trial compared 500 to 1500 mg aspirin daily vs < 75 mg daily). With direct and indirect comparisons of aspirin dose, the proportionate reduction in vascular events was 19% with 500 to 1500 mg daily, 26% with 160 to 325 mg daily, and 32% with 75 to 150 mg daily. The effects of antiplatelet drugs other than aspirin (vs control) were assessed in 166 trials that included 81,731 patients. Indirect comparisons provided no clear evidence of differences in reduction of serious vascular events (χ^2 for heterogeneity between any aspirin regimen and other antiplatelet drugs = 10.8; ns). Most direct comparisons assessed the effects of replacing aspirin with another antiplatelet agent.

The effect of adding another antiplatelet drug to an aspirin regimen (vs aspirin alone) has been assessed in 43 trials that included 39,205 patients. Overall, a 15% reduction in serious vascular events was observed ($P = .0001$). The benefits of adding an intravenous GP-IIb/IIIa receptor antagonist to aspirin were particularly evident among patients undergoing percutaneous coronary intervention (PCI).

Coronary Artery Bypass Grafting

More than 20 clinical trials have been conducted to determine the effectiveness of antiplatelet therapy in preventing early (≥ 10 days) and late (6 to 12 months) saphenous vein graft occlusion. Ten of these trials investigated aspirin in doses ranging from 100 mg to 975 mg daily. Several also assessed patients who were given internal mammary coronary bypass grafts.^{62,63}

Considered collectively, and aided by the Antiplatelet Trialists' Collaboration overview, data reveal improved saphenous vein graft patency with aspirin administration. Although a direct benefit for internal mammary bypass grafts has not been established, treatment is recommended on the basis of the common coexistence of vascular disease (and the risk for thrombotic events).

Transient Ischemic Attacks/Stroke

The International Stroke Trial and the Chinese Acute Stroke Trial^{64,65} evaluated the efficacy and safety of aspirin given at a daily dose of 300 mg and 160 mg, respectively, to nearly 40,000 patients with acute ischemic stroke. Treatment was initiated within 48 hours of symptom onset and continued for 2 to 4 weeks. Combined results suggest an absolute benefit of 10 fewer deaths or nonfatal strokes per 1000 patients during the first month of treatment. The risk of hemorrhagic stroke was also increased (two excess events per 1000 patients).

Long-term aspirin administration reduces the likelihood of stroke (and other vascular events) in patients with transient ischemic attacks (TIAs) and completed minor strokes. Although debate is ongoing within the neurology com-

munity regarding the optimal daily dose, 75 to 325 mg is considered an acceptable range.

The combination of aspirin (25 mg) and extended-release dipyridamole (200 mg twice daily) is more effective than aspirin alone for the prevention of stroke. Patients who are unable to take aspirin should be treated with clopidogrel (75 mg daily).

Percutaneous Coronary Intervention

PCI, including standard balloon angioplasty, rotational atherectomy, and laser angioplasty, with or without stent placement, is associated with vascular injury, atheromatous plaque disruption, platelet activation, and, at times, coronary thromboembolism. Several studies performed over the past decade have documented reduced periprocedural complications, including thrombus formation, abrupt closure, and MI, with antiplatelet therapy given prior to PCI (relative risk reduction [RRR], 60%).^{66,67}

The current recommendations for PCI include aspirin (325 mg daily) for the secondary prevention of cardiovascular events; for patients unable to tolerate aspirin, pretreatment with clopidogrel (300 mg) followed by 75 mg daily is suggested.

Aspirin Response Variability

The ability of aspirin to inhibit platelet aggregation is discordant and is seen in upward of 30% of individuals who are nonresponders or who exhibit a paradoxical increase in platelet aggregation and activation after high-dose (325 mg) administration.

The ability of aspirin to reduce COX activity varies considerably among individuals; in addition, atherosclerosis is associated with increased TF level expression caused by cytokine-mediated induction. It is important to recognize that an acquired form of aspirin resistance may be induced by concomitant administration of ibuprofen.⁶⁸ Lastly, genetic polymorphisms and resulting gene expression of COX and thromboxane synthase may limit the effectiveness of aspirin.⁶⁹

A classification scheme for aspirin resistance has been proposed^{70,71} that includes three categories: type 1, inhibition of platelet TxA_2 formation in vitro but not in vivo; type 2, inability of aspirin to inhibit TxA_2 formation in vitro and in vivo; and type 3, TxA_2 -independent platelet activation (pseudoresistance).

Clinical Impact of Aspirin Resistance and Failure

Despite its proved benefit, aspirin therapy has inherent limitations; the existing literature supports the conclusion that patients who are receiving aspirin can and do experience cardiovascular events. Accordingly, ongoing investigations are designed to better define aspirin failure and aspirin resistance.^{72,73} A recent editorial calls into question both the existence and significance of aspirin resistance.^{73a}

Clopidogrel

Clopidogrel, a thienopyridine derivative, is a platelet antagonist that is several times more potent than ticlopidine, yet is associated with fewer adverse effects. The important role of ADP-mediated platelet activation and aggregation in

atherothrombotic vascular disease has made the surface P2Y₁₂ receptor a favored target.

In Vitro and Ex Vivo Effects on Platelets

Clopidogrel, a prodrug, is extensively metabolized in the liver to an active compound with a plasma elimination half-life of 7.7 ± 2.3 hours. Dose-dependent inhibition of ADP-mediated platelet aggregation is observed several hours after a single oral dose of clopidogrel is given, with more significant inhibition achieved with loading doses (≥ 300 mg). A 600-mg oral loading dose achieves effective platelet inhibition in 2 to 3 hours. Repeated doses of 75 mg clopidogrel per day inhibit aggregation, and steady state is reached between days 3 and 7. At steady state, the average inhibition to ADP is between 40% and 60%.

Clopidogrel selectively inhibits the binding of ADP to its platelet receptor (P2Y₁₂) and the subsequent G-protein-linked mobilization of intracellular calcium and activation of the GP-IIb/IIIa complex.⁷⁴

Absorption

Clopidogrel is rapidly absorbed after oral administration, with peak plasma levels of the predominant circulating metabolite occurring approximately 60 minutes later.

Safety

Available information suggests that clopidogrel offers safety advantages over ticlopidine, particularly with regard to bone marrow suppression and other hematologic abnormalities. Although thrombotic thrombocytopenic purpura (TTP) has been reported with clopidogrel,⁷⁵ its occurrence (11 cases per 3 million patients treated) is rare, and it has not been reported in randomized clinical trials performed to date.

Clinical Experience

The well-documented benefits derived from platelet-directed therapy among patients with atherosclerotic vascular disease, coupled with a worrisome adverse effect profile associated with ticlopidine, have fostered the rapid development of clopidogrel as a potential alternative to existing therapies. The Clopidogrel versus Aspirin in Patients at Risk for Ischemic Events (CAPRIE) Study⁷⁶ was designed to test the hypothesis that clopidogrel (75 mg daily) would reduce vascular events in high-risk patients by approximately 15% compared with aspirin (325 mg daily). The study population consisted of patients with atherosclerotic vascular disease manifested as recent ischemic stroke, recent MI, or symptomatic peripheral arterial occlusive disease. A total of 19,185 patients were enrolled in the international trial. Mean duration of follow-up was 1.91 years. Patients treated with clopidogrel (by intention-to-treat analysis) had a 5.32% annual risk of ischemic stroke, MI, or vascular death compared with 5.83% among aspirin-treated patients (RRR, 8.7%; 95% confidence interval [CI], 0.3 to 16.5; $P = .043$).

Although CAPRIE was not empowered to identify differences between specific subsets, for patients experiencing a stroke, the average event rate per year was 5.03% in the clopidogrel group compared with 4.84% in the aspirin group (relative risk increase, 3.7%; $P = .66$). In contrast, patients with peripheral vascular disease experienced a 3.71% annual event rate with clopidogrel and a 4.86% rate with aspirin (RRR, 23.8%; $P = .002$).

No major differences in safety were noted between treatment groups; however, a greater proportion of patients receiving aspirin had the study drug permanently discontinued because of GI hemorrhage, indigestion, nausea, or vomiting. Approximately 1 of every 1000 patients treated with clopidogrel experienced neutropenia (<1200 per microliter) (similar to outcomes with aspirin treatment).

In the CAPRIE study,⁷⁷ all-cause mortality, vascular death, MI, stroke, and rehospitalization were determined for 1480 patients who had previously undergone bypass grafting. Those randomly assigned to clopidogrel had a 31.2% RRR in events compared with those given aspirin treatment. Considering the composite end point used in the main CAPRIE trial—vascular death, MI, or ischemic stroke—a 36.3% relative reduction was seen with clopidogrel (5.8% per year) compared with aspirin (9.1% per year) ($P = .004$).

The trial design employed in CAPRIE could not provide an answer to the important question of dual platelet inhibition (aspirin plus clopidogrel). Accordingly, an additional study was undertaken. The CHARISMA (Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance) study⁷⁸ randomly assigned 15,603 patients with clinically evident cardiovascular disease or multiple risk factors to receive low-dose aspirin. Patients were subsequently followed for a median of 28 months, with a primary efficacy end point of the composite of MI, stroke, or clopidogrel plus aspirin reported in 7.3% with placebo plus aspirin (relative risk, 0.93; 95% CI, 0.83 to 1.05; $P = .22$). Respective rates for the principal secondary end point, which included hospitalization for ischemic events, were 16.7% and 17.9% (relative risk, 0.92; 95% CI, 0.86 to 0.995; $P = .04$). Rates of severe bleeding were 1.7% and 1.3%, respectively. Among patients with clinically evident atherothrombosis, the secondary end point primarily occurred in 6.9% of patients receiving combination therapy versus 7.9% of those given aspirin alone (relative risk, 0.88; 96% CI, 0.77 to 0.998; $P = .046$). In contrast, patients with multiple risk factors (but not documented atherothrombotic disease) experienced a primary end point rate of 6.6% with combination therapy versus 5.5% with aspirin alone (relative risk, 1.2; 95% CI, 0.91 to 1.59; $P = .20$). The rate of death from cardiovascular causes was higher with combination therapy (3.9% vs 2.2%; $P = .01$).

On the basis of available data from CHARISMA, one could conclude that the combination of clopidogrel plus aspirin is not more effective than aspirin alone in reducing the rate of MI, stroke, or death from cardiovascular causes among patients with stable cardiovascular disease or multiple cardiovascular risk factors. In contrast, benefit has been noted among individuals with symptomatic atherothrombotic disease. However, this observation requires further investigation.

Percutaneous Coronary Stenting

A multicenter, randomized, controlled trial, Clopidogrel Plus ASA vs Ticlopidine Plus ASA in Stent Patients Study (CLASSICS),⁷⁹ included 1020 patients undergoing coronary stent placement who received aspirin (325 mg once daily) plus ticlopidine (250 mg twice daily), aspirin plus clopidogrel (75 mg daily), or aspirin plus front-loaded clopidogrel (300 mg as an initial dose followed by 75 mg once daily). Treatment was continued for 28 days after stent placement. Intravenous GP-IIb/IIIa antagonists were not

administered to patients enrolled in the trial. The primary safety end point was a composite of neutropenia, thrombocytopenia, bleeding, and drug discontinuation for adverse events (noncardiac). The secondary efficacy end point was a composite of MI, target vessel revascularization, and cardiovascular death.

The primary end point occurred in 9.1% of ticlopidine-treated patients, 6.3% of clopidogrel-treated patients (75 mg), and 2.9% of front-loaded clopidogrel-treated patients. Early drug discontinuation was reported in 8.2%, 5.1%, and 2.0% of patients, respectively. The most commonly observed adverse effects that prompted drug discontinuation were allergic reactions, GI distress, and skin rash. Secondary cardiovascular end points were reached by 0.9%, 1.5%, and 1.3% of patients, respectively.

The importance of adequate platelet inhibition preceding and following PCI (with stenting) was confirmed in the Percutaneous Coronary Intervention–Clopidogrel in Unstable Angina to Prevent Recurrent Events (PCI-CURE) study.⁸⁰ A total of 2658 patients undergoing PCI were randomly assigned to double-blind treatment with clopidogrel or placebo (aspirin alone) for, on average, 6 days before the procedure followed by 4 weeks of open-label thienopyridine (after which the study drug was resumed for 8 months). The primary end point (cardiovascular death, MI, or urgent target vessel revascularization within 30 days) was reached in 4.5% of clopidogrel-treated patients and 6.4% of placebo-treated patients (30% RRR). Long-term administration of clopidogrel was associated with a lower rate of death, MI, or any revascularization and no increase in bleeding complications.

Intracoronary radiation therapy is an available method for treating patients with in-stent restenosis; however, late total occlusion and thrombosis are serious complications, with rates approaching 10% to 15%. Accumulating evidence suggests that prolonged treatment with clopidogrel and aspirin (≥ 6 months) is more effective in preventing late thrombosis when compared with an abbreviated course (1 month).⁸¹

At least 3 months of clopidogrel treatment are recommended after a sirolimus (Cypher; Johnson and Johnson, New Brunswick, NJ) drug-eluting stent (DES) is placed; 6 months are required for those receiving a paclitaxel (Taxus; Boston Scientific, Natick, MA) DES.

Acute Coronary Syndromes

The benefits of therapy with aspirin and clopidogrel were considered in the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial.⁸² A total of 12,562 patients experiencing an acute coronary syndrome without ST segment elevation received clopidogrel (300 mg immediately, 75 mg daily) plus aspirin (75 to 325 mg daily) or aspirin alone for 3 to 12 months. The composite of death, MI, or stroke occurred in 9.3% and 11.4% of patients, respectively (RRR, 20%). In hospital refractory ischemia, congestive heart failure and revascularization procedures were also less likely to occur in clopidogrel-treated patients. Although a greater risk of major hemorrhage was observed with combination therapy (3.7% vs 2.7%; relative risk, 1.38), life-threatening bleeding and hemorrhagic stroke occurred at similar rates across groups.

Pretreatment with Clopidogrel and Clinical Benefit

The CREDO (Clopidogrel for the Reduction of Events During Observation) trial⁸³ evaluated the long-term benefit (12 months) of treatment with clopidogrel after PCI, as well as the potential benefits of initiating clopidogrel with a preprocedural loading dose (in addition to aspirin therapy). A total of 2116 patients scheduled for elective PCI were randomly assigned to receive clopidogrel (300 mg) or placebo beginning 3 to 24 hours before PCI. All patients were given aspirin (325 mg). More than two thirds of patients had experienced a recent MI or unstable angina as an indication for PCI. Thereafter, all patients received clopidogrel (75 mg daily) through day 28. From day 29 through 12 months, patients in the loading dose group were given clopidogrel (75 mg daily) or placebo. Both groups continued to receive standard therapy, including aspirin (81 to 325 mg daily). Pretreatment with clopidogrel was associated with a nonsignificant 18.5% RRR for the combined end point of death, MI, or target vessel revascularization at 28 days. It is biologically conceivable that larger loading doses (600 mg) or more prolonged pretreatment may yield enhanced benefit.

Two recent trials—the Clopidogrel as Adjunctive Reperfusion Therapy (CLARITY)-Thrombolysis in Myocardial Infarction (TIMI) 28 trial⁸⁴ and the Clopidogrel and Metoprolol in Myocardial Infarction Trial/Second Chinese Cardiac Study (COMMIT/CCS-2-Clopidogrel)⁸⁵—suggested a role for clopidogrel in the treatment of patients with ST segment elevation MI. In the CLARITY-TIMI 28 trial, the addition of clopidogrel (300 mg loading dose, then 75 mg per day) to a regimen of aspirin plus thrombolysis before angiography improved the patency rate of the infarct-related artery and reduced ischemic complications in patients who presented within 12 hours of onset of ST segment elevation MI. The primary efficacy end point (a composite of infarct-related arterial occlusion [TIMI grade 0/1], death, or recurrent MI before angiography) was reduced by 36% with clopidogrel, and effects were driven predominantly by a reduction in arterial occlusion; no increase in major bleeding or intracranial hemorrhage occurred.

Approach to Patients Receiving Long-Term Clopidogrel Therapy

Two series of 20 consecutive patients with coronary artery disease received 600 mg of clopidogrel. The first patient group had not received clopidogrel previously; the second group had taken 75 mg previously for at least 30 days. Six hours after loading, platelet aggregation in response to ADP (20 μ mol per liter) was inhibited by 31% and 51%, respectively. Clopidogrel inhibited ADP-induced expression of platelet GP-IIb/IIIa and P-selectin receptors as well.⁸⁶

Clopidogrel Response Variability

Although the incidence rates and mechanism likely differ, clopidogrel and aspirin resistance may have cumulative clinical relevance. Available evidence suggests that clopidogrel resistance ($<10\%$ inhibition of ADP-mediated platelet

aggregation) occurs in upward of 20% of patients after a 300 mg loading dose⁸⁷ and may reveal patients who are at risk for coronary arterial events.⁸⁸ Patients with heightened platelet activity (prior to treatment) appear to be at greatest risk for clopidogrel resistance.⁸⁹ Although the mechanism(s) underlying clopidogrel resistance have not been elucidated, alterations in cytochrome P450 metabolism activity (conversion of prodrug to active drug), polymorphisms of the platelet ADP receptor, or individual differences in post-receptor signaling pathways are likely contributors.

PLATELET GLYCOPROTEIN (GP)-IIb/IIIa RECEPTOR ANTAGONISTS

The GP-IIb/IIIa receptor (totaling 50,000 to 70,000 copies per platelet) represents a common pathway for platelet aggregation in response to a wide variety of biochemical and mechanical stimuli. Accordingly, it represents an attractive target for pharmacologic inhibition that can be applied to patients with acute coronary syndromes.

INTRAVENOUS PLATELET GP-IIb/IIIa RECEPTOR ANTAGONISTS

The evolution of GP-IIb/IIIa receptor antagonists began with murine monoclonal antibodies and recently has focused on small peptide or nonpeptide molecules that have structural similarities to fibrinogen. Three intravenous GP-IIb/IIIa receptor antagonists have been approved by the U. S. Food and Drug Administration: abciximab (ReoPro; Centocor, Leiden, The Netherlands), tirofiban (Aggrastat; Merck & Co., Inc., Whitehouse Station, NJ), and eptifibatide (Integrilin; Millennium Pharmaceuticals, Inc., Cambridge, Mass.).

ABCIXIMAB

Abciximab (ReoPro) is the Fab fragment of the chimeric human-murine monoclonal antibody c7E3.

Pharmacokinetics

After an intravenous bolus has been administered, free plasma concentrations of abciximab decrease rapidly with an initial half-life of less than 10 minutes and a second-phase half-life of 30 minutes, representing rapid binding to the platelet GP-IIb/IIIa receptor. Abciximab remains in the circulation for 10 or more days in the platelet-bound state.

Pharmacodynamics

Intravenous administration of abciximab in doses ranging from 0.15 mg/kg to 0.3 mg/kg produces a rapid dose-dependent inhibition of platelet aggregation in response to ADP. At the highest dose, 80% of platelet GP-IIb/IIIa receptors are occupied within 120 minutes, and platelet aggregation, even in response to 20 mM ADP, is inhibited

completely. Sustained inhibition is achieved with prolonged infusions (12 to 24 hours), and low-level receptor blockade is present for up to 10 days after cessation of the infusion; however, platelet pharmacodynamics during infusions beyond 24 hours has not been fully characterized. Platelet aggregation in response to 5 mM ADP returns to more than 50% of baseline within 24 hours of drug cessation.

Clinical Experience

In nearly 2100 patients undergoing balloon coronary angioplasty or atherectomy who were at high risk for ischemic (thrombotic) complications, abciximab (0.25 mg per kilogram bolus) followed by 12-hour continuous infusion (10 µg per minute) reduced by 35% the occurrence of death or MI or the need for an urgent intervention (repeat angioplasty, stent placement, balloon pump insertion, or bypass grafting).⁹⁰ At 6 months,⁹¹ the absolute difference between patients with a major ischemic event and those with elective revascularization was 8.1% among patients who received abciximab (bolus plus infusion) compared with those administered placebo (35.1% vs 27.0%; 23% relative reduction). At 3 years,⁹² the composite end point occurred in 41.1% of those who were given an abciximab bolus plus infusion, 47.4% of those receiving an abciximab bolus *only*, and, 47.2% of those to whom placebo was given.

The Evaluation in PTCA (Percutaneous Transluminal Coronary Angioplasty) to Improve Long-term Outcome with Abciximab GPIIb/IIIa Blockade (EPILOG) study⁹³ included 2792 patients who were undergoing elective or urgent percutaneous coronary revascularization and who received abciximab with standard, weight-adjusted unfractionated heparin (UFH; initial bolus, 100 U per kilogram; target activated clotting time [ACT] ≥300 seconds) or placebo along with standard-dose, weight-adjusted heparin. At 30 days, the composite event rate was observed in high-risk and low-risk patients.

The c7E3 Fab Antiplatelet Therapy in Unstable Refractory Angina (CAPTURE) study⁹⁴ was designed to investigate whether abciximab, infused for 18 to 24 hours prior to coronary angioplasty, could improve outcomes in patients with refractory (myocardial ischemia despite nitrates, heparin, and aspirin) unstable angina. A total of 1265 patients were randomly assigned to abciximab or placebo. Within 30 days, the primary end point (death, MI, urgent revascularization) occurred in 11.3% of abciximab-treated patients and 15.9% of placebo-treated patients ($n = 0.012$). The rate of MI was lower *before* and *during* coronary interventions with abciximab administration.

Patients who participated in the Global Use of Strategies to Open Occluded Arteries in Acute Coronary Syndromes trial (GUSTO-IV-ACS)⁹⁵ had chest pain and ST segment depression or elevated troponin levels. They were randomly assigned to receive placebo, abciximab for 24 hours, or abciximab for 48 hours with recommended avoidance of revascularization during the initial 48 hours. Neither abciximab group fared better than the placebo group with respect to death or MI at 30 days. In addition, early mortality rates were higher with prolonged abciximab infusion, suggesting a prothrombotic (or other adverse) effect.

The Abciximab Before Direct Angioplasty and Stenting in Myocardial Infarction Regarding Acute and Long-Term

Follow-Up (ADMIRAL) trial⁹⁶ included 300 patients with PCI (plus stenting) who were infused with abciximab or placebo. At 30 days, a composite of death, reinfarction, or urgent revascularization (target vessel) had occurred in 6% of abciximab-treated and 14.6% of placebo-treated patients; at 6 months, the corresponding figures were 7.4% and 15.9%, respectively. Early administration of abciximab improved coronary patency before stenting, success rates of the procedures, and rate of patency 6 months after the procedure.

In the GUSTO V study,⁹⁷ 16,588 patients with acute ST segment elevation MI received reteplase (standard dose) or half-dose reteplase plus abciximab. Although 30-day mortality rates did not differ significantly, fewer nonfatal ischemic complications of MI occurred with reteplase plus abciximab compared with reteplase alone. Intracranial hemorrhage rates did not differ between treatments; however, moderate to severe bleeding was more likely with combined therapy, and patients >75 years of age were at increased risk for hemorrhagic stroke (odds ratio [OR], 1.91). All patients in GUSTO V received UFH and aspirin therapy.

TIROFIBAN

Tirofiban (Aggrastat; Merck & Co., Inc., Whitehouse Station, NJ), a tyrosine derivative with a molecular weight of 495 kD, is a nonpeptide inhibitor (peptidomimetic) of the platelet GP-IIb/IIIa receptor.

Pharmacodynamics

Tirofiban, like other nonpeptides, mimics the geometric, stereotactic, and charge characteristics of the RDG sequence (of fibrinogen), thus interfering with platelet aggregation.

Three doses of tirofiban were evaluated in a phase 1 study of patients undergoing coronary angioplasty who received one of three regimens intravenously with a bolus dose of 5, 10, or 15 μg per kilogram and a continuous (16- to 24-hour) infusion of 0.05, 0.10, or 0.15 $\mu\text{g}/\text{kg}/\text{min}$.⁹⁸ Dose-dependent inhibition of ex vivo platelet aggregation was observed within minutes of bolus administration and was sustained during the continuous infusion.

Clinical Experience

The Randomized Efficacy Study of Tirofiban Outcomes and Restenosis (RESTORE) trial⁹⁹ was a randomized, double-blind, placebo-controlled trial of tirofiban in patients with ACS who were undergoing PCI.

Patients ($n = 2139$) received tirofiban as a 10 μg per kilogram intravenous bolus over a 3-minute period and a continuous IV infusion of 0.15 $\mu\text{g}/\text{kg}/\text{min}$ over 36 hours. All patients received UFH and aspirin therapy. The primary composite end point (death, MI, angioplasty, failure requiring bypass surgery or unplanned stent placement, recurrent ischemia requiring repeat angioplasty) at 30 days was reduced from 12.2% in the placebo group to 10.3% in the tirofiban group (16% relative reduction).

The Platelet Receptor Inhibition in Ischemic Syndrome Management (PRISM) trial¹⁰⁰ included 3231 patients with non-ST segment elevation acute coronary syndrome (ACS).

All patients received aspirin and were randomly assigned to treatment with UFH or tirofiban, given as a loading dose of 0.6 $\mu\text{g}/\text{kg}/\text{min}$ over 30 minutes followed by a maintenance infusion of 0.15 $\mu\text{g}/\text{kg}/\text{min}$ for 48 hours (angiography/revascularization was discouraged during the infusion period). The primary composite end point (death, MI, refractory ischemia) at 48 hours was attained in 3.8% of tirofiban-treated patients and 5.6% of placebo (aspirin/heparin)-treated patients (risk reduction, 33%). Benefit was maintained but overall was more modest at 7 and 30 days.

The PRISM in Patients Limited by Unstable Signs and Symptoms (PLUS) trial¹⁰¹ included 1915 patients with non-ST segment elevation ACS who were treated with aspirin and UFH and were subsequently randomly assigned to tirofiban (0.4 $\mu\text{g}/\text{kg}/\text{min}$ IV for 30 min, then 0.1 $\mu\text{g}/\text{kg}/\text{min}$ for a minimum of 48 hours and a maximum of 108 hours) or placebo (UFH). Angiography and revascularization were performed at the discretion of the treating physician. Tirofiban-treated patients had a lower composite event rate over 7 days than the placebo group (12.9% vs 17.9%; risk reduction, 34%). This benefit was mainly due to a reduced incidence of MI (47% risk reduction) and refractory ischemia (30% risk reduction). Benefit was maintained at 30 days (22% risk reduction in composite event rate) and at 6 months. The trial originally included a tirofiban alone arm (no heparin) that was dropped because of excess mortality at 7 days.

The importance of early PCI among patients with non-ST segment elevation ACS was underscored in the Treat Angina With Aggrastat and Determine Cost of Therapy With an Invasive or Conservative Strategy (TACTICS)—Thrombolysis in Myocardial Infarction (TIMI) 18 trial,¹⁰² as was the benefit of aggressive pharmacologic therapy (GP-IIb/IIIa receptor antagonist) in combination with PCI for patients at greatest risk for adverse ischemic outcomes (prior MI, ST segment changes, elevated cardiac biomarkers).

EPTIFIBATIDE

Eptifibatide (Integrilin; Millennium Pharmaceuticals, Inc., Cambridge, Mass) is a nonimmunogenic cyclic heptapeptide with an active pharmacophore that is derived from the structure of barbourin, a platelet GP-IIb/IIIa inhibitor from the venom of the southeastern pigmy rattlesnake.¹⁰³

Pharmacokinetics

The plasma half-life of eptifibatide is 10 to 15 minutes, and clearance is predominantly renal (75%) and to a lesser degree hepatic (25%). The antiplatelet effect has a rapid onset of action and causes a rapid decline in activity.

Pharmacodynamics

In a pilot study of PCI, patients were randomly assigned to one of four eptifibatide dosing schedules: 180 $\mu\text{g}/\text{kg}$ bolus, 1 $\mu\text{g}/\text{kg}/\text{min}$ infusion; 135 $\mu\text{g}/\text{kg}$ IV bolus, 0.5 $\mu\text{g}/\text{kg}/\text{min}$ IV infusion; 90 $\mu\text{g}/\text{kg}$ IV bolus, 0.75 $\mu\text{g}/\text{kg}/\text{min}$ IV infusion; and 135 $\mu\text{g}/\text{kg}$ IV bolus, 0.75 $\mu\text{g}/\text{kg}/\text{min}$ IV infusion.

All patients received aspirin and UFH and were continued on study drug for 18 to 24 hours. The two highest bolus doses produced >80% inhibition of ADP-mediated

platelet aggregation within 15 minutes of administration in most patients (>75%). A constant IV infusion of 0.75 µg/kg/min maintained the antiplatelet effect, whereas an infusion of 0.50 µg/kg/min IV allowed gradual recovery of platelet function. In all dosing groups, platelet function returned to >50% of normal from baseline within 4 hours of termination of the infusion.¹⁰⁴

Clinical Experience

The Integrilin to Minimize Platelet Aggregation and Coronary Thrombosis (IMPACT-II) trial¹⁰⁵ enrolled 4010 patients undergoing elective, urgent, or emergent PCI. Patients were assigned to placebo, a IV bolus of 135 µg per kilogram eptifibatide followed by an IV infusion of 0.5 µg/kg/min for 20 to 24 hours, or a 135 µg per kilogram bolus followed by a 0.75 µg/kg/min infusion. Within 30 days, the composite end point (death, MI, unplanned revascularization, stent placement for abrupt closure) occurred in 11.4%, 9.2%, and 9.9% of patients, respectively. Although the benefits of treatment were maintained at 6 months, differences between groups were not statistically significant.

The IMPACT-After Myocardial Infarction (AMI) Study¹⁰⁶ was designed to determine the effects of eptifibatide on coronary arterial patency when used adjunctively with tissue plasminogen activity (tPA). A total of 132 patients with MI received tPA, heparin, and aspirin and were randomly assigned to receive a bolus and continuous infusion of one of six eptifibatide doses or placebo. Doses ranged from 36 to 180 µg per kilogram (bolus) to 0.2 to 0.75 µg/kg/min (IV infusion). Study drug was started within 24 hours. The highest-dose eptifibatide groups had more complete reperfusion (TIMI grade 3 flow) and shorter mean time to ST segment recovery than placebo-treated patients. The composite clinical event rate (death, reinfarction, revascularization, heart failure, hypertension, stroke) was relatively high in all groups: 44.8% in eptifibatide-treated patients and 41.8% in placebo-treated patients.

The Platelet Glycoprotein IIb/IIIa in Unstable Angina Receptor Suppression Using Integrilin Therapy (PURSUIT) trial¹⁰⁷ included patients with non-ST segment elevation ACS with symptoms within 24 hours and electrocardiographic changes within 12 hours (of ischemia). A total of 10,948 patients were randomly assigned to eptifibatide, 180 µg per kilogram bolus plus 1.3 µg/kg/min infusion; eptifibatide, 180 µg per kilogram IV bolus plus 2.0 µg/kg/min IV infusion; or placebo for up to 3 days (in addition

to UFH [in most patients] and aspirin). The 30-day event rate of death or nonfatal MI was 14.2% with eptifibatide and 15.7% with placebo (1.5% absolute reduction). Reduction in MI or death (composite) with eptifibatide was observed at later time points.

The Enhanced Suppression of the Platelet GPIIb/IIIa Receptor with Integrilin Trial (ESPRIT) was designed to test the hypothesis that a minimum threshold of 80% GP-IIb/IIIa receptor blockade was required for benefit.¹⁰⁸ A total of 2064 patients received eptifibatide (180 µg per kilogram IV boluses [$\times 3$] 10 minutes apart, followed by continuous IV infusion of 2.0 µg/kg/min for 18 to 24 hours) or placebo prior to PCI. The trial was terminated early for efficacy because patients receiving eptifibatide had a 4.0% absolute reduction in death, MI, urgent target vessel revascularization, or “bail out” GP-IIb/IIIa antagonist use within 48 hours compared with placebo. Major events were significantly fewer at 30 days as well.

GP-IIb/IIIa RECEPTOR ANTAGONISTS AND DIABETES MELLITUS

Patients with diabetes mellitus experience increased mortality in the setting of ACS. A meta-analysis of diabetic populations enrolled in six large-scale clinical trials ($n = 6458$ patients) revealed a 30-day mortality reduction with GP-IIb/IIIa receptor antagonist use from 6.2% to 4.6% (26% RRR). Benefit was greatest in those undergoing PCI (70% RRR).¹⁰⁸

Agent-Specific Characteristics

Although considered collectively as GP-IIb/IIIa receptor antagonists, abciximab, tirofiban, and eptifibatide differ at several levels, including molecular weight, binding characteristics, route of clearance, plasma half-life, platelet-bound and biologic half-lives, potential reversibility, approved indications, and use in clinical practice (Table 20-2).

The duration of platelet inhibition after drug discontinuation and the potential for reversing pharmacologic effects are particularly important properties in cases of emergent surgery and major hemorrhagic complications. In general, return of platelet function toward a physiologic state ($\geq 50\%$ inhibition) occurs within 4 hours after cessation of tirofiban and eptifibatide treatment. In contrast, cessation of 12 hours are required for return of platelet function following abciximab (Fig. 20-8). Some of the

Table 20-2 Agent-Specific Characteristics for Glycoprotein (GP)-IIb/IIIa Receptor Antagonists

Characteristic	Abciximab	Eptifibatide	Tirofiban
Type	Antibody	Peptide	Nonpeptide
Molecular weight, daltons	≈50,000	≈800	≈500
Platelet-bound half-life	Long	Short	Short
Plasma half-life	Short (min)	Extended (2 hr)	Extended (2 hr)
Drug/GP-IIb/IIIa receptor ratio	1.5–2.0	250–2500	>250
50% return of platelet function (without transfusion)	12 hr	≈4 hr	≈4 hr
Route of clearance	RES	Renal/hepatic	Renal
Dose adjustment required with renal insufficiency	No	Yes	Yes

RES, reticuloendothelial system.

Figure 20-8 The biologic half-life for the small molecule glycoprotein (GP)-IIb/IIIa antagonists (eptifibatide, tirofiban) is relatively brief compared with that for abciximab. The vertical scale is percentage of normal platelet function.

delayed return of physiologic platelet function that occurs after abciximab termination may be counterbalanced by its low free plasma concentrations and drug/receptor ratio. These properties are consistent with the observed return of hemostatic potential after platelet transfusion (and may also limit platelet-inhibiting potential with marked mobilization of GP-IIb/IIIa receptors from intraplatelet storage pools). In contrast, high plasma concentrations observed with small-molecule inhibitors limit the effectiveness of platelet transfusions. Fibrinogen supplementation (fresh frozen plasma, cryoprecipitate) is the logical choice for restoration of hemostatic potential, given the competitive nature of binding and the relative availability of platelet GP-IIb/IIIa receptors.¹⁰⁹

Do Platelet GP-IIb/IIIa Receptor Antagonists Achieve a Mortality Reduction?

When considering the potential benefits of treatment, a clinician must carefully consider the inherent risk for adverse outcomes. A meta-analysis of 19 randomized, placebo-controlled trials that included more than 20,000 patients with ACS (ST elevation and non-ST ACS) reported a 31% risk reduction (for mortality) at 30 days and 21% at 6 months in those patients given a platelet GP-IIb/IIIa receptor antagonist (vs those not treated) in the setting of PCI.¹¹⁰ Major bleeding was increased only in trials in which anticoagulant therapy (UFH) was continued after the procedure (relative risk, 1.70).

Aggrenox

The dipyridamole component of Aggrenox and cilostazol, both phosphodiesterase inhibitors, are used predominantly in patients with peripheral vascular and cerebrovascular disease.

Aggrenox (Boehringer Ingelheim Pharmaceuticals Inc., Ridgefield, Conn) is a combination platelet antagonist that includes aspirin (25 mg) and dipyridamole (200 mg extended-release preparation). It is typically administered twice daily.

Mechanisms of Action

The mechanism of action of aspirin has been discussed previously. Dipyridamole inhibits cyclic adenosine monophosphate (cAMP)-phosphodiesterase (PDE) and cyclic-3',5'-GMP-PDE.¹¹¹

Pharmacokinetics

The pharmacokinetic profile of aspirin has been summarized previously. Peak dipyridamole levels in plasma are achieved within several hours of oral administration (50 mg aspirin and 400 mg dose of Aggrenox). Extensive metabolism via conjugation with glucuronic acid occurs in the liver. No significant pharmacokinetic interactions have been reported between aspirin and dipyridamole coadministered as Aggrenox.

Pharmacodynamics

Dipyridamole inhibits platelet aggregation through two distinct mechanisms. First, it attenuates adenosine uptake into platelets (as well as endothelial cells and erythrocytes). The resulting increase elicits a rise in cellular adenylyl cyclase concentrations, resulting in elevated cAMP levels, which inhibit platelet activation to several stimuli, including ADP, collagen, and platelet-activating factor. Dipyridamole also inhibits PDE. The subsequent increase in cAMP elevates nitric oxide concentration, facilitating platelet inhibitory potential.¹¹²

Adverse Effects

The ESPS (European Stroke Prevention Study)-2¹¹³ reported that 79.9% of patients experienced at least one on-treatment adverse event. The most common adverse effects were GI complaints and headache.

Dipyridamole has vasodilatory effects and should be used with caution in patients with severe coronary artery disease, in whom episodes of angina pectoris may increase. Patients receiving Aggrenox should not be administered adenosine for myocardial perfusion studies.

Administration in Older Patients

Plasma concentrations of dipyridamole are nearly 40% higher in patients older than 65 years of age compared with younger individuals.

Clinical Experience

Aggrenox has not been studied in patients with ACS. The ESPS-2¹¹³ included 6602 patients with ischemic stroke (76% of the total population) or transient ischemic attack who were randomly assigned to receive Aggrenox, dipyridamole alone, aspirin alone, or placebo. Aggrenox reduced the risk of stroke by 22.1% compared with aspirin, and by 24.4% compared with dipyridamole. Both differences were statistically significant ($P = .008$ and $P = .002$, respectively). Aggrenox is not considered interchangeable with its individual components, particularly aspirin, which may be required in larger doses among patients with coronary artery disease (CAD). In addition, the vasodilatory effects of dipyridamole may cause coronary "steal" and angina pectoris. Accordingly, Aggrenox should be used cautiously, if at all, in the setting of advanced CAD.

Cilostazol

Cilostazol is a guinolinone derivative that inhibits cellular PDE.

Mechanism of Action

Cilostazol inhibits PDE III, reducing cAMP degradation. The resulting increase within platelets and endothelial cells impairs platelet aggregation and leads to vasodilation.

Pharmacokinetics

Cilostazol is well absorbed after oral administration, particularly when given with a high-fat meal. Metabolism occurs via the hepatic cytochrome P450 enzymes, and most metabolites are excreted in the urine (75% of overall clearance). One of two active metabolites is responsible for more than 50% of PDE III inhibition. The elimination half-life of cilostazol (and its metabolites) is approximately 12 hours.

Pharmacodynamics

Increasing cAMP concentrations within endothelial cells cause vasodilation, whereas elevated levels within platelets impair their ability to aggregate.

Adverse Effects

The adverse effect most commonly associated with cilostazol administration is headache. Other relatively frequent causes of drug discontinuation include palpitations and diarrhea.

Several PDE III inhibitors have been associated with decreased survival in patients with class III/IV congestive heart failure. Accordingly, cilostazol should *not* be administered to patients with congestive heart failure (of any severity).

Use in Older Patients

The clearance of cilostazol (and its metabolites) has not been determined in patients older than age 65.

Use in Patients with Renal Insufficiency

Moderate to severe renal impairment increases cilostazol metabolite levels and alters protein binding of the parent compound. Patients with advanced renal insufficiency have not been studied.

Clinical Experience

Cilostazol is approved for the treatment of patients with intermittent claudication. Across eight clinical trials, improvement in walking distance (compared with placebo) was approximately 40% to 50%.¹¹⁴ Although experience with cilostazol after coronary arterial stenting has been reported,¹¹⁵ its long-term administration to patients with CAD has not been studied. Short-term coadministration with aspirin reduced ADP-mediated platelet aggregation by 30% to 40% (compared with aspirin alone). No randomized clinical trials of cilostazol in ACS have been conducted; however, it has been used for thromboprophylaxis after coronary arterial stenting.^{116–119}

Cilostazol is recommended for patients with disabling claudication, particularly when revascularization cannot be offered. Although it has platelet-inhibiting properties, cilostazol should not be considered a substitute for aspirin or clopidogrel in patients with ACS who have concomitant peripheral vascular disease.

Hemorrhagic Complications Associated with Platelet-Directed Therapy

The contribution of platelets to the clinical expression of atherosclerotic vascular disease and the well-documented benefits derived from their pharmacologic attenuation provide a strong rationale for use in daily practice. Although the risk of drug-related complications must be considered in terms of all treatment strategies, this effort is particularly important for agents that impair hemostasis. It is not uncommon in current clinical practice for several platelet antagonists to be administered concomitantly.

A meta-analysis of 50 randomized clinical trials,¹²⁰ which included a total of 338,191 patients with atherosclerotic vascular disease, found a very low risk of hemorrhagic stroke (0.2%) with aspirin (≤ 325 mg daily), thienopyridines, and intravenous GP-IIb/IIIa receptor antagonists. The risk of major hemorrhage was greater, ranging from 1.7% with aspirin to 3.6% in those given intravenous GP-IIb/IIIa receptor antagonists (Fig. 20-9). Incidences of combined major and minor hemorrhagic events were 3.6% for low-intensity aspirin (< 100 mg daily), 9.1% for moderate-intensity aspirin (100 to 325 mg daily), and 8.5% for clopidogrel.

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most commonly used pharmaceutical agents in the United States. Although the potential cardiovascular risk associated with their use, particularly when taken over prolonged periods of time, has not yet been defined, most physicians recommend short courses of therapy at the lowest effective dose. A listing of NSAIDs that emphasizes their platelet-inhibiting properties and biologic half-lives appears in Table 20-3.

Anticoagulants

The participation of coagulation proteases, particularly factor Xa and factor IIa (thrombin), in several phases of cell-based coagulation forms the basis for the routine use of pharmacologic therapy in patients with thrombotic disorders of the arterial circulatory system. Among hospitalized patients, thrombin-inhibiting drugs (UFH, LMWH, pentasaccharide [fondaparinux]) and direct thrombin inhibitors (DTIs) are used frequently, often in combination with platelet-directed antagonists, creating substantial perturbations in hemostasis.

Unfractionated Heparin

Unfractionated heparin is a heterogeneous, negatively charged mucopolysaccharide consisting of approximately 18 to 50 saccharide units (molecular weight, 5000 to 30,000 daltons). Antithrombin III (ATIII) neutralizes thrombin and other activated serine proteases (factors Xa, IXa, XIa, and XIIa)—a reaction that is increased 10^3 - to 10^4 -fold by binding of heparin to ATIII.

After IV administration, heparin binds to a variety of plasma proteins, endothelial cells, and macrophages, explaining, in part, the wide variability in anticoagulant effects

Figure 20-9 Major bleeding according to treatment with platelet antagonists. Weighted combination of major bleeding events with 95% confidence interval (CI) across treatment group. (From Patrono C: Aspirin as an antiplatelet drug. *N Engl J Med* 330:1287–1294, 1994.)

Table 20-3 Platelet-Inhibiting Properties of Nonsteroidal Anti-Inflammatory Drugs

Drug	Site of Action	Route	Biologic $t_{(1/2)}$	Recommended Time off Therapy*
Piroxicam	COX-1, -2	PO	50 hr	10 days
Indomethacin	COX-1, -2	PO/PR	5 hr	2 days
Ketorolac	COX-1, -2	PO/IV	7 hr	2 days
Ibuprofen	COX-1, -2	PO	2 hr	1 day
Naproxen	COX-1, -2	PO	13 hr	2 days
Diclofenac	COX-1, -2	PO	2 hr	1 day
Celecoxib	COX-2	PO	10–17 hr [†]	None

*Prior to invasive procedures.

[†] $t_{(1/2)}$ increases with dose.

$t_{(1/2)}$, half-life; COX, cyclo-oxygenase.

observed for a given dose. It is cleared from the circulation through a rapid saturable mechanism and a slower first-order mechanism. The result is a dose-dependent half-life that ranges from 60 minutes after an IV dose of 100 U per kilogram to 180 minutes for a dose of 400 U per kilogram.^{121,122}

Adverse Effects

Heparin-induced thrombocytopenia (HIT) (see Chapter 25) and hemorrhage are the most feared complications of heparin administration. Another adverse effect is osteopenia (with long-term administration).

Clinical trials have been conducted to compare the benefits of heparin and aspirin among patients with unstable angina and non-ST segment elevation MI. The first trial, performed by Thérout and colleagues,¹²³ compared aspirin (325 mg twice daily), heparin (5000 U bolus, 1000 U per hour by intravenous infusion), their combination, and placebo in 479 patients. This is the only study that compared heparin (alone) and aspirin (alone), as well as their combination. Refractory angina occurred in 8.5%, 16.5%, and

10.7% of patients, respectively (0.47 relative risk for heparin compared with aspirin [95% CI, 0.21 to 1.05; $P = .06$]). MI occurred in 0.9%, 3.3%, and 1.6% of patients, respectively (0.25 relative risk [95% CI, 0.03 to 2.27; $P = .18$]), and any event was observed in 9.3%, 16.5%, and 11.5% of patients, respectively (0.52 relative risk [95% CI, 0.24 to 1.14; $P = .10$]). Serious bleeding, defined as a fall in hemoglobin concentration of 2 g or more, or the need for a transfusion, occurred in 1.7%, 1.7%, and 3.3% of patients, respectively. Most events were followed by cardiac catheterization.

Remaining trials investigated the potential advantages of combination therapy (heparin plus aspirin) over aspirin monotherapy. Although these treatments were not statistically different, consistent trends observed across each study favored combined pharmacotherapy and its ability to reduce death or MI (combined end point). Pooled analysis of the Antithrombotic Therapy in Acute Coronary Syndromes (ATACS) trial, the Research Group on Instability in Coronary Artery Disease in Southeast Sweden (RISC)

study, and the Thérout and colleagues trial yielded a relative risk of 0.44 (95% CI, 0.21 to 0.93) for death/MI, in favor of combination therapy.^{124–128}

Therapeutic Levels of Anticoagulation

Although the pathobiology of non-ST segment ACS is fundamentally understood, the required intensity of anticoagulation remains poorly defined. The challenge is multifactorial but likely relates to inherent complexities in the pharmacokinetics and pharmacodynamics of heparin, the dynamic nature of coronary arterial thrombosis, and the use of coagulation tests designed primarily to assess hemostatic potential. In essence, current laboratory-based tests are oriented more toward the drug (and its potential to cause bleeding) than the disease.

Available evidence supports a weight-adjusted dosing regimen with heparin therapy as a means of providing a more predictable and constant level of systemic anticoagulation. An initial bolus of 60 to 70 U per kilogram (maximum, 5000 U; initial infusion, 12 to 15 U/kg/hr IV [maximum, 1000 U per hour]) titrated to a target partial thromboplastin time (PTT) of 50 to 75 seconds is recommended, assuming the pretreatment PTT is normal.^{128–130}

A “weaning” schedule at the time of treatment completion may reduce the occurrence of rebound thrombin generation and ischemic/thrombotic events.¹³⁰

Indirect, Selective Factor Xa Inhibitors

Synthetic Pentasaccharide

Fondaparinux (Arixtra; GlaxoSmithKline, Research Triangle Park, NC) is a synthetic pentasaccharide that requires ATIII for selective FXa binding.¹³¹ Different from heparin compounds, fondaparinux does not interact with platelets (or platelet-derived proteins). After subcutaneous administration in healthy volunteers, fondaparinux is nearly 100% bioavailable, and absorption is rapid (maximum plasma concentration [C_{max}] within 2 hours).¹³² Clearance occurs through renal mechanisms with a terminal half-life of 17 ± 3 hours (slightly longer in elderly volunteers). Overall, drug clearance is 25% slower in patients with mild renal impairment (creatinine clearance [CrCl], 50 to 80 mL per minute), approximately 40% slower with moderate renal impairment (CrCl, 30 to 50 mL per minute), and 55% slower in the setting of severe renal impairment (CrCl, <30 mL per minute).

The OASIS (Organization to Assess Strategies in Acute Ischemic Syndromes)-5 Study¹³³ assigned 20,078 patients with ACS to receive fondaparinux (2.5 mg daily SQ) or enoxaparin (1 mg per kilogram of body weight twice daily SQ) for a mean of 6 days and evaluated death, MI, or refractory ischemia at 9 days (the primary outcome measure), as well as major bleeding and a combination of the two. The numbers of patients with primary outcome events were similar in the two groups (fondaparinux, 5.8%, vs enoxaparin, 5.7%; hazard ratio in the fondaparinux group, 1.01; 95% CI, 0.90 to 1.13), satisfying the noninferiority criteria. The rate of major bleeding at 9 days was markedly lower with fondaparinux than with enoxaparin (2.2% vs 4.1%; hazard ratio, 0.52; $P < .001$). A composite of the primary outcome measure in major bleeding at 9 days favored fondaparinux (7.3% vs 9%; hazard ratio, 0.81; $P < .001$).

Fondaparinux was always associated with a significant reduction in the number of patients with fatal bleeding and TIMI major bleeding. Regardless of treatment, patients who had major bleeding during hospitalization had significantly higher rates of death, reinfarction, or stroke at 30 days and at 180 days than did patients without major or minor bleeding. These higher event rates associated with bleeding persisted after adjustments were made for a number of clinical characteristics that are commonly associated with bleeding. Accordingly, almost the entire difference in mortality between fondaparinux- and enoxaparin-treated patients at the end of the study could be attributed to the lower rate of bleeding associated with fondaparinux.

In a subgroup analysis, benefits and risks were found to be consistently in favor of fondaparinux. Rates of bleeding were consistently lower with fondaparinux, regardless of whether UFH was administered before randomization. The proportions of patients undergoing PCI (39.5% in the fondaparinux group and 39.5% in the enoxaparin group) and coronary arterial bypass grafting (15.3% and 14.5%, respectively) were similar in the two groups. Rates of the combination of death, MI, and refractory ischemia were similar at 9 days, at 30 days, and at the end of the study. An increase in guiding catheter thrombus formation was observed with fondaparinux (0.9% vs 0.3%); however, rates of other complications, including pseudoaneurysm formation, large hematomas, major bleeding, and complications involving the vascular access site, were all less common with fondaparinux than with enoxaparin. Collectively, the rate of death, MI, stroke, major bleeding, or any procedural complication at 9 days was 16.6% with fondaparinux as compared with 20.6% with enoxaparin (relative risk, 0.81; 95% CI, 0.73 to 0.90; $P < .001$).

The OASIS-6 study¹³⁴ was a randomized double-blind comparison of fondaparinux 2.5 mg once daily versus placebo for up to 8 days in 12,092 patients with ST segment elevation MI. The composite of death or reinfarction at 30 days served as the primary outcome measure, with secondary assessments at 9 days and at final follow-up (3 to 6 months). Death or reinfarction at 30 days was significantly reduced from 11.2% in the control group to 9.7% among patients receiving fondaparinux (hazard ratio, 0.86; 95% CI, 0.77 to 0.9; $P = .008$). These benefits were observed at 9 days and at study completion. Mortality was significantly reduced throughout the study in patients receiving fondaparinux; in a comparison of patients receiving fondaparinux versus those given UFH, fondaparinux was found to be superior in preventing death or reinfarction at 30 days (hazard ratio, 0.82; 95% CI, 0.66 to 1.02; $P = .08$) and at study end (hazard ratio, 0.77; 95% CI, 0.64 to 0.93; $P = .008$). Significant benefit was observed among patients receiving fibrinolytic therapy (hazard ratio, 0.79; $P = .003$) and those not given reperfusion therapy. No benefit was noted in patients undergoing primary PCI. Rates of death, MI, and severe bleeding were significantly lower at day 9 with fondaparinux (hazard ratio, 0.83; 95% CI, 0.73 to 0.94; $P = .003$), as they were at study completion. The composite outcome of death, MI, or stroke was reduced at all three time points.

The use of a single fixed dose (2.5 mg once daily SQ) of fondaparinux without monitoring or dose adjustment for

weight across a broad range of creatinine levels, coupled with simplicity, safety, and efficacy in ACS, will likely facilitate its use and may transfer, with further investigation, to prehospital and possibly posthospital settings among carefully selected patients. The apparent lack of HIT associated with fondaparinux use is also attractive.

Low Molecular Weight Heparin

LMWH is prepared by the depolymerization of porcine heparin. A variety of processes are used, yielding distinctive products whose molecular weights range from 4000 to 6500 daltons.¹³⁵ Similar to heparin, approximately one third of LMWH polysaccharide chains contain the pentasaccharide sequence necessary for binding to ATIII. The LMWH/ATIII complex (consisting of a predominance of shorter chain polysaccharides) has relatively weak thrombin inhibitory activity but retains the ability to inactivate factor Xa. The ratio of anti-Xa activity to anti-IIa activity ranges from 2:1 to 4:1. Similar to heparin, LMWH is not able to inhibit thrombin bound to fibrin.

Pharmacokinetics

When LMWH is administered in fixed or weight-adjusted doses by the subcutaneous route, more than 90% of the dose is absorbed. In contrast to heparin, LMWH has minimal binding to cells or plasma proteins, resulting in persistence of free drug in the circulation and a longer plasma half-life of activity. Although the half-life of heparin averages about 90 minutes, the plasma half-life of LMWH averages about 180 minutes (the half-lives of three LMWHs range from 90 to 260 minutes). However, because LMWH is nearly always administered subcutaneously, the functional half-life may be considerably longer.

Antibodies directed against complexes of LMWH and platelet factor 4 may develop but at a rate lower than is experienced with heparin therapy. Full-blown HIT may occur. Equally rare is necrosis at the site of skin injection with LMWH, which may represent a form of local HIT. LMWH cannot be administered as a substitute for heparin in patients with HIT.

Clinical Experience

Original experiences with LMWH¹³⁶ involved 205 patients with unstable angina who were randomly assigned to aspirin (200 mg daily), aspirin (200 mg daily) plus heparin (5000 U bolus, 400 U/kg/day IV infusion), or high-dose nadroparin (214 IU per kilogram twice daily by subcutaneous injection) plus aspirin (200 mg daily). Patients underwent continuous ST segment monitoring during the first 48 hours of treatment. Overall, 73% of patients receiving LMWH were free from ischemic events, compared with 39% of those given heparin and 40% of patients given aspirin alone. Fewer silent ischemic events occurred in the LMWH group (18%) compared with those receiving heparin (29%) or aspirin alone (34%). Recurrent angina occurred in 95%, 26%, and 19% of patients, respectively, and MIs were not reported in LMWH-treated patients (compared with 1% in the heparin and 6% in the aspirin alone groups). Major bleeding occurred infrequently in all treatment groups.

A larger study (FRagmin during InStability in Coronary artery disease [FRISC]-1)¹³⁷ included 1506 patients with

unstable angina and non-ST segment elevation MI who were randomly assigned to LMWH (dalteparin, 120 IU per kilogram of body weight subcutaneously [maximum 10,000 IU] twice daily for 6 days, then 7500 IU once daily for 35 to 45 days) or placebo. All patients received SQ PO aspirin (300 mg first dose, 75 mg daily thereafter). Accordingly, FRISC-1 investigated the combination of LMWH plus aspirin versus aspirin alone. The risk of death or MI was reduced by 63% at day 6. The probability of death or MI and the need for revascularization remained lower in LMWH-treated patients at 40 days; however, little difference between groups was observed beyond the treatment period.

In the FRIC (FRagmin In unstable Coronary artery disease) study,¹³⁸ 1482 patients with unstable angina and non-ST segment elevation MI were assigned twice-daily weight-adjusted SC injections of LMWH (dalteparin 120 IU per kilogram SQ) or dose-adjusted (target PTT, 1.5× control) IV heparin for 6 days (acute treatment phase). Patients randomly assigned to UFH received a continuous infusion for at least 48 hours and were given the option of continuing the infusion or changing to a SQ regimen (12,500 U every 12 hours). In the double-blind comparison that took place from days 6 to 45 (prolonged treatment phase), patients received LMWH (dalteparin, 7500 IU SQ once daily) or placebo. Aspirin (75 to 165 mg/day) was started in all patients as early as possible after hospital admission and was continued throughout the study. During the first 6 days, rates of death, recurrent angina, and MI were 7.6% in heparin-treated patients and 9.3% in LMWH-treated patients (relative risk, 1.18; 95% CI, 0.84 to 1.66). Revascularization was required in 5.3% and 4.8% (CI, 0.57 to 1.35). Between days 6 and 45, the composite end point was reached by 12.3% of patients in the LMWH and placebo groups.

The ESSENCE (Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q Wave Coronary Events) trial¹³⁹ randomly assigned 3171 patients with angina at rest or non-ST segment elevation MI to LMWH (enoxaparin, 1 mg per kilogram SQ twice daily) or IV heparin (target PTT, 55 to 85 seconds). Therapy was continued for a minimum of 48 hours (maximum, 8 days). All patients received aspirin (100 to 325 mg daily). Median duration of therapy for both groups was 2.6 days. At 14 days, the risk of death, recurrent angina, or MI was 16.6% among patients receiving LMWH and 19.8% in those given heparin (16% risk reduction). A similar risk reduction (15.0%) for the composite outcome was observed at 30 days. The benefit of LMWH treatment was maintained at 1 year.¹⁴⁰

The TIMI-11B study compared enoxaparin and heparin in 3910 patients with unstable angina and non-ST segment elevation MI.¹⁴¹ This trial design had several unique features that differentiated it from the ESSENCE design. First, enoxaparin therapy was initiated with a 30 mg IV bolus, followed by 1.0 mg per kilogram SQ twice daily. Second, heparin treatment was given according to a weight-adjusted dosing strategy (a 70 U per kilogram bolus, followed by 15 U/kg/h IV infusion to a target PTT 1.5 to 2.5× control). Finally, an out-of-hospital treatment phase compared enoxaparin and placebo for approximately 6 weeks (patients ≥65 kg received 60 mg SQ twice daily; those <65 kg were given 45 mg SQ twice daily for a total of 43 days). Treatment with enoxaparin was associated with

a significant reduction in the composite outcome of death, MI, or urgent revascularization compared with heparin at day 14 (14.2 vs 16.7%; RRR, 15%; $P = .03$). Continued treatment beyond the initial hospital phase did not provide added benefit (17.3 vs 19.7%; RRR, 12%; $P = .051$).

A meta-analysis of the ESSENCE and TIMI-IIb trials, totaling 7081 patients with non-ST segment elevation ACS, revealed a 20% reduction in the risk of any ischemic event,¹⁴² favoring enoxaparin over heparin. Differences were statistically significant at 48 hours and 43 days. The combined end point of death or MI was reduced by 20% at 48 hours ($P = .02$) and by 18% at 43 days ($P = .02$). A significant treatment benefit for enoxaparin on rate of death, nonfatal MI, or urgent revascularization was observed at 1 year (hazard ratio, 0.88; $P = .008$; absolute difference, 2.5%). A progressively greater treatment benefit was observed as the level of patient risk at baseline increased.

Combined Pharmacology and Interventional Strategies

FRISC-2 (FRagmin and fast revascularization during InStability in Coronary artery disease)¹⁴³ included 2267 patients with unstable coronary disease who received 5 days of dalteparin (120 IU per kilogram SQ every 12 hours) and were then randomly assigned to an invasive or conservative treatment strategy. In a separate randomization, patients received dalteparin (5000 to 7500 IU SQ every 12 hours) or placebo injections for 3 months. By 30 days, a significant reduction in death or MI favored dalteparin-treated patients (3.1 vs 5.9%; $P = .002$). This benefit decayed over the next 2 months. An invasive strategy (coronary angiography and revascularization) was associated with a significant reduction in death or MI at 6 months compared with ischemia-driven revascularization (9.4% vs 12.1%; $P = .03$). Mortality rates were 1.9% and 2.9%, respectively. At the 24-month follow-up, reductions in mortality (3.7% vs 12.7%; risk ratio, 0.72; $P = .005$) and in the composite end point of death or MI (12.1 vs 16.3%; risk ratio, 0.74; $P = .003$) were noted in the invasive rather than the noninvasive group. The need for repeat hospitalizations and late revascularization procedures was reduced with an early invasive strategy as well.

The RITA (Randomized Intervention Trial of unstable Angina) study randomly assigned 1810 patients with non-ST segment elevation ACS who received enoxaparin (1 mg per kilogram SQ twice daily for 2 to 8 days) and aspirin to an early intervention or conservative strategy.¹⁴⁴ At 4 months, 9.6% of patients randomly assigned to early intervention had died, experienced an MI, or experienced refractory angina compared with 14.5% in the conservative group (risk ratio, 0.66; 95% CI, 0.51 to 0.85; $P = .001$). Death or MI was similar in both treatment groups at 1 year (7.6% vs 8.3%, respectively; risk ratio, 0.91; 95% CI, 0.67 to 1.25; $P = .58$). Fewer patients undergoing early intervention experienced symptoms of angina or required antianginal medications.

In the SYNERGY (Superior Yield of the New Strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors) trial,¹⁴⁵ 10,027 high-risk patients were randomly assigned to heparin or enoxaparin. Overall, 92% of patients underwent coronary angiography, 47% had PCI (in hospital), and 57% received GP-IIb/IIIa antagonists. The primary end point of death or nonfatal MI at 3 days occurred in 14.5% of patients assigned to heparin and 14.0% of those given enoxaparin (OR, 0.956; 95% CI, 0.869 to 1.063),

fulfilling the noninferiority criteria. No differences in ischemic events during PCI occurred among the various thrombin inhibitors. Major bleeding was modestly increased with enoxaparin; however, transfusion rates did not differ, and a relationship between advancing age, reduced creatinine clearance, and risk of hemorrhage was noted.

The SYNERGY trial supports enoxaparin as an alternative to heparin in high-risk patients who are treated aggressively. The impact of age and renal insufficiency on bleeding risk is important and should stimulate further investigation of preferred dosing strategies.

In the ExTRACT (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment)-TIMI 25 study,¹⁴⁶ 20,506 patients with ST segment elevation MI who were scheduled to undergo fibrinolysis received enoxaparin throughout the index hospitalization or heparin for at least 48 hours. The primary efficacy end point, death or nonfatal recurrent MI through day 30, occurred in 12% of patients in the heparin group and 9.9% of those in the enoxaparin group (17% reduction in relative risk; $P < .001$). Nonfatal reinfarction occurred in 4.5% of patients receiving heparin and 3% of those who were given enoxaparin (33% reduction in relative risk; $P < .001$). A nonstatistically significant reduction in death occurred (7.5% vs 6.9%, respectively; $P = .11$). Major bleeding occurred in 1.4% and 2.1% of patients, respectively. The composite of death, nonfatal reinfarction, or nonfatal intracranial hemorrhage (a measure of net clinical benefit) occurred in 12.2% of patients administered heparin and 10.1% of those given enoxaparin ($P < .001$).

LMWH and Platelet GP-IIb/IIIa Receptor Antagonist Combination Therapy

The effective level of factor Xa inhibition has not been determined for patients with ACS who are receiving LMWH. Available information, derived from clinical trials of PCI, shows that anti-Xa activity >0.5 IU per milliliter is associated with a low incidence of ischemic/thrombotic and hemorrhagic events.¹⁴⁷ Attenuative coagulation tests, including traditional PTT and activated clotting time (ACT) assays, may provide some insight into LMWH preparations characterized by low anti-Xa/anti-IIa activity.¹⁴⁸

The potential benefits of enoxaparin (1 mg per kilogram IV every 12 hours) and the platelet GP-IIb/IIIa receptor antagonist tirofiban (10 $\mu\text{g/kg}$ IV bolus over 3 min, followed by 0.1 $\mu\text{g/kg/min}$ IV for 48 to 108 hours) versus weight-adjusted UFH and tirofiban were investigated in the A to Z trial¹⁴⁹—a prospective, open-label, randomized study of 3987 patients with non-ST segment elevation ACS. Death, recurrent MI, or refractory ischemia at 7 days occurred in 8.4% of enoxaparin-treated patients and 9.4% of those receiving heparin (hazard ratio, 0.88) (criteria for noninferiority satisfied). Risk reductions were of greater magnitude (favoring enoxaparin) among patients at highest risk and those treated conservatively. Major bleeding was more common in patients receiving enoxaparin (0.9% vs 0.4% with heparin; one excess major hemorrhagic event for every 200 patients treated); however, transfusion rates were low overall (0.9%) and did not differ between groups.

A systematic evaluation of clinical trials comparing enoxaparin and heparin for the treatment of patients with ACS was conducted by Petersen and colleagues.¹⁵⁰ A total of 6 trials that included 21,946 patients were analyzed; a statistically significant reduction in the combined

30-day end point of death or MI favored enoxaparin (10.1% vs 11.0%; OR, 0.91). Patients who were receiving no pretreatment anticoagulant therapy were found to derive a particularly robust benefit from enoxaparin (8.0% vs 9.4%; OR, 0.81). Major hemorrhage and blood transfusion rates did not differ between treatment groups.

In the ACUTY (Acute Catheterization and Urgent Triage Strategy) trial¹⁵¹ (presented at the American College of Cardiology National Meeting, Atlanta, GA, 2006), 13,819 patients with ACS randomly received bivalirudin plus a GP-IIb/IIIa receptor antagonist, heparin (heparin or enoxaparin) plus a GP-IIb/IIIa receptor antagonist, or bivalirudin alone. The primary outcome, which consisted of all-cause mortality, MI, or unplanned revascularization for ischemia at 30 days, did not differ significantly between groups. Bivalirudin alone was associated with a 50% reduction in major bleeding complications. On the basis of findings from ACUTY, bivalirudin use in hospitalized patients increased, necessitating greater familiarity with its properties among consulting hematologists.

Influence of Renal Function

Factor Xa inhibition pharmacokinetics was studied in 445 patients receiving enoxaparin (1.0 to 1.25 mg per kilogram SQ every 12 hours).¹⁵² Mean apparent clearance, distribution volume, and plasma half-life were 0.733 L per hour, 5.24 L, and 5 hours, respectively. CrCl emerged as the most important factor affecting apparent clearance, area under the curve, and anti-Xa activity. Clearance was reduced by 22% in patients with CrCl <40 mL per minute (compared with patients with normal renal performance [CrCl >80 mL per minute]). These patients had higher peak and trough anti-Xa activity and were more likely to experience major hemorrhagic events. Renal performance may not influence pharmacokinetics after single-dose intravenous administration of enoxaparin. Studies designed to evaluate appropriate dosing and possible dose titration in patients with end-stage renal disease must be undertaken to provide guidance in ways to approach optimal patient care.

Direct Thrombin Inhibitors

The pivotal role of thrombin in all phases of coagulation, cellular proliferation, and cellular interactions involved centrally in inflammatory processes provides an attractive target for pharmacologic inhibition. Because these agents

directly inhibit thrombin independently of ATIII, they are referred to as a class of direct thrombin inhibitors (DTIs). The development of DTIs has evolved rapidly to include intravenous and oral preparations.

Hirudin. Hirudin is extracted from the parapharyngeal gland of the medicinal leech *Hirudo medicinalis*. Several derivatives and recombinant preparations have been developed, including the most widely used agent lepirudin (Refludan; ZLB Behring GmbH, Marburg, Germany).

Hirudin binds to the catalytic and fibrinogen-binding sites of thrombin and thus is considered a bivalent inhibitor.

Pharmacokinetics. The plasma half-life of hirudin is 50 to 65 minutes, and it has a biologic half-life of 2 hours.¹⁵³ Properties of heparins, hirudin, and bivalirudin are highlighted in Table 20-4. The predominant renal clearance of hirudin must be emphasized for safe clinical use.

Hirudin forms a tight complex with thrombin, inhibiting the conversion of fibrinogen to fibrin and thrombin-induced platelet aggregation. These actions are independent of ATIII. Thrombin bound to fibrin is also complexed and inhibited. On the downside, the ability of thrombin to complex with thrombomodulin and activating protein C is also inhibited. Hirudin does not bind to platelet factor 4, nor does it elicit antibodies that induce platelet and endothelial cell activation; thus, it can be safely administered to patients with HIT. Hirudin has weak immunogenicity, so that diminished (or rarely increased) responsiveness after repeated dosing is possible. The use of hirudin in the management of heparin-induced thrombocytopenia is discussed in Chapter 25.

Clinical Use. In the GUSTO IIb trial,¹⁵⁴ patients with non-ST segment elevation ACS received heparin or hirudin (0.1 mg per kilogram IV bolus; 0.1 mg/kg/h IV infusion). At 24 hours, the risk of death or nonfatal MI was reduced in hirudin-treated patients (1.3% vs 2.1%; $P = .001$). The primary end point of death or nonfatal MI at 30 days was reached in 8.9% and 9.8% of patients, respectively (OR, 0.89; $P = .006$). The risk of moderate bleeding was increased with hirudin treatment (8.8% vs 7.7%; $P = .03$).

The OASIS-1 study¹⁵⁵ included 909 patients with unstable angina or suspected MI without ST segment elevation who were randomly assigned to receive heparin (5000 U bolus IV; infusion of 1000 to 1200 U per hour), low-dose hirudin (0.2 mg per kilogram bolus; IV infusion of 0.1 mg/kg/hr), or moderate-dose hirudin (0.4 mg per kilogram IV bolus; infusion of 0.15 mg/kg/hr IV). Doses of heparin

Table 20-4 Properties of Heparins, Bivalirudin, and Hirudin

Property	Heparin	LMWH	Fondaparinux	Bivalirudin and Hirudin
Thrombin inhibition	Requires ATIII	Requires ATIII	Requires ATIII	Directly inhibited
Clot-bound thrombin	Not inhibited	Not inhibited	Not inhibited	Inhibited
Thrombocytopenia	Yes	Yes	Not reported	No
Immunogenicity	Yes	Yes	Not reported	Rare
Effects on PTT	Yes	No	No	Yes
Effects on PT	Minimal, some at high doses	No	No	Moderate*
Metabolism	Cellular and renal binding	Renal	Renal	Renal
Antidote	Protamine	Protamine partially	None	None

*Greater effect with bivalirudin.

PTT, activated partial thromboplastin time; ATIII, antithrombin III; LMWH, low molecular weight heparin; PT, prothrombin time.

and hirudin were titrated to a target PTT of 60 to 100 seconds. Hirudin, compared with heparin, reduced the composite incidence of cardiovascular death, MI, or refractory angina at 7 days (OR, 0.57; 95% CI, 0.32 to 1.02), as well as a composite of death, MI, or refractory/severe angina requiring revascularization at 7 days (OR, 0.49; 95% CI, 0.27 to 0.86). Overall event rates were lowest in the moderate-dose hirudin group.

Favorable results in OASIS-1 prompted a large phase 3 trial, OASIS-2,¹⁵⁶ which randomly assigned 10,141 patients with non-ST segment elevation ACS to a 72-hour infusion of moderate-dose hirudin (as defined in OASIS-1) or heparin. The primary outcome (composite of death or MI at 7 and 35 days) was reported in 3.6% and 4.2% of patients (OR, 0.87; 95% CI, 0.75 to 1.01), respectively. Although statistically significant differences between groups were not observed, the combined OASIS-1 and OASIS-2 experience revealed a significant reduction in the likelihood of death or MI at 35 days among hirudin-treated patients (OR, 0.86; 95% CI, 0.74 to 0.99).

Hirudin is almost exclusively excreted through the kidneys; as a result of this fact, renal function must be considered carefully prior to administration. Most clinical trials excluded patients with a serum creatinine of 2.0 mg per deciliter or greater. It is important to acknowledge that even in the setting of mild renal impairment (CrCl, 50 to 80 mL per minute), excessive levels of systemic anticoagulation (and accompanying risk for hemorrhage) may occur without dosing modification. If hirudin is administered to patients with renal insufficiency, frequent PTT monitoring is highly recommended.

Bivalirudin. Bivalirudin (Angiomax; The Medicines Company, Parsippany, NJ) is an intravenous DTI that acts by binding to the catalytic and anion-binding exosite. It prolongs thrombin time, PTT, and prothrombin time (PT) in a concentration-dependent manner.

Pharmacokinetics. After a 1 mg per kilogram IV bolus is given, peak concentrations are achieved rapidly, and a plasma half-life of 25 minutes is seen among patients with normal renal function. Drug elimination is reduced by 20% in the setting of moderate renal impairment, by 50% in severe renal impairment, and by 80% in dialysis-dependent patients. Pharmacokinetic characteristics translate to half-lives of 34 minutes, 57 minutes, and 3.5 hours, respectively.

Bivalirudin is U. S. Food and Drug Administration (FDA) approved for use in patients with non-ST segment elevation ACS who are undergoing PCI. The basis for approval stems from several large-scale clinical trials.¹⁵⁷ Among 4312 patients with new-onset, severe, accelerating, or resting angina undergoing PCI, a 22% reduction in death, MI, or urgent revascularization at 7 days was observed in those given bivalirudin compared with heparin (6.2 vs 7.9%; $P = .03$). Absolute and relative differences were maintained at 90 days. A marked reduction (62%) in bleeding complications was reported among bivalirudin-treated patients.

In the REPLACE-1 (Randomized Evaluation in Percutaneous coronary intervention Linking Angiomax to reduced Clinical Events) trial,¹⁵⁸ 1020 patients received bivalirudin (0.75 mg per kilogram IV bolus; infusion of 1.75 mg/kg/hr IV) or heparin. Prior treatment with aspirin and a

thienopyridine was encouraged in anticipation of stenting. A platelet GP-IIb/IIIa receptor antagonist was administered to 71% of patients. Bivalirudin was associated with a 19% reduction in the clinical end point of death, MI, urgent revascularization, and bleeding complications (minor, major, transfusions) at 48 hours.

REPLACE-2¹⁵⁹ randomly assigned 6010 patients undergoing urgent or elective PCI to bivalirudin plus a provisional GP-IIb/IIIa receptor antagonist (abciximab or eptifibatide) or to UFH plus a GP-IIb/IIIa receptor antagonist. Aspirin and clopidogrel pretreatment were recommended. Approximately 45% of patients had unstable angina or MI (within the prior 7 days). The composite of death, MI, and urgent revascularization at 30 days occurred in 7.1% of heparin-treated patients and in 7.6% of those treated with bivalirudin (OR, 0.917; 95% CI, 0.772 to 1.089; $P = .32$). Major bleeding was documented in 4.1% and 2.4% of patients, respectively ($P = .001$). Minor bleeding (25.7% vs 13.4%; $P = .001$) and thrombocytopenia (<100,000 per microliter) (1.7% vs 0.7%; $P < .001$) were also less common with bivalirudin treatment. GP-IIb/IIIa receptor antagonist therapy was given to 7.2% of bivalirudin-treated patients.

Impact of Renal Insufficiency. Patients with moderate and severe renal impairment have reductions in bivalirudin clearance; however, analyses of data derived from 4312 patients with unstable angina showed increased bleeding risk for bivalirudin- and heparin-treated patients with progressive degrees of renal insufficiency. The incidence of major bleeding was, however, consistently less for bivalirudin than heparin at all levels of renal impairment.¹⁵⁷

Overall data suggest that a bivalirudin dose adjustment is indicated for patients with moderate or severe renal impairment. Encouraging results from REPLACE-2 may provide guidance for reducing hemorrhagic risk in patients with renal insufficiency by virtue of the short infusion length for bivalirudin administration and provisional use of GP-IIb/IIIa receptor antagonists (which may themselves increase the risk of hemorrhage in this high-risk patient subset).¹⁵⁹

The use of bivalirudin among individuals with and those at risk for HIT who require PCI is favored (over argatroban) by many interventional cardiologists on the basis of experience in the angioplasty suite and comparative analyses among patients with ACS.

Argatroban. Argatroban (Glaxo-SmithKline) is a synthetic DTI derived from L-arginine that acts by binding reversibly to the active site of thrombin. A linear relationship has been noted between argatroban plasma levels and prolongations of thrombin time, PTT, and PT.

Pharmacokinetics. Peak concentrations of argatroban are reached rapidly after IV injection, and the plasma half-life ranges between 39 and 51 minutes. Metabolism occurs in the liver by hydroxylation and aromatization via CYP3A4/5.

Clinical Use. Argatroban is approved for use among patients with HIT, including those with current HIT and previous HIT and/or those with heparin-dependent antibodies.

Comparative Benefits of Direct Thrombin Inhibitors. A meta-analysis of clinical trials was performed to obtain additional information and precise estimates of DTIs in

the management of ACS.¹⁶⁰ A total of 11 randomized trials that included 35,970 patients were identified. Compared with heparin, DTIs were associated with a lower risk of death or MI at the end of treatment (up to 7 days) (4.3% vs 5.1%; OR, 0.85; 95% CI, 0.77 to 0.94; $P = .001$) and at 30 days (7.4% vs 8.2%; OR, 0.91; 95% CI, 0.84 to 0.99; $P = .02$). Seven trials studied 30,154 patients who had an ACS (unstable angina or non-ST segment elevation MI) or were undergoing PCI. In those with ACS, treatment with a DTI was associated with a reduction in death or MI compared with UFH (3.7% vs 4.6%; OR, 0.80; 95% CI, 0.70 to 0.92). Similar reductions were observed in PCI trials (3.0% vs 3.8%; OR, 0.79; 95% CI, 0.59 to 1.06). A statistically insignificant increased rate of major bleeding with DTIs was seen in trials of ACS (1.6% vs 1.4%; OR, 1.11; 95% CI, 0.93 to 1.34), but a significant difference was noted in PCI trials (3.7% vs 7.6%; OR, 0.46; 95% CI, 0.36 to 0.59). No differences in rates of intracranial hemorrhage were noted.

Risk reduction in death or MI at the end of treatment was similar in trials comparing hirudin or bivalirudin with UFH, but a slight excess was seen with univalent inhibitors (4.7% vs 3.5%; OR, 1.35; 95% CI, 0.89 to 2.05). When major bleeding outcomes were analyzed by specific DTIs, hirudin was associated with an excess of major bleeding compared with heparin (1.7% vs 1.3%; OR, 1.28; 95% CI, 1.06 to 1.55), whereas both bivalirudin (4.2% vs 9.0%; OR, 0.55; CI, 0.34 to 0.56) and univalent inhibitors (0.7% vs 1.3%; OR, 0.55; 95% CI, 0.25 to 1.20) were associated with lower rates of major bleeding.

CURRENT GUIDELINES FOR ANTITHROMBOTIC THERAPY IN CARDIOVASCULAR DISEASE

Several national and international task forces, assembled by the American Heart Association, American College of Cardiology, American College of Chest Physicians, and Society for Cardiovascular Angiography and Interventions, have established guidelines for the management of ACS.^{161–163} Recommendations for the use of antithrombotic therapy are summarized in Tables 20-5, 20-6, and 20-7.

Special Clinical Settings

The hematology consultant may be confronted with a variety of conditions for which antithrombotic therapy is recommended.

Mural Thrombosis and Embolic Events

Left ventricular mural thrombosis is a potential complication of acute MI,¹⁶⁴ particularly in cases involving the wall and the apex.

A meta-analysis performed by Vaitkus and Barnathorn¹⁶⁵ highlights the risk of cardioembolism among patients with mural thrombosis diagnosed by transthoracic echocardiography, along with the beneficial impact of anticoagulant therapy in reducing events.¹⁶⁵

Atheromas of the Ascending Aorta

The consistently high incidence of “cryogenic stroke” in most stroke registries and databases led to further consideration of

alternative causes beyond carotid artery disease, atrial fibrillation, and left heart cardioembolism. The development of transesophageal echocardiography and its use in the assessment of patients experiencing acute ischemic stroke have provided much needed insight.^{166,167} Atheromas of the ascending aorta are present in upward of 25% of patients with stroke and/or peripheral embolism. In this setting, the incidence of recurrent events is high, approaching 15% to 25% within 1 year of the original event. Features associated with an increased incidence of embolic events (atheroemboli, thromboemboli) include plaque thickness greater than 4 mm,¹⁶⁸ absence of calcification, ulceration,

Table 20-5 Recommended Antithrombotic Agents

Antiplatelets

Class I

1. Aspirin 162 to 325 mg should be given PO on day 1 of ST elevation myocardial infarction (STEMI); in the absence of contraindications, it should be continued indefinitely on a daily basis thereafter at a dose of 75 to 162 mg PO. (Level of Evidence: A)
2. A thienopyridine (preferably clopidogrel) should be orally administered to patients who are unable to take aspirin because of hypersensitivity or major gastrointestinal intolerance. (Level of Evidence: C)
3. For patients taking clopidogrel for whom coronary artery bypass grafting (CABG) is planned, if possible, the drug should be withheld for at least 5 days, preferably for 7, unless the urgency for revascularization outweighs the risks of bleeding. (Level of Evidence: B)
4. For patients who have undergone diagnostic cardiac catheterization and for whom percutaneous coronary intervention (PCI) is planned, clopidogrel should be started and continued for at least 1 month after bare metal stent implantation and for several months after drug-eluting stent implantation (3 months for sirolimus, 6 months for paclitaxel) and up to 12 months in patients who are not at high risk for bleeding. (Level of Evidence: B)

Anticoagulants

Class I

1. Intravenous unfractionated heparin (UFH; bolus, 60 U per kilogram; maximum, 4000 U IV; initial infusion, 12 U per kilogram per hour; maximum, 1000 U per hour) or LMWH should be used in patients after STEMI who are at high risk for systemic emboli (large or anterior myocardial infarction [MI], atrial fibrillation, previous embolus, known LV thrombus, or cardiogenic shock). (Level of Evidence: C)

Class IIa

1. It is reasonable that STEMI patients not undergoing reperfusion therapy who do not have a contraindication to anticoagulation should be treated with intravenous or subcutaneous UFH or with subcutaneous LMWH for at least 48 hours. In patients whose clinical condition necessitates prolonged bed rest and/or minimized activities, it is reasonable that treatment should be continued until the patient is ambulatory. (Level of Evidence: C)

Class IIb

1. Prophylaxis for deep venous thrombosis (DVT) with subcutaneous LMWH (dosed appropriately for specific agent) or with subcutaneous UFH, 7500 U to 12500 U twice per day until completely ambulatory; may be useful, but the effectiveness of such a strategy is not well established in the contemporary era of routine aspirin use and early mobilization. (Level of Evidence: C)

Table 20-6 Acute Management of Non-ST Elevation Acute Coronary Syndrome (NSTEMI ACS)

Antiplatelet Therapies

Aspirin

For all patients who present with NSTEMI ACS, without a clear allergy to aspirin, we recommend immediate aspirin, 75 to 325 mg PO, and then daily, 75 to 162 mg PO (Grade 1A).

Thienopyridines

For all NSTEMI ACS patients with an aspirin allergy, we recommend immediate treatment with clopidogrel, 300 mg dose PO, followed by 75 mg per day PO indefinitely (Grade 1A).

In all NSTEMI ACS patients in whom diagnostic catheterization will be delayed or when coronary bypass surgery will not occur until >5 days after coronary angiography, we recommend that clopidogrel should be administered immediately as PO therapy (300 mg), followed by 75 mg per day PO for 9 to 12 months, in addition to aspirin (Grade 1A).

Glycoprotein (GP)-IIb/IIIa Inhibitors

In moderate- to high-risk patients who present with NSTEMI ACS, we recommend IV eptifibatide or tirofiban for initial (early) treatment, in addition to treatment with aspirin and heparin (Grade 1A). In these moderate- to high-risk patients who are also receiving clopidogrel, we recommend eptifibatide or tirofiban as additional initial treatment (Grade 2A).

For patients who present with NSTEMI ACS, we recommend **against** abciximab as initial treatment, except when coronary anatomy is known and percutaneous coronary intervention (PCI) is planned within 24 hours (Grade 1A).

Antithrombin Therapies

Unfractionated Heparin (UFH)

For patients who present with NSTEMI ACS, we recommend IV UFH over no heparin therapy for short-term use with antiplatelet therapies (Grade 1A). We recommend weight-based dosing of UFH and maintenance of partial thromboplastin time (PTT) at between 50 sec and 75 sec (Grade 1C+).

For the acute treatment of patients with NSTEMI ACS, we recommend SQ LMWH over UFH (Grade 1B).

We recommend **against** routine monitoring of the anticoagulant effects of LMWH (Grade 1C).

We suggest that LMWH should be continued during PCI treatment of the NSTEMI ACS patient when it has been started as the “upstream” anticoagulant (Grade 2C).

For patients who receive glycoprotein (GP)-IIb/IIIa inhibitors as upstream treatment for NSTEMI ACS, we suggest LMWH over UFH as the anticoagulant of choice (Grade 2B).

Direct Thrombin Inhibitors (DTIs)

In patients who present with NSTEMI ACS, we recommend **against** the use of DTIs as routine initial antithrombotic therapy (Grade 1B).

Underlying values and preferences: This recommendation acknowledges the limitations of individual trials of DTIs in NSTEMI ACS, as well as the complexities of using DTIs rather than UFH or LMWH.

Post-Myocardial Infarction (MI) and Post-ACS

In patients with ACS with and without ST segment elevation, the following apply:

We recommend aspirin given in initial doses of 160 to 325 mg PO, and then indefinite therapy, 75 to 162 mg/day PO (Grade 1A).

For patients with a history of aspirin-induced bleeding or with risk factors for bleeding, we recommend lower doses (≤ 100 mg) of aspirin (Grade 1C+).

For patients in whom aspirin is contraindicated or is not tolerated, we recommend clopidogrel, 75 mg per day PO, for long-term administration (Grade 1A).

and superimposed thrombi (particularly with a mobile component).^{169,170}

Treatment of patients with atheromas involving the ascending aorta includes meticulous atherosclerotic vascular disease risk factor modification and use of hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors. Patients with cerebrovascular events and mobile thrombus seen on transesophageal echocardiography should receive anticoagulant therapy with an oral vitamin K antagonist to a target international normalized ratio (INR) of 2.5 (range, 2.0 to 3.0).^{171–173} All other patients should receive platelet-directed therapy with aspirin.

Ventricular Assist Devices

Chronic left ventricular heart failure, the end result of advanced ischemic heart disease and nonischemic cardiomyopathy, is the leading cause of death in the United States and developed countries, affecting nearly 10 per 1000 individuals 65 years of age and older.¹⁷⁴ The development of left ventricular assist devices (LVADs) and the start of the artificial heart program in 1964 provide a much needed “bridge” to transplantation and, in some instances, a successful temporizing measure for clinical stabilization of recovery, referred to as “destination therapy.”

LVADs receive blood from the left ventricle by means of an inflow cannula and subsequently pump it to the aorta via an outflow cannula. Early-generation devices used an external drive pump and vent, predisposing to infection and limited patient mobility. Later devices employed a powerpack placed subcutaneously and internal venting systems of various designs.¹⁷⁵

Cardiac devices currently used for cardiac mechanical support are summarized in Table 20-8. Most require anticoagulant therapy because of a recognized risk for thrombosis and thromboembolism, which, in the early experience, approached 20% to 30% of patients.^{176,177} The HeartMate device (Thoratec Corporation, Pleasanton, CA) is associated with a lower reported incidence of thromboembolism¹⁷⁸; as a result, platelet-directed therapy with aspirin may, in select patients, provide adequate thromboprophylaxis. Nevertheless, thrombosis/thromboembolism remains a constant concern in patients with mechanical ventricular assist devices.^{179,180}

Dosing Dilemmas: An Opportunity for Improved Safety

In a prospective observational analysis of 30,136 patients with non-ST segment elevation ACS, 42% received an initial dose of heparin, LMWH, or LMWH or a GP-IIb/IIIa receptor antagonist outside the recommended range of dosing (Table 20-9). Patient characteristics associated with excess drug dosing included older age, female sex, low body weight, renal insufficiency, diabetes mellitus, and congestive heart failure. Excess antithrombotic drug dosing was associated with major bleeding complications, increased length of hospital stay, and higher rates of mortality.¹⁸¹

An Evolving View of Blood Transfusion

The frequency of anemia among hospitalized patients has led to the liberal use of blood (erythrocyte) transfusions. Current clinical practice still acknowledges (and follows) the age-old “10/30” rule, first proposed in 1942.¹⁸² This

Table 20-7 Antiplatelet and Antithrombotic Adjunctive Therapies for Percutaneous Coronary Intervention (PCI)**Class I**

1. Patients already taking daily long-term aspirin therapy should take 75 to 325 mg of aspirin PO before the PCI procedure is performed. (Level of Evidence: A)
2. Patients who are not already taking daily long-term aspirin therapy should be given 300 to 325 mg of aspirin PO at least 2 hours and preferably 24 hours before the PCI procedure is performed. (Level of Evidence: C)
3. After the PCI procedure has been completed, in patients with no aspirin resistance, allergy, or increased risk of bleeding, aspirin 325 mg daily PO should be given for at least 1 month after bare metal stent implantation, 3 months after sirolimus eluting stent implantation, and 6 months after paclitaxel eluting stent implantation, after which daily long-term PO aspirin use should be continued indefinitely at a dose of 75 to 162 mg PO. (Level of Evidence: B)
4. A loading dose of clopidogrel should be administered before PCI is performed. (Level of Evidence: A) An oral loading dose of 300 mg, administered at least 6 hours before the procedure is begun, has the best established evidence of efficacy. (Level of Evidence: B)
5. In patients who have undergone PCI, clopidogrel 75 mg PO daily should be given for at least 1 month after bare metal stent implantation (unless the patient is at increased risk of bleeding; then it should be given for a minimum of 2 weeks), 3 months after sirolimus stent implantation, and 6 months after paclitaxel stent implantation, and ideally up to 12 months in patients who are not at high risk of bleeding. (Level of Evidence: B)

Class IIa

1. If clopidogrel is given at the time the procedure is performed, supplementation with glycoprotein (GP)-IIb/IIIa receptor antagonists may be more beneficial than clopidogrel alone in facilitating earlier platelet inhibition. (Level of Evidence: B)
2. For patients with an absolute contraindication to aspirin, it is reasonable to give a 300-mg oral loading dose of clopidogrel, administered at least 6 hours before PCI, and/or GP-IIb/IIIa antagonists, administered at the time of PCI. (Level of Evidence: C)
3. When a loading dose of clopidogrel is administered, a regimen greater than 300 mg PO is reasonable for achieving higher levels of antiplatelet activity more rapidly, but efficacy and safety compared with a 300 mg PO loading dose are less well established. (Level of Evidence: C)
4. It is reasonable that patients who undergo brachytherapy should be given daily clopidogrel 75 mg PO indefinitely and daily aspirin 75 to 325 mg PO indefinitely, unless the risk of bleeding is significant. (Level of Evidence: C)

Class IIb

In patients in whom subacute thrombosis may be catastrophic or lethal (unprotected left main, bifurcating left main, or last patent coronary vessel), platelet aggregation studies may be considered, and the dose of clopidogrel increased to 150 mg PO per day, if less than 50% inhibition of platelet aggregation is demonstrated. (Level of Evidence: C)

60-year-old study demonstrated an increase in cardiac output when hematocrit was below 30%—a response that was believed to be maladaptive. In 2003 to 2004, 3500 patients received erythrocyte transfusions each day in U.S. hospital intensive care unit (ICU) settings, totaling 1.25 million transfusions per year in the ICU alone.¹⁸³ However, few hard data are available to support this “reflex transfusion response.” A retrospective case-controlled study showed that elderly patients who presented with acute MI experienced a lower 30-day mortality rate when erythrocyte transfusions were administered to achieve hematocrit greater than 30%.¹⁸⁴ Whether these data provide definitive support for transfusion practices has been questioned because of the study’s lack of randomization, unequal numbers in case and control groups, and low overall frequency of transfusion.

In contrast, a prospective, randomized, multicenter trial of 357 critically ill patients with underlying cardiovascular disease failed to show mortality reduction with liberal transfusion; only a trend toward fewer deaths was observed in a relatively small subgroup of patients ($n = 77$) characterized by severe ischemic heart disease (unstable angina or acute MI).¹⁸⁵

Rao and colleagues¹⁸⁶ examined the potential impact of erythrocyte transfusion in 24,111 patients with ACS. Several surprising observations were reported from the post hoc analysis. First, significantly higher 30-day all-cause mortality and 30-day death or MI rates were described among patients who received transfusions. Second, this increased risk persisted after adjustment was made for potentially confounding clinical variables (adjusted hazard ratio, 3.94) and after several statistical methods were used to adjust for bias. Third, 30-day mortality was

particularly high when transfusions were given for hematocrit levels of 25% or above (compared with hematocrit less than 25%).

Hebert and colleagues¹⁸⁷ enrolled 838 critically ill patients with euvoolemia after initial treatment who had hemoglobin levels lower than 9.0 g per deciliter within 72 hours of ICU admission and randomly assigned them to a restrictive strategy of transfusion (red cells transfused if hemoglobin <7.0 g per deciliter) or a liberal strategy (transfusion if hemoglobin fell to below 10.0 g per deciliter). Rates of 30-day mortality were similar in the two groups (18.7% vs 23.3%; $P = .11$), with an exception noted among patients younger than 55 years of age and those with an Acute Physiology and Chronic Health Evaluation (APACHE) II score of less than 20, in whom rates were lower with a restrictive strategy of transfusion. Cardiac events, including pulmonary edema and MI, were more frequent in the liberal strategy group than in the restricted strategy group during the ICU stay; however, no significant differences in rates of cardiac events (or infectious complications) were reported among those who died during the 48 hours preceding death. Similarly, no significant differences in mortality were observed between treatment groups in the modestly sized subgroup of patients with a primary or secondary diagnosis of cardiac disease (20.5% in the restrictive strategy group and 22.9% in the liberal strategy group). Finally, transfusion emerged as a risk factor for poor outcomes in patients with trauma who experienced a higher mortality rate during hospitalization when blood products were administered (after control was provided for the degree of anemia and shock).¹⁸⁸

Table 20-8 Comparison of Available Cardiac Devices**Pulsatile Pumps****Thoratec**

Indications	Right, left, or biventricular support
Advantages	Fits in a wide range of patient sizes (body surface area, 0.73 to 2.5 m ²) Pump can be changed without invasive surgery Can replace the entire function of the supported ventricle
Disadvantages	Requires strict anticoagulation with risks of bleeding and thromboembolism High risk of infection Limited patient mobility Not approved for home use

HeartMate

Indications	Left ventricular support
Advantages	No need for anticoagulation Portability of controller and batteries permits good patient mobility and hospital discharge Can replace the entire function of the supported ventricle
Disadvantages	Drive line crossing the skin poses a risk of infection Left ventricle support only Not suitable for patients with body surface area ≤ 1.5 m ²

Novacor

Indications	Left ventricular support
Advantages	Portability of controller and batteries permits patient mobility and hospital discharge
Disadvantages	Need for strict anticoagulation with higher risk of bleeding or thromboembolism Drive line crossing the skin poses a high risk of infection Left ventricle support only Not suitable for patients with body surface area ≤ 1.5 m ²

Continuous Flow Pumps

Indications	Left ventricular support
Advantages	Small size permits patient mobility Quiet Suitable for wide range of patient body habitus
Disadvantages	Need for anticoagulation; risks of bleeding and thromboembolism unknown May not replace the entire function of the supported ventricle Nonpulsatile flow Still in early clinical trials

Modified from Nemeh HW, Smedira NG: Mechanical treatment of heart failure: The growing role of LVADs and artificial hearts. *Cleveland Clin J Med* 3:223–233, 2003.

Data derived predominantly from retrospective and modestly sized prospective studies raise the suspicion that an association between transfusion and morbidity or mortality may exist, yet questions remain about whether the relationship is causal and how contributing factors may differ (or may manifest differently) on the basis of coexisting illness and accompanying conditions.

Table 20-9 Dosing Recommendations and Categories of Antiplatelet and Antithrombin Agents for Non-ST Segment Elevation Acute Coronary Syndrome*

Dosing Recommendations	
Unfractionated heparin	IV bolus of 60–70 U per kilogram followed by an infusion of 12–15 U/kg/hr IV. Elderly patients (>60 years) may require lower heparin doses.
Low molecular weight heparin	Enoxaparin: 1 mg/kg SQ every 12 hours. Dose is reduced by 50% by increasing intervals to every 24 hours if creatinine clearance <30 mL per minute. Elderly patients at high risk of bleeding. Dalteparin: Use caution in elderly patients with low body weight or predisposed to renal insufficiency.
Glycoprotein-IIb/IIIa inhibitors [†]	Eptifibatide: Bolus 180 μ g per kilogram IV and infusion of 2.0 μ g/kg/min IV for 72–96 hours. Reduce infusion rate by 50% to 1 μ g/kg/min if creatinine clearance is ≤ 30 mL per minute or serum creatinine is 2 to 4 mg per deciliter. Tirofiban: IV bolus 0.4 μ g per kilogram per minute and infusion of 0.1 μ g per kilogram per minute IV for 48 to 96 hours. Reduce bolus and infusion by 50% to 0.05 μ g/kg/min IV if creatinine clearance ≤ 30 mL per minute. Systeme Internationale (SI) conversions: To convert creatinine clearance to mL per second, multiply by 0.0167; serum creatinine to μ mol per liter, multiply by 88.4.

*Dosing recommendations from guidelines and product labels. Mild and major excess categories are subgroups of excess categories.

[†]Insufficient numbers for underdosing of glycoprotein-IIb-IIIa inhibitor group.

Defining Hemorrhagic Risk

Risk of hemorrhage associated with antithrombotic therapy, in addition to its intrinsic effects on primary hemostasis, secondary hemostasis, and intensity of effect, is influenced strongly by patient characteristics. Advanced age, renal insufficiency, presence of hypertension, and combined drug therapy contribute to the overall risk of hemorrhagic events, including central nervous bleeding.¹⁸⁹ Table 20-10 suggests some treatment pathways (in addition to time) for hemorrhagic complications associated with these agents.

GI hemorrhage is second only to mucocutaneous bleeding as a source of major bleeding and as a source of major events among patients receiving platelet-directed therapy. In a large case-controlled study,¹⁹⁰ relative risks of upper GI bleeding associated with long-term administration were as follows: aspirin, 4.0; clopidogrel, 2.3; dipyridamole, 0.9; indobufen, 3.8; and ticlopidine, 3.1. Available evidence suggests that risk is increased when aspirin and clopidogrel are used in combination. Although protein pump inhibitors reduce the likelihood of aspirin-related recurrent GI bleeding among patients with treated peptic ulcer disease,¹⁹¹

Table 20-10 Agent-Specific Approach to Hemorrhagic Complications

Agent	Category	Mechanism of Action	Antidote	Available Substrate for Attenuating Effects
Aspirin	Platelet antagonist	Cyclo-oxygenase inhibition	DDAVP	Platelet transfusion
Clopidogrel	Platelet antagonist	ADP receptor inhibition	None	Platelet transfusion
Ticlopidine	Platelet antagonist	ADP receptor inhibition	None	Platelet transfusion
Abciximab	Platelet antagonist	GP-IIb/IIIa receptor inhibition	None	Platelet transfusion, FFP, Cryoprecipitate
Tirofiban	Platelet antagonist	GP-IIb/IIIa receptor inhibition	None	Cryoprecipitate, FFP, platelet transfusion
Eptifibatide	Platelet antagonist	GP-IIb/IIIa receptor inhibition	None	Cryoprecipitate, FFP, platelet transfusion
UFH	Anticoagulant	Anti-IIa and -Xa via ATIII	Protamine	None
LMWH	Anticoagulant	Anti-IIa and -Xa via ATIII	Protamine (60% effective)	None
Fondaparinux	Anticoagulant	Anti-Xa via ATIII	None	None
Lepirudin	Anticoagulant	Anti-IIa (direct)	None	FFP, plasmapheresis
Argatroban	Anticoagulant	Anti-IIa (direct)	None	FFP, plasmapheresis
Danaparoid	Anticoagulant	Anti-IIa (direct)	None	Plasmapheresis

DDAVP, 1-deamino-8-D-arginine vasopressin; ADP, adenosine diphosphate; GP, glycoprotein; UFH, unfractionated heparin; LMWH, low molecular weight heparin; FFP, fresh frozen plasma.

their protective effects with clopidogrel have not been established.¹⁹²

Minimizing Surgical Bleeding Risk

The recommended approach for minimizing major hemorrhage in the surgical setting begins with a thorough understanding of antithrombotic drugs that includes their pharmacological pharmacodynamics, biologic half-lives, preoperative dosing and antidotes, and neutralizing agents or potential removal strategies, as clinical circumstances and the risk/benefit relationship dictate.¹⁹³ The timing of surgery and the specific technique used must also be considered carefully. Hospitalized patients with an ACS are particularly prone and unnecessarily disadvantaged at the time of surgery if they receive excessive doses of antithrombotic therapy over the days leading up to surgery (of if emergent surgery is required).¹⁸¹

Antifibrinolytic agents such as aprotinin¹⁹⁴ have been used during cardiac surgery to reduce blood loss, transfusion requirements, and the proinflammatory state that accompanies cardiopulmonary bypass.¹⁹⁵ Aprotinin has also been shown to reduce postoperative blood loss among clopidogrel-treated patients, including those given the platelet antagonist within 5 days of surgery.¹⁹⁶ Emerging data that suggested that the use of alternative antifibrinolytic agents such as ϵ -aminocaproic acid and tranexamic acid may be safer than administration of aprotinin and require further evaluation.¹⁹⁷

Recombinant factor VIIa, a hemostatic agent licensed for the treatment of bleeding episodes among patients with hemophilia and inhibitors, may also have a place in the management of bleeding associated with platelet disorders,¹⁹⁸ including the coagulopathy induced by cardiac surgery.¹⁹⁹ In vitro studies suggest a factor Xa/thrombin-dependent mechanism of platelet activation.²⁰⁰ As with any and all treatments given with the intent of shifting the hemostatic balance toward thrombosis, potential risks must be weighed carefully against benefits.²⁰¹

Chapter 21

Risk Factors for Cardiovascular Disease and Arterial Thrombosis

Mary Cushman, MD, MSc • Barbara M. Alving, MD

INTRODUCTION

The hematologist, working in concert with cardiologists and vascular surgeons, may play an important role in guiding the effective and appropriate assessment of the patient who has sustained or is at risk for arterial thrombosis. This chapter reviews established risk factors and newer markers, such as C-reactive protein (CRP), that are used to determine risks for atherosclerosis and arterial events. Tests determined not to be helpful through evidence-based methods are also listed, and discussion of future areas of needed research is provided.

Major established risk factors for coronary heart disease (CHD) that are used to identify treatments for lowering low-density lipoprotein (LDL) cholesterol have been extensively reviewed in the third report of the National Cholesterol Education Program Adult Treatment Panel III (ATP III) on the detection, evaluation, and treatment of adults with high blood cholesterol.^{1,2} This report focuses on level of risk and appropriate treatment for the primary prevention of CHD and for prevention of progression and acute events in those with established CHD. The first step in risk assessment is to calculate a 10-year predicted risk of CHD with the use of a tool such as the Framingham Risk Score.³ Online calculators are available to assist clinicians (<http://hp2010.nhlbi.nih.gov/atpiii/calculator.asp>). Accepted major risk factors include cigarette smoking, hypertension, high levels of LDL cholesterol, low levels of high-density lipoprotein (HDL) cholesterol, history of premature CHD in first-degree relatives, and patient age and gender (Table 21-1). Diabetes and other manifestations of arterial disease (e.g., peripheral artery disease, stroke) are considered CHD risk equivalents. In these settings, and when multiple risk factors are present that would confer a greater than 20% 10-year risk of CHD, treatment given to lower LDL cholesterol levels to <70 mg per deciliter is recommended. Among those with a 10-year predicted risk of 10% to 20%, benefits of lipid-lowering drugs are sometimes uncertain, and in this group, new risk factors might be considered.

Major risk factors have been validated in populations of various ethnicities.⁴ Furthermore, prospective trials have found that 80% to 90% of patients with CHD have one or more of these conventional risk factors.⁵ Between 87% and 100% of patients with fatal CHD have a history of at least one major risk factor.⁶ Thus, the challenge of validating risk factors that provide additional value above that provided by those already recognized is great.^{7,8}

NEWER MARKERS FOR ASSESSING ARTERIAL THROMBOSIS

Optimal assessment of new biomarkers of vascular risk should be conducted in prospective studies in which evaluation of the exposure of interest is done at baseline in apparently healthy individuals at risk for future cardiovascular disease (CVD). When the clinician considers application of these markers to treat a patient with a potentially new risk factor, several criteria must be met (Table 21-2). Measurement of the potential new risk marker must enhance the clinician's ability to predict risk compared with established traditional risk factors^{9,10}; this value must be generalizable to a diverse population and should provide information that will guide the clinician in selecting a prevention strategy. Optimally, the risk factor that is assessed ought to be modifiable, or at least, its assessment should reveal an appropriate treatment that might not otherwise be administered. The analyte of interest must be measurable with an assay that is easy to apply to the population, is cost effective, and has appropriate sensitivity and specificity.¹¹

C-Reactive Protein

Epidemiologic studies of new plasma and genetic markers for coronary risk have focused on three major domains: reduced fibrinolytic potential, increased thrombotic potential, and inflammation. CRP, one of the most extensively studied inflammation markers, appears to provide additional value in selected settings. CRP is synthesized by hepatocytes and rises several hundred-fold in response to circulating cytokines induced by acute injury. In the absence of acute inflammation, CRP levels tend to be stable within individuals over long periods, and they provide an index of underlying low-grade inflammation.

Many biologic roles have been described for CRP in relation to atherosclerosis.¹² Whether CRP has a direct role in thrombus formation is not clear, although its circulating level is directly correlated with levels of some hemostatic factors,¹³ and experimental evidence has shown that CRP can induce monocyte tissue factor expression.¹⁴ CRP colocalizes with complement in atherosclerotic plaques¹⁵; it can activate complement¹⁶ and may regulate adhesion molecule expression by endothelial cells.¹⁷ Further, CRP is chemotactic for monocytes within plaques.¹⁸

Many prospective epidemiologic studies have linked baseline levels of CRP to future risks of myocardial infarction,

Table 21-1 Risk Factors for Arterial Thrombosis

Major Risk Factors for Coronary Heart Disease (CHD)*
Cigarette smoking
Hypertension (blood pressure $\geq 140/90$ mm Hg or patient receiving antihypertensive medication)
Low high-density lipoprotein (HDL) cholesterol and high low-density lipoprotein (LDL) cholesterol
Diabetes mellitus
Other forms of atherosclerosis (i.e., peripheral arterial disease)
Family history of premature CHD in first-degree relatives (males <55 years of age; females <65 years of age)
Other Markers for Consideration
C-reactive protein (CRP) (measured as high sensitivity-CRP [hs-CRP])
Lipoprotein-associated phospholipase A2 (Lp-PLA ₂)
Cardiolipin antibody and lupus anticoagulant
Genetic markers for Fabry disease (stroke)
Tests Not Proved to Add Clinical Value
Fibrinogen levels
Homocysteine levels
Methylenetetrahydrofolate reductase (MTHFR) polymorphisms
Markers of Fibrinolysis
Tissue-type plasminogen activator (tPA) levels
Plasminogen activator inhibitor-1 (PAI-1) levels
Markers for Venous Thrombosis Risk (examples)
Factor V Leiden
Prothrombin 20210
Protein C
Lipoprotein(a) levels
D-Dimer levels

*Adapted from reference 1.

Table 21-2 Criteria for Consideration in Evaluation of Biochemical Risk Markers

Clinically applicable assay
High sensitivity and specificity
High within-person reproducibility
Significant population variability
Generalizability to diverse populations
Data obtained through valid epidemiologic study designs
Additive to predictive capacity of established risk factors
Cost-effectiveness
Assessment has the potential to result in a treatment or prevention strategy that would not otherwise have been used

stroke, and coronary heart disease mortality among individuals free of known cardiovascular disease.¹⁹ The first report that linked elevated CRP (measured as high-sensitivity [hs]-CRP) with risk of future vascular events included patients with unstable angina.²⁰ In this study, higher levels of hs-CRP were associated with the development of recurrent acute coronary syndromes. In 1996, this finding was extended when a report from the Multiple Risk Factor Intervention Trial (MRFIT) showed that baseline hs-CRP was associated with future fatal coronary heart disease among male smokers who had other cardiac risk factors.²¹ In that study, hs-CRP was measured in blood samples drawn 5 to 17 years before the onset of clinical events, pointing out

the potential for discriminating very long-term risk, and suggesting that hs-CRP measurement did not simply reflect generalized illness. In a larger study of apparently healthy middle-aged American men followed for 8 years, those with hs-CRP levels in the highest quartile at baseline had a two-fold increase in the risk of future stroke, a threefold increase in the risk of myocardial infarction, a fourfold increase in the risk of undergoing surgery for peripheral vascular disease compared with study participants with lower levels of hs-CRP, but no increased risk of venous thrombosis.^{22,23} These effects were additive to those of total cholesterol and HDL cholesterol in terms of risk prediction.²⁴

Similar data confirming these observations have been reported in many prospective observational studies that studied other types of populations, such as women²⁵ and the elderly.²⁶ A meta-analysis reported that hs-CRP concentrations in the top one third of the population distribution were associated with a twofold increased risk of myocardial infarction.²⁷ Among individuals with stable and unstable coronary syndromes, and in those who have a prior history of myocardial infarction, hs-CRP may be useful for developing a prognosis and for choosing treatment.^{20,28–32}

hs-CRP assays, along with World Health Organization standards for calibration, are commercially available for use in the clinic.^{33,34} Standard clinical assays for CRP do not have adequate sensitivity and accuracy to detect levels in the range that is relevant for coronary risk prediction; accordingly, hs-CRP assays are required. Current guidelines (published in 2003) prepared by a group convened by the Centers for Disease Control and Prevention and the American Heart Association state that hs-CRP is the best marker of inflammation in assessment of risk for CVD (Table 21-3).³³ The guideline report and subsequently published studies indicate that measurement of hs-CRP may be useful in directing prevention of first CHD events for those individuals determined to be at intermediate risk for CHD (10% to 20% predicted risk over 10 years). Relative risk categories, which were derived on the basis of hs-CRP levels (as averaged from two measurements taken 2 weeks apart) are as follows: low risk, <1 mg per liter; average risk, 1 to 3 mg per liter; high risk, >3 mg per liter. In the current guideline report, it is suggested that values >10 mg per liter should prompt a workup for clinical inflammatory conditions; however, 5% to 10% of apparently healthy individuals have levels in this range, and two studies published subsequently showed that these values are

Table 21-3 Recommendations for Testing for High-Sensitivity C-Reactive Protein (hs-CRP) in Clinical Practice

- hs-CRP level may be useful in directing primary prevention of coronary heart disease (CHD) for individuals at intermediate predicted risk (10%–20% over 10 years).
- hs-CRP might be useful in those without known heart disease to encourage improvement in lifestyle risk factors.
- hs-CRP can be used in patients with stable CHD or acute coronary syndromes as an independent marker of prognosis for recurrent events (e.g., myocardial infarction, restenosis after percutaneous coronary intervention).
- The benefits of measuring hs-CRP in the clinical settings described above have not been established.

Adapted from reference 33.

associated with an even higher risk of CHD,^{26,34} so they may have meaning as well in risk prediction. In the general population, about one third of people have CRP >3 mg per liter, although this proportion may be higher in some groups, such as women and some nonwhite ethnic groups.³⁵

Once elevated levels of hs-CRP have been detected, interventions may be selected that may reduce those levels. Because levels are correlated with risk factors such as smoking, obesity, fitness, and physical inactivity, knowledge of the level may be motivational in encouraging patients to improve their lifestyles (although this has not been studied specifically). Statin therapy also lowers hs-CRP; some studies in primary and secondary prevention settings suggest that those with higher hs-CRP may derive benefit from therapy, regardless of LDL level.^{31,36,37}

Although high levels of hs-CRP provide an independent marker for risk of CHD, the clinical benefit of measurement of hs-CRP is debated. Levels of hs-CRP in patients with stable coronary disease or acute coronary syndromes are an independent marker of prognosis for recurrent events, such as myocardial infarction or restenosis after percutaneous coronary intervention.³³ Two large trials reported that the lower the concentration of hs-CRP from intensive statin therapy 30 days after an acute coronary syndrome, the lower the risk of subsequent vascular events, regardless of statin dose.^{31,37} In primary prevention settings, it remains unresolved whether patients with desirable lipid levels and elevated hs-CRP will derive benefit from initiation of statin therapy, although one study did suggest this.³⁶ An ongoing large prevention trial will address this question.³⁸

For the practicing hematologist who sees patients with established arterial disease, if hs-CRP is elevated (>3 mg per liter on more than one occasion), statin therapy would currently be indicated (essentially, all patients with established arterial disease should be treated anyway with the goal of attaining a target LDL cholesterol <70 mg per deciliter). Optimal blood pressure control (<120/80 mm Hg) should be recommended, regardless of hs-CRP. The accuracy of monitoring hs-CRP to tailor the statin dose has not been substantiated, but it has been suggested that the lower the hs-CRP value, the lower the subsequent risk of vascular events. In primary prevention settings (where a hematologist is less likely to be involved), if a nondiabetic patient with a 10-year predicted CHD risk of 10% to 20% has hs-CRP >3 mg per liter on more than one occasion, lifestyle changes are indicated regarding smoking cessation, weight loss, increased physical activity, and a prudent diet. If LDL cholesterol is in the borderline range, indicating statin therapy by current guidelines, the practitioner may elect earlier introduction of treatment.

MARKERS FOR STROKE

Lipoprotein-associated phospholipase A2 (Lp-PLA₂), an enzyme synthesized by monocytes and macrophages, hydrolyzes oxidized phospholipids, thereby generating lysophosphatidylcholine and oxidized fatty acids, which have proinflammatory properties in atherosclerotic plaque. This enzyme, which is bound mainly to LDL cholesterol in the circulation, has been assessed in a prospective observa-

tional study, the Atherosclerosis Risk in Communities (ARIC) study, which involved more than 15,000 healthy middle-aged men and women.³⁹ Investigators in this study found that measurements of Lp-PLA₂ and hs-CRP may be useful beyond assessment of traditional risk factors (smoking, systolic hypertension, lipid levels, and diabetes) for risk prediction of stroke. Those who had the highest tertile of hs-CRP or Lp-PLA₂ were about twice as likely to have an ischemic stroke as those in the lowest tertile.³⁹ On the basis of these and other findings, the U.S. Food and Drug Administration approved a test that measures Lp-PLA₂. This test, known as the PLAC test (diaDexus, San Francisco, Calif), is available at reference laboratories and has been associated with risk of myocardial infarction and stroke in other studies.^{40–42} The exact clinical role of Lp-PLA₂ testing remains to be defined, and specific inhibiting drugs are currently under development.

Two additional markers for stroke risk include appropriate tests to rule out antiphospholipid syndrome (see Chapter 19) and testing for Fabry disease. One-time laboratory tests for antiphospholipid antibodies after acute stroke were not helpful in determining long-term treatment in one clinical trial,⁴³ emphasizing the need for proper diagnosis. According to a report on persons between the ages of 18 and 55 years with unexplained acute cerebrovascular events, 4.9% of men and 2.4% of women had a biologically significant α -galactosidase gene mutation. Deficient α -galactosidase induces endothelial dysfunction and results in the phenotypic expression of Fabry disease.⁴⁴

MARKERS OF UNPROVED OR INSIGNIFICANT VALUE IN CLINICAL PRACTICE

None of the hemostatic factor gene polymorphisms that have been studied in CHD provides increased value in risk prediction over traditional risk factors.⁴⁵ These include factor V Leiden, prothrombin 20210, and the plasminogen activator inhibitor-1 (PAI-1) 4G/5G variant (which results in elevated PAI-1 levels). Few population-based data are available on association of the rarer thrombophilic disorders with arterial disease (e.g., deficiency of protein C, protein S, or antithrombin III).

Epidemiologic studies that related hemostatic gene polymorphisms to arterial disease have been inconsistent and largely negative.^{45–50} Although in some subgroups, such as young women, these factors may be associated with myocardial infarction,^{51,52} optimal treatment approaches for such patients and the role of anticoagulant therapy, compared with aspirin or control of conventional risk factors, is not known. Because of this, assessment must be individualized. Standard guidelines do not exist.

Total Plasma Homocysteine

Homocysteine, a sulfhydryl amino acid, plays a major role in the metabolism of methionine. Patients with rare inherited deficiencies in the enzymes methionine synthase, methylenetetrahydrofolate reductase (MTHFR), and, in particular, cystathione beta-synthase may have marked plasma elevations of homocysteine and often

Figure 21-1 Prospective studies of homocysteine as a risk factor for future cardiovascular disease in populations free of clinical disease. (From Christen WG, Ajani VA, Glynn RJ, et al: Blood levels of homocysteine and increased risks of cardiovascular disease: Causal or casual? *Arch Intern Med* 160:422–434, 2000, with permission.)

experience premature atherothrombosis or venous thrombosis. Several mechanisms may link severe hyperhomocysteinemia (plasma concentration >100 μmol per liter) to vascular damage, including direct endothelial toxicity, induction of vascular smooth muscle proliferation, impairment of endothelially derived relaxing factor, and accelerated oxidation of LDL cholesterol.⁵³ On a population basis, severe hyperhomocysteinemia is rare. Mild to moderate hyperhomocysteinemia (plasma concentration >15 μmol per liter) is present in up to 10% of individuals; however, this prevalence has decreased dramatically in countries that have instituted fortification of grain with folic acid because the usual cause of mild to moderate hyperhomocysteinemia is low dietary folate intake. Folic acid, cyanocobalamin (vitamin B₁₂), and pyridoxine (vitamin B₆) are all involved in the regulation of methionine metabolism; several studies have detected inverse associations between homocysteine concentration and plasma levels of these vitamins. Administration of folic acid in doses between 0.5 and 5.0 mg per day produces a reduction in homocysteine levels.

Screening for hyperhomocysteinemia among asymptomatic individuals to determine risk is controversial and is not currently recommended by the American College of Cardiology or the American Heart Association.⁵⁴ Published reports on the relative risk of CHD with elevated homocysteine are shown in Figure 21-1; this illustration shows the differences between retrospective and prospective studies,

as well as among prospective studies. Several possible reasons have been proposed for conflicting results among prospective studies. Studies may be too heterogeneous in terms of methods or population source to be comparable with one another. Larger associations are evident in studies with shorter versus longer follow-up periods. Adjustment for potential confounders, such as vitamin intake, varies widely. Conflicting data suggest that the magnitude of any increased risk associated with hyperhomocysteinemia is likely to be modest and may be limited to those relatively few individuals with substantial elevations in total plasma homocysteine.

Four clinical trials of B vitamin supplementation published since 2004 have shown no benefit of homocysteine lowering for arterial vascular events. A trial of 3749 patients with acute myocardial infarction showed no benefit of various combinations of folic acid, vitamin B₁₂, and vitamin B₆ in terms of recurrent cardiovascular events; it was suggested that harm may result from triple-vitamin therapy.⁵⁵ Another trial randomly assigned 5522 patients 55 years of age and older with established CVD or diabetes to triple therapy with 2.5 mg folic acid, 50 mg vitamin B₆, and 1 mg vitamin B₁₂ daily or placebo; results showed no overall benefit in reduction of cardiovascular events or death from CVD, with the exception of a 25% reduction in stroke (95% confidence interval [CI], 0.59 to 0.97).⁵⁶ However, another large, randomized trial of 3680 patients with stroke compared high-dose

vitamin B supplementation (25 mg vitamin B₆, 0.4 mg vitamin B₁₂, 2.5 mg folic acid daily) with low doses found in multivitamins (200 µg vitamin B₆, 6 µg vitamin B₁₂, and 20 µg folic acid daily); no clinical benefit of plasma homocysteine lowering was discerned in the prevention of recurrent stroke or other end points.⁵⁷ A smaller study of high-dose folate (15 mg daily) or placebo in patients with chronic renal failure showed no effect on measures of atherosclerosis or clinical events.⁵⁸ Although only the last study specifically included patients with elevated plasma homocysteine levels, on the basis of these findings, homocysteine testing to define vascular risk does not seem appropriate at this time, given the lack of availability of an effective intervention. Genetic testing for the thermolabile variant of MTHFR is similarly not indicated.

Lipoprotein(a)

Lipoprotein(a) (Lp[a]) is composed of an apo B-containing lipoprotein structure that is virtually identical to that of LDL; it is attached by a single disulfide bond to a long, carbohydrate-rich protein designated apolipoprotein(a) (apo[a]). Apo(a) is highly homologous with plasminogen,⁵⁹ and it has been hypothesized that Lp(a) competes with plasminogen for binding sites on fibrin and endothelial cell surfaces, thus inhibiting fibrinolysis. Several lines of evidence support a biologic role for Lp(a) in atherothrombosis, including *in vitro* inhibition of plasminogen binding to fibrin and inhibition of tissue-type plasminogen activator (tPA)-catalyzed fibrinolysis.^{60–62} A role in atherogenesis is suggested by other data: Lp(a) is more likely to accumulate in plaques from patients with unstable compared with stable angina, and it colocalizes with macrophages in unstable plaques.⁶³ Lp(a) also induces monocyte chemoattractant activity in human vascular endothelial cells.⁶⁴

The clinical role of Lp(a) as a marker of risk for future coronary events is controversial. To date, more than a dozen prospective studies of Lp(a) have been published; many, but not all, have reported positive associations. For example, in three large studies, no association between baseline plasma concentration of Lp(a) and subsequent vascular risk was reported.^{65–67} In contrast, four other studies reported positively graded associations between plasma Lp(a) level and risk of CHD.^{68–71} A meta-analysis of prospective studies reported a relative risk of 1.7 (95% CI, 1.4 to 1.9) for Lp(a) in the top one third compared with the bottom one third of the distribution.⁷²

Most guideline authorities do not recommend that Lp(a) evaluation be included in general screening programs. One reason not to recommend inclusion of Lp(a) evaluation in general screening programs is that Lp(a) levels vary among different racial cohorts, and at least one study has found no association between Lp(a) and vascular disease among African Americans.⁷³ Further, conflicting data in women suggest that findings in men cannot easily be generalized.⁷⁴ In a cohort of initially healthy women, very high levels (>90th percentile) were associated with increased risk for CVD in those women who also had high levels of LDL cholesterol.⁷⁵ Thus, the predictive value of Lp(a) may be limited to those with underlying hyperlipidemia—a relationship attenuated by

LDL cholesterol reduction.⁷⁶ Additionally, lack of uniformity has been noted in methods used for testing for Lp(a).⁷⁷ In part, the tandem-repeat structure of apo(a) has made commercial assays difficult to calibrate—an issue that may be overcome by developing assays that make use of apo(a) monoclonal antibodies specific for unique epitopes of the Lp(a) molecule. However, whether such specific antibodies will improve the predictive value of Lp(a) testing remains uncertain.

Fibrinogen

Fibrinogen directly affects blood clotting, plasma rheology, platelet aggregation, and endothelial function. Further, plasma fibrinogen plays a major role in monocyte adhesion, and both fibrinogen and fibrin degradation products have been shown to stimulate smooth muscle proliferation. Thus, through hemostatic and inflammatory mechanisms, plasma fibrinogen level is closely related to thrombus formation.⁷⁸ Of the major novel markers for coronary artery disease, fibrinogen was the earliest to undergo extensive epidemiologic evaluation. Prospective data from many studies^{45,79–81} all confirm that higher plasma fibrinogen levels are associated with risk of future myocardial infarction, stroke, or cardiovascular death, and in some studies, with non-CVD mortality. In a pooled analysis involving more than 150,000 participants from 31 prospective studies, after adjustment was made for conventional risk factors, each 1 g per liter higher fibrinogen increment was associated with a 1.8-fold higher risk of vascular events.⁸² In some studies^{83,84} but not in others, evidence has been presented that assessment of plasma fibrinogen levels adds to the predictive value of lipid screening. At the present time, because it is not clear how one should intervene for patients with higher fibrinogen levels, and because of assay standardization problems, no convincing evidence supports the value of measuring plasma levels of fibrinogen levels as a marker of CVD risk.

Fibrinolysis

The balance between plasminogen activators, primarily tPA and its main inhibitor, PAI-1, determines the overall activity of the fibrinolytic system. Fibrinolytic proteins may be detected in plasma with the use of sensitive assays for antigen and activity levels. In general, an increased PAI-1 concentration is associated with impaired fibrinolysis, which may lead to reduced plasmin, accumulation of fibrin and activation of metalloproteinase activity.⁸⁵ Determination of plasma fibrinolytic activity, however, has not provided additional predictive power in the establishment of risk for CVD.

Some of the difficulties associated with assessment of plasma fibrinolytic activity might be overcome by assessment of genetic markers of fibrinolytic function; genetic variations associated with PAI-1 and tPA production have been described. However, studies of an insertion–deletion polymorphism in the promotor region of the PAI-1 gene and of an Alu-repeat insertion–deletion polymorphism in the tPA gene have been inconsistent regarding relation to risk of CVD.

Hemostatic Activation Markers

D-Dimer is formed by the degradation of crosslinked fibrin by plasmin; therefore, plasma levels of D-dimer reflect ongoing fibrin formation and breakdown. Epidemiologic studies suggest that D-dimer may have predictive power for first and recurrent vascular events.^{11,86–91} However, little evaluation has been conducted of the clinical usefulness of D-dimer measurement, and its generalizability remains uncertain.

FUTURE DIRECTIONS IN CORONARY RISK PREDICTION

In the future, cardiovascular risk reduction will involve the development of interventions that stabilize plaques and that incorporate evolving genetic approaches. Some of these interventions may be based on studies of the novel risk factors mentioned in this chapter. Novel therapeutic targets currently in development include new anti-inflammatory drugs, as well as antithrombotics and drugs that interfere with cytokine function, metalloproteinase activity, and nuclear receptor/transcription factors.⁹²

Genetic screening is likely to represent a dramatic paradigm shift in coronary disease prevention in the future. Although it is clear that family history is a determinant of the risk of myocardial infarction, the net impact of family history on risk is modest. Although association of single-gene polymorphisms with atherothrombosis has so far been disappointing,⁹³ the advent of high-throughput multilocus gene screening should provide a more robust approach to cardiovascular risk prediction.

Chapter 22

Peripheral Arterial Disease

William R. Hiatt, MD

INTRODUCTION

Peripheral arterial disease (PAD) of the lower extremities is one of the major manifestations of systemic atherosclerosis. The disease affects from 4% to 12% of adults (depending on the population studied).^{1,2} Risk factors are typical of those for atherosclerosis and include advanced age, cigarette smoking, diabetes mellitus, hyperlipidemia, hypertension, and inflammation; the most important are diabetes and smoking.^{1,3}

Clinical manifestations of PAD range from asymptomatic in 20% to 50%, atypical leg pain in 40% to 50%, typical claudication in 10% to 35% and critical leg ischemia (CLI) in 1% to 2% (Fig. 22-1). Asymptomatic patients with PAD have severely limited limb function, including limited walking distance and speed.⁴ Therefore, from a functional perspective, all patients with PAD have symptomatic limitations.

Claudication is pain in the legs on walking, primarily in the calves, which does not go away with continued walking and is relieved by rest. Among patients with claudication, symptom severity follows a stable course over 5 years in 70% to 80%, with only 10% to 20% developing worsening claudication and 1% to 2% experiencing the onset of CLI, which is the most severe manifestation of PAD.⁵ Patients with CLI have severe arterial occlusive disease, usually involving multiple segments. Clinical evidence of CLI includes ischemic pain in the distal foot, ischemic ulceration, or gangrene. Patients with CLI are at high risk of limb loss.

PAD is highly associated with critical coronary and carotid artery diseases, and it predisposes patients with these conditions to markedly increased risks of myocardial infarction, ischemic stroke, and vascular death.⁶ For example, in patients with PAD, adjusted cardiovascular mortality is increased sixfold.⁷ This risk is approximately equal between men and women, and it is elevated even if the patient has had no prior clinical evidence of cardiovascular disease.⁸ With increasing severity of PAD, as measured by the ankle-brachial index (ABI), come concomitant increased risks of myocardial infarction, ischemic stroke, and vascular death.⁹ After 5 years, 20% of patients experience a nonfatal myocardial infarction or stroke, and 15% to 30% die (see Fig. 22-1). Therefore, the initial goals of management are to recommend changes in lifestyle, to identify and modify cardiovascular risk factors, and to administer antiplatelet drugs to reduce the risk of cardiovascular events. These treatments may also slow the progression of atherosclerosis in the peripheral circulation and may inhibit clinical progression of disease.

In patients with claudication, the goal of treatment is to improve exercise performance, community-based walking ability, and quality of life. In patients with CLI, the goals of therapy are to prevent limb loss, to heal ischemic ulcers, to relieve pain at rest, and to improve functional status. For patients with claudication, approaches used to treat symptoms include supervised exercise rehabilitation, administration of cilostazol, and select use of revascularization procedures. In contrast, no effective medical therapy for CLI is available, as these patients require restoration of blood flow to heal wounds, relieve ischemic pain, and prevent limb loss.

DIAGNOSIS

All patients at risk for arterial disease (age >50 years with a history of smoking or diabetes, and all persons >70 years of age)¹⁰ should undergo history and physical examination for assessment of symptoms of claudication or CLI. Palpation of arterial pulses should be performed, with focus on the brachial, femoral, and pedal arteries (posterior tibial and dorsalis pedis). Absence of a femoral pulse indicates inflow disease of the aorta or iliac arteries; in patients with a palpable femoral pulse but no pedal pulse, disease is confined to the arteries in the leg. Patients with CLI develop pain in the distal foot at rest that can progress to ischemic ulceration and gangrene. The ulcers are painful, do not bleed when manipulated, and often have a dark necrotic base.

Any patient with reduced or absent pulses in the leg should be suspected of having PAD and should undergo measurement of the ABI, which is also a class I recommendation. The ABI is the ratio of systolic blood pressure in the ankle divided by systolic blood pressure in the arm. A Doppler ultrasound instrument is required to detect pulse, and typically, pressures in both arms and each tibial vessel in both ankles are measured. The standard calculation is based on the highest pressure in each ankle and the highest arm pressure. Each leg receives an independent ABI measurement, and a value <0.90 in either leg indicates PAD.^{11,12}

Vascular Laboratory and Imaging

Although the ABI is an accurate screening test for PAD, it does have limitations (Table 22-1). In a few patients with diabetes or renal disease, the tibial vessels become calcified and incompressible. With incompressible vessels, ankle pressure is often >200 to 250 mm Hg, leading to an ABI

Figure 22-1 Natural history of peripheral arterial disease. CLI = critical leg ischemia. (From Hirsch AT, Haskal ZJ, Hertzler NR, et al: ACC/AHA 2005 guidelines for the management of patients with peripheral arterial disease (lower extremity, renal, mesenteric, and abdominal aortic): Executive summary, a collaborative report from the American Association for Vascular Surgery/Society for Vascular Surgery, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, Society of Interventional Radiology, and the ACC/AHA Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Patients with Peripheral Arterial Disease) endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation; National Heart, Lung, and Blood Institute; Society for Vascular Nursing; TransAtlantic Inter-Society Consensus; and Vascular Disease Foundation. *J Am Coll Cardiol* 47:1239-1312, 2006.)

value >1.40 . In these patients, additional testing followed by results from the vascular laboratory may help the clinician to make an accurate diagnosis of PAD. These tests include toe pressures and pulse volume recordings. In some patients with claudication, the ABI may be falsely normal with an iliac artery stenosis and no other occlusive disease distal to the iliac lesion. In this situation, the stenosis is not hemodynamically significant at rest, but a pressure drop can be induced with exercise. A resting ABI is obtained in each ankle, and then the patient is asked to walk on a treadmill for up to 5 minutes. Exercise may also consist of toe raises until claudication pain occurs. The ABI is repeated immediately after exercise; a 20% decrease from rest is diagnostic of PAD.¹³ Additional diagnostic tests include transcutaneous measurements of tissue oxygen content. These evaluations may provide information on the potential for ulcer healing in patients with CLI.

The vascular laboratory can also provide information on localization and severity of arterial lesions. Anatomic localization can be achieved with noninvasive imaging tests. The decision to proceed to this stage of evaluation is predicated on the need for revascularization as the next step in

treatment. Therefore, indications for revascularization must be considered before additional testing is performed. These indications include lifestyle-limiting claudication that has not responded to medical therapy (i.e., lifestyle modification, exercise training, and/or drug therapy), CLI (including management of ischemic rest pain and ischemic ulcers), and prevention of limb loss. Tests used for disease localization include segmental limb pressure, pulse volume recording, Doppler segmental waveform, arterial duplex ultrasonography, magnetic resonance angiography (MRA), and computed tomographic angiography (CTA).

With the use of sequential limb blood pressure cuffs placed on the upper and lower thigh, calf, and ankle, segmental limb arterial blood pressures may be obtained. Each pressure measurement is compared with the cuff above and the contralateral limb. For example, pressure obtained in the proximal thigh cuff is normally >30 mm Hg higher than the brachial pressure. Lower pressures suggest the presence of inflow aortoiliac artery disease. Pressure in each cuff should be no greater than 20 mm Hg lower than that in the pressure cuff proximal to that level. Disease localization occurs one segment proximal to the cuff with the lower

Table 22-1 Vascular Laboratory and Imaging Tests

Vascular Laboratory Examination	Information Obtained	Limitations
Segmental limb pressure	Localizes arterial disease to specific vascular segments May aid in predicting wound healing potential Used to monitor the results of revascularization	Inaccurate in patients with noncompressible arteries Special cuffs required Proximal thigh cuff occasionally uncomfortable for patient
Pulse volume recording	Localizes arterial disease Monitors results of revascularization Predicts wound healing Accurate even when ankle vessels are noncompressible	Semiquantitative Requires a skilled technologist
Duplex ultrasound	Provides anatomic localization of arterial lesions Defines severity of focal stenosis Aids in decisions regarding revascularization Used for graft surveillance after surgery	Requires a skilled technologist Limited when aorta and iliac vessels are evaluated in some patients Limited with arterial calcification
Magnetic resonance angiography	Provides disease localization throughout lower extremity arterial circulation Aids in decisions regarding revascularization Avoids iodinated contrast	Overestimation of degree of stenosis Inaccurate in arteries with metal clips
Computed tomographic angiography	Provides disease localization throughout lower extremity arterial circulation Aids in decisions regarding revascularization	Requires iodinated contrast Requires multislice detectors Accuracy not fully determined

pressure. Therefore, if the pressure in the lower thigh cuff is 30 mm Hg lower than that in the high thigh cuff, superficial femoral artery occlusive disease is suggested.

Pulse volume recordings are plethysmographic measurements that provide semiquantitative hemodynamic information. The same cuffs are used as for segmental limb pressure, but they are inflated to pressures that do not occlude flow. Each arterial pulse displaces volume in the cuff, which is recorded as an arterial waveform. With increasing arterial occlusive disease, the pulse volume recording changes in amplitude and contour. These tests require a highly trained technologist, along with a vascular physician, for interpretation of results. The test is particularly useful in patients with calcified, noncompressible tibial vessels. In this situation, the pulse waveform can still be interpreted, and this information may be used to rule PAD in or out.

Arterial duplex ultrasonography provides accurate arterial imaging and grading of arterial stenoses. Current methods use both color imaging and Doppler velocity to determine the location and severity of arterial disease. A doubling in peak systolic velocity suggests stenosis greater than 50%. Arterial duplex ultrasonography requires a highly skilled technologist, is time intensive, and requires a vascular physician for interpretation of results.

MRA is the preferred noninvasive imaging modality in many centers.¹⁴ It is safe and provides high-resolution, three-dimensional imaging of the major vessels from the abdomen to the feet. MRA is useful for treatment planning before intervention and for assessing the suitability of lesions for endovascular approaches. MRA avoids the use of iodinated contrast, which is relatively contraindicated

in patients with contrast allergy or renal insufficiency. Its limitations include that it is contraindicated in patients with implanted defibrillators, spinal cord stimulators, and certain arterial stents. In particular, Nitinol stents (Cordis Corporation, Miami Lakes, Fla) produce the least artefact. Also, heavily calcified arteries can be evaluated by MRA but not by CTA.

CTA is also highly accurate for evaluating the location and extent of arterial disease; accuracy is greater than that of duplex imaging, particularly when multislice detectors are used.¹⁵ Multislice CTA enables rapid imaging of the abdominal, pelvic, and lower extremity vessels with significant resolution. Major limitations of CTA involve the use of iodinated contrast, radiation exposure, and loss of accuracy in heavily calcified vessels. Arterial stents may cause significant artefact, possibly precluding adequate evaluation.

Contrast angiography remains the primary arterial imaging modality; it is often done in the same setting as angioplasty. The test carries risks for severe reaction to contrast (approximately 0.1%) and similarly low risks of mortality. Other complications include arterial dissection, atheroemboli, contrast-induced renal failure, and access site complications (e.g., pseudoaneurysm, arteriovenous fistula, hematoma).

TREATMENT

Cardiovascular Risk Reduction Therapies

Patients with PAD have multiple cardiovascular risk factors that require aggressive management to individual target

goals. Evidenced-based therapies are summarized in Table 22-2.

Smoking Cessation

Cigarette smoking is associated with a markedly increased risk for cardiovascular events, progression of leg arterial disease, amputation, and worsened patency of revascularization procedures. Given these associations, smoking cessation has been a cornerstone in the management of PAD. Although advice to stop smoking is associated with modest quit rates, the addition of nicotine replacement and

behavior programs is associated with reasonable quit rates at 5 years and a survival advantage over the long term.¹⁶ Pharmacologic therapy, including nicotine replacement and antidepressant drug therapy, can be helpful in smoking cessation.¹⁷ The drug bupropion has been shown to be effective in many smokers.¹⁸ Thus, a practical approach would be to combine behavior modification, nicotine replacement therapy, and bupropion to achieve the best quit rates.

The role of smoking cessation in relieving the symptoms of claudication is not clear, and studies have not consistently

Table 22-2 Evidence-Based Drug Therapy for Peripheral Arterial Disease

Indication	Drug	Dose	Duration	Efficacy	Safety
Cardiovascular Prevention	Aspirin	81 mg/day	Life	• 25% CV risk reduction over placebo in patients with history of MI or stroke • 18% nonsignificant risk reduction in PAD without prior MI or stroke	Peptic ulcer disease UGI bleed
	Clopidogrel	75 mg/day	Life	• 24% risk reduction over aspirin 325 mg/day	Rash Pruritus
	Ramipril	10 mg/day	Life	• 20% CV risk reduction over placebo	Cough Renal insufficiency
	Simvastatin	40 mg/day	Life	• 24% CV risk reduction over placebo • Effective even in PAD with no prior history of MI or stroke • Effective even when baseline LDL cholesterol level <116 mg/dL	Rare myositis Rare hepatocellular toxicity
	Bisoprolol	5–10 mg/day	Perioperative period	• Reduced risk of perioperative MI and cardiac death with vascular surgery	Asthma exacerbation
Graft Patency	Aspirin	81–325 mg/day	Life	• 43% risk reduction in graft occlusion compared with placebo • Effective in prosthetic grafts	As above
	Warfarin	INR $\approx$ 3.0	Up to 2 years	• Effective in vein grafts	Higher bleeding risk
Claudication	Pentoxifylline	400 mg TID	Years	• 0%–25% improvement in ACD	Nausea
	Cilostazol	50 to 100 mg BID	Years	• 50% improvement in ACD	Headache Diarrhea No increase in CV death Avoid in heart failure

CV, cardiovascular events, including myocardial infarction (MI), stroke (cerebrovascular accident [CVA]), and vascular death; PAD, peripheral arterial disease; UGI, upper gastrointestinal; LDL, low-density lipoprotein; INR, International Normalized Ratio; ACD, absolute (maximal) walking distance on a treadmill. (From Hirsch AT, Haskal ZJ, Hertzler NR, et al: ACC/AHA 2005 guidelines for the management of patients with peripheral arterial disease (lower extremity, renal, mesenteric, and abdominal aortic): Executive summary, a collaborative report from the American Association for Vascular Surgery/Society for Vascular Surgery, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, Society of Interventional Radiology, and the ACC/AHA Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Patients with Peripheral Arterial Disease) endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation; National Heart, Lung, and Blood Institute; Society for Vascular Nursing; TransAtlantic Inter-Society Consensus; and Vascular Disease Foundation. *J Am Coll Cardiol* 47:1239–1312, 2006.)

shown that smoking cessation is associated with improved walking distance.^{19,20} Therefore, patients should be encouraged to stop smoking primarily to reduce their systemic risk and their risk of progression to amputation, but they should not be promised improved symptoms immediately on cessation.

Hyperlipidemia

Current recommendations for the management of lipid disorders in PAD are to achieve a low-density lipoprotein (LDL) cholesterol level of less than 100 mg/dL and to modulate the increased triglyceride and low high-density lipoprotein (HDL) pattern.²¹ More recent guidelines recommend that high-risk patients with PAD reduce their LDL cholesterol level to less than 70 mg/dL.²² Subgroup analyses of previous trials in patients with coronary artery disease showed that aggressive lipid lowering was associated with a decreased risk of claudication or an absent femoral pulse.²³

The most direct evidence for statin therapy in PAD comes from the Heart Protection Study.²⁴ This study enrolled more than 20,500 subjects at high risk for cardiovascular events, including 6748 patients with PAD. Many of the patients with PAD had not had a previous cardiovascular event. Overall, simvastatin 40 mg/day was associated with a 12% reduction in total mortality, 17% reduction in vascular mortality, and 24% reduction in coronary heart disease (CHD) events. Similar results were obtained in the PAD subgroup, independent of the baseline prevalence of coronary artery disease. This is the first large, randomized trial of statin therapy to show that aggressive lipid modification can significantly improve outcomes in the PAD population.

Hypertension

Hypertension is an independent risk factor for PAD that requires aggressive therapy to reduce cardiovascular risk. Current guidelines recommend achieving a blood pressure lower than 140/90 mm Hg, except in patients with diabetes or renal insufficiency, for whom the goal is a blood pressure lower than 130/80 mm Hg.²⁵ Regarding specific drug choice, β -adrenergic blocking agents have previously been contraindicated in PAD because of the possibility of worsening claudication symptoms.²⁶ However, this concern has not been borne out by randomized trials; thus, β -adrenergic blocking agents can be used in patients with claudication.²⁷ In particular, patients with PAD who also have concomitant coronary disease may receive additional cardio-protection from β -adrenergic blocking agents. Therefore, this should be considered a viable drug class for these patients.

Angiotension-converting enzyme (ACE) inhibitor drugs have shown benefit beyond blood pressure lowering in high-risk groups. Specific results were derived from the HOPE (Heart Outcomes Prevention Evaluation) study of 4046 patients with PAD.²⁸ In this subgroup, a 22% risk reduction was observed in patients randomly assigned to ramipril compared with placebo, which was independent of blood pressure lowering. On the basis of this finding, ramipril received approval for cardiovascular risk reduction. Thus, as a drug class, ACE inhibitors would certainly be recommended in these patients.

Diabetes

Diabetes, the most potent risk factor for PAD, is associated with peripheral neuropathy that, when combined with

arterial insufficiency, greatly increases the risks of foot ulceration and limb loss. Several studies of patients with type 1 and type 2 diabetes have shown that aggressive blood sugar lowering can prevent microvascular complications (particularly retinopathy) but not cardiovascular disease or PAD.^{29,30} A more recent study in which pioglitazone was used in patients with diabetes and cardiovascular disease showed a reduction in risks of myocardial infarction, stroke, and vascular death as a secondary end point of the study.³¹ Additional studies will be needed to confirm this cardiovascular benefit of the drug class. The current American Diabetes Association–recommended goal for treatment of patients with diabetes is a hemoglobin (Hb)_{A1C} of 7%. However, it is not clear whether achieving that goal with current medications will have a cardiovascular protective effect.

Additional PAD Risk Factors

Elevated plasma homocysteine levels are an independent risk factor for PAD, but information on the clinical benefit of lowering homocysteine levels with folate is lacking.³² C-reactive protein (CRP) is an independent risk factor for PAD. Measurement of CRP may guide lipid therapy in that statin drugs lower CRP levels, and reduction in CRP levels may contribute to the benefits of statin drugs.³³ Alterations in coagulation are not typically associated with PAD, and no evidence suggests that anticoagulant therapy prevents the development of PAD or claudication.

Antiplatelet Drug Therapy

Aspirin is a well-established antiplatelet drug for the secondary prevention of cardiovascular events in patients with known cardiovascular disease. The Antithrombotic Trialists' Collaboration meta-analysis showed a 25% odds reduction in subsequent cardiovascular events with the use of low-dose aspirin (75 to 160 mg/day).³⁴ In patients with PAD who have not had a cardiovascular event, no conclusive evidence has proved that aspirin is beneficial.³⁵ In the more recent meta-analysis, when PAD data were combined with those from trials in which not only aspirin but more effective agents such as clopidogrel and ticlopidine were given, a significant 23% odds reduction in ischemic events occurred.³⁴ Thus, although antiplatelet drugs are clearly indicated in the overall management of PAD, aspirin does not have U.S. Food and Drug Administration (FDA) approval for use in patients with PAD who do not have other clinical evidence of cardiovascular disease (e.g., prior myocardial infarction, stroke).³⁶

Thienopyridines are adenosine diphosphate (ADP) antagonists that have been well studied in patients with cardiovascular disease. Ticlopidine has been evaluated in several trials in patients with PAD and has shown benefit in reducing the risks of myocardial infarction, stroke, and vascular death.³⁷ Clopidogrel also has been shown to reduce the risk of myocardial infarction, ischemic stroke, and vascular death in patients with PAD. The overall benefit of clopidogrel in PAD was a 24% risk reduction over the use of aspirin, with a highly acceptable safety profile.³⁸ Thus, current American Heart Association/American College of Cardiology (AHA/ACC) guidelines recommend both aspirin and clopidogrel as acceptable antiplatelet drugs for the PAD population.²²

Hypercoagulable States

Abnormalities of coagulation are commonly associated with the development of venous thrombosis and thromboembolism, yet they play a negligible role in arterial events. Arterial and venous thrombosis has been associated with elevations in homocysteine levels. However, known inherited hypercoagulable states have been less well evaluated in patients with PAD. In one study, presence of the lupus anticoagulant was associated with peripheral atherosclerosis.³⁹ Also, markers of platelet activation, such as increased β -thromboglobulin levels, are also associated with PAD.⁴⁰ Hypercoagulability has been associated with decreased long-term patency of bypass grafts.⁴¹ Routine testing for hypercoagulability is not indicated in the evaluation of PAD.

Treatment of Claudication

Figure 22-2 provides an overview of the treatment of claudication.

Exercise Rehabilitation

A supervised exercise rehabilitation program is a safe and effective treatment approach for patients with claudication.⁴² A walking- or treadmill-based training program conducted in a cardiac rehabilitation or other supervised setting produces the best results.⁴³ Patients should be monitored by a skilled nurse or technician. A typical supervised exercise program begins with 30 minutes of intermittent exercise and increases to 60 minutes as tolerated. The initial workload of the treadmill is set to a speed and grade combination that brings on claudication pain within 3 to 5 minutes. Patients walk at this work rate until they achieve claudication of moderate severity. They rest until the claudication abates, and then they resume exercise. On a weekly basis, patients should be reassessed clinically as they are able to walk farther and farther at their chosen workload. The typical duration of an exercise program is 3 months. On completion of the exercise program, similar evaluations are performed to define improvements in treadmill walking distance and questionnaire end points.⁴⁴ Mechanisms of benefit include improvements in walking efficiency and adaptations in skeletal muscle metabolism and microcirculation.⁴⁵

Claudication Drug Therapy

The goals of claudication therapy are to enhance walking speed and distance, exercise performance, and the physical aspects of quality of life. A number of drugs have not been shown to be effective in the treatment of patients with claudication. Examples include vasodilators, prostaglandins, and serotonin receptor antagonists.^{46–48} Pentoxifylline has been approved for the treatment of claudication, with early trials suggesting a modest improvement in maximum treadmill walking distance.⁴⁹ However, in a recent study, pentoxifylline was no more effective than placebo and was inferior to cilostazol.⁵⁰ A meta-analysis concluded that the drug produced modest increases in treadmill walking distance over placebo, but the overall clinical benefits were questionable.⁵¹

Cilostazol provides the best evidence for efficacy among currently available drugs for claudication. This drug is a phosphodiesterase type 3 inhibitor that has favorable effects on HDL cholesterol metabolism, produces vasodilation,

and exhibits antiplatelet properties. In a number of studies, cilostazol improved pain-free and maximum walking distance as compared with placebo.^{52–54} In these same studies, cilostazol improved the physical domains of quality of life—a finding confirmed through a meta-analysis of six trials.⁵⁵ The most common adverse effects of cilostazol include headache, transient diarrhea, palpitations, and dizziness. Cilostazol should not be given to patients with claudication who also have heart failure; this recommendation is based on previous concerns about increased mortality risk with this class of drugs in patients with heart failure.⁵⁶ Safety data have been gathered from more than 2700 patients treated with cilostazol and followed for up to 6 months. Total cardiovascular morbidity and all cause mortality were 6.5% for cilostazol 200 mg/day, 6.3% for cilostazol 100 mg/day, and 7.7% for placebo.⁵⁷ These data do not show an increased cardiovascular mortality risk with cilostazol, yet this drug has an FDA “black box” warning stating that its use should be avoided in patients with PAD who also have clinical evidence of heart failure.

Additional drugs are now being studied in clinical trials for their potential use in patients with claudication. Propionyl-L-carnitine is a metabolic agent that has been shown to improve treadmill performance and quality of life in patients with claudication.^{58,59} Angiogenic agents also are potentially valuable and are currently under study.

Revascularization

The decision to proceed to revascularization, whether endovascular or surgical, should be based on a lack of response to overall medical management that includes a supervised exercise program or claudication drug therapy. Patients considered for revascularization should have a severe physical disability, defined as inability to conduct work or other ambulatory activities. Patients should be carefully evaluated to ensure that no other significant comorbidity is present that would continue to limit the patient's physical capacity. These limitations may include arthritis or pulmonary and cardiac disease that limits activity to a greater extent than claudication does. In this situation, even successful treatment of claudication would not be expected to provide overall benefit to the patient if other medical conditions are more limiting. In addition, vascular laboratory and imaging modalities must confirm the presence of a suitable lesion for treatment, and the patient should not be at high risk to undergo an invasive procedure. In general, specific decisions about which procedure to perform (angioplasty or vascular surgery) should be based on the current TransAtlantic Inter-Society Consensus (TASC) and AHA/ACC guidelines.^{22,60}

Angioplasty

Percutaneous transluminal angioplasty (PTA) to treat peripheral arterial stenoses or occlusions has been an accepted therapy for patients with severe intermittent claudication or CLI. Patients who benefit the most from PTA are those with proximal aortoiliac stenosis or occlusions or short segment femoropopliteal stenosis or occlusion.^{61,62} For iliac stenosis or occlusion, 1-year patency rates range from 60% to 80%, and for those with a stent, those rates increase to 70% to 90%.²² Femoropopliteal angioplasty has a 1-year patency rate

Figure 22-2 Treatment algorithm for claudication. (From Hirsch AT, Haskal ZJ, Hertzner NR, et al: ACC/AHA 2005 guidelines for the management of patients with peripheral arterial disease (lower extremity, renal, mesenteric, and abdominal aortic): Executive summary, a collaborative report from the American Association for Vascular Surgery/Society for Vascular Surgery, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, Society of Interventional Radiology, and the ACC/AHA Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Patients with Peripheral Arterial Disease) endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation; National Heart, Lung, and Blood Institute; Society for Vascular Nursing; TransAtlantic Inter-Society Consensus; and Vascular Disease Foundation. *J Am Coll Cardiol* 47:1239–1312, 2006.)

ranging from 50% to 89%, and with the addition of a stent, the range is 60% to 80%.²²

Percutaneous revascularization procedures are generally safe, but they may be associated with low rates of such adverse effects as arterial dissection, bleeding, hematoma, thrombosis, atheroembolism, and contrast nephropathy. Patients who have complex lesions that require prolonged procedures and many catheter manipulations are at greatest risk of severe complications. The severe complication rate from PTA for intermittent claudication is approximately 1% to 2%.

Vascular Surgery

Surgical revascularization is rarely required to treat intermittent claudication because of the strong likelihood that medical therapy and angioplasty will be successful. Vascular surgery also is associated with significant perioperative morbidity and mortality. Therefore, clinicians must carefully weigh the risks and benefits of surgery before recommending it to patients with intermittent claudication. In particular, a failed bypass graft may lead to the development of CLI (due to the loss of collaterals) in a patient who may not have ever been at risk for this complication. In contrast, patients with CLI should be considered for revascularization. Again, the critical issues are vascular disease anatomy, availability of conduit material (vein is preferred), and patient comorbidities.

With aortoiliac and aortofemoral bypass surgery, the perioperative mortality rate is 1% to 3%, but 5-year patency rates range from 85% to 90%. Vein-to-below knee femoropopliteal bypass has a perioperative mortality rate of 1% to 6% and a patency rate of 65% at 5 years. However, with prosthetic material, the patency rate drops to 33% at 5 years.⁶³ Femoral-to-tibial bypass with vein (often used for limb salvage) has a patency rate of up to 75% at 5 years.

Drug Therapy to Reduce Cardiac Risk in Vascular Surgery

Patients with PAD who undergo vascular surgery are at high risk of cardiovascular complications. Previous attempts to address this risk through risk stratification prior to vascular surgery relied on clinical assessment and cardiac imaging.⁶⁴ Clinical risk factors for major vascular surgery include age greater than 70 years, angina, and history of myocardial infarction, heart failure, or stroke.⁶⁵ Although clinical and imaging strategies can be used to identify high-risk patients for vascular surgery, the benefit derived from coronary revascularization prior to vascular surgery remains unproved. A recent study randomly assigned 5859 patients scheduled for vascular surgery (elective aortic or leg bypass surgery) to coronary artery revascularization or best medical therapy.⁶⁶ The coronary revascularization strategy did not improve long-term outcomes. Therefore, evaluation of the coronary or carotid circulation prior to peripheral vascular surgery should not be a routine matter, and it should be considered only in patients with symptoms in that regional circulation that merit further study.

An alternative method of reducing cardiac risk in patients undergoing vascular surgery is to provide perioperative β -adrenergic blockade. For example, oral metoprolol prior to vascular surgery reduced cardiac ischemia during surgery.⁶⁷ The best evidence is seen with bisoprolol

(a selective β_1 -adrenergic blocker) given to high-risk patients undergoing vascular surgery.⁶⁸ In a study of high-risk vascular patients defined as having cardiac risk factors and a positive dobutamine stress echocardiogram, bisoprolol prevented nonfatal myocardial infarction and cardiac death at 30 days. At 2-year follow-up of the same patients, the incidence of a cardiac event was 12% in the treated group and 32% in the placebo group ($P = .025$; number needed to treat is 5).⁶⁹ A meta-analysis of all studies to date confirms the cardioprotective effects of β -adrenergic blockade in patients with PAD undergoing vascular surgery.⁷⁰ Thus, the use of a β -adrenergic blocker was associated with short- and long-term reductions in cardiac events after major vascular surgery.

Drug Therapy for Graft Patency

Aspirin has provided good evidence for the prevention of graft occlusion after peripheral vascular surgical bypass.⁷¹ Ticlopidine has also been shown to promote vein graft patency.⁷² Anticoagulation has been recommended as an adjuvant to maintain surgical graft patency, but its use remains controversial. Aspirin has been compared with oral anticoagulation in the Dutch Bypass Oral Anticoagulants or Aspirin study in 2690 patients undergoing infrainguinal bypass.⁷³ The primary end point of graft patency was equal between groups after 21 months of follow-up. However, when patients were divided into subgroups according to type of graft material used, anticoagulation maintained vein graft patency better than aspirin but with a higher risk of bleeding complications. In contrast, aspirin maintained prosthetic graft patency better than anticoagulation. These results were robust and therefore suggest that patients receiving vein grafts should be preferentially treated with warfarin, and those treated with prosthetic material should be treated with aspirin.

CONCLUSIONS

Peripheral arterial disease is a common manifestation of atherosclerosis. Early detection is easily achieved with the ABI, and additional noninvasive testing can be performed in the vascular laboratory. Given the systemic nature of atherosclerosis, all patients with PAD, whether they have a prior history of coronary disease or not, should be considered for secondary prevention strategies. These include aggressive management of smoking, reduction of LDL cholesterol to <100 mg/dL (<70 mg/dL in high-risk patients), reduction of blood pressure, and treatment for diabetes to target goals. Drugs shown to have particular benefit in these patients include the statins for LDL reduction, ACE inhibitors to treat blood pressure, and β blockers in the perioperative setting. In addition, all patients should be given an antiplatelet drug; clopidogrel is known to produce greater benefit than aspirin in the PAD population.

Treatment for claudication includes a formal exercise rehabilitation program and cilostazol as a medical option. A trial of exercise or drug therapy should continue for at least 3 months so that efficacy can be determined. Primary revascularization options for claudication consist of angioplasty, and for CLI, angioplasty and vascular bypass surgery for limb salvage.

INTRODUCTION

Patients with cancer are highly susceptible to venous thromboembolism (VTE), a complication that may contribute significantly to the morbidity and mortality of the disease. All mechanisms for the production of the hypercoagulable state characteristic of cancer are not well defined. Those mechanisms that are known seem to interdigitate the biology of cancer with the major regulatory pathways that mediate blood coagulation, platelet–vessel wall interaction, fibrinolysis, and inflammatory cytokine production. Thus, the events responsible for thrombosis in cancer appear to be a result, in part, of an overexuberant host response in an attempt to delimit tumor growth.

Although many parallels exist between the host response to tumor growth and other biologic processes such as inflammation (e.g., cancer viewed by the pathologist as a “wound that will not heal”),¹ the close-knit relationship between thrombosis and cancer appears unique from the view of the epidemiologist, as follows. First, an association exists between idiopathic VTE and occult malignancy. The increased risk for a new cancer diagnosis within 6 to 12 months of the diagnosis of an episode of idiopathic VTE (including pulmonary embolism) is supported by data from retrospective analyses of large numbers of unselected patients; population-based, retrospective cohort analyses from large registries; and, more recently, by the results of well-designed, prospective studies. Odds ratios favoring the risk of cancer in idiopathic VTE from these studies range from a four- to sevenfold increased risk. Second, cancer survival is significantly worse in patients in whom the diagnosis of VTE is established concurrently with or soon after the diagnosis of cancer, as compared with patients without cancer. Third, the risk that VTE will complicate cancer is substantially higher than in patients without cancer. In surgical patients with known cancer, for example, the odds ratio for an episode of postoperative VTE is approximately 2, when compared with a control group of patients without cancer subjected to the same procedures. A similar odds ratio of approximately 2 to 3 exists for the relative risk for recurrence of VTE in the first 3 months after an initial episode of acute VTE in patients with cancer whose VTE were treated with unfractionated heparin and warfarin, compared with patients without cancer.

Therefore, patients with idiopathic VTE are at increased risk for harboring occult cancer and patients with cancer are at increased risk for VTE and recurrent VTE. Indeed, patients with cancer are considered among the highest-risk patients for VTE and, therefore, should routinely receive

prophylaxis prior to surgery. Less clear are appropriate recommendations regarding anticoagulant prophylaxis for the prevention of thrombosis of central venous catheters, or during radiotherapy and/or chemotherapy. Unfortunately, bleeding complications in anticoagulated patients with cancer also occur with increased frequency. Several randomized, controlled studies have now been completed and suggest better strategies for anticoagulant management of these patients.

EPIDEMIOLOGY

Idiopathic Venous Thromboembolism and Occult Cancer

The close relationship between tumor growth and activation of blood coagulation has been known since the days of Professor Armand Trousseau, who first described the clinical association between idiopathic VTE and occult malignancy,² and has been reviewed recently.^{3–5} Migratory thrombophlebitis as a presenting manifestation of cancer, which has come to be known as Trousseau syndrome, is rather uncommon. However, several prospective studies have shown that patients with carefully defined idiopathic or primary VTE are at significantly higher risk for the subsequent diagnosis of malignancy than are patients who present with secondary VTE (i.e., VTE due to known causes, including congenital thrombophilia, use of oral contraceptives, pregnancy, immobilization, and so forth) (Fig. 23-1).^{4,5}

Even though several studies have suggested that idiopathic VTE may be a sign of an occult malignancy,^{4–8} it remains unclear whether rigorous investigation of such patients for an occult tumor will prove cost effective. The results of a small randomized trial evaluating extensive screening versus no screening in patients who present with idiopathic VTE have been published.⁹ The battery of tests used in the extensively screened group included ultrasound and computed tomography of the abdomen and pelvis, a hemocult test, gastroscopy, colonoscopy, sputum cytology, mammography, pelvic examination, prostate examination, and tumor markers. Of 99 patients in the extensively screened group, cancers were detected initially in 13, compared with none of 102 patients in the control group. However, 10 patients in the control group and 1 in the screened group developed cancer during the 2-year follow-up period. No statistically significant difference was detected in cancer-related mortality in the two groups (3.9% vs 2%, respectively). Given such results, it is premature to recommend

Figure 23-1 Incidence of cancer in patients with venous thromboembolism.

*True prospective studies (in the studies reported by Monreal and associates, data were collected prospectively, but analyses were performed retrospectively).^{4,5} (From Rickles FR, Levine MN: Epidemiology of thrombosis in cancer. *Acta Haematol* 106:6–12, 2001, with permission.)

extensive screening in patients who present with idiopathic VTE, particularly because many of the cancers detected by screening cannot be cured by currently available therapy. Often a complete history, physical examination, chest x-ray, and rectal examination can provide clues as to the presence of an underlying cancer. This approach is supported by the retrospective cohort study reported by Cornuz and colleagues.¹⁰ A decision analysis of screening, however, suggested possible gains in life expectancy with targeted screening for prostate, colon, and bladder cancers in men and for colon, breast, and endometrial cancers in women.¹¹

Venous Thromboembolism as a Complication of Cancer

Thromboembolism is a frequent finding in autopsy series of patients with cancer,^{2–4} but the true incidence of VTE in these patients is difficult to determine from the literature.

Incidence of Thrombosis in Patients with Malignancy

The incidence of thrombosis in patients with cancer can be gleaned from several different sources. Large epidemiologic studies specifically examining the incidence of VTE in patients with cancer had been lacking until recently. In the general population, the incidence of a first episode of deep vein thrombosis (DVT) or pulmonary embolism (PE) was recorded in Olmsted County, Minnesota, from 1966 through 1990.¹² During this period, the overall age- and sex-adjusted annual incidence of VTE was 117 per 100,000. A dramatic rise in incidence rates occurred among patients older than 65 years, with rates almost doubling for each subsequent decade of age. This study population was composed of patients with cancer and patients without cancer. Observed incidence rates may represent a very conservative estimate of the incidence of VTE in a cancer population. In a nested case-controlled study of 625 patients with a first episode of VTE from this database, risk factors for thrombosis were examined.¹³ Malignancy was associated with an odds ratio of 6.5 for the occurrence of VTE.

In another population-based study, Levitan and colleagues¹⁴ examined the discharge diagnoses of more than 7000 Medicare patients (>65 years of age) admitted to the hospital with a diagnosis of malignancy and either DVT or PE. The ratio of the number of patients with a particular type of cancer who had VTE to the number of patients with that type of malignancy provided an estimate of which cancers were most likely to lead to thrombosis. Highest rates were found with cancer of the ovary (120 per 10,000 patients), brain tumor (117 per 10,000 patients), and cancer of the pancreas (110 per 10,000 patients). In a recently reported case-controlled study of more than 3000 consecutive patients with a first episode of VTE, Blom and colleagues¹⁵ reported an overall sevenfold increased risk of VTE in patients with malignancy (odds ratio, 6.7; confidence interval [CI], 5.2 to 8.6) versus persons without malignancy (Fig. 23-2).^{15,16} Patients with hematologic malignancies had the highest risk, adjusted for age and sex (odds ratio, 28.0; CI, 4.0 to 199.7), followed by lung and gastrointestinal cancers. Risk was highest in the first few months after the cancer was diagnosed, and those with distant metastases had a higher risk compared with patients without metastases (adjusted odds ratio, 19.8; CI, 2.6 to 149.1). Similar results to those of the Levitan study were reported more recently by Blom and colleagues¹⁷ on the basis of a linkage analysis of the complete databases of the Cancer Registry of the Western Netherlands (86,151 subjects) and of the anticoagulation clinics of Leiden and The Hague (157,482 subjects). In this latter study, overall cumulative incidence of VTE in the first 6 months was 12.3 of 1000 patients with cancer (95% CI, 11.5 to 13.0), and patients with tumors of the bone, ovary, brain, and pancreas had the highest cumulative incidence of VTE. The different representation of tumors with high incidence of VTE in the two Blom studies most likely reflects the different methods used. In the more recent study, the use of much larger databases may have facilitated a more accurate assessment of VTE with a relatively low incidence of tumors.

Although VTE has been reported at autopsy in up to 30% of patients with cancer,¹⁸ the optimal study design for determining the true incidence of clinical VTE in patients with cancer is a prospective cohort study, which has not been described. Alternatively, the incidence of thrombosis may be derived from prospective clinical trials of systemic therapy in women with early breast cancer (Table 23-1).⁴

The rate of thrombosis over a 5-year period in women with axillary node-negative breast cancer on tamoxifen therapy was approximately 0.9%. It was recognized early that tamoxifen therapy was thrombogenic in women with breast cancer. The Breast Cancer Prevention Trial conducted by the National Surgical Adjuvant Breast and Bowel Project (NSABP) provided an opportunity to examine prospectively this relationship and to estimate the thrombogenic effects of tamoxifen alone. In this trial, healthy women at risk for developing breast cancer were randomly assigned to tamoxifen or placebo for 5 years. The risk of DVT was increased in the tamoxifen-treated group compared with the placebo group: 0.13% per year versus 0.084% per year. Corresponding rates for PE were 0.069% and 0.023%, respectively. The highest rates of thrombosis associated with the use of tamoxifen were observed in women older than 50 years of age; with tamoxifen, the risk of stroke was increased while no increase was observed in the risk for myocardial infarction.

A, adriamycin; C, cyclophosphamide; F, fluorouracil; M, methotrexate; P, prednisone; T, tamoxifen; V, vincristine. (NOTE: Full citations for these studies can be found in References 3 and 4; adapted from Levine M, Lee AYY, Kakkar AK: Cancer and Thrombosis. In: Hemostasis and Thrombosis, 5th Ed. (eds.) RW Colman, VJ Marder, A Clowes, et al. Lippincott Williams & Wilkins, Philadelphia, Chapter 85, pp. 1251–1262, 2005, with permission.)

Rates of thrombosis in women with node-positive breast cancer on chemotherapy ranged between 1% and 9%, with the highest rates of thrombosis observed in postmenopausal women. In these trials, groups of women receiving chemotherapy plus tamoxifen showed an increased risk of thrombosis over chemotherapy alone. Rates of thrombosis in women with metastatic breast cancer vary. In a case series reported by Goodnough and colleagues (see Table 23-1),¹⁹ the rate of thrombosis in patients receiving chemotherapy for metastatic breast cancer was 17.5%, although in a randomized trial reported by Levine and associates,²⁰ the rate was only 4.5% (see Table 23-1). Clinicians are often faced with the scenario of a patient with a past history of VTE who develops breast cancer and requires therapy with a hormonal agent. On the basis of results from recent trials, aromatase inhibitors appear to have a much lower risk of thrombosis when compared with tamoxifen (see Chapter 34). Even in women with advanced breast cancer, thrombosis rates of only 2% to 4% were reported with these agents.^{21,22}

Data on the incidence of thrombosis in other patient groups are limited and are summarized in Table 23-2. Another group of patients discovered to be at high risk for thrombosis were those with brain tumors, who are on extended follow-up. In a review by Marras and coworkers,²³ rates of symptomatic VTE as high as 18% per year were described in a single study,²⁴ in which the authors reported an overall risk rate of 24% (see Table 23-2). Among patients with germ cell tumors, 8.4% of 179 patients given platinum-based chemotherapy developed VTE. Reported rates of VTE in other solid tumors include

Table 23-2 Incidence of Thrombosis in Different Tumors

Study	Tumor Type*	Patients	Thrombosis, %

*Patients with advanced cancer receiving chemotherapy. (From Levine M, Lee AYY, Kakkar AK: Cancer and Thrombosis. In: Hemostasis and Thrombosis, 5th Ed. (eds.) RW Colman, VJ Marder, A Clowes, et al. Lippincott Williams & Wilkins, Philadelphia, Chapter 85, pp. 1251–1262, 2005, with permission.)

the following: 4.4% per year in patients with lung cancer, 10.6% in women with advanced ovarian cancer receiving chemotherapy, 17% in men with prostate cancer receiving chemotherapy, and 3% in women with carcinoma of the cervix receiving concurrent chemotherapy and radiation. Of particular interest in the latter study, erythropoietin (EPO) appeared to increase thrombotic risk to 23%.

Emerging evidence suggests that this erythroid hormone increases thrombotic risk, particularly among patients with cancer. In a study of women with advanced cervical cancer receiving radiation, cisplatin chemotherapy, and EPO, the rate of thrombosis was 13%.²⁴ A randomized trial that evaluated EPO in women with advanced breast cancer was stopped early, when four of 14 patients (28.5%) in the EPO arm developed thrombosis compared with none of 13 women in the control arm.²⁵ See Update on Erythropoietin Therapy at the end of this chapter.

Other hematopoietic growth factors have not been well studied. Barbu and colleagues²⁶ conducted a meta-analysis of studies in which patients with cancer were treated with hematopoietic growth factors. Although the analysis was not conclusive, the authors suggested that an increased risk of thrombosis was associated with the use of granulocyte-macrophage colony stimulating factor (GM-CSF). Multiple mechanisms for an increased risk of thrombosis associated with the use of hematopoietic growth factors have been postulated, including reduced blood flow associated with simple elevation of hematocrit as expected with EPO use, direct effects of EPO on the vessel wall, leukocyte stasis in response to GM-CSF, and so forth, but few specific data are available to shed light on this important area of research.

Reports from most trials in patients with colorectal cancer receiving chemotherapy have not included rates of thrombosis. The explanation for this is unclear, but it is possible that it is due to underreporting.²⁷ A careful audit of early deaths in a randomized trial of irinotecan, 5-fluorouracil (5-FU), and leucovorin versus 5-FU/leucovorin as adjuvant therapy in colon cancer, however, noted an excessive number of vascular deaths (arterial and venous) in the former arm (1.9% vs 0.6%, respectively).²⁸ In a trial of irinotecan plus 5-FU/leucovorin versus 5-FU/leucovorin in patients with metastatic colorectal cancer, a statistically significant increased rate of thromboembolic events was

reported in patients given the three-drug regimen versus 5-FU/leucovorin (5% vs <1%, respectively).²⁷ Thrombosis rates of 5% to 10% have been reported in patients with Hodgkin or non-Hodgkin lymphoma who were receiving chemotherapy, along with a rate of 6.3% in adult patients with acute leukemia; the highest rates were reported in patients with acute promyelocytic leukemia.

Interest in the thrombogenicity of anticancer agents has been rekindled among medical oncologists and hematologists, in part because of the unexpectedly high rate of VTE among patients with cancer receiving novel anticancer agents aimed at specific molecular targets within the cancer cell, often shared by the tumor vascular endothelium. For example, drugs that target the vascular endothelial growth factor (VEGF) receptor or VEGF itself, including thalidomide, have been shown to increase the risk of thrombosis, particularly when used in association with traditional chemotherapy drugs (Table 23-3).^{27–37} Kuenen and colleagues³³ conducted a phase 1 study of cisplatin, gemcitabine, and SU5416 in patients with solid tumors. SU5416 inhibited the autophosphorylation of the VEGF receptor that followed the interaction of the receptor with VEGF, thereby blocking the intracellular signaling pathway. This trial was stopped early because 8 of 19 patients experienced thrombosis. It is likely that chemotherapy combined with the antiangiogenic agent leads to thrombin generation and endothelial cell activation, resulting in a net shift toward a prothrombotic state.³⁸

The anti-VEGF agent bevacizumab (Avastin; Genentech, Inc., South San Francisco, Calif) has been evaluated in a number of randomized clinical trials (see Table 23-3). In the first trial, which was reported by Kabbinnar and colleagues,³⁵ patients with metastatic colon cancer were treated with 5-FU plus leucovorin compared with these agents plus bevacizumab. A statistically significant increase in VTE was observed among patients who received the anti-VEGF agent. In addition, an increase in bleeding complications was noted. In a later trial conducted by Hurwitz and colleagues,³⁷ chemotherapy was compared with chemotherapy plus bevacizumab; no difference was detected in the rate of VTE between treatment groups. Bevacizumab has been evaluated in two randomized trials in women with metastatic breast cancer.^{39,40} In one trial, capecitabine was compared with

Table 23-3 Incidence of Thrombosis with Antiangiogenesis Agents

Study	Tumor	Patients	Thrombosis, %
Zangari, 2001	<i>Myeloma:</i> Chemotherapy plus thalidomide	87	35.0
	Chemotherapy alone	134	15.0

	5-FU + L + bevacizumab (5 mg/kg)	35	14.2
	5-FU + L + bevacizumab (10 mg/kg)	33	6.2
Hurwitz, 2004	5-FU + L	411	16.2
	5-FU + L + bevacizumab	402	19.4
Miller, 2005	<i>Metastatic breast cancer:</i> Capecitabine	215	5.6
	Capecitabine + bevacizumab	229	7.4
Miller, 2005	Paclitaxel	330	0.3
	Paclitaxel + bevacizumab	342	1.2

(NOTE: Adapted and updated from Levine M, Lee AYY, Kakkar AK: Cancer and Thrombosis. In: Hemostasis and Thrombosis, 5th Ed. (eds.) RW Colman, VJ Marder, A Clowes, et al. Lippincott Williams & Wilkins, Philadelphia, Chapter 85, pp. 1251–1262, 2005, with permission.)

capecitabine plus bevacizumab. In the second trial, paclitaxel plus bevacizumab was compared with paclitaxel alone. No increase in VTE was observed in patients treated with bevacizumab. In a trial reported by Johnson and associates,⁴¹ patients with non-small cell lung cancer were randomly assigned to carboplatinum and paclitaxel versus the same agents plus two different doses of bevacizumab.⁴¹ No difference was detected between the groups in terms of VTE rate, but a statistically significant increase in bleeding was associated with bevacizumab. It is unclear why increased VTE was observed in the first randomized trial of bevacizumab in patients with colon cancer, but not in subsequent trials.

Recently, thalidomide has been widely used in the treatment of patients with multiple myeloma, and the risk for VTE has been reported to be increased (see Table 23-3). Although thalidomide therapy *alone* has not been associated typically with a particularly high risk of thrombosis in patients with advanced or refractory myeloma (1%),⁴² when combined with chemotherapy, Zangari and colleagues³⁰ reported that 14 of 50 patients (28%) developed VTE, compared with only 2 of 50 patients (4%) given chemotherapy and dexamethasone without thalidomide. Thalidomide in combination with dexamethasone also appears to be associated with an increased risk of thrombosis, as reported in 6 of 50 patients (12%) newly diagnosed with myeloma.⁴³ The increased incidence of VTE in the thalidomide plus dexamethasone arm persisted (17% vs 3% in the dexamethasone alone arm) when the cohort doubled in size, as was reported recently by these same authors.⁴⁴ Of interest, this combination did not result in an increased rate of VTE in a recently published series of 31 patients with amyloidosis, in which only one case of VTE was reported.⁴⁵ As might be expected, risk of VTE rises when hematopoietic cell transplantation is added into the equation, as was shown recently by the 30% rate in the series reported by Barlogie and colleagues.⁴⁶

Finally, patients with cancer with indwelling central venous catheters (CVC) are believed to be at increased risk for thrombosis of the axillary-subclavian vein, with incidence rates of up to 35% reported in the older literature.^{47,48} In addition, the catheters themselves are prone to thrombotic occlusion, despite the use of routine heparin

flushes. As will be noted subsequently, however, the risk of thrombosis in more recent randomized, controlled trials has been substantially lowered (e.g., 4% to 5%), perhaps because of improved local measures in the care of CVC and/or improved biocompatibility of catheter materials (see Chapter 32).

Cancer Survival and Thromboembolism

Patients with cancer who develop VTE have a short life expectancy. In a population-based study reported by Silverstein and colleagues,¹² the presence of cancer was an independent predictor of worse survival in patients who presented with acute VTE. Similarly, Sorensen and colleagues⁴⁹ showed that patients with cancer who present concurrently with clinically apparent VTE had a worse survival rate than those with cancer without VTE. Levitan and associates¹⁴ reported after analysis of the Medicare database, that the mortality rate for patients with VTE and malignant disease was substantially increased compared with that for malignant disease alone.¹⁴

Increased Risk of Venous Thromboembolism in Patients With Cancer Subjected to Surgery

Patients with cancer who undergo surgery are at an approximate twofold increased risk of postoperative thrombosis compared with noncancer patients subjected to the same operations.^{50,51} The risk of VTE in patients with cancer who undergo specific types of surgery can be derived from the “no treatment” control arms of trials undertaken to evaluate prophylactic measures in surgery.⁵² The outcome measured typically in these studies was thrombosis, as detected by fibrinogen leg scanning; approximate rates were as follows: general surgery, 29%; gynecologic surgery, 20%; urologic surgery, 41%; orthopaedic surgery, 50% to 60%; and neurosurgery, 28%. However, many of these thrombi were asymptomatic, and some studies included patients without cancer. On the basis of these data, however, patients with cancer have been stratified by the 2004 Consensus Conference of the American College of Chest Physicians into their highest risk category,⁵³ compelling the routine use of “short-term” anticoagulant therapy as prophylaxis against VTE in preparation for surgery.

We will discuss this in greater detail in a subsequent section.

Tumors Associated With Thrombosis

Sack and colleagues⁵⁴ compiled a series of case reports from the literature and reported that the cancers most commonly associated with thrombosis were pancreas, lung, and stomach.⁵⁴ Lieberman and coworkers, in a retrospective series,⁵⁵ reported that lung and pancreas were the most common cancers associated with thrombosis in men, and that gynecologic, colorectal, and pancreas were the most common sites associated with thrombosis in women.⁵⁵ However, it is likely that the distribution of specific cancers associated with thrombosis follows the frequency of cancer in the general population.⁵⁶ This is best observed in patients entered into prospective clinical trials of anti-thrombotic agents. In a study by Levine and associates,⁵⁷ which evaluated outpatient therapy with low molecular weight heparin (LMWH) for proximal DVT, 103 of 500 patients had cancer. The most common anatomic sites in men were the prostate, colorectal, brain, and lung, and the most common sites in women were the breast, ovary, and lung.

PATHOGENESIS OF VENOUS THROMBOEMBOLISM IN CANCER

Virchow Triad

Patients with cancer have multiple reasons to develop VTE, which can be classified according to the pathophysiologic

mechanisms first proposed by Virchow in 1856.⁵⁸ Patients with cancer often experience stasis, which is caused by prolonged bed rest or obstruction of vascular flow from extrinsic compression or direct vascular invasion by tumor. Vascular damage may occur as the result of direct invasion by tumor, and more subtle vascular injury often occurs because of the frequent use of central venous access devices, aggravated by the administration of cancer chemotherapy drugs. Indeed, virtually all commonly used intravenous cancer chemotherapy agents have been shown to be capable of activating blood coagulation in vivo, presumably through induction of vascular injury.⁵⁹ Finally, patients with cancer have a primary hypercoagulable state, the pathogenesis of which is exceedingly complex^{3,60}; this is summarized diagrammatically in Figure 23-3 and discussed below.

Tumor Procoagulants

Tumor cells themselves possess a variety of procoagulant properties, including tissue factor (TF) and cancer procoagulant (CP), both of which directly activate clotting, as well as procoagulant cytokines such as interleukin (IL)-1 β , tumor necrosis factor (TNF)- α , IL-8, and VEGF, which indirectly activate clotting via their proinflammatory properties particularly targeted to the endothelium. Tumor cell VEGF is chemotactic for macrophages and endothelial cells; it activates TF in both cells. Tumor cells also activate platelets and polymorphonuclear leukocytes and, via integrin expression, they form adhesive interactions with platelets and the endothelium of blood vessels. Tumor cell interaction with the vessel wall reduces endothelial cell secretion of tissue plasminogen activator (tPA) and expression of the angiogenesis inhibitor thrombomodulin

Figure 23-3 Principal pathways of tumor cell interaction with the hemostatic system. TF, tissue factor; PAI, plasminogen activator inhibitor; u-PAR, urokinase-type plasminogen activator receptor; u-PA and tPA, urokinase-type plasminogen activator and tissue plasminogen activator; IL-1, interleukin-1; TNF- α , tumor necrosis factor alpha; VEGF, vascular endothelial growth factor. (From Falanga A, Rickles FR: The pathogenesis of venous thromboembolism in cancer. *N Oncol Thromb* 1:9–16, 2005, with permission.)

(TM), and enhances endothelial cell synthesis of plasminogen activator inhibitor-1 (PAI-1). Finally, substantial experimental evidence supports the presence of increased numbers of activated monocytes/macrophages in the circulation of patients with cancer in proximity to growing tumors.⁶¹ These antigen-processing cells express TF on their surface, presumably as part of the host immune response to the tumor and/or in response to secretion of tumor products. Tumor-associated macrophages have been shown to assemble the entire coagulation cascade and form cross linked fibrin (XLF) on their surface in apposition to growing tumor.^{3,61} The activation of coagulation in the tumor microenvironment, which routinely spills into the circulation of patients with cancer (*vide infra*), may be a primitive effort on the part of the host to limit the spread of tumor cells.

Coagulation Activation, Fibrin Generation, and Tumor Angiogenesis

Interleukin-8, previously known as melanoma growth factor, is a potent proangiogenic cytokine elaborated by a variety of cells, including the endothelial cell itself. XLF formed on the surface of vascular endothelial cells (VECs) can upregulate the gene for IL-8 and induce the synthesis and release of IL-8 from endothelial cells in a dose-dependent fashion. Therefore, it seems likely that multiple products of blood coagulation, including both thrombin and fibrin, can stimulate the activation and migration of endothelial cells (perhaps via IL-8 release) and induce a self-perpetuating system for further activation of blood coagulation (by induction of TF).^{62,63} In addition, however, expression of the proangiogenic cytokine, VEGF, by human tumor cells is regulated by transfection of the cells with the gene for TF.⁶⁴ Once transplanted into a xenogeneic murine recipient, human breast and melanoma tumor cells expressing high levels of the TF gene are capable of inducing a significant increase in angiogenesis in the animal. TF and VEGF have been colocalized to tumor cells in patients with breast or lung cancer,⁶¹ and TF likely induces cell signaling that results in enhanced VEGF synthesis.

These results suggest a new role for TF in the stimulation of angiogenesis, independent of its role in blood coagulation,^{63,64} and might result ultimately in a novel therapeutic approach to cancer therapy. Indeed, other groups have successfully targeted TF in tumor cells and VECs in experimental approaches to model tumors^{65–67}; phase 1 studies are under way to explore the treatment of human tumors through the use of several different hybrid antitumor agents designed to target the neovascular response of growing tumors—so-called vascular targeting agents.⁶⁸ At the molecular level, it has now been shown in several tumor models that oncogene expression activates TF, influences systemic blood coagulation, modulates other regulators of hemostasis, and triggers angiogenesis.^{69–71} Therefore, effective targeting of TF may prove useful in limiting tumor growth and reducing the hypercoagulability characteristics of cancer.^{68,72,73} In the meantime, more effective strategies for reducing the risk of VTE are under development, particularly because any cancer therapy that perturbs the highly prothrombotic tumor angiogenic endothelium may result in an increased risk of VTE.

VENOUS THROMBOEMBOLISM PROPHYLAXIS IN PATIENTS WITH CANCER

Primary Prophylaxis

Surgical Patients

Clinical trials have shown the efficacy of low-dose, unfractionated heparin (UFH) in preventing deep vein thrombosis and PE in patients undergoing major surgery.^{51,74} In these studies, many of the patients had cancer. Standard UFH can be depolymerized to low molecular weight fragments.^{75,76} LMWH has a more predictable anticoagulant response than UFH, a longer plasma half-life, and better bioavailability when administered subcutaneously (less nonspecific binding to plasma proteins and circulating blood cells). In addition, in laboratory studies, LMWH preparations cause less bleeding with equivalent antithrombotic effects. Standard UFH is usually given three times a day, whereas LMWH can be administered once a day. Recent studies have shown equal efficacy and enhanced safety for LMWH compared with UFH in high-risk major surgery.^{77,78} In 2001, Mismetti and colleagues⁷⁹ published a meta-analysis of trials that compared LMWH with UFH in high-risk major surgery. In their analysis, which included patients undergoing surgery for cancer, no differences were detected in rates of asymptomatic DVT, clinical PE, death, or major bleeding between LMWH and UFH. Mechanical methods of thromboprophylaxis have also been shown to be effective in surgical patients,⁵¹ although these are less effective than anticoagulation, and when used alone are particularly ineffective in patients with cancer. Thus, in the patient with cancer who is undergoing surgery, prophylaxis should consist of low-dose UFH or LMWH, together with graduated compression stockings. Regarding the duration of prophylaxis, the definition of “short-term” anticoagulant therapy as prophylaxis against VTE in cancer remains an open question. Berqvist and colleagues⁸⁰ demonstrated a significantly lower rate of VTE when cancer patients were treated with prophylactic doses of LMWH for at least 1 month after surgery. These results are supported by data from a more recent open-label trial by Rasmussen and associates,⁸¹ in which 343 patients undergoing major abdominal surgery were randomly assigned to receive 7 days of standard thromboprophylaxis with 5000 IU of the LMWH dalteparin once daily or extended prophylaxis with the same dose for 3 additional weeks. Patients had mandatory bilateral venography at day 28. The cumulative incidence of VTE was reduced from 16.3% with short-term prophylaxis to 7.3% after prolonged prophylaxis ($P = 0.01$; relative risk reduction [RRR], 55%). The number needed-to-treat to prevent one case of VTE was 12, and no significant difference was noted between groups with regard to bleeding events.

Medical Patients

Fewer data are available on prophylaxis in ambulatory patients with cancer. Levine and associates⁸² conducted a trial that showed that very low dose warfarin is safe and effective for the prevention of VTE in patients with metastatic breast cancer receiving chemotherapy. The warfarin dose was 1 mg daily for 6 weeks; it was adjusted so

that an International Normalized Ratio (INR) could be maintained at between 1.3 and 1.9. An economic analysis of this trial showed the cost-effectiveness of the approach.⁸³ Despite this study, oncologists do not routinely use prophylaxis in patients with cancer who are receiving chemotherapy with oral anticoagulants. The most likely reasons are concern for bleeding and the logistics of laboratory monitoring and dose adjustment. An alternative is to reserve prophylaxis for high-risk situations (e.g., previous history of VTE, a pelvic mass that causes poor venous drainage from the lower limbs), but clearly, more research is needed in these high-risk groups. In addition, patients with cancer who are bedridden are at risk for thrombosis, which occurs often in the setting of an acute hospitalization for a complication related to cancer (e.g., pain crisis, infection, hypercalcemia). Patients with advanced cancer are also admitted to the hospital on occasion for palliative care. Low-dose UFH and LMWH have been found to be effective in patients hospitalized with acute medical illness.^{84,85} It would seem reasonable, therefore, for practitioners to institute prophylaxis with low-dose UFH or LMWH for patients with advanced malignancy when admitted to the hospital.

Venous Catheters

Strategies for the prevention of venous catheter-associated thrombosis in patients with cancer have also been reported, as noted previously (see Chapter 32). Studies of very low dose warfarin (1 mg/day) or LMWH (e.g., dalteparin sodium at 2500 IU/day) have shown significant reduction in the incidence of catheter-related thrombosis.^{47,48} In these earlier trials, many thrombotic events were asymptomatic. Despite the results of these trials, substantial variation characterizes the use of antithrombotic prophylaxis in standard practice. Further, it should be noted that 1 mg per day of warfarin, which was originally believed to not significantly prolong the prothrombin time, may lead to substantial elevation of the INR in patients with colorectal cancer given infusional 5-FU.⁸⁶ Recently, the results of four randomized trials in patients with central vein catheters were reported.^{87–90} In the trial by Reichardt and colleagues,⁸⁷ patients with cancer were randomly assigned to dalteparin (5000 U once daily) or placebo.⁸⁷ Screening ultrasonography was done at the end of the study. Rates of thrombosis were very low in both groups, at about 3%. In the trial by Couban and colleagues,⁸⁸ patients with cancer received 1 mg of warfarin or placebo.⁸⁸ No difference was detected in symptomatic thrombosis, and rates were low in both groups, at approximately 4%. In an Italian trial reported by Verso and coworkers,⁸⁹ patients with cancer were randomly assigned to enoxaparin LMWH or placebo.⁸⁹ Patients underwent venography, which detected thrombosis in 18% of the placebo-treated group and 14% of the LMWH group. This difference was not statistically significant. Rates of symptomatic thrombosis were low in both groups (3.1% vs 1%, respectively). Results of the most recent trial were reported by Young and colleagues from the United Kingdom.⁹⁰ Patients with cancer with central vein catheters were randomly assigned to warfarin 1 mg daily, or no prophylaxis if the physician was uncertain about the efficacy of prophylaxis. If the physician was certain about prophylaxis, patients were randomly assigned

to 1 mg of warfarin or warfarin adjusted to an INR of 1.5. The overall rate of symptomatic catheter-associated thrombosis was only 5%. In the first stratum, warfarin did not reduce thrombosis (odds ratio, 0.94) and was associated with increased major bleeding (2% vs 0.2%). In the second stratum, the rate of thrombosis was reduced with adjusted-dose warfarin (3% vs 7%; odds ratio, 0.43), but major bleeding was increased (4% vs 2%). A recent cohort study also reported low rates of thrombosis in patients with cancer with central vein catheters.⁹¹ The reason for the observed low rates of thrombosis in these trials is unclear, although both the availability of new generations of catheters with better biocompatibility and improved catheter care have been implicated. Further research is required. At this juncture, the weight of the evidence would not support the routine use of antithrombotic prophylaxis in such patients, although selected high-risk patients may be an exception.

Secondary Prophylaxis

Patients with cancer who have established VTE are more likely to develop recurrent VTE during oral anticoagulation than are patients without cancer.^{92,93} In a trial reported by Levine and associates,⁹⁴ patients with proximal DVT were randomly assigned to UFH by continuous intravenous infusion in the hospital or to LMWH given subcutaneously at home. Both groups received 3 months of oral anticoagulant therapy. No difference was detected in the rate of recurrent thromboembolism between treatment groups. However, the rate of recurrent VTE in 103 patients with cancer was 14% compared with 4% among 317 noncancer patients ($P = .001$).⁹⁴ Prandoni and coworkers⁹² reported data from long-term follow-up of a large series of patients with proximal DVT, who received at least 3 months of oral anticoagulant therapy. The frequency of recurrent VTE was 10.3% in 58 patients with cancer compared with 4.7% among 297 noncancer patients ($P = .12$). This difference achieved statistical significance for the subgroup of patients in the therapeutic range (i.e., INR, 2 to 3; 8.6% vs 1.3%; $P < .01$). In a more recent update of these data, this important observation was validated for all patients.⁹³ In the trial reported by the Columbus investigators,⁹⁵ which compared LMWH with UFH for proximal DVT, rates of recurrent thromboembolism were 8.6% in patients with cancer and 4.1% in noncancer patients. Therefore, patients with cancer were at higher risk for recurrence of VTE in that study, suggesting that they may be relatively resistant to treatment with oral anticoagulants.

Several, large, prospective, randomized clinical trials comparing the relative efficacy of extended LMWH therapy versus oral anticoagulation as secondary prophylaxis in patients with cancer patients have been completed recently.

Results of the CLOT (Comparison of Low molecular weight heparin versus Oral anticoagulant Therapy for prevention of recurrent venous thromboembolism in patients with cancer) study were reported by Lee and colleagues⁹⁶; they confirmed the superiority of LMWH over warfarin for long-term secondary prophylaxis in patients with cancer. These results have established at least 6 months of LMWH as the new standard of care for patients with cancer with VTE.⁵³

TREATMENT OF PATIENTS WITH ESTABLISHED VENOUS THROMBOEMBOLISM

The objectives of treating patients with VTE are to prevent death from pulmonary embolism, to reduce morbidity from the acute event, to minimize postphlebotic symptoms, and to prevent thromboembolic pulmonary hypertension. The physician is often confronted with the issue of whether VTE in a patient with terminal malignant disease should be treated. Treatment may be useful for palliation of symptoms of acute VTE, including reduction of painful swelling of the leg from DVT and reversal of dyspnea and chest pain in pulmonary embolism. The decision to treat with anticoagulants is particularly difficult in a patient with a very short life expectancy.

Initial Treatment

Treatment of acute venous thrombosis should be initiated with heparin followed by oral anticoagulant therapy.⁷⁸ LMWH has largely replaced UFH as initial therapy for acute venous thrombosis. Historically, patients required hospital admission to receive UFH by continuous intravenous infusion, and the infusion rate was adjusted so that a target partial thromboplastin time (PTT) could be maintained. LMWH is administered subcutaneously and does not typically require monitoring by a laboratory test of coagulation.

In several randomized trials, LMWH has been shown to be as safe and effective as UFH for the treatment of hospitalized patients with acute proximal DVT. Three large randomized clinical trials in patients with acute proximal DVT compared intravenous UFH in the hospital with LMWH administered at home.^{94,95,97} In a subgroup analysis of these three studies, consisting of 405 patients with cancer, no difference was detected in recurrent VTE between treatment groups—a finding confirmed in two more recent cohort studies.^{98,99} These results show that LMWH can be used safely and effectively to treat patients with acute VTE (including uncomplicated pulmonary embolism) in the home setting and should reassure the treating physician that home therapy of VTE with LMWH is a reasonable alternative for selected patients with cancer.

Secondary Prevention—Best Choice of Anticoagulant and Appropriate Duration of Therapy

Patients with DVT who are treated with an initial course of heparin therapy require continual anticoagulant therapy to prevent recurrence. Vitamin K antagonists have been shown to be effective in preventing recurrent thrombosis in patients with established VTE.⁷⁸ The risk of clinical bleeding for patients with INR in the therapeutic range is relatively low (approximately 2% per year in recent clinical trials).¹⁰⁰ Once again, however, this rate is based primarily on studies of patients *without* cancer, and conventional wisdom suggests that patients with cancer are at higher risk of hemorrhagic complications while receiving oral anticoagulant drugs. The results of two previous prospective cohort studies had been reassuring, with rates of major

bleeding similar in anticoagulated patients with cancer (3.4%) to those in patients without cancer (3%),⁹² or 0.004 event per patient-month of treatment versus 0.003 event per patient-month of treatment, respectively.¹⁰¹ A more recent prospective 11-year study by Prandoni and colleagues,⁹³ however, reports a significant, twofold increased risk of major bleeding in anticoagulated patients with cancer versus patients without cancer.

It is common practice to continue oral anticoagulant therapy for 3 months after a first episode of proximal DVT or PE. The patient with active malignant disease who has had an episode of established thrombosis is likely to be at continuing risk of recurrent VTE, even after 3 months of warfarin.^{80,81} Although no clinical trials have yet examined prospectively as the primary end point the appropriate length of oral anticoagulant therapy in patients with cancer and VTE, three studies have considered the issue of duration of anticoagulant therapy in patients with idiopathic DVT—a group considered to be at continuing risk of thromboembolism.^{102–104} Schulman and colleagues¹⁰² randomly assigned patients with idiopathic proximal DVT to 6 weeks or 6 months of oral anticoagulant therapy after initial heparin therapy. Patients who received 6 months of treatment had a significant reduction in the rate of recurrent thromboembolism. Investigators then randomly assigned patients with a second episode of DVT to 6 months or indefinite duration of oral anticoagulant therapy. Patients who received treatment of longer duration had a significant reduction in recurrent thromboembolism and a small increase in bleeding.¹⁰³ Kearon and coworkers¹⁰⁴ reported the results of a trial in which patients with idiopathic DVT were randomly assigned to receive 3 months or 2 years of oral anticoagulant therapy. A significant reduction in recurrence favored patients who received anticoagulant therapy of longer duration. On the basis of the results of these trials, it would seem prudent to continue anticoagulant therapy beyond 3 months while these patients remain at high risk for VTE recurrence. In the patient at particularly high risk for bleeding, the dose of warfarin can be lowered to maintain an INR close to 2.0; the efficacy of maintaining the patient's INR between 1.5 and 2.0, however, remains controversial.^{105,106}

Warfarin therapy is particularly complicated in the patient with cancer for a number of reasons. It is often difficult to maintain the INR within the therapeutic range because patients with cancer experience anorexia and vomiting, limiting their dietary intake of vitamin K. In addition, drug interactions (e.g., chemotherapy/antibiotics) can influence the anticoagulant effects of vitamin K-dependent anticoagulants (in either direction). Interruption of oral anticoagulant therapy occurs commonly in patients with cancer because of the development of thrombocytopenia, or for the performance of diagnostic or therapeutic procedures such as thoracentesis and abdominal paracentesis. Reversal of the anticoagulant effect with vitamin K may be required. Subsequently, it may require days to weeks to achieve the target therapeutic range after reintroduction of warfarin. Finally, frequent blood sampling is required for monitoring the INR, and venous access may be difficult to attain in these patients.

Therefore, certain features of long-term anticoagulant therapy with LMWH are attractive for patients with cancer. For example, LMWH does not require laboratory monitoring

and can be administered subcutaneously once or twice daily on the basis of body weight. Clinical experience suggests that LMWH may be effective in warfarin failure.¹⁰⁷ Finally, on the basis of preclinical data and meta-analyses, the potential for less bleeding exists. In several small trials, long-term oral anticoagulant therapy has been compared with long-term LMWH^{108–114}; regrettably, very few patients with cancer were studied. Several recent randomized trials have provided new information on the long-term treatment of patients with cancer with VTE.

In the trial reported by Meyer and colleagues,¹¹⁵ patients with cancer with acute VTE were randomly assigned to 3 months of enoxaparin or warfarin at a targeted INR of 2.0 to 3.0. The primary outcome measure was a composite of major bleeding and recurrent VTE. In 71 patients who received warfarin, the outcome event rate was 21%, compared with 10.5% in 67 patients who received LMWH ($P = .09$). This observed difference, which was not statistically significant, was attributed primarily to the rates of major bleeding in the two groups: 16.9% in patients given warfarin versus 7.5% in those given LMWH. Lee and associates (the CLOT trial),⁹⁶ as noted in the previous section, randomly assigned cancer patients to long-term dalteparin versus long-term oral anticoagulant therapy. Over the 6-month study period, 27 of 336 patients in the dalteparin group compared with 53 of 336 patients in the oral anticoagulant group experienced recurrent VTE. The probability of VTE at 6 months was reduced from 17.4% in the oral anticoagulant group to 8.8% in the dalteparin group; the hazard ratio was 0.48 ($P = .0017$). No statistically significant difference was detected in major bleeding between groups (3.6% and 5.6%, respectively). The rate of any bleeding (major plus minor) was 18.5% in the oral anticoagulant group compared with 13.6% in the dalteparin group ($P = .09$). On the basis of the results of these trials, long-term therapy with LMWH should be viewed as an important advance in the management of patients with cancer and acute VTE. Therapy with LMWH substantially reduces the rate of recurrent VTE without an increase in bleeding, thereby improving the quality of life of patients with cancer. Long-term use of LMWH also simplifies the management of such patients. It avoids the need for laboratory monitoring, which is advantageous for both the patient and the physician. If a patient requires an urgent procedure, the LMWH is simply discontinued; it is not necessary to reverse the anticoagulant effect.

In general, the duration of long-term treatment of patients with VTE is based on the individual patient's risks for recurrent thrombosis and bleeding. In patients with malignancy, the risk of recurrent thrombosis depends on the usual thrombotic risk factors (e.g., surgery, bed rest), as well as factors specific to cancer, such as stage or activity of cancer and the use of chemotherapy and hormonal agents.

Currently, the recommendation from the American College of Chest Physicians (ACCP) for patients with cancer who experience an acute thromboembolic event is to treat them for a minimum of 3 to 6 months with LMWH, then with "anticoagulant therapy indefinitely or until the cancer is resolved."¹¹⁶ However, as in patients without cancer, the exact duration of therapy should be tailored individually. In patients with metastatic disease, anticoagulant therapy should be continued indefinitely, or until

a contraindication to anticoagulation develops. In those who have active but nonmetastatic disease, anticoagulant therapy should be given for at least 6 months and as long as cancer is evident, or while the patient is receiving chemotherapy. In patients with cancer who have no evidence of active cancer and who have developed a thrombotic event in association with a strong risk factor such as surgery, a minimum of 3 months of anticoagulant treatment is probably reasonable, especially if relative contraindications are evident for continuing anticoagulation.

Patients at Particular Risk of Hemorrhage

In patients with a "relative" contraindication to anticoagulation therapy (e.g., those with metastatic brain or pericardial tumor with intense vascularity, such as melanoma, renal, and so forth), it is reasonable to use LMWH as initial treatment for acute VTE and then to use either adjusted-dose UFH or LMWH to reduce the bleeding risk associated with long-term oral anticoagulant therapy. Alternatively, an inferior vena cava (IVC) filter can be placed electively in patients at high risk for bleeding to avoid the need for long-term anticoagulant therapy. Although it is not without complications (e.g., leg edema, recurrent or remote [visceral or cerebral] DVT), the overall rate of pulmonary embolism in this high-risk group in whom a filter is used is low ($\approx 2\%$).¹¹⁷

Inferior Vena Cava Filters

Placement of an inferior vena cava filter should be reserved for patients who have active bleeding, those at high risk for bleeding, and those who develop recurrent VTE despite adequate anticoagulation therapy (defined by appropriate laboratory test results) (see Chapter 31). If a filter is inserted concurrently with administration of anticoagulant therapy, the risk of pulmonary embolism is reduced initially. However, in the absence of concurrent anticoagulant therapy, a very high percentage of patients develop venous hypertension after filter placement and are far more likely to develop recurrent DVT over the long term (see Chapter 31); the protective effects of IVC filters are much diminished beyond the short term (e.g., 2 to 6 weeks). The recent availability of removable IVC filters makes it possible to use these filters for at least 2 to 6 weeks.^{118,119} Indeed, early results of small, observational studies, most of which have included a significant percentage of patients with cancer, are encouraging in that removal may be possible after up to 6 months or even longer.^{120–122} However, the absence of randomized, controlled trials or even rigorous, prospective cohort studies makes it difficult to adequately assess the cost/benefit ratio of these new devices. Cautious optimism is warranted, but better studies are needed and long-term follow-up is essential.

Central Vein Thrombosis

As was noted previously in the section on prevention, central vein catheters, which are used commonly in patients with cancer, particularly for the administration of chemotherapy and the provision of long-term supportive care (e.g., antibiotics, blood products, growth factors),

present a particular problem for the oncologist. Although the rate of thrombosis has been reduced presumably by improved biocompatibility of the catheters and enhanced local care, thrombosis still occurs with sufficient frequency to represent an impediment to good care. Catheter-related thrombi may involve the tip of the catheter alone or the length of the catheter (i.e., with formation of a “fibrin sheath”), or they may extend to involve the veins of the upper limbs, neck, and mediastinum.¹²² The usual treatment for catheter tip thrombosis is low-dose thrombolytic therapy with streptokinase, urokinase, or tPA.¹²³ Recommended treatment of patients with symptomatic upper limb vein thrombosis related to use of a catheter is full-dose anticoagulant therapy with heparin (UFH or LMWH given initially) followed by oral anticoagulant therapy. Available data are insufficient to reveal whether thrombolytic therapy and/or catheter removal should be used in the setting of catheter-associated upper limb thrombosis, in which full-dose anticoagulant therapy is used. At present, considerable variation in common practice has been noted; therefore, this issue needs to be resolved, if possible, through appropriately designed clinical trials.

ANTICOAGULATION THERAPY AND SURVIVAL IN CANCER

Since the publication in 1981 of the results of the first randomized trial of warfarin as an adjuvant to chemotherapy in patients with small cell carcinoma of the lung (SCCL),¹²⁴ an old theory that anticoagulation may enhance survival in cancer has been revitalized. In the Veterans Administration Cooperative Studies Program trial (CSP #75), patients with SCCL and no clinical evidence of VTE were treated with the same chemotherapy regimen but were randomly assigned to receive standard doses of warfarin or no anticoagulation therapy. Survival was twice as long in the warfarin group (50 weeks vs 24 weeks; $P = .03$); this could not be accounted for by protection against clinically apparent VTE or serious bleeding.¹²⁴ These results, which were replicated in a trial conducted by the Cancer and Leukemia Group B,¹²⁵ together with the results of a cancer subset analysis of several large, randomized clinical trials of LMWH versus UFH therapy in patients with acute proximal DVT,¹²⁶ have stimulated a renewed interest in the potential anticancer effects of antithrombotic agents.

In the trial reported by Hull and colleagues,¹²⁷ the overall mortality rate for patients with cancer was 9.6% in hospitalized patients receiving standard UFH compared with 4.7% in patients treated with LMWH ($P = .05$). In a trial reported by Prandoni and colleagues,¹²⁸ the overall mortality rate for patients with cancer in the UFH-treated group was 12% compared with 7% among LMWH-treated patients (not statistically significant). In 1995, Lensing and coworkers¹²⁹ conducted a meta-analysis of trials of LMWH versus standard UFH for the treatment of patients with DVT. The overall mortality rate was 3.9% for patients treated with LMWH versus 7.1% for those treated with standard UFH—a relative risk reduction of 47% ($P < .04$). In 195 patients with cancer in the studies subjected to meta-analysis, mortality risk reduction was 64% in favor of LMWH ($P < .01$). Two more recent meta-analyses have confirmed these findings.^{130,131} These findings suggest that LMWH might exert an inhibitory

effect on tumor growth that is superior to that observed with standard UFH, although it remains difficult to explain how short-term therapy (e.g., 7 days) with LMWH can influence the natural history of a malignant tumor that has existed for many months.

Several clinical trials evaluating longer-term administration of LMWH to patients with cancer with and without VTE have recently been completed (e.g., FAMOUS [Fragmin for Advanced Malignancy Outcome Study], CLOT, MALT [Malignancy And Low molecular weight Treatment trial]) and have provided additional support for the antineoplastic properties of LMWH. In the CLOT study,¹³² for example, 12-month cumulative mortality was 20% and 35% for patients with cancer without metastasis at the time of presentation with VTE, who received LMWH or warfarin, respectively (hazard ratio, 0.50; 95% CI, 0.27 to 0.95; $P = .03$; Fig. 23-4). However, both the CLOT study and the FAMOUS trial¹³³ demonstrated through post hoc analyses survival advantages for patients with limited-stage disease. In view of the limitations of post hoc subgroup analysis, both reports must be viewed principally as hypothesis-generating studies. However, two additional studies provided prospective data that are supportive. Altinbas and colleagues¹³⁴ recently published the results of LMWH therapy (18 weeks) as an adjunct to chemotherapy in patients with small cell lung cancer without VTE, and Klerk and associates (the MALT trial)¹³⁵ treated patients with a variety of advanced cancers (also without VTE) with LMWH or placebo for 6 weeks. Both studies showed statistically significant survival advantages for LMWH-treated patients, regardless of initial stage of disease. Additional studies are needed to confirm these encouraging results. However, evidence is accumulating that supports adoption of the routine clinical practice of recommending lifelong anticoagulation for patients with active cancer and VTE disease.

Figure 23-4 Survival of “good-risk” patients in the CLOT (Comparison of Low molecular weight heparin versus Oral anticoagulant Therapy for prevention of recurrent venous thromboembolism in patients with cancer) Study. Post hoc analysis of patients with cancer with no evidence of distant metastasis at the time of presentation treated with oral anticoagulants (OAC) or low molecular weight heparin (dalteparin) for a concurrent venous thromboembolic event. (From Lee AY, Rickles FR, Julian J, et al, for the CLOT Investigators: Impact of dalteparin low-molecular-weight heparin (LMWH) on survival: Results of a randomized trial in cancer patients with venous thromboembolism (VTE). *J Clin Oncol* 23:2123–2129, 2005, with permission.)

UPDATE ON ERYTHROPOIETIN THERAPY

One approach in managing anemia in cancer patients is to use recombinant human erythropoietin (EPO). There are several different erythropoietin stimulating agents (ESAs) which include epoetin alfa, darbopoetin alfa, and epoetin beta. Multiple trials in cancer patients have shown that treatment with ESAs increases hemoglobin levels and decreases the need for erythrocyte transfusions. It is unclear however, whether ESAs improve the quality of life of cancer patients. In recent years there has been considerable discussion about the thrombogenic potential of ESAs and whether they are associated with tumor growth.^{136–138}

Three randomized trials in cancer patients reported an increased risk of thrombotic and cardiovascular events associated with ESAs and were prematurely stopped.¹³⁹ A recent meta-analysis conducted by the Cochrane Institute demonstrated a 1.67 increased risk of thrombosis associated with ESAs.¹⁴⁰ The etiology of thrombosis related to ESAs is unclear but likely to be multifactorial in cancer and other ill patients already prone to thrombosis.

The Food and Drug Administration (FDA) issued a recent public health advisory (March 9, 2007), describing “an increased risk of death, blood clots, strokes and heart attacks in patients with chronic renal failure when ESAs were administered at higher than recommended doses. In other studies, more rapid tumor growth occurred in patients with head and neck cancer who received these higher doses.”¹⁴¹ In the 1,400 subject CHOIR study of patients with CRF,¹⁴² the composite end point of death and all cardiovascular events was significantly more frequent in the group with a target hemoglobin of 13.5 g/dL than in the group with a target hemoglobin of 11.3 g/dL ($p = 0.03$ by log rank test with a hazard ratio of 1.3; 95% CL 1.03–1.74). In the Danish Head and Neck Cancer Study Group trial (DAHANCA 10), the 3-year loco-regional control in patients treated with an ESA was significantly worse than for those not receiving the ESA ($p = 0.01$) and there was a non-significant trend toward worse overall survival.¹⁴³ The risk for deep vein thrombosis in elective spinal surgery patients randomized to receive an ESA preoperatively for hemoglobin values > 10 and ≤ 13 g/dL was 4.7%, more than twice that of patients who received usual blood conservation care (2.1%).¹⁴¹ These FDA warnings support to “adjust the ESA dose to maintain the lowest hemoglobin level needed to avoid transfusions” . . . in those patients with appropriate indications (e.g., anemia of chronic renal failure, cancer with anemia caused by chemotherapy, major surgery to reduce potential blood transfusions and for anemia due to zidovudine therapy in HIV patients).

A second FDA Oncology Drug Advisory Committee meeting on the safety of erythropoietin was held in May 2007.¹⁴⁴ Concern was expressed regarding the safety of ESAs in terms of thromboembolism and tumor growth and the panel recommended more restrictions on labeling and more studies exploring safety. Meanwhile it seems prudent to be judicious in the use of ESAs in cancer patients (limiting it to those on chemotherapy) and in most if not all patients in general. The ESA-stimulated hemoglobin level should not exceed the recommended indication, currently 12 gms/dL.

SUMMARY AND CONCLUSIONS

Patients with idiopathic VTE are at higher risk for the development of cancer, and patients with cancer are at higher risk for the development of VTE. The risk of clinically important VTE after surgery is at least twofold greater in patients with cancer than in those without cancer, and the risk for recurrent VTE in patients with cancer is two- to threefold greater than in patients without cancer, in spite of therapeutic levels of oral anticoagulation. Patients with cancer are at high risk for VTE because they are often immobilized and exposed to prothrombotic challenges (e.g., chemotherapy, use of central venous catheters), and because they are intrinsically hypercoagulable. The hypercoagulable state in cancer is multifactorial, mediated by the potent direct procoagulant properties of tumor cells and the indirect procoagulant effects of tumor cells on the host immune response and the vascular endothelium. Angiogenic blood vessels are particularly susceptible to thrombosis because, in contrast to normal blood vessels, the VECs of tumor blood vessels express TF *de novo*. For all these reasons, primary prophylaxis is absolutely indicated for patients with cancer who are undergoing surgery, and it should be strongly considered for high-risk patients with central venous catheters and for those receiving chemotherapy—particularly in the treatment of those with mucin-secreting adenocarcinoma, brain tumor, and other high-risk malignancies. Secondary prophylaxis should be considered and should last as long as the cancer is active. LMWH has proven superior to oral anticoagulants for secondary prophylaxis of VTE in some patients with cancer, and it may contribute to increased survival through as yet undefined mechanisms.

INTRODUCTION

Thrombotic thrombocytopenic purpura (TTP) is the most extensive and dangerous intravascular platelet clumping disorder. For about 55 years after the disease was first recognized, almost everyone with TTP died quickly. Physicians were fascinated by the dramatic clinical presentations and were horrified by the near 100% mortality rate. Many hematologists, even those with limited experience in trying to manage this rarely encountered patient, believed intuitively that an understanding of the mechanism of systemic intravascular platelet aggregation in TTP would provide important insights into the pathophysiology of common, localized forms of arterial platelet thrombosis (e.g., heart attack, stroke).

Until the 1970s and 1980s, most physicians had never seen a case of TTP. Hematologists, even after years in practice, could recall one or two patients, at most, who had been given this diagnosis. Then, for unknown reasons, the disease increased in prevalence. Probably about 2000 new cases of acute acquired idiopathic TTP now occur annually in North America. At the Texas Medical Center in Houston, about 30 to 50 patients newly diagnosed with TTP are admitted each year (compared with 0 to 2 per year in the 1970s). This is likely to represent a true increase in acute acquired idiopathic TTP, and not simply improvement in recognition of a disorder with long-established clinical and laboratory characteristics. Furthermore, several drugs in common use during the 1990s (e.g., ticlopidine) were found to induce, in a fraction of the many exposed patients, a type of TTP that is clinically indistinguishable from the acute acquired idiopathic type. Therefore, the remark several years ago in reference to paroxysmal nocturnal hemoglobinuria made by Dr. Wendell Rosse of the Duke University Medical Center that “more people study the disease than have it” no longer applies to TTP.

HISTORICAL REVIEW

Eli Moschcowitz was born in Hungary in 1879 and was brought to the United States at the age of 2 years. He received his doctor of medicine degree from the College of Physicians and Surgeons of Columbia University in 1900 and was subsequently trained in surgery and histopathology in New York City and Berlin.¹ On September 15, 1923, Dr. Moschcowitz admitted “Patient KZ,” a 16-year-old girl, to the Beth Israel Hospital in New York City. She had experienced abrupt onset of petechiae, anemia, and pallor; these

were followed rapidly by paralysis, coma, and, on September 20, 1923, death. Moschcowitz believed that he had observed a new disease and reported the tragic course of his young patient in 1924 in the *Proceedings of the New York Pathological Society*.² Terminal arterioles and capillaries in the unlucky teenager were occluded by hyaline thrombi, later determined to be composed mostly of platelets, without perivascular inflammation or endothelial desquamation. Moschcowitz suspected a “powerful poison which had both agglutinative and hemolytic properties”^{2,3} as the cause of this frightening new disease, now known as thrombotic thrombocytopenic purpura (TTP).

Before researchers had any inkling of the pathophysiology of TTP, Byrnes and Khurana⁴ reported in 1977 that relapses in chronic TTP could be prevented or reversed by the infusion of only a few units of fresh frozen plasma (FFP) or its cryoprecipitate-poor fraction (cryosupernatant) without concurrent plasmapheresis. It was also discovered by Byrnes and Khurana⁴ and Bukowski and colleagues⁵ (and subsequently confirmed by studies in several hundred patients^{6,7}) that plasma infusion combined with plasmapheresis (plasma exchange) allows most patients to survive an episode of TTP. In most of these patients, the disorder neither recurs nor produces persistent overt organ damage.⁶

In 1982, “unusually large” von Willebrand factor (VWF) multimers found in the plasma of patients with the rarest subtype of the disorder, chronic relapsing TTP, were proposed by Moake and coworkers⁸ as the agglutinative substance. Unusually large VWF multimers are: (1) more immense and more adhesive to platelets than the largest VWF multimeric species normally circulating in plasma⁹; (2) secreted in long strings by human endothelial cells¹⁰; (3) designed to entangle (after retrograde secretion by endothelial cells) with subendothelial fibrous components, to maximize VWF-mediated platelet adhesion onto subendothelium exposed by vascular damage; and (4) eliminated rapidly through a vigilant processing activity^{8,11} that occurs in normal plasma. The 1982 report concluded that “patients with chronic relapsing TTP have a defect in the processing of very large VIII:VWF multimers [as the VWF component of the factor VIII was then known] after synthesis and secretion by endothelial cells, and . . . this defect makes patients susceptible to periodic relapses.”⁸

In 1997 and 1998, Furlan and associates^{12–14} and Tsai and Lian¹⁵ reported that the “VWF processing activity” is a VWF-cleaving metalloprotease enzyme that is absent in patients with familial TTP and is transiently inhibited in many patients with acquired idiopathic TTP. This VWF-cleaving metalloprotease was soon thereafter characterized

as a member of a large array of structurally related enzymes known as the “ADAMTS” family (defined later).^{16–18}

CLINICAL MANIFESTATIONS

Severe thrombocytopenia and hemolytic anemia with one or several fragmented red cells (schistocytes) in many 1000-power, immersion oil fields of the blood smear (i.e., >1% of total red cells),¹⁹ along with neurologic symptoms and signs, constitute the characteristic clinical triad. Neurologic disorders may range in severity from transient bizarre mentation and, behavior to sensorimotor deficits, aphasia, seizures, or coma. The peripheral blood smear typically shows increased reticulocytes (polychromatic large erythrocytes) and, often, nucleated red blood cells, in response to intense hemolysis. Fever and/or renal dysfunction occurs in a minority of patients. Renal abnormalities may include proteinuria and hematuria, as well as azotemia. Symptoms and signs of ischemia in the retinal (visual defects), coronary (conduction abnormalities), and abdominal circulation (abdominal pain) may be noted. Microvascular occlusions that cause ischemia of the sinoatrial or atrioventricular node, or of the bundle of His or the Purkinje conduction system, may cause sudden death.^{20–22} Abdominal manifestations, sometimes resembling pancreatitis, have been more commonly recognized during the past few years. Perhaps 5% to 10% of TTP episodes may now begin with abdominal symptoms.²³

Early, evolving, and overt manifestations of an acute acquired idiopathic TTP episode and of the therapeutic actions triggered are summarized in Table 24-1. A patient may appear in the emergency department or the physician’s office at any stage of the disorder.

LABORATORY FINDINGS

The degree of thrombocytopenia in TTP reflects the extent of intravascular platelet clumping. Platelet counts are often less than 20,000 per microliter during acute episodes of TTP. Erythrocyte fragmentation occurs as red blood cells attempt to bypass at high flow rates microvascular platelet aggregates, producing characteristic schistocytes on peripheral blood films (Fig. 24-1). Occasionally, schistocytes do not appear until one or several days after the initial clinical presentation. Hemolysis is predominantly intravascular and, along with tissue damage, contributes to increased serum levels of lactate dehydrogenase (LDH).²³ Thrombo-

Figure 24-1 Peripheral blood smear from a patient with TTP. Notice that several red blood cells are schistocytes, which result from mechanical hemolysis. Some resemble apples from which a large bite has been taken.

cytopenia, hemolytic anemia, schistocytosis, and LDH elevations are often less extreme in diarrhea-associated acute renal failure of the hemolytic-uremic syndrome (HUS) than in TTP.

Coagulation studies are characteristically normal during the early stages of a TTP episode.²³ If considerable tissue necrosis occurs, however (as during an especially severe or protracted episode of TTP), secondary disseminated intravascular coagulation (DIC) may also occur as a result of overactivation of the coagulation pathway. This overactivation follows the binding of factor VIIa to exposed tissue factor on injured tissue cells. The ominous development of secondary DIC can be detected by the appearance of elevated levels of D-dimers or fibrin degradation products, prolongation of prothrombin or partial thromboplastin time, and decreased fibrinogen levels.

TYPES OF THROMBOTIC THROMBOCYTOPENIC PURPURA

Since plasma therapy has been generally applied, many patients have survived episodes of TTP. It has become apparent that several conditions are associated with the disorder, which may have more than one cause (Table 24-2).²³ About two thirds of adult patients with the relatively

Solid organ transplantation

TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic-uremic syndrome.

common acquired idiopathic TTP (“out-of-the-blue” TTP) have a single episode that never recurs (presuming that treatment is successful). About one third of adult patients who recover from an initial TTP episode have recurrences at irregular intervals, often commencing within the first year after the initial episode. TTP occasionally occurs during pregnancy, especially in the last trimester.²⁴

In a less common type of the disease, familial (or congenital) TTP, frequent episodes may occur at regular (≈3- to 4-week) intervals. This entity, which has also been called chronic relapsing TTP, is usually (but not always) seen initially in infants and children.^{8,12,25}

During the past few years, the structurally similar platelet function inhibitors ticlopidine (Ticlid; Roche Pharmaceuticals, Nutley, NJ, USA)^{26,27} and clopidogrel (Plavix; Bristol-Myers Squibb/Sanofi Pharmaceuticals Partnership, New York, NY, USA)²⁸ have been associated with the induction of TTP in a fraction of exposed patients. These two drugs, which differ from each other by a single carboxymethyl group, inhibit a platelet adenosine diphosphate (ADP) receptor site and are used to suppress arterial platelet thrombosis. A fraction of patients with human immunodeficiency virus-1 (HIV-1) infection also develop TTP.

Mitomycin C, quinine, cyclosporine FK506 (tacrolimus), chemotherapeutic agents in combination, gemcitabine, and total body irradiation have been associated with the subsequent development of thrombotic microangiopathy.^{29–38} This syndrome often more closely resembles HUS than TTP and usually develops weeks to months after exposure.³⁴ Patients who have been treated for various illnesses with bone marrow/stem cell transplantation make up a relatively large subgroup.³⁴ Thrombotic microangiopathy has also been reported after solid organ transplantation (i.e., kidney, liver, heart, and lung).³³

CAUSES AND PATHOPHYSIOLOGY OF THROMBOTIC THROMBOCYTOPENIC PURPURA

Early vascular lesions in TTP consist almost exclusively of platelet thrombi without evidence of perivascular inflammation or other overt vessel wall disease.^{39,40} Microvascular (“hyaline”) occlusions are seen in most organs, including the lungs and the eyes. Most frequently involved are the brain, heart, spleen, kidneys, pancreas, and adrenals.

Histopathologic and clinical findings in TTP suggest that organ ischemia and thrombocytopenia may be caused by direct, potentially reversible platelet adhesion/aggregation in the microcirculation of multiple organs concurrently. Immunohistochemical studies of TTP thrombi reported in 1985 by Asada and coworkers⁴⁰ revealed an abundance of VWF with little fibrinogen/fibrin, supporting the 1982 suggestion⁸ that VWF is involved in the microvascular platelet adhesion/aggregation that characterize the disorder.

von Willebrand Factor, ADAMTS13, and Thrombotic Thrombocytopenic Purpura

Monomers of VWF (280,000 daltons) are linked together by disulfide bonds into multimers with varying molecular masses that range into the millions of daltons.⁴¹ Multimers of VWF are constructed within megakaryocytes and endothelial cells and are stored within platelet α granules and endothelial cell Weibel-Palade bodies. Most plasma VWF multimers are derived from endothelial cells. Both endothelial cells and platelets produce VWF multimers that are larger than the multimers in normal plasma.⁴¹ These ultra-large (or “unusually large”) von Willebrand factor (ULVWF) multimers bind more efficiently than the largest plasma VWF multimers to the glycoprotein (GP)-Ib α components of the platelet GP-Ib-IX-V receptors.^{9,42} The initial attachment of ULVWF multimers to GP-Ib α receptors,⁴² and subsequently to activated platelet integrin α IIB β 3 (GP-IIB/IIIa complexes), induces platelet adhesion and aggregation in vitro in the presence of elevated levels of fluid shear stress.^{9,43} After retrograde secretion by endothelial cells, ULVWF multimers become entangled in subendothelial collagen, thereby maximizing VWF-mediated adhesion of blood platelets to any subendothelium exposed by vascular damage and endothelial cell desquamation. An efficient “processing activity”^{8,11} in normal plasma prevents the highly adhesive ULVWF multimers, which are also secreted antegrade into the vessel lumen, from persisting in the bloodstream.

The VWF processing activity is now known to be a specific VWF-cleaving metalloprotease in normal plasma that prevents persistence in the circulation of ULVWF multimers.^{12,14,15} The enzyme degrades ULVWF multimers by cleaving 842Tyr-843Met peptide bonds in susceptible A2 domains of VWF monomeric subunits.^{44–46} The VWF-cleaving metalloprotease is number 13 in a family of 18 distinct ADAMTS-type enzymes identified to date that share structural similarities.^{16,17} ADAMTS13 (*a* disintegrin and metalloproteinase with thrombospondin components) has eight thrombospondin-1-like domains. More precisely, plasma ADAMTS13 is composed of an aminoterminal repolysin-type metalloprotease domain followed by the following: a disintegrin domain; a thrombospondin-1-like domain; a cysteine-rich domain that contains an arginine-glycine-aspartate (RGD) sequence; a spacer domain; seven additional thrombospondin-1-like domains; and two non-identical CUB-type domains at the carboxylterminal end of the molecule (Fig. 24-2). CUB domains contain peptide sequences similar to complement subcomponents C1r/C1s, embryonic sea urchin protein egf, and bone morphogenic protein-1.⁴⁷ ADAMTS13 is a Zn²⁺- and Ca²⁺-requiring

Figure 24-2 Domain structure of ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin components), the plasma von Willebrand Factor (VWF)-cleaving metalloprotease. P, propeptide; MP, metalloprotease (proteolytic) domain; TSP, thrombospondin-1-like domain (eight are present); CUB, two nonidentical domains that contain peptide segments similar to complement components, C1r/C1s, a sea urchin protein, and a bone morphogenic protein. *Indicates the location of mutations in patients with familial TTP that affect secretion or function of ADAMTS13 (above enzyme structure). The percentages of polyclonal autoantibodies directed against specific domains of ADAMTS13 in 25 patients with acquired idiopathic TTP are indicated below the enzyme structure.⁷⁰

190,000-dalton glycosylated protein that is encoded on chromosome 9q34 and is produced predominantly in the liver. ADAMTS13 is inhibited *in vitro* by ethylenediaminetetraacetic acid (EDTA); therefore, functional assays of the enzyme are usually performed with the use of citrate plasma.^{12,14–17,44–46,48,49} Plasma anticoagulated with heparin, chloromethylketones (e.g., phenylalanine-proline-aspartate-chloromethylketone [PPACK]), hirudin, and other direct thrombin inhibitors would also probably be satisfactory for testing.

ULVWF multimers are cleaved by ADAMTS13 as they are secreted in long “strings” from stimulated endothelial cells (Fig. 24-3).^{10,50} ULVWF multimeric strings may be anchored in the endothelial cell membrane to P-selectin molecules that are secreted concurrently with ULVWF multimers from Weibel-Palade bodies.⁵¹ Included among the agents that stimulate endothelial cells to secrete ULVWF multimers are the proinflammatory cytokines, tumor necrosis factor (TNF)- α , interleukin (IL)-8, and IL-6 (in complex with the IL-6 receptor),⁵² as well as the Shiga toxins (discussed later). One of the repeated CUB domains at the carboxylterminal end of each ADAMTS13 enzyme, along with the cysteine-rich/spacer region, may modulate the binding of ADAMTS13 to ULVWF multimers as they are secreted by endothelial cells.^{53–55} Specifically, ADAMTS13 enzymes may attach under flowing conditions to accessible A3 domains in the monomeric subunits of ULVWF multimers⁵⁰; they then cleave 842Tyr-Met0843 peptide bonds in adjacent A2 domains (see Fig. 24-3). Partial unfolding of emerging ULVWF multimers through fluid shear stress may increase the efficiency of ADAMTS13 attachments to ULVWF multimers, followed by ULVWF cleavage.^{10,44} The VWF A1 domain may exert a negative steric influence on VWF cleavage by ADAMTS13, because platelet GP-Ib α binding to the VWF A1 domain renders the adjacent VWF A2 domain more susceptible to proteolysis by ADAMTS13.⁵⁶

Failure to degrade ULVWF multimers has long been suspected to cause familial and acquired idiopathic types of TTP, or to predispose an individual to these disorders (see Fig. 24-3).^{8,57} Critical experiments conducted to verify this concept were reported in 1997 and 1998. Four patients were described with chronic relapsing TTP who had a deficiency of VWF-cleaving protease activity (ADAMTS13) in plasma.¹² Because no inhibitor of the enzyme was detected, this deficiency was ascribed to an abnormality in production, survival, or function of the protease. During the following year, the pathogenesis of the more common acquired idiopathic type of TTP was elucidated.^{13–15} Patients with acquired idiopathic TTP had little, if any, plasma VWF-cleaving protease activity during acute episodes; however, this activity increased toward normal on recovery. Although the plasma assays in these studies were “nonphysiologic,” they were, nonetheless, innovative and informative. Immunoglobulin (Ig)G autoantibodies against components of the enzyme probably accounted for the lack of protease activity in most patients with acquired idiopathic TTP.^{13–15} The reasons for this transient immune dysregulation, as well as for the selective antigenic targeting of the VWF-cleaving protease, are not yet known.

Patients with familial chronic relapsing TTP frequently have ULVWF multimers in their plasma.^{8,57} ULVWF multimers are also detected using a sensitive gel electrophoresis method in some patient plasma samples during acute episodes of acquired idiopathic TTP, but not after recovery.⁵⁷ These findings were explained by investigators^{12–15} who discovered a chronic absence from plasma of the VWF-cleaving protease (ADAMTS13) in familial chronic relapsing TTP, as well as transient inhibition of the enzyme during acute episodes of acquired idiopathic TTP.

Most patients with familial TTP have less than about 5% of normal ADAMTS13 activity in their plasma, regardless of whether plasma is obtained during or after

Figure 24-3 (Legend appears on next page)

Figure 24-3 Proposed mechanism of ultra-large von Willebrand factor (ULVWF) multimeric string cleavage by ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin components). **A**, Stimulation of endothelial cells causes secretion of long ULVWF multimeric strings. **B**, “Close-up” of one of the many monomeric subunits that make up a ULVWF multimeric string. ULVWF multimeric strings may be anchored in the endothelial cell membrane to P-selectin molecules that are secreted concurrently with ULVWF multimers from Weibel-Palade bodies. The A1, A2 (with the 842Tyr-843Met ADAMTS13 proteolytic cleavage site), and A3 domains are shown. Adequate quantities of ADAMTS13 enzymes are present in the plasma of normal individuals. The carboxylterminal CUB region (two nonidentical domains that contain peptide segments similar to complement components, C1r/C1s, a sea urchin protein, and a bone morphogenic protein) is indicated, and the proteolytic metalloprotease domain (MP) is drawn as a pincer-like structure on the aminoterminal portion of the enzyme. **C**, Platelets from flowing blood adhere to the long ULVWF multimeric strings immediately after string secretion. **D**, Platelet adherence (via platelet glycoprotein [GP]-Ib α) to the A1 domain of ULVWF monomeric subunits increases the exposure of neighboring A2 842Tyr-843Met peptide bonds in ULVWF multimeric strings. ADAMTS13 molecules attach via one of their CUB domains to the A3 domain of ULVWF monomeric subunits, and then cleave the adjacent (and now exposed) 842Tyr-843Met bond. **E**, ADAMTS13 cleavage through this mechanism occurs in various monomers along the length of ULVWF multimeric strings. The smaller VWF forms that circulate after cleavage do not induce the adhesion and aggregation of platelets during normal blood flow. **F**, Absent or severely reduced activity of ADAMTS13 in the plasma of patients with TTP prevents the timely cleavage of ULVWF multimeric strings as they are secreted from endothelial cells. Uncleaved ULVWF multimers induce the adhesion and subsequent aggregation of platelets in flowing blood. TTP may be caused by familial deficiencies of ADAMTS13 secretion or activity caused by ADAMTS13 gene mutations, or they may result from acquired autoantibody-induced defects of ADAMTS13 activity (or survival).

acute episodes (provided that they have not recently received plasma infusions). Most patients with acquired idiopathic types of TTP have less than about 5% of normal ADAMTS13 activity in their plasma only during acute TTP episodes.^{12–15,23,58} Severe deficiency of ADAMTS13 activity in plasma from patients with TTP correlates with failure to cleave ULVWF multimers as they emerge from the surfaces of endothelial cells (see Fig. 24-3).¹⁰ As a consequence, ULVWF multimers secreted by endothelial cells remain anchored to these cells in long strings (Fig. 24-4).¹⁰ This anchoring may occur via P-selectin molecules that have transmembrane domains and are secreted along with ULVWF multimers from the Weibel-Palade bodies of endothelial cells.⁵¹ (P-selectin molecules are predominantly retained in the cell membrane as the Weibel-Palade contents are secreted.) Passing platelets adhere via their GP-Ib α receptors to these long, uncleaved ULVWF multimeric strings.¹⁰ (Platelets do not adhere to the smaller VWF forms that circulate after

cleavage of ULVWF multimers.⁴¹) Many additional platelets subsequently aggregate under flowing conditions, probably via activated GP-IIb/IIIa, onto the ULVWF multimeric strings to form large, potentially occlusive platelet thrombi (see Fig. 24-3).^{10,59}

ULVWF multimeric strings are capable of detaching from endothelial cells in the absence of ADAMTS13 activity and in the presence of fluid shear stress and with the increasing torque generated as platelets adhere and aggregate onto ULVWF strings.¹⁰ The detached ULVWF–platelet strings may “embolize” to microvessels downstream and contribute to organ ischemia. The formation of ULVWF–platelet thrombi and emboli may account for the following observations: (1) ULVWF multimers are chronically detected in the plasma of familial TTP patients, as well as in the plasma of some patients with acquired idiopathic TTP, during acute episodes^{8,11,23,57}; (2) increased VWF antigen is found, through flow cytometry, on platelets during episodes of familial or acquired TTP⁶⁰; and (3)

Figure 24-4 Unusually large (UL) VWF multimeric strings, secreted by human umbilical vein endothelial cells stimulated by histamine under flowing conditions, were stained green by rabbit anti-human VWF IgG + goat anti-rabbit-fluorescein isothiocyanate (FITC) in the absence (left) or presence (right) of the red nuclear stain, propidium iodide.

abundant VWF antigen (but not fibrinogen) is observed by immunohistochemistry on platelet occlusive lesions in TTP.⁴⁰

Plasma ADAMTS13 activity is almost always absent or severely reduced in patients with familial TTP,^{12,61,62} as a consequence of homozygous (or doubly heterozygous) mutations in each of the two ADAMTS13 9q34 genes.^{18,23,24,58,63} Mutations in familial TTP have been detected all along the gene in regions that encode different domains (see Fig. 24-2).^{18,23,24,58,63} With severe familial deficiency of ADAMTS13 activity, episodes of TTP usually commence during infancy or childhood. In some patients, however, overt TTP episodes do not develop for years (e.g., during a first pregnancy),²⁴ if ever. This latter observation suggests that in vivo ADAMTS13 cleavage of ULVWF multimers that are emerging from stimulated endothelial cells may exceed plasma enzyme activity measured through in vitro non-physiologic assays. Additionally, or alternatively, accentuated secretion of ULVWF multimers by endothelial cells induced by estrogen or proinflammatory cytokines⁵² may be required to provoke TTP episodes in some patients with severe plasma ADAMTS13 deficiency.

In some infants with <5% ADAMTS13 and neonatal onset of familial chronic relapsing TTP, transient or progressive renal failure is a prominent component of the disorder.⁶⁴ These patients clinically resemble two patients described in 1960 by Schulman and colleagues^{8,65} and in 1978 by Upshaw^{8,66}; consequently, this pediatric subgroup is sometimes said to have “Upshaw-Schulman syndrome.”

Many patients with acquired idiopathic TTP have absent or severely reduced plasma ADAMTS13 activity during an initial episode, as well as during later recurrences.^{13–15} ADAMTS13 activity increases in these patients after recovery from a single, or recurrent, episode. IgG antibodies (presumably autoantibodies) that inhibit plasma ADAMTS13 activity can be detected in 44% to 94% of patients through the nonphysiologic techniques that are currently available.^{13–15,24,67,68} These results suggest the presence of a transient, or intermittently recurrent, defect in immune regulation in many patients who have acquired idiopathic TTP associated with transient, or recurrent, ADAMTS13 deficiency. Antibodies that inhibit plasma ADAMTS13 have also been identified in a few patients with ticlopidine- or clopidogrel-associated TTP.^{28,69} It is not yet known whether a transient, severe defect in ADAMTS13 production or survival occurs in patients with acquired TTP who do not have detectable autoantibodies against the enzyme. Alternatively, failure to detect autoantibodies in some patients may reflect the limited sensitivity of the test systems that are currently in use.

In one recent study of polyclonal autoantibodies against ADAMTS13 in 25 patients with acquired TTP,⁷⁰ epitope targets always included the cysteine-rich/spacer domain sequence, and antibodies were exclusively directed against the cysteine-rich/spacer domain sequence in 3 of the 25 patients. The other 22 autoantibodies reacted with the cysteine-rich/spacer domain sequence plus the CUB domains (64%), the metalloprotease/disintegrin-like/first thrombospondin-1-like domain sequence (56%), or the second-to-eighth thrombospondin-1-like domain sequence (28%) (see Fig. 24-2). The propeptide region was also identified by 20% of autoantibodies,⁷⁰ indicating that removal

of the propeptide is not required for secretion of active enzyme.⁷¹ Autoantibodies inhibit the activity of ADAMTS13 or decrease its survival.

The propensity to produce ADAMTS13 autoantibodies is almost certainly genetically determined. This is emphasized by the recent discovery in twin sisters of acquired idiopathic TTP caused by IgG autoantibodies against ADAMTS13.⁷²

Relapses occur in 23% to 44% of patients with acquired idiopathic TTP,^{24,67,73,74} often during the first year after the initial episode.²⁴ These relapsing patients usually have acquired idiopathic TTP with severe plasma ADAMTS13 deficiency that is often due to the presence of autoantibodies against ADAMTS13.²⁴

In a few instances, pregnancy-related episodes of TTP have been caused by autoantibodies against ADAMTS13.²⁴ The risk of recurrent TTP during any subsequent pregnancies is controversial, with estimates of possible recurrence (per woman) ranging from 26% to 73%.²⁴

Plasma ADAMTS13 activity in healthy adults ranges from approximately 50% to 178% with the use of currently available static, nonphysiologic assays. Activity is often reduced to below normal levels in liver disease, disseminated malignancies,⁷⁵ chronic metabolic and inflammatory conditions, and pregnancy, as well as in newborns.⁷⁶ With the exception of those peripartum women who develop overt TTP,^{24,67} ADAMTS13 activity observed in patients with these conditions is not reduced to the extremely low values (<5% of normal) found in most patients with familial or acquired idiopathic TTP.

OTHER OBSERVATIONS

About twice as many women as men develop acquired idiopathic TTP. Most patients are in the 20- to 60-year age range; no racial or seasonal predisposition is obvious, and case clustering is rare. Most patients who develop acute idiopathic TTP have no identifiable associated risk factor, although TTP during pregnancy or the postpartum period accounts for a small percentage of cases. Neame⁷⁷ suggested that abnormal immune modulation might contribute to its onset under these circumstances. Indeed, a specific defect in immune regulation is likely to be the basis for the “escape” of autoantibody production against ADAMTS13 in most patients with acute idiopathic TTP. How ticlopidine or clopidogrel might promote this anti-ADAMTS13 “escape” in occasional patients is not currently known.

The possibility that immunologic events are involved in acute idiopathic TTP is supported by studies that suggest macrophage/lymphocyte activation in some patients.^{78,79} Elevated levels of IL-1, IL-6, the soluble IL-2 receptor, TNF- α , and transforming growth factor- β (TGF- β) have been reported in the disorder. Evidence also suggests that patients who lack the class II major histocompatibility locus antigen, DR53, may be susceptible to thrombotic microangiopathy.⁸⁰

Acquired idiopathic TTP has been associated occasionally with diseases characterized by autoimmune or other types of abnormal immune responses, including systemic lupus erythematosus (SLE),⁸¹ autoimmune “idiopathic” thrombocytopenic purpura (ITP),⁸² and the acquired immunodeficiency syndrome (AIDS).^{83–85}

REPRESENTATIVE CASES OF TTP

Case 1

A 3-month-old girl became pale and jaundiced and had several transient episodes of hemiparesis. Physical examination findings were normal. Hemoglobin was 8.4 g per deciliter, platelets were 11,000/ μ L, and reticulocytes (polychromatophilic red cells) and 3+/4+ schistocytes were seen on her peripheral blood film. Serum LDH level was elevated fivefold, and unconjugated bilirubin was increased. Computed tomography of the brain showed ischemic changes.

Several days after admission, it was determined that ADAMTS13 activity was not detectable in a citrate plasma sample obtained prior to any therapy, and that the sample did not contain a detectable inhibitor directed against ADAMTS13.

Packed red blood cells and FFP were administered; this was followed by rapid clinical and hematologic remission over 2 days. Neurologic recovery was complete.

A regimen of periodic FFP infusions was tentatively planned (10 mL per kilogram every 3 weeks) for her probable familial (congenital) chronic relapsing TTP.

Case 2

A 22-year-old man developed headache and confusion. He had been healthy previously and was taking no medicine. His hemoglobin was 6.7 g per deciliter, and platelets were 5000/ μ L. Schistocytes (4+/4+) and reticulocytes were prominent on his peripheral blood film. Serum LDH level was 10 times normal. Computed tomography showed no intracerebral hemorrhage.

The admission citrate plasma sample obtained before treatment was later found to have no detectable ADAMTS13 activity; a high-titer inhibitor to ADAMTS13 was found in this sample.

The patient was given high-dose methylprednisolone, packed red blood cells, immediate FFP infusion, and 3 days of plasma exchange (with FFP) commencing on the night of admission. On day 4, he became comatose, and cryosupernatant was substituted for FFP in the daily exchanges. He awakened on day 7, and neurologic symptoms disappeared by day 8. On day 10, platelets were 43,000/ μ L; by day 17, platelets were 203,000/ μ L, and LDH levels were normal. Plasma exchange with cryosupernatant was continued for 5 additional days and was then stopped. Glucocorticoids were tapered over a period of weeks. The patient has not had a recurrence of the acute acquired idiopathic TTP episode over the subsequent several years.

OTHER THROMBOTIC MICROANGIOPATHIES

Some patients develop the characteristic clinical manifestations of thrombotic microangiopathy without overt associated conditions or plasma ADAMTS13 deficiency (at least as measured by techniques currently available).^{67,73,74,86,87} The cause of the disorder in this subgroup of patients, who have a higher mortality rate than patients with severe ADAMTS13 deficiency, is unknown. In some of these patients, any possible relationship with ADAMTS13

deficiency is clouded by the transfusion of normal blood products that contain ADAMTS13 before testing of patient plasma for enzyme activity.²⁴

Neither bone marrow/stem cell transplantation-associated thrombotic microangiopathy nor diarrhea-associated HUS (caused by Shiga toxin-producing enterohemorrhagic *Escherichia coli*) is usually associated with absence or severely reduced levels of plasma ADAMTS13 activity.^{14,26,73,88,89} The explanation for VWF abnormalities in the plasma of some patients with chemotherapy/transplant-associated thrombotic microangiopathy is unknown.³² (See also section on "Types of TTP.")

DIFFERENTIAL DIAGNOSIS OF THROMBOTIC THROMBOCYTOPENIC PURPURA

The constellation of thrombocytopenia, hemolysis, and schistocytosis also occurs (to an extent that is usually less extreme than in TTP) in HUS, DIC, preeclampsia/eclampsia, the HELLP syndrome (preeclampsia-associated Hemolysis, Elevated Liver function tests, and Low Platelets), malignant hypertension, severe vasculitis, scleroderma with associated hypertension and renal failure, and Evans syndrome (concurrent autoimmune thrombocytopenia and direct Coombs test-positive autoimmune hemolysis); in patients with a malfunctioning prosthetic cardiac valve; and, occasionally, after cocaine use (Table 24-3).^{23,90}

Of these, the most frequently troublesome diagnostic dilemma is TTP versus either HUS or DIC. The other types of thrombotic microangiopathy are usually quickly suspected on the basis of the patient's recent medical history.

Of all the conditions mentioned here, only TTP is associated with absent or severely reduced plasma ADAMTS13 levels. Absence and/or severe reduction in ADAMTS13 is always present in familial TTP, but it occurs only during episodes of acquired idiopathic TTP.

DISTINCTION BETWEEN THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC-UREMIC SYNDROME

Platelet adhesion/aggregation on uncleaved ULVWF multimeric strings in the microcirculation in TTP produce fluctuating ischemia or infarction in various organs, including

Table 24-3 Differential Diagnosis of Thrombotic Thrombocytopenic Purpura

†Hemolysis, Elevated Liver function tests, and Low Platelets.

the brain, in 50% to 71% of episodes.^{6,7} In the closely related HUS, initially reported by Gasser and colleagues in 1955,⁹¹ ischemia is predominantly renal and occurs as a consequence of platelet adhesion/aggregation and fibrin polymer formation atop glomerular endothelial cells. Thrombocytopenia, erythrocyte fragmentation, and increased serum levels of LDH are usually less extreme in HUS (Table 24-4). However, the variability of organ dysfunction in TTP (including renal abnormalities in 50% to 75% of episodes)⁷ and the extrarenal manifestations that may complicate HUS can make the two syndromes difficult to distinguish.^{6,7,23,92} Furthermore, clinical presentations that resemble TTP or HUS are sometimes associated with similar conditions (e.g., transplantation, chemotherapy/total body irradiation).

HUS consists of the triad of thrombocytopenia, acute renal failure, and intravascular hemolytic anemia with schistocytosis and elevated serum LDH. Renal dysfunction is severe in HUS, in contrast to most cases of TTP, and often requires dialysis. Oliguria, anuria, chronic renal failure, and hypertension sometimes complicate HUS; however, this is uncommon in patients who recover from episodes of TTP. Although the microvascular thrombi in HUS are usually predominantly renal, other organs are sometimes involved.^{23,92,93}

Especially in children, HUS is frequently preceded by hemorrhagic enterocolitis caused by cytotoxin-producing serotypes of *E coli* (e.g., 0157:H7) or *Shigella* species.^{23,92,94,95} Shiga toxin (Stx)-1 and Stx-2 produced by enterohemorrhagic *E coli* usually cause diarrhea-associated HUS. This relatively common disorder is characterized by obstruction of the glomerular microvasculature by platelet–fibrin thrombi, acute renal failure, thrombocytopenia, intravascular hemolytic anemia, elevated plasma VWF antigen, and plasma levels of ADAMTS13 activity that are within a broad normal range.^{14,23,26} This latter finding may partially explain the poor response of these patients to plasma infusion or exchange.

It has recently been shown⁹⁶ that either Stx-1 or Stx-2 stimulates the rapid and profuse secretion of unusually large ULVWF multimeric strings from human endothelial cells, including glomerular microvascular endothelial cells. Perfused normal human platelets immediately adhere to the secreted ULVWF multimeric strings, and the rate of ULVWF–platelet string cleavage by ADAMTS13 is delayed in the presence of Stx-1 or Stx-2. Studies suggest that Stx-induced formation of ULVWF strings and impairment

of ULVWF–platelet string cleavage by ADAMTS13 explain the initial platelet adhesion that is noted atop Stx-stimulated glomerular endothelial cells in diarrhea-associated HUS. These findings may explain glomerular microvascular occlusion and acute renal failure in diarrhea-associated HUS.⁹⁶

Truly recurrent episodes of acquired idiopathic TTP are distinct from a single protracted episode with brief intervening periods of incomplete remission.⁶ Recurrence of acquired idiopathic TTP occurs in at least 11% to 36% of patients with TTP.^{6,7,24} HUS usually occurs as a single episode, except in rare individuals who have a familial, recurrent type of the disease. In these latter patients (often children), the level of a plasma complement control protein, factor H, may be abnormally low. The result is overactivation of complement component 3 (C3) to C3b whenever the alternative complement pathway is activated.^{97,98} A similar clinical syndrome results from deficiency in another alternative complement pathway control substance, membrane cofactor protein (MCP),⁹⁸ or from deficiency of C3b-cleaving protease (factor I).⁹⁹

In adults, a thrombotic microangiopathy (TMA) that clinically more often resembles HUS than TTP may occur after: (1) the administration of mitomycin, cyclosporine, or quinine; (2) bone marrow or solid organ transplantation; (3) total body irradiation; or (4) the use of gemcitabine or multiple chemotherapeutic agents.^{34,92,100} Plasma ADAMTS13 levels are within a broad normal range, and the pathophysiology is currently unknown.^{23,88}

TTP and HUS are clinical diagnoses. Tissue obtained from a biopsy specimen of bone marrow, gingiva, or kidney may be taken at a time when only a few (or no) arterial thrombi are found in the microvessels of the area sampled. This may account for the finding of characteristic microvascular hyaline thrombi in only about 50% of gingival biopsy specimens from patients considered on the basis of clinical evidence to have TTP.¹⁰¹ Biopsy samples are infrequently useful acutely in diagnosis. In severely thrombocytopenic patients, the procedure may be unsafe.

TTP and HUS are manifestations of excessive microvascular platelet adhesion/aggregation. If the platelet adhesion/aggregation is systemic and extensive, and especially if the central nervous system is involved, the disorder is called TTP. If platelet adhesion/aggregation (and fibrin formation) is relatively less extensive and predominantly involves the kidneys, the patient is considered to have HUS. Severe renal involvement in a patient with TTP or extrarenal manifestations in a patient with HUS can hopelessly obfuscate clinical boundaries between the two syndromes. This situation will persist until rapid, trustworthy, and accessible clinical laboratory tests become available to detect plasma ADAMTS13 activity. Furlan and colleagues¹⁴ initially reported in 1998 that patients given a diagnosis of TTP had little or no plasma VWF–cleaving metalloproteinase (now ADAMTS13) activity, whereas plasma activity was normal (or nearly so) in patients considered to have acquired HUS. These provocative findings, verified since that time by other investigators,^{26,58} may eventually provide the basis for more precise differentiation of the two entities and probably explain why plasma therapy, which is frequently so effective in TTP, is often disappointing in acquired HUS.

Table 24-4 Distinction Between Thrombotic Thrombocytopenic Purpura and Hemolytic-Uremic Syndrome

Thrombocytopenia/schistocytosis/LDH elevation is usually more severe in TTP
Renal ischemia/injury is usually more severe in HUS
Nonrenal organ ischemia/injury is usually more severe in TTP
Plasma ADAMTS13 activity is often absent/severely reduced in TTP; within a broad normal range in HUS

LDH, lactate dehydrogenase; TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic-uremic syndrome; ADAMTS13, a disintegrin and metalloproteinase with thrombospondin domains.

TREATMENT OF PATIENTS WITH THROMBOTIC THROMBOCYTOPENIC PURPURA

The demonstration by Byrnes and Khurana in 1977⁴ that TTP relapses could be prevented or reversed by the infusion of FFP or cryosupernatant (plasma depleted of VWF-rich cryoprecipitate, fibrinogen, fibronectin, and IgM) was followed in 1985 by the observation that the processing of ULVWF multimers was restored in patients with familial chronic relapsing TTP through the transfusion of FFP, cryosupernatant,^{11,102} or solvent/detergent-treated plasma.²⁵ These plasma products were effective alone, in quantities ranging from one to several units, without the need for concurrent plasmapheresis. Tsai and Lian¹⁵ and Furlan and associates¹⁴ proved in 1998 that these plasma products contain functionally active ADAMTS13.

Infants and young children with familial TTP produce inadequate quantities, or functionally defective forms, of ADAMTS13.^{12,23,61} The reason why the infusion of normal ADAMTS13 only about every 3 weeks prevents TTP episodes in these patients is unknown. The plasma half-life of infused ADAMTS13 activity is relatively long (≈ 2 days).⁶¹ The functional half-life of the enzyme may be even longer because ADAMTS13 docks and cleaves one ULVWF multimeric string after another as each string is secreted from endothelial cells.^{50,54}

Adults and older children with acquired idiopathic TTP episodes associated with ADAMTS13 deficiency require daily plasma exchange (Table 24-5). Plasma exchange combines plasmapheresis (which may remove circulating ULVWF-platelet strings, agents that stimulate endothelial cells to secrete ULVWF multimers, and autoantibodies against ADAMTS13) with the infusion of FFP or cryosupernatant (both of which contain uninhibited ADAMTS13). Solvent/detergent-treated plasma and methylene blue/light-treated plasma¹⁰³ (for inactivation of lipid envelope viruses) also contain active ADAMTS13; however, protein S activity is below normal in solvent/detergent plasma.¹⁰³

Skipping even one day before complete remission may lead to rapid relapse. More than one exchange per day has not been proved to be beneficial. Infusion of normal FFP at a rate of about 30 mL/kg/day can be provided initially until plasma exchanges are arranged. This should occur as quickly as practical but often requires a few to many hours. Plasma infusion alone is less effective in acquired

idiopathic TTP than is plasma exchange,⁷ and it may result in volume overload. Patients with TTP who experience coma, cardiac failure, or severe renal dysfunction should begin to receive plasma exchange as soon as possible (see Chapter 30).

Cryosupernatant is at least as effective as FFP in plasma exchange procedures,^{4,104,105} and it is certainly no less effective. If a patient with TTP responds minimally within the first few days of therapy, or actually deteriorates, cryosupernatant can be substituted for FFP in the plasma exchange procedures.¹⁰⁵ Adult patients with TTP who are refractory to FFP exchanges may respond better to exchanges with cryosupernatant.¹⁰⁵

The process of treating plasma with a solvent and detergent to inactivate lipid envelope viruses (HIV-1, hepatitis B and C viruses) also removes large VWF multimers. Both solvent/detergent-treated plasma^{15,103} and methylene blue/light-treated plasma¹⁰³ (which also inactivates lipid envelope viruses) contain active ADAMTS13. Although solvent/detergent-treated plasma is effective in treating patients during episodes of TTP,²⁵ its production and use has declined because the manufacturing process results in protein S activity that is below the levels of untreated normal plasma.¹⁰³

Plasma exchange with FFP or cryosupernatant allows about 80% to 90% of patients with acquired, “out-of-the-blue” TTP to survive an episode.^{6,7,24} Patients with acquired idiopathic TTP who have severe ADAMTS13 deficiency often respond more effectively and rapidly to this procedure than do patients with normal levels of ADAMTS13 who are given a diagnosis of TTP. This was shown in a recent study of 38 consecutive patients at one hospital who were diagnosed with TTP.¹⁰⁶ Of 10 patients who did not respond to daily plasma exchange, 8 had normal plasma ADAMTS13 (activity was absent in the other 2). In contrast, of 28 patients who responded to plasma exchange, 25 had absent or severely reduced plasma ADAMTS13 (activity was normal in the other 3). Of 25 patients with severe ADAMTS13-deficient TTP who responded to plasma exchange, 15 required only 7 exchanges to attain platelet counts above 150,000/ μ L and normal serum LDH values.

Lower titers of plasma ADAMTS13 autoantibodies may be associated with better response to plasma exchange procedures than are higher levels of anti-ADAMTS13 antibodies produced for longer periods.^{74,107,108} In association with plasma exchange, production of ADAMTS13 autoantibodies may be suppressed by high-dose glucocorticoids,⁶ four to eight weekly doses of rituximab (monoclonal antibody against CD20 on B lymphocytes),^{109–112} rituximab combined with cyclophosphamide,^{24,113} or (most radically) splenectomy.^{114–116}

Recovery from TTP is not usually associated with persistent, overt organ damage^{6,7}; however, some compromise of cognitive function may be subsequently detectable through careful testing.²⁴ Although almost all TTP recurrences can be quickly recognized by blood counts and LDH measurements, several disturbing exceptions have been reported. For example, three women who had recovered from previous episodes of TTP subsequently experienced symptoms of stroke without thrombocytopenia, but with absent ADAMTS13 yet with symptomatic response to plasma exchange.^{112,117}

Table 24-5 Treatment of Patients with Thrombotic Thrombocytopenic Purpura

Immediate infusion of FFP (30 mL/kg/day)
Daily plasma exchange with FFP or cryosupernatant* (3–4 L/day)
Glucocorticoids (e.g., intravenous prednisolone at 200 mg/day)
Red blood cells as needed
Platelets only for life-threatening events, including intracerebral or GI hemorrhage, or before invasive procedures with high bleeding risk

*Cryosupernatant = plasma depleted of VWF-rich cryoprecipitate. FFP, fresh frozen plasma; GI, gastrointestinal; VWF, von Willebrand factor.

If a patient who is experiencing a TTP episode is taking ticlopidine or clopidogrel, or any other suspicious drug (e.g., mitomycin, cyclosporine, quinine), then this medicine should be stopped immediately.

Although many adult patients have recovered from TTP episodes without receiving glucocorticoids, in one large series, a subset of patients with TTP recovered after receiving glucocorticoid therapy alone.⁶ On the basis of this study by Bell and colleagues,⁶ it is probably prudent to institute glucocorticoid therapy—in association with plasma exchange—in all adult patients with initial or recurrent TTP episodes, unless a strong contraindication is present. The usefulness of glucocorticoids may reflect the proposed autoimmune pathogenesis in most adult patients (e.g., glucocorticoids may suppress the production of autoantibodies against ADAMTS13). Bell and coworkers⁶ administered prednisolone intravenously immediately after diagnosis was confirmed at a dosage of about 200 mg per day and continued this regimen until the patients recovered.

Depending on the hemoglobin level and intensity of hemolysis, red blood cell transfusions may be required. If the platelet count is very low and bleeding is a primary problem, or if intracranial bleeding is noted on computed tomography scanning or magnetic resonance imaging, then transfusion of platelets will be necessary. (Anecdotal observations suggest that this might be done at a slow rate, to avoid infusion of a large bolus of platelets in only a few minutes.) With some exceptions (Table 24-5), it is probably better to withhold platelet transfusions because they have been temporally associated with exacerbation of the microcirculatory thrombotic process within the central nervous system.^{39,118}

Plasma exchange should be continued for longer than three days⁶ after patients attain complete remission (i.e., a normal neurologic status, a platelet count of 150,000 to 200,000/ μ L, a rising hemoglobin value, and a normal serum LDH level). Schistocytes in declining numbers often persist for many days on peripheral blood films, and so these cannot be used as a reliable marker for remission. With only three additional post-remission exchanges, incomplete response with rapid relapse is likely.⁶ At least five additional post-remission exchanges are currently used empirically in some centers (e.g., the Texas Medical Center hospitals in Houston). The procedure should then be stopped, and the glucocorticoid dosage tapered and discontinued over a period of several weeks. Decreasing frequency of plasma exchanges over days or weeks has not been shown to provide additional benefit in most patients. Platelet counts should be monitored regularly so that incipient relapse can be detected. If TTP does recur, the same treatment program (i.e., glucocorticoids/plasma exchange) that has previously induced remission should be repeated.

Many adult patients with acquired idiopathic TTP who turn out to have recurrent episodes will have their first recurrence during the year after the initial episode.²⁴ In others, episodes do not recur for months to years after an initial episode. A small study of a few patients (before the availability of rituximab) suggests that frequent relapses may be controlled by splenectomy.¹¹⁵

In patients who achieve only a partial response, or whose condition worsens during therapy, plasma exchanges should be continued for a period of a few to many additional days in an effort to achieve complete remission. In these patients, concomitant heparin-associated thrombocytopenia (HIT) or

bacterial infection (e.g., from the plasma exchange catheter) should be suspected (Tables 24-6 and 24-7). HIT is especially likely if platelets begin to decrease without a concomitant increase in the LDH values that have decreased progressively toward normal during therapy. In the latter situation, exposure of the patient to heparin should be eliminated (including via keep-open intravenous lines or indwelling catheters, during dialysis, or on the tips of Swan-Ganz catheters). It is not known whether any treatment other than heparin removal (e.g., hirudin, argatroban) is required in patients with HIT who are also undergoing plasma exchange for TTP. In the absence of evidence to the contrary, the addition of hirudin or argatroban during therapy for TTP is probably too dangerous in most patients.

First-line treatment does not work in some patients with acquired idiopathic TTP episodes. Other forms of therapy may be added if plasma exchanges with FFP or cryosupernatant, glucocorticoids, and rituximab are unsuccessful or are only partially successful (see Table 24-6). Treatment options include the addition of vincristine,¹¹⁹ which depolymerizes platelet microtubules and may alter the availability of GP-Ib α -IX-V or GP-IIb/IIIa receptors for VWF on platelet surfaces; splenectomy¹¹⁴ (removal of immunologic cells involved in ADAMTS13 autoantibody production); and the addition of other immunosuppressive agents in an attempt to suppress production of these autoantibodies (e.g., azathioprine [Imuran; Burroughs-Wellcome, Phoenix, Ariz., USA]¹²⁰ or cyclophosphamide [Cytoxan; Bristol-Myers Squibb, Princeton, NJ, USA]¹¹³).

Table 24-6 Treatment Options for Patients with Refractory Acquired Idiopathic Thrombotic Thrombocytopenic Purpura

Continuation of daily plasma exchange with cryosupernatant (3–4 L/day)
Rituximab (375 mg/kg weekly for 4–8 weeks)
Elimination of heparin from catheter lines and ports
Search for and management of catheter (or other) infections
Vincristine (no more than 2 mg on day 1; then, 1 mg on days 4, 7, and 10)
Splenectomy
Azathioprine (Imuran; 50–150 mg/day) or cyclophosphamide (Cytoxan; 1 g/m²)

Table 24-7 Relapse After Partial Remission During Plasma Exchange Therapy for Acquired Idiopathic TTP

Possible Explanations

Failure to perform uninterrupted series of *daily* exchanges
Premature discontinuation of daily exchange before durable remission
Infection (e.g., of vascular access catheter) or inflammation*
Heparin-induced thrombocytopenia (HIT)[†]
Undiagnosed mimicking disorder (e.g., disseminated malignancy)

*Infection or inflammation may provoke secretion of ULVWF multimeric strings by cytokine-mediated stimulation of endothelial cells.

[†]HIT during TTP therapy may resemble a TTP relapse. In superimposed HIT, however, the falling platelet count may not be accompanied by another increase in serum LDH.

The use of aspirin during TTP episodes is controversial.^{121,122} Platelet adhesion/aggregation onto uncleaved ULVWF multimeric strings under arterial flowing conditions is the underlying pathophysiology of the ADAMTS13-deficient types of TTP. Aspirin would not be expected to impair this process because blockade of cyclooxygenase-mediated platelet thromboxane A₂ generation by aspirin does not inhibit shear-induced platelet adhesion/aggregation in vitro.¹²³ Aspirin may actually exacerbate hemorrhagic complications in some patients,¹²¹ especially those who are severely thrombocytopenic.

TREATMENT OF PATIENTS WITH OTHER TYPES OF THROMBOTIC MICROANGIOPATHY (TMA)

This group of disorders often more closely resembles HUS than TTP. They usually occur weeks to months after exposure to mitomycin C, cyclosporine FK506 (tacrolimus), chemotherapeutic agents in combination, gemcitabine, total body irradiation, bone marrow/stem cell transplantation, or solid organ transplantation. Recent exposure to quinine induces a similar syndrome.

Discontinuation of any putative disease-inducing drug should occur immediately. Patients in this “pathogenesis unknown” category of thrombotic microangiopathy, as well as those with diarrhea-associated HUS, often respond poorly to plasma exchange.^{23,34} It has been shown recently, however, that some patients improve in association with exchange.⁶⁷ It is, therefore, appropriate to commence daily plasma exchange procedures and continue them for a sufficient period so that effectiveness can be determined.

Several patients with HUS-like thrombotic microangiopathy after solid organ transplantation have been reported to respond to plasma exchange plus intravenous immune globulin (IVIg).^{124,125} Plasma adsorption over staphylococcal protein A columns has been reported to be useful in thrombotic microangiopathy that results from mitomycin C exposure.¹²⁶

Creative ideas about the causes and treatments of these disorders are urgently needed.

NEW APPROACHES TO THERAPY

As testing for plasma ADAMTS13 has become increasingly available, results of testing during remission have allowed new observations and have generated thoughtful speculation (Table 24-8).

The sequence of the 190,000-dalton ADAMTS13 has been determined, and the enzyme has been partially purified from normal human plasma fractions.^{16,17,46} Recombinant, active ADAMTS13 has also been prepared¹²⁷ and may soon be produced in therapeutic quantities through the use of insect or mammalian cells (capable of ADAMTS13 glycosylation) or bacteria (incapable of glycosylating ADAMTS13; problem with endotoxin contamination). As a consequence, purified or recombinant ADAMTS13 may soon be developed for therapeutic use in TTP. A plasma level of ADAMTS13 of only about 5% of normal is sufficient to prevent or truncate TTP episodes in most patients.^{23,48,58,62,73} Gene therapy, consequently, may eventually offer a practical approach to

Table 24-8 Recent Clinical Insights/Speculations

Familial vs. Acquired Idiopathic TTP:

- Familial TTP may present later in life (even in middle age) more frequently than previously anticipated.
- Some patients with an initial TTP episode in childhood or adolescence may have familial TTP.
- Relapses in familial TTP may be intermittent, irregular, and occur at unpredictable intervals (i.e., less frequent and regular episodes than previously anticipated).
- Familial TTP patients are probably included in most published series on “acquired” TTP therapy and are likely to respond more quickly to plasma manipulation than patients with autoantibody-mediated acquired idiopathic TTP.

TTP Testing and Therapy:

- A TTP patient of any age with extremely low ADAMTS13 activity or antigen levels *during remission* has familial TTP, and may respond rapidly to plasma infusion alone during subsequent relapse.
- If plasma infusion alone does not induce remission in a familial TTP patient within a few days, especially if the episode has been induced by infection (cytokine-stimulation of endothelial cell ULVWF string secretion), then it may be appropriate to proceed to plasma exchange.*
- Some doubt remains about the superiority of plasma exchange over plasma infusion alone for the treatment of all (unclassified) adult TTP patients.[†]
- Avoidance or reversal of fluid overload is a major advantage of plasma exchange (which has more iatrogenic complications).

*Poorly responsive infection-induced episodes of TTP may occasionally be an indication for *twice daily* plasma exchange (Kitchens CS, personal communication, 2006)

†Coppo P, et al: High-dose plasma infusion versus plasma exchange as early treatment of thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome. *Medicine* 82:27–38, 2003.

attaining more lasting remissions in children with familial chronic relapsing TTP.

It may also be possible to produce active, altered forms of recombinant ADAMTS13 that have less binding affinity for ADAMTS13 autoantibodies. These types of ADAMTS13 may prove useful in the treatment of patients with acquired idiopathic TTP.¹²⁸

New additives to blood products capable of destroying viruses, both with and without lipid envelopes (e.g., parvovirus B19), may become available to supplant the solvent/detergent combination that eliminates HIV, hepatitis B and C viruses, and other lipid envelope viruses from plasma.²⁵ These additives may be useful if they have little or no negative effects on ADAMTS13 in plasma or cryosupernatant, or on purified or recombinant enzyme preparations.

Efficient techniques for removing ADAMTS13 autoantibodies (e.g., new types of protein A or protein G immunoadsorption columns), combined with infusion of concentrates of purified or recombinant ADAMTS13, may eventually prove useful. This type of therapy may be especially helpful in patients who have allergic reactions to other plasma components. Removal of ADAMTS13 autoantibodies by whatever technique will remain difficult because most autoantibodies identified to date have been IgG,¹⁵ which has an extensive extravascular distribution.

COST CONTAINMENT

The treatment of patients with acute episodes of acquired idiopathic TTP is labor intensive, prolonged, and usually requires the services of hematologists and transfusion medicine specialists. Large volumes of FFP or the more expensive cryosupernatant are consumed. Cost reduction of consequence with the use of presently effective therapeutic options is unlikely. On the contrary, if purified or recombinant ADAMTS13 is ultimately used in place of FFP and cryosupernatant, costs are likely to increase.

MEDICAL-LEGAL IMPLICATIONS

TTP is no longer a rare disorder; therefore, the diagnosis must be considered in every patient whose initial complete blood cell count shows thrombocytopenia and the presence of schistocytes. Under this circumstance, a serum LDH value should be obtained immediately, and if it is considerably elevated, physicians should mobilize to begin treatment for TTP. Until physicians develop a heightened—almost reflex—wariness about the increasing possibility of TTP in patients who present to general and emergency medicine settings, the burgeoning cottage industry in TTP-related malpractice claims will continue to thrive.

If the constellation of severe thrombocytopenia, schistocytosis and an elevated LDH level indicates that the diagnosis of TTP is likely, or even possible, then the treating physician should make this presumptive diagnosis and proceed with therapy on an emergency basis. Procrastination is unwise and dangerous. FFP infusion as temporary therapy, accompanied (if possible) by high-dose glucocorticoid administration, should commence as soon as possible. This should be followed by the insertion of a large-bore catheter and initiation of plasma exchange. These latter procedures may require from a few to many hours, sometimes up to 24, to implement. The daunting logistic difficulties are compounded if the patient must be transferred from an admitting hospital that lacks plasmapheresis equipment and personnel to another facility that has the capacity to perform plasma exchange procedures.

Before any severely thrombocytopenic patient who is not exsanguinating is transfused with platelets, the treating physician should specifically determine if either schistocytosis or an elevated serum LDH value is present.

Even with rapid diagnosis and proper therapy, perhaps 10% to 20% of patients die during TTP episodes. Under these circumstances, it is essential that health care practitioners help family members understand how a previously healthy individual can succumb “out of the blue” to an unpronounceable, incomprehensible disorder. Many patients continue to die unexpectedly from TTP, even when exceptional care is provided. Family members (and their lawyers) often blame physicians, when the true culprit is usually the confusing, dangerous, increasingly common, not-always-treatable disease that has been killing young people for more than 80 years.

If explanations are not thorough and thoughtful, a frequent next step is to presume that the tragic outcome must be the fault of the treating physicians and hospital. The likelihood is near 100% that some malpractice attorney will be eager to agree.

CONSULTATIVE CONSIDERATIONS

Disorders characterized by thrombocytopenia, hemolysis, schistocytosis, and LDH elevation are summarized in [Table 24-3](#). HIT (see Chapter 25), which often causes progressive thrombocytopenia and thrombosis, is not usually accompanied by schistocytes.

The consulting hematologist should review quickly and personally the peripheral blood smear and then should rapidly focus on the likely diagnosis on the basis of patient examination findings and the results of a few additional laboratory studies done on an emergency basis (i.e., prothrombin time, partial thromboplastin time, D-dimer, fibrinogen, direct Coombs test, and creatinine).

If the differential diagnosis in an adult patient is believed to be TTP or HUS, then the patient should be presumed to have TTP, and steps to initiate therapy should be taken immediately.

Heparin-Induced Thrombocytopenia

Theodore E. Warkentin, MD

HISTORICAL OVERVIEW¹

In 1958, a vascular surgeon, Rodger Weismann, and his resident, Richard Tobin, reported ten patients from whom they had extracted unusual platelet–fibrin thrombi that formed during a 1- to 2-week treatment course with heparin. These physicians suspected a causal relationship with heparin, perhaps via heparin-induced embolization of thrombus from the proximal aorta (the paucity of red cells in the thrombi argued against a cardiac origin). It was not until 1973, however, that another vascular surgeon (Donald Silver), a resident (R. H. Dixon), and a medical student (Glen R. Rhodes) recognized the concurrence of thrombocytopenia in similar patients. They observed that heparin rechallenge soon after platelet count recovery caused abrupt recurrence of thrombocytopenia. Moreover, patient plasma and heparin added to normal platelets *in vitro* caused platelet aggregation, suggesting that a patient-dependent factor such as immunoglobulin G (IgG) was responsible. In 1977, Silver and colleagues described eight patients with thrombocytopenia that complicated heparin use, noting thrombotic complications (usually affecting arteries) in seven of the patients. Drawing on the similar clinical profile depicted by Weismann and Tobin almost two decades before, Silver proposed the existence of a heparin-induced, antibody-mediated prothrombotic disorder with a paradoxical association with thrombocytopenia and a predilection for causing arterial thromboembolism.

Over the next two decades, the clinical and pathologic features of this distinct syndrome—now known as heparin-induced thrombocytopenia (HIT)—gradually emerged.^{1–3} The presence of heparin-dependent, platelet-activating IgG antibodies became the laboratory hallmark of this syndrome, and sensitive and specific platelet activation assays were developed to detect the antibodies.^{4,5} In 1992, Jean Amiral and associates identified the target antigen of HIT—a multimolecular complex between platelet factor 4 (PF4) and heparin.⁶ This breakthrough led to the development of a new class of antigen assays that could be used to detect pathogenic “HIT antibodies.” Over time, it became apparent that the spectrum of thrombosis complicating HIT included venous thrombosis; indeed, deep venous thrombosis (DVT) and pulmonary embolism appeared to occur even more often than arterial thrombosis.^{3,7–9} The importance of venous thrombosis in HIT was underscored by the recognition in 1997 of an iatrogenic syndrome of limb loss in HIT—venous limb gangrene—in which warfarin treatment was implicated as the cause for progression of DVT to limb necrosis.¹⁰ This study also

found marked *in vivo* thrombin generation in HIT, giving rise to the concept that parallel activation of coagulation—rather than platelet activation alone—was central to the prothrombotic nature of HIT. This new concept coincided with the recognition that effective treatments for HIT consist of agents that reduce thrombin generation or directly inhibit thrombin.²

TERMINOLOGY

Most patients who develop thrombocytopenia during heparin treatment do not have HIT. Accordingly, various terms have been developed to distinguish HIT from other explanations for thrombocytopenia (Table 25-1).² The widely used term *heparin-induced thrombocytopenia* generally refers to the antibody-mediated syndrome and is used in this context in this chapter. Sometimes, however, *HIT type II* is used to indicate the immune-mediated syndrome. Although heparin may contribute to mild thrombocytopenia via nonimmune platelet-activating mechanisms (sometimes designated *HIT type I*), from a practical standpoint, this phenomenon usually cannot be distinguished from other clinical explanations for thrombocytopenia. Thus, the recommended term for these patients is *nonimmune heparin-associated thrombocytopenia*. Sometimes, such a patient’s clinical picture so strongly resembles HIT that the term *pseudo-HIT* may be appropriate (*vide infra*).¹¹ *Subclinical seroconversion* refers to the situation in which anti-PF4/heparin antibodies may be detected but are not believed to be causing adverse clinical events such as thrombocytopenia or thrombosis. For example, a patient with septicemia-associated thrombocytopenia who has received heparin and who has detectable anti-PF4/heparin antibodies of the (nonpathogenic) IgM class has subclinical seroconversion.

PATHOGENESIS

The main pathologic event in HIT is formation of heparin-dependent antibodies of the IgG class that activate platelets via platelet FcγIIa receptors.^{12,13} These antibodies recognize multimolecular complexes between a positively charged platelet α-granule protein, PF4 (member of the C-X-C subfamily of chemokines), and heparin.^{6,14,15} Antigens formed appear on one or more sites of PF4 that have been conformationally modified because of binding to heparin.^{16–19} Certain negatively charged substances other than

Table 25-1 Terminology of Thrombocytopenia Complicating Heparin Treatment

Terminology	Comment
Heparin-Induced Thrombocytopenia (HIT)	<i>Recommended term:</i> ² widely used and denotes role of heparin in inducing thrombocytopenia
HIT type II	Popular term first used by Chong ¹
Heparin-associated thrombocytopenia (HAT)	Confusing, as term is used for both immune and nonimmune thrombocytopenias
Heparin-induced thrombocytopenia/ thrombosis syndrome (HITT or HITTs)	Sometimes used to denote that the patient with HIT has developed thrombosis
White clot syndrome	Indicates that the patient has platelet-rich thrombi in the artery(ies)
Delayed-onset HIT	Indicates HIT that begins after heparin exposure has been stopped
Nonimmune Heparin-Associated Thrombocytopenia (Nonimmune HAT)	<i>Recommended term:</i> ² makes explicit the lack of immune causes, as well as the uncertain relationship between platelet count fall and heparin
HIT type I	Popular term first used by Chong ¹
Pseudo-HIT	Clinical situation that strongly mimics HIT
Subclinical seroconversion	Anti-platelet factor 4 (PF4)/heparin antibodies detected but not believed to be responsible for thrombocytopenia or other clinical events

heparin also support antigenic modification of PF4. For example, platelet-associated chondroitin sulfate can support binding of PF4,²⁰ which may explain the occurrence or persistence of HIT in some patients after heparin has been stopped. The highly sulfated anticancer agent pentosan polysulfate can induce thrombocytopenia and thrombosis caused by antibodies indistinguishable from those generated in HIT.²¹ Also, PF4 complexed with polyvinyl sulfonate binds HIT antibodies²²; this provides the basis for a commercial antigen assay for HIT.

Ultra-large PF4/heparin complexes are more efficiently formed by unfractionated heparin (UFH) rather than by low molecular weight heparin (LMWH),²³ which perhaps helps to explain why the former heparin type is more likely to cause HIT.^{7,8} Heparin chains must be at least 12 to 14 saccharide units in length to form the HIT antigen, together with PF4.^{22,24} However, recent studies²⁵ suggest that the thrombin inhibitor pentasaccharide, fondaparinux, can induce anti-PF4/heparin antibodies at a frequency similar to that of LMWH; ironically, these antibodies bind poorly to PF4/fondaparinux.^{25,26} These observations suggest that immunogenicity (formation of antibody) and cross-reactivity (binding of antibodies to PF4/polyanion complexes) of polysaccharide anticoagulants are dissociated.²⁷ (See also section on prevention of HIT at the end of this chapter.)

Figure 25-1 summarizes the pathogenesis of HIT and emphasizes the central role of thrombin generation.²⁸ Levels of thrombin/antithrombin complexes (a marker of in vivo thrombin generation) are far greater in patients with HIT than in control subjects.^{10,29} At least two factors probably contribute to increased thrombin generation. First, Fc receptor-mediated platelet activation by HIT/IgG antibodies causes formation of procoagulant, platelet-derived microparticles that accelerate coagulation reactions.^{30–32} Second, PF4 released from platelets neutralizes the anticoagulant effects of heparin. In addition, it is possible that HIT antibodies effect procoagulant changes to endothelium³³ and monocytes,³⁴ as well as aggregation of polymorphonuclear leukocytes.³⁵ Such pancellular activation may help to explain the dramatic nature of some HIT-associated thrombi, such as white clots in large arteries. However, it remains uncertain whether activa-

tion of cells other than platelets results from direct binding of HIT antibodies, or whether it occurs via intermediaries such as activated platelets or their products (microparticles).^{36,37}

No clear genetic predisposition to HIT has been identified. Unlike some other immune-mediated thrombocytopenic disorders, no human leukocyte antigen (HLA) association has been identified.³⁸ Although an Arg₁₃₁/His₁₃₁ FcγRIIa receptor polymorphism is known to influence antibody-induced platelet activation, evidence conflicts regarding whether one of the genotypes is significantly more likely to be associated with HIT.³⁹ Recently, an FcγRIIIa receptor polymorphism—Phe₁₅₈/Val₁₅₈—was shown to influence risk of HIT among patients in whom anti-PF4/heparin antibodies had formed: the concept proposed was that the homozygous Val₁₅₈ predisposes to HIT by leading to greater platelet clearance by the phagocytic system.⁴⁰ Finally, the surprising observation was reported that repeated heparin exposure in patients with a previous history of HIT does not usually cause recurrence of HIT antibodies.⁴¹ A related observation is that HIT antibodies are transient and are usually not detectable several weeks or months after an episode of HIT (mean time to antibody nondetectability, 50 to 80 days, depending on the assay performed).⁴¹ Perhaps, absence of long-lasting immunologic memory explains these unusual clinical features of HIT.

Only a few of the patients in whom anti-PF4/heparin antibodies form during heparin treatment develop thrombocytopenia.^{7,8,42} High-titer antibodies of the IgG class⁴³ that are detectable through sensitive platelet activation assays⁴⁴ are most likely to cause thrombocytopenia. Although anecdotal reports suggest that IgM and/or IgA antibodies may cause HIT,⁴⁵ this remains to be confirmed and seems unlikely.^{46,47} Besides formation of pathogenic antibodies, some platelet-dependent factors, such as high FcγIIa receptor numbers⁴⁸ and high platelet-associated PF4 levels,²⁰ may also be important.

Coexisting clinical factors strongly influence localization of thrombosis in HIT. For example, postoperative orthopaedic patients with HIT are much more likely to develop venous thrombosis, including pulmonary embolism, than arterial thrombotic events.^{7,8} In contrast,

Figure 25-1 Pathogenesis of heparin-induced thrombocytopenia (HIT): a central role for thrombin generation. This figure illustrates two explanations for thrombosis in HIT. (1) Activation of platelets (Plt) by anti-platelet factor 4 (PF4)/heparin immunoglobulin (IgG) antibodies (HIT antibodies), leading to formation of procoagulant, platelet-derived microparticles and neutralization of heparin by PF4 released from activated platelets, leads to marked increases in thrombin ("hypercoagulability state") that are characterized by increased risk for venous and arterial thrombosis and coumarin-induced venous limb gangrene. (2) However, it is also possible that unique pathogenetic mechanisms operative in HIT may explain unusual thromboses, such as arterial "white clots." For example, HIT antibodies have been shown to activate endothelium and monocytes (leading to cell surface tissue factor expression), although this stimulation may be largely "indirect" because of poorly defined mechanisms involving platelet activation and, possibly, formation of platelet-derived microparticles. Further, aggregates of platelets and polymorphonuclear (PMN) leukocytes have been described in HIT. To what extent these cooperative interactions between platelets, platelet-derived microparticles, PMN leukocytes, monocytes, and endothelium may lead to arterial (or venous) thrombotic events in HIT in large or small vessels remains unclear. (From Warkentin TE: An overview of the heparin-induced thrombocytopenia syndrome. *Semin Thromb Hemost* 30:273–283, 2004, with permission.²⁸)

post-cardiac surgery and medical patients are about as likely to develop arterial thrombosis as venous events.⁴² Injury to blood vessels, such as that caused by indwelling catheters, is strongly associated with thrombosis in the affected vein or artery.^{49,50}

FREQUENCY

The type of heparin preparation, the duration of treatment, the definition of thrombocytopenia used, and the patient population to whom heparin is given are among the factors that influence the frequency of HIT.⁴² UFH causes HIT

far more often than does LMWH (by at least an order of magnitude).^{7,8,42,51–53} A meta-analysis found that heparin obtained from bovine lung is more likely to cause HIT than is heparin derived from porcine gut⁴²; another study reported a higher rate of antibody formation with bovine compared with porcine UFH.⁵⁴ Greater immunogenicity and increased risk of HIT with bovine UFH likely reflect a longer chain length and a greater degree of sulfation, compared with porcine UFH.⁴²

Because HIT typically begins after 5 or more days of heparin use, limiting heparin use to less than 5 days, when appropriate, should theoretically reduce the frequency of HIT. However, this approach may fail on occasion because even a brief exposure to heparin occasionally triggers formation of potent HIT antibodies that may cause thrombocytopenia and thrombosis, beginning several days after heparin has been stopped, so-called delayed-onset HIT.^{50,55–58}

Sometimes, the "standard" platelet count threshold that indicates thrombocytopenia (150,000/ μ L) is inappropriate for use in defining HIT. For example, transient thrombocytopenia is common 1 to 2 weeks after major surgery is performed. In such patients, an otherwise unexpected fall in platelet count during heparin treatment that exceeds 50% from the postoperative peak strongly suggests HIT.^{8,50} When this definition of thrombocytopenia is used, the frequency of HIT is about 3% to 5% in postoperative orthopaedic patients who are administered UFH prophylaxis for 2 weeks.^{8,52} Some investigators have used a lower proportionate platelet count decline of 30%^{52,59} or 40%⁶⁰ to define thrombocytopenia.

Some patient populations are at greater risk for HIT (Fig. 25-2).^{42,44} For example, cardiac surgical patients are most likely to form anti-PF4/heparin antibodies (approximately 50% to 70% risk^{42,44,61}), but less than 5% of antibody-positive patients develop HIT (overall frequency of HIT, 1% to 2%). In contrast, although IgG antibodies form that are detectable by antigen assay in only 15% to 30% of orthopaedic patients who are administered UFH, as many as one sixth to one third of these patients develop HIT (overall frequency of HIT, 3% to 5%) (see Fig. 25-2).^{42,44,46} HIT is less common in medical than in surgical patients and is rare during pregnancy.⁴² Women are somewhat more likely than men to develop HIT.⁶²

Platelet Count Monitoring for Heparin-Induced Thrombocytopenia

In recent years, recommendations to guide platelet count monitoring for HIT have taken into account the risk of HIT in various clinical situations.^{5,63} Table 25-2 summarizes these recommendations. Platelet count should also be measured within a day of heparin initiation in a patient who has recently received this drug (within the past 100 days),⁶³ or in any patient who presents with thrombosis or other sequelae of HIT during or soon after receiving heparin therapy.

CLINICAL FEATURES

Table 25-3 lists the typical clinical features of HIT.

Figure 25-2 Multiple-iceberg model of heparin-induced thrombocytopenia (HIT). A schematic “iceberg,” shown on the lower “water line,” illustrates relations among HIT-associated thrombosis, thrombocytopenia, HIT antibodies detected by serotonin release assay (SRA), and HIT antibodies detected by platelet factor 4 (PF4)/polyanion enzyme immunoassay (EIA). Above, the relative sizes of the various icebergs reflect the relative frequency of HIT antibody formation, thrombocytopenia, and HIT-associated thrombosis among several different patient populations. Note that unfractionated heparin (UFH) is more likely than low molecular weight heparin (LMWH) to cause HIT among post-orthopaedic surgery patients. However, patient population-dependent effects are also evident (e.g., although cardiac surgical patients are more likely to form HIT antibodies, among patients who form HIT antibodies, orthopaedic patients are most likely to develop HIT). (From Lee DH, Warkentin TE: Frequency of heparin-induced thrombocytopenia. In Warkentin TE, Greinacher A [eds]: Heparin-Induced Thrombocytopenia, 3rd ed. New York, Marcel Dekker, 2004, pp 107–148, with permission.)

Table 25-2 Platelet Count Monitoring for Heparin-Induced Thrombocytopenia

Risk of HIT	Frequency of Platelet Count Monitoring
High (>1%): postoperative patients receiving UFH thromboprophylaxis; patients receiving therapeutic doses of UFH	At least alternate day platelet counts from day 4 to day 14 (if still receiving heparin)
Moderate (0.1%–1%): postoperative patients receiving LMWH; medical patients receiving UFH	Minimum, 2 or 3 platelet counts between day 4 and day 14 (if still receiving heparin)
Low (<0.1%): e.g., medical or pregnant patients receiving LMWH	Routine platelet count monitoring <i>not</i> recommended

This table summarizes recommendations found elsewhere.^{5,63}
UFH, unfractionated heparin; LMWH, low molecular weight heparin.

Temporal Profile

The hallmark of HIT is a platelet count fall that begins between days 5 and 10 after heparin is started (first day of heparin use = day zero) (Fig. 25-3).⁴¹ Such a “typical” onset is observed in about 70% of patients with HIT. In the remaining patients, a “rapid” onset of HIT occurs. Generally speaking, this situation is characterized by a patient who has recently received heparin (within the past 5 to 100 days), and in whom resumption of heparin causes an abrupt fall in the platelet count. This profile is caused by acute platelet activation in a patient with circulating, pre-existing HIT antibodies, formed in relation to recent heparin exposure, rather than rapid regeneration of HIT

antibodies because of an “anamnestic” (immune memory) response.^{41,64}

Severity of Thrombocytopenia

Mild to moderate severity of thrombocytopenia is characteristic of HIT; the median platelet count nadir is about 60,000/ μ L,⁶⁵ and the platelet count falls to below 15,000/ μ L in only 5% of patients (Fig. 25-4). Remarkably, even when a patient with HIT develops such severe thrombocytopenia, petechiae usually are not seen. This clinical profile differs strikingly from that of patients with drug-induced immune thrombocytopenic purpura caused by quinine, quinidine, and sulfa antibiotics, in which the platelet count

Table 25-3 Clinical Features of Heparin-Induced Thrombocytopenia**Timing of Thrombocytopenia**

Typical onset: between days 5 and 10 after heparin initiation (first day of immunizing heparin exposure = day 0)

Rapid onset: <1 day after resumption of heparin (in a patient recently exposed to heparin, and who therefore has residual circulating HIT antibodies)

Severity of Thrombocytopenia

Platelet count nadir: 15,000 to 150,000/ μ L in about 90% of patients (median nadir, about 50,000 to 60,000/ μ L in large patient series); sometimes, a platelet count decline that does not fall below 150,000/ μ L occurs in HIT; platelet count <15,000/ μ L occurs in only 5% of patients

Thrombosis is Common

>50% develop new thrombosis

Venous thrombosis: DVT > pulmonary embolism > warfarin-induced venous limb gangrene > adrenal hemorrhagic necrosis* > cerebral sinus thrombosis

Arterial thrombosis: limb artery thrombosis > stroke syndrome > myocardial infarction > mesenteric artery thrombosis > other arterial thromboses

Absence of Petechiae (even when platelets <15,000/ μ L)**Skin Lesions at Heparin Injection Sites**

Severity ranges from erythematous plaques to skin necrosis

Acute Systemic (Anaphylactoid) Reactions After Intravenous Bolus Heparin

Acute inflammatory or cardiorespiratory signs, or neurologic (headache, transient global amnesia) or miscellaneous (e.g., flushing, diarrhea) signs and symptoms associated with abrupt platelet count fall

*Evidence suggests that adrenal hemorrhage complicating HIT is associated with adrenal infarction related to adrenal vein thrombosis. HIT, heparin-induced thrombocytopenia; DVT, deep venous thrombosis.

Figure 25-3 Platelet count profile of heparin-induced thrombocytopenia (HIT) and HIT-associated thrombosis in a post-orthopaedic surgery population. The bold line and shaded area indicate the geometric mean (± 2 SD) platelet count in normal post-orthopaedic patients. Eighteen patients developed HIT ($\geq 50\%$ fall in platelet count between postoperative days 4 and 14): 9 patients had a platelet count nadir of less than 150,000/ μ L, and 9 patients had a platelet count nadir equal to or above 150,000/ μ L. Overall, 18 thrombotic events occurred in 13 of 18 patients with HIT. Note: Bilateral deep venous thrombosis (DVT) is counted as two thrombotic events, and pulmonary embolism (PE) is also counted as a thrombotic event. (This figure is a composite of two previous published figures from the following: Warkentin TE, Levine MN, Hirsh J, et al: Heparin-induced thrombocytopenia in patients treated with low-molecular-weight heparin or unfractionated heparin. *N Engl J Med* 332:1330–1335, 1995, with permission⁷; and Warkentin TE, Roberts RS, Hirsh J, Kelton JG: An improved definition of immune heparin-induced thrombocytopenia in postoperative orthopedic patients. *Arch Intern Med* 163:2518–2524, 2003, with permission.⁸)

nadir is below 15,000/ μ L in most patients, and mucocutaneous hemorrhage is characteristic.

Venous Thrombosis

Venous thrombosis is the most common thrombotic complication.^{3,9,50} As many as 50% of patients with HIT develop

symptomatic DVT, and about half of these patients develop pulmonary embolism.^{50,66} Some patients with DVT experience severe limb ischemia, including phlegmasia cerulea dolens and venous limb gangrene (vide infra). Adrenal vein thrombosis is believed to be the explanation for adrenal hemorrhagic necrosis, which occurs in about 3% to 5% of patients with HIT.⁵⁰ Bilateral adrenal hemorrhage causes

Figure 25-4 Platelet count nadirs of 142 patients with heparin-induced thrombocytopenia (HIT). A log-normal distribution of platelet count nadirs is seen (median platelet count nadir, $59,000/\mu\text{L}$). HIT-associated thrombosis occurred in most patients with HIT, irrespective of the platelet count nadir. (From Warkentin TE: Clinical presentation of heparin-induced thrombocytopenia. *Semin Hematol* 35(suppl 5):9–16, 1998, with permission.⁶⁵)

acute and/or chronic adrenal failure, and prompt recognition of this complication, with institution of cortisol replacement, can be lifesaving.⁶⁷ Cerebral sinus thrombosis is another unusual life-threatening venous thrombotic event that is associated with HIT.^{57,58,68}

Arterial Thrombosis

Arterial thrombosis was the first complication identified as a feature of HIT.¹ Characteristic pale thrombi extracted by surgeons led to the term *white clot syndrome* that is still sometimes used to indicate HIT. The typical location of thrombi in HIT, namely, lower limb artery occlusion > stroke syndrome > myocardial infarction, is the converse of that observed in (non-HIT) atherothrombosis (myocardial infarction > stroke syndrome > lower limb artery occlusion).⁵⁰

Limb Ischemic Syndromes

Several explanations may be offered for limb-threatening ischemia in a given patient with HIT:⁵⁰ (1) occlusion of the distal aorta or iliofemoral or other large limb arteries by occlusive platelet-rich thromboemboli; (2) microembolization to small arteries/arterioles, or in situ formation of small thrombi within the microcirculation (distal limb ischemia despite palpable or Doppler-identifiable pulses); (3) severe DVT progressing to phlegmasia cerulea dolens; and (4) warfarin-induced venous limb gangrene. The last syndrome was the most common explanation for limb loss in one series.¹⁰ Overt (decompensated) disseminated intravascular coagulation (DIC) manifest as hypofibrinogenemia, elevated international normalized ratio (INR), or red cell fragmentation is sometimes observed in patients with limb ischemia associated with microvascular thrombosis.⁵⁰

Microvascular Thrombotic Complications of Warfarin

Table 25-4 summarizes two syndromes of tissue necrosis that may complicate coumarin (warfarin) therapy in patients with HIT:^{10,29,69–73} venous limb gangrene and classic skin necrosis. In both syndromes, a profound disturbance in procoagulant/anticoagulant balance, namely, a failure of the protein C natural anticoagulant pathway to downregulate increased thrombin in the microvasculature, is believed to be present (Fig. 25-5).^{10,69,70} Of the two syndromes, HIT is more likely to be complicated by venous limb gangrene.

Venous limb gangrene reportedly occurred in 8 of 66 (12%) patients with acute DVT complicating HIT in whom treatment included warfarin.¹⁰ In some patients, concomitant use of a defibrinogenating snake venom, anecrod, may have contributed to this complication by increasing thrombin generation.⁷⁴ Although the frequency of this syndrome may be less than 5% to 10% in patients administered warfarin alone,⁷⁵ it is prudent to avoid warfarin anticoagulation in acute HIT until the patient is well anticoagulated with a parenteral agent that reduces thrombin generation, and until thrombocytopenia has substantially or, preferably, completely recovered.^{63,76,77} Further, if HIT is diagnosed in a patient who is receiving warfarin, vitamin K should be promptly administered.^{63,76–78}

Warfarin-induced venous limb gangrene has a distinct feature: a supratherapeutic INR that coincides with progression of DVT to distal limb necrosis. This characteristic elevation in INR is caused by a severe reduction in factor VII that parallels a severe reduction in protein C,¹⁰ that is, the high INR is a surrogate marker for a low protein C level.⁷⁹ Early recognition of this syndrome and reversal of

Table 25-4 Warfarin-Induced Necrosis Syndromes: Venous Limb Gangrene Versus Classic Skin Necrosis

	Warfarin-Induced Venous Limb Gangrene	Classic Warfarin-Induced Skin Necrosis (WISN)
Clinical Picture	Necrosis of acral tissues in limb(s) affected by DVT during warfarin therapy that results in a supratherapeutic INR (typically, >3.5); this syndrome may follow a prodrome of phlegmasia cerulea dolens	Necrosis of skin and subdermal tissues, especially in central sites (e.g., breasts, buttocks, abdomen, thighs, calves) that begins 3 to 7 days after warfarin is begun
Predisposing Disorders	(1) Acute HIT; (2) adenocarcinoma associated with DIC	(1) Congenital deficiency of natural anticoagulant: (protein C > protein S > antithrombin III); (2) factor V Leiden; (3) acute HIT
Pathogenesis	Acquired severe deficiency of protein C, usually during initiation of warfarin therapy; at the same time, warfarin fails to downregulate increased thrombin generation associated with the underlying disorder (HIT or adenocarcinoma)	Unknown; believed to be caused in some patients by acquired severe deficiency of protein C related to preexisting congenital deficiency and rapid further fall in protein C levels on starting warfarin treatment (because of short half-life for protein C)

DVT, deep venous thrombosis; INR, international normalized ratio; HIT, heparin-induced thrombocytopenia; DIC, disseminated intravascular coagulation.

Figure 25-5 Two syndromes of coumarin (warfarin)-induced necrosis. (1) Coumarin-induced skin necrosis (central necrosis) and (2) coumarin-induced venous limb gangrene. Coumarin-induced skin necrosis most commonly affects the breasts, abdomen, thighs, buttocks, and calves and is often symmetrical; it is usually associated with congenital or acquired abnormalities in the protein C natural anticoagulant pathway. In contrast, venous limb gangrene occurs in patients with disseminated intravascular coagulation (DIC) associated with heparin-induced thrombocytopenia (HIT) or adenocarcinoma. This syndrome is characterized by microvascular thrombosis in a limb affected by deep venous thrombosis (DVT) that leads to acral (distal extremity) ischemic necrosis. (Reprinted, with modifications and with permission, from Warkentin TE: Heparin-induced thrombocytopenia: IgG-mediated platelet activation, platelet microparticle generation, and altered procoagulant/anticoagulant balance in the pathogenesis of thrombosis and venous limb gangrene complicating heparin-induced thrombocytopenia (HIT). *Transfus Med Rev* 10:249–258, 1996.⁷⁰)

warfarin anticoagulation with intravenous vitamin K and fresh frozen plasma may be limb saving.¹⁰ Uncontrolled DIC associated with adenocarcinoma is another clinical situation that has been associated with limb gangrene during warfarin therapy.^{11,79,80}

Heparin-Induced Skin Lesions

Inflammatory plaque-like or necrotic lesions that begin 6 or more days after subcutaneous injections of UFH or LMWH are begun are a manifestation of the HIT syndrome.^{50,81,82} For unknown reasons, only a minority of patients who develop HIT during subcutaneous heparin usage develop injection site skin lesions. Many patients with heparin-induced skin lesions do not develop concomitant thrombocytopenia, even when HIT antibodies are

detected by sensitive antigen or activation assays. Platelet counts should continue to be monitored for a few days in all patients with heparin-induced skin lesions; thrombocytopenia and thrombosis sometimes occur after heparin therapy has been discontinued.⁸³

Neurologic Syndromes

Stroke syndromes caused by arterial (or even venous) thrombi are relatively common in HIT.⁵⁰ Cerebral sinus thrombosis^{57,68,84} is suggested by headache, a decreased level of consciousness, and focal neurologic defects. Transient global amnesia is a rare complication of HIT that may follow an intravenous bolus of heparin.^{50,85} Lower limb paralysis associated with infarction of the spinal cord or lumbosacral plexus has been reported.

Cardiac Syndromes

Besides myocardial infarction, other cardiac complications of HIT include intraventricular and intra-atrial thrombus formation that may lead to peripheral or pulmonary embolism. Cardiopulmonary arrest occurring shortly after intravenous heparin bolus administration is another manifestation of HIT.^{50,86}

Outpatient Presentation of Heparin-Induced Thrombocytopenia (Delayed-Onset HIT)

HIT is often viewed as a diagnosis that affects hospital inpatients. However, some patients can develop potent platelet-activating antibodies after a brief course of heparin that results in thrombocytopenia and thrombosis, beginning several days after cessation of heparin.^{50,55–58} With a diagnosis of *delayed-onset HIT*, such patients typically have very strong positive test results for HIT antibodies by immunoassay or platelet activation assay.⁵⁵ Platelet activation in the absence of heparin is another feature that is exhibited by some sera.

Heparin-Induced Thrombocytopenia in Children

HIT has been reported in children.^{87–89} However, the frequency is less than that seen in adults. Although neonates develop HIT rarely, if at all,⁹⁰ older infants and children are at risk, particularly after cardiac surgery^{88,91} or during treatment of thrombosis with UFH.⁸⁸ The ratio of venous to arterial thrombosis may be even higher in pediatric than in adult HIT.⁸⁸ Experience in treating children with HIT has been limited.^{87–89,92}

DIFFERENTIAL DIAGNOSIS

Thrombocytopenia occurs commonly in hospitalized patients; most patients who develop a platelet count fall

during heparin therapy do not have HIT. Indeed, in the intensive care unit, the estimated frequency of HIT (about 0.3% to 0.5%) is 100 times less than the frequency of thrombocytopenia from any cause (30% to 50%).^{93–95} When thrombocytopenia occurs early during heparin treatment (within the first 4 days), the explanation usually rests with the patient's reason for hospitalization (e.g., hemodilution and platelet consumption after surgery, septicemia, DIC). However, HIT should be suspected in a patient with early-onset thrombocytopenia when the degree of platelet count fall is greater than would be expected for the patient's clinical situation and when the patient has recently been exposed to heparin (past few weeks or months). Indeed, such a rapid onset of thrombocytopenia occurs in about 25% of all patients in whom HIT is diagnosed.⁴¹

Pseudo-HIT refers to the condition diagnosed in patients whose clinical profile appears to suggest HIT, but in whom HIT antibodies cannot be detected by sensitive assays (Table 25-5).¹¹ For example, Figure 25-6 shows the courses of two patients with very similar platelet count profiles: one patient had pulmonary embolism-associated thrombocytopenia, and the other had HIT-associated pulmonary embolism.^{11,96} For the former patient with pseudo-HIT, increased doses of heparin (to overcome heparin "resistance") resulted in platelet count and clinical recovery (see Fig. 25-6A).

CLINICAL SCORING SYSTEM

In evaluating a patient for possible HIT, the use of a clinical scoring system might be helpful. In one system, the 4 T's⁹⁷ (Table 25-6), the clinician assesses the likelihood of HIT on the basis of (1) magnitude of thrombocytopenia, (2) timing of thrombocytopenia, (3) presence of thrombosis (or other sequelae of HIT), and (4) whether other plausible explanations for thrombocytopenia or thrombosis are present. A low score (≤ 3 points) makes HIT unlikely ($<2\%$)^{98,99} (i.e., high negative predictive value). In some clinical settings, a high score indicates a high probability of HIT.^{98,99}

Table 25-5 Pseudo-HIT Disorders: Thrombocytopenia and Thrombosis

Pseudo-HIT Disorder	Pathogenesis of Thrombocytopenia and Thrombosis
Adenocarcinoma	DIC secondary to procoagulant material(s) produced by neoplastic cells; platelet fall often occurs <i>after</i> heparin is stopped
Pulmonary embolism	Platelet activation by clot-bound thrombin*
Diabetic ketoacidosis	Hyperaggregable platelets in ketoacidosis
Antiphospholipid syndrome	Multiple mechanisms described, including platelet activation by antiphospholipid antibodies
Thrombolytic therapy	Platelet activation by thrombin bound to fibrin degradation products
Septicemia-associated purpura fulminans	Symmetrical peripheral gangrene resulting from DIC with depletion of protein C and antithrombin III
Infective endocarditis	Infection-associated thrombocytopenia; ischemic events caused by septic emboli
Paroxysmal nocturnal hemoglobinuria	Platelets susceptible to complement-mediated damage; platelet hypoproduction
Posttransfusion purpura (PTP)	"Pseudospecific" alloantibody-mediated platelet destruction (exception: bleeding, not thrombosis)

These "pseudo-HIT" disorders may mimic HIT by causing thrombocytopenia and thrombosis in association with heparin treatment. An exception is PTP, which causes bleeding but not thrombosis; however, PTP may resemble HIT in that both disorders usually occur about a week after major surgery requiring blood and postoperative heparin.

HIT, heparin-induced thrombocytopenia; DIC, disseminated intravascular coagulation.

*See Figure 25-6A for an example of thrombocytopenia associated with pulmonary embolism.

From Warkentin TE: Pseudo-heparin-induced thrombocytopenia. In Warkentin TE, Greinacher A (eds): Heparin-Induced Thrombocytopenia, 3rd ed. New York, Marcel Dekker, 2004, pp 313–334, with permission.

Figure 25-6 Two patients with pulmonary embolism (PE): Pseudo-heparin-induced thrombocytopenia (HIT) versus HIT. **A**, Platelet count fell by 59% (387,000 to 159,000/μL) during unfractionated heparin (UFH) therapy complicated by PE. Testing for HIT antibodies by serotonin release assay (SRA) and platelet factor 4 (PF4)/heparin enzyme immunoassay (EIA) was negative. Increase in heparin dose to overcome heparin “resistance” led to resolution of thrombocytopenia. Platelet count fell by 57% (378,000 to 161,000/μL) during UFH therapy after cardiopulmonary bypass (CPB) surgery complicated by PE. Testing for HIT antibodies was strongly positive. Substitution of heparin by danaparoid led to resolution of thrombocytopenia. Similar platelet count profiles in these two patients with postoperative PE illustrate how difficult it may be to diagnose HIT on clinical grounds alone. (From Warkentin TE: Pseudo-heparin-induced thrombocytopenia. In Warkentin TE, Greinacher A [eds]: *Heparin-Induced Thrombocytopenia*, 3rd ed. New York, Marcel Dekker, 2004, pp 313–334, with permission.)

In addition to the physician’s estimate of the pretest probability of HIT, results of laboratory testing for HIT antibodies (vide infra) are important because they may be associated with a high likelihood ratio (strong positive test result) or a very low likelihood ratio (negative testing by one or more sensitive assays).¹⁰⁰ Thus, in a clinicopathologic disorder such as HIT, the physician must carefully integrate clinical and laboratory data to arrive at the diagnosis (see “Interpretation of HIT Antibody Test Results”).

LABORATORY TESTING

Two major classes of assays detect HIT antibodies: platelet activation (functional) and PF4/polyanion antigen assays.^{4,5,101} Platelet activation assays, which include aggregation of platelets in citrate-anticoagulated platelet-rich plasma (developed in the 1970s), as well as assays that use washed platelets (developed in the 1980s), implicate the presence of HIT antibodies via their platelet-activating

properties.⁴ In contrast, PF4/polyanion antigen assays, which were developed in the 1990s,⁶ detect HIT antibodies on the basis of their reactivity with PF4 complexed to heparin or other polyanions. Thus, laboratory testing for HIT parallels another hypercoagulable state, the antiphospholipid syndrome, in which both functional (“lupus anticoagulant” testing) and antigen (anticardiolipin antibody) assays are used for diagnosis (see Chapter 19).

Platelet Activation Assays

Platelet activation assays detect HIT antibodies of the IgG class via their ability to crosslink platelet FcγIIa receptors in the presence of heparin, causing platelet activation.¹² Because platelet activation is a nonspecific end point, care must be taken to distinguish HIT antibodies from thrombin, immune complexes, or other platelet activators.^{4,101}

Washed Platelet Activation Assays

Washed platelet activation assays that use platelets resuspended in calcium-containing buffer are reliable assays for HIT, provided that platelets are handled properly; for example, the use of apyrase (an enzyme that degrades adenine nucleotides) during platelet washing is important for maintaining sensitivity of platelets to subsequent stimulation by adenosine diphosphate (ADP), an important potentiating factor in HIT.^{4,102}

The platelet serotonin release assay (SRA) quantitates the release of ¹⁴C-labeled serotonin from platelets as a marker of platelet activation.^{103,104} The clinical usefulness of this assay has been validated: a positive test result was strongly associated with thrombocytopenia beginning on or after 5 days of heparin therapy (indicating probable HIT) in a large study (odds ratio, approximately 80).⁸ Use of a flow cytometer to detect platelet-derived microparticles involves similar platelet handling methods but avoids a radioisotope.¹⁰⁵

The heparin-induced platelet activation (HIPA) assay^{106–108} assesses aggregation of washed platelets incubated with patient serum and heparin in U-bottomed polystyrene microtiter wells containing two stainless steel spheres, under conditions of platelet stirring. At 5-minute intervals, the wells are examined against an indirect light source: a change in appearance of the reaction mixture from turbidity (nonaggregated platelets) to transparency (aggregated platelets) indicates platelet activation.

Advantages of washed platelet activation assays include (1) their high sensitivity for detecting clinically significant HIT antibodies; (2) their (relatively) low sensitivity for detecting clinically insignificant HIT antibodies, compared with antigen assays; and (3) their ability to permit batch evaluation of many patient samples under several reaction conditions, thereby enhancing test specificity. Because washed platelets are activated by IgG (but not by IgA and/or IgM) HIT antibodies, washed platelet activation assays have greater specificity for clinical HIT compared with antigen assays that detect antibodies of all three antibody classes.^{46,47}

Disadvantages include the technically demanding nature of these assays¹⁰⁸ (including requirement for fresh platelets from normal platelet donors) and the need for radiolabeling (SRA), expensive equipment (flow cytometer), and a

Table 25-6 Estimating the Pretest Probability of HIT: “4 T’S” Scoring System

	2	1	0
Thrombocytopenia (acute)	>50% platelet count fall to nadir $\geq 20,000/\mu\text{L}$	30%–50% platelet count fall (or >50% directly resulting from surgery); or nadir 10,000–19,000/ μL	<30% platelet count fall; or nadir <10,000/ μL
Timing* of platelet count fall, thrombosis, or other sequelae of HIT (first day of heparin course = day 0)	Day 5–10 onset; or day 1 (if recent heparin exposure within past 5–30 days)	Consistent with day 5–10 fall, but not clear (e.g., missing platelet counts); or day 1 (heparin exposure within past 31–100 days); or platelet fall after day 10	Platelet count fall ≤ 4 days without recent heparin exposure
Thrombosis or other sequelae (e.g., skin lesions, ASR)	Proved new thrombosis; or skin necrosis; or post–intravenous heparin bolus ASR	Progressive or recurrent thrombosis; erythematous skin lesions; or suspected thrombosis (not proved)	None
Other cause for thrombocytopenia	No explanation for platelet count fall is evident	Possible other cause is evident	Definite other cause is present

Pretest probability score: 6–8 = high; 4–5 = intermediate; 0–3 = low.
Points: 0, 1, or 2 for each of 4 categories: maximum possible score = 8.
HIT, heparin-induced thrombocytopenia; ASR, acute systemic reaction.

*First day of immunizing heparin exposure considered day 0 (the most immunizing exposure should be considered first, e.g., unfractionated heparin [UFH] received during cardiac surgery is more immunogenic than UFH or low molecular weight heparin given for acute coronary syndrome); the day the platelet count begins to fall is considered the day of onset of thrombocytopenia (it generally takes 1 to 3 more days before an arbitrary threshold that defines thrombocytopenia is passed).

From Warkentin TE, Heddle NM: Laboratory diagnosis of immune heparin-induced thrombocytopenia. *Curr Hematol Rep* 2:148–157, 2003.⁹⁷
Reprinted, with modifications, with permission.

subjective observer-dependent end point (HIPA). Further, the laboratory must maintain a panel of positive control sera. Test serum also must first undergo controlled heat treatment (to inactivate thrombin), which sometimes causes ex vivo formation of IgG immune complexes, yielding an indeterminate test result (activation of platelets at all heparin concentrations).^{4,101} Platelet-activating anti-HLA alloantibodies may also yield an indeterminate result.

Quality control involves selecting blood donors whose platelets respond well to HIT sera, as well as testing various strong and weak positive control sera. Because HIT sera and washed platelets exhibit variable reactivity in a hierarchical manner,¹⁰⁴ a positive result with the use of a “weak” positive HIT serum control ensures that platelet handling was adequate to permit accurate interpretation of test results.

Platelet Aggregation Assays that Use Platelet-Rich Plasma

Aggregation assays that use platelet-rich plasma are the most widely used activation assays for detecting HIT antibodies because they require the ubiquitous platelet aggregometer and involve relatively simple methods.^{109,110} The aggregation response of platelets (prepared as citrated platelet-rich plasma from a normal donor) to platelet-poor plasma obtained from the patient, in the presence of therapeutic heparin levels (0.5 to 1.0 U per milliliter), is assessed and compared with reactivity in the presence of buffer control and high heparin concentrations (100 U/ μL). Unfortunately, these aggregation assays are relatively insensitive for diagnosing HIT: As few as 33% to 50% of samples that test positive in a washed platelet assay yield a positive aggregation assay result.¹⁰⁷ Another problem is that nonspecific platelet activation may occur more commonly than with washed platelet methods, increasing the chance of a false-positive result.⁴

PF4/Polyanion Immunoassays

Solid Phase Enzyme Immunoassays

Antigen assays use enzyme immunoassay (EIA) methods to detect binding of HIT antibodies to their PF4-containing antigen target, which is usually immobilized to a solid phase. Two antigen assay kits are available commercially. One assay (Asserachrom HPIA; Diagnostica Stago, Paris, France) uses PF4/heparin complexes, whereas the other test (available from Genetic Testing Institute, Waukesha, Wis, USA) uses PF4 bound to polyvinyl sulfonate (PVS).²² Both commercial tests detect HIT antibodies of the three major immunoglobulin classes (IgG, IgA, IgM). However, this might not provide an advantage over antigen assays that detect only IgG antibodies: Our laboratory found that an “in-house” EIA that detected only IgG anti-PF4/heparin antibodies¹¹¹ yielded positive results in all 15 patients identified with HIT in prospective clinical trials (high sensitivity).⁴⁴ Further, the assay was more specific for HIT than were commercial EIAs,⁴⁶ yielding superior operating characteristics (i.e., sensitivity/specificity tradeoff at any given cutoff between negative and positive results).

Fluid Phase Enzyme Immunoassays

A fluid phase PF4/heparin EIA was developed by investigators in Australia.¹¹² Through this method, patient serum or plasma reacts with biotin–PF4/heparin complexes in a fluid phase, prior to capture of IgG antibodies—and any bound antigen—with staphylococcal protein A. Biotinylated antigen/antibody complexes, now bound to protein G sepharose via the Fc moieties of HIT IgG, are separated from unbound antigen by centrifugation and washing. Streptavidin-conjugated peroxidase is used to quantitate biotin–PF4/heparin/IgG complexes (streptavidin binds to biotin). This method may result in a lower false-positive rate

because it avoids denaturation of the antigen caused by binding to a solid phase, and it detects only anti-PF4/heparin antibodies of the IgG class. It also permits the detection of in vitro cross-reactivity of HIT antibodies against various heparins and heparinoids.¹¹²

Rapid Immunoassays

A particle gel immunoassay uses PF4/heparin complexes bound to red, high-density polystyrene beads; after patient serum or plasma is added, anti-PF4/heparin antibodies bind to antigen-coated beads.¹¹³ However, IgG class antibodies do not agglutinate polystyrene beads well; therefore, a secondary anti-human immunoglobulin antibody is added into the sephacryl gel. The rationale behind this (and other gel centrifugation assays) is that on centrifugation, agglutinated beads (indicating the presence of anti-PF4/heparin antibodies) do not migrate through the sephacryl gel, whereas nonagglutinated beads (indicating absence of antibodies) pass through the gel, thus forming a red band at the bottom. This method is available to blood banks that use a gel centrifugation technology system. Currently, particle gel immunoassay is available in Europe and Canada and is under investigation in the United States.

Limited assessment suggests sensitivity and specificity for HIT that are intermediate between washed platelet activation assays and standard solid-phase EIA.^{114,115} Operating characteristics of the assay may be improved by determination of the titer of the blood sample that produces a positive result; a titer of 4 or greater appears to be of greater clinical significance than a positive result with neat or 1 in 2 diluted sera.¹¹⁵

Recently, another rapid immunoassay—the Health-TEST Heparin/Platelet Factor 4 Antibody Assay (Akers Biosciences, Inc., Thorofare, NJ, USA)—received U.S. Food and Drug Administration (FDA) approval for use in detecting anti-PF4/heparin antibodies. This assay uses a system known as Particle ImmunoFiltration Assay (PIFA), wherein patient serum is added to a reaction well that contains dyed particles coated with PF4 (*not* PF4/heparin). Lack of requirement for heparin presumably reflects formation of HIT antigens through close approximation of PF4 tetramers²⁶ (achieved under conditions of PF4 binding to particles). Subsequently, only nonagglutinated particles will migrate through the membrane filter. Thus, a negative test is shown by a blue color in the result well, whereas no color indicates a positive test. Operating characteristics of this assay remain largely undefined.

Interpretation of HIT Antibody Test Results

Interpretation of HIT antibody test results is complicated by the fact that only a minority of patients who develop anti-PF4/heparin antibodies experience thrombocytopenia.^{7,8,46,116} A corollary to this is that a positive HIT test result may not therefore actually indicate HIT, particularly if a weak positive result is obtained and another convincing explanation for the thrombocytopenia can be provided.^{4,46} Thus, tests for HIT should be interpreted in the clinical context of pretest probability. Further, the magnitude of a positive test result should be considered, with a “strong” test result

indicating a greater likelihood for HIT than is suggested by a “weak” result.^{46,100} Because antigen assays are more likely than activation assays to detect clinically insignificant HIT antibodies,^{25,44,117} one algorithmic approach involves screening for HIT antibodies with a commercial antigen assay, but performing further confirmatory testing with a washed platelet activation assay if the clinical situation suggests another more plausible diagnosis despite a positive EIA. However, because existing antigen and washed platelet activation assays are extremely sensitive in detecting clinically significant HIT antibodies, negative results in one or (especially) both classes of assay provide strong evidence against HIT, irrespective of the patient’s clinical course. Occasionally, when an unexpected negative test result is obtained with use of an antigen assay, referral for further testing by activation assay may be needed in that anecdotal evidence that a false-negative EIA event may result is rarely caused by antibodies directed against “minor” antigens other than PF4/heparin (e.g., interleukin-8, neutrophil-activating peptide-2); in such patients, sensitive activation assays yield positive results.¹¹⁸

By the time of discharge from the hospital, it is usually clear whether a patient had HIT or some imitator. The final diagnosis should be clearly stated in the discharge summary in order to minimize confusion in the future as patients may well be readmitted and given consideration for heparin exposure again.

TREATMENT OF PATIENTS WITH HIT-ASSOCIATED THROMBOSIS

Overall, about 50% to 75% of patients with a diagnosis of clinical HIT supported by a positive SRA develop new, progressive, or recurrent thrombosis during or soon after their episode of thrombocytopenia.^{42,66} Thus, an alternative, rapidly acting, nonheparin anticoagulant must be used frequently for patients with strongly suspected (or confirmed) HIT. Two major FDA-approved options are available in the United States: lepirudin and argatroban. Both of these are direct thrombin inhibitors (DTIs). A third option, danaparoid, is available in some other countries (e.g., Canada, European Union). Oral anticoagulants, also known as vitamin K antagonists (VKAs), are *contraindicated* during acute HIT but may be used for long-term management of thrombosis following an episode of HIT. Table 25-7 lists some recommendations of the American College of Chest Physicians (ACCP) that may be helpful in the management of HIT.^{63,119}

Lepirudin

Lepirudin (Refludan) is a derivative of hirudin—a DTI that is synthesized naturally by the salivary glands of the medicinal leech and is manufactured through recombinant technology.^{120–122} The 65 amino acid polypeptide (6980 Da; Ki for thrombin, 60 fmol per liter) differs minimally in structure from its natural counterpart. Hirudin and its synthetic derivatives form noncovalent but irreversible complexes with thrombin, binding to two sites on thrombin (active site cleft and fibrinogen-binding site). Differing from heparin, hirudin acts independently of the plasma cofactors

Table 25-7 Recommendations of the Seventh Conference of the American College of Chest Physicians on Antithrombotic and Thrombolytic Therapy⁶³

Nonheparin Anticoagulants for HIT

- For patients with strongly suspected (or confirmed) HIT, whether or not complicated by thrombosis, we recommend use of an alternative, nonheparin anticoagulant in therapeutic doses, such as lepirudin (grade 1C+), argatroban (grade 1C), bivalirudin (grade 2C), or danaparoid (grade 1B), over further UFH or LMWH therapy, and over no further anticoagulation (with or without vena caval filter).

Ultrasonography of Lower Limb Veins

- For patients with strongly suspected (or confirmed) HIT, whether or not clinical evidence of lower limb DVT is noted, we recommend routine ultrasonography of lower limb veins for investigation of DVT over not performing routine ultrasonography (grade 1C).

Vitamin K Antagonists (VKAs; Coumarins)

- For patients with strongly suspected (or confirmed) HIT, we recommend **against** the use of vitamin K antagonist (coumarin) therapy until after the platelet count has been substantially increased (e.g., to at least 100,000/ μ L and preferably 150,000/ μ L); that the VKA should be administered only during overlapping alternative anticoagulation (minimum, 5-day overlap) and should be begun with low maintenance doses (maximum, 5 mg warfarin; 6 mg phenprocoumon); that the alternative anticoagulant should not be stopped until the platelet count has reached a stable plateau and during at least the last 2 days, the INR is within the target therapeutic range (all grade 1C).
- For patients receiving VKAs at the time of diagnosis of HIT, we recommend use of vitamin K (grade 2C).

LMWH

- For patients with strongly suspected HIT, whether or not complicated by thrombosis, we recommend **against** the use of LMWH (grade 1C+).

Prophylactic Platelet Transfusions

- For patients with strongly suspected or confirmed HIT who do not have active bleeding, we suggest that prophylactic platelet transfusions should **not** be administered (grade 2C).

The implications of the grades of recommendation shown above are as follows:¹¹⁹

Grade of Recommendation	Clarity of Risk/Benefit	Methodologic Strength of Supporting Data	Implications
1C+	Clear	No RCTs, but strong RCT results may be unequivocally extrapolated, or overwhelming evidence can be obtained from observational studies	Strong recommendation; may apply to most patients in most circumstances
1B	Clear	RCTs with important limitations (inconsistent results, methodologic flaws)	Strong recommendation, likely to apply to most patients
1C	Clear	Observational studies	Intermediate-strength recommendation; may change when stronger evidence becomes available
2C	Unclear	Observational studies	Very weak recommendation; other alternatives may be equally reasonable

HIT, heparin-induced thrombocytopenia; UFH, unfractionated heparin; LMWH, low molecular weight heparin; DVT, deep venous thrombosis; RCT, randomized controlled trial.

From Warkentin TE, Greinacher A: Heparin-induced thrombocytopenia: Recognition, treatment, and prevention. The Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. Chest 26(suppl):3115–3375, 2004, with permission.⁶³

antithrombin III and heparin cofactor II. Hirudin also differs from heparin in terms of its greater ability to inhibit clot-bound thrombin. Thus, dependable thrombin neutralization may occur, even in the procoagulant milieu of HIT.

In normal subjects, the half-life of lepirudin is about 1.3 hours. However, this agent is renally excreted, and the half-life can rise substantially (by as much as 2 days) in patients with renal failure, leading to high risk for drug accumulation and bleeding. Lepirudin is usually monitored with the use of partial thromboplastin time (PTT), which reveals a fair correlation with plasma drug levels in many (but not all) situations. The target therapeutic range is 1.5 to 2.5 times the patient's nonanticoagulated baseline PTT (if known), or 1.5 to 2.5 times the mean of the laboratory normal range.²⁹ Although interpatient differences in lepirudin metabolism are known to occur, most patients show stable anticoagulation during lepirudin treat-

ment. However, the high frequency with which antilepirudin antibodies develop (which paradoxically enhances the anticoagulant response to lepirudin in some patients) means that daily PTT monitoring should be performed.¹²³ No antidote for lepirudin exists.

Anaphylaxis has been reported after intravenous bolus injection of lepirudin.^{124,125} This event is likely related to high levels of antihirudin antibodies, in that patients with fatal reactions usually had received lepirudin over the previous few weeks or months.

Two prospective cohort studies^{126,127} (with historical controls) of lepirudin for the treatment of patients with HIT-associated thrombosis and given according to a pre-specified dosing schedule led to its approval for this indication both in the European Union (March 1997) and in the United States (March 1998). The first study¹²⁶ showed a significantly reduced frequency of a composite end point

of mortality, limb amputation, and new thromboembolic complications compared with outcomes in controls (cumulative frequency, 10% vs 23% at day 7 follow-up, and 25% vs 52% at day 35 follow-up, respectively; $P = .014$). The second study¹²⁷ found a trend in favor of lepirudin (cumulative frequency of composite end point, 31% vs 52%; $P = .12$). A meta-analysis²⁹ of these two studies found that a subtherapeutic PTT ratio (<1.5) was associated with an increased risk for thrombosis, whereas a therapeutic PTT ratio above the therapeutic range (>2.5) was associated with increased bleeding and no further reduction in anti-thrombotic efficacy. However, even for patients within the target therapeutic range, bleeding was increased significantly compared with outcomes in historical controls (relative risk = 3.21 [95% confidence interval, 1.7 to 6.0]; $P < .001$). Thus, more recent recommendations consist of avoiding the initial bolus in most situations and beginning with a lower maintenance rate (0.10 mg/kg/hr), with PTT monitoring provided at 4-hour intervals until stable PTT levels within the therapeutic range are documented (Table 25-8).^{63,76,122,128,129}

A third prospective study (HAT-3 [Heparin-Associated Thrombocytopenia])¹²⁸ found that the frequency of the composite end point (categorical analysis) assessed on the basis of diagnosis of HIT among 205 study patients was 29.8%; the individual end point of new thrombosis was 13.7%. If events that occurred only after initiation of study drug are included, corresponding rates are 21.0 and 5.4%, respectively.

When findings from all three prospective studies (HAT-1, HAT-2, and HAT-3) are combined¹²⁸ and analysis is performed from the start of treatment, highly statistically significant ($P < .0001$) differences between lepirudin-treated patients and historical controls are seen for new thromboses (7.4% vs 25.0%, respectively) and for the composite end point (20.3% vs 43.3%, respectively). A trend toward reduced mortality (11.7 vs 17.5%; $P = .095$) is also seen. However, limb amputation rates were similar between lepirudin-treated patients and controls (5.5 vs 6.7%; $P = .618$). Major bleeding rates, ranging from 4% to 33% (for serum creatinine levels <50 μmol per liter and >90 μmol per liter), varied greatly in keeping with creatinine levels. Overall, 17.6% of lepirudin-treated patients—about 1 in 6—experienced a major bleeding event. The authors noted that because serum creatinine levels do not adequately reflect impaired renal function in the elderly and in critically ill patients, and because the overall mean maintenance dose

of lepirudin in the HAT-3 study was only 0.11 mg/kg/hr, an initial maintenance dose of 0.10 mg/kg/hr is appropriate in most situations with normal renal function.¹²⁸

Results of a postmarketing study¹³⁰ of the use of lepirudin for the treatment of patients with HIT-associated thrombosis ($n = 496$ patients) revealed rates of new thrombosis (5.2%), death (10.9%), limb amputation (5.8%), and major bleeding (6.5%) that were similar to or lower than those reported in the three HAT trials. The mean maintenance dose (0.12 mg/kg/hr) also supports the use of a lower initial maintenance dose of up to 0.10 mg/kg/hr.

Table 25-9 summarizes the outcomes of lepirudin^{29,128,130} and argatroban^{131,132} treatment for HIT-associated thrombosis in prospective cohort studies (historical controls).

Argatroban

Argatroban (Novastan in some countries; marketed as Argatroban in the United States [GlaxoSmithKline, Research Triangle Park, NC, USA]) is a small-molecule DTI (527 Da; K_i for thrombin, 40 nmol per liter) that was associated with a lower thrombotic event rate in two prospective cohort treatment studies^{131–133} that used a historical control group. Patients received argatroban at an initial dose of 2 $\mu\text{g/kg/min}$ (no initial bolus) for an average of 6 days. The half-life of argatroban is relatively short (40 to 50 minutes).¹³⁴ Argatroban is primarily excreted into the hepatobiliary system; thus, the dose should be reduced by 75% in patients with impaired liver function. Table 25-10 provides an argatroban dosing schedule for the treatment or prevention of thrombosis in HIT.^{134–139} As with lepirudin, postapproval experience indicates that lower initial dosing (e.g., 0.5–1 $\mu\text{g/kg/min}$) may be appropriate in some situations (e.g., critically ill patients,^{136,137} those who are renally impaired^{138,139}). No antidote for argatroban exists.

On June 30, 2000, argatroban was approved by the U.S. FDA for the treatment of patients with HIT-associated thrombosis; it was launched for use in the United States in mid-November of the year 2000. Because clinical studies included patients with isolated HIT, argatroban also received this second indication from the FDA (prevention of HIT-associated thrombosis). Identical (therapeutic) doses are recommended for patients with isolated HIT and for those with HIT-associated thrombosis. Recently, argatroban was approved for use in anticoagulation during percutaneous coronary intervention (PCI) in patients in whom heparin

Table 25-8 Dosing Schedule for Lepirudin (Recombinant Hirudin)

For Rapid Intravenous Therapeutic Dose Anticoagulation:

Loading dose: ± 0.4 mg per kilogram IV bolus*

Maintenance: 0.10 mg/kg/hr IV,[†] with adjustments to maintain PTT at 1.5 to 2.5 times the mean of the normal laboratory range

*Avoid bolus except in situations of life- or limb-threatening ischemia in which immediate anticoagulation is desired.

[†]Although the U.S. Food and Drug Administration (FDA)-approved initial dosing is 0.15 mg/kg/hr, it is recommended^{63,76,122,128,129} that the initial maintenance level be reduced to 0.10 mg/kg/hr (and even lower with documented renal insufficiency[‡]), and that monitoring be provided at 4-hour intervals until stable PTT values are documented (then once daily).

[‡]Reduce initial lepirudin infusion rate in patients with renal insufficiency, as follows (subsequent dose adjustments by PTT):¹²⁰ (1) normal renal function (serum creatinine [sCr], <1.0 mg per deciliter [<90 μmol per liter]): 0.10 mg/kg/hr; (2) mild renal dysfunction (sCr, 1.0–1.6 mg per deciliter [90–140 μmol per liter]): 0.05 mg/kg/hr; (3) moderate renal dysfunction (sCr, 1.7–4.5 mg per deciliter [140–400 μmol per liter]): 0.01 mg/kg/hr; (4) severe renal dysfunction (sCr, >4.5 mg per deciliter [>400 μmol per liter]): 0.005 mg/kg/hr or intermittent boluses of 0.005 mg/kg.

Table 25-9 Treatment Outcomes of HIT-Associated Thrombosis: Comparison of Two DTIs

Anticoagulant	Dosing (Duration of DTI Treatment, Mean Days)	N*	Study Design (Control Group)	% New Thrombosis (Controls)	% Limb Amputation (Controls)	% Composite End Point [†] (Controls)	% Major Bleeds (Controls)	Comment
Lepirudin ²⁹	Bolus, 0.4 mg per kilogram; 0.15 mg/kg/hr [‡] (13.3)	113	Prospective (historical controls)	10.1% (27.2%) [§] RRR = 63%	6.5% (10.4%) RRR = 38%	21.3% (47.8%) [§] RRR = 55%	18.8% (7.1%) [§]	Meta-analysis of two prospective (historical control) studies (HAT-1 ¹²⁶ , HAT-2 ¹²⁷); all patients tested positive for HIT-Abs
Lepirudin ¹²⁸	See above (14.0)	98	Prospective	5.1%	6.1%	18.3%	20.4%	Extension study (HAT-3) performed awaiting regulatory approval; all patients tested positive for HIT-Abs
Lepirudin ¹³⁰	See above (12.1)	496	Postmarketing study	5.2%	5.8%	21.9% [¶]	5.4%	77% of patients tested positive for HIT-Abs; thrombotic death rate = 1.8%
Argatroban ¹³¹	2 μ g/kg/min ^{¶¶} (no bolus) (5.9)	144	Prospective (historical controls)	19.4% (34.8%) [§] RRR = 44%	11.8% (10.9%) ^{**} RRR = -8%	43.8% ^{††} (56.5%) RRR = 22%	11.1% (2.2%)	Positive testing for HIT-Abs not required for study entry (65% of patients shown to have HIT-Abs)
Argatroban ¹³²	See above (7.1 days)	229	Prospective (historical controls)	13.1% [§] RRR = 62%	14.8% RRR = -36%	41.5% ^{††} RRR = 27%	6.1%	Positive testing for HIT-Abs not required for study entry (number testing positive not reported)

End points shown represent time-to-event analysis (day 35) for meta-analysis of HAT-1 and HAT-2 lepirudin studies, categorical analysis for other lepirudin studies shown, and categorical analysis (day 37) for argatroban.

*The denominator, N, indicates the number of patients treated with DTI; controls, N = 75 (lepirudin) and N = 46 (argatroban).

[†]Composite end point: all-cause mortality, all-cause limb amputation, and/or new thrombosis (each patient counted only once), unless otherwise indicated.

[‡]PTT (partial thromboplastin time) adjusted to 1.5 to 2.5 times patient's baseline PTT (or mean laboratory normal range if the patient's baseline PTT is unavailable); indicated dosing given to 105 of 113 patients (remaining 8 patients received 0.2 mg per kilogram IV bolus in conjunction with thrombolytic therapy).

[§]Statistically significant difference ($P < .05$).

[¶]Composite end point likely overestimated, as some patients may have had more than one end point.

^{¶¶}PTT adjusted to 1.5 to 3.0 times patient's baseline PTT.

^{**}One additional patient each is included in the DTI and control groups (compared with original publication¹³¹), as these two patients died and sustained limb amputation (personal communication, Dr. M. Hursting).

^{††}P values not significant by categorical analysis, but $P = .014$ (hazard ratio = 0.57) and $P = .008$ (hazard ratio = 0.56) for Arg-911 and Arg-915 studies, respectively, with the use of time-to-event analysis. DTI, direct thrombin inhibitor; HIT-Abs, heparin-induced thrombocytopenia antibodies; RRR, relative risk reduction (compared with historical controls); HAT, Heparin-Associated Thrombocytopenia trial.

Table 25-10 Dosing Schedule for Argatroban**For Rapid Intravenous Therapeutic Dose Anticoagulation:**

Initial dose: 2 µg/kg/min IV*†

Maintenance: Above initial dose adjusted to maintain PTT 1.5 to 3.0 times the initial baseline value (not to exceed 100 sec)

For Percutaneous Coronary Intervention (PCI):

Initial dose: 350 µg per kilogram (IV over 3–5 min)

Maintenance: 25 µg/kg/min (adjusted to maintain activated clotting time [ACT] between 300–450 sec; additional bolus doses of 150 µg per kilogram may be given as needed)

*Reduce starting dose to 0.5 µg/kg/min in a patient with hepatic dysfunction.

†Literature^{136–139} supports starting at a lower initial dose (e.g., 0.5–1 µg/kg/min) in critically ill or renally compromised patients. IV, intravenous; PTT, partial thromboplastin time.

is contraindicated because of acute HIT or a history of HIT.¹³⁵

The primary adverse effect is bleeding. Argatroban is not immunogenic,¹⁴⁰ and (in contrast to lepirudin) anaphylaxis has not been reported with its use.

Monitoring is provided with use of the PTT, targeted at 1.5 to 3.0 times the patient's baseline value (maximum, 100 sec). Argatroban prolongs the INR to a greater extent than the other DTIs¹²¹ (Fig. 25-7)—an issue that must be considered when warfarin treatment is overlapped (see “Direct Thrombin Inhibitor–Warfarin Overlap”).

In prospective trials of DTI therapy for HIT-associated thrombosis, duration of argatroban therapy was only about half that of lepirudin treatment (6 to 7 days vs 13 to 14 days, respectively).¹⁴¹ Given that a median of 4 days is needed for a platelet count of 150,000/µL to be reached (at which point initiation of warfarin therapy can be considered⁶³), and that at least 5 days of DTI–warfarin overlap is required, it seems likely that patients with confirmed HIT who are treated with argatroban usually require a longer duration of treatment than was used in the prospective trials. Indeed, most thrombi that occurred during argatroban treatment of venous thromboembolism occurred soon after this agent was stopped, suggesting that the duration of DTI therapy had been too brief.¹⁴²

Bivalirudin

Bivalirudin (Angiomax; The Medicines Company, Parsippany, NJ, USA) is a hirulog, that is, an analogue of hirudin. It is a 20 amino acid peptide (2180 Da) that is made through solid phase peptide synthesis.^{121,143,144} Bivalirudin unites a C-terminal segment of 12 amino acids derived from native hirudin (residues 53 to 64) to an active site-binding tetrapeptide sequence (D-Phe-Pro-Arg-Pro) at its N-terminus, bridged by four glycine residues. The aminoterminal segment has high affinity and specificity for binding to the active site of thrombin, and the C-terminal domain binds to the fibrin(ogen) recognition site of thrombin. One difference between bivalirudin and hirudin is that the binding of bivalirudin to the active site of thrombin is transient, whereas with lepirudin, irreversible thrombin/hirudin complexes are formed. Its affinity for human thrombin ($K_i = 2$ nmol per liter) is somewhat

greater than that of the univalent DTI, argatroban ($K_i = 40$ nmol per liter), but it is much less than that of hirudin ($K_i \sim 0.0001$ nmol per liter).¹²¹

In theory, bivalirudin has several pharmacologic advantages over other DTIs,¹⁴⁵ including a shorter half-life (25 to 30 minutes), predominant nonorgan (80% enzymic) clearance with only minor renal excretion (20%), minimal prolongation of the INR, and minimal (if any) immunogenicity. However, only anecdotal experience in the treatment of HIT has been reported,^{146,147} and appropriate dosing for HIT remains unknown. One approach is to begin with an initial infusion rate of between 0.15 and 0.25 mg/kg/hr (initial bolus of 0.1 to 0.75 mg/kg) adjusted to a PTT of 1.5 to 2.5 times baseline.¹⁴⁵

Bivalirudin was recently approved by the FDA for use in patients with, or at risk of, HIT or HIT-associated thrombosis who are undergoing PCI (see “Percutaneous Coronary Intervention”).¹⁴⁸

Direct Thrombin Inhibitor–Warfarin Overlap

Although all DTIs may prolong the INR, relative effects at therapeutic concentrations vary considerably, as follows: argatroban $\approx$ (xi)melagatran > bivalirudin > lepirudin (see Fig. 25-7).^{121,149} Interestingly, when expressed in molar terms, lepirudin exhibits the greatest INR-prolonging effect (see Fig. 25-7, inset).¹⁴⁹ However, its high affinity for thrombin and low molar dosing requirements mean that it has the least effect compared with other DTIs given in clinically relevant doses.

Careful attention to overlap of DTI and warfarin is required to avoid adverse events such as recurrent thrombosis (including microvascular thrombosis) due to vitamin K antagonism and severe protein C depletion. In the argatroban trials, approximately 10% of patients developed thrombosis during the argatroban–warfarin overlap period; it is interesting to note that several of these patients had supratherapeutic INR levels (potentially indicating protein C depletion) at the time of thrombosis.¹⁵⁰

As a general rule, warfarin should not be started until the patient has been satisfactorily anticoagulated with a parenteral anticoagulant and the platelet count has substantially recovered, usually to $\geq 150,000/\mu\text{L}$.⁶³ Because of the marked effects of argatroban in prolonging the INR, the target therapeutic range during argatroban–warfarin cotherapy is approximately 3.0 to 5.0 when a relatively sensitive thromboplastin reagent (international sensitivity index [ISI] = 0.88) is used to determine the INR, and even higher (≈ 4.0 to 6.0) when an insensitive thromboplastin reagent (ISI = 1.31 or higher) is used.^{134,151} Such high INR values do not appear to be associated with an increased risk of bleeding.¹⁵² The potential risk of warfarin-associated microvascular thrombosis is an important reason why warfarin overlap should not be commenced until substantial resolution of thrombocytopenia has been attained and any symptomatic thrombosis is noted to be clinically stable or improving.

For patients in whom HIT is not diagnosed until treatment with warfarin has commenced, it is suggested that warfarin should be antagonized by vitamin K (≥ 5 mg), preferably given by slow intravenous infusion (over a minimum of 30 minutes). One reason for this approach is that warfarin prolongs both the PT and the PTT; therefore,

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

Figure 25-7 Prolongation of prothrombin time (PT) and international normalized ratio (INR) by direct thrombin inhibitors (DTIs). Three DTIs differ in their relative ability to prolong PT and INR with a given increase in partial thromboplastin time (PTT), as follows: argatroban > bivalirudin > lepirudin.¹²¹ However, as is shown in the inset, when INR is plotted against molarity, it can be seen that the relative effects of the DTIs differ, as follows: lepirudin > bivalirudin > argatroban.¹⁴⁹ The explanation for this apparent paradox is that relative therapeutic concentrations of DTIs—when expressed in molar concentrations (μmol per liter)—differ markedly: The approximate therapeutic concentration of lepirudin (e.g., when estimated by the concentration that doubles the PTT) is about $0.0625 \mu\text{mol}$ per liter, whereas the corresponding concentration is about $0.25 \mu\text{mol}$ per liter for bivalirudin, and $1.0 \mu\text{mol}$ per liter for argatroban. This hierarchy presumably reflects the different affinities of the DTIs for thrombin, which can be ranked as follows: lepirudin ($K_i = 0.0001 \text{ nmol}$ per liter) > bivalirudin ($K_i = 2 \text{ nmol}$ per liter) > argatroban ($K_i = 40 \text{ nmol}$ per liter). Data shown in the figure are based on addition of DTIs to pooled normal human plasma; PT (INR) values were obtained with a sensitive thromboplastin reagent (international sensitivity index [ISI] = 1.0). If an insensitive thromboplastin had been used, the relatively greater prolongation of the INR by argatroban would have been even more marked. (From Warkentin TE: Bivalent direct thrombin inhibitors: Hirudin and bivalirudin. *Best Pract Res Clin Haematol* 17:105–125, 2004¹²¹; and Warkentin TE, Greinacher A, Craven S, et al: Differences in the clinically effective molar concentrations of four direct thrombin inhibitors explain their variable prothrombin time prolongation. *Thromb Haemost* 94:958–964, 2005, with permission.¹⁴⁹)

suboptimal anticoagulation with lepirudin or argatroban may result when PTT-based monitoring is provided.⁷⁸ Another reason why this approach should be used is that it reduces the risk of warfarin-induced microvascular thrombosis resulting from severe depletion in protein C activity.^{10,71,72}

Danaparoid

Danaparoid sodium (Orgaran; Organon, Oss, The Netherlands) is a mixture of anticoagulant glycosaminoglycans, predominantly heparan sulfate (84%), dermatan sulfate (12%), and chondroitin sulfate (4%).^{153,154} Heparan sulfate provides most of the anti-factor Xa activity of danaparoid, which is mediated via binding to antithrombin III. Dermatan sulfate, by binding to heparin cofactor II, provides some antithrombin III (anti-IIa) activity. However, the anti-Xa/anti-IIa ratio of danaparoid is at least 22, which is much higher even than that of LMWH (usual ratio, approximately 2 to 4). Danaparoid exhibits minimal nonspecific binding to plasma proteins; thus, resistance to its anticoagulant effects due to elevated acute phase reactants is usually not seen.

Danaparoid is well absorbed after subcutaneous administration, with peak levels reached 4 to 5 hours post injection. The near-100% bioavailability makes it easy for clinicians to determine the appropriate subcutaneous dosage for a stably anticoagulated patient who is receiving intravenous danaparoid. For example, 190 U per hour by

intravenous infusion is approximately equal to 2250 U given twice daily by subcutaneous injection (both provide about 4500 U per 24 hours). Despite the long half-life of its anti-factor Xa activity (≈ 25 hours), the drug should be given intravenously or (at least) twice daily via the subcutaneous route, as the half-life for antithrombin III activity is about 2 to 4 hours. Danaparoid is renally metabolized, and the dose should be reduced somewhat (by about one third) for patients with renal failure. No antidote is available for danaparoid.

Danaparoid prolongs neither the PTT nor the PT, which facilitates assessment of overlapping warfarin therapy. Monitoring of the anticoagulant effects of danaparoid, when needed, is done by measuring plasma anti-factor Xa activity through chromogenic assay. This is similar to monitoring of LMWH, except that the standard calibration curve must be constructed with the use of danaparoid (if an LMWH standard curve is used, danaparoid concentrations will be overestimated). Anti-factor Xa monitoring for danaparoid is not widely available, but because danaparoid produces predictable anticoagulant effects, monitoring is often not necessary when a standard dose is given (Table 25-11). Patients in whom monitoring should be considered include those with substantial renal impairment, unusually low or high body weight, or life- or limb-threatening thrombosis; those in whom unexpected bleeding occurs should also be monitored. The usual target therapeutic range for danaparoid is 0.5 to 0.8 anti-Xa U/ μL , although a higher level (about 1 U/ μL) in a patient with severe thrombosis is appropriate.

Table 25-11 Dosing Schedule for Danaparoid

For Rapid Intravenous Therapeutic Dose Anticoagulation:
 Loading dose: 2250 U IV bolus,* followed by 400 U per hour for 4 hours, and 300 U per hour for 4 hours; then, maintenance: 150–200 U per hour, aiming for anti-factor Xa level of 0.5–0.8 U/mL.

*Adjust initial intravenous bolus for body weight: <60 kg, 1500 U; 60–75 kg, 2250 U; 75–90 kg, 3000 U; >90 kg, 3750 U.

In contrast to the DTIs, danaparoid has no effect on the INR and the PTT; thus, monitoring of overlapping warfarin therapy remains unchanged. Because the half-life of danaparoid is relatively long, this drug usually can be stopped after 4 or 5 days of warfarin treatment, once the INR has reached the lower therapeutic range. For all these situations, it is prudent to start with expected maintenance doses of warfarin, rather than an initial loading dose.

Theoretically, the recommendation to give vitamin K to a patient who is receiving warfarin when HIT is diagnosed might not be applicable if treatment with danaparoid is planned, given the lack of interference by danaparoid with the INR. Figure 25-6B shows an example of a situation in which warfarin therapy was continued in a patient with HIT-associated thrombosis, although bridge therapy with therapeutic doses of danaparoid was provided until platelet count recovery occurred.

A randomized open-label clinical trial¹⁵⁵ found a higher frequency of complete clinical recovery from thrombosis (the primary end point) in patients treated with danaparoid and warfarin, compared with dextran and warfarin (56% vs 14%; $P = .02$). For the secondary end point of complete or partial clinical recovery, corresponding results were 86% versus 53%. Venous thrombotic events were almost three times more likely to show complete clinical recovery than were arterial thrombotic events.

A retrospective historical cohort study that compared outcomes in patients treated with danaparoid (with or without coumarin) versus outcomes in controls (anecdotal [defibrinogenating snake venom], coumarin, or both) reported reduction in the day 35 efficacy end point (composite of thrombosis, thrombotic death, or limb amputation) in danaparoid-treated patients compared with controls (12 of 62 = 19.4% vs 24 of 56 = 42.9%; $P = .0088$).¹⁵⁶ Major bleeding occurred significantly less often in danaparoid-treated patients than in controls (11.3 vs 28.6%; $P = .0211$). Retrospective uncontrolled case series also support the efficacy of danaparoid as a treatment for patients with HIT-associated thrombosis.^{157–159}

Danaparoid has been approved for DVT prophylaxis after hip replacement surgery (750 U two or three times daily by subcutaneous injection). This low-dose regimen would be appropriate for a patient with previous HIT who requires postoperative thromboprophylaxis. However, for patients with acute HIT, with or without thrombosis, a therapeutic regimen should be given (see Table 25-11).^{160,161} In April 2002, danaparoid was withdrawn from the U.S. market, although it remains available (and widely used) in Canada and Europe.¹⁵⁴

In vitro cross-reactivity against danaparoid can be detected in some HIT sera.¹¹² However, this cross-reactivity is generally weak and does not predict adverse clinical outcomes. In the author's opinion, treatment should not be delayed so that in vitro cross-reactivity studies can be conducted, nor is detectable in vitro cross-reactivity a contraindication to the use of danaparoid.

Fondaparinux

Fondaparinux is a sulfated pentasaccharide anticoagulant that catalyzes antithrombin III-mediated inhibition of factor Xa (but not thrombin). It has been approved in the United States for post-orthopaedic and abdominal surgery thromboprophylaxis (2.5 mg once daily, given subcutaneously) and for treatment of patients with DVT and pulmonary embolism (7.5 mg once daily, given subcutaneously [5.0 and 10.0 mg once daily subcutaneously for body weight <50 kg and >100 kg, respectively]).^{162–164} Although use of fondaparinux in post-orthopaedic surgery thromboprophylaxis has been reported to be associated with formation of anti-PF4/heparin antibodies^{25,165} at a frequency similar to that of LMWH,²⁵ the absence of cross-reactivity of these antibodies and of antibodies within HIT serum¹⁶⁶ for PF4/fondaparinux suggests that fondaparinux likely will have a lower (perhaps negligible) frequency of HIT, compared with LMWH (see section on the prevention of HIT).²⁷ To date, only one case of fondaparinux-associated HIT has been reported.^{166a} Fondaparinux is an attractive anticoagulant option for patients with a history of HIT who require prophylactic or therapeutic doses of anticoagulation.

Some anecdotal experience with fondaparinux has been reported for the treatment of patients with acute HIT (with or without thrombosis).^{167–169} Given the negligible in vitro cross-reactivity of HIT antibodies for PF4/fondaparinux complexes, fondaparinux may be considered a promising treatment option for acute HIT. However, caveats include uncertainty as to optimal dosing and minimal experience with this use thus far.

Choice of Parenteral Anticoagulant

The choice of parenteral anticoagulant depends on several factors, including patient renal and hepatic function, anticipated need to reverse anticoagulation quickly, monitoring methods used, drug availability/cost, and physicians' experience with a given agent.

Adjunctive Treatments

Adjunctive treatments can be useful in select patients with HIT.⁷⁶ Surgical thromboembolectomy can be limb saving in patients with acute occlusion of large limb arteries by platelet-rich thromboemboli. Lepirudin, argatroban, or danaparoid can be used for intraoperative anticoagulation during vascular surgery.¹⁷⁰ Thrombolytic therapy with streptokinase or tissue plasminogen activator may be tried in highly select patients, but issues such as the optimal choice and dose of concomitant parenteral anticoagulant remain unresolved (thrombolytic agents increase thrombin generation because thrombin bound to fibrin degradation products is relatively protected from inhibition by antithrombin III¹⁷¹). High-dose intravenous γ globulin

can inhibit HIT antibody-mediated platelet activation¹⁷² and may therefore be a useful treatment adjunct in patients with severe thrombocytopenia, DIC, or microvascular ischemia.¹⁷³ Antiplatelet agents, such as aspirin, can be tried in patients at high risk for arterial thrombosis, but issues such as bleeding when combined with antithrombotic drugs have not yet been resolved. (Notably, HIT may occur even in patients given combined antiplatelet therapy consisting of aspirin and clopidogrel.¹⁷⁴)

CAVEATS IN THE MANAGEMENT OF HEPARIN-INDUCED THROMBOCYTOPENIA

Physicians must be vigilant to ensure that heparin is not inadvertently given to patients with acute HIT. Because heparin is often given routinely (e.g., via “flushes” to indwelling catheters, or as heparin bonded to pulmonary artery catheters), a simple order to “discontinue heparin” may not necessarily result in removal of all heparin sources. Also, it is now recognized that certain treatments that might have intuitive appeal can actually worsen treatment outcomes in HIT:

- Warfarin-induced phlegmasia, venous limb gangrene, and skin necrosis syndromes. As discussed earlier, vitamin K antagonists can cause precipitous severe deficiency of protein C while at the same time not adequately reducing thrombin generation in acute HIT. Thus, during acute HIT, warfarin should be considered **contraindicated**. After substantial recovery of thrombocytopenia (preferably, $>150,000/\mu\text{L}$), and an alternative anticoagulant (e.g., lepirudin, argatroban, danaparoid, bivalirudin, fondaparinux) is being given, warfarin may be commenced at low maintenance doses (maximum initial dose, 5 mg), with at least 5 days of overlapping anticoagulation occurring before the parenteral anticoagulant is stopped. Sometimes, a patient is recognized as having HIT after several days of warfarin have already been given. In these situations, it is suggested that the coumarin effect should be reversed with vitamin K.⁶³ This is appropriate for two reasons: first, it reduces the risk of warfarin-induced venous limb gangrene (which can evolve quickly) because DTIs are usually monitored with the use of PTT, and second, warfarin-induced PTT prolongation may lead to underdosing of the DTI in a patient who is receiving warfarin.
- LMWH is less likely than UFH to cause HIT antibody formation^{7,8,42,51–53}; unfortunately, this does not mean that it is an acceptable treatment for HIT. Through the use of sensitive activation assays, it has been determined that HIT antibodies are just as capable of activating platelets in the presence of LMWH as with UFH,^{7,175} and clinical experience suggests that the risk for new, progressive, or recurrent thrombosis during treatment for HIT with LMWH approaches 50%.¹⁷⁶ Thus, LMWH should be considered **contraindicated** as treatment for HIT.⁶³
- Platelet transfusions are relatively contraindicated for prophylaxis of bleeding in patients with acute

HIT.^{63,177} This is so because petechiae and other signs of bleeding are usually not clinical features of HIT, despite even severe thrombocytopenia.⁵⁰ Further, platelet transfusions have been associated with thrombotic events in anecdotal reports.^{178,179} However, if bleeding caused by anatomic or other factors complicates HIT, therapeutic platelet transfusions in this clinical context may be appropriate.

- Vena caval filters are not recommended by the author because they likely predispose to inferior vena cava or lower limb thrombosis,^{76,180,181} and their deployment and use may encourage discontinuation or avoidance of further anticoagulation.
- Fasciotomies are sometimes performed in patients with ischemic limbs associated with HIT. Physicians should consider whether limb ischemia may be due to evolving microvascular thrombosis due to warfarin therapy and/or DIC, which might be better treated by intravenous vitamin K and aggressive anticoagulation.^{170,182}

TREATMENT OF PATIENTS WITH ISOLATED HEPARIN-INDUCED THROMBOCYTOPENIA

Stopping heparin is an important step in managing proved or suspected HIT. However, several studies^{66,183–185} indicate that cessation of heparin alone is ineffective therapy for patients with HIT, including those in whom HIT was diagnosed on the basis of thrombocytopenia alone (isolated HIT). A retrospective cohort study⁶⁶ estimated the risk for thrombosis as 10% at follow-up of 2 days, 40% at 7 days, and about 50% at 30 days. Other investigators reported¹⁸⁴ a 38% thrombotic event rate despite stopping of heparin; it is surprising that the frequency of thrombosis was not lower in patients in whom the heparin had been stopped soon (<48 hours) after onset of HIT, compared with patients in whom the diagnosis was made later (45% vs 34%; $P = .26$). A recent study by Zwicker and colleagues¹⁸⁵ found a frequency of 38% among patients with suspected isolated HIT in whom the diagnosis was supported by an EIA with an optical density greater than 1.0 U.

Tardy and colleagues¹⁸⁶ systematically performed compression ultrasonography or contrast venography in patients with isolated HIT. They thereby identified subclinical DVT in 8 of 16 consecutive patients with isolated HIT. These eight patients were treated with therapeutic doses of danaparoid, and the remaining eight patients without thrombosis received danaparoid in prophylactic doses. One death from fatal thrombosis was observed using this treatment approach. The high frequency of subclinical DVT at first recognition of HIT may explain the high risk for development of clinically evident venous thrombosis (40% to 50%) when patients are treated with heparin cessation alone.

Given this unfavorable natural history of isolated HIT, the Consensus Conference of the ACCP recommends that physicians consider giving a rapidly acting alternative anticoagulant for strongly suspected (or serologically confirmed) isolated HIT⁶³ (see Table 25-7). The author

recommends that *therapeutic* doses of an alternative nonheparin agent (e.g., lepirudin, argatroban, danaparoid) should be given in this setting because standard *prophylactic* doses may not suffice in a clinical setting such as acute HIT.¹⁶¹ (Note that lepirudin commenced at an initial infusion rate of 0.05 to 0.10 mg/kg/hr and without an initial bolus loading dose is considered to be a therapeutic dosing regimen because the intent is to attain a “therapeutic” PTT of 1.5 to 2.5 times baseline.¹³⁰) However, use of prophylactic doses may be a reasonable approach if subclinical DVT has been excluded by imaging studies, or if the patient is judged to be at high risk for bleeding, or if confidence in the diagnosis of HIT is not high.⁶³ Nonheparin anticoagulant regimens that provide “prophylactic dose” anticoagulation include lepirudin 15 mg given subcutaneously twice daily (assumes normal renal function), fondaparinux 2.5 mg given subcutaneously daily, or danaparoid 750 U given subcutaneously twice or three times daily.⁶³

Reported outcomes (end point of new thrombosis) for patients with isolated HIT have ranged from 4.4% (lepirudin)¹⁸⁷ to about 7%^{132–134} (argatroban), which were substantially lower rates than those seen in controls ($\approx$ 15% and 24%, respectively). Major bleeding rates were approximately 14% (lepirudin) and 4% (argatroban).

REEXPOSURE TO HEPARIN AFTER PREVIOUS HEPARIN-INDUCED THROMBOCYTOPENIA

Subsequent use of heparin is generally considered contraindicated in patients with a history of proven or suspected HIT. However, evidence suggests that it may be safe to use heparin again—at least for a brief period—in patients who have recovered from an episode of HIT.^{41,76,188–190}

This is so because HIT antibodies are transient and are usually not detectable a few weeks or months after HIT has been resolved.⁴¹ Moreover, HIT antibodies may not recur quickly (or at all) upon reexposure to heparin, requiring at least 5 days before clinically significant levels are attained.⁴¹

From a practical point of view, however, such deliberate reuse of heparin in patients with previous HIT is performed only in exceptional circumstances (e.g., patients who require cardiac surgery),^{41,188–190} for which ideal alternative anticoagulants do not exist. Even in this situation, heparin would be given only for cardiopulmonary bypass itself. Use of heparin should be avoided in the preoperative and postoperative periods; alternative agents should be given for anticoagulation during heart catheterization or for postoperative anticoagulation.

SPECIALIZED CLINICAL SITUATIONS

Cardiac Surgery

The management of acute HIT in patients requiring cardiac surgery poses special problems. Table 25-12 lists various anticoagulant options when routine UFH use for cardiac surgery is contraindicated because of acute HIT or because of recent HIT in which platelet-activating anti-PF4/heparin antibodies remain detectable (subacute HIT).^{145,188–191} In general, it is preferable to defer surgery whenever possible pending resolution of HIT, given the risk of coronary revascularization or valve replacement during an acute hypercoagulable state. Moreover, the oftentimes rapid disappearance of HIT antibodies within a few weeks or months after an episode of HIT^{41,188} makes possible the subsequent use of heparin. For patients in whom

Table 25-12 Recommendations of the Seventh Conference of the American College of Chest Physicians on Antithrombotic and Thrombolytic Therapy for Cardiac Patients with HIT⁶³

Patients with Previous HIT Undergoing Cardiac or Vascular Surgery

- For patients with a history of HIT who are HIT antibody negative and require cardiac surgery, we recommend the use of UFH over a nonheparin anticoagulant (grade 1C).
Remark: Preoperative and postoperative anticoagulation, if indicated, should be administered with a nonheparin anticoagulant.

Patients with Acute or Subacute HIT Undergoing Cardiac Surgery

- For patients with acute HIT (thrombocytopenic, HIT antibody positive) who require cardiac surgery, we recommend one of the following alternative anticoagulant approaches (in descending order of preference): delaying surgery (if possible) until HIT antibodies are negative (see above) (grade 1C); using bivalirudin for intraoperative anticoagulation during cardiopulmonary bypass (if ecarin clotting time [ECT] available*) (grade 1C) or during off-pump cardiac surgery (grade 1C+); using lepirudin for intraoperative anticoagulation (if ECT available and patient has normal renal function) (grade 1C); using UFH plus the antiplatelet agent, epoprostenol (if ECT monitoring not available or renal insufficiency precludes lepirudin use) (grade 2C); using UFH plus the antiplatelet agent, tirofiban (grade 2C); or using danaparoid for intraoperative anticoagulation (if anti-factor Xa levels are available) (grade 2C).
- For patients with subacute HIT (platelet count recovery, but continuing HIT antibody positive), we recommend delaying surgery (if possible) until HIT antibodies are negative, then using heparin (see above) (grade 1C). Alternatively, we suggest the use of a nonheparin anticoagulation (see above) (grade 2C).

Percutaneous Coronary Interventions (PCIs)

- For patients with acute or previous HIT who require cardiac catheterization or PCI, we recommend use of an alternative anticoagulant, such as argatroban (grade 1C), bivalirudin (grade 1C), lepirudin (grade 1C), or danaparoid (grade 2C), over the use of heparin.

*A recent protocol for bivalirudin anticoagulation during cardiopulmonary bypass employs the activating clotting time (ACT), rather than the ECT, for intraoperative anticoagulant monitoring.^{145,192}
HIT, heparin-induced thrombocytopenia; UFH, unfractionated heparin.

UFH is contraindicated, bivalirudin is emerging as a major nonheparin anticoagulant option¹⁴⁵ on the basis of its pharmacology (e.g., short half-life, predominant enzymic metabolism), the potential for monitoring with the use of activated clotting time (ACT), growing experience in patients with HIT, and satisfactory outcomes in a randomized trial versus UFH for surgery requiring cardiopulmonary bypass (non-HIT patients).¹⁹² However, the cardiac surgeon, anesthesiologist, and perfusionist must be aware of important technical issues, such as the need to avoid stagnant blood (because ongoing proteolysis of bivalirudin may lead to loss of its anticoagulant effect).¹⁴⁵

Percutaneous Coronary Intervention

Both argatroban and bivalirudin have been approved in the United States for use in PCI when heparin is contraindicated because of acute HIT or a history of HIT. The recommended dose of bivalirudin is an initial intravenous bolus of 0.75 mg per kilogram, followed by a continuous infusion of 1.75 mg/kg/hr for the duration of the procedure.¹⁴⁵ Recommended argatroban dosing is shown in Table 25-9.

With both DTIs, procedural success in at least 95% of patients has been observed.^{135,148}

Hemodialysis

Protocols have been published for the use of argatroban,^{193–195} lepirudin,^{193,194} or danaparoid^{154,193,194} for anticoagulation during hemodialysis (HD) or hemofiltration (HF) in patients for whom heparin is contraindicated because of HIT. HD can also be performed in some patients with the use of saline. Anticoagulation of the ports after HD can be achieved with a nonheparin anticoagulant (e.g., danaparoid 750 U in 500 mL saline, with 5 to 10 mL of this solution inserted into each port; or hirudin 5 mg per milliliter per port, with just enough solution injected into each port to fill the lumen only [this must be aspirated prior to the next HD session]).¹⁹³

Argatroban is an attractive nonheparin anticoagulant that may be used in HD or HF because it undergoes hepatic rather than renal excretion. No consensus has been reached as to the ideal dosing regimen, however. For HD, O'Shea and colleagues¹⁹³ reported the use of an initial pre-HD argatroban bolus of 100 µg per kilogram, followed

Figure 25-8 Dissociation of immunogenicity and cross-reactivity of sulfated polysaccharides for anti-platelet factor 4 (PF4)/polyanion antibodies. Of the three sulfated polysaccharide anticoagulants listed, unfractionated heparin (UFH) is most immunogenic (largest iceberg), whereas low molecular weight heparin (LMWH) and fondaparinux exhibit similar immunogenicity. However, in contrast to UFH and LMWH, which can form well with PF4 the antigens recognized by anti-PF4/heparin antibodies, fondaparinux forms these antigens poorly with PF4. It is uncertain whether the fondaparinux iceberg protrudes above the waterline (i.e., whether it might cause a syndrome resembling heparin-induced thrombocytopenia [HIT] or not). Note that the symbols indicate that cross-reactivity profile of LMWH differs in vivo (++) and in vitro (++++). EIA, enzyme immunoassay; HIT-T, HIT-associated thrombosis; SRA, serotonin release assay. (Reprinted, with permission, from Warkentin TE: HIT: Lessons learned. *Pathophysiol Haemost Thromb* 35:50–57, 2006.²⁷)

by a continuous infusion of 100 to 200 µg/kg/hr (1.7 to 3.3 µg/kg/min), to maintain the PTT at 1.5 to 3.0 times the normal mean PTT. In contrast, Murray and coworkers¹⁹⁵ reported the use of a somewhat higher initial argatroban bolus (250 µg per kilogram) but a similar infusion rate (2 µg/kg/min); observed PTT values were approximately 2 times those at baseline when this regimen was used. For HF, argatroban can be commenced at 0.5 to 1.0 µg/kg/min, with subsequent dose adjustments made by PTT (target, 1.5 to 2.0 times the normal mean PTT).^{193,194}

Lepirudin anticoagulation for intermittent HD (every second day) can be achieved by a pre-HD bolus ranging from 0.08 to 0.15 mg/kg, with a target PTT of about 2.0 to 2.5 times the normal mean PTT (see Table 25-8).^{193,194} For HF, an initially low-dose infusion rate (0.005 to 0.01 mg/kg/hr) with PTT monitoring (target, 1.5 to 2.0 times the normal mean PTT) is recommended, but careful attention to the PTT is warranted because gradual lepirudin accumulation may occur over time.^{193,194}

Danaparoid anticoagulation for intermittent HD (every second day) can be achieved by administration of 3750 anti-factor Xa U before dialysis is begun.^{154,193,194} Because of the long half-life of danaparoid, by the time of the third and fourth HD sessions, smaller pre-HD boluses (e.g., 3000 and 2250 U, respectively) should be given, preferably guided by measurement of anti-factor Xa levels (target, <0.4 U per milliliter pre-HD; >0.5 U per milliliter during HD). Recommended dosing for HF includes an initial bolus of 2250 U for an average-size patient, followed by 600 U per hour for 4 hours, then 400 U per hour for 4 hours, then infusion of between 200 and 400 U per hour based on anti-factor Xa levels (target, 0.5 to 1.0 U per milliliter).

PREVENTION OF HEPARIN-INDUCED THROMBOCYTOPENIA

Compared with UFH, use of LMWH is associated with a 50% lower risk that anti-PF4/heparin antibodies will be formed,⁴⁶ but an even greater reduction (≈90%) of HIT.^{7,8,42,51–53} Whether the lower risk of HIT with LMWH, which has been established in post-orthopaedic surgery thromboprophylaxis, applies to other surgical patients is unclear. For example, intraoperative use of UFH during cardiac or vascular surgery may result in the production of HIT antibodies that can cause HIT even if a “safer” LMWH is used during the postoperative period (although one nonrandomized study⁶⁰ suggests that HIT risk is reduced by LMWH after cardiac surgery). In addition, data are conflicting as to whether risk of HIT is reduced by LMWH compared with UFH in medical patients.^{42,196–198}

An apparent dissociation between immunogenicity and cross-reactivity of sulfated polysaccharides has been noted (Fig. 25-8).²⁷ Whereas UFH and LMWH both exhibit strong cross-reactivity with HIT antibodies in vitro, UFH is much more immunogenic than LMWH. In contrast, whereas LMWH and fondaparinux exhibit similar immunogenicity, fondaparinux exhibits negligible cross-reactivity with HIT antibodies. Thus, fondaparinux might convey a very low (perhaps negligible) risk that a syndrome resembling HIT will be induced. In addition,

although the use of UFH or LMWH for venous thromboembolism after surgery may occasionally result in rapid-onset HIT (in a patient sensitized by recent perioperative use of heparin), this complication would not be expected to occur with fondaparinux.

Part IV

Therapeutic Measures

Chapter 26

Antithrombotic Agents

Charles W. Francis, MD

INTRODUCTION

Antithrombotic drugs are among the most frequently used drugs in medicine. They include potent agents that affect hemostasis and are used to prevent or treat thrombotic disease. Knowledge of their properties and skill in therapeutic application are necessary to achieve maximum benefit and limit the frequency of bleeding complications. This chapter focuses on practical issues in the use of commonly used antithrombotic drugs and describes several new agents that have been introduced into clinical practice.

ORAL ANTICOAGULANTS

Historical Perspective

The development of vitamin K antagonists as oral anticoagulants is one of the most interesting stories in medicine. It began in the 1920s with investigation of a hemorrhagic disease in cattle, the cause of which was eventually found to be moldy hay that led to hypoprothrombinemia and a bleeding disorder. Additional studies ensued, and a coumarin derivative that inhibited vitamin K was eventually purified and introduced into clinical practice in the 1940s. Early studies showed that it was effective in treating patients with thrombosis, but bleeding complications were frequent, and a high degree of biologic variability in response was acknowledged. Several laboratory tests were investigated as approaches to improving anticoagulant control and outcomes, and eventually, the prothrombin time (PT) was widely adopted. Current therapy emphasizes the regulation of anticoagulant control with the international normalized ratio (INR), a derivative of the PT that normalizes test results on the basis of variability in potency of the thromboplastin used. Clinical outcomes have also greatly improved through application of modern clinical research methods to define the optimum therapeutic range, the most effective duration of treatment, and the patient populations most likely to benefit. Anticoagulation with vitamin K antagonists remains a challenging clinical problem because of the narrow therapeutic margin and high biologic variability; this limitation is counterbalanced by the high degree of efficacy of warfarin use in most of its indications. Intense efforts are under way to develop safe and effective alternative oral anticoagulants.

Mechanism and Pharmacology

The oral anticoagulants include several coumarins that act as competitive inhibitors of vitamin K and thereby inhibit

the carboxylation reactions required for synthesis of several coagulation proteins, including factors II, VII, IX, and X.^{1,2} Proteins C and S, which are involved in the inhibitory regulation of hemostasis, are also vitamin K dependent, and their levels also decrease during oral anticoagulation. The synthesis of all these vitamin K-dependent proteins is inhibited to a similar extent, and steady state levels during long-term therapy are reduced to the same degree. The initial rate of decrease, however, varies because of differences in plasma half-lives. Therefore, factor VII with a half-life of 6 hours declines rapidly, whereas prothrombin with a half-life of 72 hours decreases slowly after treatment has been initiated.

In North America, the most commonly used coumarin is warfarin (Coumadin; Bristol-Myers Squibb, Princeton, NJ). Warfarin is nearly completely absorbed after oral administration, and treatment is administered orally, although an intravenous preparation is available for use in circumstances in which oral intake is precluded. It does not work faster, however, than oral warfarin. Drug metabolism is complicated by binding to plasma proteins, including albumin, and also by hepatic metabolism, resulting in a variable plasma half-life. A number of drugs interact with warfarin by altering protein binding or hepatic metabolism. Because warfarin is a competitive vitamin K antagonist, its biologic action is further complicated by variability in dietary vitamin K intake. Polymorphisms in the hepatic microsomal P450 enzyme responsible for metabolism also affect individual dose response.^{3,4} Together, these effects result in wide biologic variability in response to warfarin, so that close laboratory monitoring is required.

Administration and Monitoring

After therapy has begun, the onset of action is delayed as levels of vitamin K-dependent proteins decrease. Usually between 4 and 7 days of treatment is required for comparably decreased levels of vitamin K-dependent factors to be attained. The anticoagulant effect is monitored through measurement of PT, which is sensitive to decreases in vitamin K-dependent factors; this approach is further standardized by conversion to the INR. This reporting is now standard because different thromboplastins used to determine the PT vary in their sensitivity to the anticoagulant effect. Therefore, the degree of prolongation of the PT is variable with the use of different thromboplastins, but the INR is independent of the thromboplastin used. Administration of a large initial dose ("loading") results in rapid prolongation of the PT—an effect due largely to an initial rapid decrease in factor VII, which has a short half-life.

Table 26-1 Hints for the Successful Long-Term Use of Warfarin

Do not needlessly start and stop therapy (e.g., for biopsies or dental work). Low therapeutic international normalized ratios (INRs) (range, 2.0 to 2.2) will not result in excessive bleeding. Additionally, following this hint will minimize the risk of warfarin skin necrosis on reinitiation of warfarin therapy.

It is helpful to think of a patient's warfarin dose in terms of a cumulative weekly quantity, and then to make adjustments in daily doses of warfarin, which are small (i.e., only $\pm 10\%$ to 15%) in most cases. Skipping a day of therapy itself represents a 14% change in weekly dosage. Too frequently, changes are excessive, with undesirable results.

When changing doses, do not expect reliable changes in INR before 4 to 7 days. Doing so often results in misleading information and therapeutic overcompensation.

Do not be frustrated by INRs such as 1.8 or 3.3 in patients who have a desired INR range of 2.0 to 3.0, which is actually a very narrow range that is achievable only about 75% of the time under the best of circumstances.

Significant variances (e.g., INRs <1.5 or >6.0) nearly always have an explanation, such as missed or double doses, an intercurrent illness, significant changes in diet, and especially, the addition or substitution of some new drug or over-the-counter agent.

Instruct patients not to take or discontinue any medications, over-the-counter drugs, drug samples, alternative medicines, or drugs from friends or family without your knowledge.

If a new drug or therapy is added or diet is significantly changed, recheck the INR at day 4 to 5 to observe effects. This is better than relying on long lists of drug interactions or on one's memory.

The agents most commonly used to greatly increase (i.e., at least double or triple) the INR include amiodarone, metronidazole, and cimetidine. Those that greatly decrease the INR include dietary supplements (e.g., Ensure) and multivitamin pills that contain vitamin K.

In reversing the anticoagulant effects of warfarin, recall that warfarin's action occurs through its anti-vitamin K action. Accordingly, vitamin K therapy is usually the most logical, cheapest, safest, fastest, and most enduring therapy. Even INRs greater than 20 are normalized within 6 to 8 hours after slow IV infusion of vitamin K. Fresh frozen plasma is slow, expensive, and cumbersome, and it represents a major fluid challenge (6 to 8 U) in patients with very high INRs; its effects last only for the half-lives of the replaced factors (i.e., on the order of only 6 to 8 hours).

For long-term management, patients should become involved with their physicians in decision making. Use of a "warfarin diary" maintained by the patient greatly helps with recording of drugs and INRs and helps the patient realize that noticeable changes in INR may occur in association with changes in lifestyle and dietary alterations.

Warfarin clinics, which are often run by a health care provider or a physician who is dedicated to running such a clinic, greatly facilitate long-term warfarin therapy. This is accomplished, if by no other way, by INRs performed on site with notification of the patient within minutes. Accordingly, the duration of overanticoagulation or underanticoagulation intensity is enormously minimized.

Provide patients with a prescription for a small quantity of vitamin K tablets to be taken in case of an excessively elevated INR. This may help prevent a trip to the emergency department.

This is, however, not an adequate reflection of true anti-thrombotic effectiveness, which depends on a balanced reduction of all vitamin K-dependent factors. Such treatment may result in excessive factor VII reduction, which may produce bleeding, or it may cause a profound early decrease in the anticoagulant protein C, which may produce an unfavorable balance of antithrombotic and prothrombotic effects.^{5,6} Anticoagulation should be initiated with a dose close to the expected daily maintenance requirement, which is usually between 5 and 10 mg. Lower doses should be used for small, elderly, or poorly nourished patients or those with an increased bleeding risk, and higher doses should be used for patients at low risk of bleeding who are younger and larger. Effects should be monitored at least every other day during initiation of treatment and less frequently during long-term therapy, depending on the stability of anticoagulation. Self-monitoring with a portable device may lead to excellent results in select patients (see Chapter 40).

Problems with therapy include variability in the anti-coagulant response, which is frequently due to drugs that can increase or decrease the effects or to changes in the vitamin K content of the diet.⁷ Patients should be advised to report any changes in medications to their physicians and to maintain a stable diet, particularly with respect to the content of foods high in vitamin K, including green vegetables, and dietary supplements that contain vitamin K (see Chapter 33). Variability in anticoagulation may also result from changes in absorption due to gastrointestinal illness, poor compliance, excessive use of alcohol, or over-the-counter alternative medications (Table 26-1).

Indications

Warfarin is used for prophylaxis of venous and arterial thromboembolism. It is highly effective in the primary prevention of venous thromboembolism in patients at high risk, such as orthopaedic patients undergoing hip or knee replacement. Short-term postoperative administration for a period of 7 to 14 days at an INR of 2 to 3 is effective in reducing the risk of venous thrombosis (Table 26-2). Oral anticoagulation is also highly effective as secondary prophylaxis in preventing recurrence after an initial episode of deep venous thrombosis or pulmonary embolism. After initial acute treatment with heparin or low molecular

Table 26-2 Recommended INR Values During Oral Anticoagulant Therapy

Condition	Target INR (Range)
Deep venous thrombosis treatment	2.5 (2.0–3.0)
Pulmonary embolism treatment	2.5 (2.0–3.0)
Deep venous thrombosis prophylaxis	2.5 (2.0–3.0)
Atrial fibrillation	2.5 (2.0–3.0)
Cardiac valve replacement	
Tissue valves	2.5 (2.0–3.0)
Mechanical valves	3.0 (2.5–3.5)
Acute myocardial infarction	2.5 (2.0–3.0)

INR, international normalized ratio.

weight heparin (LMWH) is provided, oral anticoagulation is continued on a long-term basis at an INR of 2 to 3 for variable periods depending on the risk of recurrence in the individual patient. Oral anticoagulation also is indicated for prophylaxis of arterial thromboembolism in patients with atrial fibrillation (currently or in past) or with artificial heart valves who are at risk of systemic embolization and stroke. In patients with mechanical heart valves, anticoagulation to a higher intensity of an INR of 2.5 to 3.5 is recommended. After an acute myocardial infarction (MI) occurs, oral anticoagulation is also indicated to prevent systemic embolization or recurrent MI.

Adverse Effects

The most serious and common complication of oral anticoagulation is bleeding, and its risk is related primarily to patient characteristics, intensity of the anticoagulation, and length of therapy.^{8–10} Older age has been related to bleeding risk in several studies. The risk of bleeding is increased with surgery or significant trauma during oral anticoagulation. Similarly, a history of gastrointestinal bleeding, particularly if recent, is a major risk; renal insufficiency, hypertension, and a history of cerebrovascular disease may also be related to bleeding risk. Alcoholism and poor compliance are common causes of poor control and poor outcomes. The intensity of anticoagulation as reflected by the INR is the most important predictor of bleeding risk, which is low in the usual therapeutic range but begins to increase above INR 4.0. The cumulative risk of bleeding increases with longer duration of treatment, whereas the absolute risk appears greatest early, possibly because of unmasking of asymptomatic pathologic lesions. Overall, the total risk of bleeding with a 3-month course of anticoagulation for venous thromboembolism is between 3% and 5%, and in patients anticoagulated for prosthetic heart valves or atrial fibrillation, the yearly rate of major bleeding is also between 3% and 5%.

Warfarin skin necrosis is a rare complication of warfarin therapy that usually, but not always, occurs early in the course of anticoagulation or on reinitiation of treatment after a hiatus in therapy. Initial complaints typically consist of burning and tingling at the affected site, such as the breast, buttock, or thigh, or at another location with significant underlying adipose tissue. Painful hemorrhagic full-thickness skin infarction develops; it heals slowly and frequently requires skin grafting (see Fig. 11-22). Histopathology shows thrombosis in dermal and subdermal venules, and it is hypothesized that this is due to disproportionate rapid reduction of anticoagulant proteins C and S, predisposing to thrombosis. A recent publication pictorially demonstrates these changes well.^{10a} The reason for its occurrence at anatomic sites with extensive subcutaneous fat is unknown.

Oral anticoagulation is avoided in pregnancy because warfarin crosses the placenta, and exposure during organogenesis in the first trimester can lead to fetal embryopathy with significant cranial bone malformations.¹¹ Anticoagulation later during pregnancy increases bleeding complications. Oral anticoagulants may be considered during the second trimester, but they are generally avoided because heparin, LMWH, and fondaparinux are reasonable alternatives.

Reversal of Oral Anticoagulation

Frequently, anticoagulation is reversed because of bleeding, surgery, trauma, or, especially, overdose. For patients with excessively prolonged INRs (e.g., greater than 6) without bleeding, appropriate interventions consist of holding warfarin doses, administering low doses of vitamin K, and increasing the frequency of monitoring (Table 26-3).^{12,13} Serious bleeding or major warfarin overdose (e.g., INR >10) requires factor replacement and/or larger vitamin K doses that may need to be given intravenously. Anticoagulated patients who need invasive procedures represent a challenging management problem (Table 26-4).^{14,15} Clinical decisions should be based on the need to balance the risk of thromboembolism with that of bleeding (see Chapter 38).

The goal of warfarin treatment is to induce anticoagulation and thereby avoid thromboembolism. It is important to note that the baseline risk of thromboembolism further increases during the immediate postoperative period.

Table 26-3 Reversal of Warfarin Therapy

Indication	Plan
INR <6	Lower or hold dose
INR 6–10	Give vitamin K 1–2 mg PO*; recheck INR 12–24 hours later
INR >10	Give vitamin K 2–4 mg PO*; recheck INR 12–24 hours later
Serious bleeding or major overdose	Give vitamin K 5–10 mg IV, plus, occasionally, fresh frozen plasma or prothrombin complex concentrate, rarely rFVIIa.

*Can also be given subcutaneously, but response is slower.

INR, international normalized ratio.

rFVIIa, recombinant activated factor VII.

Table 26-4 Reversing Warfarin Anticoagulation for Surgery

Low risk of thrombotic recurrence: Hold warfarin 4 to 5 days preoperatively. Check the INR 1 day before surgery, and perform surgery if it is 1.5 or less. Warfarin can be started postoperatively.

Moderate risk of thrombotic recurrence: Hold warfarin 4 to 5 days preoperatively. Check INR 1 day before surgery is performed to confirm it is below 1.5. Start unfractionated heparin or LMWH in prophylactic doses preoperatively, and continue until warfarin effect is in the therapeutic range after postoperative initiation.

High risk of thrombotic recurrence: Effective anticoagulation must be maintained. Warfarin should be stopped 4 to 5 days preoperatively. When INR is below 2.0, heparin or LMWH should be begun in therapeutic doses given intravenously or subcutaneously, respectively. Heparin should be held 6 hours and subcutaneous LMWH 24 hours preoperatively. Start heparin or LMWH in therapeutic doses postoperatively as soon as the bleeding risk is decreased and acceptable. Restart warfarin. Stop heparin when a therapeutic INR is achieved.

INR, international normalized ratio; LMWH, low molecular weight heparin.

In general, the bleeding risk is highest during surgery and begins to decrease toward baseline levels after approximately 1 week. Most surgery can be done with minimal bleeding risk in patients receiving warfarin with an INR near 1.5, although studies documenting an ideal INR or values of INR at which surgery is unsafe do not yet exist. After acute thrombosis, the risk of recurrence is high initially and declines over time. For example, recurrent venous thromboembolism occurs often during the first 1 to 2 weeks after diagnosis but is much less frequent after 8 to 12 weeks. Elective surgery and other invasive procedures associated with a high bleeding risk should be postponed if possible during the first several months after thrombosis is reported.

HEPARIN

Historical Perspective

Heparin derives its name from its original identification in approximately 1920 within an aqueous extract of liver that exhibited anticoagulant activity *in vitro*. It was not until approximately 1940, however, that heparin was used successfully as a treatment for thrombosis. Its use expanded subsequently as thrombotic disease was recognized more commonly and as extracorporeal and prosthetic vascular conduits came into use. Heparin is a biologic tissue extract that is highly heterogeneous. It was recognized early that most molecules in therapeutic preparations had no anticoagulant activity. The search for heparin derivatives with improved properties led to the introduction of LMWH in the 1990s. These preparations are derived from heparin through biologic or enzymatic degradation, and they exhibit improved pharmacologic properties. The culmination of these efforts led to identification of the five-saccharide sequence that mediates binding of heparin to antithrombin III, leading to its anticoagulant effects. Fondaparinux, a pentasaccharide based on this sequence, represents the newest addition as a therapeutic agent and the newest chapter in this long history.

Mechanism and Pharmacology

Heparin, a mixture of sulfated glycosaminoglycans, is a commonly used, rapidly acting parenteral anticoagulant.¹⁶ It is extracted from the lungs and intestinal tissue of cows and swine, and it is assayed biologically. Heparin has no direct anticoagulant effects, but it acts through antithrombin III, a plasma serine protease inhibitor. Antithrombin III inhibits thrombin, factor Xa, and other coagulation enzymes in a reaction that is relatively slow but is accelerated more than 1000-fold in the presence of heparin. Heparin is not absorbed after oral ingestion, so it must be given subcutaneously or intravenously. Heparin interacts with proteins and cells in the blood, resulting in complex pharmacokinetics characterized by rapid equilibration and slower clearance. Heparin causes release of endothelial cell-bound tissue factor pathway inhibitor (TFPI), and this may contribute to its therapeutic actions. Plasma half-life increases with higher doses and is variable among individuals. After subcutaneous administration, bioavailability may be less than 50% and peak plasma levels occur after 30 to 60 minutes.

Administration and Monitoring

Heparin is usually given intravenously for full anticoagulation, and clinical studies have shown a reduced occurrence of bleeding complications with continuous intravenous rather than intermittent bolus therapy. The anticoagulant effect is immediate, but laboratory monitoring is needed because of variability in response among patients. This is most conveniently done with partial thromboplastin time (PTT). The appropriate PTT range for heparin therapy is usually between 1.5 and 2.5 times the mean of the normal range, but this varies depending on laboratory reagent and instrumentation, and each laboratory should establish a therapeutic range that is based on appropriate correlation with heparin levels. Clinically useful nomograms for treating patients with venous thromboembolism are available for use in adjusting heparin dose (Table 26-5).^{17,18} Alternatively, heparin can be monitored with the use of anti-Xa levels, and this approach is useful when the PTT cannot be relied on, such as in patients with baseline prolongation of the PTT due to lupus anticoagulant. Other indications for using such heparin levels are listed in Table 26-6. The therapeutic range with a chromogenic anti-Xa assay is 0.3 to 0.7 U per milliliter. Somewhat lower heparin doses are recommended for patients with acute coronary syndromes. In patients with unstable angina and non-ST segment MI, an initial bolus of 60 to 70 U per kilogram (up to 5000 U) followed by an infusion of 12 to 15 U/kg/hr (up to 1000 U per hour) is recommended.¹⁹ For patients who undergo thrombolysis with tissue plasminogen activator (tPA), a bolus of 60 U per kilogram (up to 4000 U) followed by an infusion of 12 U per kilogram (up to 1000 U per hour) is suggested.²⁰ Maintenance of levels in the therapeutic range provides an adequate antithrombotic level and limits bleeding. For prophylaxis of venous thromboembolic disease, heparin is administered subcutaneously in doses of 5000 U every 8 to 12 hours, with the 8-hourly regimen more appropriate in patients at higher risk. Minor prolongation of the PTT may occur, but monitoring is neither recommended nor required. When very high doses are administered, as occurs during cardiopulmonary bypass, on-site monitoring is provided with the use of activated clotting time (ACT).

Heparin Resistance

Causes of heparin resistance include increased heparin clearance during pregnancy and antithrombin III deficiency. Acquired antithrombin III deficiency may be seen in patients with extensive thrombosis or disseminated intravascular coagulation (DIC) or during cardiopulmonary bypass. Treatment with antithrombin III concentrates or recombinant human antithrombin III has been shown to restore heparin sensitivity in patients undergoing renal replacement therapy²¹ or cardiac surgery with cardiopulmonary bypass.²² Some patients appear to respond poorly to heparin, with inadequate prolongation of the PTT despite apparently adequate or even high heparin dosages (Table 26-7). This is often referred to as “heparin resistance,” and it is due rarely to antithrombin III deficiency; more commonly, it is due to the acute phase response, which results in high levels of procoagulant proteins, particularly factor VIII and fibrinogen. The antithrombotic effects of heparin correlate best with plasma heparin levels,

Table 26-5 Intravenous Heparin Dosing Nomograms

Fixed-Dose Nomogram* ¹⁷				
PTT, sec [†]	Bolus Dose, U	Stop Infusion, min	Change in Infusion Rate [‡]	Time of Repeat PTT
<50	5000	0	+3 mL/hr	6 hours
50–59	0	0	+3 mL/hr	6 hours
60–85	0	0	0	Next morning
86–95	0	0	–2 mL/hr	Next morning
96–120	0	30	–2 mL/hr	6 hours
>120	0	60	–4 mL/hr	6 hours

Weight-Based Nomogram ¹⁸		
Dose Adjustment		
PTT, sec [§]	Bolus, U/kg	Infusion, U/kg/hr
<35	80	Increase rate by 4
35–45	40	Increase rate by 2
46–70	0	No change
71–90	0	Decrease rate by 2
>90	0	Decrease rate by 3

*These modifications occurred after initial heparin loading and maintenance infusion.

[†]Reference range is 35 to 37 seconds. Therapeutic range is 60 to 85 seconds, corresponding to a plasma heparin level approximating 0.3 to 0.7 U per milliliter by anti-factor Xa activity.

[‡]1 mL/hr equals 40 U per hour.

[§]Reference range, 20 to 30 seconds.

PTT, partial thromboplastin time.

Table 26-6 Clinical Situations in which Measurement of Heparin Levels is Appropriate

Some clinical conditions are associated with prolonged PTT before heparin is administered. These include inherited factor deficiencies, severe liver deficiency, and antiphospholipid syndrome. Accordingly, monitoring of heparin dosage via PTT is greatly obfuscated. Check baseline PTT, begin heparin therapy at a reasonable dose, and confirm heparin levels with an anti-Xa assay to establish that the heparin level is in the therapeutic range.

In some cases, the clinical situation is such that one wishes, on the one hand, to treat a severe thrombotic episode with adequate heparin; on the other hand, one would not like to have excessive heparin levels. These would include situations in which the patient is bleeding, has recently had surgery or a stroke, or is given a diagnosis of severe thrombocytopenia.

Treatment of patients with massive thrombosis occasionally is complicated by heparin resistance. As more and more heparin is administered in an attempt to achieve a therapeutic PTT, one becomes concerned. It is comforting to determine the heparin level when one is giving massive doses such as $\geq 40,000$ U of standard heparin per day. In these cases, the dose can be titrated until an anti-Xa level of 0.3 to 0.7 U per milliliter is achieved.

When LMWH or fondaparinux is used, determination of anti-factor Xa activity is useful in all cases described above, as well as when the clinician is uncertain regarding dosages in patients who are massively obese, or in those who are renally insufficient. Should a patient have a bleeding episode while receiving what one had considered to be appropriate doses of these agents, it is of value to confirm the level at which the adverse effect took place.

Obtaining heparin levels to rule out the presence of heparin when a patient theoretically had not been administered heparin is useful. One such clinical situation is postoperative bleeding with a very long PTT, which strongly suggests the possibility of heparin. This can also be useful when an unexpectedly prolonged PTT is detected in a patient with an indwelling heparinized central line, for whom the sample could be contaminated with heparin. Establishing that heparin was present or absent can help to narrow diagnostic considerations.

PTT, partial thromboplastin time; LMWH, low molecular weight heparin.

which may be adequate in these circumstances despite an apparent subtherapeutic PTT. Therefore, for patients who require more than 1500 U per hour, periodic monitoring with an anti-Xa assay is appropriate and provides a better indication of plasma levels.²³

Indications

Heparin is commonly used in the prevention and treatment of venous thromboembolic disease. Treatment is

initiated with an IV bolus followed by a constant infusion to maintain desired anticoagulant effects for a minimum of 5 days; this is followed by a longer period of oral anticoagulation. Heparin is also used in the treatment of patients with acute coronary syndromes and is effective in the short-term treatment of those with unstable angina and MI, as an adjunct to thrombolytic therapy, and in preventing acute reocclusion after angioplasty or stenting (see Chapter 20). It is used to maintain vascular patency during vascular surgery and in high doses and high levels

Table 26-7 Heparin Resistance

Definition: Inadequate prolongation of PTT or ACT despite administration of high doses of heparin (e.g., >1500 U/hr for treatment of venous thromboembolism, or 400 U/kg during cardiopulmonary bypass).

Causes: High levels of factor VIII and fibrinogen; antithrombin III deficiency; increased clearance during pregnancy.

Management: Measure antithrombin III levels. If low (e.g., <70%), consider giving antithrombin III to increase levels to 100%. If antithrombin III deficiency is not present, monitor heparin therapy with anti-Xa levels.

PTT, partial thromboplastin time; ACT, activated clotting time.

(e.g., approximately 3 U/mL) to permit extracorporeal circulation during cardiopulmonary bypass. In patients with DIC, heparin can be used in attempts to reduce hemostatic activation, prevent microvascular occlusion, and improve overall hemostasis (see Chapter 12).

Heparin is often used for anticoagulation during pregnancy (see Chapter 36).¹¹ Short-term treatment is administered as in the nonpregnant patient, and long-term anticoagulation may be provided with subcutaneous administration. Heparin is often the anticoagulant of choice during pregnancy because warfarin is associated with risks for fetal defects. For full anticoagulation, subcutaneous doses of 17,000 U or more every 12 hours may be required, with monitoring provided to maintain the PTT in the therapeutic range 4 to 6 hours after administration. Heparin requirements may increase during pregnancy, particularly in the third trimester. Heparin does not cross the placenta and exerts no anticoagulant effect in the fetus. It can, however, increase bleeding during delivery, and heparin may be discontinued briefly at the beginning of labor or prior to planned operative delivery.

Adverse Effects

The most frequent complication of heparin administration is bleeding that is related to the dose and intensity of treatment and to patient characteristics. Given the wide range of patients in whom heparin is used, it is difficult to state an average bleeding risk. However, in large groups of patients who receive heparin for treatment of venous thromboembolic disease, approximately 3% may have a major bleeding complication. Lower doses, such as those used for thromboprophylaxis, are rarely the sole or chief cause of hemorrhage.

Heparin-induced thrombocytopenia (HIT) (see Chapter 25) is immune-mediated platelet consumption caused by an antibody directed against a complex of heparin and platelet factor 4.^{16,24,25} Platelets can fall to low levels associated with bleeding, yet HIT is more often associated with severe arterial or venous thromboembolic complications. HIT, when defined as a 50% reduction in baseline platelet count or a platelet count lower than 150,000 per microliter during therapy, occurs in about 3% of patients. In patients administered heparin for the first time, HIT usually occurs after 5 days, but thrombocytopenia may develop earlier if prior exposure has occurred. Platelet counts should be monitored during treatment and heparin discontinued if thrombocytopenia occurs. If a rapidly acting parenteral anticoagulant is needed, a direct thrombin inhibitor or fondaparinux can be used as an alternative.

Long-term heparin therapy causes radiographic evidence of bone loss in more than 15% of women receiving prolonged treatment during pregnancy. Symptomatic vertebral fractures occur in approximately 2%. Bone loss resolves after heparin is discontinued,^{26,27} and risks with short-term use are not appreciable.

Reversal of Effect

A major advantage of heparin is its short half-life. Anticoagulant effect is eliminated within 2 to 3 hours after discontinuation of an intravenous infusion. Therefore, stopping the infusion and taking local measures are usually adequate to control bleeding (Table 24-8). In major or life-threatening bleeding, the anticoagulant effects of heparin may be neutralized with protamine sulfate, which is a basic polypeptide that binds tightly to the acidic heparin molecule. The usual dose of protamine is 1 mg, given to neutralize 100 U of heparin. The dose to be administered is based on an estimate of the amount of heparin remaining in the circulation. Protamine is routinely used to neutralize heparin after cardiopulmonary bypass with the use of standard formulas and ACT monitoring. Fresh frozen plasma has no role in reversing the effects of heparin.

LOW MOLECULAR WEIGHT HEPARIN

Mechanism and Pharmacology

Significant clinical problems with heparin include unpredictable absorption and bioavailability after subcutaneous administration and variable binding to plasma proteins and cells. When these problems occur simultaneously, heparin therapy must be monitored with coagulation tests and doses adjusted. Bleeding is a serious complication, osteoporosis may develop with prolonged use, and HIT occurs in approximately 3% of patients. These limitations led to studies of structural and functional relationships with heparin and eventually to the development of LMWHs. Preparations are produced through chemical or enzymatic treatment of heparin to decrease the size of the polysaccharide chains, yielding a product with a restricted molecular weight distribution with a mean of approximately 4000 to 5000 daltons.¹⁶ Similar to heparin, LMWH exerts its antithrombotic effects through interaction with antithrombin III. In the presence of LMWH, antithrombin III inactivates factor Xa, as does unfractionated heparin, but it is less able to inactivate thrombin because of the shorter polysaccharide length. A comparison of the important clinical properties of heparin, LMWH, and fondaparinux is presented in Table 26-9. Several LMWH preparations are available, and they share many clinical and pharmacologic properties. Also, effectiveness and safety have proved similar in clinical trials. However, because each is produced by a different method and has some unique properties, pharmacologic properties and clinical results may vary.

LMWH preparations can be administered intravenously but are usually given subcutaneously because of their nearly complete absorption and obviously enhanced convenience. This is a clear benefit over unfractionated heparin, which exhibits variable and dose-dependent absorption after subcutaneous administration. Moreover, different from

Table 26-8 Approach to Hemorrhaging Patients Receiving Heparin

Questions	Considerations	Actions
Is bleeding due to heparin?	Do not assume that hemorrhage is necessarily due to heparin. Consider and evaluate for structural defects such as a tumor, ulcer, or nonligated vessel. Consider other inherited or acquired problems.	Apply local pressure, if possible. Correct structural bleeding. Ligate vessels.
Are aggravating factors present?	Rule out contribution to hemorrhage by thrombocytopenia, antiplatelet agents such as aspirin or NSAIDs, thrombolytic agents, oral anticoagulants, or acquired vitamin K deficiency.	Administer DDAVP for antiplatelet agent reversal and vitamin K for that deficiency. Transfuse platelets for thrombocytopenia.
Is the concentration of heparin unacceptably high if actions thus far implicate heparin?	Identify time and dose (confirmed by discussion with pharmacy and nursing) of last heparin administration. Estimate half-life of remaining heparin. Check heparin level.	Cease heparin administration. Attempt protamine reversal in exceptional cases. Do not administer FFP.
Is the indication for continuing anticoagulation stronger than the contraindication?	Failure to treat patients with thromboembolic indications with heparin is usually much more dangerous than the very rare hemorrhaging fatality caused by the use of heparin.	Lower the dose of heparin, and transfuse as necessary. Consider IVC devices in exceptional cases to prevent PE.

NSAIDs, nonsteroidal anti-inflammatory drugs; DDAVP, 1-deamino-8-D-arginine vasopressin; desmopressin; FFP, fresh frozen plasma; IVC, inferior vena cava; PE, pulmonary embolism.

Table 26-9 Comparisons Among Heparin, LMWH, and Fondaparinux

	Heparin	LMWH	Fondaparinux
Bioavailability after subcutaneous injection	Dose dependent, low	High	High
Half-life	1–2 hours	3–5 hours	17 hours
Need for monitoring	Routine	Occasional	Not yet known
Cost	Negligible	High	High
Prolongation of PTT	Dose dependent	Minimal	Minimal/none

LMWH, low molecular weight heparin; PTT, partial thromboplastin time.

heparin, LMWH exhibits much less binding to plasma proteins and cells. Consequently, blood levels and anticoagulant effects are more predictable after LMWH is administered. Also, LMWH preparations have a longer plasma half-life than does unfractionated heparin—a desirable effect in the absence of bleeding. Together, these properties make possible once- or twice-daily subcutaneous LMWH regimens that are practical for prophylaxis and therapy. LMWH preparations have significant renal clearance, and high plasma levels can rapidly accumulate after repeated doses are given to patients with reduced renal function. Therefore, monitoring of anti-Xa levels and dose adjustments are needed in patients with renal impairment. Markedly obese patients also represent a difficult group, in that dosing regimens have not been specifically tested in these patients and very high levels can result from weight-based dosing. Many experts “cap” the dose at the equivalent of approximately 12,500 U twice daily. Accordingly, in select cases, monitoring levels is very useful when combined with LMWH therapy (see [Table 26-6](#)).

Clinical Uses

The use of LMWH has expanded to encompass many applications for which heparin has been used traditionally.

The findings of extensive clinical studies are now available to guide prophylaxis and therapy of venous thromboembolic disease. Dosing regimens for LMWH preparations approved for use in North America and Europe are listed in [Table 26-10](#). As of the date of this writing, enoxaparin (Lovenox; Aventis Pharmaceuticals Inc., Bridgewater, NJ, USA), dalteparin (Fragmin; Pfizer Inc., New York, NY, USA), and tinzaparin (Innohep; Pharmion Corporation, Boulder, Colo, USA) have been approved by the U.S. Food and Drug Administration (FDA) for use in the United States. Each is marketed for specific indications and labeling differs, with some assayed in anti-Xa units and some in milligrams. In general, 1 mg is approximately equivalent to 100 anti-Xa U. For details regarding indications and dosages, specific prescribing information should be reviewed.

For prophylaxis in surgery, regimens vary according to the risk of thrombosis.²⁸ Lower doses are recommended for low-risk patients, and increased doses are given to higher-risk patients, such as those undergoing surgery for active malignancy. Patients undergoing orthopaedic surgery are at particularly high risk, and increased daily or twice-daily doses are recommended. Generally, high doses are given the night before or postoperatively rather than immediately preoperatively to decrease the risk of surgical

	Drug*	Regimen
Prophylaxis		
General surgery Low risk	Dalteparin	2500 U, 1–2 hr preop and qd
	Enoxaparin	20 mg, 1–2 hr preop and qd
	Tinzaparin	3500 U, 2 hr preop and qd
High risk	Dalteparin	5000 U, 10–12 hr preop and qd
	Enoxaparin	40 mg, 10–12 hr preop and qd
Orthopaedic surgery	Dalteparin	5000 U, 8–12 hr preop and qd
	Enoxaparin	30 mg q12h starting 12–24 hr postop or 40 mg qd starting 12 hr preop
	Tinzaparin	50 U/kg, 2 hr preop and qd or 75 U/kg qd starting 12–24 hr postop
Spinal injury	Enoxaparin	30 mg q12h
Multiple trauma	Enoxaparin	30 mg q12h
Medical patients	Enoxaparin	20 mg qd (40 mg qd more effective in high-risk patients)
	Dalteparin	5000 U qd
Treatment		
Venous thromboembolism	Enoxaparin	1 mg/kg q12h or 1.5 mg/kg qd
	Dalteparin	100 U/kg q12h or 200 U/kg qd
	Tinzaparin	175 U/kg qd
Unstable angina	Enoxaparin	1 mg/kg q12h
	Dalteparin	100 U/kg q12h

*Brand names: dalteparin, Fragmin; enoxaparin, Lovenox; tinzaparin, Innohep. LMWH, low molecular weight heparin.

bleeding. In patients who are given epidural anesthesia, the catheter should be placed prior to administration of LMWH or at the time of anticipated trough level. Additional doses are usually held for at least 2 hours after catheter insertion, withdrawal, or manipulation because of the risk of bleeding into the spinal canal.²⁹ LMWH is also effective in high-risk patients after spinal injury or multiple trauma. It can be used for prophylaxis in medical patients, and large prospective studies suggest that 40 mg of enoxaparin is more effective than 20 mg once daily in medical patients with acute illnesses.³⁰ Administration of dalteparin 5000 U once daily was also effective in acutely ill medical patients in a recent study.³¹

The pharmacokinetic properties of LMWH preparations make them suitable for treatment of patients with acute deep venous thrombosis and pulmonary embolism through subcutaneous administration; clinical studies have established the efficacy and safety of this approach.^{32–34} High-dose regimens are used, and once- or twice-daily administration has been effective. Similar doses are used for treatment of those with acute coronary syndromes; evidence from clinical trials shows improved outcomes in patients with unstable angina who are treated acutely with LMWH as compared with unfractionated heparin. LMWH does not cross the placenta and has been used successfully for prophylaxis and treatment of pregnant patients with venous thromboembolic disease. Because of changes that may occur in weight and renal function, occasional monitoring with anti-Xa levels is advisable.

Adverse Effects

The primary complication of LMWH is bleeding. Minor bruising at injection sites is common and annoying but of

little clinical consequence. Major bleeding occurs at approximately the same frequency as it does with unfractionated heparin when used in similar patient groups for the same indication. HIT is much less common with LMWH, occurring only 10% to 15% as often as with heparin, suggesting that HIT may be reduced by 80% through the use of LMWH. However, cross-reactivity of the antibody occurs, and LMWH is *not* an acceptable choice for continued anticoagulation in patients with HIT. Animal studies suggest that osteoporosis may be uncommon with LMWH; few clinical data are available.

Choice of Heparin Versus LMWH

Factors that govern the selection of heparin or LMWH include effectiveness, safety, convenience, and cost. Differences in characteristics (Tables 26-9 and 26-11) among these agents are exploited for the benefit of specific needs of each patient's situation; one drug is not "better" than the others. For prophylaxis in most surgical and medical patients, evidence indicates that heparin and LMWH are equally effective, and the lower cost of heparin makes it an attractive choice. In orthopaedic patients, LMWH is more effective than heparin and is therefore preferable. For treatment of those with venous thromboembolic disease, the safety and effectiveness of LMWH have been reported to be superior to those of unfractionated heparin. Subcutaneous regimens of LMWH offer enhanced patient convenience, and outpatient home treatment is the preference of most patients. Outpatient therapy requires intensive patient education, adequate medical supervision, and considerations of drug costs, insurance coverage, and adequate follow-up. The overall cost of outpatient therapy is much less than the cost of inpatient intravenous heparin treatment.

In some specific circumstances, however, unfractionated heparin may be preferable.

In patients who may require an invasive procedure on an urgent basis, the short half-life of heparin administered intravenously is attractive. Also, patients with renal insufficiency have an increased bleeding risk, and decreased LMWH clearance may lead to high levels; intravenous heparin offers some advantages. LMWH is only incompletely reversed by protamine sulfate, making it difficult to use for bypass surgery. The use of LMWH for acute coronary syndromes is rapidly evolving and involves consideration of combination therapy, including potent antiplatelet agents and mechanical interventions. Some studies indicate greater effectiveness of LMWH in the treatment of patients with acute coronary syndromes.^{35,36} A recent analysis has questioned the appropriateness of heparin dosing in several trials in which heparin and LMWH were compared for safety and efficacy.³⁷

Fondaparinux

Fondaparinux is a completely synthetic heparin-like molecule with selective anti-factor Xa activity.³⁸ Its structure is based on the heparin sequence that interacts specifically with antithrombin III. It binds reversibly and with high affinity to antithrombin III, resulting in a conformational change that makes it effective in inhibiting factor Xa. However, its pentasaccharide chain is not long enough to interact with thrombin. Consequently, it has no appreciable thrombin inhibitory activity, and its mechanism of action involves reducing thrombin generation. Fondaparinux does not induce allergic responses because it is produced synthetically and contains no animal products.

After subcutaneous administration, peak plasma levels are reached after approximately 2 hours, and the elimination half-life is approximately 17 hours. Bioavailability is nearly complete after subcutaneous or intravenous administration. Intrasubject and intersubject availability is low, and little accumulation is noted after multiple daily doses. Fondaparinux plasma levels can be measured with the anti-factor Xa assay, and little effect is seen with the use of other coagulation tests, including PT, PTT, and thrombin time (TT).

Clinical studies have evaluated fondaparinux in the prevention and treatment of venous thromboembolism.^{39–41} It has been approved by the FDA for the prevention of venous thromboembolism after major orthopaedic surgery at a dose of 2.5 mg administered subcutaneously once daily. This dose is effective for thromboprophylaxis in a variety of medical and surgical patients. It is also effective and has been approved for the treatment of those with deep vein thrombosis and pulmonary embolism when used at a dose of 7.5 mg subcutaneously once daily. Fondaparinux is available in therapeutic doses of 5 mg for smaller patients and 10 mg for larger patients.

Bleeding is the principal adverse effect, and frequency and severity of this effect have been similar to those observed with LMWH. Because the drug is excreted in the urine, elevated levels may be observed with renal insufficiency. Caution should be used in administering fondaparinux to patients with renal compromise.

No cross-reactivity with antibodies causing HIT has been reported; thus, fondaparinux has been used for (off-label) anticoagulation in patients with HIT. HIT has not yet been reported in patients given fondaparinux. This agent may be a particularly good choice in those who require subcutaneous administration. Although it has not yet been approved for the treatment of patients with HIT, many have used fondaparinux in this difficult situation.

LEPIRUDIN

Mechanism and Pharmacology

Hirudin, the anticoagulant that is present in the salivary glands of the medicinal leech, *Hirudo medicinalis*, is a highly specific direct inhibitor of thrombin (see Table 26-11). The biosynthetic polypeptide molecule called lepirudin is composed of 65 amino acids and is identical to natural hirudin, except for substitution of leucine for isoleucine at the N-terminus and the absence of a sulfate group on tyrosine 63. Lepirudin (Refludan; Berlex, Montville, NJ, USA) binds tightly and nearly irreversibly to the catalytic site of thrombin,

Table 26-11 Comparison of Properties of Anticoagulant Agents

	UFH	LMWH	Fondaparinux	Lepirudin	Argatroban	Bivalirudin
Size	Very large	Large	Small	Small	Very small	Small
MW, daltons	15,000	5000	1728	7000	527	2180
Thrombin inhibition	Indirect	Indirect	None	Direct	Direct	Direct

Route of administration	IV, SC	SC, IV	SC	IV, SC	IV	IV
Onset	Rapid	Rapid	Rapid	Rapid	Rapid	Rapid
Reversibility	Rapid	Slower	Slow	Slow	Rapid	Rapid
Clearance	Hepatic	Renal	Renal	Renal	Hepatic	Renal; proteolysis
Inhibition of clot bound	No	No	No	Yes	Yes	Yes
Tests for monitoring	PTT, Anti-Xa	Anti-Xa	Anti-Xa	PTT, ACT	PPT, ACT	PTT, ACT

UFH, unfractionated heparin; LMWH, low molecular weight heparin; MW, molecular weight; PTT, partial thromboplastin time; ACT, activated clotting time; IV, intravenous; SC, subcutaneous.

which imparts a prolonged duration of action. Lepirudin is renally excreted and so may accumulate in patients with renal impairment and potentially increase the risk of bleeding. The half-life appears to be 1 to 3 hours in normal volunteers but may be as long as 2 days in dialysis-dependent patients.

Administration and Monitoring

Lepirudin must be administered parenterally, which results in dose-dependent prolongation of PTT, PT, and TT. The usual dose is a bolus of 0.4 mg per kilogram given intravenously, followed by 0.15 mg/kg/hr given as a continuous infusion. Therapy is monitored, and the dose is adjusted on the basis of PTT, with a target range 1.5 to 2.5 times the mean control range. Because lepirudin is cleared by the kidneys, high plasma levels may result in patients with renal dysfunction; dose adjustments are required.

Indications and Clinical Use

Lepirudin is approved for anticoagulation in patients with HIT and associated thromboembolic disease to prevent additional thromboembolic complications. It has been used successfully in clinical trials for the treatment of patients with deep venous thrombosis and those with acute coronary syndromes. This direct thrombin inhibitor has no structural homology with heparin and thus no cross-reactivity with HIT antibodies. Two clinical trials of lepirudin use in patients with HIT have been completed.^{42,43} In the Heparin-Associated Thrombocytopenia (HAT)-1 trial, lepirudin was associated with rapid and sustained recovery of platelet counts and adequate anticoagulation as assessed by PTT.⁴² In HAT-2, a follow-up study, investigators showed that hirudin successfully prevented death, limb amputation, and new thromboembolic complications in patients with HIT.³⁵ Several patients in the HAT trials were treated with lepirudin and underwent successful percutaneous coronary intervention.^{42,43}

Adverse Effects

Primary adverse effects have involved bleeding. Formation of antihirudin antibodies has been observed in about 40% of patients with HIT who were treated with lepirudin, which may decrease drug clearance and thus *increase* anticoagulant effects, possibly through delayed renal elimination of lepirudin/antihirudin complexes, which retain anticoagulant properties.⁴⁴

Reversal of Effect

Lepirudin has no known antidote. If overdosage or excessive bleeding occurs, infusion should be discontinued immediately, PTT and other coagulation measurements obtained as appropriate, and the patient's hemoglobin concentration with preparations for blood transfusion assessed. Case reports suggest that hemofiltration or hemodialysis (with high-flux dialysis membranes with a cutoff point of 50,000 daltons) may be useful. Studies in pigs have shown reductions in bleeding with infusion of von Willebrand factor.

ARGATROBAN

Mechanism and Pharmacology

Argatroban is a small-molecule synthetic derivative of arginine that reversibly binds directly to the catalytic site of the thrombin molecule (see Table 26-11).^{45,46} It has no homology with heparin and thus no cross-reactivity. The primary route of metabolism involves the liver, and the terminal elimination half-life is 39 to 51 minutes.

Administration and Monitoring

The recommended initial dose of argatroban for adult patients without hepatic impairment is 2 µg/kg/min, administered as a continuous infusion. Therapy is monitored through monitoring of the PTT. Steady state levels as determined by tests of anticoagulant effects (e.g., PTT) typically occur within 1 to 3 hours after argatroban therapy is initiated. Dose adjustment may be required to maintain the target PTT. Thus, the PTT should be assessed 2 hours after therapy is begun, to confirm that PTT is within the desired therapeutic range. The dose is then adjusted as clinically indicated (≤ 10 µg/kg/min) until the steady state PTT is 1.5 to 3 times the initial baseline value (≤ 100 seconds). The package insert should be reviewed before the patient's dose is determined.

Indications and Clinical Use

Argatroban recently received FDA approval as an anticoagulant for the prophylaxis or treatment of thrombosis in patients with HIT.⁴⁷ In two series, argatroban has been evaluated in patients with HIT who underwent coronary angioplasty.^{48,49} A total of 50 patients were assessed. Procedural success was achieved in 98% of patients; complications included one retroperitoneal hematoma and one abrupt vessel closure. The anticoagulant effect of the drug is often difficult to predict in the catheterization laboratory, and no effective reversal agent has been identified.^{48–50}

Adverse Effects

Hemorrhagic signs and symptoms and allergic reactions are the most commonly reported adverse effects.

Reversal of Effect

No specific antidote to argatroban has been identified. Excessive anticoagulation, with or without bleeding, may be controlled by decreasing the infusion rate or discontinuing argatroban. In clinical studies at therapeutic levels, anticoagulation parameters generally return to baseline within 2 to 4 hours after discontinuation of the drug. Reversal of anticoagulant effects may take longer in patients with hepatic impairment. If overdosage or excessive bleeding occurs, the infusion should be discontinued immediately, PTT and other coagulation parameters obtained as appropriate, and the patient's hemoglobin concentration made with preparations for blood transfusion assessed.

BIVALIRUDIN

Mechanism and Pharmacology

Bivalirudin (Angiomax; BenVenue Laboratories, Bedford, OH, USA) (see Table 26-11) is a 20 amino acid molecule that is engineered from naturally occurring hirudin to consist of only two amino acid sequences of hirudin that are important in binding to and inhibiting thrombin, which is connected by a bridge of four glycine residues. This bridge permits easy cleavage of the molecule, providing a more reversible interaction with the catalytic site of thrombin than hirudin, and resulting in a significantly lower bleeding risk. The half-life is relatively short (24 to 45 minutes) and administration results in rapid, dose-dependent prolongation of the ACT. Elimination of bivalirudin occurs primarily via the liver. Approximately 20% of standard doses are recovered in the urine. Bivalirudin has no structural similarity to heparin.

Administration and Monitoring

For reducing ischemic complications in patients with unstable or postinfarction angina who are undergoing coronary angioplasty, bivalirudin has been given intravenously at a dose of 1 mg per kilogram as an initial bolus, followed by a continuous infusion of 2.5 mg/kg/hr for 4 hours, then 0.2 mg/kg/hr for 14 to 20 hours. Bivalirudin was initiated immediately before angioplasty was performed, and aspirin (300 to 325 mg PO) was also given to all patients.⁵¹ The package insert should be reviewed before the patient dose is determined.

Indications and Clinical Use

Bivalirudin is FDA approved as an anticoagulant in patients with unstable angina who are undergoing percutaneous transluminal coronary angioplasty (PTCA). In two clinical trials, bivalirudin was shown to be a safe substitute for heparin in patients without HIT undergoing percutaneous coronary intervention.^{51,52} In an open-label, dose-finding trial of 258 patients, bivalirudin was used as an alternative to heparin.⁵² Bivalirudin was associated with reduced bleeding complications, including retroperitoneal hemorrhage, a decreased need for transfusion, and less frequent occurrences of major hemorrhage than with heparin.

Adverse Effects

Bleeding is the most common adverse effect. Because of its small size and secondary structure, bivalirudin would not be expected to induce strong antibody responses on readministration, in contrast to larger molecules that have more significant secondary structures (such as hirudin). Antibivalirudin antibodies have not been detected during or up to 4 weeks after intravenous bivalirudin therapy in several studies. No allergic phenomena have been reported to date.

Reversal of Effect

No specific antidote to bivalirudin is available. Excessive anticoagulation, with or without bleeding, may be controlled

by decreasing or discontinuing the infusion of bivalirudin. If overdosage or excessive bleeding occurs, the infusion should be discontinued immediately, PTT and other coagulation measurements obtained as appropriate, and the patient's hemoglobin concentration made with preparations for blood transfusion assessed.

Chapter 27

Blood Component and Pharmacologic Therapy of Hemostatic Disorders

Charles D. Bolan, MD • Harvey G. Klein, MD

SYNOPSIS

Patients with disordered hemostasis present one of the greatest challenges to blood banks and transfusion practitioners. Early intervention with appropriate directed therapy can provide adequate hemostasis for a variety of bleeding conditions; however, the rapidly hemorrhaging patient can deplete the transfusion service's inventory and have a major impact on the hospital and the community. With the advent of potent agents such as recombinant factor VIIa (rFVIIa) therapy for use in a wide variety of disorders, the issues of cost, efficacy, adverse effects, monitoring, and optimal integration of pharmacologic treatment with blood transfusion therapies have achieved a highly prominent and visible role in patient care. This chapter addresses various blood-derived biologics, non-blood derived drugs, and strategies to prevent hemorrhage and manage hemostatic disorders. These biologics, pharmacologic agents, and other therapies and their use are discussed in this chapter and, where indicated, elsewhere in the text (Table 27-1).

INTRODUCTION AND HISTORICAL OVERVIEW

The evolution of the treatment of bleeding disorders with transfusions and pharmacologic therapy both parallels and differs from developments in traditional pharmacology. Early pharmaceutical preparations, such as digitalis, insulin, and vitamin B₁₂, were crude extracts that have been replaced by purer preparations or even by recombinant products. Similarly, the early use of whole blood transfusion to treat patients with conditions such as hemophilia and thrombotic thrombocytopenic purpura (TTP) has been supplanted by recombinant clotting factors, specific blood component therapy, and U.S. Pharmacopeia (USP)-standardized antidotes such as vitamin K to treat warfarin toxicity.^{1,2} As progress in pharmacology has depended on an improved understanding of disease pathophysiology, so has progress in transfusion medicine depended on a detailed understanding of the mechanisms involved in hemostasis and the development of diagnostic laboratory assays to monitor management. To some extent, rational transfusion management remains impeded by the lack of widely accessible assays to measure platelet function, assess components of the fibrinolytic system, and

measure the impact of hemostatic therapies at the site of cellular injury.

Several sentinel discoveries have played critical roles in blood transfusion and pharmacologic therapies for bleeding patients. Landsteiner's discovery of blood groups at the turn of the century allowed pretransfusion testing to be performed to avert reactions due to ABO-incompatible whole blood transfusion. Blood group compatibility remains of critical importance in red blood cell transfusion therapy and may exert significant impact when plasma, apheresis platelets, or manufactured plasma fractions that contain red blood cell antibodies are used. With the development of citrate anticoagulant for blood storage, whole blood transfusion was successfully adapted during the First World War, ultimately leading to the birth of the modern blood bank. The advent of the sterile plastic interconnected bag system has made component therapy possible.

Costs of the new safer blood components and fractions have risen dramatically. Likewise, the costs of pharmaceuticals and recombinant biologics are substantial. At the same time, the emergence of strategies for using pharmacologic agents to control bleeding associated with surgery may reduce the need for reoperation, improve overall mortality, reduce requirements for transfusion, and decrease exposure to allogeneic donors. Further, such agents may reduce the cost of therapy and may provide superior hemostasis when compared with traditional blood components. The promise of new agents, such as rFVIIa, is tempered by issues of cost, monitoring, and safety. Further, these agents have not yet undergone the same degree of scrutiny that revealed lower than expected efficacy or higher than expected toxicity during more extensive follow-up with previous agents such as 1-deamino-8-D-arginine vasopressin (DDAVP) or aprotinin. Despite these costs and uncertainties, the treating physician now has a variety of choices and a variety of considerations when faced with a hemorrhaging patient or one who is being prepared for procedures that are likely to challenge the hemostatic system.³

TRADITIONAL BLOOD COMPONENTS

The blood bank can now provide a wide range of blood components and plasma fractions, each with characteristic hemostatic properties and toxicities. Available products include those obtained by traditional single donation and by centrifugal separation of whole blood or donor aphere-

Table 27-1 Blood Components, Blood Products, and Pharmaceutical Agents

Traditional blood components
Red blood cells (RBCs)
Platelets
Fresh frozen plasma (FFP)
Cryoprecipitate
Plasma fractions
Recombinant coagulation factors (also see Chapter 4)
Recombinant factor VIIa (rFVIIa)
Pharmaceutical agents
DDAVP (1-deamino-8-D-arginine vasopressin)
Lysine analogue antifibrinolytics
Aprotinin
Vitamin K
Estrogens
Protamine
Pharmacologic Agents Covered in Other Chapters
Antiplatelet agents (aspirin [ASA] and clopidogrel) (see Chapter 20)
Platelet glycoprotein IIb/IIIa inhibitor (abciximab, tirofiban, and eptifibatide) (see Chapter 20)
Warfarin (see Chapter 26)
Unfractionated heparin (see Chapter 26)
Low molecular weight heparin (LMWH) (see Chapter 26)
Fondaparinux (see Chapter 26)
Direct thrombin inhibitors (DTIs) (lepirudin, argatroban, and bivalirudin) (see Chapter 26)
Fibrinolytic agents (see Chapter 28)

sis, as well as those obtained from fractions of pooled products processed from collections from tens of thousands of donors, such as prothrombin complex concentrates (PCCs). Recombinant blood proteins such as rFVIIa, although not blood derived, may be considered interchangeable with their plasma-derived relatives or may be considered as a pharmacologic agent. The hemostatic properties and toxicities of these products are intimately related to the preparation processes. Increasingly, recombinant proteins have replaced virus-inactivated pooled plasma products for management of hemophilia A and B, and intermediate purity factor VIII (FVIII) preparations have replaced cryoprecipitate in the treatment of von Willebrand disease (VWD). Cryoprecipitate remains the mainstay of treatment for fibrinogen and factor XIII deficiencies, and fresh frozen plasma (FFP) may be used to provide replacement for deficiencies of other coagulation factors (factors XI, X, V, and II). Platelet concentrates and FFP are the blood components most frequently used for hemostasis; however, red blood cells and granulocytes, as well as other preparations, may have important hemostatic effects related to their plasma content or other properties.

Red Blood Cells

Red blood cells (RBCs), commonly referred to as “packed cells,” may be prepared by whole blood donation or through apheresis procedures. Although not typically considered a hemostatic component, RBCs may contribute to normal clot formation, or perhaps more accurately, a decrease in RBCs may contribute to a bleeding tendency. Template bleeding time is prolonged as hematocrit falls, and RBC transfusions alone have been shown to improve hemostasis in patients with uremia⁴ and chronic anemia.⁵ The mechanism for this effect is not known but may involve

movement of platelets toward the vessel wall with increasing intravascular RBC mass,⁶ or the action of RBC surface proteins that function as adhesion molecules.⁷ RBC adhesion to endothelial cells plays a prominent pathologic role in malaria and sickle cell crisis, although the possible beneficial role of RBC adhesion during surgery or other conditions of compromised hemostasis is not known.

The adverse association of hematocrit with bleeding is greatest at hemoglobin concentrations <6 g per deciliter⁵; RBC transfusions may produce rapid hemostatic effects while restoring oxygen-carrying capacity. RBC transfusions provided to maintain hemoglobin concentrations greater than 9 g per deciliter produce no significant increment in hemostasis. Transfusions given to patients to maintain hemoglobin concentrations above 9 g per deciliter may be associated with decreased survival in intensive care units when compared with that reported in patients maintained at hemoglobin concentrations between 7 and 9 g per deciliter.⁸

Administration of the erythroid lineage cytokine erythropoietin (EPO) has become standard therapy in the treatment of anemia and in raising hemoglobin concentration in patients with renal disease and chronic conditions. Although EPO administration may have some effects on platelet reactivity,⁹ the improvement in baseline hematocrit that occurs during EPO administration may account for the reduced incidence of bleeding in patients with uremia.¹⁰

Exclusive reliance on RBC replacement in the rapidly bleeding patient may induce a hemostatic defect. Stored RBCs contain no functional platelets and include as little as 5% to 10% plasma, depending on the preservative solution and method of collection used. Serial testing for platelet count and screening coagulation assays such as prothrombin time (PT) and partial thromboplastin time (PTT) should be performed to guide component replacement when large numbers of RBC concentrates are transfused in trauma cases involving massive transfusion,¹¹ which is conventionally defined as transfusion that exceeds one blood volume within 24 hours. Early balanced transfusion therapy is vital for massively bleeding patients and may prevent the onset of microvascular hemorrhage.¹² A proactive approach from the transfusion service is warranted.

Platelets

Platelet concentrates may be prepared by pooling platelets obtained through centrifugation from individual units of whole blood. A “unit” of platelets has been defined as containing at least 5.5×10^{10} platelets—hence the term “six pack,” which describes a standardly prescribed dose of 3.3×10^{11} . Recent trends in blood center collection procedures have resulted in the attainment of most platelet products by single-donor apheresis, with the “dose” expressed by dividing the measured platelet content of the product by 3.0×10^{11} . These are arbitrary designations. Assessment of clinical response according to the dose of platelets administered and a posttransfusion platelet count measured within 1 hour of transfusion should be performed in all patients as a guide to further therapy (see later).

Apheresis or “single-donor” collections result in fewer donor exposures for a given dose of platelets. Apheresis platelets may contain 200 to 250 mL of donor plasma, but heat-labile clotting factors decay rapidly at a storage

temperature of 22°C. It has been surprisingly difficult to document an advantage of single-donor apheresis platelets over pooled random donor components, although one suspects that alloimmunization, bacterial contamination, and virus transmission should all be reduced.¹³

Platelets are transfused for prophylactic and therapeutic indications. Prophylactic transfusion triggers remain controversial. Previous recommendations of using 20,000/μL in stable patients were based on estimates of bleeding in children with leukemia, many of whom had received aspirin prior to our realization that aspirin is such a powerful antiplatelet agent.¹⁴ Subsequent studies, while avoiding aspirin, indicate that even far lower numbers are safe.^{15,16} Many clinicians now administer prophylactically to stable, nonbleeding patients with amegakaryocytic thrombocytopenia due to chemotherapy and/or leukemia platelet transfusions given at platelet counts less than 5000/μL.¹⁷ A trigger of 20,000/μL may be more prudent for patients who are febrile, have rapidly falling counts, or have evidence of additional hemostatic defects. Platelet counts of at least 50,000/μL may be more reassuring to the clinician when invasive procedures such as endoscopy, lumbar puncture, and bronchoscopy are anticipated. Meager evidence suggests that higher counts reduce morbidity and mortality. Clinical indications for therapeutic platelet transfusions are controversial and should be based on the patient's clinical condition, the cause of bleeding, and the number and function of circulating platelets.¹⁸

Bleeding due to platelet defects acquired after cardiopulmonary bypass surgery or aspirin ingestion often responds to platelet transfusion; oozing related to uremia does not respond in this way because transfused platelets rapidly acquire the uremic defect.¹⁹ Evolving algorithms for platelet transfusion in surgical settings based on point-of-care testing of platelet count and function have the potential to improve patient care and blood product utilization.²⁰

Most platelet transfusions are administered to patients with defects in platelet production or function. However, some patients with immune-mediated thrombocytopenia may have satisfactory responses to platelet transfusions.²¹ Platelet survival generally lasts no longer than a few hours. Therefore, patients rarely benefit from prophylactic transfusions, although therapeutic transfusions may be lifesaving. Platelet transfusions are ordinarily considered to be contraindicated in patients with thrombotic platelet destruction, such as those with TTP, heparin-induced thrombocytopenia, and possibly disseminated intravascular coagulation (DIC).

Platelet transfusions should be monitored through baseline and posttransfusion platelet counts. Some physicians prefer to standardize this evaluation by calculating a "corrected count increment" (CCI)²² as follows:

$$\text{CCI at 1 hour} = \frac{(\text{platelet count}_{\text{post}} - \text{platelet count}_{\text{pre}}) \times \text{body surface area (m}^2\text{)}}{\text{number of units transfused}}$$

A CCI above 4000 to 5000/μL suggests an adequate response to platelet transfusion, although two consecutive poor CCIs in the absence of fever, splenomegaly, active bleeding, consumption, ABO incompatibility, or other

causes associated with increased platelet destruction suggest refractoriness.²³ Development of platelet immune refractoriness presents a vexing clinical problem. Many patients can be treated well with platelets from human leukocyte antigen (HLA)-compatible relatives or even unrelated matched donors. When such donors are unavailable, treatment of refractory patients by HLA "best-matching" or platelet cross-matches should be tried, but this may be cumbersome, expensive, and not uniformly efficacious. A computer-assisted matching program is proving increasingly helpful.²⁴ Repeated platelet transfusion in the absence of documented increments exposes patients to the potential risks of transfusion without evidence for any benefit and depletes an often scarce and costly blood resource.

Fresh Frozen Plasma

FFP is prepared by freezing the plasma component of a unit of whole blood within 6 to 8 hours of collection. Hemostatic activity of the coagulation factors is maintained even after storage for 1 year or longer, depending on the storage temperature. Once thawed, the plasma can be stored at a refrigerated temperature for no longer than 24 hours. On average, 1 mL of FFP contains 1 unit of each coagulation factor. However, the volume of a "unit" of FFP, the concentration of coagulation factors, and the citrate anticoagulant concentration are variable, depending on the donor blood composition and the anticoagulant solution used. In one study of individual units collected from 51 regular plasma donors, the 5th and 95th percentiles for factor V concentrations ranged from 69 to 127 U per deciliter and for factor VII from 83 to 169 U per deciliter, and the fibrinogen concentration ranged from 180 to 370 mg per deciliter and antithrombin III from 92 to 129 U per deciliter.²⁵

FFP remains the blood component of choice for patients with deficiencies of factors II, V, X, and XI who require treatment.²⁶ FFP is commonly used to treat bleeding patients with acquired deficiencies of multiple coagulation factors, such as those with DIC, liver disease, dilutional coagulopathy, and TTP. FFP may also be used for rapid yet temporary reversal of the coagulopathy induced by oral anticoagulants (see later); these patients may require vitamin K therapy for long-term control, and those with cerebral hemorrhage may benefit from the use of rFVIIa or the higher concentration of vitamin K-dependent factors contained in PCC.²⁷ FFP has also been employed for replacement of deficiencies of protein C or S or other anticoagulant proteins in patients with thrombophilia. Prophylactic administration of FFP has not been found to improve patient outcomes in the setting of massive transfusion unless bleeding is associated with documented coagulopathy; these patients should be followed with coagulation tests to guide replacement therapy.²⁸ Depending on the cause of the prolongation, mild prolongations of PT and PTT (<1.5 times midpoint of the normal laboratory range) do not mandate for FFP prophylaxis for trauma patients or for those scheduled to undergo elective invasive procedures^{29,30} (see Chapter 37). FFP transfusion in critically ill patients has limited efficacy and is associated with significant morbidity, in particular, pulmonary edema and acute lung injury.³¹ Indiscriminate transfusion of FFP for mild,

clinically insignificant prolonged PT may result in unnecessary allergic reactions and delays in diagnostic procedures.³ No clinical benefit has been documented.

Solvent detergent (SD) plasma is FFP that has been pooled and treated to inactivate lipid-encapsulated viruses such as human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). SD plasma is no longer available in the United States but is widely used in Europe. SD plasma has more uniform concentrations of coagulation factors and reduced concentrations of high molecular weight von Willebrand factor (VWF)—a potential advantage for therapy of TTP but a potential disadvantage in other hemostatic disorders.³² SD plasma also has reduced concentrations of protein S and α_2 -plasmin inhibitor.³² Use of SD in stable patients and in critically ill neonates, in women with obstetric and gynecologic emergencies, and in patients with liver disease appears safe and improves laboratory indices of coagulopathy.³³ The advantages of a product that is free of the major class of transfusion-transmitted viruses must be weighed against the potential disadvantages of trading a relatively safe single-donor component for one made from larger pools that may contain nonencapsulated viruses such as hepatitis A and parvovirus B19.

Cryoprecipitate

Cryoprecipitate is the cold insoluble fraction formed when FFP is thawed at 4°C. “Cryo” is rich in FVIII, FXIII, VWF, and fibrinogen.^{26,34} The product can be stored frozen at –20°C for up to a year. When resuspended in a plasma volume of 10 to 20 mL after preparation from single-donor plasma, cryoprecipitate contains 80 to 100 U of FVIII/VWF, representing 40% to 70% of the original amount in the plasma, 100 to 250 mg fibrinogen, and approximately 30% of the original amount of FXIII.³⁴ Because of its higher concentration of these factors compared with FFP, cryoprecipitate served for decades as the primary replacement therapy for patients with hemophilia A and VWD. Cryoprecipitate for first-line therapy has been replaced by DDAVP (see later) for most mild cases of either disease, and by virus-inactivated or recombinant preparations, and it should no longer be used for these purposes unless other therapies are not available. Similarly, the use of cryoprecipitate to treat uremic bleeding (10 U per treatment) has largely been supplanted by treatment with DDAVP, estrogen or RBC transfusion, and EPO.¹⁰ The use of cryoprecipitate as the source of fibrinogen for “home brewed” “fibrin glue” preparations is expected to disappear with the advent of standardized commercial products that contain virus-inactivated human fibrinogen³⁵ (see Chapter 29).

Currently, cryoprecipitate is used primarily as replacement therapy in patients with hypofibrinogenemia that is congenital (rare) or acquired (i.e., after thrombolytic therapy, DIC, plasmapheresis, or massive transfusions).^{11,26} When used for these indications, 10 to 20 units are normally pooled and infused, with repeat doses administered every 6 to 8 hours, depending on clinical status and measurements of laboratory tests of coagulation or fibrinogen concentration. Fibrinogen levels greater than 50 mg/dL are considered sufficient to support physiologic hemostasis, resulting in normal PT or PTT. Cryoprecipitate may also be useful for treatment of patients with FXIII deficiency, a rare

congenital deficiency, or an acquired disorder resulting from autoantibody formation.²⁶ Commercially prepared, virus-inactivated fibrinogen concentrates are not yet available in the United States.

ADVERSE EFFECTS OF BLOOD TRANSFUSION THERAPY

All single-donor components carry approximately equivalent risks for HIV, HBV, and HCV infection. In the United States, the most widely quoted estimate of the risk of HIV transmission is 1 in 2,135,000 U transfused; of human T-lymphotropic virus (HTLV), 1 in 2,993,000 U; of HCV, 1 in 1,935,000 U; and of HBV, 1 in 205,000 U from blood provided by repeat donors. Slightly higher risks are observed in blood obtained from first-time donors.³⁶ The overall risk of transmission of HIV or HCV from a blood unit is estimated to be on the order of 1 in 2,000,000.³⁶ New and emerging pathogens such as West Nile virus, babesia, and infectious prions continually threaten world blood supplies.³⁷ Thus, despite increasingly sophisticated testing and screening strategies, until activation procedures for cellular components become available, infections from current and emerging agents will prevent realization of a zero-risk blood supply.³⁸

Other adverse events are presently much more common than transfusion-transmitted viral infection. The reactions most often associated with transfusion are febrile nonhemolytic transfusion reactions (FNHTRs) from RBC or platelet transfusions, and urticarial reactions associated with FFP or plasma transfusion. These reactions are not life-threatening but may cause apprehension in the patient and may lead to significant delays in procedures or diagnostic studies until the cause has been determined. FNHTRs typically occur in less than 1% of transfusions overall but are more common with platelet transfusions and are observed in as many as 6% to 12% of adults with hematologic malignancies and in pediatric patients.³⁹ Urticarial allergic reactions may occur in 1% to 3% of transfusions of RBCs, platelets or FFP; anaphylactic shock occurs once per 20,000 to 47,000 U of blood components transfused.⁴⁰ Severe hemolytic transfusion reactions are associated almost exclusively with incompatible red cells, but hemolysis related to antibodies in plasma or platelet concentrates remains an important cause of morbidity and mortality.⁴¹ Acute hemolytic transfusion reactions due to intravascular hemolysis may occur in one in 25,000 U, and delayed hemolytic transfusion reactions occur 5 to 10 times more frequently.⁴¹ Both acute and delayed hemolytic reactions are associated with mortality, with estimated risks of 1 in 630,000 and 1 in 1,150,000 U, respectively.⁴¹ Errors that result in transfusion of ABO-incompatible units are responsible for most fatal acute hemolytic transfusion reactions.⁴²

The incidence of bacterial contamination and related shock is of particular concern in platelet transfusion. This component must be stored at room temperature and thus is particularly susceptible to bacterial growth. The true risk of contamination and frequency of reactions are unknown but are probably underreported. A wide variety of Gram-positive and Gram-negative organisms are associated with platelet contamination, and *Yersinia* species and other

cryophilic organisms are most frequently implicated in RBC transfusions.⁴³ An estimated 25% of cases of transfusion-related bacterial sepsis are severe, resulting in septic shock or death.⁴³

Estimates from early prospective studies indicate that bacterial contamination occurs in 0.3 of every 10,000 red blood cell units, 0.5 to 23 of every 10,000 apheresis platelet concentrates, and 5 to 30 of every 10,000 pooled random donor platelet concentrates.⁴³ Screening strategies recently introduced to detect bacterial contamination in plateletpheresis components can detect up to 75% to 90% of contaminated units prior to release, which increases transfusion safety.⁴⁴ Current screening tests reduce effective platelet shelf life by 24 to 48 hours and have less than 100% sensitivity and specificity; thus, significant efforts to develop new strategies to reduce bacterial contamination are ongoing.⁴⁴

Less common but dramatic and more severe reactions may occur as the result of transfusion-related acute lung injury (TRALI),⁴⁵ posttransfusion purpura (PTP),⁴⁶ and transfusion-associated graft-versus-host disease (TAGVHD).⁴⁷ The former two reactions are caused by plasma-containing components, and TAGVHD is associated with transfusion of cellular elements. These reactions are likely underdiagnosed, but each may be associated with clinically significant reactions.

TRALI is a life-threatening complication that occurs with severe acute pulmonary edema and hypoxemia associated with normal cardiac filling pressures that is indistinguishable from adult respiratory distress syndrome, occurring within 1 to 6 hours (usually within 1 to 2 hours) of plasma-containing blood component transfusion.⁴⁸ Treatment is supportive. The mechanisms of TRALI are unknown but likely involve a combination of immunologic effects mediated by HLA-specific antibodies or leukagglutinins in donor plasma, particularly in plasma obtained from multiparous female donors, and a neutrophil priming activity that depends in part on the patient condition.⁴⁹ According to one hypothesis, most instances of TRALI occur in a two-event model: first, a priming step involving adherence of polymorphonuclear white blood cells to the activated pulmonary endothelium in “at-risk” patients; second, infusion of antibodies directed against white blood cell antigens and/or biologic response modifiers from the stored blood component. In this model, patients at highest risk for TRALI include those with recent surgery, infection, volume overload, and other factors capable of pulmonary endothelial activation.

Because of the preexisting patient condition, TRALI may remain unsuspected as a cause of worsening pulmonary function and may go underdiagnosed. The true incidence of TRALI is unknown but may be as high as 0.34% of transfusions. TRALI reactions have been implicated in up to 12% of all transfusion-related fatalities and may be the single most common cause of death due to transfusion. Diagnosis and reporting of TRALI are important, so that the transfusion service can make an appropriate donor evaluation, including possible deferral from future donation.

PTP is characterized by dramatic precipitous thrombocytopenia occurring within 3 weeks of blood transfusion in a patient with a history of prior transfusion or pregnancy.⁴⁶ The sera of patients characteristically reveal the presence of

a potent antibody directed against donor platelet antigens that the recipient lacks. Profound thrombocytopenia occurs because of a poorly characterized reaction, resulting in destruction of transfused *and* autologous (patient) platelets, referred to as an “innocent bystander effect.” The syndrome is most common after RBC transfusions but may occur after infusion of single-donor plasma and platelet products. Patients are refractory to transfusion of antigen-negative or -positive platelets but may respond rapidly to intravenous immune globulin (IVIg) or plasmapheresis with albumin replacement. Steroid therapy is ineffective.

TAGVHD is far less common than TRALI, although the precise incidence remains unknown.⁴⁷ Its presentation mimics bone marrow transplant-related graft-versus-host disease, with the additional clinical finding of bone marrow aplasia, typically occurring 8 to 10 days (maximum of 4 weeks) after transfusion. TAGVHD occurs when immunocompetent donor T cells in the blood component engraft within the recipient. The most susceptible patients are those who receive transfusions from closely matched family members and those who are immunocompromised, including organ and bone marrow transplant recipients, premature infants, patients with particular neoplasms, and those receiving therapy with purine analogue agents for malignancy or for autoimmune disease.⁵⁰ Leukocyte reduction is not effective prophylaxis. Blood product irradiation prevents TAGVHD.⁵¹ Once present, TAGVHD is almost always fatal; thus, it is imperative that treating clinicians recognize at-risk patients and request blood product irradiation from the transfusion service.

Commercial Plasma Fractions

A variety of products prepared through special processing of plasma pools are used to treat patients with hemostatic disorders. Among the earliest preparations are the so-called PCCs, which are impure mixtures of vitamin K-dependent proteins that are isolated by ion exchange chromatography from the cryoprecipitate supernatant of large plasma pools after removal of antithrombin III and factor XI.⁵² Various processing techniques involving ion exchangers permit production of four-factor concentrates, which include factor VII, or three-factor concentrates which consist mainly of factors II, IX, and X. The PCCs are standardized according to their factor IX content.⁵² During production, activated clotting factors are produced that are later inactivated through a variety of processes, including manipulation of pH and addition of heparin and/or antithrombin III. These products may be further adjusted to produce activated PCCs used for treatment of patients with acquired FVIII or IX inhibitors (see Chapter 6). PCCs are now treated to inactivate transfusion-transmitted viruses. Adverse events associated with PCCs include immediate allergic reactions, heparin-induced thrombocytopenia (for preparations containing heparin), and thromboembolic complications such as DIC, arguably the most important adverse effect.⁵² PCC administration is indicated only when the desired increase in factor activity cannot be achieved through other therapeutic measures (see treatment of cerebral bleeding in excessive oral anticoagulation with vitamin K later). PCCs should not be used in the treatment of hemophilia B or congenital factor VII

deficiency, with the exception of emergency situations when specific factor replacements are not available.⁵³

Virus-inactivated, intermediate purity factor VIII preparations with high VWF content have replaced cryoprecipitate as the primary therapy for VWD.^{54–56} One of these products, Humate P (Centeon LLC, Kanakee, Ill, USA), has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of patients with VWD, and the package insert now provides the concentration of ristocetin cofactor activity required to facilitate dosing.

RECOMBINANTLY DERIVED PLASMA COAGULATION PROTEINS

Recombinantly derived coagulation factors, such as factor-VIII and IX preparations used to treat hemophilia A and B, are more expensive than virus-inactivated pooled products. However, these agents provide physicians and patients with a variety of products of high purity and safety and have become the mainstay of therapy for previously untreated patients and those newly identified with these disorders (see Chapter 4). Of special interest in the field of hemostasis and transfusion medicine has been the adaptation of rFVIIa, developed initially for the treatment of hemophilic patients with inhibitors,⁵⁷ to a much broader use in a wide variety of hemostatic disorders^{58,59} (see Chapter 6).

Recombinant Factor VIIa (rFVIIa) (NovoSeven)

Background

Since the first startling reports of hemostatic response in trauma patients with uncontrolled hemorrhage,^{59,60} a growing body of literature has addressed the use of rFVIIa in settings outside the therapy of hemophilic patients with high-titer inhibitors. Although treatment of hemophilic patients with inhibitors and, more recently, treatment of patients with congenital factor VII deficiency⁶¹ remain the only approved indications for rFVIIa in the United States, a body of published trials and anecdotal evidence describes the diversity of applications for this agent, reflective of its widespread use in community practice. Despite its high cost, rFVIIa is used in a variety of hemostatic disorders. Efficacy for these conditions, as well as appropriate dosing and laboratory monitoring, has not been fully established. A complete assessment of the risk:benefit ratio of rFVIIa, in light of its potential efficacy and a small but real incidence of significant toxicity, is not possible at the present time. Whether or not rFVIIa will achieve the promise of a safe, effective, broadly applicable or “universal” hemostatic agent continues to be debated.^{62,63} Until more information becomes available, this agent should be reserved for life-threatening or urgent bleeding not controlled by traditional methods or in situations in which compatible blood components are unavailable. An overview of rFVIIa is presented in Table 27-2.

Mechanism of Action

rFVIIa was developed to produce hemostatic “bypassing” activity, without the adverse events associated with the use of PCCs in the treatment of hemophilic patients with inhibitors.⁶⁴ Although the full spectrum of activity and the interrelated mechanisms responsible for its clinical

Table 27-2 Overview of Recombinant Factor VIIa

Action

In combination with tissue factor expressed on the cell surface at sites of injury acts to initiate coagulation with a small burst of thrombin produced via the factor X/factor V complex, leading to thrombin-mediated platelet activation and generation of factor IXa, resulting in a much larger burst of thrombin generation. May produce a stronger clot that is relatively resistant to fibrinolysis.

Administration

Administered as an intravenous bolus after reconstitution (20 minutes) by pharmacy, at 90 µg per kilogram for hemophilic patients with inhibitors, which, along with congenital factor VII deficiency, is the only approved indication in the United States.

Doses in other settings are not well established. Smaller doses of 20 to 40 µg per kilogram may be effective in oral anticoagulant reversal. A vial-based dosing algorithm that uses patient weight and indication has been used by some experienced transfusion services.⁷³

Repeat dose is based on clinical response within 2 hours. No widely applicable satisfactory monitoring algorithms have been developed. Excess dosing should be avoided.

General Use

Control of bleeding hemophilia with inhibitors to factor VIII, factor IX, and congenital factor VII deficiency, and von Willebrand disease with von Willebrand factor inhibitors. Urgent hemostasis in factor XI deficiency, thrombocytopeny, refractory thrombocytopenia, diffuse alveolar hemorrhage, trauma, and massive transfusion.

May be useful in “blood avoidance surgery” for patients whose clinical conditions or religious beliefs are incompatible with blood component therapy.

Possible Contraindications

Unlikely to be effective in patients with severe thrombocytopenia and zero levels of fibrinogen, factor V or X.

Consider giving concomitantly with fresh frozen plasma or platelets.

Use cautiously in disseminated intravascular coagulation.

Toxicity

Associated with a slight but real increased background incidence of arterial and venous thromboembolic events that may increase with higher doses or repeated dosing.

Contraindicated in patients with known hypersensitivity to manufacturing components.

activity have not been fully elucidated,^{64,65} evidence suggests that the effects of this agent extend beyond those that are measurable through traditional in vitro assessments of hemostasis. In a cell-based model of coagulation described by Roberts, Hoffman, and Monroe (Fig. 27-1), rFVIIa, in combination with tissue factor (TF) locally exposed on damaged cell surface and factors V and X, generates thrombin, which catalyzes a series of reactions on the platelet membrane involving factors XI, VIII, and IX to cause platelet activation, release of VWF, and yet a larger burst of thrombin that further augments hemostasis. In addition to coagulation and platelet activation effects, thrombin activates factor XIII, resulting in fibrin crosslinking. The high local concentrations of thrombin produce a stable clot structure that is relatively resistant to fibrinolysis⁶⁶ and further counteracts fibrinolysis through activation of the thrombin activatable fibrinolysis inhibitor (TAFI).⁶⁷

Figure 27-1 Hemostatic effects of recombinant factor VIIa, illustrated according to a cell-based model of coagulation. In combination with tissue factor expressed on the cell surface at sites of injury, recombinant factor VIIa acts to initiate hemostasis with a *small burst* of thrombin produced via the factor X/factor V complex. This leads to thrombin-mediated platelet activation and generation of factor IXa, resulting in coagulation caused by the much *larger burst* of thrombin generation. In addition to the effects on platelet activity and thrombin generation, this may result in a stronger clot that is relatively resistant to fibrinolysis. (Used with permission from HR Roberts 2006.)

Additional considerations for the clinical use of rFVIIa involve hypothermia and acidosis. Hypothermia inhibits platelet adhesion at mild temperatures (33°C to 37°C) and both platelet adhesion and coagulation at lower temperatures (below 33°C); acidosis further inhibits coagulation and can worsen hemorrhage.⁶⁸ Clinical anecdotal experience suggests that rFVIIa is effective in some hypothermic patients with acidosis; in vitro⁶⁸ and clinical studies indicate that activity is more significantly reduced by acidosis than by hypothermia.⁶⁹ The concomitant existence of hypothermia and acidosis complicates interpretation of the rFVIIa response, especially in trauma settings. Efforts to prevent hypothermia, maintain perfusion, and correct acidosis should be considered in the application of rFVIIa and in the interpretation of its response (see Chapter 46).

Dose and Administration

The appropriate dose of this agent has not been established outside of the recommendations given for patients with hemophilia. Dose drives costs to some extent for many aspects of medical therapy; at an average wholesale price of \$1.60 per unit for rFVIIa in 2006, costs of \$1908, \$3816, and \$7632 for available vial sizes of 1200, 2400, and 4800 µg, respectively, or \$10,000 for a 70-kg individual treated at 90 µg per kilogram, are reminiscent of initial costs for recombinant FVIII therapy but involve an agent with a much broader and less clearly defined patient population.

rFVIIa has a short half-life in the circulation of 2 to 3 hours, and although circulating levels are not predictive of local response, the agent is given as an intravenous bolus every 2 to 3 hours until bleeding stops.^{64,65} The package insert recommended dose is 90 µg per kilogram for hemophilic patients with inhibitors; effective doses of 20 to 25 µg per kilogram have been described in patients

with congenital factor VII deficiency.⁶⁵ Low doses in the range of 20 to 40 µg per kilogram have been effective for control of excessive oral anticoagulation⁷⁰ and as prophylaxis against surgical bleeding,⁷¹ although higher doses are favored by some investigators.⁷² In nonhemophilic patients, follow-up treatment schedules are problematic, and administration must be based on clinical response. After administration of the initial dose and formation of a stable clot at the site of bleeding in responding patients, repeat dosing may not provide further benefit and may result in increasing concentrations of rFVIIa at other nonbleeding sites with the potential for toxicity due to thrombosis. In patients who do not respond to the initial dose, repeated administration after a second dose may be a futile but costly approach. Issues of cost and vial wastage and lack of established dosing regimens have led transfusion services to develop vial-based dosing algorithms for rFVIIa based on the clinical condition and a broader range of patient weights.⁷³

No laboratory monitoring tests have been clinically established to guide dosing or response,⁷⁴ and consideration of repeat dosing must be based on clinical response. This is not surprising given that the multiple interrelated mechanisms responsible for the activity of rFVIIa act at the site of tissue injury and may not be readily reflected in systemic circulation blood samples. In most patients, significant shortening of PT and PTT is observed, and the degree of shortening in trauma settings has been shown to correlate roughly with control of bleeding.⁷² Preliminary studies indicate that rFVIIa may be futile in patients suffering from severe acidosis, or in those with markedly prolonged PT, poor prognosis trauma score, or elevated lactic acid levels.⁶⁹ Fibrinogen levels must be adequate (>40 to 50 mg per deciliter) to support clot formation. However, considerable overlap has been noted in these

responses, and the results in practice are difficult to use to guide initial therapy. It has been proposed that more global assessments of hemostasis that more accurately reflect the kinetics of clot formation, such as the thromboelastogram (TEG), may provide a more reliable assessment of activity.⁷⁴ At the present time, these tests provide limited practical information but possibly may reassure clinicians that high-dose therapy has not produced a thrombogenic coagulation profile.⁷⁴

Indications

Treatment of patients with hemophilia A or B who have developed inhibitors to factors VIII and IX, respectively, and, more recently, treatment of patients with congenital factor VII deficiency are the only FDA-approved indications for the use of rFVIIa in the United States⁶¹; however, in Europe, this treatment is also indicated for use in patients with Glanzmann thrombasthenia.⁷⁵ On the basis of its mechanism of action, rFVIIa would not be expected to provide hemostasis in patients without measurable levels of fibrinogen, factor V, or factor X, or in those with severe thrombocytopenia who have counts below 5000 per microliter,⁶⁵ in which case concomitant infusion of cryoprecipitate, FFP, or platelet concentrates has been attempted to provide a minimal level of substrates.⁷⁶

Patients with coagulation factor deficiencies, thrombocytopenia, and qualitative platelet defects have been successfully treated with rFVIIa.^{64,65} In factor VII-deficient patients, doses of 15 to 20 µg per kilogram are administered every 2 to 3 hours, and in factor XI deficiency, doses ranged from 90 to 120 µg per kilogram given according to a similar schedule.^{77,78} rFVIIa has been used in patients with both quantitative and qualitative platelet defects.^{79,80} In one study of rFVIIa administration to patients with thrombocytopenia, shortening of the bleeding time by at least 2 minutes occurred after administration of 50 or 100 µg per kilogram of rFVIIa in 32% of patients with platelet counts lower than 20,000/µL, in 56% of those with counts of 21,000 to 39,000/µL, and in 68% of those with counts of at least 40,000/µL.⁵⁸ In this same study, full control was attained in 66%, and partial control in 33% of 9 bleeding episodes, which occurred in eight patients treated with rFVIIa; no association was observed between dose and response.⁵⁸ Similarly, in an international survey of responses to rFVIIa in Glanzmann thrombasthenia, responses were observed in 29 of 31 procedures and in 77 of 103 bleeding episodes, with "optimal" efficacy observed when a bolus of at least 80 µg per kilogram was repeated every 2.5 hours as needed.⁸⁰ As in the hemophilia setting, rFVIIa may be useful for patients with VWD who have developed antibodies against VWF or who have failed to respond to conventional therapy.⁸¹

Two recent placebo-controlled studies evaluated the use of rFVIIa in orthotopic liver transplantation (OLT), which may be associated with excessive blood loss from surgical causes, decreased concentrations of coagulation factors, hyperfibrinolysis, and thrombocytopenia. Planinsic and associates⁸² randomly assigned 83 patients who were undergoing OLT for end-stage liver disease to treatment with placebo or a single bolus dose of 20, 40, or 80 µg per kilogram rFVIIa given 10 minutes before surgery, resulting in a significant reduction in requirement for FFP in the 80 µg per kilogram group.⁸² A larger study compared

the efficacy and safety of doses of 60 µg per kilogram and 120 µg per kilogram rFVIIa given 10 minutes prior to skin incision, followed by repeat dosing every 2 hours until 30 minutes prior to the expected start of reperfusion of the transplanted liver.⁸³ Of the group of 179 patients who completed the observation period, 10% in the 60 µg per kilogram group avoided transfusion, as did 7% in the 120 µg per kilogram group and 0% of placebo-treated subjects ($P < .03$). No thromboembolic events or hepatic artery occlusions occurred in either of these studies. In patients with cirrhosis, rFVIIa shortened PT to normal or near normal values after doses of 5, 20, and 80 µg per kilogram without adverse effects.⁸⁴ In another study involving liver biopsy, rFVIIa dosed at 5, 20, 80, and 120 µg per kilogram resulted in a maximum reduction in PT values 30 minutes after dosing; a longer duration of shortening occurred with 80 and 120 µg per kilogram doses, and achievement of hemostasis occurred within 10 minutes of dosing in 74% of patients who were assessed by direct visualization via laparoscopic biopsy, with no effects attributable to treatment dose.⁸⁵ In contrast to these studies, no beneficial effects compared with placebo were observed after rFVIIa infusion (20 or 40 µg per kilogram 5 minutes prior to infusion) in patients who underwent partial hepatectomy.⁸⁶

rFVIIa has been increasingly applied for reversal of oral anticoagulation⁸⁷—a setting in which responses frequently are observed at doses much lower than 90 µg per kilogram. In a group of volunteers pretreated with acenocoumarol in which the international normalized ratio (INR) was elevated to >2 , and factor X and factor IX levels were reduced from between 9% and 46%, a single dose of rFVIIa given at 5 µg per kilogram normalized the INR within 12 hours, and doses of rFVIIa >120 µg per kilogram were found to correct INR for periods of 24 hours without signs of systemic coagulation.⁸⁸ In a clinical study of 13 patients with critically increased INR caused by warfarin-induced anticoagulation (including five in which the INR was >10 , four who were at risk of clinical hemorrhage, and four who underwent procedures involving bleeding risk requiring immediate reversal), rFVIIa given at doses ranging from 15 to 90 µg per kilogram was associated with rapid and effective responses, with elevated INRs, and avoidance or reversal of bleeding.⁷⁰ In addition, in seven patients who experienced intracranial hemorrhage while receiving oral anticoagulants, doses of rFVIIa between 10 and 40 µg per kilogram were effective in augmenting hemostasis and in lowering the INR from pretreatment values of 1.7 to 6.6 down to less than 1.5 within 10 minutes.⁸⁹

A recent double-blind, placebo-controlled study in patients with acute intracerebral hemorrhage who were not taking oral anticoagulants compared the effects of treatment with 40 µg per kilogram (108 patients), 80 µg per kilogram (92 patients), and 160 µg per kilogram (103 patients) of rFVIIa versus placebo (96 patients) given within 1 hour of diagnostic computed tomography (CT) (see Chapter 43).⁹⁰ Compared with a 29% growth in hematoma volume among placebo-treated patients, reduced growth at 24 hours was observed in the 40, 80, and 160 µg per kilogram rFVIIa treatment groups (16%, 14%, and 11%, respectively). Pooled data for all doses of rFVIIa indicated that treatment resulted in a 52% relative reduction in hemorrhage volume growth compared with placebo ($P = .01$). A 38% relative reduction in mortality at

3 months was reported for patients receiving rFVIIa (placebo 29% mortality vs 18% mortality for all doses of rFVIIa; $P = .02$), along with an absolute reduction in the risk of death or severe disability (death/disability: 69% placebo vs 53% for all doses of rFVIIa combined; $P = .004$ for all doses vs placebo). No dose response was associated with survival or disability; however, a significant increase in arterial thrombotic events was observed in rFVIIa-treated patients (see toxicity discussion later).

In spite of the dramatic response described in the initial report of successful use of rFVIIa for a rapidly exsanguinating patient with acidosis, hypothermia, and DIC due to a high-velocity gunshot injury,⁵⁹ it has been surprisingly difficult to clearly define the efficacy and optimal dose of rFVIIa in trauma settings.⁶⁹ Although recent placebo-controlled studies have revealed a trend toward improved survival and have pointed toward a reduced incidence of massive transfusion and reduction in RBC transfusion requirements in patients with blunt and penetrating trauma,⁷² the overall benefits in randomized trials have not reflected the dramatic responses described in anecdotal reports or contained in the personal experience of many treating clinicians. Although human trials have not been powered to study survival end points,⁷² results with animal models in the laboratory have yielded conflicting data, with favorable responses reported in some studies⁹¹ and no effect described in others.⁹² Although some trauma guidelines suggest an initial dose as high as 120 µg per kilogram,⁹³ even higher doses have been used,⁷² while responses have been observed with doses as low as 20 µg per kilogram⁹⁴ or 60 µg per kilogram, as described in the initial report.⁵⁹ These clinical ambiguities are illustrated in a retrospective analysis of rFVIIa use in 40 patients with massive bleeding who were unresponsive to conventional therapy, in which 18 stopped bleeding completely and 14 experienced significant slowing of bleeding, for an

overall response of 80% (Fig. 27-2). The median number of doses of rFVIIa used was two (range, 1 to 18), and individual doses ranged from 15 to 180 µg per kilogram. Only two patients had a history of trauma, and no evidence suggested a dose response in patients who achieved hemostasis or in those with thromboembolic complications (see toxicity discussion later).⁹⁴

A large number of reports describe the use of rFVIIa in other settings. A small double-blind study of suprapubic prostatectomy that compared placebo (12 patients) with two different doses of rFVIIa (20 µg per kilogram [8 patients] and 40 µg per kilogram [16 patients]) found a significant dose-dependent reduction in perioperative blood loss (1235 mL and 1089 mL in the 20 and 40 µg per kilogram groups, respectively, vs 2688 mL in the placebo group [$P = .001$]), along with reduced operating room times for treated patients compared with controls.⁷¹ No patients in the 40 µg per kilogram group received transfusions of any type, whereas more than half of those in the placebo group required allogenic RBC transfusion. This study is notable for the higher than expected RBC transfusion requirements in the placebo group, and it is similar in this respect to earlier randomized, blinded, placebo-controlled studies that pointed toward a beneficial effect of DDAVP on transfusion requirements in coronary artery bypass grafting.⁹⁵

A more recent randomized, double-blind study of rFVIIa 90 µg per kilogram or placebo given to 48 patients who underwent semi-elective open reduction on traumatic pelvic and pelvic acetabular fractures reported only very modest results, with greater measured operative blood loss in rFVIIa-treated than in placebo-treated patients (2070 mL vs 1535 mL) and a trend over 48 hours that was not statistically significant toward reduced transfusion requirements (46% vs 67%) and reduced overall blood loss (2146 mL vs 2787 mL).⁹⁶ Similarly, no convincing efficacy

Figure 27-2 Individual responses according to control of bleeding and thromboembolic events in 40 patients (x axis) who received recombinant factor VIIa for intractable bleeding according to dose (y axis). Toxicity occurred in three patients (black bars)—two at the site of prior vascular manipulations and one with multiple pulmonary emboli in the setting of disseminated intravascular coagulation and occult lymphoma. Non-responding patients are shown as white bars. No relationship was noted between dose, response and toxicity in this retrospective study of data maintained on a nationwide registry. (Reproduced with permission from O'Connell NM, et al: Recombinant FVIIa in the management of uncontrolled hemorrhage. *Transfusion* 43:1711–1716, 2003.)

of rFVIIa therapy was observed in 100 patients with moderate or severe bleeding (lower or upper gastrointestinal tract; hemorrhagic cystitis; pulmonary, intracerebral, and other sites) that occurred 2 to 180 days after hematopoietic stem cell transplantation, as assessed in a double-blind design in which placebo was compared with 40, 80, or 160 µg per kilogram of rFVIIa administered every 6 hours for 36 hours.⁹⁷ Although patients who received the intermediate dose of 80 µg per kilogram were found to have reduced bleeding scores in a post hoc analysis, no significant reduction in transfusion requirements was observed among the treatment groups, and authors concluded that additional trials should be conducted to identify patients in this setting for whom rFVIIa is effective. Successful use of rFVIIa has also been described for control of bleeding in cardiac surgery,⁹⁸ pancreatitis,⁹⁹ refractory postpartum hemorrhage,¹⁰⁰ hemorrhage associated with low molecular weight heparin (LMWH),¹⁰¹ and other conditions.⁶³ However, the use of rFVIIa in fit, healthy patients with normal laboratory results appears unwarranted during elective surgery in the absence of special circumstances that may justify its use.⁹⁶

Toxicity

Initial assessments from clinical studies and registry data indicate a rate of serious complications of about 1%.¹⁰² More recent data support an overall beneficial safety profile for patients with life-threatening hemorrhage associated with a small but real incidence of thrombotic events such as cerebrovascular accident, acute myocardial infarction, other arterial thrombosis, pulmonary embolism, and clotted devices in approximately 1% of 4520 estimated patients treated during the year 2004 (including 10 deaths).⁶¹ Other non-life-threatening complications, such as rash, nausea, and allergic reactions, possibly related to the manufacturing process, may occur. Data collected in a smaller registry from the United Kingdom involving surgical and nonsurgical causes of bleeding revealed thrombotic complications in 3 of 40 (7.5%) evaluable patients, including two at sites of vascular manipulation and one with pulmonary emboli in a background of occult lymphoma, with no relationship noted between dosing and complications.⁹⁴ No data have established the safety or efficacy of rFVIIa in pregnancy, outside of anecdotal reports on postpartum hemorrhage and other obstetric complications.

More rigorous safety data in the setting of treatment for intracerebral hemorrhage were described by Mayer and colleagues,⁹⁰ who reported serious arterial thrombosis in 0 of 96 placebo-treated patients versus 16 (5%) of 303 rFVIIa-treated patients (including 6 of 108 [6%] at 40 µg per kilogram, 2 of 92 [2%] at 80 µg per kilogram, and 8 of 103 [8%] at 160 µg per kilogram; $P = .012$ for all rFVIIa groups vs placebo), as well as serious venous thrombosis in 2 (2%) placebo-treated patients versus 5 (2%) rFVIIa-treated patients (1% at 40 µg per kilogram, 2% at 80 µg per kilogram, and 2% at 160 µg per kilogram).⁹⁰ Overall survival and morbidity favored rFVIIa-treated patients; however, the manufacturer has released a safety warning as a result of this study to alert treating clinicians to the potential for thrombotic complications in “off-label” indications.⁶¹

The package insert also advises that thromboembolic risk may be increased in patients who have DIC, crush

injury, and septicemia.⁶¹ Despite this warning, a number of anecdotal reports describing safety in sepsis and DIC indicate that cautious use of rFVIIa may be beneficial in life-threatening bleeding in this setting,¹⁰² without the degree of thrombosis that is associated with lysine analogue antifibrinolytic agents.¹⁰³ Similarly, although caution has also been advised when rFVIIa is used in conjunction with other hemostatic agents, anecdotal reports have described efficacy and safety when it is used concomitantly with antifibrinolytic agents^{94,104} or after PCC use.¹⁰⁵ Thus, the appropriate application, dosing, and toxicity profile of rFVIIa are not yet fully known and remain areas of active clinical investigation.

PHARMACEUTICAL AGENTS

Pharmaceutical agents are occasionally used for replacement therapy but are more commonly used as adjunctive therapy along with blood products in the treatment of patients with hemostatic disorders.^{10,106} A broad spectrum of agents is available. For example, DDAVP, a synthetic analogue of L-vasopressin, can be used for most mild forms of hemophilia A and VWD, and it is increasingly recognized to have multiple less well-defined effects that have been applied in a variety of hemostatic defects. Lysine analogues that inhibit fibrinolysis, such as ε-aminocaproic acid (EACA) and tranexamic acid (AMCA), are used systemically and locally for acquired and inherited defects in hemostasis and thrombocytopenia. Aprotinin, a bovine-derived serine protease inhibitor with potent antifibrinolytic activity, has been widely used to enhance surgical hemostasis after cardiopulmonary bypass. Vitamin preparations in the naphthoquinone family (vitamin K) are used to prevent neonatal bleeding syndromes and to reverse warfarin anticoagulation or to treat patients who have ingested super-warfarin-like rodenticides. Other agents may be used as well, such as estrogens to treat uremic bleeding and protamine to reverse heparin-induced anticoagulation. With the rapid advent of rFVIIa therapy for diverse hemostatic disorders, the choice of optimal therapy in many settings has not been established, and this decision awaits the findings of future studies. An overview of selected hemostatic agents is provided in Table 27-3.

DDAVP

Background

The agent 1-deamino-8-D-arginine vasopressin (DDAVP), or desmopressin, is a synthetic analogue of the antidiuretic hormone L-vasopressin¹⁰⁷ that has been used to control bleeding in patients with mild congenital or acquired bleeding disorders for longer than 25 years.^{108,109}

DDAVP may be self-administered by patients at home to prevent or treat bleeding episodes.¹⁰⁸ DDAVP is not a general hemostatic tonic reducing blood loss in all surgical settings.^{110–112} It seems most efficacious in patients with prior aspirin ingestion¹¹³ or possible platelet dysfunction from other causes.¹¹⁴ An overview of DDAVP is presented in Table 27-4. Current uses of DDAVP in adults and children have been summarized in several comprehensive reviews.^{108,115}

Table 27-3 Overview of Hemostatic Agents

Amicar (ϵ -aminocaproic acid) is manufactured by Wyeth Ayerst, Madison, NJ, USA.

Table 27-4 Overview of DDAVP

Action

Releases stored FVIII and VWF within 30 to 60 minutes; peak effect at 2 to 4 hours, lasts 6 to 12 hours. Has other hemostatic effects on platelets and endothelium.

Administration

Daily by intravenous, subcutaneous, and intranasal routes. Does not require concomitant use of antifibrinolytic agents. Tachyphylaxis may occur at more frequent dosing intervals or after several daily administrations.

General Use

Short-term control of various bleeding states. Initial efficacy usually preestablished with a test infusion. Primary therapy for mild hemophilia A and VWD. More useful for type 1 than type 2 VWD, may be useful in some cases of severe type 3 VWD. Widely used to control bleeding in acquired and congenital platelet defects, as well as in other conditions. Efficacy in this setting is less well defined because of the lack of appropriate tests to assess platelet function. Use in surgical setting is not consistently associated with clinical improvement, except after aspirin ingestion. Aprotinin and antifibrinolytics are superior in cardiac bypass. Efficacy may be improved for selected patients in whom platelet defects were identified by perioperative testing.

Possible Contraindications

Worsens thrombocytopenia in some patients with type 2B VWD. Use cautiously in elderly patients and those with coronary artery disease.

Toxicity

Mild flushing and nausea are most common. Water retention and hyponatremia which can be associated with seizures and headaches. Possibly associated with myocardial infarction in the cardiac bypass setting.

DDAVP, 1-deamino-8-D-arginine vasopressin; FVIII, factor VIII; VWF, von Willebrand factor; VWD, von Willebrand disease.

Mechanisms of Action and Tachyphylaxis

The best characterized hemostatic activity of DDAVP involves its effect on raising circulating FVIII and VWF levels—an effect that appears to be due to its chemical similarity to vasopressin.^{107,108} Compared with vasopressin, DDAVP has increased affinity for V-1 receptors that cause renal free water retention and rapid release of preformed FVIII and VWF from cellular stores, as well as markedly

decreased affinity for V-2 receptors that mediate vasoconstriction.¹⁰⁷ In normal subjects, DDAVP increases FVIII and VWF levels within 30 minutes of infusion.¹¹⁶ Levels peak at 300% to 400% of baseline in 1 to 2 hours and persist for 6 to 12 hours.¹⁰⁸

DDAVP also induces a transient fivefold to sevenfold increase in tissue plasminogen activator (tPA) activity with resultant generation of plasmin, but the excess plasmin is rapidly counteracted by endogenous levels of α_2 -plasmin inhibitor.¹¹⁷ Adhesion of RBCs and platelets to endothelial cells is increased by DDAVP when studied in vitro.^{118,119} These effects may be produced by direct action on the vessel wall,¹¹⁹ or possibly by release of high molecular weight VWF at the endothelial cell surface.¹²⁰ In addition, shear stress at the vessel wall is decreased after DDAVP is infused in patients with congenital platelet defects, possibly as the result of higher circulating levels of high molecular weight multimers.^{121–123} Other studies have shown that DDAVP may also (1) increase platelet microparticle formation,¹²⁴ (2) enhance the expression of TF on endothelial cells,¹²⁵ and (3) promote the expression of P-selectin¹²⁶ and the adhesive glycoprotein Ib on platelet membranes.¹²⁷ One or more of these or other unidentified effects may explain the observations that DDAVP shortens bleeding times in patients with severe VWD who have already received cryoprecipitate infusions¹²⁸ and in those with qualitative platelet disorders such as uremia,¹²⁹ liver disease,¹³⁰ or other acquired or congenital conditions^{130–132} in which levels of FVIII and VWF are usually normal. In some studies, patients who had previously experienced severe bleeding during surgery attained adequate surgical hemostasis after they were given DDAVP.¹³²

The mechanisms of action of DDAVP explain some important clinical observations. First, infusion in hemophilia A and VWD produces short-term increases in circulating FVIII and VWF, levels of which decrease after initial release from preformed cell stores.¹⁰⁸ DDAVP has been used alone in these conditions for brief minor surgical procedures, endoscopy, or dental work, but it is inadequate for procedures that require prolonged (i.e., >2 to 3 days) hemostasis. Second, repeat administration of DDAVP at less than 24-hour intervals or over several days is associated with tachyphylaxis caused by reduced laboratory and clinical responses.¹³³ The blunted response is presumably related to depletion of intracytoplasmic stores of FVIII and VWF. The pattern of tachyphylaxis is not predictable and is more marked in general for patients with hemophilia A compared with those with VWD. In one study of daily dosing, responses after a second dose were 30% of the first

Table 27-5 Hemostatic Preparations of DDAVP

Route	Concentration	Dose*	Volume	Cost†	Peak Response‡
Intravenous	4 µg/mL	21 µg (0.3 µg/kg)	5.25 mL (in 50 mL saline)	\$116.00 per dose	30–60 minutes
Intranasal spray (Stimate)	1.5 mg/mL	One spray per nostril, 300 µg total	0.1 mL per spray	\$46.00 per dose	90–120 minutes
Subcutaneous	4 µg/mL	21 µg (0.3 µg/kg)	5.25 mL	\$116.00	90–120 minutes
Subcutaneous§	40 µg/mL§	21 µg (0.3 µg/kg)	0.52 mL	Not available in United States	90–120 minutes

Stimate is manufactured by ZLB Behring LLC, King of Prussia, Pa, USA.

day response, but responses were not further reduced after the third and fourth doses.¹³³ In contrast to the diminished FVIII and VWF responses reported after repeated doses, fibrinolytic,¹³⁴ renal,¹⁰⁷ and platelet responses do not appear altered when doses are repeated frequently.¹³⁵ Although the hemostatic response to initial administration of DDAVP varies among patients, it is usually reproducible for a given patient.¹³³ Ideally, patients who may be given DDAVP should receive an initial test infusion at least several days prior to any planned invasive procedures to determine response.

Dose and Administration

DDAVP may be administered by intravenous, subcutaneous, and intranasal routes (Table 27-5). The intravenous dose is 0.3 µg per kilogram, administered over 30 minutes in 50 mL of normal saline for adults (and in 10 mL for children weighing less than 10 kg). The maximum response occurs at intravenous doses of 0.3 µg per kilogram. The subcutaneous dose is 0.3 to 0.4 µg per kilogram, and peak responses occur approximately 230% above baseline at 60 minutes after administration (slightly lower and later than the peak dose after intravenous administration). The intranasal dose is an order of magnitude higher than the intravenous or subcutaneous dose, generally 300 µg in adults. Higher doses do not enhance efficacy but may be associated with increased toxicity. A concentrated nasal spray formulation is available in the United States and in Europe. However, a concentrated preparation for subcutaneous use is not available in the United States, and the substantial volume required (7 mL for a 70-kg person) cannot be easily administered by subcutaneous injection. DDAVP is cleared by the liver and kidneys and has a plasma half-life of 124 minutes. Because many of its known hemostatic effects are caused indirectly, drug levels may be more relevant to renal effects and toxicity than to hemostasis.¹³⁶

Indications

No controlled studies have evaluated the use of DDAVP compared with placebo or factor concentrates in patients with hemophilia A and VWD.¹⁰⁸ Because the bleeding tendency in hemophilia A, and to a lesser degree in VWD, correlates with measured blood levels of the deficient factor, the ability of DDAVP to transiently raise levels of FVIII and VWF has resulted in its approval for use in these disorders. DDAVP is now the treatment of choice for minor and even moderately invasive procedures in patients with these

disorders who respond to a test infusion. More recent data highlight the variable activity of DDAVP in patients with VWD, indicating that the frequency of responders is relatively low when strict criteria are used, which may be defined as increases in FVIII and VWF ristocetin cofactor activity of at least 30 IU per deciliter and threefold over baseline, and shortening of the bleeding time to 12 minutes or less (Fig. 27-3).¹³⁷ Although FVIII and VWF ristocetin cofactor activity responses occurred in most patients, a complete response, including shortening of the bleeding time, was observed in only 7 of 40 patients with type 1 VWD (18%), in 1 of 15 with type 2A (7%), in 3 of 21 with type 2M (14%), and in 3 of 4 with type 2N (75%).¹³⁷ In this study, VWD genotype was more predictive of response than was phenotype in types 2A and 2N, but not in type 1 VWD, underscoring the need for a test infusion and assessment of response in individual patients. This has caused some to question if shortening of the bleeding time is an appropriate objective.

The use of DDAVP in type IIB VWD is controversial in that patients may develop mild thrombocytopenia related to affinity of the VWF for platelets.⁵⁶ Infusion of DDAVP and release of endogenous VWF stores into the circulation may worsen thrombocytopenia. Nevertheless, several studies have reported improved hemostasis in type IIB VWD after infusion of DDAVP associated with little or only mild thrombocytopenia. Therefore, it is reasonable to consider the use of DDAVP in carefully selected patients with type IIB VWD.^{138,139} Although most patients with severe VWD do not respond to DDAVP, a minority may achieve sufficient increases in FVIII levels to provide hemostasis for minor procedures.¹⁴⁰ In patients with severe hemophilia A, FVIII levels do not increase after DDAVP infusion; however, DDAVP may provide potential benefit by increasing VWF levels, resulting in an associated increased response in activity of infused FVIII concentrates.¹⁴¹ DDAVP may also further shorten the bleeding time in patients with severe VWD who did not fully respond after cryoprecipitate infusion, possibly because of nonspecific effects on hemostasis.¹²⁸ Finally, DDAVP is useful in some mild cases of acquired VWD¹⁴² but not when the disease is immune mediated, or when acquired VWD is associated with monoclonal gammopathy of uncertain significance.¹⁴³

DDAVP augments hemostasis in a variety of acquired and congenital conditions with impaired hemostasis and limited treatment options.¹⁰⁸ In one double-blind, placebo-controlled study of patients with congenital platelet defects, DDAVP shortened the bleeding time most

Figure 27-3 Biologic responses in factor VIII:C (left), ristocetin cofactor activity (middle), and bleeding time (right) after administration of DDAVP (1-deamino-8-D-arginine vasopressin) (0.3 μ g per kilogram) to 26 patients with type 1 von Willebrand disease (VWD) (A), 15 patients with type 2A VWD (B), and 21 patients with type 2M VWD (C). A complete response, defined as at least a threefold increase in levels for factor VIII:C and ristocetin cofactor activity with a bleeding time of less than 12 minutes, was observed in only 27% of patients with type 1 VWD, as well as in 7% of those with type 2A, and 14% of patients with type 2M VWD. The variability of response underscores the importance of assessment of response after administration of a test dose of DDAVP in patients who have not previously been treated with this medication. (Reprinted with permission from Federici AB, Mazur C, Berntorp E, et al: Biologic response to desmopressin in patients with severe type 1 and type 2 von Willebrand disease: Results of a multicenter European study. *Blood* 103:2032–2038, 2004.)

effectively in those with normal platelet–dense granule stores.¹⁴⁴ DDAVP has also reduced the bleeding time or has provided adequate surgical hemostasis in patients with storage pool defect,^{131,145} Bernard-Soulier disease,¹⁴⁶ aspirin ingestion,¹³⁵ and other defects in platelet function.^{108,132} DDAVP has been administered to patients with Ehlers-Danlos syndrome¹⁴⁷ and to those with mild factor XI

deficiency.¹⁴⁸ DDAVP shortens the bleeding time in some hemorrhagic diseases of multifactorial origin, such as hepatic cirrhosis and uremia. The usefulness of DDAVP in these conditions should be extrapolated with caution.

Except in surgical studies of transfusion requirements after aspirin ingestion, most studies have determined the efficacy of DDAVP by observing a shortening of the

bleeding time and/or by assessing surgical hemostasis without controls and in only a small numbers of patients. Because bleeding time is a poor predictor of surgical bleeding, interpretation of these studies is problematic.¹⁴⁹ It may, however, be reasonable for the clinician to consider the use of DDAVP in these conditions when other treatments are not available, and after hemostasis has been maximized with the use of local measures, such as fibrin sealant or other agents.

Bleeding symptoms did not improve and may have worsened when DDAVP was combined with the vasoactive agent terlipressin for the treatment of acute variceal hemorrhage in patients with hepatic cirrhosis, perhaps because of competitive inhibition of drug activity.¹⁵⁰ Similarly, its use in uremia seems to be diminishing as increasing use of EPO and higher baseline hematocrits have decreased the frequency of uremic bleeding.¹⁰ Other approaches may be useful in uremia; long-term control may be achieved with the use of estrogens, and patients with short-term bleeding may respond to RBC transfusions.¹⁰⁶

Initial reports that DDAVP decreased blood loss and transfusion requirements after cardiac and spinal surgery have not been confirmed in follow-up studies.¹⁰⁸ A recent large meta-analysis revealed no reduction in bleeding after the use of DDAVP in cardiac surgery, in contrast to comparative studies with the lysine analogue antifibrinolytics and aprotinin.¹⁵¹ Both aprotinin and antifibrinolytics were associated with a decreased need for repeat thoracotomy, and neither aprotinin nor antifibrinolytics increased the incidence of myocardial thrombosis. In contrast, DDAVP had no effect on repeat thoracotomy but was associated with a two- to fourfold increased risk of coronary thrombosis.¹⁵¹ Although this study showed no beneficial reduction in blood loss after the use of DDAVP, average surgical blood loss was relatively small. Earlier analyses have suggested a potential benefit for the use of DDAVP in patients with greater blood loss.¹⁵²

Methods that can be used to identify a subset of patients who might benefit from administration of DDAVP prior to surgery would be useful.¹⁵² One such group appears to consist of patients with preoperative platelet defects, especially those who have been treated with aspirin. Blood loss was markedly reduced in patients with preoperative defects in platelet function identified by point-of-care testing who were given DDAVP compared with those who received placebo.¹¹⁴ Three randomized, double-blinded, placebo-controlled trials have shown clinically significant reductions in blood loss and transfusion requirements after the use of DDAVP in patients who ingested aspirin before undergoing cardiac surgery.^{113,153,154} DDAVP also reduced bleeding in an unblinded comparison with placebo in patients who ingested aspirin before cholecystectomy.¹⁵⁵ In addition, DDAVP has been shown to shorten bleeding time in normal volunteers after aspirin ingestion,¹³⁰ perhaps through its direct effects on platelets or increases in VWF.¹³⁵ rFVIIa has been reported to be used successfully in a case of aspirin-related bleeding,¹⁵⁶ and aprotinin has been shown to reduce bleeding in aspirin-treated patients who were undergoing cardiac bypass; however, these agents have not been compared directly with DDAVP.¹⁵⁷

DDAVP has been used without adverse effects to control hemorrhage during pregnancy in a patient with Ehlers-Danlos syndrome¹⁵⁸; however, little additional information

is available on the safety of DDAVP or other hemostatic agents in pregnant women with bleeding disorders.¹⁵⁹ A review of the use of DDAVP to treat 53 pregnant women with diabetes insipidus found no risk to mother or child. However, the average daily dose of DDAVP in these cases—29 µg (range, 7.5 to 100 µg)—was significantly lower than that commonly used to augment hemostasis.¹⁶⁰

Although some studies have indicated that DDAVP is not effective in patients with afibrinogenemia,¹⁶¹ thrombocytopenia,¹³⁰ or Glanzmann disease,¹³⁰ other patients with Glanzmann disease or thrombocytopenia have reportedly responded.^{162,163}

Toxicity

Most adverse effects associated with DDAVP are minor. Facial flushing, often marked, and minimal elevation in pulse rate or blood pressure are observed, more frequently with the intravenous than with the subcutaneous or intranasal route.¹⁶⁴ The most common clinically significant adverse event is hyponatremia, which results from the anti-diuretic effects of this vasopressin analogue. Hyponatremic seizures have been observed in children 1 month to 8 years of age, especially when hypotonic fluids and multiple doses of DDAVP are administered in the surgical setting.¹¹⁵ Less severe but significant symptoms of headache, nausea, and lethargy have been reported in adults after intranasal¹⁶⁵ or repeated intravenous and subcutaneous administration.¹⁶⁶ Careful monitoring of fluids, urine output, and electrolytes is therefore important, especially in children who are given DDAVP perioperatively and in older patients when mild renal insufficiency reduces their ability to excrete free water. Patients should be instructed to restrict fluid intake for 24 hours after receiving DDAVP.

Thrombosis is an obvious concern when drugs that enhance hemostasis are used. Isolated cases of thrombosis such as myocardial infarction, cerebral thrombosis, and unstable angina have been reported after use of DDAVP in patients at risk for thrombotic events.¹⁶⁷ In the surgical setting, one randomized, placebo-controlled study that was specifically designed to detect deep venous thrombosis in 50 patients undergoing hip surgery¹⁶⁸ and an early meta-analysis¹⁶⁹ did not detect an increased incidence of thrombosis after DDAVP therapy. A recent meta-analysis reported a two- to fourfold (95% confidence interval, 1.02 to 5.60) increased risk of myocardial infarction in patients undergoing cardiac surgery who received DDAVP.¹⁵¹ Some experienced hemophilia centers do not routinely administer DDAVP to elderly patients or those with risk factors for coronary artery disease.¹⁷⁰ It therefore seems prudent to carefully evaluate patients who are receiving DDAVP for possible occult coronary artery disease and to avoid the concurrent use of antifibrinolytic agents in these patients.

Lysine Analogue Antifibrinolytic Agents

Background

Fibrinolysis occurs when plasmin that has been generated from plasminogen by plasminogen activators digests fibrin clots.¹⁷¹ Both plasmin and plasminogen bind to fibrin through lysine-binding sites.¹⁷² The synthetic lysine analogs AMCA and EACA delay fibrinolysis by competitively reducing the binding of plasminogen to fibrin.^{172,173} These

agents have been used for longer than 30 years to inhibit fibrinolysis and ensure clot stability.^{173,174}

AMCA was developed within a few years of the development of EACA; it was noted to inhibit fibrinolysis more potently on a molar basis and to cause a reduced incidence of gastrointestinal problems at equivalent antifibrinolytic doses in healthy volunteers.¹⁷⁵ Much of the early use of antifibrinolytics in the United States involved EACA, whereas AMCA was used relatively more frequently in Europe.¹⁷³ Although AMCA and EACA have been considered as equivalent agents,¹⁷³ optimal dosing regimens have not been developed for either agent in most clinical settings, and reported toxicities vary.^{176,177} Therefore, strict comparisons are difficult to make, and generalizations should be made cautiously when study findings are compared.

Lysine analogue antifibrinolytic drugs are effective and are clearly indicated in rare inherited conditions associated with excessive fibrinolysis, such as congenital α_2 -plasmin inhibitor deficiency.¹⁷⁸ However, much of the recent enthusiasm for these drugs has focused on acquired disorders with evidence of excessive systemic fibrinolysis, especially cardiac bypass surgery and, to a lesser degree, orthopedic surgery performed with the use of tourniquets. It is important to note that either agent is useful when administered topically in areas with excessive local fibrinolysis, such as the oral cavity and the uterine cavity. In these instances, efficacy is well established and adverse effects are reduced compared with systemic administration.^{10,106,179} AMCA and EACA are also frequently administered to reduce bleeding in such conditions as amegakaryocytic and peripheral immune-mediated thrombocytopenia, where the indication is less obvious and efficacy is presumably due to stabilization of fibrin clots.^{180–183} As might be expected, there is less evidence of efficacy noted in these settings.¹⁸³ An overview of the use of these agents is given in Table 27-6.

Excessive thrombosis is a potentially devastating complication in clinical settings involving excessive procoagulant activity, such as DIC.^{103,184} Thrombosis is not statistically increased with the use of AMCA or EACA in most settings other than DIC. However, the risk of this complication may have limited the more widespread application of these drugs in conditions such as menorrhagia or upper gastrointestinal hemorrhage, despite randomized studies that have shown benefit.^{173,174}

Dose and Administration

Either agent may be administered orally, intravenously, or topically. EACA and AMCA are well absorbed orally and are cleared virtually unchanged by the kidneys.¹⁷² These drugs are distributed widely throughout the body. AMCA crosses into the cerebrospinal fluid, semen, synovial fluid, and cord blood but is not secreted in saliva.¹⁷⁴ In the nonoperative setting, the half-life for both agents is approximately 1 to 2 hours in patients with normal renal function. The dose should be reduced in renal failure.^{174,185} AMCA is approximately 6 to 10 times more potent than EACA on a molar basis¹⁷²; however, few direct clinical pharmacokinetic and pharmacodynamic comparisons of the two agents have been performed.¹⁷⁴ A typical total daily oral dose for EACA is 10 to 24 g, administered as 2 to 4 g every 3 to 4 hours, and for AMCA, 3 to 4 g, administered as 1 g every 6 to 8 hours. Dosage in individual studies varies widely.¹⁷³ Studies have attempted to optimize dosing for these agents

Table 27-6 Overview of Lysine Analogue Antifibrinolytic Agents

Action

Clot stabilization by rapid inhibition of fibrinolysis associated with competition at lysine-binding sites of plasmin and plasminogen activators. Tranexamic acid is more potent on a molar basis than is ϵ -aminocaproic acid.

Administration

Every 4 to 8 hours by oral, intravenous, and topical routes. Dose should be reduced in kidney disease and has not been optimally determined in many conditions.

General Use

Short- and long-term control of various bleeding states. Consistent benefit in blinded, randomized studies of upper gastrointestinal bleeding and menorrhagia. Effective topically, with decreased systemic effects in oral and cardiac surgery and ophthalmologic and other conditions, with excessive local fibrinolysis. Wide use in thrombocytopenic states, with less consistent benefit noted. Effective in rare acquired or congenital conditions characterized primarily by excessive fibrinolysis. Effective in cardiac bypass surgery; less expensive and possibly less toxic than aprotinin at conventional doses. Anecdotal use in conditions that lack effective and specific therapy.

Relative Contraindications

Disseminated intravascular coagulation (may be beneficial in those with primary fibrinolysis). Urologic bleeding conditions.

Toxicity

Nausea, cramping, and diarrhea, more commonly with ϵ -aminocaproic acid. Myonecrosis after longer-term oral use with ϵ -aminocaproic acid. Thrombosis in settings requiring compensatory fibrinolysis, such as disseminated intravascular coagulation.

in conditions such as cardiac surgery, in which the clearance and distribution of these agents are altered.^{185–187} Anecdotal and controlled studies have described improved control of bleeding with short-term, bolus,^{188–190} and local or topical administration.^{191–193} The optimal dose and route of administration may depend on the patient, the disease, or both.¹⁷⁴ In 2006, the average wholesale price for EACA was 7 cents per 250-mg oral tablet and \$2.73 per 500-mg intravenous ampule; for AMCA, the wholesale price was \$4.00 per 100-mg intravenous ampule (with the oral preparation not available through the U.S. government pharmacy in 2006).

Indications

Data on the efficacy of AMCA and EACA given to improve hemostasis in thrombocytopenic patients are conflicting and difficult to interpret. Two retrospective uncontrolled studies of 31 patients with thrombocytopenia, involving amegakaryocytic and immune-mediated origins, showed benefit with oral EACA.^{180,181} A smaller study found that bleeding was controlled by EACA bolus infusion when platelet transfusions were unavailable or delayed,¹⁸⁹ and a larger, more recent retrospective analysis of 77 patients with mostly malignant hematology/oncology diseases and treatment-related thrombocytopenic bleeding described

complete (66%) or partial (17%) cessation in bleeding and reduced platelet and RBC transfusion requirements after treatment with EACA given at a median 6 g per day for 8 days.¹⁹⁴

A randomized, double-blinded, placebo-controlled study of AMCA administered to 38 patients to reduce bleeding in acute myeloid leukemia found a significant reduction in bleeding episodes and platelet transfusions during consolidation but not during induction therapy.¹⁸² However, a smaller study of 8 patients with amegakaryocytic thrombocytopenia (7 with severe aplastic anemia and 1 with myelodysplasia) treated with AMCA in a placebo-controlled, double-blinded, crossover design found no improvement in bleeding. Only three patients were able to complete all phases of the study. Bleeding increased in patients who were receiving AMCA.¹⁸³ Such studies are extremely difficult to perform,¹⁹⁵ yet antifibrinolytic agents continue to be widely used for this indication.¹⁰

Lysine analogues are often used in cardiac bypass surgery, in which excessive bleeding and fibrinolysis are associated with the use of extracorporeal devices. Although early studies did not reveal a uniformly beneficial effect, antifibrinolytic use has increased recently as a cost-effective and perhaps safer alternative to aprotinin.¹⁹⁶ In contrast to DDAVP, these antifibrinolytic agents are administered prior to bypass and are associated with significant reductions in blood loss. A meta-analysis of placebo-controlled studies of antifibrinolytic agents in cardiac surgery that did not distinguish between AMCA and EACA showed lower rates of reexploration, improved mortality, and no significantly increased risk of myocardial infarction in the treatment group.¹⁵¹ More recently, tranexamic use has been associated with decreased transfusion requirements in “off-pump” bypass grafting, indicating that activity is not limited to counteracting effects of the extracorporeal circulation.¹⁹⁷ In general, studies indicate that AMCA is more effective than EACA. However, these conclusions must be interpreted cautiously because the optimal dose of AMCA¹⁸⁶ or EACA¹⁸⁵ has yet to be determined.

Antifibrinolytic agents have also been shown to reduce bleeding in total knee arthroplasty, in which use of a tourniquet produces excessive fibrinolysis.^{198,199}

When used in patients undergoing liver transplantation, antifibrinolytic agents reduced fibrinolysis²⁰⁰ and showed efficacy similar to that of aprotinin.²⁰¹ Although individual studies do not uniformly document a reduction in transfusion requirements in these settings, meta-analyses²⁰² and critical reviews²⁰³ support a positive effect. Studies that have attempted a cost/benefit analysis uniformly favor AMCA or EACA over aprotinin.^{204–207} Although the issue of the optimal antifibrinolytic agent for use in bypass surgery is the subject of extensive and unresolved debate,^{208–210} recent safety data appear to favor the use of lysine analogue agents over aprotinin.^{196,211} On the basis of proposed mechanisms of action for efficacy and toxicity, some would favor these agents over aprotinin until similar safety data are obtained in other settings.²¹²

Other applications of lysine analogues are increasingly supported by controlled studies, in contrast to the largely anecdotal use that previously characterized their use.^{10,174} In a randomized, double-blinded, placebo-controlled study of 214 patients undergoing hepatectomy for tumor

resection, preoperative intravenous administration of 500 mg AMCA followed by 250 mg every 6 hours for 72 hours was associated with significantly reduced blood loss and transfusion requirements (0% vs 16% of patients) and no thromboembolic complications.²¹³ Similarly, intraoperative and postoperative blood loss was significantly reduced in elective nasal surgery (endoscopic sinus surgery combined with septoplasty and conchotomy) in 200 patients who received AMCA (1 g orally every 8 hours, starting 2 hours before surgery and continuing for 5 days) compared with 200 patients who did not receive this agent; rebleeding requiring packing occurred in no AMCA patients and in 5 controls.²¹⁴ AMCA was associated with a reduced incidence of rebleeding and a 30% to 40% reduction in mortality in a meta-analysis that included 1200 patients from double-blinded, placebo-controlled trials of treatment in gastrointestinal hemorrhage.²¹⁵ A similar analysis found significant improvement in women with menorrhagia who received antifibrinolytic agents compared with hormonal methods and other treatment modalities.²¹⁶ Concern for thromboembolism has tempered the widespread use of these agents for excessive menstrual bleeding; however, studies have not shown an increased incidence of this complication to date.

AMCA reduced the incidence of rebleeding in patients with subarachnoid hemorrhage in two double-blinded, placebo-controlled studies; however, neurologic outcome was not improved.^{217,218} Although uncontrolled studies have suggested that shorter courses of high-dose EACA¹⁸⁸ or lower-dose AMCA²¹⁹ might reduce rebleeding and prevent the complications associated with long-term use, the use of antifibrinolytic agents to treat patients with subarachnoid hemorrhage is not supported by recent evidence or practice recommendations.²²⁰ In addition, a recent study reported no beneficial effect on hematoma enlargement when EACA was used to treat patients with intracerebral hemorrhage²²¹ (see Chapter 43).

Anecdotal reports indicate that antifibrinolytic agents may be successful in hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome),²²² in disorders with excessive local fibrinolysis due to vascular malformations such as Klippel-Trénaunay²²³ or Kasabach-Merritt syndrome,²²⁴ and in rare instances in which hemorrhage is caused by excessive fibrinolysis, such as in the setting of prostate cancer.²²⁵ Administration of antifibrinolytic agents to patients with excessive local coagulation due to vascular malformations was associated with thrombosis and obliteration of intravascular channels. Because of the potential for thrombosis in DIC, these drugs should be used with extreme caution, if at all, in this setting.

Topical or local administration of these drugs has been successful in a variety of clinical settings. Topical AMCA dramatically reduced the incidence of rebleeding after traumatic hyphema, with decreased systemic symptoms compared with oral administration, and it improved long-term outcomes compared with those seen in untreated controls.¹⁹³ Similarly, the usefulness of topical administration was illustrated in a double-blinded study of patients undergoing cardiac surgery in whom a solution of tranexamic acid (1 g in 100 mL saline) was poured into the pericardial cavity and over the mediastinal tissues before closure. Chest tube drainage but not transfusion requirements were significantly reduced, and AMCA blood levels

were undetectable.²²⁶ In menorrhagia associated with the use of an intrauterine device, local administration of AMCA or aprotinin reduced the pain and symptoms of bleeding.¹⁹¹

In the setting of dental surgery, antifibrinolytics are proposed to counteract excessive fibrinolysis in the oral cavity, which occurs because of the absence of endogenous fibrinolytic inhibitors.²²⁷ Blinded placebo-controlled studies over 30 years ago showed reduced bleeding and decreased requirements for clotting factor concentrates in patients with hemophilia A and B who received systemic oral administration of EACA, 6 g four times daily for 7 to 10 days.²²⁸ In a prospective, double-blinded study of 20 anticoagulated patients, AMCA mouthwash or placebo administered as 10 mL of a 4.8% aqueous solution was applied prior to sutures and as a 2-minute rinse four times a day for 7 days; 10 bleeding episodes occurred in 8 patients in the placebo group, and only one bleeding episode was reported in the treatment group. Only one patient had detectable blood levels of AMCA (2.5 µg per milliliter of plasma).²²⁷ Since that time, topical administration of AMCA, along with the use of DDAVP and fibrin sealant, has become part of established multimodality therapy in hemophilia dental centers.¹⁷⁰

Local measures to provide hemostasis are preferred to temporary discontinuation of warfarin in anticoagulated patients—a practice that may result in thromboembolism.²²⁹ It is interesting to note that in one placebo-controlled trial of patients receiving oral anticoagulants, the addition of AMCA mouthwash offered no benefit over the use of local measures alone, such as gelatin sponge and fibrin glue.²³⁰ Because placebo rinses may interfere with the formation of stable clot in the oral cavity, these early placebo-controlled studies should be evaluated in the context of studies in which improved local control measures were applied. Similar results have been observed in the treatment of epistaxis, in which no difference in efficacy was reported when gel impregnated with AMCA or placebo was used for treatment.²³¹

Toxicity

The most common adverse effects of lysine analogue antifibrinolytic therapy consist of mild dose-dependent gastrointestinal symptoms such as nausea, cramping, and diarrhea. These symptoms are less frequently reported with AMCA than with EACA.^{172–174} Myonecrosis, possibly due to inhibition of carnitine synthesis, has been described, although rarely, after long-term oral administration of EACA (therapy >4 weeks).^{176,177} Myonecrosis has not been reported after AMCA administration, and some patients who have developed this complication while on EACA have been successfully treated for many months with AMCA.¹⁷⁴ Reversible visual impairment due to nonthrombotic malfunction of the pigmented retina has been described in a patient with renal failure who was receiving AMCA for control of a bleeding ulcer.²³² Administration of EACA, primarily through the intravenous route, has rarely been associated with hypotension and subsequent acute tubular necrosis; rapid infusion of this agent may result in bradyarrhythmia or tachyarrhythmia.²³³

These drugs do not appear to differ in their potential to cause thrombosis at usual clinical doses. Widespread thrombosis has occurred in DIC, in which increased

fibrinolysis may mitigate organ ischemia.¹⁸⁴ Some studies have attempted to use antifibrinolytic therapy in conjunction with heparin anticoagulation in DIC and “excessive” fibrinolysis characterized by low levels of α_2 -plasmin inhibitor. Although bleeding improved in most cases, some patients developed generalized organ system failure attributed to thrombosis.¹⁸⁴

Renal complications associated with the use of lysine analogue antifibrinolytics, including ureteral obstruction, renal infarction, and electrolyte disturbances such as anion gap metabolic acidosis and hyperkalemia, may cause infrequent but clinically significant effects.²³³ High-grade ureteral obstruction due to clot formation caused by inhibition of urokinase may occur when antifibrinolytics are used to treat patients with gross hematuria. No increased risk of this complication was observed in nine patients with macroscopic hematuria of various causes when EACA was given at divided oral doses (150 mg per kilogram total daily dose administered every 6 hours for up to 21 days)²³⁴; in a contrasting report, thrombosis occurred in patients who had evidence only of microscopic hematuria and who were treated with standard AMCA therapy (4 to 4.5 g total daily dose administered every 6 to 8 hours for 1 to 3 days).²³⁵ Local therapy, administered by irrigation, has been successful for control of intractable urinary bleeding localized to the bladder.^{192,236} Animal studies have indicated a possible teratogenic effect for EACA²³⁷; however, a review of AMCA use in pregnancy found no significant thrombosis or fetal injury.²³⁸

Aprotinin

Aprotinin is a bovine-derived protein that inhibits plasmin and multiple other human proteases.²³⁹ Before its hemostatic applications were discovered, aprotinin had been widely used in Europe for the treatment of patients with pancreatitis and other inflammatory conditions.²¹⁰ During studies of aprotinin given to reduce neutrophil activation in cardiac bypass surgery,²⁴⁰ investigators noted that the operative field was dry, and that transfusion requirements for patients undergoing repeat open heart surgery were markedly reduced.

The precise role of aprotinin in cardiac bypass surgery is not clear because this condition is associated with abnormal platelet function, decreased factor levels, activation of the fibrinolytic system, and coagulopathy related to heparin and protamine sulfate (see Chapter 37).^{106,241} However, a series of studies have clearly established aprotinin as effective in reducing blood loss during open heart surgery.¹⁵¹ Aprotinin may have similar activity in orthotopic liver transplantation, in which bleeding may also occur, in part because of excessive fibrinolysis.²⁴² Aprotinin is effective also in reducing blood loss in surgical patients who were recently treated with aspirin.¹⁵⁷ In a meta-analysis of pharmacologic strategies designed to reduce blood loss in cardiac surgery, aprotinin was the only agent associated with reduced mortality, and both aprotinin and lysine analogue antifibrinolytic agents reduced overall transfusion requirements and the need for reexploration.¹⁵¹ However, serious concerns about the safety of aprotinin have been raised in two recent studies in which propensity scoring analysis was used. This is a retrospective technique that may be more suitable for detection of drug toxicity.²¹²

In one study, the use of aprotinin (1295 patients), EACA (883 patients), or AMCA (822 patients) resulted in decreased blood loss compared with no agent (1295 patients); however, the use of aprotinin was associated with a greater than twofold increase in the risk of renal failure requiring dialysis in primary or complex surgery, as well as a 55% increase in the rate of myocardial infarction and a 181% increase in the risk of stroke or encephalopathy in complex surgery, with no associated increase in these values observed for EACA or AMCA.¹⁹⁶ In the second study, transfusion requirements and survival in patients undergoing cardiac bypass surgery who received aprotinin or AMCA were similar; however, a higher incidence of postoperative renal dysfunction or dialysis requirement was observed in the aprotinin group—an effect that was greatest in those who had impaired preoperative renal function.²¹¹ Aprotinin is also significantly more expensive than lysine analogue antifibrinolytics, with an average wholesale price in 2006 of \$314 for a 10 mL ampule of 10,000 KIU per milliliter. Although the cost-effectiveness and merits of aprotinin compared with lysine antifibrinolytics continue to be debated,^{205,207,208} recent safety studies have raised concerns about the routine use of aprotinin versus these agents in coronary artery bypass surgery.^{196,211}

Interpretation of such study findings remains complicated by methods used to assign weight to end points such as mortality and reexploration, total blood use, and long-term outcomes, as well as the effects of various dosing regimens.²⁰⁶ Although aprotinin-mediated inhibition of plasmin may be the primary mode of action for reduction of blood loss,²³⁹ inhibition of other enzymes and binding to renal vascular endothelium may be associated with its other effects.^{151,196,210}

A unique toxicity of significant concern with aprotinin (a bovine protein) is anaphylaxis, which occurs in approximately 0.5% of initial exposures and up to 9% of repeat exposures and may result in shock and death.²⁴³

Vitamin K

Background

Vitamin K, *koagulationvitamin*, was discovered by Dam,²⁴⁴ who demonstrated that chicks fed an ether-extracted diet developed a hemorrhagic diathesis that responded to a fat-soluble factor. He showed shortly thereafter that administration of vitamin K corrected the prolonged clotting tests of patients with obstructive jaundice, further noting that this correction occurred more rapidly after intramuscular than after subcutaneous administration.²⁴⁵ Vitamin K was soon demonstrated to correct bleeding in hemorrhagic disease of the newborn.²⁴⁴ With recognition that the bleeding in “spoiled sweet clover disease of cattle” was due to a compound (identified later as bishydroxycoumarin, or dicumol) that interfered with vitamin K–dependent synthesis of active prothrombin, vitamin K subsequently acquired an established role in the management of excessive anticoagulation due to warfarin, super-warfarin rodenticides, and other orally active anticoagulants with similar mechanisms of action. Vitamin K is also indicated in acquired vitamin K deficiency, which occurs frequently in intensive care settings,^{246,247} and it is effective in some cases of hepatic cirrhosis.²⁴⁸

Compounds with vitamin K activity exist in nature in two forms. Each possesses the 2-methyl-1,4-naphthoquinone ring that is required for activity, but all differ in terms of the three-position side chain.²⁴⁹ Vitamin K₁ phytylquinones are synthesized by plants that possess the same phytol side chain as chlorophyll, and they are the major dietary source of vitamin K. Vitamin K₁ content varies widely among foods, and diet is a major potential source of variation in response to oral anticoagulants. Absorption of dietary vitamin K occurs in the ileum and requires the formation of mixed micelles composed of bile salts and the products of pancreatic lipolysis.²⁴⁹ Thus, oral absorption is impaired in conditions of biliary obstruction or pancreatic insufficiency. Vitamin K₂ menadiones are synthesized by gut bacteria and comprise a spectrum of molecular forms with side chains based on repeating unsaturated 5-carbon units. The physiologic importance of the large quantity of vitamin K₂ menadiones produced by bacterial flora of the large intestine is not clear.²⁴⁹ Great numbers of menadiones, which are stored in the liver, may perform a reserve function of protecting against dietary vitamin K deficiency, which is rare in healthy adults. Whether slow, chronic, inefficient absorption of high concentrations of colonic vitamin K₂ is physiologically relevant compared with the highly efficient absorption of lower concentrations of intermittent dietary vitamin K₁ in the ileum remains a matter of debate.^{249,250}

Mechanism of Action, Dose, and Administration

Vitamin K functions as an essential cofactor in the post-translational gamma-carboxylation of glutamic acid moieties in the N-terminal region of a series of proteins.²⁵¹ Originally recognized as essential for the synthesis of functional prothrombin, vitamin K later was identified as necessary for several normal functioning coagulation factors (II, VII, IX, and X), naturally occurring anticoagulant proteins (protein C and S), and, more recently, other proteins such as osteocalcin that are involved in bone metabolism.²⁵⁰ Gamma-carboxylation produces protein-constituent amino acids with stable divalent anionic charges that may interact with calcium ions by localizing clotting factors to appropriate areas of phospholipid membranes or by allowing formation of internal calcium channels.²⁵¹ Prior to participating in the carboxylation reaction, vitamin K must first be reduced to an active hydroquinone form. This carboxylation reaction produces a gamma-carboxylic glutamic acid as the hydroquinone is converted to an inactive vitamin K epoxide. Vitamin K epoxide is reduced back to the active hydroquinone by vitamin K epoxide reductase, regenerating additional vitamin K to participate in carboxylation.²⁵¹ Thus, vitamin K is recycled in a process that involves 100 to 1000 times more vitamin K daily than is absorbed from dietary or colonic sources.²⁴⁹ Decarboxylated, functionally inactive forms of vitamin K–dependent proteins (also called *proteins induced by vitamin K absence, or PIVKA*) may be detected in the circulation of patients on oral anticoagulant therapy or in those with vitamin K deficiency due to malabsorption or with functional vitamin K deficiency induced by liver disease.²⁵²

Enzymes that reduce and recycle vitamin K and vitamin K epoxide have different sensitivities to oral anticoagulant-induced inhibition.²⁵¹ This biochemical quirk explains why vitamin K functions as an antidote to excessive oral

anticoagulation, and why patients on warfarin therapy who receive higher doses of vitamin K may appear resistant to reinstitution of warfarin therapy. The primary site of inhibition by warfarin is vitamin K epoxide reductase, which, under physiologic conditions, is the enzyme that reduces vitamin K to the active hydroquinone required for carboxylation.²⁵¹ A second reductase is present that is not inhibited by warfarin. This warfarin-insensitive reductase can reduce vitamin K to the active hydroquinone in the presence of high tissue concentrations of vitamin K. Thus, exogenous vitamin K can produce additional active vitamin K hydroquinone via this warfarin-insensitive step, bypassing the warfarin-induced inhibition of vitamin K epoxide reductase and reversing excessive anticoagulation.²⁵¹ If vitamin K levels accumulate, this same process may lead to warfarin resistance on resumption of anticoagulation.²⁵³ Therefore, only small, if even incremental, doses of vitamin K should be administered to control excessive anticoagulation in patients who will require further antithrombotic therapy.

High oral doses of vitamin K do not affect the synthesis or raise the concentration of coagulation factors in normal, healthy subjects.²⁵³ Lowered levels of vitamin K–dependent factors in patients on oral anticoagulants recover at the same rate during the first 8 hours after vitamin K administration; thereafter, recovery depends on the rate of synthesis of newly gammacarboxylated factors by the liver.²⁵³ Levels of factor VII reconstitute most rapidly, followed by levels of factors IX and X, and finally by levels of prothrombin.²⁵³ The differential rate of circulating factor levels after vitamin K administration has practical importance in monitoring recovery from anticoagulant therapy. Oral anticoagulation is most frequently monitored with the INR (and the PT, from which the INR is calculated); the INR is most sensitive to acute decreases in factor VII levels. The INR attempts to account for the variable sensitivity of different thromboplastin reagents by adjusting the degree of prolongation of the PT according to the International Sensitivity Index (ISI) provided for each reagent used to perform the test.²⁵⁴ During stable anticoagulant therapy, the INR is determined on the basis of decreases in several vitamin K–dependent coagulant and anticoagulant protein levels, which remain in relatively constant ratios to one another. However, initial improvement of a markedly prolonged INR after administration of vitamin K for excessive anticoagulation may relate largely to a rapid increase in the factor VII level alone. In this setting, the slower recovery of factor IX may remain at clinically significant low levels, which may appear as a persistently prolonged PTT. Thus, the INR in this setting may be misleading and should not be used alone in interpreting levels attained during stable anticoagulation. If available, measurement of factor levels may be useful in predicting bleeding risk before invasive procedures are performed or in guiding further therapy.

Dose and Administration

Vitamins K₁ and K₂ are active when administered orally or intravenously. However, the only preparation currently available in the United States is a vitamin K₁ preparation, phytonadione (AquaMEPHYTON; Merck & Co., West Point, Pa, USA). A similar product (Konakion; Roche Colorado, Boulder, Colo, USA) for intravenous use is available in

Europe and Australia. Both liquid preparations are prepared as a colloid solution, each milliliter containing 2 or 10 mg of phytonadione in a polyoxyethylated fatty acid derivative, which functions as a cremaphor to solubilize the vitamin K. The AquaMEPHYTON preparation is effective when administered intravenously, subcutaneously, intramuscularly, or orally. Intramuscular administration may cause hemorrhage in anticoagulated patients and should be used only for prophylaxis against hemorrhagic disease of the newborn. The adverse effects reported with intravenous administration (see later) have limited its use, even though intravenous administration is more rapid and reliable than the subcutaneous or oral route.^{253,255,256} A colloidal system based on mixed micelles of lecithin and glycocholic acid that solubilize lipophilic vitamin K was developed to reduce the toxicity attributed to the cremaphor component of current preparations; however, significant symptoms were reported when this preparation was used, and it is no longer under development.²⁵⁷ Scored tablets, containing 5 mg of phytonadione, are available; these permit a dose as low as 2.5 mg; therefore, administration of smaller doses of oral vitamin K requires the use of liquid preparations. Although injectable and oral preparations have been available for nearly half a century, the appropriate dose and route of administration remain controversial.²⁵⁸ Despite careful pharmacodynamic studies, clinical guidelines have changed frequently^{254,259–261} because of variability in patient responses and concerns regarding toxicity.²⁵⁸ In 2006, average wholesale prices for vitamin K were 65 cents per 5-mg oral tablet and \$3.61 per 1-mg intravenous ampule.

Indications

Vitamin K is used most often to reverse excessive anticoagulation caused by warfarin. Indications include patients with serious bleeding and those requiring only temporary control of therapeutic anticoagulation in preparation for surgical procedures. The goals of therapy are prompt control of bleeding without toxicity, prevention of resistance to reinstitution of warfarin, and avoidance of subtherapeutic anticoagulation.²⁶² The response to vitamin K administration may depend on the direction, rate of change, and degree of prolongation of clotting times; the time, dose, and type of anticoagulant administered; and the presence of concurrent liver disease, antibiotic use, or dietary factors.²⁶³ Vitamin K and other effective therapies used to reduce the INR in patients receiving warfarin are listed in Table 27-7.

Anticoagulant reversal is more prompt with intravenous than with subcutaneous administration of vitamin K^{255,256} (Fig. 27-4). In a prospective, randomized, single-blinded study of 22 patients, the INR decreased from a mean initial value of 8.0 down to 4.6 and 3.1 after 8 and 24 hours, respectively, in patients who received 1 mg intravenously, compared with a mean initial value of 8.5, which decreased down to 8.0 and 5.0 at the same times in patients who were given 1 mg SC.²⁵⁶ Similarly, the response after oral ingestion of vitamin K, although less rapid than after intravenous vitamin K, is more rapid than after subcutaneous administration (Fig. 27-5). Oral vitamin K administration is also more rapid than that observed after simple discontinuation of warfarin,²⁵⁸ which may be prolonged in elderly patients.²⁶⁴ Oral doses as low as 0.5²⁷ to 2.0 mg^{27,260} have been recommended in patients at risk for mild to moderate prolongation of the

Table 27-7 Effective Therapies in Reducing International Normalized Ratio (INR) in Patients Administered Warfarin

Method	Mechanism	Clinical Situation	Advantages	Drawbacks
Reduction of warfarin dosage	Decreases total warfarin dose	Outpatient INR 3–6; no bleeding	Safe, effective	Slow (days); possibly confusing to patient
Holding of warfarin dose 1–2 days	Decreases total warfarin dose	Outpatient INR 5–8; no bleeding	Safe, effective	Slow (days); often confusing to patient
Ingestion of spinach or salads	Increases vitamin K intake	Outpatient INR 5–8; no bleeding	Safe, probably effective	Slow (24 hours); never studied
Low dose (≈ 1 mg) vitamin K given orally	Increases vitamin K intake	Outpatient INR 6–12; no bleeding	Effective within 24 hours	Difficult dosage to obtain
Moderate dose (2–5 mg) vitamin K given orally	Increases vitamin K intake	Inpatient or outpatient INR 10–15; no bleeding or INR 5–10 with bleeding	Effective within 24 hours	Takes ≈ 24 hours to work; often results in subtherapeutic INR
Low dose (0.5–1 mg) vitamin K given intravenously	Increases vitamin K intake	Inpatient or outpatient INR 6–12 with or without bleeding or INR 2–5 prior to invasive procedure	Works within 6–8 hours; rarely results in subtherapeutic INR; useful for patients who wish to remain on warfarin	Slight risk of anaphylaxis
High dose (5–20 mg) vitamin K, given intravenously	Greatly increases vitamin K intake	Inpatient INR ≥ 8 with bleeding or accidental warfarin ingestion	Relatively safe; very rapid (6–8 hours) effect; inexpensive	Slight risk of anaphylaxis; often results in subtherapeutic INR
Fresh frozen plasma (FFP)	Supplies missing coagulation factors	Inpatient INR ≥ 8 with bleeding	Effective in 1–2 hours in actual practice*; effective “immediately” in theory	Cumbersome; short half-lives of factors, warfarin not reversed; risks of infusion include volume and infection
Prothrombin complex concentrates (PCCs)	Supplies missing coagulation factors	Inpatient INR ≥ 8 with bleeding; CNS bleeding	Effective in 1–2 hours in actual practice	Not always available; expensive; risks of thrombosis and DIC; short half-lives of factors, warfarin not reversed
Recombinant factor VIIa (NovoSeven)	Induces thrombin generation at site of injury with platelet activation	Inpatient; urgent reversal; INR > 8 with bleeding or CNS bleeding	Effective in 20 minutes; short half-life; must follow clinically	Very expensive; risk of thrombosis probably less than PCCs; warfarin not reversed

*Including time for diagnosis, thawing, procuring, and administration.
 CNS, central nervous system; DIC, disseminated intravascular coagulation.
 NovoSeven is manufactured by Novo Nordisk, Inc., Princeton, NJ, USA.

INR who are not bleeding. An algorithm has been developed for estimating an appropriate oral dose on the basis of the INR²⁶⁵; however, results should be confirmed by institutions that use the respective thromboplastin reagents.

Simple discontinuation of warfarin for excessive anticoagulation may have unanticipated adverse thrombotic effects.²⁶⁶ The use of large oral and subcutaneous doses of vitamin K has been associated with thrombosis and subsequent warfarin resistance requiring heparin therapy.²⁶⁷ Thrombosis may be related to attainment of subtherapeutic INR levels and more rapid recovery of factor VII and other coagulant enzymes compared with proteins C and S.²⁶⁶ Smaller vitamin K doses of 0.5 to 1 mg given intravenously are frequently effective for reversal of excessive anticoagulation.^{268–270} In patients scheduled to undergo minor procedures while they are maintained on a stable dose of warfarin, 1 mg intravenous vitamin K transiently

normalized INR, with the effect vanishing within several days.²⁷¹ In another study of healthy volunteers who were given stable doses of oral anticoagulants, the effect of 1 mg of vitamin K administered intravenously was detectable for several days, and the effects of 5 and 25 mg were detectable on laboratory tests for up to 1 and 2 weeks, respectively.²⁵³ Similar results have been attained with the use of low-dose oral vitamin K.²⁶⁵ The subcutaneous route produces a more prolonged effect than the oral or intravenous route and results in a higher frequency of subtherapeutic INR values²⁵⁸; in one study, INR values below 2.0 were observed in 5 of 22 subjects (23%) at 72 hours after intravenous treatment compared with 14 of 33 subjects (42%) after subcutaneous therapy.²⁵⁵ The use of the subcutaneous route is rational for its depot effect in the long-term replenishment of vitamin K in malnourished patients.

In patients who require more rapid reversal of anticoagulation, plasma products produce results within minutes.

Figure 27-4 Individual values of the international normalized ratio (INR) at baseline and at 24 and 72 hours after vitamin K therapy following subcutaneous administration in 33 patients (A) and intravenous administration in 22 patients (B). Subjects with an INR between 6 and 10 received 0.5 mg (25 subcutaneous and 20 intravenous), and those with an INR between 6 and 10 received 3.0 mg (8 subcutaneous and 2 intravenous). (Adapted from Nee R, Doppenschmidt D, Donovan DJ, Andrews TC: Intravenous versus subcutaneous vitamin K₁ in reversing oral anticoagulation. *Am J Cardiol* 83:288, 1999. With permission from Excerpta Medica, Inc.)

If one discounts the 30 to 45 minutes generally required to thaw FFP and the time for infusion, results with FFP or PCC occur more rapidly than with vitamin K alone, but they are transient and less durable because of the 6- to 7-hour half-life of infused factor VII. In one study, volunteer subjects who were therapeutically anticoagulated after four daily doses of 7.5 mg oral warfarin received 1 L of FFP over 100 minutes (mean dose, 12 mL per kilogram), resulting in a mean 0.12 IU per milliliter increase in factor VII levels and a mean 2-second decrease in PT at 15 minutes, followed by a return to pre-FFP infusion levels within 8 hours.²⁷² The very modest improvement in these patients with minimal prolongation of coagulation tests, along with other adverse effects associated with FFP use described earlier, indicates that the very large doses of FFP required to restore adequate levels of vitamin K-dependent factors in excessively anticoagulated patients may be clinically difficult or impossible to administer, particularly in elderly patients. Additionally, the synthesis of new factors

continues to be inhibited by residual warfarin after FFP or PCC is used. The use of either product should be monitored and supplemented with vitamin K as appropriate. Infusion of PCC provides the most rapid infusion of all vitamin K-dependent factors and may provide a superior clinical outcome compared with FFP for patients with intracranial hemorrhage²⁷³; use of rFVIIa in this setting has also provided rapid control of hemostasis.⁸⁹ As with FFP, the factor content of PCC is variable, and a dose based on factor IX levels is often used. In such cases, the risks of thrombosis and DIC associated with PCC must be balanced against the risk of the clinical condition and the risk of slower response to treatments with less toxicity. Although infusion of vitamin K may surprisingly correct an astronomically prolonged INR rapidly in patients with good hepatic function,²⁷⁴ rFVIIa or possibly PCC therapy should be also be used for patients with anticoagulant-associated intracerebral hemorrhage.

Vitamin K is established therapy for the prevention of hemorrhagic disease in the newborn because of transient vitamin K deficiency during the first week of life and onset of vitamin K deficiency weeks to months later.²⁷⁵ Its effectiveness in other conditions is less well documented. Patients with cirrhosis²⁴⁸ or liver cancer²⁷⁶ may have circulating descarboxylated coagulation factors similar to those seen in vitamin K deficiency, which may be due to an acquired deficiency of the vitamin K decarboxylase. Although the mechanism was not described, administration of 10 mg vitamin K subcutaneously for 3 days as described in one report normalized prolonged PT values in 37% of patients with cirrhosis.²⁴⁸ Vitamin K deficiency occurs commonly in malnourished patients in intensive care units, with or without concomitant antibiotic use,²⁷⁷ accounting for four or five cases yearly in one tertiary care referral center²⁴⁶ and for 20% of cases with prolongation of the PT (more than 1.5 times normal) in another.²⁴⁷ Intravenous administration over 30 minutes of 5 to 25 mg vitamin K corrected the coagulopathy within 12 hours in these critically ill patients.^{246,277} A much smaller dose of vitamin K—1 mg given intravenously—is effective within 24 hours when vitamin K deficiency is due to malabsorption in patients who are not critically ill, and the effect lasts 1 to 2 weeks.²⁵³ Patients with severe hemorrhagic diathesis due to ingestion of the powerful super-warfarin rodenticide brodifacoum may require initial oral administration of 100 mg daily of vitamin K for 2 months, tapered slowly over 300 days because of the extremely prolonged half-life of the poison.²⁷⁸ In contrast, prolonged PT values associated with the relatively weaker anticoagulant activity of some antibiotics (moxalactam, cefoperazone, cefamandole, cefotetan, and cefmetazole) that have the N-methylthiotetrazole (NMTT) side chain, respond rapidly to small doses in many cases.^{279,280}

Toxicity

The major toxicity associated with administration of vitamin K is the rare but dramatic occurrence of anaphylaxis, which has been associated with fatalities.²⁸¹ Published studies have reported fatalities due to vitamin K administration only after intravenous administration of “relatively modest doses” of 10 mg, and data obtained via the U.S. Department of Health and Human Services Food and Drug Administration Spontaneous Reporting System Adverse Reactions

Figure 27-5 Individual values of the international normalized ratio (INR) at baseline and 1 day after 1 mg oral and 1 mg subcutaneous vitamin K. Oral vitamin K acted more quickly than subcutaneous vitamin K, and more patients had an INR between 1.8 and 3.2 after oral administration. (Adapted from Crowther MA, Douketis JD, Schnurr T, et al: Oral vitamin K lowers the international normalized ratio more rapidly than subcutaneous vitamin K in the treatment of warfarin-associated coagulopathy. *Ann Intern Med* 137:251–254, 2002, American College of Physicians, Philadelphia.)

describe very rare nonfatal anaphylaxis after oral or subcutaneous administration and fatal anaphylaxis after intramuscular and intravenous administration.²⁸² Symptoms of flushing and chest pain after intravenous administration of phytonadione were described as early as 1952, and cardiac irregularities in the 1960s were attributed to injections given more rapidly than 10 mg per minute or to the propylene glycol content of an older preparation that has since been withdrawn from the market.²⁸³ Although these reactions have been attributed to the cremaphor excipient used in this preparation, severe anaphylaxis also occurred in a patient who received an intravenous injection of a mixed micelles vitamin K₁ preparation composed of glycolic acid and lecithin that was designed to reduce anaphylaxis.²⁸⁴ It is not clear whether the vitamin, the excipient, formation of a hapten between vitamin K and emulsifying agents, or nonimmunologic mechanisms led to this reaction.²⁸⁴

What is known about reactions after vitamin K administration may be summarized as follows: (1) anaphylactic reactions occur and are unpredictable; (2) repeated administration to the same patient does not necessarily carry the same risks; (3) slow injection does not prevent these reactions but permits interruption of the injection as soon as the onset of symptoms occurs²⁸⁵ (although it is recommended that the rate of intravenous administration should not exceed 1 mg per minute, fatalities have occurred despite adherence to these guidelines²⁸¹); (4) severe reactions have been reported most frequently in elderly patients who have received doses greater than 5 mg and after repeat dosing²⁸¹ (however, anaphylaxis has occurred in young patients even after the first administration); (5) some patients have reported no adverse events after subsequent administration following prior anaphylaxis²⁸⁶; (6) no dose dependency is evident in the frequency of reactions; however, reactions are rare when doses of 1 mg or less are used, and no fatalities have been reported at these

doses^{253,255,256,268–271,287}; (7) the cremaphor excipients in various preparations used in the United States and overseas are not identical but may carry the same risks²⁸⁵; and (8) shock occurs as the result of severe peripheral vasodilation, and treatment should be directed to counteract this effect.²⁸⁶ One patient appeared to respond to an injection of high-dose steroids (100 mg dexamethasone).²⁸⁸

Caution should be exercised with intravenous vitamin K administration. However, when other routes are not feasible, or when rapid, reliable dosing is required, it seems prudent to dissolve the preparation in 125 mL of isotonic solution²⁸⁵ and administer it carefully over 20 to 30 minutes.²⁸⁸ Small doses usually suffice, and the infusion should be halted if flushing or hypotension occurs.

OTHER AGENTS

Estrogens

Conjugated estrogens, which have been used since the 1960s to augment hemostasis for a wide variety of conditions, also have hemostatic effects in uremia.^{289,289–296} Livio and coworkers²⁹² demonstrated in a double-blinded, placebo-controlled study that conjugated estrogens given intravenously at a dose of 0.6 mg per kilogram daily shortened bleeding time in patients with uremia; this effect lasted 2 weeks and was manifest within 6 hours of the initial dose, with the maximum effect achieved at between 5 and 7 days. Additional studies in patients with uremia have confirmed the effectiveness of estrogens in shortening bleeding time with single, or repeated, intravenous doses of 0.6 mg per kilogram; administration of 0.3 mg per kilogram was ineffective.²⁹⁷ A single dose of 25 mg of Premarin (Wyeth Pharmaceuticals Inc., Philadelphia, PA, USA) administered intravenously 2 hours prior to surgery produced no effect on hemostatic parameters and did not

reduce blood loss.²⁹⁸ Oral estrogens (50 mg daily of Premarin) also shorten bleeding time and may control bleeding symptoms in uremic patients after 7.0 ± 4.2 days of therapy.²⁹⁹ Similarly, transdermal administration of estradiol at 50 or 100 μg per 24 hours every 3.5 days has been reported to shorten bleeding time in uremia and reduce transfusion requirements.³⁰⁰

Estrogens have also been used for patients with VWD. Three women who previously required blood product therapy for control of bleeding due to VWD were able to undergo successful surgical procedures after they were treated with oral estrogens administered as replacement therapy or for contraception for 2 years prior to surgery, followed by 5 mg of conjugated estrogens daily during postoperative recovery. Each patient had previously exhibited a decrease in VWD-related bleeding during pregnancy and subsequent normalization of coagulation tests during oral estrogen treatment; results of these same tests were abnormal when they were performed 8 weeks after treatment discontinuation.²⁹⁰

The mechanism of action for estrogen therapy has not been well characterized and may involve effects on the mucopolysaccharide content of the vessel wall, increased synthesis of VWF by endothelial cells, or other less clearly defined effects on hemostasis.^{289,301,302} These actions may explain the efficacy of oral estrogens in patients with gastrointestinal bleeding due to Osler-Weber-Rendu syndrome or angiodysplasia.²⁹⁵ Significant hemostatic toxicity has not been reported. Mild gynecomastia, weight gain, and dyspepsia have been reported in men.²⁹⁵ Adverse effects in men and gynecologic symptoms in women are frequently not specifically addressed.

Protamine

Protamine sulfate is a polycationic, highly positively charged protein derived from salmon sperm protein, with a molecular weight of approximately 4500 daltons.³⁰³ Protamine has been used to neutralize anticoagulation due to unfractionated heparin administration (UFH) after cardiac bypass surgery in more than 2,000,000 patients yearly.³⁰³ The mechanism of action involves binding to the negatively charged heparin molecules, forming a stable complex, and displacing antithrombin III (ATIII) from the heparin:ATIII complex.³⁰⁴ Protamine is the only effective available antidote to excessive anticoagulation produced by UFH; it is not nearly as effective against the anticoagulant activity of LMWH or fondaparinux; coagulation tests such as PTT are not useful in monitoring its action against these agents.³⁰⁵ Although it has not been established by controlled studies or supported by animal models, anecdotal evidence suggests that rFVIIa (50 to 120 μg per kilogram) may be effective in controlling massive bleeding associated with LMWH.^{101,156} Protamine possesses additional intrinsic anticoagulant activities (including induction of platelet clumping with resultant thrombocytopenia, and interference with the formation of fibrin by thrombin),³⁰⁶ so that doses in excess of those calculated to neutralize UFH should be avoided. Protamine administration may be associated with other adverse effects during bypass surgery, including hypotension, increased pulmonary artery pressure, pulmonary neutrophil sequestration, and anaphylaxis, which are mediated by complement activation, histamine release,

thromboxane and nitric oxide production, and antibody production.³⁰³ In one report, the frequency of allergic reactions may be increased in patients with a history of prior insulin use but probably not in those with a history of fish allergy or vasectomy.³⁰³

Protamine sulfate, which is administered by intravenous infusion, has an immediate onset and duration of action of about 2 hours. Dosing strategies to neutralize excessive anticoagulation induced by UFH are often based on the use of 1 mg of protamine to neutralize 80 to 100 USP U of heparin.³⁰⁶ Because the action of protamine is shorter than that of heparin, follow-up coagulation tests should be performed to detect a "heparin rebound" effect. Ordinarily, the dosage should not exceed 100 mg given over 2 hours, unless blood coagulation tests indicate a need for larger doses.

Protamine is administered after completion of bypass surgery according to estimates of circulating heparin concentrations attained with dosing algorithms and measurement of the activated clotting time (ACT).³⁰⁷ Monitoring protocols can markedly influence protamine doses used to neutralize UFH. In some but not all prospective studies, point-of-care hemostasis testing systems developed to replace traditional ACT-based empirical regimens have reduced protamine dosage and postoperative bleeding.³⁰⁷ In addition to improved monitoring, UFH neutralization may be enhanced in the future by refinements in monitoring and by the use of new agents such as low molecular weight protamine,³⁰⁴ recombinant platelet factor 4, or heparinase.³⁰⁷ The usefulness of protamine in most outpatient settings has been greatly reduced by the use of LMWH instead of UFH for most nonprocedural indications.

MANAGEMENT OF PATIENTS WHO REFUSE OR ARE REFRACTORY TO BLOOD TRANSFUSION THERAPY

One of the most challenging clinical activities in transfusion medicine involves control of hemostasis or perioperative management for patients who refuse transfusion, or those whose clinical status renders them transfusion refractory or for whom compatible blood components are otherwise not available.³⁰⁸ Examples of the former include those whose religious beliefs preclude the use of various blood-derived compounds; examples of the latter include those who have rare blood types with multiple red cell alloantibodies, thrombocytopenia with severe HLA alloimmunization, or multiple coagulation factor deficiencies in the setting of immunoglobulin (Ig)A deficiency and a history of anaphylaxis with prior plasma infusion.

In most settings, a careful approach coordinated through the hospital transfusion committee (Table 27-8) that consists of anesthesia, surgery, transfusion medicine, and hemostasis specialists may be useful in elective settings or in planned approaches to acute management. Information derived from surgery in Jehovah's Witnesses (see later) who undergo elective surgery without transfusion indicates that morbidity and mortality begin to rise sharply as postoperative hemoglobin falls to the range of 5 to 6 g per deciliter.³⁰⁹ A variety of approaches involving the use of autotransfusion devices, normovolemic hemodilution, autologous donation, evaluation of anemia, and use of

EPO therapy may be employed to augment red cell mass and minimize the need for RBC transfusion therapy³¹⁰; the choice of hemostatic agents to optimize hemostasis should be tailored to the clinical condition (see Table 27-3).

Several additional caveats must be considered in the approach to patients who refuse blood transfusion because of religious beliefs, such as Jehovah's Witness patients.³¹¹ As with beliefs involving diet or work habits, no single set of criteria that is uniformly adhered to by all followers of a religion, including Jehovah's Witness patients, can be used for transfusion support. Although most patients refuse transfusion with RBCs, platelets, or plasma, some may also refuse albumin, recombinant proteins, or the use of procedures in which their blood is physically separated from the body, such as preoperative autologous donation and some methods of acute normovolemic hemodilution. In these situations, it is prudent and essential to work carefully in advance with the patient and to include religious advisors and other church representatives if desired to define allowable therapies and review the planned approach. The application of a comprehensive approach for Jehovah's Witness patients undergoing liver transplantation (involving preoperative consent for refusal of transfusion and specific consent for therapeutic techniques, including cell salvage, acute normovolemic hemodilution, preoperative EPO therapy, and use of rFVIIa and antifibrinolytic agents) resulted in 100% survival after 19 living donor procedures and 75% survival in 8 deceased donor cases.³¹²

SUMMARY

Research into and development of new blood products and pharmaceutical agents will continue to offer increasingly sophisticated approaches for the care and management of patients with disordered hemostasis.³¹³ Strategies for appropriate use may be best established, reviewed, and revised in collaborative settings such as with the hospital transfusion committee (see Table 27-8). For those patients with congenital hemostatic disorders, recombinant products and the advent of gene therapy promise additional safety and efficacy but will also be associated with the potential for increased costs of development. Improved laboratory testing and rapid identification of appropriate therapy in surgical and other settings based on point-of-care testing and collaboratively developed guidelines promise additional benefits for those patients with acquired disorders.¹¹⁴

Chapter 28

Thrombolytic Therapy

Victor J. Marder, MD

INTRODUCTION

Thrombolytic therapy represents an acute phase of a prolonged antithrombotic management plan; decisions regarding the risk:benefit ratio are related to this usually brief but aggressive approach to vascular occlusion.¹⁻⁴ This review describes the properties of thrombolytic agents, the physiopathology of thrombolysis and bleeding complications, and the effects of treatment on blood coagulation and fibrinolytic parameters.

PLASMINOGEN ACTIVATORS

All of the currently approved thrombolytic agents are plasminogen activators (PAs) that induce plasmin action on fibrin contained within a thrombus, yielding an associated greater or lesser degree of plasma fibrinogenolysis (lytic state). Degradation of fibrin has the beneficial effect of reducing thrombus size (thrombolysis), but at the same time, PAs may cause bleeding through lysis of hemostatic plugs^{2,3} or through vascular matrix degradation (Table 28-1). Rethrombosis may follow initial reperfusion, generally as the result of a persistent vascular lesion and plasma hypercoagulability. Relationships of these biologic actions of thrombolysis, loss of vascular integrity, rethrombosis, and the plasma lytic state control the effectiveness and safety of thrombolytic treatment. Six PAs have been approved by the U.S. Food and Drug Administration (FDA)⁵ for use in major thrombotic disease: streptokinase (SK), urokinase (UK), alteplase (man-made form of tissue plasminogen activator [tPA]), anistreplase (anisoylated plasminogen streptokinase [APSAC]), reteplase, and tenecteplase (TNK-tPA) (UK is no longer available in the United States, and anistreplase is rarely used). Recombinant forms of UK, saruplase (pro-UK, scu-PA), staphylokinase, and bat-PA (PA from the salivary gland of *Desmodus rotundus*), chimerics of tPA and pro-UK, bifunctional agents composed of antifibrin or antiplatelet antibodies complexed to PA, and a recombinant plasminogen that is activated by thrombin are at various stages of testing.⁵

Primary differences among PAs relate to their antigenicity, half-life, potential for inducing a lytic state, and hemorrhagic potential (Table 28-2). Those PAs that are derived from a human protein (UK, alteplase, reteplase, saruplase, tenecteplase, lanoteplase) are minimally antigenic

or nonantigenic, whereas those produced by a bacterial species (SK, anistreplase, staphylokinase) present a potential for allergic response that may preclude prolonged or follow-up administration. The half-life of each PA determines whether it can be administered as a bolus injection, short infusion, or continuous infusion. The most suitable agents for bolus injections are anistreplase (half-life, approximately 40 minutes),⁶ reteplase,⁷ and tenecteplase⁸; the least suitable is alteplase (half-life, 5 minutes),⁹ which is best administered by continuous infusion. Clinical results suggest that some of the newer agents (e.g., tenecteplase) produce less of a plasma lytic state,¹⁰ but to date, all PAs are associated with a significant bleeding risk. The rate of bleeding is roughly equivalent for all agents, except for the higher rate of intracranial hemorrhage (ICH) seen with tPA^{4,5} or tPA mutant derivatives,⁷ relative to results when SK is used. Anticipation of greater safety with a new PA on the basis of findings of biochemical studies must be considered cautiously; no agent has yet been shown to be free of hemorrhagic risk.¹¹

DIRECT FIBRINOLYTIC AGENTS

An approach that was studied in the 1950s¹² has recently been reassessed as a potentially safe method of inducing therapeutic thrombolysis, namely, the use of direct thrombolytic enzymes, such as plasmin^{13,14} or its recombinant

Table 28-1 Principal Biologic Effects of Thrombolysis Therapy

Clinical Result	Process	Cellular and Biochemical Events
Benefit	Thrombolysis	Degradation of fibrin and disruption of platelets in the thrombus
Adverse effect	Systemic lytic state	Plasma fibrinogenolysis and derangement of platelet function
Complications	Bleeding	Degradation of fibrin in hemostatic plugs and of matrix in abnormal vessels, plus blood hypocoagulability
	Rethrombosis	Persistent local vascular lesions plus permissive status of blood coagulation

This chapter is adapted from Marder VJ: Foundations of thrombolytic therapy. In Colman RW, Marder VJ, Clowes AW, et al (eds): Hemostasis and Thrombosis: Basic Principles and Practice, 5th edition. Philadelphia, Lippincott Williams & Wilkins, 2006.

derivatives,¹⁵ and alfineprase, a genetic modification of a snake venom extract (fibrolase).¹⁶ The potential for safety is based on regional administration of the agent by catheter,¹³ after which it is quickly neutralized by plasma inhibitors, thereby minimizing its generalized circulation and reducing bleeding at sites of vascular injury.^{13,17,18} Animal studies supportive of this hypothesis show that more than fourfold the therapeutic dose of plasmin does not induce bleeding, whereas tPA causes bleeding at the therapeutic dose and at dosages as low as 25% of the optimal therapeutic amount.¹⁹ Thrombolysis under conditions of limited plasminogen content (restricted blood flow) yields better results with plasmin than are attained with tPA¹³; only the latter requires a replenished supply of this plasminogen for continued thrombolytic action.¹⁷ The safety and efficacy profile of this approach in animals suggests that clinical use of direct fibrinolytic agents will provide a treatment option that will be associated with a greatly reduced risk of bleeding.

ADJUNCTIVE ANTITHROMBOTIC AGENTS

Aspirin and Heparin

The first definitive demonstration of adjunctive antiplatelet efficacy involved the use of aspirin in addition to SK to reduce mortality after acute myocardial infarction (AMI).²⁰ In patients treated within 6 hours, aspirin reduced 35-day mortality by 23%, equal to the reduction achieved by SK alone; the two agents used together produced an additive effect that amounted to a 39% relative risk reduction. The GUSTO (Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries) study²¹ documented that early intravenous heparin is no more effective than delayed subcutaneous heparin in enhancing patient survival 30 days after AMI. Coronary artery patency studies show that intravenous heparin added to aspirin and SK increases bleeding without the benefit of improved vascular patency.²² Although delayed subcutaneous heparin combined with aspirin is relatively safe, Collins and associates²³ concluded that “there is little evidence of any additional clinical advantage with subcutaneous or with intravenous heparin” added to PA therapy.

Although it is generally agreed that heparin does not contribute significantly to a regimen of SK plus aspirin in AMI,²³

physicians in the United States continue to use intravenous heparin in concert with tPA and aspirin.²⁴ The recommendation of the Seventh American College of Chest Physicians (ACCP) Conference is to use weight-adjusted heparin in combination with tPA.²⁵ The ASSENT-3 PLUS (Assessment of the Safety and Efficacy of a New Thrombolytic 3 Plus) trial²⁶ showed advantages of low molecular weight heparin (LMWH) over unfractionated heparin (UFH) in the composite efficacy end point of mortality, reinfarction, and ischemia, but a higher rate of ICH was observed with LMWH. Subcutaneous heparin added to aspirin during PA infusion increases the risk slightly (0.6% vs 0.4%),²⁷ but the use of tPA is a most important predictor,²⁸ along with age greater than 65 years, weight less than 70 kg, hypertension on admission, and a prior history of transient ischemic attack or cerebrovascular accident (CVA). A retrospective comparison of SK (41,000 patients), anistreplase (21,000 patients), and tPA (41,000 patients) showed incidences of ICH of 0.2%, 0.6%, and 0.6%, respectively.¹¹ Recent observations of accelerated regimen tPA versus SK, reteplase, or double-bolus tPA showed an overall risk of approximately 0.8% for accelerated tPA, with a significantly higher risk (2.1%) noted in elderly patients (>75 years of age).^{22,29,30}

Direct Thrombin Inhibitors and Platelet Glycoprotein-IIb/IIIa Antagonists

Pilot studies in patients with AMI showed encouraging increases in 90-minute patency rates with hirudin rather than heparin,³¹ but the relatively high dosages of this anticoagulant therapy resulted in unacceptable rates of ICH.³² With a scaled-back dosage regimen of anticoagulant in patients receiving tPA or SK along with aspirin, a large patient trial of 3002 patients (Thrombolysis and Thrombin Inhibition in Myocardial Infarction [TIMI-9B]) showed no significant difference in clinical outcome with the use of heparin or hirudin.³³ Bivalirudin (Hirulog) use showed higher reperfusion rates than were seen with heparin when used with SK for AMI,³⁴ but a study of 17,000 patients with AMI treated with bivalirudin plus SK showed no improvement in survival over SK plus heparin.³⁵ Other antithrombin strategies, such as dalteparin with SK, efegatran with SK, and argatroban with tPA, have been tested for effect on coronary artery patency, but no convincing data have suggested improved efficacy.⁵

Effective glycoprotein (GP)-IIb/IIIa inhibition can be achieved by the monoclonal antibody 7E3 (abciximab; Centocor, Inc., Malvern, Pa) and by small-molecule inhibitors that block fibrinogen binding to platelets and prevent the cascade of biochemical events leading to aggregation. A phase 2 trial that compared reteplase with low-dose reteplase plus abciximab showed enhanced TIMI 3 flow with the combination regimen, but major bleeding was increased.³⁶ The GUSTO-V trial showed no difference in mortality between low-dose reteplase plus abciximab versus standard reteplase, but a higher rate of ICH was noted in the combination therapy group in patients older than 75 years.³⁷ The ACCP guidelines recommend against reduced dosage regimens of tenecteplase or reteplase with abciximab, in comparison with standard dosages of these thrombolytic agents.²⁵

Ultrasound

The mechanism whereby ultrasound may produce its accentuation of PA-mediated lysis is not known, but thrombolysis may be achieved locally at the same time that systemic hemorrhage is avoided. Percutaneous, transvascular ultrasonic disruption of a femoral artery thrombus³⁸ and ultrasound as adjunct to tPA administration have been assessed in patients with acute ischemic stroke, with short-term patency advantage, albeit with uncertain long-term clinical benefit.³⁹

Catheter-Directed (Regional) Infusion

The rationale for regional therapy is compelling for peripheral arterial occlusions (PAOs) because the thrombus is usually localized to a single vessel downstream from the catheter tip. Regional treatment of arterial thrombi achieves better thrombolysis than systemic therapy, but the PA is not strictly localized. During the infusion, the lytic state may be comparable with that following systemic administration, and bleeding or ICH may complicate therapy.⁴⁰ Local therapy for venous thromboembolic disease has a less compelling rationale, but this approach achieves an impressive degree of vascular reperfusion⁴¹; again, bleeding complications, including ICH, are not avoided.⁴² For the treatment of thrombotic stroke, most studies have used systemic treatment to save time, but a local approach has also been effective.⁴³ Widespread application of mechanical revascularization therapy may render obsolete the question of local coronary artery delivery of thrombolytic agents.⁴⁴ Regional treatment for slower-progressing illnesses that offer the luxury of time required for this approach is most applicable for dissolving thrombi in occluded catheters.

PLASMA PROTEOLYTIC ("LYTIC") STATE

The "lytic state" describes the effect of plasmin in the circulation,⁴⁵ the most physiologic definition of which is a true decrease in plasma fibrinogen (Table 28-3) rather than a laboratory artefact, caused, for example, by heparin. Free plasmin also decreases platelet aggregation⁴⁶ after an initial phase of hyperaggregability.⁴⁷ Thus, a patient may experience sequential hypercoagulability, hypocoagulability,

Table 28-3 Development of the Plasma Proteolytic (Lytic) State

Biochemical State	Laboratory Parameter
Circulating plasminogen activator	Short euglobulin lysis time
Plasminogen converted to plasmin	Decreased plasminogen
Antiplasmin neutralizing plasmin	Low antiplasmin, plasmin/antiplasmin complexes
Free plasmin	Decreased fibrinogen, increased degradation products (including D-dimer)
Action on platelets	Hyperfunction and/or hypofunction
Hypocoagulable state	Prolonged global coagulation tests (PTT) and bleeding time

PTT, partial thromboplastin time.

or even the simultaneous occurrence of both, depending on the phase of lytic state that exists.

According to the concept that the actions of PAs in the blood and on the thrombus are separate events,³ thrombolysis or bleeding would not necessarily correlate with the degree of lytic state. However, a recurring assumption holds that a PA with fibrinogen-sparing properties would cause less bleeding because the induced lytic state is minimized. For example, UK or SK treatment of pulmonary embolus (PE) or DVT regularly induces the lytic state, but changes in fibrinogen concentration, plasminogen, or euglobulin lysis time are not significantly different in patients with or without a hemorrhagic complication.^{48,49} Further, SK-treated patients in the TIMI trial, phase 1, showed significantly lower fibrinogen values than did those treated with tPA, but the incidence of bleeding complications was the same with both treatments.⁵⁰ Also, patients treated with tPA who suffered ischemic (thrombotic) or hemorrhagic CVA had the same nadir concentration of fibrinogen.⁵¹ The template bleeding time is prolonged during thrombolytic therapy, but no distinction is made between patients with and without hemorrhagic complications.⁵² The only predictive blood value for hemorrhagic complications during tPA treatment is plasma tPA concentration (3.4 µg per milliliter in bleeders vs 2.2 µg per milliliter; $P = .002$).⁵³ The higher value noted in those who bled suggests that tPA has a direct effect on susceptible hemostatic plugs or vascular sites, to a greater extent with higher concentrations, independent of changes in fibrinogen concentration. This effect helps to explain the higher rate of ICH that occurs with high therapeutic dosages of tPA⁵⁴ and supports the concept that bleeding occurs independent of PA effect on blood coagulation; it probably is the result of action at sites of vascular injury or malformation.⁴ A retrospective analysis of more than 40,000 patients in the GUSTO-I study found that independent predictors of hemorrhage consisted of older age, lighter body weight, female sex, and African ancestry, rather than any known degree of laboratory derangement.⁵⁵

Laboratory results also do not predict vascular reperfusion or degree of patency. When a large systemic dose of

UK was used to treat acute PE, no correlation was noted between laboratory results and decreased embolus size⁴⁸; DVT trials also showed no correlation of fibrinogen concentration with venographic change.⁴⁹ Even intracoronary SK for AMI showed no difference in nadir plasma fibrinogen in patients who did or did not reperfuse,⁵⁶ and similar measurements in patients with AMI receiving tPA also failed to show a correlation with posttreatment coronary artery patency.⁵³ Although universal agreement has not been reached, the data do suggest that changes in blood coagulation or fibrinolytic assays after PA administration do not directly reflect degree of thrombolysis. A reasonable approach to noninvasive measurement of successful thrombolysis would be to measure plasma levels of crosslinked fibrin degradation products (FDPs), but the data thus far are not conclusive; some show high predictability for successful vascular reperfusion,⁵⁷ and others fail to document such a correlation.⁵⁸

Laboratory Monitoring

Different from treatment regimens with thrombin inhibitory agents such as heparin, PA dosage regimens are standardized, so dosage regulation on the basis of laboratory findings is unwarranted. Once a lytic state has been attained, the dose of PA does not have to be regulated because alterations based on laboratory markers would neither improve the chance of thrombolysis nor decrease the risk of hemorrhagic complications. An exception to this rule involves the use of direct thrombolytic agents, for which a direct relationship of dose to plasma fibrinogen has been identified¹⁹; only when fibrinogen is totally depleted would hemostatic safety possibly be compromised.

COMPLICATIONS

Bleeding

Absolute contraindications to PA therapy are those that may result in ICH or massive, life-threatening hemorrhage; in decisions regarding PA use, this risk must be weighed against the potential benefits of accelerated thrombolysis (Table 28-4). Thus, some patients with life-threatening thrombotic disease, for example, massive PE with profound shock or a large anterior wall AMI, may require potentially life-saving thrombolytic therapy even in the face of “absolute” contraindications. Patients with relatively less threat-

ening thrombotic disease such as limited DVT would reasonably not receive PA therapy if the history includes a transient ischemic attack, prior thrombotic stroke, or untreated hypertension; those with an increased risk of symptomatic but not serious bleeding, for example, with arteriotomy or venotomy, active menses, or minor surgical or biopsy procedures, might be administered a PA. The elderly patient with AMI has a greater risk of bleeding, especially from ICH, but also a higher risk of death from AMI than does the younger patient. Therefore, the survival benefit in patients older than age 70 is relatively greater than in those younger than 60 years (80 vs. 25 lives saved per 1000 treated).^{20,59}

In patients with life-threatening bleeding or sudden emergencies that require surgical intervention, normal hemostasis can quickly be reestablished by the clinician who discontinues PA infusion, replenishes plasma fibrinogen with whole plasma or cryoprecipitate, and provides fresh platelets to correct dysfunctional platelets (Table 28-5). If the PA has not yet been cleared from the circulation, fibrinolytic activity can be neutralized with a fibrinolytic inhibitor such as ϵ -aminocaproic acid or aprotinin. Coronary artery bypass graft surgery may be performed after PAs are used (both SK and TPA), but such therapy carries a risk of bleeding, albeit with a greater need for blood transfusion if performed at 12 hours rather than at 18 to 48 hours.^{60,61} This procedure may be used to replace a deficient or defective pool of plasma fibrinogen. One possible reason for bleeding as late as 24 hours after PA infusion is that is the time required for fibrinogen to be synthesized sufficient for surgery. It is reasonable to replenish fibrinogen with cryoprecipitate because essentially no normal fibrinogen is present during SK⁶² or tPA infusion⁶³; also, platelet function may be restored with fresh platelet transfusions given for up to 24 hours after PA administration. In addition, anti-fibrinolytic therapy should be administered prophylactically if PA continues to circulate—an expected situation for varying lengths of time after the infusion has been stopped.⁶⁴

Unhealed vascular trauma sites are susceptible for about 10 days after trauma to fibrinolytic bleeding caused by PA exposure. Once the clinician plans to treat a patient with a PA, unnecessary trauma should be avoided. For example, medications should be administered by mouth or intravenously, rather than intramuscularly, phlebotomy sites should be compressed for 5 or 10 minutes, and unnecessary arteriotomy should be postponed or avoided. Bleeding that occurs during PA infusion should be managed with blood replacement and, if necessary, with discontinuation of the infusion. Depending on the half-life of the activator, a fibrinolytic inhibitor may or may not be required, but fresh fibrinogen replacement and platelet transfusion are usually required to ensure hemostasis, whether one has administered a long- or a short-acting agent and independent of whether the patient is in a potent or mild plasma lytic state.

Allergy and Embolism

Treatment may be terminated in the face of allergic or pyrogenic adverse effects, which may also require administration of corticosteroids, antihistamines, or adrenergic agents for anaphylaxis, and antipyretics for fever. Allergic reactions are three to five times more frequent with

Table 28-4 Absolute Contraindications to Fibrinolytic Therapy

Risk	Condition
Intracranial bleeding	Hemorrhagic cerebrovascular accident, known intracranial neoplasm, recent cranial surgery or trauma (within 10 days), uncontrolled severe hypertension
Massive hemorrhage	Major surgery of thorax or abdomen (within 10 days), prolonged cardiopulmonary resuscitation, current severe bleeding site (e.g., gastrointestinal tract)

Table 28-5 Resolution of Hypocoagulable State Induced by Plasminogen Activators

	During Treatment	Immediately After Treatment	6 to 36 Hours After Treatment
Plasma fibrinogen	Low	Nadir	Progressive recovery
Need for cryoprecipitate	Yes	Yes	Yes
Bleeding time	Long	Variable	Normal*
Need for platelets	Yes	Yes	No
Circulating activator	Present	Variable	Absent
Need for antifibrinolytics	Yes	Yes	Yes

*Unless aspirin is also administered, in which case the potential for bleeding may persist.

bacterially derived products than with tPA-type derivatives, but even the latter may induce an allergic reaction such as bronchospasm or angioneurotic edema.^{65,66} Hypotension occurs in about 12% of patients with AMI exposed to SK and 7% of those exposed to tPA, in comparison with only 1.5% of patients not exposed to a PA.⁶⁷ Embolic phenomena of clinical importance are distinctly unusual in patients with venous thromboembolic disease. In the Urokinase PE Trial (UPET),⁴⁸ recurrent PE occurred in 15% of patients receiving UK or heparin, but release of a venous thrombus to function as a fatal pulmonary embolus during PA treatment is distinctly unusual. Distal systemic embolization from a cardiac source during PA treatment is unusual, but up to 20% of patients with PAO suffer sudden distal embolism and new ischemia of the extremity.⁶⁸ In this circumstance, the best treatment is continued local instillation of PA, which usually is successful in dissolving the new embolus.

CLINICAL APPLICATIONS

Table 28-6 summarizes the FDA-approved agents included in the major categories of vascular thrombotic disease, namely MI, PAO, DVT, PE, acute ischemic stroke (CVA), and catheter occlusion. These approvals are based on pivotal clinical trials, but actual practice may reflect an evolution of dosage schedules or mode of administration. Table 28-7 summarizes the clinical benefits anticipated with the use of PA in patients with major vessel occlusion.

Deep Venous Thrombosis

The typical patient with DVT manifests a generally benign course. However, an occasional patient experiences marked proximal extension of the thrombus and massive pulmonary embolization despite anticoagulant treatment; in addition, postphlebotic syndrome may occur in 25% of

Table 28-6 Current Clinical Usages of Available Plasminogen Activators*

Agent	Clinical Indication	FDA-Approved Regimen	Common Use
Urokinase (Abbokinase)	PE Acute MI PAO, DVT	12-hr IV infusion Intracoronary only Not approved	Agent intermittantly available. Widespread usage by regional and catheter-directed route. Agent currently available.
	Thrombosed central line or shunt	5000 U in 1 mL	
Streptokinase (Streptase)	Acute MI PE	IV or IC IV over 12 hr	Used primarily by intravenous route. Effective when given for shorter courses, even 2 hr.
	DVT PAO Thrombosed arteriovenous cannulas	IV for up to 36 hr IV Local instillation	Shorter infusions (e.g., over 18 hr) safer. IV route not as effective as regional route.
Retaplast (Retavase)	Acute MI	Two bolus injections 30 min apart	Approved in 1999.
	PAO	Not approved	Used regionally "off-label".
Alteplase (Activase)	Acute MI Acute ischemic stroke	3 hr or 90 min 90 mg over 1 hr	Accelerated dosage used most often. Limited usage, as must be applied within 3 hr of onset of symptoms.
	PE	100 mg/2 hr	Urokinase over 2 hr, equal efficacy.
Anistreplase (Eminase)	Acute MI	30 U over 2–5 min	Infrequently used.
Tenecteplase (TNKase)	Acute MI	Single bolus, weight adjusted	Approved in 2000.

DVT, deep vein thrombosis; FDA, U.S. Food and Drug Administration; IV, intravenous; IC, intracardiac; MI, myocardial infarction; PAO, peripheral arterial occlusion; PE, pulmonary embolism.

*Based on Physicians' Desk Reference. Montvale, NJ, Medical Economics Co., 2000.

Table 28-7 Natural History and Anticipated Clinical Benefit of Thrombolytic Treatment for Acute Thrombosis

Thrombotic Disorder	Natural History (with Antithrombotics)	Potential Benefit of Thrombolytics	Clinical Decisions
DVT	Slow resolution, subclinical PE frequent, postphlebotic syndrome in 25%–50% with proximal thrombi.	Treatment within 7 days, complete lysis in one half of cases; decreased incidence of postphlebotic syndrome.	Treat large proximal thrombi, especially with coexistent PE. Catheter delivery (urokinase, alteplase, reteplase) in wide usage but still under study.
PE	Slow (1 wk) reduction of pulmonary hypertension. Overall mortality 7%, up to 30% with massive PE and hypotension.	Earlier treatment (within 48 hr) induces rapid thrombolysis and accelerates reversal of pulmonary hypertension. Possible increased survival in patients with clinical shock.	Thrombolytics for massive PA with shock, coexistent cardiopulmonary disease, or submassive PE, if no contraindications.
PAO	Major surgical intervention in 95%, cardiopulmonary complications in 50%, loss of limb in 20%, 1-yr mortality up to 40%.	Striking thrombolysis in 70%, surgery avoided in 35%, no change in limb salvage but potential for decrease in 1-yr mortality.	Catheter delivery of PA superior to systemic infusion. Thrombolytic treatment preferred over surgery for initial treatment for the ischemic but salvageable limb.
MI	Overall mortality 11.5% vs 8.0% for inferior MI, 17.0% for anterior MI.	Overall mortality reduced by 20%–50%, most striking in patients with anterior MI treated within 4 hr after symptom onset.	Indicated for most patients within 6 hr of symptoms; angioplasty offers advantages and is increasingly used.
CVA	Irreversible deficits and risk of death depending on location; hemorrhagic transformation relatively infrequent (3%).	Good results only if treatment initiated within 3 hr, reversal of neurologic deficit at a cost of increased parenchymal hematoma.	Clear-cut functional benefit without increased mortality risk if treatment before 3 hr, but with increased risk of hemorrhagic transformation.

CVA, cerebrovascular accident; DVT, deep vein thrombosis; MI, myocardial infarction; PA, plasminogen activator; PAO, peripheral arterial (or graft) occlusion; PE, pulmonary embolism.

patients⁶⁹ as a late, disabling sequela of proximal DVT. Both of these eventualities are rationales for thrombolytic treatment.⁷⁰ Venous thrombi are lysed more rapidly and effectively when a PA is used (concurrently with anticoagulation); complete lysis is achieved in 50% of patients versus 10% with heparin alone.⁷¹ Effective thrombolysis reduces the incidence of postphlebotic syndrome from about 40% to 10%,⁷² presumably because of more rapid clot lysis, which preserves venous valve leaflet integrity. However, with systemic (intravenous) administration of a PA over an interval of 2 to 7 days, the period of continued risk of hemorrhage results in an incidence of ICH that approaches 1%.⁷³

Over the past 10 years, a more aggressive approach to PA delivery has consisted of regional perfusion by catheter directly into the thrombus, often combined with stent placement. Impressive recanalization rates have been attained, with up to 90% complete and partial lysis, and in anecdotal cases, substantial benefit has been noted in patients with symptoms lasting longer than 4 weeks.^{41,74–76} It is likely that the clinical impression that old thrombi are resistant to thrombolysis may in fact reflect a problem of inadequate intravenous delivery of PA to a fully occluded vessel—a situation that may be overcome by direct catheter delivery of PA to a thrombus that is still amenable to thrombolysis. Although outcomes when regional infusion is combined with stenting are impressive, no prospective comparison has been made with systemic treatment, and bleeding complications continue to occur in 11% of cases, and death due to PE or ICH is not eliminated.⁷⁷ Inferior vena caval (IVC) filters are reasonably used in the management of proximal DVT in those few patients with strong contraindications to thrombolytic therapy, and in those with

serious, coexistent PE, but such devices preclude neither subsequent proximal thrombolysis or recurrent PE nor subsequent chronic anticoagulant therapy⁷⁸ (see Chapter 31).

Pulmonary Embolism

The anticipated clinical course of patients with PE varies according to the size of the embolus and the existing cardiopulmonary reserve.^{48,79,80} With routine heparin anticoagulation, the overall risk of mortality is 7% to 9%, and much higher mortality rates are seen in patients with massive PE and concomitant shock due to acute cor pulmonale. Thrombolytic therapy is beneficial in reversing cardiovascular compromise and preventing chronic pulmonary hypertension (see Chapter 45). Short-term improvement follows treatment with UK, SK, or tPA plus heparin compared with heparin alone, as reflected by rate of thrombolysis, pulmonary artery reperfusion, recovery of abnormal perfusion lung scans, decrease in pulmonary arterial pressure, and improved right ventricular function. These benefits are most pronounced in patients with acute symptoms of less than 48 hours duration.⁴⁸ In long-term follow-up studies (mean, 7.4 years), pulmonary vascular response to exercise suggests that thrombolytic therapy may prevent chronic sequelae such as pulmonary hypertension.⁸¹

In a comparison of 2 hours of tPA versus 12 hours of SK, thrombolysis was more rapid with tPA, but no difference was observed in pulmonary artery obstruction on follow-up at 1 day or 10 days.⁸² Two-hour infusions of tPA or UK produced equal angiographic benefit,⁸³ and SK compared with tPA also produced equal benefit on pulmonary resistance.⁸⁴ Bolus reteplase demonstrated

a decrease in pulmonary resistance that was comparable with that produced by 2 hours of tPA.⁸⁵ Thus, by extrapolation, a short course of any PA is expected to be effective for reducing pulmonary resistance in massive PE. Administration of PA directly into the pulmonary artery is not superior to treatment with systemic PA.⁸⁶

Controlled trials of PA versus heparin in patients with massive, submassive, or small PE have not shown differences in mortality,⁸⁷ perhaps because of the small patient enrollment. Case series of tPA during cardiopulmonary resuscitation of patients after fulminant PE have demonstrated dramatic survival benefit,⁸⁸ and uncontrolled studies show that patients with massive PE and clinical shock have a better outcome with PA therapy than with thoracotomy and pulmonary embolectomy.⁸⁹ Given the risk of ICH, a limited time window for maximum therapeutic response, and unproved mortality benefit to date, patient selection for thrombolysis should be limited to the seriously ill patient who would benefit the most in the immediate short term and avoidance of those at highest risk for ICH.

Peripheral Arterial Occlusion

A combined radiologic and medical approach is superior to surgery as initial therapy for the acutely threatened but not irreversibly ischemic limb. However, protection from serious hemorrhage is no greater with regional delivery of PA, and generalized atherosclerosis, hypertension, and other manifestations of arterial disease make thrombolytic therapy more likely to cause bleeding complications than in patients with venous thromboembolic disease. Chronic arterial occlusions do not respond to systemic (intravenous) PA administration,⁹⁰ but acute occlusions are amenable if therapy is undertaken within hours of symptom onset, especially if occlusion is due to an embolus.⁹¹ Occlusion of small distal arteries technically unapproachable by surgery also may be responsive to systemic PA infusion.

Dotter and colleagues⁹² first reported success with an intra-arterial thrombolytic agent (SK) in 1974, and despite hypotheses to the contrary, this approach did not prevent a systemic lytic state or associated hemorrhage. Subsequent studies of regional administration validate that reperfusion can be attained in 50% to 80% of cases, although an underlying stenosis may require angioplasty or bypass surgery to prevent prompt reocclusion.^{93,94}

A prospective randomized comparison of regional thrombolytic therapy versus surgical bypass grafting as initial management of patients with ischemic limbs caused by arterial occlusion was reported in 1994.⁹⁵ In this study of 114 patients, catheter-directed infusion of UK reperused 70% of thrombosed grafts or vessels, one third of which required simple angioplasty or patch grafting for long-term patency. Although overall limb salvage and in-hospital mortality were the same for patients receiving intra-arterial UK and surgical repair, 1-year mortality was lower in the thrombolytic group (16% vs 42%) because of the lower incidence of cardiopulmonary complications.

This study design was duplicated with recombinant UK, which achieved patency in 70% of cases and reduced the need for major surgical procedures by 40% (313 vs 551)⁹⁶ but failed to demonstrate a survival benefit. Serious bleeding occurred in 13% of patients who were given

recombinant UK (vs 6% with surgery), and ICH occurred in 1.5% of patients, perhaps as a result of concomitant heparin use. In a similar trial of tPA and UK, no clinical advantage was noted for PA administration over surgery.⁹⁷

Retrospective analyses show tPA or UK to be superior to SK in terms of thrombolytic revascularization of occluded arteries (80% vs 64%) and hemorrhagic complications (5% vs 25%).⁹⁸ However, no prospective comparison has been conducted between SK and tPA or UK. Only one study directly compared tPA with UK⁹⁷; no difference in clinical outcomes was reported. The similar efficacy of various PAs in comparative trials of PE and acute MI suggests that all agents offer equivalent advantages relative to surgery in the treatment of the salvageable ischemic limb. Reteplase, which was evaluated in a small series, achieved complete dissolution of a high percentage of occlusions, but with a 9% risk of major hemorrhage.⁹⁹ Intra-arterial staphylokinase achieved complete revascularization in 83% of occlusions; amputation-free survival at 1 year was 90.2%, but fatal ICH occurred in 2.1% of cases.¹⁰⁰

Myocardial Infarction

Systemic PA infusion reduces mortality after AMI by more than 40% when administered within 1 to 2 hours, and by 20% to 25% at 4 to 6 hours after onset of symptoms²⁷—a survival advantage that persists for at least a decade.¹⁰¹ Aspirin virtually doubles the survival benefit of PA alone,¹⁰² and heparin is problematic as an adjunct for SK¹⁰³ but is still considered important for tPA usage.¹⁰⁴ The GISSI-2 and ISIS-3 studies^{105,106} showed the same mortality with SK, tPA, and anistreplase, but the GUSTO trial¹⁰⁷ showed a small but significant mortality advantage in favor of accelerated tPA plus IV heparin over SK—6.3% versus 7.2%, representing a difference of 9 patients per 1000 treated. The incidence of ICH was significantly higher with tPA in all three trials (0.7% vs 0.35% to 0.5%), mitigating against a clear-cut advantage for tPA. Reteplase restores coronary patency (TIMI 3 flow) more effectively than accelerated tPA (60% vs 45%),¹⁰⁸ but no decrease in mortality was reported for reteplase over tPA (7.47% vs 7.24%),¹⁰⁹ or even over SK (9.02% vs 9.53%),¹¹⁰ despite the prior advantage demonstrated for tPA over SK. Tenecteplase achieved equivalent 30-day mortality against accelerated tPA (6.18% vs 6.15%) and equivalent rates of ICH (about 0.9%).¹¹¹ A third mutant PA, lanoteplase, was tested against tPA and was found to have an equivalent mortality rate but a significantly higher rate of ICH (1.12% vs 0.64%),¹¹² which likely explains why this agent has not been approved by the FDA for this particular indication.

Improvements in PA efficacy, especially with regard to coagulation-related reocclusion, have been addressed by the use of alternatives to heparin and aspirin as adjunctive agents (see earlier). Tenecteplase (plus LMWH or UFH) compared with reduced-dose tenecteplase (plus lower dose UFH and abciximab)¹¹³ showed no significant 30-day mortality benefit; the same rate of ICH was reported in all groups (0.9%). Similarly, low-dose reteplase plus abciximab showed no significant difference in 30-day mortality in comparison with standard reteplase (5.6% vs 5.9%). Although overall ICH was not increased (0.6%), the rate was higher in patients older than 75 years of age (2.1% vs 1.1%) in the group given reteplase plus abciximab.¹¹⁴

Direct thrombin inhibitors (DTIs) such as bivalirudin accelerate reperfusion when used with SK, but not tPA.¹¹⁵ The HERO-2 (Hirulog and Early Reperfusion/Occlusion) study in 17,000 patients with MI showed no difference in 30-day mortality (10.8% vs 10.9%),³⁵ again illustrating a disparity between 90-minute patency and mortality benefit. ICH was slightly but not significantly higher with hirudin than with heparin (0.6% vs 0.4%). If only to avoid the excess risk of ICH, immediate angioplasty is a feasible approach for large centers with this technical capacity.

Ischemic Stroke

In the 1990s, six randomized, blinded trials of systemic (IV) PA investigated the treatment of patients with ischemic stroke; three studied the use of SK, and three evaluated the effectiveness of tPA.¹¹ The most important distinguishing factor between these trials was the time delay from onset of symptoms to treatment; only one trial limited entry to 3 hours.¹¹⁶ The three SK trials were terminated before completion because of an excess in mortality at 10 days, generally attributed to ICH; a fourth study showed a trend for increased 30-day mortality ($P = .08$).¹¹ The only study that showed no increase in mortality at 30 days was conducted by the National Institute of Neurological Disorders and Stroke rtPA Stroke Study Group; this group assessed tPA in patients enrolled within 3 hours of symptom onset; higher rates of death and severe disability were reported when placebo was used versus tPA (21% vs 17%).¹¹⁶ Whether this distinction between the SK and tPA studies is due to the agent or to the regimen that was applied (less than vs more than 3-hour delay) was assessed by subgroup analyses of the Australian Streptokinase Trial¹¹⁷ and the ECASS (European Cooperative Acute Stroke Studies)¹¹⁸ trials with tPA. All studies showed favorable functional outcomes in patients treated within 3 hours, without excess mortality. Further evidence of the critical nature of this 3-hour time window is reflected by the ATLANTIS (Alteplase Thrombolysis for Acute Noninterventional Therapy in Ischemic Stroke) study of tPA,¹¹⁹ in which 547 patients were treated at between 3 and 5 hours after symptom onset. Greater neurologic improvement was described at 24 hours for tPA-treated patients (40% vs 21%), but functional improvement at 3 months was not different (34% vs 32%), and symptomatic ICH (7% vs 1.1%; $P < .001$), fatal ICH (3% vs 0.3%; $P < .001$) at 10 days, and higher mortality at 3 months (11% vs 6.9%; $P = .09$) were more common with tPA. A meta-analysis of thrombolytic therapy in acute ischemic stroke (17 trials; 5216 patients)¹²⁰ concluded that thrombolytic therapy administered up to 6 hours after ischemic stroke significantly reduced death or dependence at follow-up (55.2% vs 59.7%) by 44 patients per 1000 treated; for treatment within 3 hours, the advantage increased to 126, but at a risk of 70 additional episodes of ICH per 1000. Only tPA has been tested in sufficient numbers of patients within this "golden window" of opportunity¹²¹; no direct comparison of tPA with SK has been undertaken.

Direct intra-arterial thrombolysis has been tested in a controlled trial with the use of saruplase (recombinant pro-UK) in patients with middle cerebral artery occlusion who present within 6 hours of symptoms.¹²² Recanalization

was more frequent with active agent (66% vs 18%) and at 90 days; a greater number of saruplase-treated patients were functionally independent (40% vs 25%). However, 90-day mortality was the same for treatment and placebo groups, and ICH was more frequent with saruplase (10.9% vs 3.1%).¹²³ A small trial evaluated intra-arterial reteplase in 16 patients with acute ischemic stroke that affected varying arterial locations¹²⁴; reperfusion was evident in 88% and neurologic improvement at 24 hours was observed in 44%, but ICH occurred in 25%, and the overall mortality rate was 56%. The direct-acting fibrinolytic agents (see earlier) have the potential for safer therapy than is provided by PAs, but studies have not yet been initiated.

Chapter 29

Topical Hemostatic Agents for Localized Bleeding

Mark R. Jackson, MD

INTRODUCTION

For many years, topical hemostatic agents have consisted primarily of various forms of animal collagen and gelatin. These commercially prepared products have been used by surgeons in the operating room as adjuncts to surgical hemostasis. Most of these products have limited, if any, inherent coagulation properties and merely serve as a scaffold for fibrin deposition. Newer products, such as fibrin sealant, are now available as commercial preparations. These materials are combinations of highly purified, virally inactivated human thrombin and fibrinogen, and as such, they provide the final step in the coagulation cascade. Other products include combinations of gelatin matrix with bovine thrombin that possess some of the properties of the older agents and provide some inherent coagulation properties. Newer still are hemostatic, nonthrombogenic products designed primarily as sealants and adhesives, which can serve such purposes as sealing vascular anastomoses.

These materials are best categorized into two groups—topical sponge and mesh materials, and sealant and adhesive materials. In this chapter, we review these products, their intended and potential future uses, and the clinical settings in which they are used.

INTRAOPERATIVE AND POSTOPERATIVE BLEEDING

The most common cause of significant intraoperative bleeding is inadequate surgical hemostasis, so-called “silk deficiency.” No pharmacologic or blood bank products can be substituted for careful dissection and attention to technical detail. Application of digital pressure to an area of active bleeding is a useful maneuver while more definitive steps are in progress. Even apparently trivial bleeding from skin edges and subcutaneous tissue may cause up to 100 to 200 mL of blood loss, if unattended.¹ Dissection with the use of electrocautery rather than a scalpel reduces blood loss.^{2,3}

Intraoperative disorders of hemostasis occur for a number of reasons. Coagulopathy in patients with vascular trauma is related more to hypotension and hypoperfusion than to dilutional factors.⁴ Tissue hypoxia may cause release of plasminogen activators, thereby stimulating fibrinolysis. Hypothermia may be another contributing factor, particularly in the trauma patient. Dilutional thrombocytopenia

can occur in the massively transfused patient, particularly after infusion of 20 or more units of banked or cell salvage blood.⁵

To successfully manage hemostasis at the local level, physicians in the operating room must first correct systemic attributes that contribute to coagulopathy. Hemodynamic stability and normal temperature must be restored. Dilutional coagulopathy should be addressed with platelet or factor replacement, as indicated by laboratory markers of hemostasis. Disorders of hemostasis caused by antiplatelet agents and anticoagulation introduce an additional layer of complexity in patients such as those undergoing cardiac or vascular surgery and for whom reversal of antithrombotic therapy might be undesirable or not practical. Topical hemostatic agents may provide a useful adjunct to securing adequate hemostasis in patients who have persistent local bleeding despite all reasonable efforts to restore systemic coagulation mechanisms, even with the use of sutures and electrocautery.

TOPICAL SPONGE AND MESH MATERIALS

Collagen-Based Materials

A number of absorbable bovine collagen products are available commercially for use as topical hemostatic agents (Table 29-1). These materials are often packaged as sheets that can be cut to various sizes once opened and placed on the sterile surgical field. These materials are somewhat stiff, so they often can be more easily used and manipulated if they are moistened with saline solution or blood from the wound. Also, when these materials are dry, they are somewhat “sticky” and are not as easily handled. Many surgeons moisten these products with solutions of bovine thrombin. Once moistened, these sheets have the consistency of wet felt and can be easily wrapped around a vascular anastomosis, or placed in a single layer on a relatively flat bleeding wound surface. Such materials may be useful for small capsular tears of the spleen, for example. Collagen-based topical agents are absorbable and therefore may remain in the wound if necessary.

Microfibrillar collagen has a consistency similar to sawdust and is packaged as a powder. Similar to other collagen products, it absorbs surrounding blood and basically functions as a mechanical template on which the patient’s fibrin clot is formed. Microfibrillar collagen has a tendency to adhere to the surgeon’s gloves and instruments, as well as

Table 29-1 Summary of Commonly Used Topical Hemostatic Agents Available in the United States

Agent	Manufacturer	Composition	Clinical Comments
Sealants and Adhesives			
Tisseel VH	Baxter	Human fibrin sealant	Purified, pasteurized human proteins. Component proteins mixed using “two-into-one” syringe. Preparation may require 20 minutes because of the need for warming of constituent protein solutions. Does not adhere well to some prosthetic vascular grafts.
CoSeal	Baxter	Polymerized polyethylene glycol	Newer product. Adheres well to prosthetic grafts; works well for suture line bleeding. Prepared from a “two-into-one” syringe, as with fibrin sealant. Prepared at room temperature.
BioGlue	Cryolife Inc.	Bovine serum albumin crosslinked with glutaraldehyde	Used most often in cardiac and thoracic aortic dissection surgery. Tenacious bonding properties.
Absorbable Sponge and Mesh Materials			
Surgicel	Ethicon, Johnson & Johnson	Oxidized regenerated cellulose	Applied in “sheets,” meshlike consistency. Can be easily “rolled” for endoscopic use.
Surgicel Fibrillar	Ethicon, Johnson & Johnson	Oxidized regenerated cellulose	“Feltlike” consistency. Bulkier than Surgicel, which may be advantageous in deeper wounds.
FloSeal	Baxter	Collagen particles and bovine thrombin	“Slurry-like” consistency. Easily prepared.
Gelfoam	Upjohn & Pharmacia	Gelatin	Stiff, sheetlike consistency. Often moistened and used with bovine collagen.
Avitene	CR Bard	Microfibrillar collagen	Several preparations—sheets and powder. Powder form has a “sawdust” consistency. Clings tenaciously to wound and surgeon’s fingers. Bulkiness is advantageous in deeper wounds and in “wetter” wounds.

to the wound. Because of its powder-like consistency, it can be placed easily within irregular surfaces and crevices of deep wounds.

Collagen materials have demonstrated hemostatic efficacy in preclinical and clinical studies.^{6,7} Early preclinical studies of the hemostatic properties of microcrystalline collagen in a canine model of arterial injury reported a 93% rate of early hemostasis when collagen was applied to a carotid artery puncture made with a 17-gauge trocar.⁶ Hemostasis was far superior with microcrystalline collagen than with oxidized cellulose or pressure alone. An interesting finding from these experiments involved the use of collagen in animals anticoagulated with intravenously administered heparin (300 IU per kilogram). Of this group, 24% had delayed bleeding during the 1-hour experiment, suggesting that intact coagulation mechanisms are instrumental in ensuring maximal effectiveness of these collagen topical agents.

Cellulose-Based Materials

Topical hemostatic agents composed of oxidized regenerated cellulose are also available as fabric-like and as fibrillar (powder-like) products. The cellulose fabric can be cut to conform to the wound or to wrap a vascular anastomosis. Because the material is softer than collagen and gelatin products, predeployment wetting is optional. The cellulose fabric is also thinner than most collagen products and is knitted in a manner that produces interstices. A potential

advantage of cellulose over collagen and gelatin-based agents is that oxidized regenerated cellulose has exhibited antibacterial properties in vitro.^{8,9} Similar to collagen, oxidized regenerated cellulose is absorbable and can remain in the wound. Cellulose products come in two configurations—a mesh material and a feltlike (fibrillar) material (see Table 29-1). Fibrillar cellulose is preferred by the author during open vascular surgery procedures for which a mass of thrombogenic material is desired for tamponade effect and when sealant properties are not required.

Gelatin-Based Materials

Purified gelatin of bovine origin is also used as a topical hemostatic agent. It is prepared as a thin, wafer-like sheet that has the consistency of styrofoam. Once moistened, it is pliable and easily conforms to the shape of a wound or a vascular anastomosis. Similar to collagen and cellulose-based agents, gelatin-based materials are absorbable and can remain in the wound after closure. Many surgeons use bovine thrombin as the wetting agent. Gelatin-based topical hemostatic agents have been compared with collagen-based agents in a number of animal models of hemostasis. Although some studies have shown superiority of the collagen products,^{10,11} others have demonstrated equivalency.^{12,13}

Recently, another gelatin-based hemostatic agent has been approved by the U.S. Food and Drug Administration (FDA) (FloSeal). This product is composed of bovine source

gelatin granules and bovine thrombin. These two ingredients are mixed together and placed in a single-barrel syringe prior to use. The gelatin and thrombin mixture is then applied to the site of bleeding. The final product has a granular, gel-like consistency, and is easily applied with the accompanying syringe. Recently, investigators at Columbia University College of Physicians and Surgeons reported results of a multicenter, randomized clinical trial in which this hemostatic agent was evaluated in a total of 309 patients who were undergoing cardiac, vascular, and spinal surgery.¹⁴ Patients were randomly assigned to receive FloSeal or bovine thrombin-soaked Gelfoam (Upjohn and Pharmacia, Kalamazoo, Mich, USA) applied at sites of bleeding that required topical hemostatic agents. Hemostasis at 10 minutes was achieved in 94% of patients with FloSeal, and in only 60% in the control group ($P = .001$). All patients were tested preoperatively and at 6 to 8 weeks for the development of antibodies to bovine thrombin and factor V. Although no evidence of antibody-related hemorrhage was noted in either group, bovine thrombin antibodies were detected by enzyme-linked immunosorbent assay in 9 patients treated with FloSeal and in 12 control patients ($P = .76$). Bovine factor V antibodies were detected in 11 patients treated with FloSeal and in 15 controls ($P = .43$).

FloSeal has been evaluated in a multicenter randomized clinical trial of hemostasis during peripheral vascular surgery and was found to be more effective than Gelfoam and bovine thrombin.¹⁵ The primary end point, cessation of bleeding within 10 minutes of application, was met in 94% of FloSeal patients and in only 76% of controls ($P = .036$). Time to hemostasis was also superior in the FloSeal group at 2.5 minutes versus 6.5 minutes. Although these differences are statistically significant, differences in time to hemostasis are modest in the context of an operation that could take 2 or more hours, particularly in a setting with little need for blood transfusion.

SEALANTS AND ADHESIVES

Combinations of Thrombin and Fibrinogen

The use of fibrin-based topical hemostatic products was reported as early as 1909.¹⁶ Subsequent developments allowed the purification of thrombin and fibrinogen, which eventually led to the development of fibrin sealant products in the 1970s. Because of concerns regarding transmission of viral blood-borne infection, the FDA revoked the license for commercial fibrinogen concentrates in 1978. Since then, careful donor selection and the development of a variety of viral inactivation methods have largely resolved the viral safety issue.

Until the recent approval of Tisseel VH (Baxter Healthcare Corporation, Deerfield, Ill, USA), the use of fibrin sealant in the United States was restricted to the so-called “home-brews” of bovine thrombin and human pooled cryoprecipitated plasma as sources of fibrinogen. With the availability of commercial fibrin sealant preparations and other newer hemostatic agents, such “home-brews” are used less often. Such preparations are also limited by the lack of viral inactivation methods. Single donor and autologous cryoprecipitates have also been used in an effort to minimize

infectious risk. Additional limitations of these preparations include a relatively low fibrinogen concentration and induction of antibodies against bovine factor V.^{17–19} The bovine thrombin preparation with the lowest concentration of bovine factor V is produced by Jones Medical Industries (St. Louis, Mo, USA).²⁰

Antibodies to bovine factor V and thrombin may produce coagulopathy and bleeding and are not merely a laboratory abnormality (see Chapter 6). The classic feature of such an acquired factor V deficiency caused by antibody formation is excessive bleeding that is not responsive to administration of vitamin K or fresh frozen plasma.²⁰ Laboratory findings include prolonged prothrombin time (PT) and partial thromboplastin time (PTT) that are not corrected by mixing patient and normal plasma in vitro and by reduced factor V activity (usually <30%).²⁰ Bleeding patients should be treated with fresh frozen plasma or platelet transfusion for factor V replacement. Immunosuppression with steroids has also been used effectively.²⁰ For patients who require continued anticoagulation, it should not be assumed that elevations in PT and PTT indicate a state of “autoanticoagulation.”²¹ Nonetheless, the probability of increased risk of bleeding with continued anticoagulation must be weighed against the risk of thrombosis; therefore, the decision for or against anticoagulation must be individualized for each patient. Cessation of pharmacologic anticoagulation through monitoring for thrombus by serial echocardiography has been used successfully in one such patient with a prosthetic aortic valve.²²

Cryoprecipitate-based fibrin glue is prepared with equal volumes of thawed cryoprecipitated plasma as the source of fibrinogen and bovine thrombin with calcium chloride.²³ These solutions are placed in separate syringes and are mixed together to form a layer of fibrin polymer. The consistency of such home brews varies widely for two primary reasons. First, the fibrinogen concentration of cryoprecipitate varies considerably, ranging from approximately 4 mg per milliliter to 25 mg per milliliter.²⁴ Fibrinogen concentration has been shown to correlate with the tensile and adhesive strength of fibrin sealant.¹⁶ Another limitation that may compromise the final material properties of the fibrin polymer is the method of fibrinogen/thrombin mixture used. The tensile strength of the fibrin polymer is less when incomplete or inadequate mixture occurs.²⁵ A dual-syringe delivery device similar to that used to apply the two components of epoxy glue is commercially available and can simplify the simultaneous administration and mixing of fibrinogen and thrombin solutions (Micro-medics, Inc., St. Paul, Minn, USA). The two syringes are connected and are joined at their tips by a “Y” connector, through which the two solutions mix as they are applied to the wound. Catheter and spray tips are also available to allow the use of different delivery methods according to the nature of the bleeding site. Catheter tips work well when precise application is important, such as to the suture line of a vascular anastomosis. Spray tips are better suited for application over a large surface area, such as the donor site in skin grafting procedures.

Commercially Prepared Fibrin Sealants

In processing their protein concentrates, most manufacturers of commercial fibrin sealant use two of six approved

viral inactivation methods. These six processes include solvent/detergent treatment, two-step vapor heat, wet heat, dry heat, nanofiltration, and ultraviolet light.²⁶

Although several commercial preparations are currently in use in clinical trials, Tisseel VH is the only product that has been approved in the United States. This two-component fibrin sealant product contains separate vials for a purified human fibrinogen concentrate and a purified human thrombin concentrate. In addition to several filtration steps and freeze drying, protein concentrates are subjected to a two-step vapor heat treatment for viral inactivation. Aprotinin, an antifibrinolytic agent of bovine origin, is present in the fibrinogen component of Tisseel VH. In addition to viral inactivation, advantages of commercial fibrin sealants over “home-brew” fibrin glue include higher fibrinogen concentration (50 to 150 mg per milliliter)²⁶ and ready availability, without the need for cryoprecipitate from the blood bank to be thawed. Most commercial preparations require warming to 37°C prior to use. Warming devices are available to facilitate this step.

A number of fibrin sealant products have been evaluated in prospective and retrospective studies. In a randomized clinical trial in which the hemostatic efficacy of human fibrin sealant was evaluated during cardiac reoperation, 92.6% of patients randomly assigned to receive fibrin sealant had complete hemostasis at 5 minutes, compared with only 12.4% of patients treated with conventional topical agents.²⁷ At 1 year of follow-up, no evidence of inflammation in response to fibrin sealant was apparent. A post hoc analysis of data showed improved survival, a shorter hospital stay, and less blood loss at 12 hours in the group treated with fibrin sealant.²⁸ In another randomized clinical trial, fibrin sealant prepared by the Scottish National Blood Transfusion Service was evaluated in vascular surgery procedures.²⁹ Seventeen patients who were about to undergo carotid endarterectomy with adjunctive polytetrafluoroethylene (PTFE) patch angioplasty were randomly assigned to receive fibrin sealant or nothing on PTFE patch suture holes. Suture holes in PTFE graft material have an inherent tendency to bleed and may be associated with hemorrhagic complications.³⁰ Fibrin sealant was prepared with the use of heat-treated fibrinogen from pooled donor plasma cryoprecipitate and solvent/detergent-treated human thrombin. The fibrinogen concentration ranged from 29 to 39 mg per milliliter. The fibrin sealant was administered through a dual-syringe technique. A statistically significant reduction was reported in time to achieve hemostasis in the fibrin sealant group (5.5 minutes) compared with controls (19 minutes; $P < .005$). No difference was noted in survival or measured blood loss. No thrombotic or neurologic complications occurred in patients treated with fibrin sealant. Another clinical trial comparing the hemostatic efficacy of human fibrin sealant with thrombin-soaked Gelfoam during PTFE carotid patch closure showed no differences between the two groups.³¹ It was this author's observation that fibrin sealant did not adhere well to PTFE graft material.

Other studies support the hemostatic efficacy of fibrin sealant products in liver surgery and burn surgery. A randomized clinical trial comparing human fibrin sealant with standard topical hemostatic agents during liver resection surgery showed improved hemostasis at 10 minutes in the fibrin sealant group.³² Hemostasis was achieved in 91% of fibrin sealant-treated patients compared with

70% of controls. In a multicenter clinical trial in which fibrin sealant was compared with no treatment at split-thickness skin graft donor sites, fibrin sealant was found to achieve hemostasis within 2.5 minutes compared with 7 minutes without treatment.³³ The relatively modest improvement in time to hemostasis and lack of a control treatment group made it difficult for investigators to recommend fibrin sealant for this clinical application.

Most of the attention focused on fibrin sealant products is related to issues of safety and hemostatic efficacy of the sealant itself. Although this is understandable and appropriate, the development of customized delivery devices that allow optimal application of fibrin sealant for different clinical uses is an important and sometimes overlooked issue. The standard dual-syringe technique is adequate for most applications; however, some limitations have been noted. For example, tips that attach to the “Y” connector frequently become plugged with fibrin, such that replacement is generally required for repeat administration from the same dual-syringe device. The current Tisseel VH Kit does not contain a spray tip, thus limiting the clinician's ability to apply a thin layer of sealant over a large surface area wound, such as a skin graft harvest site or a full-thickness burn tangential excision wound. Currently available catheter tips are not long enough to reach into deep wounds; when compared with the short tip, a longer single-channel tip might be more predisposed to plugging problems.

Another issue related to the importance of the delivery device is the cost of using large volumes of fibrin sealant. Considerable advantage is provided by a device that would allow efficient use of a limited volume of fibrin sealant to cover larger wounds. For example, a stellate liver fracture from blunt trauma would likely require multiple kits for complete application. The maximum total volume provided in the Tisseel VH Kit is 10 mL of sealant. Although this quantity or smaller amounts would be adequate for many indications, it is likely that several kits would be necessary for some wounds. The development of application devices that would release a finer spray might allow more cost-effective use of a given volume of sealant.

Fibrin sealant products are best used for diffuse, nonsurgical bleeding, such as suture hole bleeding at a vascular anastomosis, parenchymal bleeding after suture of vessels, and general oozing of blood from wound edges in patients with hemostatic defects. More significant bleeding sources should be sutured or treated with electrocautery, as appropriate. Although fibrin sealant appears to be a useful adjunct to surgical hemostasis, it is not a substitute. If fibrin sealant is applied to an actively bleeding wound, the sealant will usually “float off” the area of bleeding without achieving hemostasis. Moreover, current forms of liquid fibrin sealant make application of pressure, an often vital maneuver, somewhat problematic. Application of pressure may disrupt the adhesive bond of the sealant to the wound, causing the sealant to adhere more to the surgeon's glove or to gauze material, which may result in disruption of the sealant when pressure is removed. These material properties of liquid fibrin sealant limit its usefulness in wounds that are associated with significant or active bleeding.

The use of fibrin sealant incorporated into a dry dressing offers the potential of addressing some of the material property limitations associated with actively bleeding wounds. Commercially prepared fibrin sealant dressings

consisting of a thin layer of lyophilized human thrombin and fibrinogen applied to one side of a sheet of equine collagen have been used clinically in Europe but currently are not approved for use in the United States. Clinical reports on the use of such fibrin sealant dressings are encouraging,³⁴ although randomized clinical trials are needed. A dry dressing of lyophilized fibrinogen and thrombin mounted on an absorbable backing delivers a higher concentration of fibrin to the wound and permits the application of pressure—a critically important adjunctive maneuver in surgical hemostasis. The mass effect of the backing material might also be important for maintaining contact of the fibrin sealant with the bleeding wound. Such materials are easy to handle; once they have become wet with blood in the wound, they can assume the contour of the wound surface.³⁵ Preclinical studies have reported superior hemostasis with fibrin sealant dressings compared with controls consisting of collagen fleece,³⁵ Silastic and immunoglobulin G,³⁶ and surgical gauze.^{37,38} In a study in which the hemostatic efficacy of a fibrin sealant dressing was explored in a porcine model of femoral artery injury, a fibrin sealant dressing with 15 minutes of minimal pressure was effective in achieving complete hemostasis at femoral artery lacerations 4 mm in length.³⁶ It is unlikely that use of liquid fibrin sealant alone, particularly when used without adjunctive pressure application, would be effective with brisk arterial bleeding, as was encountered in this study.

Other Sealants

CoSeal is a surgical sealant formed by polymerization of two polyethylene glycols (PEGs). The two PEGs are mixed through a “Y-adapter” attached to two syringes, each containing one PEG material. This product received FDA approval in December of 2003. This material is well suited for sealing leaks such as those that occur at a vascular anastomosis. In the author’s experience, this product appears to be more adherent to PTFE grafts than are fibrin sealant products. The Premarket Approval Application (PMA) submitted to the FDA in 2003 presented data showing superior efficacy of CoSeal for immediate sealing of vascular anastomoses compared with absorbable gelatin sponge/thrombin. Because this is a relatively new product, clinical reports describing hemostatic efficacy are limited.

BioGlue (CryoLife Inc., Kennesaw, Ga, USA), another surgical adhesive that can be used for vascular hemostasis, is an animal-based sealant made of bovine serum albumin cross-linked by glutaraldehyde. The two components are mixed in a predefined ratio and the enclosed delivery device is used. Polymerization begins within 30 seconds and is achieved at full strength within 2 minutes. This product forms a tenacious, firm bond. It is used most frequently by cardiac surgeons and appears to be particularly well suited for use as an adhesive agent during surgical repair of thoracic aortic dissection. BioGlue has been used successfully during cardiac surgery, as was reported in a registry of 115 consecutive patients.³⁹

SUMMARY

Although topical hemostatic agents are no substitute for precise surgical technique in the treatment of patients with localized bleeding disorders, several products may serve as

useful adjuncts in these situations. Historically, collagen, cellulose, and gelatin-based products have been used most frequently in the United States as topical hemostatic agents, but with the recent FDA approval of fibrin sealant, this may change. As additional manufacturers bring fibrin sealant products to market, it is likely that newer application devices and fibrin sealant formulations will be developed that are more closely tailored to specific clinical needs. Newer agents with a gelatin and collagen base are now available, and additional agents are under development. These products will add choices to our present array of topical agents. Sealant agents such as CoSeal and BioGlue have strong adhesive properties that appear attractive for use with vascular anastomoses (both) and for aortic dissection repair (BioGlue). Clinical indications for these products will be determined in well-designed clinical trials. Better delivery devices for the application of these sealant materials are under development and will greatly improve the clinical usefulness of these hemostatic agents.

Chapter 30

Therapeutic Apheresis

Chelsea A. Sheppard, MD • Christopher D. Hillyer, MD

INTRODUCTION

The hematologist, in his or her role as the admitting physician or as a consultant, invariably must consider, prescribe, or oversee a variety of procedures that remove or modify a portion of the circulating blood. These procedures are collectively called *apheresis*, from Greek *aphairesis* meaning “to take away by force, or withdraw.” Apheresis is most often used in the treatment of patients; this use is called *therapeutic apheresis*. It is different from *donor apheresis*, which is used to collect platelets, granulocytes, or peripheral blood stem cells (PBSCs) from normal individual donors. To allow the primary or consulting hematologist to determine whether, if, how, and when therapeutic apheresis procedures and technologies are appropriately used, this chapter provides background, mechanical, and technical information; the use and complications of therapeutic apheresis in specific disease categories and entities are discussed (Fig. 30-1). Additionally, specialized applications, including the approach to pediatric patients, photopheresis, and liposorption technology, are detailed.

THERAPEUTIC APHERESIS— TERMINOLOGY

Therapeutic apheresis is a process in which whole blood is removed from a patient and separated by centrifugation into components, thus allowing a single element to be removed or modified while the remaining components are returned to the patient. The decision of whether plasma or cells are to be removed or modified leads to the two common subtypes of therapeutic apheresis: (1) *plasmapheresis*, and (2) *therapeutic cytappheresis*. Plasmapheresis is also called *therapeutic plasma exchange* (TPE). In TPE, the patient's plasma is removed and the plasma volume is replaced with saline, albumin, and/or fresh frozen plasma (FFP), thus maintaining volume and oncotic equilibrium. During therapeutic cytappheresis, pathologic or excess cells are separated from circulation and discarded, while remaining blood components are replaced. Generally, the addition of a prefix to -pheresis indicates which element is being removed, thus the terms *leukapheresis*, *plateletpheresis*, and *erythrocytapheresis*. In leukapheresis and therapeutic plateletpheresis, excess and/or abnormal cells are removed and discarded; therefore, the terms stand alone. However, in erythrocytapheresis, abnormal or damaged red blood cells (RBCs) must be replaced with banked RBCs so that adequate oxygen delivery can be maintained;

the term *erythrocytapheresis* is used synonymously with the term *RBC exchange*. Historically, RBC exchange was used as a therapeutic modality, and the term has a treatment-related connotation. More recently, RBC exchange has been used in a prophylactic setting to allow for transfusion of patients with sickle cell anemia and removal of sickle hemoglobin blood, thus minimizing iron overload and preventing hyperviscosity. This procedure has come to be known as *prophylactic erythrocytapheresis*.

MECHANICAL AND TECHNICAL CONSIDERATIONS OF THERAPEUTIC APHERESIS

Most readers will appreciate that therapeutic apheresis is an automated procedure that is available in most tertiary care hospitals or is provided via contract services such as the local or regional blood or dialysis center. It is important to know, however, that apheresis can be performed manually by a hematologist, even in adults, through serial removal of 50-mL aliquots of venous whole blood and replacement of this with an equal amount of allogeneic banked packed RBCs and appropriate fluids. Indeed, manual leukapheresis can be lifesaving and easily accomplished in one sitting. Finally, manual plasmapheresis or cytappheresis is the procedure of choice in infants and children who are too small to tolerate the significant extracorporeal volume required by fully automated apheresis devices.

Automated Apheresis

In general, currently used automated apheresis devices separate plasma and cellular elements by centrifugation. Depending on the separation chamber configuration and whether the blood is batched and processed, or whether separation, removal, and return are ongoing simultaneously, these systems are classified as intermittent (also called discontinuous) or continuous flow. Detailed descriptions of the various devices that are available are beyond the scope of this chapter, and the reader is referred to another source.¹ As a general rule, high-flow automated devices (1) are primed to allow for removal of all air from the circuit and maintenance of the patient's volume, (2) require venous access for inflow to the machine and blood return to the patient, (3) have a significant extracorporeal volume (ECV), which approaches 500 mL for adult configurations, (4) are programmable with patient sex, height, weight, and hematocrit entered at a keypad, as well as the blood

Figure 30-1 Flow diagram of initial apheresis steps for the consultant. AABB, American Association of Blood Banks; ASFA, American Society for Apheresis.

volume to be processed, (5) have decreasing efficiency in removal of the pathologic protein or formed element as the procedure progresses, and (6) require that an anticoagulant be added to the extracorporeal blood, usually citrate, so that clotting of blood in the apheresis tubing can be avoided. Each of these is discussed in greater detail in the following sections.

Priming

Machine tubing, or software, is most often primed with saline, and no residual air is left in the set. In anemic patients, bank blood may be used; this mitigates the dilution that the saline prime provides on machine startup. This is discussed further in the following section.

Venous Access

Any type of apheresis procedure requires adequate blood flow to and from the machine. This can be established via lines to peripheral or central veins or a combination of the two. However, placement of a central venous catheter increases the risks of infection and thrombosis and therefore should be used only when peripheral access is inadequate.² Frequently, peripheral access is attained through the large veins in the antecubital fossa. Ideally, the draw and return lines are located on different arms to prevent repeated processing of the same blood, or recirculation. Additionally, large-bore needles (i.e., 16- to 18-gauge) and draw lines capable of providing blood flow rates of up to 120 mL per minute are recommended. High hematocrit levels and plasma hyperviscosity may adversely affect flow rates. Large-bore, dual-lumen catheters designed for apheresis or hemodialysis can provide adequate flow and are recommended when central access is required. Peripherally inserted central venous catheters (PICCs), implantable ports, and standard double- and triple-lumen

catheters are generally considered inadequate and therefore should not be used.³ For single events in emergency situations, femoral catheters may be used. Ultimately, a central venous catheter should be placed if apheresis is to be continued. Any disorder in which vascular tone is diminished may preclude the use of peripheral veins for access. Adverse effects related to vascular access are discussed in the following sections.

Extracorporeal Volume

Extracorporeal volume (ECV) is the volume of all blood elements removed from the body during the procedure. These consist of blood in the bowl or chamber, the tubing, and any other devices used during the procedure, including blood warmers or affinity columns. The ECV for each system is fixed and dependent on the type of equipment used and the type of procedure performed.⁴ In asymptomatic adults and stable pediatric patients, extracorporeal blood volume should not exceed 15% of total blood volume (TBV), and intraprocedural extracorporeal hematocrit levels should be no less than 24% to avoid hypovolemia.³ Usually, at these levels, no change is noted in cardiac output or oxygen consumption.^{4,5} Anemic patients and small children, however, may be unable to tolerate this amount of extracorporeal red cell volume, although widely accepted criteria for preprocedural or intraprocedural transfusion in children are not available. Therefore, consideration must be given to the patient's condition, underlying cardiac and pulmonary disease, red cell volume (RCV), and chronicity of anemia. Several approaches, including priming of the machine with RBCs and preprocedural or intraprocedural transfusion, have been used to prevent intraprocedural hypovolemia and dilutional exacerbation of anemia. For patients in critical condition, cardiac monitoring may be warranted.

Programming and Input of Patient Values

Sex, height, weight, and hematocrit are entered on a keypad, as is the blood volume to be processed. This allows the machine to calculate the patient's TBV, RCV, and plasma volume. It is noteworthy that these algorithms used for the calculations may prove inaccurate for certain patient populations. Once started, automatic flow rate determination and time lead to display of processed blood volumes and predicted length of the procedure.

Total blood volume may be estimated by the consulting hematologist via several methods that are based on weight⁶ or weight and height (Nadler's formula)⁷; however, these calculations may vary depending on the lean body mass of the individual and may overestimate an obese patient's blood volume and underestimate a muscular patient's blood volume.³ Infants have greater blood volumes compared with adults, and men generally have greater blood volumes than equivalently sized women. Estimates of TBV that are based on patient age, sex, and weight have been published.⁶ Red cell volume is directly related to the patient's hematocrit ($RCV = TBV \times \text{pre-Hct } \%/100$) and becomes more important in anemic patients. Additionally, it has been suggested that "intraprocedural hematocrit (assuming the patient is maintained in an isovolemic state during apheresis) may be more predictive of the patient's tolerance of temporary extracorporeal red cell loss than extracorporeal percentages."³ In this circumstance, intraprocedural hematocrit may be calculated as

$(RCV - \text{Extracorporeal RCV})/TBV \times 100$. Total plasma volume ($PV = TBV - RCV$) is used to determine the appropriate apheresis dose, in milliliters to be processed. PV is generally underestimated in patients with large intravascular concentrations of paraproteins.⁸⁻¹¹

Blood or Plasma Volume to be Processed and Apheresis Frequency

The amount of blood or plasma that should be processed in a single procedure is based on a balance between the amount of blood that must be processed to achieve a desired effect, the loss of efficiency that occurs as the procedure continues, and the extent of treatment that the patient can hemodynamically tolerate. In general, 1.5 blood or plasma volumes are processed per procedure, and procedures are ordered no more often than once per day. Procedure frequency and duration are disease specific and are noted below. Additionally, the patient's condition must be considered daily when aggressive daily apheresis is attempted. Further discussion is included in the individual disease sections.

Efficiency

TPE and cytapheeresis remove patient plasma or cells, thus eliminating a part of the pathologic process and leading to clinical improvement. Because these procedures require large volume removal from the intravascular compartment, a replacement fluid (see later) is given to maintain intravascular volume, oxygen-carrying capacity, and other lost elements, such as normal coagulation proteins and immunoglobulins. This one-compartment model in essence suggests that the first aliquots of patient plasma or blood that are removed are completely of patient origin, whereas the later aliquots, with constant circulation and thus mixing, contain an ever increasing amount of normal replacement fluid and less of the pathologic component. Thus, with the first blood or plasma volume processed, a removal efficiency of approximately 60% can be considered as typical. With the second blood or plasma volume processed, approximately 25% efficiency can be sought, and for the third volume processed, efficiency is more toward 10%. This model and its development have been extensively reviewed.¹² If one assumes that the intravascular compartment is closed and the procedure is rapid (completed prior to intracompartment equilibration), as is the assumption in the one-compartment model, then substances predominantly located in the intravascular compartment (i.e., immunoglobulin [Ig]M and fibrinogen) are removed more efficiently than are those located predominantly in the extravascular compartment (i.e., IgG and albumin).^{8,10,12,13} With this knowledge, different investigators have attempted to predict the efficiency of apheresis procedures through the use of several different mathematical models. Deriving the mathematical formulas that express the fractional rates of exchange during continuous and discontinuous flow procedures is beyond the scope of this chapter. However, Chopek and McCullough⁸ used these formulas to plot a curve that predicts the fraction of a substance that remains in relation to the number of plasma volumes removed. When this curve is used, it appears that for removal of soluble substances, the most efficient and tolerable exchange consists of a 1.5 plasma volume.

The effectiveness of TPE and therapeutic cytapheeresis depends not only on the relative volume of plasma or cells

removed but also on their synthetic rate, biodistribution, and ongoing redistribution into the intravascular space.^{12,14} This becomes especially important when one considers either the distribution within total body water of IgG synthesized by a malignant clone or the production of myeloblasts in acute leukemia.

Anticoagulation

Anticoagulation is a vital component of apheresis. Citrate, the most commonly used anticoagulant for maintaining extracorporeal blood in a fluid state, binds calcium, thereby inhibiting calcium-dependent clotting reactions. Several formulations, including ACD-A and ACD-B, are used in apheresis. Citrate is generally preferable to heparin, which can cause heparin-induced thrombocytopenia (HIT). As citrate chelates calcium, hypocalcemia may result; this can in turn lead to perioral tingling and even tetany. Some populations (including children) are at greater risk for citrate toxicity; therefore, heparin, or heparin combined with citrate, may be used.

Replacement Fluids

Many physicians choose colloid replacement fluid rather than crystalloid to prevent the complication of dependent edema due to hypoalbuminemia, as has been seen when saline alone is used as the replacement.¹⁵ The two most commonly used replacement fluids are albumin and FFP. Albumin (5%) is considered the standard replacement fluid for most indications in TPE with rare exception; its use is not complicated, in general, by transmission of infectious diseases. Replacement with 5% albumin is superior to saline replacement in that it provides proteins and thus helps maintain oncotic pressure. However, this need is uncommon, and if 5% albumin is used, caution is advised.

FFP is the preferred replacement fluid when one wishes to infuse a component of FFP into the patient in addition to removing a pathologic substance. The two generally accepted diagnoses for which FFP is preferred are thrombotic thrombocytopenic purpura (TTP) and Refsum disease. FFP is associated with a 2 to 3 times higher incidence of adverse events, including allergic reactions and citrate toxicity, as compared with albumin.¹⁶⁻¹⁸ Finally, after successive instances of TPE with albumin replacement, FFP may be used to replace depleted fibrinogen. This can be accomplished by ending the procedure with replacement of FFP rather than albumin. In this circumstance, the choice and amount of FFP used should be guided by measurements attained through regular laboratory-based coagulation tests.

Evaluation and Care of the Patient

Prior to the first procedure, baseline laboratory values, including hematocrit or hemoglobin, electrolytes, platelet count, prothrombin time (PT), partial thromboplastin time (PTT), and perhaps ionized calcium (if citrate anticoagulation is to be used), should be acquired. Cardiac, renal, and hepatic function should be evaluated in patients prior to their first procedure. Other tests, such as fibrinogen and specific factor levels, may be indicated prior to the procedure if patients have known coagulation disorders. Knowledge of these baseline values is necessary in planning

fluid volume management, modifying the amount of anti-coagulation to be used, and determining the appropriate schedule for and frequency of the procedure.¹⁹

It is generally accepted that dehydration should be corrected in most patients before the procedure is performed. In patients who are volume sensitive (i.e., end-stage renal disease), the tendency is to avoid rehydration; however, these patients tend to have excessive extravascular rather than intravascular fluid and remain at risk for intravascular hypovolemia. Patients with hypoproteinemia are at greater risk for intraprocedural hypovolemia. Alternatively, patients with elevated serum protein levels (i.e., multiple myeloma) and thus expanded intravascular volumes may receive crystalloid solutions for replacement in order to decrease intravascular volume, thus allowing for more efficient removal of the offending immunoglobulin.³

Medications such as vasopressors may be continued during apheresis procedures provided patients do not develop hypertension or tachycardia.³ Given the short half-lives of most pressors, drug removal due to the procedure has only minimal effects on therapeutic blood levels. Patients who have a history of transfusion reactions may be premedicated with antipyretics and/or antihistamines to reduce future events. Regularly prescribed medication regimens should be adjusted so that medication is taken after apheresis when possible. Protein-bound medications should be given after the procedure is performed, and levels should be monitored when appropriate. Angiotensin-converting enzyme (ACE) inhibitors ideally should be discontinued 72 hours prior to transfusion to reduce allergic reactions (discussed in greater detail later).

Logistics

Many medical centers do not have their own pheresis equipment, and such work is contracted out to other facilities or consignees. This practice often delays the actual implementation of pheresis.

Other logistic barriers to the initiation of pheresis therapy include confirmation of the suspected diagnosis, informed consent, inadequate venous access (particularly with inertia of placement, as is frequently caused by those who actually insert such devices with undue concern for thrombocytopenia), availability and thawing of FFP, and other considerations. These issues often result in the accumulation of several (5–8) hours between the decision to order pheresis and actual implementation of the procedure.

Frequently, a single clinical service (typically hematology) oversees this operation, providing the equipment, personnel, and technical support for all patients who need pheresis, including those with neurologic, renal, or transplant rejection indications. Along with informed consent, it is advised that clinicians should obtain documentation stating that although the hematology service may be providing the technique, decisions regarding frequency, timing, and duration of pheresis sessions are made under the guidance of the service that is providing clinical discernment.

THERAPEUTIC PLASMA EXCHANGE

In 1985, the American Medical Association (AMA), in an attempt to guide clinicians in medical decision making,

assembled a panel of experts to review all evidence regarding the efficacy of plasmapheresis for various indications. These guidelines have been updated and revised by several different agencies since that time, including the American Association of Blood Banks (AABB), the American Society for Apheresis (ASFA), and the American Academy of Neurology. These potential indications have been classified into four categories on the basis of the amount and quality of supporting evidence favoring their use. Category I is reserved for those indications for which plasmapheresis has proved effective as a primary or standard therapy in controlled trials. Category II includes those diseases or syndromes for which plasmapheresis is supportive or adjunctive to primary therapy, or for which uncontrolled case series or reports suggest a benefit. Category III includes those syndromes for which the data are insufficient to indicate whether TPE is beneficial, and Category IV diagnoses are those for which TPE has been shown in controlled trials to provide no benefit. In the sections that follow here, the indications and rationales for apheresis for hematologic disorders (Categories I and II) are presented, as are those for nonhematologic disorders (Category I only) (Table 30-1).

Hematologic Disorders

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP), often classified as a thrombotic microangiopathy (TMA), is a microangiopathic hemolytic anemia that results from the absence or inhibition of von Willebrand–cleaving protease (VWF-cp) activity, which may lead to the accumulation of ultra-large von Willebrand factor (ULVWF) multimers in plasma (see Chapter 24). These multimers produce platelet clumping under high shear stress in the microvasculature, thus causing thrombocytopenia, renal dysfunction, brain ischemia, and intravascular fragmentation of red blood cells. The classic patient presentation consists of fever, renal impairment, thrombocytopenia, and central nervous system impairment; symptoms range from mental status alterations to seizures and coma.²⁰ In 1996, the VWF-cp was shown to be a plasma protease that is now called ADAMTS-13 (*a disintegrin and metalloprotease with thrombospondin subunits*); it cleaves VWF multimers at the 842Tyr-843Met peptide bond.^{21,22} Patients with the congenital form of TTP lack a functional enzyme altogether because of mutations in the ADAMTS-13 gene.²³ However, idiopathic or acquired TTP is the result of an inhibitory autoantibody to the protease ADAMTS-13.^{24–27}

RATIONALE FOR TPE

The presence of an antibody inhibitor of ADAMTS-13 and the accumulation of ULVWF multimers in the plasma suggest immediately that the removal of such pathologic entities would result in improvement in patients with TTP. It is interesting to note that in TTP, the use of FFP as the replacement fluid has the added benefit of infusing normal donor ADAMTS-13, which is also beneficial. Indeed, FFP was originally used to treat patients with all forms of TTP, and it may be infused if plasma exchange is not immediately available. In those patients without antibody to the cleaving protease (congenital TTP), only 10 to 15 mL/kg of FFP infused every 2 to 3 weeks can achieve remission;

Table 30-1 Indication Categories For Therapeutic Apheresis

Disease	Procedure	Indication Category
Renal and Metabolic Diseases		
Antiglomerular basement membrane antibody disease	Plasma exchange	I
Rapidly progressive glomerulonephritis	Plasma exchange	II
Hemolytic-uremic syndrome	Plasma exchange	III
Renal transplantation		
Rejection	Plasma exchange	IV
Sensitization	Plasma exchange	III
Recurrent focal glomerulosclerosis	Plasma exchange	III
Heart transplant rejection	Plasma exchange	III
	Photopheresis	III
Acute hepatic failure	Plasma exchange	III
Familial hypercholesterolemia	Selective adsorption	I
	Plasma exchange	II
Overdose or poisoning	Plasma exchange	III
Phytanic acid storage (Refsum) disease	Plasma exchange	I
Autoimmune and Rheumatic Diseases		
Cryoglobulinemia	Plasma exchange	II
Idiopathic thrombocytopenic purpura	Immunoadsorption	II
Raynaud phenomenon	Plasma exchange	III
Vasculitis	Plasma exchange	III
Autoimmune hemolytic anemia	Plasma exchange	III
Rheumatoid arthritis	Immunoadsorption	II
	Lymphoplasmapheresis	II
	Plasma exchange	IV
Scleroderma or progressive systemic sclerosis (PSS)	Plasma exchange	III
Systemic lupus erythematosus	Plasma exchange	III
Hematologic Diseases		
ABO-mismatched marrow transplant	RBC removal (marrow)	I
	Plasma exchange (recipient)	II
Erythrocytosis or polycythemia vera	Phlebotomy	I
	Erythrocytapheresis	II
Leukocytosis and thrombocytosis	Cytapheresis	I
Thrombotic thrombocytopenic purpura	Plasma exchange	I
Posttransfusion purpura	Plasma exchange	I
Sickle cell disease	RBC exchange	I
Myeloma, paraproteinemia, or hyperviscosity	Plasma exchange	II
Myeloma or acute renal failure	Plasma exchange	II
Coagulation factor inhibitors	Plasma exchange	II
Aplastic anemia or pure RBC aplasia	Plasma exchange	III
Cutaneous T-cell lymphoma	Photopheresis	I
	Leukapheresis	III
HDN	Plasma exchange	III
PLT alloimmunization and refractoriness	Plasma exchange	III
	Immunoadsorption	III
Malaria or babesiosis	RBC exchange	III
Neurologic Disorders		
Chronic inflammatory demyelinating polyradiculoneuropathy	Plasma exchange	I
Acute inflammatory demyelinating polyradiculoneuropathy	Plasma exchange	I
Lambert-Eaton myasthenic syndrome	Plasma exchange	II
Multiple sclerosis		
Relapsing	Plasma exchange	III
Progressive	Plasma exchange	III
	Lymphocytophoresis	III
Myasthenia gravis	Plasma exchange	I
Acute central nervous system inflammatory demyelinating disease	Plasma exchange	II
Paraneoplastic neurologic syndromes	Plasma exchange	III
	Immunoadsorption	III
Demyelinating polyneuropathy with IgG and IgA	Plasma exchange	I
	Immunoadsorption	III
Sydenham chorea	Plasma exchange	II
Polyneuropathy with IgM (with or without Waldenström macroglobulinemia)	Plasma exchange	II
	Immunoadsorption	III
Cryoglobulinemia with polyneuropathy	Plasma exchange	II
Multiple myeloma with polyneuropathy	Plasma exchange	III

(Continued)

Table 30-1 Indication Categories For Therapeutic Apheresis (Cont'd.)

Disease	Procedure	Indication Category
POEMS syndrome	Plasma exchange	III
Systemic (AL) amyloidosis	Plasma exchange	IV
Polymyositis or dermatomyositis	Plasma exchange	III
	Leukapheresis	IV
Inclusion body myositis	Plasma exchange	III
	Leukapheresis	IV
Rasmussen encephalitis	Plasma exchange	III
Stiff-man syndrome	Plasma exchange	III
PANDAS	Plasma exchange	II

ABO, blood type; HDN, hemolytic disease of the newborn; IgG, immunoglobulin G; IgA, immunoglobulin A; IgM, immunoglobulin M; PLT, platelet; PANDAS, pediatric autoimmune neuropsychiatric disorders; POEMS, polyneuropathy, organomegaly, endocrinopathy, M component, and skin changes; RBC, red blood cell.

patients with acquired TTP usually require total plasma exchange.^{28,29} Several investigators have studied whether TPE is indicated in those patients with clinical features of the disease but without evidence of autoantibody-mediated severe ADAMTS-13 deficiency.^{30–32} The authors of a recent review concluded that on the basis of limited available evidence, TPE was indicated for idiopathic TTP, regardless of ADAMTS-13 activity level.³³

USE OF TPE

TPE is first-line therapy for idiopathic TTP and should be commenced at the time of diagnosis.^{34,35} Plasma infusion at 30 mg/kg/day may be used while TPE is being arranged.³⁶ Additionally, evidence suggests that corticosteroids may be helpful in suppressing autoantibody formation; many authorities recommend daily doses of up to 200 mg of prednisone.³⁷ However, because evidence supporting their clinical efficacy is lacking, corticosteroids are typically adjunctive or are given to patients for whom primary therapy has failed.³⁸

Studies have shown that clinical response to TPE generally occurs within approximately 1 week (mean, 7 to 8 days); three of four patients respond within 2 weeks, and 25% may require up to 4 weeks of therapy.^{39–41} However, the rate of recurrence is high (20% to 50%).^{39,42–44} In a recent comprehensive review, Willis and Banderenko⁴¹ summarized the reasons (including scarcity of accepted definitions for recurrence and remission, lack of an adequate test for remission, variable times to response and to treatment) why physicians may have difficulty in determining disease resolution, which leads to confusion regarding when TPE should be discontinued.⁴¹ The AABB and ASFA have suggested that TPE should be continued until the patient demonstrates a platelet count of 100,000–150,000/ μ L and normal lactate dehydrogenase (LDH) for 2 consecutive days.⁴¹ Others have suggested that 1.5 plasma volume exchanges with FFP replacement should be performed daily until neurologic signs and symptoms have resolved and platelet count and LDH values have normalized (some have advocated continuation of TPE for 5 days after remission).^{37,45} Still others use a regimen of 1.5 plasma volumes for the first 3 days followed by 1 plasma volume daily.⁴⁶ The transition from daily to every-other-day TPE (“tapering”) has not proved effective^{39,47} but is frequently used anyway, most likely reflecting uncertainty among physicians regarding when therapy should be discontinued.

Despite these measures, some patients do not respond to therapy or they relapse when TPE is discontinued. In such situations, many practitioners switch from FFP to cryosupernatant as the replacement fluid because the latter consists of reduced numbers of ULVWF multimers, although recent data suggest that no benefit may be derived from this practice.^{48,49} Recently, several case series and reports have successfully employed rituximab, a chimeric monoclonal antibody directed at the CD20 antigen expressed on the surface of B lymphocytes, for the treatment of TPE-dependent patients who appear refractory to other immunosuppressive therapies (e.g., corticosteroids, azathioprine, cyclosporin A, splenectomy). Rituximab is typically given in weekly infusions of 375 mg per meter squared.

THROMBOTIC MICROANGIOPATHIES OTHER THAN IDIOPATHIC TTP AND TPE

Although the clinical manifestations of TTP and other TMAs such as AIDS-associated TTP, hemolytic-uremic syndrome (HUS), and drug-induced TTP may be similar, the use of TPE for management of these disorders is controversial, and the mechanisms of pathogenesis are likely to be different. In diarrhea-associated HUS, TPE has shown no clinical benefit.⁵⁰ Lämmle and associates³³ recently reviewed the arguments for and against TPE in cases in which the ADAMTS-13 level was normal or moderately decreased; they cited only one study in which it was shown that response to TPE, number of subsequent exacerbations, number of apheresis procedures needed to reach remission, and death rate were not different between those with and without severe ADAMTS-13 deficiency. However, the relapse rate was higher among severely deficient patients.³⁰ These facts may be due at least in part to the absence of a universally accepted and reproducible ADAMTS-13 assay.

Patients with TMAs associated with hematopoietic stem cell transplantation, malignancy, and anticancer drugs have demonstrated measurable ADAMTS-13 activity; pregnancy-associated TMA has been reported to involve severe ADAMTS-13 deficiency.³³ Therefore, the likelihood that TPE would be effective therapy in patients with the former indications is unlikely, although TPE may be beneficial for the treatment of pregnancy-induced TTP. No randomized clinical trials have addressed these indications.

TPE (in conjunction with highly active antiretroviral therapy [HAART] therapy) has been used to treat patients with HIV-associated TTP and has been shown in several

case series to be beneficial.^{51,52} In one case report, plasmapheresis was ineffective in treating a human immunodeficiency virus (HIV)-positive patient with TTP; however, when antiviral therapy was started, the patient clinically improved.⁵³ Because no randomized clinical trials have addressed this issue, it is unknown whether TPE provides added benefit over antiviral therapy alone.

Posttransfusion Purpura

Posttransfusion purpura (PTP) is a rare disorder that is characterized by severe thrombocytopenia ($<10,000/\mu\text{L}$) and destruction of the recipient's and the donor's transfused platelets 7 to 10 days after transfusion. In general, PTP is self limited but may result in bleeding; fatal intracranial hemorrhage has been reported in 10% of cases.^{54,55} Previously nontransfused, multiparous women between the ages of 30 and 80 years are most frequently affected; however, cases have been reported in men as well.^{56,57} The pathogenesis of PTP remains largely unknown; however, several hypotheses have addressed the destruction of recipient and donor platelets. These hypotheses have been extensively reviewed and summarized below.⁵⁸

RATIONALE FOR TPE

In most cases, alloantibodies to platelet membrane antigens (most notably, HPA-1a) and human leukocyte antigens (HLAs) have been implicated.^{57,59–67} Soluble antigen has been found in antigen-positive donors, and circulating immune complexes have been identified in a patient with PTP.^{68,69} Finally, some have advocated that passive adsorption of platelet antigen onto recipient platelets is causative.⁶⁸ Each of these possibilities leads one to consider that TPE may be effective in the management of PTP. A good review of these mechanisms has been recently reported.⁵⁸

USE OF TPE

Given current pathologic hypotheses that the platelet destruction observed in PTP may be antibody mediated, removal of the offending antibody by TPE emerged as a potential therapy. Anecdotally, TPE has been successful; however, no clinical trials have assessed the efficacy of TPE versus intravenous immune globulin (IVIg) in the treatment of patients with PTP. Although PTP is a Category I indication for TPE, it is generally reserved for those patients who are refractory to IVIg or steroids, or who are significantly hemorrhaging. Albumin is typically used as the replacement fluid; however, in coagulopathic patients, FFP may be used.

ABO-Incompatible Bone Marrow Transplantation

ABO-incompatible bone marrow transplantation (BMT) may result in acute hemolysis, renal failure, disseminated intravascular coagulation (DIC), or death at the time of marrow infusion.⁵⁵ Historically, plasmapheresis was used to reduce the recipient's isohemagglutinin titer prior to transplantation.^{55,70–73} However, bone marrow processing now prepares progenitor cell concentrates from harvested bone marrow with minimal residual red cell contamination.⁸⁸ Thus, at present, TPE is rarely done for patients with ABO-incompatible transplants; this is considered a Category II indication by the ASFA and a Category III indication by the AABB.

Myeloma

Plasma cell myeloma is characterized by the abnormal production of monoclonal antibodies, skeletal destruction, and anemia. In all, 10% to 30% of patients with myeloma present with renal failure.^{74–76} Of those with myeloma, 5% (50% with Waldenström macroglobulinemia) develop hyperviscosity syndrome, which may include shortness of breath, cutaneous or mucosal bleeding, blurred vision or diplopia, and neurologic symptoms ranging from headaches and dizziness to seizures and coma. These symptoms are due to the rheologic effects of the paraprotein, which may be removed through TPE.

RATIONALE FOR TPE

TPE and immunoadsorption (IA) columns have been used to remove the pathologic proteins in myeloma. TPE is considered first-line therapy for hyperviscosity syndromes and has been used with varying results for acute renal failure. Three randomized, control trials have evaluated the use of TPE in acute renal failure associated with myeloma.^{76–78} The most recent and largest clinical trial found no difference in outcomes in death versus dialysis dependence, or in glomerular filtration rate (GFR), between those patients receiving TPE and controls (who were given chemotherapy and dialysis only).⁷⁶ For symptomatic hyperviscosity syndrome, immediate TPE followed by disease-directed therapy is generally considered appropriate. Mehta and Singhal⁷⁹ reported anecdotal success (i.e., relief of symptoms) after several (two or three) 3-liter exchanges involving 5% albumin replacement. Acute renal failure and hyperviscosity syndrome associated with myeloma are considered by the ASFA and AABB to be category II indications for TPE and IA.

Other Hematologic Diseases

The removal of coagulation factor inhibitors in patients with factor deficiencies due to preformed antibodies to transfused products is considered by the ASFA and AABB to be a category II indication for TPE. The role of TPE or IA is to quickly decrease high antibody titers, thereby improving response to other therapies such as IVIg, factor VIII concentrates, prednisone, cyclophosphamide, and rituximab. Several authors have advocated combination therapy for inducing tolerance in these patients; however, no controlled trials have been performed.^{80–84}

Aplastic anemia/pure red cell aplasia, hemolytic disease of the newborn, and platelet alloimmunization and refractoriness are considered Category III indications. IA for the treatment of platelet alloimmunization and refractoriness is also considered a Category III indication for TPE. For these diseases, TPE (or IA in some cases) is used in conjunction with other therapies or when first-line therapies are contraindicated or are not technically feasible.⁵⁵ No controlled, randomized trials have been performed for these indications.

Renal and Metabolic Disorders—Category I

Rapidly Progressive Glomerulonephritis

Goodpasture disease (GPD; also called antglomerular basement antibody disease), Wegener granulomatosis, and systemic vasculitis may result in rapidly progressive

glomerulonephritis (RPGN), characterized by inflammation of the glomeruli with necrosis and a crescent-shaped appearance. In GPD, immunofluorescence reveals the presence of linear deposits of an IgG antiglomerular basement membrane antibody that targets a domain specific to type IV collagen. Patients experience deterioration in renal function over a period of weeks,⁸⁵ which may result in irreversible kidney damage. Pulmonary hemorrhage is another common symptom of GPD.⁸⁶ Other inflammatory glomerular diseases (e.g., Wegener syndrome) have similar clinical manifestations that include RPGN and pulmonary hemorrhage.

RATIONALE FOR TPE

Each disease that results in RPGN has a different pathogenic mechanism. In GPD, but not in other forms of RPGN, a circulating pathologic antibody is central to the disease. Because TPE is effective in antibody removal, many studies have shown that it offers a successful therapeutic approach.

USE OF TPE

GPD is considered a Category I indication for TPE; aggressive therapy, consisting of TPE with cyclophosphamide and pulse methylprednisolone, is advocated by most authorities.⁸⁷ Daily 4-liter exchanges have been used for 7 days as initial therapy.^{88–92} This regimen is generally followed by daily or every other day exchanges for the second week, or alternatively, until antibody titers are suppressed or pulmonary hemorrhage has ceased. Albumin (5%) given alone or in combination with FFP is generally recommended, except in those patients with pulmonary hemorrhage or eminent or recent renal biopsy in whom albumin replacement may cause a dilutional coagulopathy and worsen bleeding.⁸⁵ TPE in conjunction with prednisone or cyclophosphamide has proved effective in treating all antibody-mediated forms of RPGN.^{93,94} Because GPD is usually self limited, short-term therapy (<6 months) is generally all that is required. In addition, early treatment has been advocated by Levy and coworkers⁹⁵ after worse outcomes were noted in patients with higher creatinine levels at presentation.

Primary therapy for those forms of RPGN that are *not* antibody mediated, cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA) mediated (e.g., Wegener syndrome), or immune complex mediated (e.g., cryoglobulinemia) is focused on treating the underlying disease⁸⁵; the role of TPE is controversial. The AABB and the ASFA classify antiglomerular basement membrane–negative RPGN as a Category II indication for TPE. Some studies appear to show no benefit^{96,97}; others advocate the use of TPE in a secondary role to immunosuppressive therapy or in patients who present with severe renal disease.^{88–91,98–100} In a recent case report of diffuse alveolar hemorrhage in a patient with Wegener syndrome and a high-titer c-ANCA, the authors advocate the use of TPE and call for a reevaluation of Category II status for this indication.¹⁰¹

Protein A–based immunoadsorption columns are touted as a method of selective extraction of IgG antibodies; they differ from TPE in that non-IgG plasma proteins are returned to the patient along with other blood components, abrogating the need for replacement fluids. These are discussed in greater detail later. Case reports that describe the use of this method present conflicting data,

especially with regard to improvement in renal function.^{102–104} Vasculitis presumably secondary to percutaneous acetic acid injection (PAA-I) therapy has been reported and should be considered prior to its use.¹⁰⁵

Refsum Disease

Hereditary motor and sensory neuropathy type IV, or Refsum disease, is a rare autosomal recessive disorder that is characterized by the inability to oxidize phytanic acid; it is mentioned briefly because the AABB and the ASFA have classified it as a Category I indication for TPE. The defective enzyme is phytanoyl–coenzyme A hydroxylase, which catalyzes the breakdown of phytanic to pristanic acid. Because phytanic acid is found in a variety of foodstuffs, dietary restriction is the main therapy; however, TPE has been useful in quickly reducing phytanic acid levels, which may be desirable given that visual and hearing impairments may not respond to therapy.^{106,107} Also, FFP is used as the replacement fluid; it may provide phytanoyl–coenzyme A hydroxylase, thus promoting symptom amelioration.

Neurologic Disorders—Category I

Guillain-Barré Syndrome/Acute Inflammatory Demyelinating Polyneuropathy

Guillain-Barré syndrome (GBS) occurs with an annual incidence of 0.6 to 2 cases per 100,000 population and is thus the most commonly occurring paralytic disorder.^{108–113} A number of variants or subtypes of GBS, including acute inflammatory/demyelinating polyneuropathy (AIDP) and chronic inflammatory/demyelinating polyneuropathy (CIDP), have been classified (see later). AIDP, the most common subtype of GBS, is usually characterized as an acute peripheral neuropathy with features of weakness, hyporeflexia or areflexia, and increased cerebrospinal fluid (CSF) protein in the absence of a pleocytosis. Infections (e.g., *Campylobacter jejuni*) frequently precede AIDP¹¹⁴; these are believed to be caused by damage to neuronal axons caused by macrophages. Activated T cells cross the blood–brain barrier, where they encounter a cross-reactive antigen in the endoneurium and release cytokines that activate macrophages, which then invade myelin sheaths and denude neuronal axons.^{115,116}

RATIONALE FOR TPE

Although the precise causes of GBS and AIDP remain unknown, an antibody-mediated mechanism appears likely; thus, the fact that TPE has been used in treating these disorders is understandable. Indeed, several large and small randomized, controlled trials have reported success in decreasing the severity of acute illness and reducing the length of hospital stay and recovery time with the use of TPE.^{117–122}

USE OF TPE

At this time, experts advocate instituting TPE (usually, five to six 1.5 plasma volume procedures performed over 2 weeks) within 14 days of symptom onset.^{119,122,123} Cessation of TPE prior to control of the active phase of the disease may increase the risk of relapse.¹²⁴ Albumin (5%) is commonly used for replacing removed plasma. Studies

have shown better response rates with four 1.5-L volume exchanges for colloid replacement than with two; no further improvement has been noted with six exchanges.¹²¹ Others, however, have shown no comparative difference in outcome whether patients are treated with IVIg or TPE.¹²⁵ Therefore, the American Academy of Neurology recommended in 2003 in a practice parameter that TPE or IVIg should be used to treat patients with GBS who have lost the ability to walk.¹²⁶ However, questions remain regarding treatment failure and whether therapy is effective if delayed.¹¹⁶ Finally, Dada and Kaplan¹²⁷ reported four cases of GBS with axonal involvement in which patients failed IVIg therapy but improved with TPE.

Chronic Inflammatory Demyelinating Polyneuropathy

CIDP is a chronically progressive or relapsing symmetrical, sensorimotor disorder. Nerve conduction studies demonstrate a predominant process of demyelination.

RATIONALE FOR TPE

In two small, prospective, double-blind studies, TPE appeared to show short-term benefit that was reversed when treatment was stopped.^{128,129} Dyck and colleagues¹²⁹ randomly assigned 29 patients with static or worsening disease to receive TPE or sham exchange. One third of those who received TPE were significantly improved, and one third showed a trend toward improvement. In a crossover study, Hahn and coworkers¹³⁰ analyzed 18 patients with chronic progressive or relapsing disease. They concluded that TPE with concurrent immunosuppressive therapy was beneficial in both types of CIDP. In addition, they found that patients who were nonresponsive to TPE were improved by treatment with prednisone. Four randomized, double-blind trials evaluated the use of IVIg.^{130–133} These trials reported short-term improvement. Dyck and associates¹³⁴ described no difference in short-term improvement with the use of IVIg or TPE. Recently, a joint task force of the European Federation of Neurological Societies (EFNS) and the Peripheral Nerve Society (PNS) published new recommendations for the treatment of patients with CIDP.¹³⁵ These guidelines suggest that IVIg or prednisone should be used as first-line therapy. TPE should be reserved for patients who are nonresponsive to first-line therapy.

USE OF TPE

According to Hahn and colleagues,¹²⁸ two to three exchanges per week should be performed until improvement has been established. Then, exchanges may be tapered over several months.

Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disorder that is characterized by the presence of IgG antibodies directed against a portion of the acetylcholine receptor, thereby inhibiting electrical stimulation via acetylcholine at the neuromuscular junction. It occurs at all ages, but similar to other autoimmune disorders, it has a female predominance when occurring at a younger age. Clinically, patients experience weakness of voluntary muscle groups that worsens with exercise. In most patients (85%), MG generalizes after only 3 years, affecting the limbs, the bulbar

muscles, and the diaphragm.¹³⁶ Between 2% and 3% of patients with MG experience a crisis each year.¹³⁷

RATIONALE FOR TPE

TPE can quickly reduce the quantity of circulating antibodies to the acetylcholine receptor and is usually prescribed in conjunction with immunosuppressive therapy.¹³⁸ TPE is especially important in treating severe exacerbations when disease involves the bulbar muscles and the diaphragm. Patients will generally present with difficulty swallowing, aspiration, and/or respiratory compromise.

USE OF TPE

Although cholinesterase inhibitors and steroid and nonsteroid immunosuppressants are typically the mainstay therapies for MG,¹³⁹ TPE should be used in situations in which response to pharmacologic therapy is insufficient, or during a myasthenic crisis. TPE, when used for the treatment of an acute myasthenic crisis, should be performed by removing 1.5 plasma volumes daily and replacing with 5% albumin until the patient has clinically improved.^{140,141} Some clinicians suggest that tapering of schedules (TPE performed once or twice a month) may be beneficial until a stable response has been achieved.^{138,142} Only a few clinical trials have compared the use of IVIg with TPE in MG crisis; the largest of these, conducted by Gajdos and associates, showed similar efficacy.¹⁴³ Recently, an extensive review of the literature regarding the efficacy of IVIg in the treatment of patients with neurologic disease (including comparisons with other therapies) was published.¹⁴⁴

THERAPEUTIC CYTAPHERESIS

Plateletpheresis

Thrombocytosis may occur as the result of a reactive process or as a primary clonal hematologic disorder such as essential thrombocythemia (ET) and other myeloproliferative disorders (see Chapter 18). Patients with abnormally high platelet counts may be at risk for thrombotic and hemorrhagic complications. In fact, half of all patients with ET present with vasomotor, thrombotic, or hemorrhagic complications.¹⁴⁵ Thromboses occur in arterial and venous circulation and in the microvasculature, as well as in large arteries in the brain and heart.¹⁴⁶

Erythromelalgia is an example of one such thrombotic complication. It is a presenting feature in nearly half of all cases of ET and is characterized as a painful, burning sensation in the palms and soles that is accompanied by redness and warmth, which occur as a result of platelet aggregation that leads to microvascular thrombosis of acral vessels.¹⁴⁷

Rationale for Plateletpheresis

Studies have shown that the platelets in ET are morphologically and functionally abnormal.¹⁴⁷ However, neither the platelet count nor standard clinical laboratory tests such as platelet aggregation studies or bleeding time have been helpful in predicting who is at greater risk for thrombotic events.^{146,148} Evidence indicates that patients over the age of 60 years and particularly those with a previous thrombosis are at increased risk for a future thrombosis.^{145,149}

In these patients, it may be beneficial to attempt to lower the platelet count to prevent recurrent thrombosis.

Use of Plateletpheresis

The ASFA and AABB have classified thrombocytosis as a Category I indication for cytappheresis. The goal of TPE is simply to reduce the platelet count. Adami,¹⁵⁰ in a study of 132 patients who received plateletpheresis over a 15-year period, found that patients with ET and elevated platelet counts (greater than 1,500,000/ μ L) had a significantly greater number of symptoms than did those with lower platelet counts. Tefferi and associates¹⁵¹ advocated the use of cytoreductive therapy in high-risk patients (those age 60 years or older and/or with a history of thrombosis) aimed at maintaining platelet levels below 400,000/ μ L. However, as Greist points out in her comprehensive review of the subject,¹⁴⁶ drug therapy may take days to weeks to achieve maximum effect. Therefore, she and others believe that plateletpheresis is acutely indicated in patients with ongoing life-threatening organ dysfunction from an acute bleed or thrombotic episode (e.g., cerebrovascular ischemia).^{55,146,148,152}

No studies have determined the exact platelet count for which plateletpheresis is required. Also, it is not known what absolute platelet count leads to relief of clinical symptoms, or what an adequate postpheresis platelet count should be. General practice is to cytoreduce at $>1,000,000/\mu$ L abnormal platelets; plateletpheresis is usually performed until clinical symptoms have resolved. Some authorities recommend the use of plateletpheresis at counts between 500,000 and 1,000,000/ μ L, depending on the rate of increase noted in measured platelet count. In one study, patients with elevated platelet counts (1,000,000 to 3,500,000/ μ L) attained a 35% to 50% reduction in platelet count after a single exchange of 1.25 blood volumes.¹⁵³

The use of plateletpheresis in ET for indications other than acute events or for the prevention of a recurrent event is controversial. For instance, it is unclear whether platelet reduction is of benefit in the management of ET during pregnancy,^{151,154–156} in the perioperative setting,^{157,158} or for reactive or secondary thrombocytosis.¹⁴⁶ Evidence consists primarily of case reports and small case series.

Leukapheresis

Leukostasis is the term that is used to describe rheologic abnormalities that may occur in the cerebral and pulmonary microvasculature of patients with acute leukemia who present with high blast counts—usually $>100,000$ blasts/ μ L, or hyperleukocytosis (HL).^{159–161} The incidence of hyperleukocytosis varies according to age at diagnosis and type of leukemia (i.e., acute myeloid leukemia [AML] or acute lymphocytic leukemia [ALL]). Occurrence ranges from 5% to 30%.¹⁶² The clinical presentation also varies from exertional dyspnea to severe respiratory distress and stupor to coma. Vascular complications include retinal hemorrhage, retinal vein thrombosis, myocardial infarction, acute limb ischemia, and renal vein thrombosis.¹⁶³ DIC occurs in 15% to 40% of patients.¹⁶² HL has been associated with a higher incidence of fatal hemorrhage during the first week of chemotherapy¹⁶⁴ and a shorter duration of complete remission. The pathogenesis leading to

the development of clinical manifestations is not entirely known. Data suggest that chemokine-induced interactions between leukemic cells and the target organ endothelium may be responsible for the vascular disruption that ultimately leads to the end organ damage observed. Porcu and associates¹⁶² have described these potential mechanisms in a recent comprehensive review.

Rationale for Leukapheresis

The goal of leukapheresis in the setting of leukostasis, leukemia, and a high blast count is to remove circulating leukemic blasts from the peripheral blood; leukapheresis prior to induction therapy has been advocated. However, whether leukapheresis leads to improved survival and clinical outcomes is controversial. Some studies have shown that early death is more frequent when HL is present.^{165,166} The presumed advantages of leukapheresis involve the removal of large numbers of circulating blasts and the recruitment of marginated leukemic cell aggregates away from the microvasculature and extramedullary sites and into the intravascular space. Other investigators have found evidence to suggest that leukoreduction may mitigate the tumor lysis syndrome and hemorrhage that may occur as a result of induction therapy.¹⁶⁷ Additionally, it is unknown when, how, and for how long leukapheresis may be used effectively.

Porcu and colleagues¹⁶⁸ studied early death after leukoreduction with a target postprocedural white blood cell (WBC) count of 50,000/ μ L. Although this level was achieved, no difference in WBC count was observed at the time of death, nor at discontinuation of leukapheresis, between those who died within 1 week of therapy and those who survived.¹⁶⁸ Therefore, investigators concluded that “the value of leukapheresis in the management of leukostasis (was) not established.” Investigators, including Porcu and coworkers, have questioned whether qualitative changes in leukemic cells are more responsible for the disease than is the actual quantity of cells. However, leukapheresis for the indication of leukocytosis is still considered a Category I indication by the ASFA and the AABB.

Use of Leukapheresis

Practically, leukapheresis is a more complicated procedure than plateletpheresis because of the size of the cells and the rapid synthetic rate of the malignancy. The standard approach requires the processing of 8 to 10 liters of blood during the procedure^{55,169} and measurement of the post-procedure count. Some clinicians prescribe daily cytappheresis until the blast count, or the WBC count, is $<100,000/\mu$ L.

Erythrocytapheresis (Red Blood Cell Exchange)

Initially, red blood cell exchange (RCE) was indicated only for acute complications associated with hemoglobinopathies. In the treatment of patients with sickle cell disease, RCE is a Category I indication. RCE is also used in the treatment of infectious and metabolic diseases. The use of RCE for the treatment of protozoan infections (e.g., malaria and babesia) is considered a Category III indication; its use for erythrocytosis or polycythemia vera is considered a Category II indication. Current studies are exploring the

use of RCE as prophylactic erythrocytapheresis to prevent iron accumulation, in lieu of chronic simple transfusions, in patients with sickle cell disease.

Sickle Cell Disease

Hemolytic anemia, pain crisis, and organ ischemia are classic features of sickle cell disease (SCD), which is caused by a single amino acid (Glu to Val) substitution in the β -globin gene of hemoglobin, leading to the formation of β^S globin chains (see Chapter 47). Deoxygenated (and even poorly oxygenated) hemoglobin (Hb) S-containing cells are poorly deformable and have an increased propensity for polymerization, causing the characteristic shape change observed on peripheral smear—the sickle cell.^{170,171} It was originally believed that the end organ damage observed in SCD was solely attributable to the polymerization of these cells, which made them less deformable and therefore apt to occlude the microvasculature. This would result in even further sickling caused by local stasis and hypoxia.¹⁷² However, it is currently believed that the mechanism of tissue infarction is more complicated than just physical obstruction. Current theories and data suggest that a complex interaction occurs between these abnormal cells, inflammatory responses, and the activated endothelium that is very important in the adhesion of these cells to the endovascular.^{173–180} Furthermore, it is as yet unclear whether sickle cells that promote occlusion beget inflammatory responses, or whether inflammation triggers acute events, including stroke. Hebbel and associates¹⁸⁰ argue that multiple, overlapping factors are probably responsible; however, “the process of vaso-occlusion, regardless of its proximate cause, causes tissue ischemia and injury...”

RATIONALE OF TPE IN SCD

Because sickle cells are themselves pathologic, removal of those cells is advantageous. RCE makes it possible to remove these cells while replacing them with predominantly hemoglobin A-containing cells, thereby maintaining a net balance in iron accumulation. RCE has been used historically as first-line therapy in the management of acute sickle crisis to prevent end organ failure and for perioperative treatment of patients with SCD. Admixtures of Hb A and S improve overall solubility and reduce polymerization.

Replacement of sickle cells with Hb A-containing cells during a crisis has been shown to be clinically effective.^{181,182} Additionally, evidence suggests that RCE improves the rheologic characteristics of the patient's blood.¹⁷² Authorities in the field have published current indications for exchange transfusions, which include acute neurologic events, severe acute chest syndrome, acute multiorgan failure, preparation for major surgery, and long-term use (in lieu of simple transfusion) to avoid or reduce iron loading, as well as the management of acute priapism.^{172,183,184} Finally, RCE may have some role in the management of SCD during pregnancy.

The use of transfusion therapy in acute chest syndrome (ACS) is well documented. RCE is generally recommended to decrease Hb S concentration to 30% or less when clinical deterioration (e.g., respiratory decompensation) or organ failure is evident.¹⁸⁵ Most experts agree that RCE should be performed immediately during an acute ischemic stroke. In high-risk children, as identified by transcranial Doppler (TCD) velocity, evidence supports maintenance of Hb S

levels lower than 30% to prevent a first stroke¹⁸⁵ and long-term transfusion in children with previous strokes to prevent recurrence.^{186–188} Some authorities have written that RCE should be considered only for high-risk procedures or in patients with underlying pulmonary disease.^{183,189}

No randomized trials have examined clinical outcomes of pregnancy in transfused versus nontransfused patients. The evidence from nonrandomized trials is controversial. Prophylactic transfusion may reduce the incidence of pain crisis and thus may be indicated if painful episodes are increasing in frequency. Otherwise, most experts recommend that transfusion should be used in the same ways as it is for nonpregnant patients with SCD or prior to cesarean section.¹⁸³ Priapism is characterized by sickle cell occlusion in the corpora cavernosa. No clinical trials have evaluated the efficacy of transfusion therapy; however, in some case reports, long-term transfusion therapy and/or RCE has shown benefit in the treatment of patients with priapism.^{190,191} Serious adverse events have been reported to occur as a result of transfusion therapy (more discussion later).

USE OF RCE IN SCD

The percentage of circulating sickle cells prior to RCE, the desired final hematocrit, and the hematocrit level of the replacement product are used to calculate the volume of red cells to be removed and replaced. The hematocrit level of the replacement unit is an estimate in that all units have slightly varying hematocrit levels. The generally accepted goal of RCE is to raise the level of Hb A to 70% while lowering the level of Hb S to less than 30%. It is important, however, to maintain the patient's hematocrit below 30% (or <110% to 120% of baseline) to prevent transient hyperviscosity and maintain adequate oxygen delivery.¹⁸¹ In addition, an elevated postexchange hematocrit has been associated with the development of ASPEN syndrome (association of sickle cell disease, priapism, exchange transfusion, and neurologic events) or neurologic events (i.e., headaches, seizures, obtundation) that may occur after partial exchange transfusion associated with the release of vasoactive substances^{192,193} in the setting of priapism.

Other Hematologic Diseases

Protozoan Infection

Plasmodia and *Babesia* are protozoa that infect human red blood cells. High plasmodium parasite levels have been associated with poor prognosis,¹⁹⁴ and the pathogenesis of malaria is incompletely understood. In a recent review, Weatherall and colleagues¹⁹⁵ refuted the notion that malaria is a disorder with a single organ target and attempted to shift the paradigm of thought toward that of a complex, multisystem disorder with several key pathogenic processes, including “rapid expansion of infected red cell mass, destruction of both infected and uninfected RBCs, microvascular obstruction, and inflammatory process,” all of which may combine to compromise tissue perfusion.

RCE has been used to decrease parasite burden in heavily infected patients. Because no randomized, controlled clinical trials have been undertaken, it is difficult to assess the efficacy of this therapy. However, its proposed benefit

is the rapid removal of nonsequestered, infected red cells and the possible removal of circulating toxins that may contribute to the pathogenesis of the disease. Riddle and coworkers¹⁹⁶ have questioned the efficacy of removing nonsequestered, infected cells when sequestered cells are more pathogenic and are not removed by RCE. In this recent meta-analysis, Riddle and colleagues evaluated eight case-controlled studies and found no significant overall survival benefit with adjuvant RCE (except potentially in patients with partial immunity, for whom a relatively higher level of parasitemia is common.) Some have advocated the use of RCE in critically ill patients with high levels of parasitemia (>20% for malaria, >5% for Babesia). Again, conclusive scientific evidence to support this practice does not exist. The AFSA and the AABB list malarial infection and babesiosis as Category III indications for erythrocytapheresis.

Polycythemia Vera

Erythrocytosis and polycythemia vera are terms that are characterized by increased red cell mass that occurs as the result of a clonal disease or a secondary reaction to chronic hypoxemia. These patients have an increased hematocrit (Hct), leading to an increase in blood viscosity. Symptoms of erythrocytosis can range from headache, hypertension, visual disturbances, and confusion to cerebral infarction or hemorrhage and thrombosis of the abdominal vessels.^{55,197–199} In polycythemia vera (PV), life expectancy

and quality of life are directly related to control of red cell mass.^{55,198,199}

Removal of red cells is first-line therapy for patients with PV and is to be considered for secondary erythrocytosis.^{198–201} Maintenance of Hct at <45% with the use of phlebotomy minimizes the risk for thromboembolic complications. Thus, this value should be the highest target of treatment; many hematologists maintain the Hct between 39% and 45%.^{199–203} At a Hct level of 60%, whole blood viscosity is 2.5- to 3-fold that of blood with a Hct of 40%.²⁰⁴ Signs of hemorrhage or infarction in conjunction with an elevated Hct require immediate red cell removal through erythrocytapheresis to decrease Hct levels. This usually leads to rapid improvement.²⁰² For this indication, saline or albumin is the recommended replacement fluid.²⁰³

COMPLICATIONS

A variety of infectious and noninfectious reactions seen with simple transfusion of FFP may also be seen when plasma is used as replacement during TPE (Table 30-2). In recent years, the risk of transfusion-transmitted infectious disease has been largely eliminated with the introduction of nucleic acid testing (NAT) for HIV and hepatitis C virus (HCV). The result has been a comparative increase in the percentage of fatalities related to noninfectious serious

Table 30-2 Infectious and Noninfectious Reactions Seen with Simple Transfusion of Fresh Frozen Plasma When Plasma is Used as Replacement During Total Parenteral Nutrition

Adverse Event	Causes	Signs and Symptoms	Management
Hypovolemia	Fluid shifts Inadequate fluid replacement Pump malfunction	Drop in blood pressure Tachycardia	Saline or red cell priming; consider transfusion
Allergic reaction	Antibody to donor plasma proteins	Hives Dyspnea and facial swelling Hypotension Tachycardia and bronchospasm	IV diphenhydramine; epinephrine or corticosteroid
Atypical reactions due to ACE inhibitors	Elevated bradykinin levels	Flushing, hypotension, dyspnea, and bradycardia	Stop ACE inhibitors 72 hr prior to transfusion; if emergent pheresis is required, use FFP as replacement fluid
Isovolemic hypotension	Vasovagal reaction	Hypotension Bradycardia Sweating	Put patient in Trendelenburg position; give saline bolus
Hypocalcemia	Citrate toxicity Albumin administration	In children: Acute abdominal pain, agitation, pallor, diaphoresis, tachycardia, and hypotension In adults: Circumoral paresthesias, chills, nausea, and a tremulous feeling in the chest; rarely, overt tetany, cardiac arrhythmias	Slow the rate of infusion; give IV or PO calcium; consider switching anticoagulant from citrate to heparin
Vascular access		Hematomas Venous sclerosis Thrombosis Pneumothorax Subcutaneous emphysema Infection	Use peripheral access when appropriate
Coagulopathy	Dilution with albumin replacement	Prolonged clotting assays Bleeding	Use FFP as partial or complete replacement

IV, intravenous; ACE, angiotensin-converting enzyme; FFP, fresh frozen plasma; PO, by mouth.

hazards of transfusion, including transfusion-related acute lung injury (TRALI).

Between May and December 1995, the Hemapheresis Committee of the AABB conducted a large, prospective, multicenter study to investigate the incidence and types of adverse events observed during apheresis procedures.¹⁸ They found the overall rate of adverse events ($N = 242$) to be 4.75%. In addition, they found that the type of procedure, the type of instrument, and the patient's underlying disease were all specific factors that affected the incidence of adverse events. TPE with plasma replacement resulted in twice the number of adverse events as were seen with TPE without plasma replacement (7.8% and 3.4%, respectively). RCE yielded the largest percentage of adverse events (10.3%). Peripheral blood progenitor cell collection and selective extraction via immunoadsorption columns produced the lowest rates (1.66% and 1.19%, respectively). Citrate-related events occurred in 1.5% of procedures. Seven cases of tetany and seizure occurred during TPE procedures in which FFP was used for replacement. Vasovagal events occurred in 2.6% of procedures. In all, 1.6% of procedures were reported to have resulted in an adverse reaction that was caused by a transfused blood component; the overwhelming majority of these occurred during TPE with plasma replacement. Other studies have reported that patients with neurologic disease are more prone to hypotensive and/or vasovagal events.²⁰⁵ Peripheral or perioral paresthesias and mild lightheadedness were regarded as physiologic events and were not counted. Additionally, vascular access problems that prevented completion of the procedure were excluded. A total of three deaths were reported; however, none could be attributed to the apheresis procedure. Hypotension during apheresis has been attributed to several factors, including hypovolemia, allergic reactions, the vasovagal reflex, and complement activation.²⁰⁶

Hypovolemia

Fluid shifts that occur during the procedure, inadequate fluid replacement, and pump malfunctions that abrogate return of the patient's blood may cause hypovolemia during apheresis.³ Fluid shifts are usually tolerated by adults and older children. In standard procedures, saline is used to prime the extracorporeal circuit. First, whole blood is withdrawn from the patient, the saline prime is diverted into a waste collection bag, and replacement fluid is administered. Thus, a deficit fluid balance is maintained during the procedure. Young children, anemic patients, and those with heart disease or who are hemodynamically unstable for other reasons may be unable to tolerate the fluid shifts and hemodilution created by saline priming. These patients may require preprocedural or intra-procedural transfusions. Priming the circuitry with blood rather than saline is another technique that is used to maintain isovolemia during the procedure. In this instance, no final "rinseback" is needed.

Allergic Reactions

Allergic reactions characterized by a range of symptoms from hives, dyspnea, and facial swelling to hypotension, tachycardia, and bronchospasm have been associated with

FFP, albumin, and plasma protein fraction and plasma expanders (e.g., hydroxyethyl starch [HES]). Ethylene oxide gas used to sterilize disposable apheresis kits has been associated with periorbital edema, conjunctival swelling, and tearing.²⁰⁷ Those with mild reactions may be treated with intravenous diphenhydramine. More severe reactions may require epinephrine or corticosteroid treatment and respiratory support.

Atypical reactions have occurred in patients on ACE inhibitor therapy while they were undergoing hemodialysis, low-density lipoprotein apheresis, IgG affinity column apheresis, TPE, or desensitization immunotherapy.²⁰⁸ In a retrospective study, atypical reactions characterized by flushing, hypotension, dyspnea, and bradycardia were observed in 100% (14 of 14) of patients who were receiving ACE inhibitor therapy at the time of apheresis. Only 7% (20 of 285) of patients who were not receiving ACE inhibitors developed atypical reactions. In all, 11% of patients had an atypical reaction, with 41% of all such reactions occurring in those individuals on ACE inhibitors.²⁰⁸ One study showed that plasma bradykinin concentrations were higher in plasmapheresis donors on ACE inhibitors than they were in controls.²⁰⁹ This may help substantiate the hypothesis that a patient taking ACE inhibitors, which decrease bradykinin catabolism, who subsequently receives a large volume of albumin that contains a low level of prekallikrein activator (an activator of bradykinin) may develop a "toxic concentration" of bradykinin.²¹⁰ Bradykinin activates endothelial cells, thereby causing vasodilatation, increased vascular permeability, production of nitric oxide, and mobilization of arachidonic acid.²¹¹ As a general rule, ACE inhibitors are discontinued prior to apheresis procedures.

Vasovagal Reactions

Vasovagal reactions are the most common adverse reactions associated with donor apheresis; however, they are less likely to occur with whole blood donation.²¹² According to one multicenter, case-controlled, retrospective study, female donors, young donors, and first-time donors are more likely to experience vasovagal reactions.²¹³ The patient's or donor's pulse generally slows down, thus distinguishing this type of reaction from a hypotensive reaction. Removal of blood should be slowed or discontinued as symptoms occur or progress. The patient should be placed in the Trendelenburg position and should be maintained in this position until the reaction has resolved. Vital signs should be monitored. Some clinicians advocate saline administration.²¹⁴

Hypocalcemia and Citrate Toxicity

For a variety of reasons, ionized calcium levels may decrease during apheresis. Citrate, which binds calcium and is commonly used as an anticoagulant in blood products and during apheresis, may be infused, or calcium-free albumin, which also binds free calcium, may be used as the replacement fluid. Alternatively, citrate-rich FFP may be used as the replacement fluid. Approximately 1% of the body's calcium is found in the plasma; of this, only one half is free, or unbound.²¹⁵ Under normal physiologic circumstances, approximately 10% of plasma calcium is

bound to small anions in the circulation (e.g., phosphate). However, the infusion of exogenous anions such as citrate leads to an increase in the anion-bound fraction at the expense of the ionized calcium fraction.

The amount of citrate used during the procedure is dependent on the amount of blood to be processed, the length of the procedure, and the flow rate required. Thus, procedures such as leukapheresis, which require a large volume of citrate to be infused and in which virtually all of the anticoagulant is returned to the patient, frequently require supplemental calcium infusions to prevent citrate toxicity.²¹⁶ Additionally, citrate is present in relatively large amounts in packed red cells and plasma. Therefore, hypocalcemia may result from citrate toxicity during TPE replacement with plasma. Finally, citrate is metabolized within the liver and to a lesser extent within the kidneys and skeletal muscle.²¹⁷ Thus, in patients with liver and kidney dysfunction, unmetabolized citrate may accumulate.

Several studies have shown that during donor plateletpheresis, citrate causes a 20% to 30% decrease in ionized calcium levels.^{218,219} An increase in parathormone levels occurs in response to dropping ionized calcium levels during these procedures.^{19,220} However, an expected net calcium loss is sustained; thus, many physicians use calcium gluconate or calcium chloride prophylactically to prevent the occurrence of hypocalcemic reactions. No clinical trials support this practice.

Hypocalcemia presents differently in children than in adults. Children may experience signs and symptoms of acute abdominal pain, agitation, pallor, diaphoresis, tachycardia, and hypotension.¹⁹ Adults typically experience circumoral paresthesias, chills, nausea, and a tremulous feeling in the chest. Adults rarely experience overt tetany, and although electrocardiographic changes may be demonstrated, cardiac arrhythmias are rare. Pearl and associates^{221–223} described citrate-related alkalosis as another form of citrate toxicity in which patients with renal disease who are unable to effectively excrete bicarbonate become alkalotic after TPE with plasma replacement.

Adverse Effects Related to Vascular Access

As was previously mentioned, central venous access imposes greater risks than does peripheral access. Studies have shown that, except for a minority of cases and procedures, peripheral access is adequate.² Hematomas, venous sclerosis, thrombosis, pneumothorax, subcutaneous emphysema, and infection are not uncommon problems with indwelling catheters.²²⁴ Catheter-related infections may result in sepsis. Catheter care and heparin flushes to prevent clots in the line should be performed regularly. If platelet count starts to precipitously drop, it is important for the clinician to consider the diagnosis of heparin-induced thrombocytopenia (HIT). Cases of HIT in which heparin flushes were the only source of heparin have been reported.^{225–228}

Hypoglobulinemia and Infection

Normal immunoglobulin levels are known to decrease by approximately 60% from baseline after a single volume exchange.¹² Wing and associates,²²⁹ in a small, nonrandomized, retrospective study, showed that patients with RPGN

who had intensive TPE combined with immunosuppressive therapy were more likely to acquire a life-threatening infection than were those treated with immunosuppressive therapy alone. However, in a larger, randomized study of patients with lupus nephritis who were given immunosuppressive therapy alone or in combination with TPE,²³⁰ these findings were not well supported.⁸⁵ Still, with the use of regular TPE, measurement of IgG levels and coagulation parameters is recommended.

SPECIAL APPLICATIONS

Pediatrics

The indications and treatment protocols for apheresis in pediatric populations have been largely extrapolated from adult studies. However, the pathophysiology of a disease and response to treatment may differ in children.⁴ Some technical considerations regarding the maintenance of adequate intravascular volume and vascular access limitations are specific to children. Studies of adult patients may underestimate adverse events in children who undergo similar procedures. The use of continuous flow apheresis machines is recommended in lieu of intermittent flow devices because ECV is minimized and isovolemic fluid balance is better maintained.¹⁹ This is especially true for small, anemic, and/or hemodynamically unstable patients. In children who weigh less than 8 kg, manual exchange may be required.

Children are frequently unable to tolerate the fluid shifts and hemodilution that may occur with a saline prime. In these cases, priming the apheresis circuit with blood rather than with saline may be necessary and is recommended if the ECV exceeds 10% to 15% of the child's TBV, if the intraprocedural hematocrit decreases to below 20%, or if the child weighs 20 kg or less. Leukocyte-reduced RBCs are frequently used for this purpose; however, some advocate the use of reconstituted whole blood units for the purpose of priming in children who weigh less than 10 kg.¹⁹ As was previously mentioned, correct calculation of TBV is extremely important for accurate estimation of intraprocedural ECV. TBV estimates calculated automatically with the use of apheresis instruments and popular formulas may be significantly discrepant, especially in pediatric patients.⁴ Citrate anticoagulation is almost always used in conjunction with heparin or not at all in children because they are more susceptible to citrate toxicity. Several different methods for dosing have been described.^{4,216,231–234}

Photopheresis

Photopheresis (also called extracorporeal photochemotherapy, or ECP) is a procedure in which peripheral mononuclear cells are separated via apheresis, treated with a photoactivating agent (i.e., a psoralen compound) and ultraviolet A (UVA) light, and finally returned to the patient. In a photoconjugating reaction, DNA is cross-linked, causing strand breaks that result in inhibition of cellular proliferation and eventual apoptosis in exposed cells.²³⁵ ECP is indicated for the palliative treatment of patients with cutaneous T-cell lymphoma (CTCL) but also

has produced reported benefits in the treatment of various autoimmune diseases, solid organ allograft rejection, and graft-versus-host disease. The realization that these clinically heterogeneous diseases have similar pathophysiologic mechanisms and responses to immunosuppressive agents has led to the development of immunomodulatory hypotheses.²³⁶ Two formulations of the psoralen compound, 8-MOP (methoxsalen, 8-methoxypsoralen), may be used. An oral formulation given 2 hours prior to leukapheresis shows variability in drug absorption and may require drug level measurements to ascertain that the level is adequate. The second formulation is a sterile solution (Uvadex; Therakos Inc., Exton, Pa, USA) that may be injected directly into the buffy coat of the collection bag prior to UVA exposure. This formulation has more predictable drug levels, eliminates the 2-hour incubation period needed for the oral formulation, and reduces the amount of total 8-MOP that the patient receives, thereby reducing adverse effects.²³⁷ ECP is contraindicated in patients who have had previously documented reactions to psoralen or a history of porphyria cutanea tarda, erythropoietic protoporphyria, variegate porphyria, xeroderma pigmentosa, albinism, or other light-sensitive diseases.

CTCL

CTCL is a form of non-Hodgkin lymphoma (NHL) that is observed as CD4+ malignant T cells that typically manifest as skin patches and plaques located on the trunk. Treatment of CTCL is aimed at reducing symptoms and preventing secondary complications and progression of the disease, thereby affecting survival.²³⁸ Clinical trials have shown complete and partial remissions in erythrodermic CTCL and Sézary syndrome with ECP.^{239–241} The efficacy of ECP in the treatment of early-stage mycosis fungoides is a matter of controversy. Despite the advantages that ECP provides in terms of whole body photochemotherapy, versus PUVA (psoralen + long-wave ultraviolet radiation), one randomized clinical trial found that PUVA was superior to ECP in treating patients with skin disease at the plaque stage of mycosis fungoides.²⁴²

Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) is a common and potentially fatal complication of bone marrow transplantation (BMT). Acute and chronic GVHD have different clinical presentations and a different temporal relationship to the transplant. Acute GVHD occurs during the first 100 days after BMT. Chronic GVHD usually presents with various features, including a dry, itching rash and jaundice. Patients with chronic GVHD who are unresponsive to one or more immunosuppressive agents are usually included in ECP protocols and studies.^{243–245}

In the only prospective study, Foss and associates²⁴⁶ examined 25 patients with chronic GVHD and found that ECP is beneficial in their treatment, regardless of type of transplant (matched unrelated versus matched related), Akpek score (a prognostic scoring system based on disease onset and degree of skin involvement and thrombocytopenia, in which a score of 2.5 or more has an inferior outcome), and duration of chronic GVHD. Their findings corroborated the findings of an earlier retrospective study.²⁴⁷

Selective Extraction of Lipoproteins

Low-density lipoprotein (LDL)-apheresis (LDL-A) is used as first-line treatment for patients with familial hypercholesterolemia (FH). FH is characterized by hypercholesterolemia from birth, subsequent development of xanthomas, and premature atherosclerosis, with increased risk of premature coronary artery disease.²⁴⁸ The most common complications of homozygous FH are aortic valve fibrosis and stenosis.²⁴⁹

The goal of LDL-A therapy is to remove excess LDL while leaving high-density lipoprotein (HDL) in the circulation. Several methods, including immunoadsorption, dextran/sulfate cellulose adsorption (DSA), the heparin extracorporeal LDL precipitation system (HELP), and direct adsorption of lipoprotein through hemoperfusion (DALI), are currently used to extract lipoproteins. A full discussion of these methods is beyond the scope of this chapter; however, Naoumova and colleagues²⁵⁰ have prepared a comprehensive review of current methods of management of familial hypercholesterolemia. All of these methods have been shown to reduce LDL cholesterol (LDL-C),²⁵¹ lipoprotein(a) (Lp[a]),^{252–254} adhesion molecules,^{255,256} and C-reactive protein,^{257,258} while improving vascular endothelial function and hemorheology.^{259,260} All of these factors are likely beneficial in arresting the development of atherosclerosis.²⁶¹

The frequency, dose, and level of LDL-C reduction required to impede the progression of disease are unknown, but repetitive LDL-A is usually provided on a monthly or twice monthly basis. Naoumova and coworkers²⁵⁰ advocate the use of apheresis combined with drug therapy to achieve the lowest LDL-C levels possible in the absence of guidelines based on randomized, controlled trials. Some authorities have recommended that the frequency of apheresis should be adjusted to the activity of the LDL receptors and other individual patient factors.²⁶² Selective apheresis has been used successfully to treat children with FH.^{263–265} Pediatric tubing kits are available for DSA (Dextran-sulfate-Adsorption system; Kaneka, Osaka, Japan). Case reports of pheresis during pregnancy have shown success in control of hypercholesterolemia^{264,266–268} and improvement in uterine and umbilical flow.²⁶⁹

Chapter 31

Vena Caval Filters

Christine L. Hann, MD, PhD • Michael B. Streiff, MD

INTRODUCTION

Deep venous thrombosis (DVT) and pulmonary embolism (PE) occur in approximately 500,000 patients in the United States each year.¹ The vast majority of these episodes can be effectively managed with conventional anticoagulation, which is associated with a low incidence of recurrent thrombotic events (0.6 to 1.5 events per 100 patient-years) and major bleeding during therapy (≈ 0.9 to 4.6 events per 100 patient-years).²⁻⁴ Nonetheless, the increasing complexity of hospitalized patients ensures that all clinicians will have to treat patients with acute thrombosis for whom anticoagulation may be contraindicated. Modifications in vena caval filter technology and increased ease of insertion have prompted a number of authors to propose broadened indications for filter insertion.⁵⁻¹⁸ Perhaps as a consequence of these changes, the number of vena caval filters inserted annually in the United States has increased 25-fold since the 1970s, such that almost 50,000 filters (178 filters per million population) were placed in the United States in 1999.¹⁹ In comparison, only 20 to 30 vena caval filters are inserted annually in Sweden (3 filters per million inhabitants), an industrialized nation with a comparable quality of health care.²⁰ This 60-fold disparity warrants scrutiny. The purpose of this chapter is to review the available literature regarding vena caval filters and traditional and proposed indications for their use and to determine whether available data support current practices.

HISTORICAL PERSPECTIVE

The intellectual foundation of vena caval filtration as a means to prevent PE can be traced historically to two of the 19th century's greatest physicians, Rudolf Virchow and Armand Trousseau. In 1846, Virchow proposed the concept that pulmonary thrombi were in fact emboli that originated primarily in the veins of the lower extremities.²¹ Two decades later, in his lectures at the Hotel Dieu in Paris, Trousseau suggested that a physical barrier to the migration of emboli might be an effective preventive measure.²² In the 1930s, Homans popularized femoral vein ligation for the prevention of PE.²³ Although this procedure was effective in preventing emboli from the ipsilateral extremity, femoral vein ligation was associated with significant postthrombotic complications in the affected limb and did not provide protection from clots

that may emanate from the contralateral extremity. Consequently, an impressive array of surgical procedures and devices focusing on vena caval interruption were developed over the subsequent four decades. Surgical inferior vena caval ligation was associated with an operative mortality of 12%, with 4% of patients experiencing recurrent PE and 22% developing postphlebotic syndrome.²⁴ However, some clinical series documented recurrent PE in 20% to 50% of patients after long-term follow-up.^{25,26} To preserve caval blood flow, surgical plication was proposed to replace complete caval ligation. However, surgical plication of the vena cava proved to be technically demanding, so a variety of externally applied clips (Moretz, Miles, Adams, and Adams-DeWeese clips) were developed to reduce its complexity. Unfortunately, clinical results with these devices did not prove to be a major improvement (operative mortality, 10%; recurrent PE, 4%; postthrombotic syndrome, 16%)²⁴ but these experiences led to the development of intraluminal devices. The first widely used intraluminal device for vena caval interruption was the Mobin-Uddin umbrella filter. Although initial reports were favorable when the device was compared with caval plication (operative mortality, 0.6%; recurrent PE, 1.7%; venous stasis, 6.5%),²⁷ subsequent patient series noted higher rates of PE (7.8%), occlusion of the inferior vena cava (IVC) (53%), venous stasis (75%), and occasional episodes of cardiopulmonary migration.²⁸⁻³⁰ These problems and the introduction of the stainless steel Greenfield filter precipitated removal of the Mobin-Uddin filter from the market in 1977.

The introduction of the stainless steel Kimray-Greenfield filter (SSGF; Boston Scientific, Natick, Mass, USA) in 1972 revolutionized the field of vena caval interruption. The preservation of many of its engineering features in subsequent devices is a testament to its revolutionary design. The filter consists of a cone constructed of stainless steel wire affixed to a central apical cap. The filtration area is maximized by having each of the six wire legs make alternating right and left hand bends. At the caudal terminus, each wire ends in a hook that serves to anchor the device within the vena cava (Fig. 31-1). The funnel shape of the filter is designed such that the cross-sectional area of the IVC is reduced by only 50% when the filter is filled to a two-thirds level with thrombus, theoretically providing the body's fibrinolytic system the opportunity to lyse retained clots.³¹ Since its introduction in 1972, the Greenfield filter has been implanted in more than 120,000 patients.³²

CURRENTLY AVAILABLE VENA CAVAL FILTERS

Permanent Filters

Although placed percutaneously beginning in 1984, the original SSGF was too inflexible for easy insertion.³³

It required a 29-French (Fr) (outer diameter, OD) introducer catheter, which was felt to be partially responsible for the high incidence of insertion site thrombosis (IST) (45%) that had been noted in some studies.³⁴ Consequently, Greenfield and colleagues³⁵ developed the titanium Greenfield filter (TGF) (Boston Scientific, Natick, Mass, USA), which was introduced in 1988 and received U.S. Food

and Drug Administration (FDA) approval in 1989. Its conical design and the configuration of its six struts with terminal hooks were similar to those of the original SSGF (see Fig. 31-1). The titanium alloy (Beta II titanium alloy) allowed for greater flexibility, such that the filter could be introduced via a 12-Fr catheter (14.3-Fr OD). It was anticipated that reduction in catheter diameter would lead to a lower incidence of IST.³⁵ Because titanium is nonferromagnetic, the filter also would be at lower risk for migration during magnetic resonance (MR) imaging and may cause minimal MR imaging artefact.³⁶ Preliminary clinical studies with the TGF revealed a high rate of distal slippage and penetration of the caval wall³⁷; therefore, modifications of the hook design and base diameter were made, resulting in the modified-hook titanium Greenfield filter (MHTGF) (Boston Scientific, Natick, Mass, USA), which was introduced in 1991 (see Fig. 31-1; Table 31-1).³⁸

Although migration and penetration were largely improved in the MHTGF, tilting remained an occasional problem. To remedy this situation, the stainless steel percutaneous Greenfield filter (PGF) (Boston Scientific, Natick, Mass, USA) was developed. Similar to the SSGF in design, its apical hub differs in that it has a central hole that allows placement over a guidewire to prevent filter tilting and asymmetry. Its design gives it increased flexibility, allowing insertion via a small 12-Fr (15-Fr OD) catheter. The filter comprises six stainless steel struts, which are fitted into a cylindrical hub (see Fig. 31-1; Table 31-1). Once deployed, the filter is 49 mm in length and 32 mm in base diameter. The PGF can be used in patients with IVC diameters of 28 mm or less. To prevent migration, the anchor hooks are positioned bidirectionally, with four directed superiorly and two directed inferiorly.^{39,40} Although the filter appears to be MR safe, its stainless steel composition causes significant image artefact.⁴⁰ In 2005, all PGFs manufactured before March 10, 2004, were recalled from the market because of eight reports of detachment of the filter carrier capsule at the bond with the insertion catheter, which, in two instances, led to serious patient injury, including one death.

The Bird's Nest filter (Cordis Corporation, Miami Lakes, Fla, USA), introduced in 1982, has a unique structure and comprises four stainless steel wires 25 cm long that are folded over several times and attached to two V-shaped struts. These struts have hooks on the end that affix the filter within the vena cava (see Fig. 31-1; Table 31-1).⁴¹ It can be inserted via a 14-Fr OD catheter. Because the Bird's Nest filter expands up to a diameter of 60 mm, it is the filter of choice for patients with vena caval diameters greater than 30 mm.⁴² The original version of the Bird's Nest filter was associated with several fatal episodes of migration, a flaw that has been remedied through the introduction of a new version with stiffer anchor struts.^{43,44} The Bird's Nest filter generates the largest MR artefact of any filter because of its stainless steel construction, yet it appears to be stable in magnetic fields up to 1.5 Tesla (T).⁴⁵

The LGM or VenaTech filter (B. Braun/VenaTech, Evanston, Ill, USA) is made of Phynox (pacemaker lead material) with six struts arranged in a conical fashion, similar to the Greenfield filter models. Side rails attached to the filter struts anchor the filter within the vena cava (see Fig. 31-1; Table 31-1).⁴⁶ The VenaTech filter received FDA approval in 1989 and is MR compatible.⁴⁷ It is inserted with a 12-Fr sheath (14-Fr OD) and can be placed in venae cavae up to 28 mm in

diameter.⁴⁸ The original VenaTech filter is now no longer available on the U.S. market and has been replaced by the VenaTech Low-Profile (LP) Filter (B. Braun/VenaTech, Evanston, Ill, USA), which was approved by the FDA in 2001. In contrast to its predecessor, the VenaTech LP filter uses eight Phynox wires shaped in a conical fashion that fuse caudally in pairs to form side rails that secure the filter to the vena caval wall. Each side rail has a hook that is oriented superiorly or inferiorly (see Fig. 31-1). It can be introduced by a 7-Fr sheath and, once deployed, is 43 mm in height and 40 mm in diameter. Its use is limited to IVC diameters of 28 mm or less, and it is MR compatible.⁴⁹

The Simon Nitinol filter (Bard Peripheral Vascular, Tempe, Ariz, USA) is composed of a nickel/titanium alloy (Nitinol) that possesses thermal memory properties. At 4°C, the filter exists as a set of straight wires that automatically unfold at body temperature to form an umbrella filter with seven petals. Six hooked struts anchor the filter within the vena cava (see Fig. 31-1; Table 31-1). The FDA approved the filter in 1990, and it is designed for IVC diameters of 28 mm or less.^{50–52}

The G2 filter system (Bard Peripheral Vascular, Tempe, Ariz, USA) is a 12-legged conical filter constructed of Nitinol wires that gained FDA approval for permanent placement in November of 2005. The conical array of six short and six long curved Nitinol wires creates two planes of caval filtration and has a maximal deployment length of 41 mm. The maximal caval diameter for placement is 28 mm. The flexibility afforded by its Nitinol construction allows placement with a 7-Fr (internal diameter) catheter system from a jugular or femoral venous access site (see Fig. 31-1; Table 31-1).

The TrapEase filter (Cordis Corporation, Miami Lakes, Fla, USA) is also composed of Nitinol and consists of two conical filter baskets—one facing cranially, the other caudally—that are connected to create two levels of caval filtration (see Fig. 31-1; Table 31-1). When viewed in cross section, the filter baskets form a filtration plane composed of six diamond-shaped flow corridors. Six struts with proximal and distal hooks anchor the baskets within the vena cava. The TrapEase filter was approved for clinical use by the FDA in 2000. It can be placed through a 6-Fr sheath in patients with IVC diameters of up to 30 mm. The filter's nickel titanium alloy ensures MR compatibility and produces minimal image artefact.^{53,54}

The Günther Tulip filter (Cook, Inc., Bloomington, Ind, USA) is constructed of conichrome, an MR-compatible alloy similar to Phynox that is composed of cobalt, chromium, nickel, iron, molybdenum, and manganese. It has been in use in Europe since 1992 and first became available for use in the United States in 2001. In 2003, it received FDA approval for use as a retrievable filter. The filter basket is formed by four struts that are stabilized by wire loops that extend three quarters down the length of each strut. Hooks on the end of each strut attach the filter to the vena caval wall. A hook on the filter apex facilitates retrieval (see Fig. 31-1; Table 31-1). It can be introduced via an 8.5-Fr sheath (11-Fr OD) through a femoral or jugular approach and can be removed via a jugular approach.^{55–57}

Nonpermanent Filters

Given the long-term complications of permanent filters, development of a safe and effective nonpermanent filter

would be of great benefit to patients who have experienced an acute episode of venous thromboembolism (VTE) and have a short-term contraindication to anticoagulation. Nonpermanent filters can be divided into three categories: temporary, retrievable, and convertible. As their name suggests, temporary filters are designed only for short-term insertion and are held in place by a catheter or wire that is anchored to the insertion site. One temporary filter, the Tempo filter (B. Braun, Melsungen, Germany), was investigated in a clinical trial in the United States. Although initial results were promising,⁵⁸ subsequent episodes of catheter buckling and atrial migration halted further U.S. development.^{59,60} Currently, no temporary filters are approved for use in the United States.

Retrievable filters resemble permanent filters in that they are anchored within the IVC by tethering hooks. These anchoring hooks, however, gradually become incorporated in the wall of the IVC, such that most retrievable filters can be left in place only for a limited time before they must be removed. However, if the need for prolonged, indefinite vena caval interruption arises, these filters may be left in place to function as permanent filters. Two filters have been approved for retrieval by the FDA: the Günther Tulip filter and the OptEase filter (Cordis Corporation, Miami Lakes, Fla, USA) (Table 31-1). A third, the Bard Recovery filter, was approved for retrieval until 2005, at which point it was replaced by the Recovery G2 filter (Bard Peripheral Vascular, Tempe, Ariz, USA), which at present is approved only for permanent use.

The Günther Tulip filter was approved for use as a retrievable filter in 2003 and is described earlier in the section on permanent filters. Although the manufacturer recommends that the Günther Tulip filter be removed within 10 to 14 days of placement, several investigators have successfully retrieved filters that have been implanted as long as 126 days.^{55–57,61,62} Some have extended the caval life span by periodic filter repositioning.^{63,64} In a cohort of 90 patients with Günther Tulip filters, Millward and associates⁵⁶ removed 51 of 52 devices successfully after a mean insertion time of 9 days. The only complication reported was filter occlusion, which occurred in two patients. De Gregorio and colleagues⁶³ had similar success retrieving 69 of 72 filters (96%) in which retrieval was attempted. Among a series of 53 filters, 16 of 19 filters (84%) were successfully retrieved after a median implantation time of 34 days (range, 7 to 126 days).⁶¹ In contrast, Wicky and coworkers⁶² were unable to remove 14 of 49 (19%) Günther Tulip filters because of large trapped thrombi.

In accordance with the TrapEase filter design, the OptEase retrievable vena caval filter is composed of Nitinol and has a double-basket design. Its six struts have superior barbs to provide resistance to migration. It can be placed through a 6-Fr sheath in patients with IVC diameters of up to 30 mm and is MR compatible (see Fig. 31-1). The OptEase filter was approved for use as a retrievable filter in 2004. The manufacturer recommends retrieval within 12 days of placement. In a multicenter study of 27 patients, 21 (78%) had their filters removed a mean of 11 days (range, 5 to 14 days) after implantation. Follow-up was available for 19 of 21 patients (91%). One patient's DVT extended through the access site for filter placement; no other adverse events occurred.⁶⁵ Rosenthal and associates⁶⁶ reported 94 trauma patients who had had OptEase filters

placed by intravascular ultrasound for prevention of PE. Placement-related complications included one IST (1%), two insertion site hematomas (2%), and three misplacements (3%) that were replaced within 24 hours. Mean implantation time was 19 days (range, 5 to 25 days). Retrieval was attempted in 34 patients (36%) and was successful in 31 (91% of attempts). In three instances, retained clot in the filter precluded retrieval. One patient (3%) experienced a PE post filter retrieval. No PE occurred during the period of filter implantation.⁶⁶ The follow-up period in patients whose filters were not retrieved was not reported. Although the collective experience is extremely limited, the OptEase filter, thus far, appears to have comparable performance with the Günther Tulip filter.

In 2002, Asch⁶⁷ reported an initial experience with the Bard Recovery filter in 32 patients (see Table 31-1). The mean implantation period was 53 days, and the longest duration was 134 days. Filter retrieval was successful in all 24 patients in whom it was attempted. No symptomatic episodes of PE, IVC, or insertion site thrombosis were noted. One filter with trapped clot migrated 4 cm from its implantation site. Grande and colleagues⁶⁸ reported a series of 106 patients. Three patients (3%) presented with a symptomatic PE after placement. One was fatal (1%). No symptomatic caval migration or thrombosis occurred. Retrieval, which was attempted in only 15 patients (14%) was successful in 14 (93%) at a mean of 150 days (range, 0 to 419 days). Subsequent reports of several symptomatic migrations of the Bard Recovery filter have resulted in its discontinuation as a retrievable filter. The redesigned filter, the Bard G2 filter, is not currently FDA approved for retrieval.

The concept of a convertible filter has also been proposed and patented. This type of filter would be constructed in such a way that in the filter position, wire elements of the device would form one or two filtration planes. If caval filtration were no longer necessary, the filter could be converted into a caval stent through manipulation of a built-in release mechanism. At present, no convertible filters have been approved by the FDA.

STUDIES ON THE EFFICACY OF INFERIOR VENA CAVAL FILTERS

The only purpose for placing an IVC filter is to prevent PE. Therefore, it is essential that every physician become familiar with data supporting the effectiveness of filters in this task and with their adverse effects. Unfortunately, the vast majority of data on vena caval filters has been derived from unrandomized case series. Substantial differences exist between studies regarding subject populations (and their risk of recurrent VTE) and the intensity, comprehensiveness, and duration of follow-up. Therefore, combined results of these studies (presented in Table 31-2 and Figs. 31-2 through 31-4) should be interpreted in light of these limitations. Nevertheless, in the absence of randomized comparisons of filters, these data are the principal available means by which filter efficacy and safety can be assessed. As is shown in Table 31-2 and Figure 31-2, most available filters are roughly equivalent to one another but are somewhat less effective than anticoagulation in the prevention of PE. Several more recently approved and/or less extensively studied filter models (Günther Tulip, VenaTech LP, TrapEase,

OptEase) appear to have lower PE event rates. However, small study populations, short durations of follow-up, and wide 95% confidence intervals suggest that these estimates are fairly imprecise and may change as patient numbers and surveillance time increase. No follow-up data for the Bard G2 Recovery filter have been published.

Although randomized comparisons of various filter models have not been performed, a single randomized trial of vena caval filters in the management of VTE has been published.^{69,70} Investigators randomly assigned 400 patients with proximal DVT with or without PE who were judged to be at high risk for PE in a two-by-two factorial design to receive a vena caval filter or no filter and unfractionated heparin or enoxaparin. The subject population was clearly at high risk for adverse outcomes: 60% had idiopathic VTE, 35% had a previous history of VTE, 40% had iliac (37%) or vena caval (3%) thrombosis, and 14% had cancer. Four different types of vena caval filters were used: the VenaTech filter (56% of patients randomly assigned to the filter group), the titanium Greenfield filter

(27%), the Cardial filter (Bard, Saint-Etienne, France—not available in the United States), and the Bird's Nest filter (15.5%). Filters were placed within 48 hours of random assignment, and all patients were treated with unfractionated heparin and enoxaparin. Ventilation/perfusion scans were performed at baseline and after 8 to 12 days of anticoagulation. Warfarin was started on day 4, and heparin or enoxaparin was continued until the international normalized ratio (INR) was 2 or greater for 2 consecutive days. Ninety-nine percent of patients were discharged while on anticoagulation. Ninety-four percent received anticoagulant therapy for at least 3 months. Only 62% of filter patients and 64% of the group without filters received anticoagulation beyond 3 months. Thirty-eight percent of patients were still on oral anticoagulation at 2 years, and 35% received anticoagulation over the entire 8-year follow-up, with no significant differences noted between groups. After 12 days of treatment, vena caval filters were associated with a significant decrease in the incidence of (symptomatic and asymptomatic) PE compared with

Figure 31-4 Cumulative incidence of inferior vena caval (IVC) thrombosis and pulmonary embolism (PE) after placement of various vena caval filter models.

anticoagulation alone (1.1% vs 4.8%; $P = .03$). When only symptomatic PEs were considered, differences between the filter and no filter groups were no longer significant (1% vs 3%). At 2 years, symptomatic PE tended to be less frequent among filter recipients than among those who had received anticoagulation alone (3% vs 6%), although this difference was not significant ($P = .16$).

Fatal emboli were also more common in patients treated solely with anticoagulation (0.5% vs 2.5%). However, vena caval filters were associated with significantly more recurrent DVT than was observed with anticoagulation alone (21% vs 12%; $P = .02$). No difference in bleeding or mortality was documented. Sixteen of 37 patients (43%) with vena caval filters who had recurrent DVT also had IVC thrombosis. At 8 years, outcome data on 99% of patients became available, and 198 patients (50%) were found to be still alive. The occurrence of symptomatic PE was less frequent in filter recipients than in those treated with anticoagulation alone (6% vs 15%; $P = .008$). Fifty percent of PEs in the no filter group occurred during the first 2 years of follow-up. DVT was more frequent among filter patients (36% vs 28%; $P = .042$). Sixty-five percent of DVT occurred among filter patients within the first 2 years of follow-up. Symptomatic filter thrombosis occurred in 13% after 8 years. Postthrombotic syndrome (PTS) was observed in 70% of patients in both the filter and no filter groups. No difference in overall survival was reported.⁷⁰ These data indicate that filters, when used in conjunction with anticoagulation, offer a short-term reduction in the total number of PEs at the cost of a long-term increase in recurrent DVT with no reduction in mortality. Unfortunately, because 94% of patients received anticoagulation for at least 3 months, these data offer no insight into the outcome of the typical patient who has had a vena caval filter placed, namely, those who are believed to have contraindications to anticoagulant therapy. In addition, although it was not routine at the time the study was performed, extended duration anticoagulant therapy is commonly recommended for high-risk patients, as in the PREPIC (Prévention du Risque d'Embolie Pulmonaire

par Interruption Cave) study population. Therefore, it is likely that the benefits associated with filter placement in this study would be considerably less with currently recommended durations of anticoagulation for VTE.

Additional valuable information about the efficacy of vena caval filters can be found in the population-based observational study conducted by White and coworkers.⁷¹ Using the linked California Patient Discharge Data Set, which tracks discharge diagnoses and procedures performed in all nonfederal hospitals in California, the researchers analyzed the outcomes of patients admitted from January 1991 to December 1995 for VTE. During this 5-year period, 3632 patients received a vena caval filter for VTE and 64,333 patients did not receive a filter. Filter recipients were more likely to have had major bleeding, surgery, cancer, stroke, myocardial infarction, chronic lung disease, or congestive heart failure within 3 to 6 months of their VTE diagnosis. For purposes of comparison, filter and control patients were subdivided into groups with 0, 1, or 2 or more previous hospitalizations for VTE.

Even after adjusting for risk factors for recurrent VTE, investigators found that patients who received vena caval filters were just as likely as nonrecipients to be readmitted for a PE. Similar to the results of the Decousus study,⁶⁹ White and associates⁷¹ noted that filter placement was associated with a twofold increase in the risk of subsequent venous thrombosis, although only among patients with an initial episode of PE. Filters did not seem to have a short-term protective benefit against PE as the time course of recurrent PE was similar between filter recipients and nonrecipients. Filter recipients also were more likely to die during follow-up than were control patients. Because it is unlikely that filter placement alone is responsible for this mortality difference, the potential limitations of this type of analysis are underscored—that unidentified comorbidities may have been responsible in part for the inferior outcomes of filter recipients. Despite this limitation, the White study⁷¹ provided valuable information that should be considered by any physician who contemplates the use of a vena caval filter for the treatment of patients with VTE.

FILTER COMPLICATIONS

Permanent Filters

Complications of IVC filters may occur at the time of insertion or months to years later.⁷² Acute procedure-related complications include misplacement (1.3% of insertions), pneumothorax (0.02%), hematoma (0.6%), air embolism (0.2%), inadvertent carotid artery puncture (0.04%), and arteriovenous (AV) fistula (0.02%). According to the published case series, fatal complications of placement are rare, occurring in only 0.13% of insertions. Among various individual filter models, the published fatal complication rate is highest for the Bird's Nest filter (0.34%) compared with the original stainless steel Greenfield filter (0.11%), the titanium Greenfield filter (0.15%), and the VenaTech filter (0.07%). No fatal complications have been reported in the published literature for the PGF, the Simon Nitinol filter, the Günther Tulip filter, the Nitinol TrapEase, OptEase filters, or the Bard G2 filter,⁷³ although fatal events for several of these filters have been reported in the Manufacturer and User Facility Device Experience database, which is available through the FDA. The higher fatal complication rate associated with the Bird's Nest filter reflects primarily the results of a single study, which documented four episodes of fatal IVC thrombosis.⁷³ If one considers this experience as isolated, the fatal complication rate associated with the Bird's Nest filter is comparable with other filter models.

A common early postprocedural complication of filter placement is insertion site thrombosis (IST).^{34,74–79} IST is a DVT that develops at the venous insertion site. Given the process of filter insertion and the patient population served by it, it is not surprising that nonocclusive and occasionally occlusive thrombi develop at the venous access site. IST appears to be less common with balloon dilation as opposed to the use of serial fixed diameter dilators for site preparation.⁷⁷ Counterintuitively, the literature does not support the notion that filters requiring larger introducer catheters are at higher risk for thrombosis.^{74,75} One possible explanation for this observation may be that all introducer systems result in sufficient local endothelial trauma to precipitate VTE. Alternatively, the apparent absence of a difference in IST rates between insertion catheters of various sizes may reflect the limited number of patients investigated to date.

Delayed complications of filter placement include recurrent DVT, IVC thrombosis, filter migration, IVC penetration, and filter disruption. Because filters are often placed in patients with a VTE who cannot at least initially receive anticoagulation, recurrent DVT in this patient population is not an unexpected event. Case series data on the frequency of DVT after filter placement suggest that DVT may be more common with the titanium Greenfield filter and the VenaTech filter (see Table 31-2; Fig. 31-3). However, differences in follow-up and patient populations may be more responsible for these outcome differences than filter design. Ultimately, randomized comparisons are needed to determine whether important differences exist between filters. Consistent with the results of Decousus and White and colleagues, the rate of recurrent DVT among patients treated with anticoagulation as derived from a pooled analysis of randomized antio-

gulation trials in the treatment of VTE is approximately half that identified in most case series of vena caval filters (see Fig. 31-3).^{69–71,80}

IVC thrombosis, although substantially less problematic for contemporary filter models than for the Mobin-Uddin umbrella filter and IVC clips, remains a common event among filter recipients. Possible sequelae of IVC thrombosis include phlegmasia cerulea dolens, venous gangrene, recurrent DVT, and a heightened risk of postthrombotic syndrome and recurrent PE due to thrombi that extend proximally to the thrombosed filter. Case series data suggest that IVC thrombosis occurs in 2% to 10% of filter recipients (see Table 31-2).⁸¹ Thirteen percent of filter recipients in the PREPIC study experienced symptomatic IVC thrombosis over 8 years of follow-up.⁷⁰ Although one might predict that filters associated with a higher frequency of IVC thrombosis would be associated with fewer PEs, case series data do not support this conclusion (Fig. 31-4). One conceivable explanation for this seemingly contradictory result may be the contribution to episodes of PE made by thrombi that have propagated *proximal* to thrombosed filters. Important differences in the use and sensitivity of screening procedures for IVC thrombosis and follow-up of patients for PE also are likely to be important contributors to this paradoxical outcome.

With regard to the frequency of IVC thrombosis, a study conducted by Crochet and associates is particularly enlightening.⁸² In this study, routine radiographic surveillance, including abdominal radiography, duplex scanning, and venacavography, was performed in 142 patients who received VenaTech filters. IVC occlusion was identified in 22% and 33% of patients after 5 and 9 years of follow-up, respectively. Among the subgroup of patients with PE and anticoagulant therapy failure, the caval occlusion rate was 65%. Anticoagulation did not appear to favorably influence the rate of caval occlusion. Fifty percent of patients with caval occlusion experienced lower extremity swelling.

This study offers several important lessons. First, it strongly suggests that the frequency of IVC thrombosis is underestimated in many of the published case series. Although this study focused exclusively on the VenaTech filter, pooled data on IVC occlusion do not suggest that significant differences exist between filter types (see Fig. 31-4). Second, it suggests that trapped emboli rather than *in situ* thrombosis in the filter are primarily responsible for IVC thrombosis. In the past, thrombus trapping and *in situ* thrombosis of the filter due to its effect on blood flow have been proposed as reasons for IVC thrombosis. Patients who present with PE are more likely to experience recurrent PE than are patients with an initial DVT.^{80,83} The fact that patients with PE and failure of anticoagulation constitute the only subgroup with a higher risk of IVC occlusion supports the premise that thrombus trapping is a major contributor to IVC occlusion.

Crochet and colleagues⁸² found that anticoagulant therapy did not significantly reduce the incidence of vena caval occlusion. Two factors may have contributed to this result. The subgroup with the highest incidence of IVC occlusion comprised patients with previous anticoagulation failure and PE. The impact of this subgroup with anticoagulation resistance may have diminished the impact of anticoagulation on IVC occlusion. Unfortunately,

no subgroup analysis has been performed to investigate this possibility. In addition, data on mean achieved anticoagulation intensity are not presented. Therefore, subtherapeutic anticoagulation may have substantially contributed to thrombotic complications in this study. A prior investigation found no evidence of enhanced prothrombin activation among filter recipients compared with patients without filters who were on long-term anticoagulation.⁸⁴ Consequently, it may be premature to consider anticoagulation ineffective in preventing thrombotic complications associated with vena caval filters.

Postthrombotic syndrome (PTS) is a common complication among patients after they have experienced VTE. In a consecutive series of 528 patients treated with conventional anticoagulation, cumulative incidences of PTS at 2, 5, and 8 years of follow-up were 25%, 30%, and 30%, respectively. The risk of PTS was strongly associated with recurrent ipsilateral DVT.⁸⁵ Pooled data from case series indicate a roughly similar incidence among filter recipients (see Table 31-2; Fig. 31-5). Nevertheless, the association of vena caval filters with recurrent VTE and the established association of recurrent ipsilateral DVT with subsequent PTS would tend to suggest that these case series data may underestimate the frequency of PTS among filter recipients.^{69,71,85} In the PREPIC study, a similar proportion of filter recipients (70%) and those who received no filter (70%) experienced PTS within 8 years.⁷⁰ The high rate of PTS reflects the high-risk nature of the subject population (36% had a history of previous VTE) and the significant proportion of patients who had PTS at baseline (filter, 23%; no filter, 24%). The severity of preexisting venous insufficiency at baseline may account for the absence of any difference in PTS between groups. Alternatively, it is also possible that the ability of anticoagulant therapy to preserve valve function is insufficient to produce measurable protection against PTS. Because compression

stockings have been shown to reduce the incidence of PTS by 50%, routine use of compression stockings should be strongly encouraged among all filter patients (see Chapter 17).⁸⁶

Filter migration was a significant problem with the Mobin-Uddin filter—a fact that resulted in several deaths.^{27,29} Improved anchoring technology has made this event distinctly unusual among recipients of contemporary permanent filters (0.3%).⁸¹ One unavoidable consequence of using hooks to reduce filter mobility is IVC penetration. Penetration occurs when filter components traverse the IVC wall and enter the pericaval space. Limited penetration of the IVC wall is desired and necessary if the filter is to be anchored at its intended location. Rarely, however, filter components penetrate into adjacent structures and produce clinical consequences (0.3%).⁸¹ Small bowel obstruction,⁸⁷ duodenal perforation,^{88,89} and retroperitoneal hemorrhage^{72,90} due to penetration of the abdominal aorta or iliac artery are among the reported consequences of IVC penetration by filter components. Concomitant anticoagulation has been associated with several instances of bleeding and conceivably may enhance this risk.^{90,91} Therefore, IVC filters should be placed cautiously during anticoagulation, and the development of abdominal pain in this setting warrants prompt abdominal imaging.

Filter tilting and strut fracture theoretically may contribute to impaired filtration efficiency and thus reduced filter performance in PE prevention.^{92–94} Only a fraction of filter case series have documented tilting (5.3%) and strut fracture (2.7%).⁸¹ However, clinical studies investigating possible adverse consequences of these events remain inconclusive.^{95,96}

A recently recognized potential long-term source of complications associated with IVC filters is entrapment of guidewires used to place vascular access catheters.^{97–99} Forceful attempts to remove guidewires have led to a

Figure 31-5 Cumulative incidence of postthrombotic syndrome after placement of various vena caval filter models or treatment with anticoagulation. (Estimate derived from Prandoni, Villalta et al., 1997.)

number of filter displacements that in some instances have required filter removal or placement of a second device.^{98,100–103} One patient died from a cerebrovascular accident following anticoagulation after such an event.¹⁰⁴ Case reports and one experimental study suggest that VenaTech and Greenfield filters are more likely to result in guidewire entrapment.^{105,106} In vitro tests indicate that the TrapEase filter may also entrap 3-mm and 1.5-mm J-tipped wires. Design modifications in the VenaTech LP make it much less likely to entrap guidewires and catheters.¹⁰⁶ Simple precautionary measures that may reduce the frequency of guidewire entrapment include prominent documentation of IVC filter placement in the medical record and provision of identification bracelets to patients with filters. Use of straight-tipped guidewires, which are less likely to become entrapped than J-tipped wires and limiting insertion of guidewires to 18 cm (the mean distance to the SVC:right atrial junction), minimizes the chances of this complication.^{105–107} If a guidewire does become entrapped, physicians should immediately contact an interventional radiologist or vascular surgeon for safe removal of the wire under fluoroscopic guidance.

Filter-Specific Data from the Manufacturer and User Facility Device Experience (MAUDE) Database

Permanent Filters

The Manufacturer and User Facility Device Experience (MAUDE) database is a collection of adverse event reports associated with FDA-approved medical devices.¹⁰⁸ These voluntary reports have been collected since 1991. Although reports do not constitute a comprehensive dataset for all complications associated with vena caval filters, this database does provide narratives on commonly encountered events associated with vena caval filter implantation and use. Data on filters that received FDA approval after 1991 were collected and summarized as described below.

Between August 1996 and March 2006, 333 reports on the PGF were filed in the MAUDE database. Most reports were listed as difficulty in deployment (232 of 333; 70%). Failure to open completely was the most common reason for difficulty in deployment and was listed in 169 reports. Difficulty in guidewire removal was reported on 40 occasions. Central line guidewire entrapment was reported 8 times (2%). Filter migration was reported on 42 occasions (13%); 19 of these incidents were related to failure of the filter to open completely. Perforation was reported 10 times, and two of these cases were directly attributable to user error. In total, nine deaths were reported among patients who received a PGF; three of these appeared to be unrelated to PGF use.

Since its approval in 2000, 174 adverse events have been reported with the TrapEase filter. The most commonly reported event was filter thrombosis or occlusion (29% of reports), followed by difficulty with deployment (19%) and migration (14%). Filter or strut fracture was reported in 23 instances (13%). Perforation was reported in 9 cases (5%). Overall, 19 deaths attributable to the presence of the TrapEase filter were reported.

Since 2002, 34 reports have been filed in the MAUDE database on the VenaTech LP filter. Most of these were

listed as difficulty in deployment or failure to open (21 of 34; 62%). Filter migration was reported on 18 occasions (53%); one third of cases occurred in conjunction with failure to open. Perforation was reported once. One death attributable to placement of a VenaTech LP filter has been reported to the MAUDE database.

Fifty-two reports on the G2 filter have been filed in the MAUDE database. Most reports were listed as difficulty or failure of filter deployment (35 of 53; 66%). Filter migration was reported in 19% of cases, and perforation and tilt were described to occur at a rate of 9% each. One death was reported in a patient who received a G2 filter; however, details of this event are not available.

Nonpermanent Filters

Sixty-nine complications involving the Günther Tulip filter have been reported to the MAUDE database since its approval as a retrievable device (December 2002 to March 2006). The most commonly reported complications were related to difficulty in filter deployment 48%; in five cases, the user commented that the filter legs appeared crossed. Migration was reported in 15% and device breakage in 4%. Difficulty in retrieval was reported in 4%. Post-filter placement thrombotic events, including PE, DVT, and filter thrombosis, were reported in 6% of patients; two of these thrombotic events resulted in death. Overall, death was the listed outcome in six reports; two cases were attributed to hemorrhage caused by the filter, and two deaths were a consequence of filter migration.

With respect to the OptEase filter, 39 complications were submitted to the MAUDE database since its approval as a retrievable device (period between December 2003 and March 2006). The most commonly reported complications were strut or filter fracture (23%) and difficulty with deployment (23%), although most of the latter events appeared to be due to user error. Filter migration was also frequently reported (15%). Post-filter placement thrombotic events, including PE, DVT, and filter thrombosis, were reported in 13%. Death was the listed outcome in two of these reports, although neither event was attributed by the user to the filter.

SHOULD PATIENTS WITH PERMANENT VENA CAVAL FILTERS RECEIVE PROPHYLACTIC ANTICOAGULATION?

As was outlined in previous sections, vena caval filters have been associated with several thrombotic complications, including IST, recurrent DVT, and IVC thrombosis. Therefore, should all patients with a vena caval filter receive long-term prophylactic anticoagulation to prevent these thrombotic complications? Anticoagulant therapy with vitamin K antagonists is known to be effective in the prevention of recurrent thromboembolism; however, this protection comes at the cost of increases in hemorrhagic morbidity and mortality, even when anticoagulation is managed by specialized anticoagulation clinics. Although anticoagulant therapy is often managed by anticoagulation clinics in the United Kingdom and Europe, management by individual practitioners remains the predominant mode of care in the United States. Therefore, the risks of major

bleeding associated with any program of prophylactic anticoagulation in filter recipients in the United States are likely to be closer to 7% to 8% per patient-year of therapy, rather than the 2% to 3% per patient-year commonly reported by anticoagulation clinics.¹⁰⁹ Although anticoagulant therapy has been reported to reduce prothrombin activation in filter recipients,⁸⁴ it remains to be seen whether anticoagulant therapy would prevent clinical events or reduce mortality in patients with filters. In the PREPIC study, 35% of patients in both groups received anticoagulant therapy during the entire 8-year study follow-up period. Although indefinite anticoagulant therapy among all filter recipients may have prevented excessive thrombotic complications, it remains unclear whether the benefits of this approach would have exceeded the associated risks, because 26 filter recipients (15%) experienced major bleeding during the study period. Because no difference in mortality was observed between groups at the study conclusion, it seems unlikely that indefinite anticoagulant therapy among all filter recipients will be associated with a mortality benefit.

The case fatality rate of major bleeding in patients with VTE has been estimated to be 13%; the case fatality rate for recurrent DVT is approximately 5%.^{80,110} This hemorrhagic mortality risk translates to an absolute fatal bleeding risk of 0.3% to 1% per patient-year, depending on the mode of anticoagulation management used (individual practitioner vs anticoagulant therapy management clinic). In contrast, according to the data from Decousus and coworkers, the absolute excess risk of recurrent DVT among filter recipients is on the order of 5% per patient-year, corresponding to a maximal excess risk of thrombotic mortality of 0.25% per patient-year (because filters are effective in the prevention of PE, this estimate of thrombotic mortality based on patients without filters is likely to be an overestimate).⁶⁹ Therefore, even with optimal anticoagulant therapy control, it is doubtful whether indefinite anticoagulation for filter recipients would result in net benefit, particularly in the setting of individual practitioner management. Furthermore, because the risk of recurrent VTE declines over time while the risk of bleeding with anticoagulant therapy remains constant, it is likely that the risk:benefit ratio is likely to worsen as time passes.^{111,112} In the near future, anticoagulants with improved safety profiles may become clinically available, which should favorably alter the risk:benefit ratio for long-term anticoagulant therapy for many indications.¹¹³ Until that time, available data indicate that anticoagulant therapy for patients with IVC filters should be guided by the thrombotic history of the patient (i.e., filter placed for prophylaxis only or as part of treatment of VTE), and not solely by the presence of a filter.

CAN PATIENTS WITH VENA CAVAL FILTERS UNDERGO MAGNETIC RESONANCE IMAGING?

Magnetic resonance (MR) imaging has become an increasingly important clinical imaging modality. Therefore, patients with vena caval filters are likely to require MR imaging at some point during their medical care. Thus far, no reports of filter migration as a result of MR imaging have been published. Ferromagnetic alloys such as stainless steel, as used in the original stainless steel Greenfield filter,

the percutaneous Greenfield filter, and the Bird's Nest filter, produce artefacts on MR imaging. The greatest artefact is seen with the SSGF and the Bird's Nest filter and much less is seen with the percutaneous Greenfield filter, nonetheless, stainless steel filter components have been shown to be stable at field strengths up to 1.5 T.^{40,45,114}

Simon Nitinol, Nitinol TrapEase and OptEase, VenaTech, VenaTech LP, Günther Tulip, Bard G2, and titanium Greenfield filters are all composed of low ferromagnetic alloys, which do not cause significant MR image deterioration.^{36,50,114–117} MR imaging as early as 1 week after placement was not associated with any consequences in a small series of patients in whom the Simon Nitinol filter was used.⁵⁰ Although it is likely that other low ferromagnetic devices will behave similarly, data on other filter models should prove useful for clinical decision making.

POTENTIAL INDICATIONS FOR IVC FILTER PLACEMENT (TABLE 31-3)

Since improved percutaneous techniques have been developed for filter placement, the number of indications cited for vena caval filter placement and the number of filters placed have increased dramatically. One report on IVC filter use revealed a fivefold increase in the number of caval filters placed at a single institution from 1980 to 1996.¹¹⁸ These single-center data are corroborated by a recent analysis of U.S. national trends in filter use. Using the National Hospital discharge database, Stein and associates¹⁹ documented a 25-fold increase in vena caval filter use between 1979 and 1999, despite a relatively stable incidence of VTE during this period. Coincident with this trend has been increasing use of IVC filters for prophylactic indications, despite the absence of compelling data showing their efficacy in these situations.¹⁹ In the following sections, we review data that support the use of vena caval filters for these extended indications (see Table 31-3).

CONTRAINDICATION TO ANTICOAGULATION

Although the vast majority of patients with VTE can be managed with anticoagulation, in a small subset of patients, anticoagulant therapy seems contraindicated. Because patients with an acute episode of VTE are at substantial risk for recurrence in the absence of anticoagulation,^{119,120} vena caval filters represent a valuable treatment option for those who should not receive anticoagulation.

FAILURE OF ANTICOAGULANT THERAPY

Prevention of recurrent VTE is commonly proposed as an indication for vena caval filter placement. Although episodes of VTE do occur in patients who are therapeutically anticoagulated, these instances are unusual. Therefore, any patient with recurrent VTE despite anticoagulation should be carefully evaluated before vena caval filter placement is entertained so that potential therapeutic catastrophes can be avoided. First, it is important to determine whether the patient has been consistently therapeutic

Table 31-3 Putative Indications for Placement of Inferior Vena Caval Filters

(see text for details)	
Indications	Comments
Contraindications to adequate anticoagulant therapy	Probably greatly inflated, given risk:benefit ratio of treatment in acute VTE. Seems appropriate for fresh (e.g., <3–4 days) neurosurgery; active hemorrhage of the GI tract, retroperitoneum, CNS, and pulmonary tree; known CNS metastases* or significant CNS trauma. Treatment for patients with severe coagulopathy or severe thrombocytopenia must be individualized.
Failure of ongoing anticoagulant therapy	Very rare; far more often, prior therapy is found to be inadequate or punctuated. Trousseau syndrome is the most common exception.
Pulmonary thromboendarterectomy	Uncertain benefit but prevalent practice.
Trauma	Rational, given the high morbidity and mortality of VTE in trauma patients. Randomized studies are urgently needed to resolve this question.
Free-floating venous thrombus	This previously widely held indication has been disproved.
Thrombolytic therapy for DVT	No firm indication.
Unsubstantiated indications	
Cancer patients	No firm indication.
High-risk orthopedic patients	No firm indication.
Bariatric surgery	No firm indication.
Other	

*Particularly hemorrhagic metastases or metastases from melanoma or choriocarcinoma.

VTE, venous thromboembolism; GI, gastrointestinal; CNS, central nervous system; DVT, deep venous thrombosis.

during the period preceding the recurrent thrombotic event. If such is not the case, it is appropriate to redouble efforts to maintain the patient in the therapeutic range and perhaps increase the target INR from 2 to 3 up to 2.5 to 3.5, rather than place a vena caval filter that may thrombose and promote morbidity if subtherapeutic anticoagulant therapy continues. In the setting of a substantial pulmonary circulatory clot burden, thrombolysis followed by anticoagulation may be more appropriate than filter placement. If the patient has been clearly therapeutic, hypercoagulable syndromes that require more intensive or alternative forms of anticoagulation should be excluded before a filter is placed. Although many patients with the antiphospholipid antibody syndrome are safely managed with conventional intensity warfarin anticoagulation (INR, 2 to 3),¹²¹ a subset of these patients require high-intensity warfarin (INR, 3 to 4) to prevent thrombotic events (see Chapter 19).¹²² A panel of coagulation assays sensitive to the presence of antiphospholipid antibodies, as well as immunoassays for antiphospholipid binding protein antibodies (anticardiolipin antibodies, anti- β_2 -glycoprotein I antibodies), should be performed to diagnose this condition.¹²³

Another hypercoagulable state that is strongly associated with resistance to warfarin anticoagulation of conventional intensity is Trousseau syndrome (see Chapter 12). First recognized by Armand Trousseau 140 years ago, Trousseau syndrome is a malignancy-associated hypercoagulable state that is characterized by arterial and/or venous thromboembolism (often migratory and involving superficial veins), nonbacterial thrombotic endocarditis, disseminated intravascular coagulation, and warfarin resistance.¹²⁴ Because this condition is a systemic hypercoagulable state, regional approaches to prevent thromboembolism such as vena caval filters are never adequate and, in the authors' anecdotal experience, are often associated with substantial thrombotic morbidity and mortality. This condition is best treated with heparin anticoagulants.

Heparin-induced thrombocytopenia (HIT) is a common early cause of anticoagulation failure (see Chapter 25). In

1% to 5% of patients, treatment with unfractionated heparin (0.3% among low molecular weight heparin [LMWH] recipients) for at least 4 days precipitates a prothrombotic immune thrombocytopenia. Although HIT typically results in thrombocytopenia (50% decline from baseline) 5 to 10 days after initiation of heparin therapy, patients less commonly develop thrombocytopenia within 24 hours in the setting of preformed HIT antibodies that result from heparin exposure within the previous 120 days. Even less common is delayed HIT, in which patients develop thrombocytopenia several weeks after heparin exposure. Patients typically present after a recent hospitalization with new moderate thrombocytopenia and a new thrombotic event. Use of heparin in this setting can result in worsening thrombocytopenia and progressive thrombosis. Although each of these presentations can result in recurrent thrombosis despite adequate heparin therapy and may be interpreted as a failure of anticoagulation, use of a vena caval filter in this setting is counterproductive and has resulted in worsening thrombosis. The only effective therapy is to discontinue all forms of heparin exposure and initiate therapy with a direct thrombin inhibitor (lepirudin or argatroban) or perhaps fondaparinux.

Recurrent events in the same location should prompt consideration of vascular abnormalities such as the May-Thurner syndrome or the Paget-Schrötter syndrome (thoracic outlet syndrome), both of which are underrecognized reasons for recurrent VTE (see Chapter 16). The May-Thurner syndrome is characterized by deformation and stenosis of the left iliac vein as a consequence of the overlying right iliac artery. Resulting stenosis precipitates recurrent episodes of left iliofemoral DVT. Thrombolysis and stenting of the affected vein segment may result in long-lasting resolution.¹²⁵ Occurrence of an upper extremity DVT without clear risk factors should prompt investigation for the Paget-Schrötter syndrome, a venous manifestation of thoracic outlet syndrome. In affected individuals, the subclavian vein is compressed by local anatomic structures (e.g., anterior scalene muscle, cervical ribs). Vascular wall

damage and stasis may result in thrombosis. Historically, patients may relate a recent history of heavy lifting or exertion that involves the affected extremity. Venography of the upper limb vessels in stress positions (e.g., abduction, external rotation) is useful for demonstrating functional compression of the subclavian vein.^{126,127} Therapy for the Paget-Schrötter syndrome consists of catheter-directed thrombolysis followed by surgical correction of the anatomic abnormality and anticoagulation.

PULMONARY THROMBOENDARTERECTOMY

In most patients, PE resolves with treatment such that no permanent clinically apparent physiologic sequelae occur. In a subset of patients (3.8%), these emboli may persist, or multiple subclinical episodes of PE may occur such that patients develop chronic thromboembolic pulmonary hypertension (CTEPH) (see Chapter 45).^{128,129} Pulmonary thromboendarterectomy has proved to be the most effective treatment for patients with CTEPH.¹³⁰ Although no randomized, controlled trials have been performed, vena caval filters are commonly placed preoperatively in these patients, and one small case series identified inadequate caval filtration as a common characteristic of patients who required repeat pulmonary thromboendarterectomy.¹³¹ Although data supporting the usefulness of filters in this capacity are limited, the severity of the condition and limited treatment options for patients with CTEPH, as well as the difficulty associated with conducting a randomized trial in this patient population, indicate that indefinite anticoagulant therapy and filters should be strongly considered in all patients who undergo pulmonary thromboendarterectomy. This operation should not be confused with acute embolectomy for acute PE.

TRAUMA

VTE is a common complication of major trauma. In a prospective cohort study in which routine DVT surveillance

was used with impedance plethysmography and contrast venography, 58% of trauma patients developed a DVT during the first few weeks of hospitalization in the absence of DVT prophylaxis.¹³² Eighteen percent had a proximal DVT, and 1% experienced a symptomatic PE; half of these cases were fatal. Only 3 of 201 patients with adequate venography (1.5%) had a clinically apparent DVT. In a subgroup analysis, the authors found that patients with lower extremity orthopedic injuries (69%) and spinal trauma (62%) were at particularly high risk for DVT prophylaxis.¹³² Using routine contrast spiral computed tomography (CT) scan surveillance, Schultz and colleagues¹³³ identified asymptomatic PE in 24% (22 of 90) of trauma patients, including 4 patients with a major clot burden, 1 of whom had a saddle embolism.¹³³ Standard methods of VTE prophylaxis, including subcutaneous unfractionated heparin and/or mechanical prophylaxis with sequential compression devices, are not entirely protective against VTE in trauma patients.^{134,135} Although several studies have shown the effectiveness of LMWH with or without mechanical VTE prophylaxis,^{136–139} concerns about bleeding complications have limited the use of LMWH among high-risk trauma patients and have led to a dramatic increase in vena caval filter use in this population.¹⁴⁰ One retrospective review noted an increase in prophylactic vena caval filter insertion in trauma patients—from 3% during the five year period 1991–1996 to 57% for the five year period 1996–2001.¹⁴¹

Does the literature support the use of vena caval filters in this capacity? More than two dozen unrandomized cohort published studies have assessed the usefulness of vena caval filters in the prevention of PE in high-risk trauma patients.^{10,12,13,15,16,66,142–159} Compared with high-risk historical controls (symptomatic PE, 121 of 5765, 2.1%; fatal PE, 47 of 5765, 0.8%), permanent vena caval filters have demonstrated superior protection against PE (symptomatic PE, 12 of 1890, 0.6%; fatal PE, 2 of 1890, 0.1%). A lower frequency of events was seen among prospective controls (PE, 84 of 36,258, 0.2%; fatal PE, 9 of 36,258, 0.02%); however, these subjects were clearly at lower risk than were concurrent filter recipients (Fig. 31-6). Although many

Figure 31-6 Incidence of pulmonary embolism among trauma patients treated with or without a prophylactic inferior vena caval (IVC) filter.

studies focused on the initial hospitalization, longer-term follow-up data were provided by nine studies, in which 61% of the subject population was followed for a mean of 29.1 months. Ten percent of patients (166 of 1546) had a DVT and 3.2% (22 of 708) developed IVC thrombosis during follow-up. Migration occurred in only six patients (0.8%).

A survey of trauma centers revealed that the perceived risk of complications associated with permanent vena caval filters has tempered the enthusiasm of trauma surgeons for the routine use of filters in high-risk trauma patients. In addition, investigators found that the availability of a retrievable filter would significantly increase the number of practitioners (from 29% to 53%) who would use prophylactic filters in trauma patients.¹⁶⁰ If they functioned similarly to permanent vena caval filters, retrievable filters theoretically could provide optimal mechanical PE prophylaxis in patients with transient contraindications to pharmacologic prophylaxis, while avoiding the long-term adverse effects of permanent filters. Indeed, the predicted enthusiasm for retrievable filters among providers has been borne out by a recent single-center study that documented a threefold increase in filter placement in trauma patients since the advent of retrievable filters.¹⁴³ Although only six studies of retrievable filters (Bard Recovery, Günther Tulip, and OptEase filters) with limited follow-up have been conducted in trauma patients, preliminary results suggest that retrievable and permanent devices may have similar efficacy (see Fig. 31-6).^{66,142,143,146-148} Nevertheless, increased use of retrievable filters has not automatically translated into reduced rates of PE or filter-related complications among trauma patients.¹⁴³ These authors noted an equivalent incidence of symptomatic PE (0.2% vs 0.2%) and filter-related complications (1.8% vs 2.5%) before and after the advent of retrievable filters. The latter finding may reflect the low retrieval rate of these filters. In trauma studies of retrievable filters, only a minority (152 of 421; 36%) were retrieved. Furthermore, several reports have documented the occurrence of PE after retrieval of vena caval filters.^{66,142,146,161} Therefore, it remains unclear whether retrievable filters will, once again, fulfill their initial promise as a useful form of mechanical PE prophylaxis for trauma patients. Clearly, demonstration of the true value of vena caval filters in the prevention of VTE in trauma patients awaits the execution of randomized trials.

FREE-FLOATING VENOUS THROMBUS

The presence of free-floating venous thrombus has been variably held to be associated with an increased risk of PE.¹⁶²⁻¹⁶⁸ This observation has prompted some to suggest that IVC filters should be placed in all patients with free-floating thrombi.¹⁶⁵ Nevertheless, for several reasons, we believe it is unwise to recommend such a policy. First, the single well-executed prospective study found no evidence that free-floating clots were associated with a higher incidence of PE.¹⁶⁶ Second, in two of the previously cited studies, most PEs occurred prior to the diagnosis of free-floating DVT.^{162,168} Therefore, changes in therapeutic approach would have had no impact on the clinical course of these patients. Furthermore, no study has shown that the addition of an IVC filter to adequate anticoagulant

therapy would improve clinical outcome. Therefore, until such data are available, no firm recommendations can be made to support the value, let alone the mandate, for IVC filters in the treatment of patients in this situation.

THROMBOLYSIS FOR PROXIMAL DEEP VENOUS THROMBOSIS

The principal complications of DVT are PE and PTS. Although thrombolysis does not reduce the risk of PE associated with DVT, studies of systemic and catheter-directed thrombolysis suggest that this approach may reduce the incidence of PTS.¹⁶⁹⁻¹⁷² However, systemic thrombolysis of proximal DVT (particularly iliofemoral or IVC thrombi) has been associated with several cases of fatal and nonfatal PE.^{173,174} Therefore, prophylactic placement of vena caval filters has been proposed as a strategy for preventing PE in patients undergoing thrombolysis. When a variety of temporary filters were used during systemic thrombolysis, however, a European multicenter registry noted four cases of fatal PE (2.1%) and three cases of nonfatal PE (1.6%) despite filter protection.¹⁷⁵ Conversely, only one fatal pulmonary embolus (0.3%) occurred during a multicenter registry of catheter-directed thrombolysis without routine filter use.¹⁷² Although they are far from conclusive, these data suggest that catheter-directed thrombolysis may be associated with a lower risk of PE compared with systemic thrombolysis. Furthermore, if thrombolysis were attempted in a patient deemed to be at high risk for embolization (e.g., poorly adherent IVC, iliac thrombi) or mortality from PE (e.g., patients with concomitant PE, those with limited cardiopulmonary reserve), the experience of Lorch and coworkers¹⁷⁵ would suggest that retrievable filters might be a better option.

UNSUBSTANTIATED INDICATIONS

Patients with Cancer

Malignancy is a well-documented independent risk factor for the development of VTE. In a prospective registry study of 5451 patients with objectively confirmed DVT, cancer was present in 32% of patients.¹⁷⁶ Early studies of anticoagulant therapy in cancer patients with VTE noted a high incidence of hemorrhagic complications (as great as 50% in one series) and recurrent thrombosis, which generated considerable interest in the routine use of vena caval filters in the treatment of patients with cancer who had VTE.¹⁷⁷⁻¹⁷⁹ Case series of IVC filters in patients with cancer indicate that filters may be effective in the prevention of PE (pooled frequency of symptomatic PE, 23 of 1120, 2.0%; fatal PE, 9 of 1120, 0.8%), although the duration (7.5 months) and intensity of follow-up were limited.^{6,14,174,178,180-189} However, nonrandomized comparisons with anticoagulant therapy have found greater thrombotic morbidity among filter recipients and no improvement in survival (Fig. 31-7).^{7,177,190-193} In one single-institution retrospective study of 166 patients with cancer who had VTE, serious, life- or limb-threatening VTE complications occurred in 17% of filter recipients.¹⁹⁰ Therefore, despite the greater hemorrhagic morbidity of long-term anticoagulant therapy in patients with cancer, its risk:benefit profile appears to

Figure 31-7 Frequency of adverse clinical events in studies of vena caval filter placement or anticoagulation for the treatment of patients with cancer with venous thromboembolism (VTE).

be more favorable than that associated with IVC filter use.^{194,195} Recent studies of LMWH in the treatment of malignancy-associated VTE and clinical trials of new anti-thrombotic agents indicate that aggressive and adequate pharmacologic approaches, not mechanical approaches, will continue to be the preferred therapy for most patients with cancer who have VTE.^{113,196}

High-Risk Orthopedic Patients

Patients undergoing orthopedic surgery such as total knee arthroplasty (TKA) or total hip arthroplasty (THA) are considered to be at very high risk for the development of VTE because of a number of factors that contribute to venous stasis, such as position on the operating table, use of thigh tourniquets during knee arthroplasty to provide a “bloodless” field, postoperative immobility, and vascular injury. In the absence of prophylaxis, the risk of proximal DVT in this patient population is 10% to 20%.¹⁹⁷ Several case series attest to the efficacy of IVC filters in the prevention of PE in orthopedic patients.^{8,198–200} However, none of these studies incorporated random or masked treatment assignment or masked outcome assessment, and follow-up was of limited intensity and duration. Furthermore, many advances in orthopedic VTE prophylaxis (e.g., LMWH, fondaparinux) and anticoagulation monitoring (INR) have occurred since the time of publication of these studies. Therefore, with the availability of modern methods of VTE prophylaxis, it is doubtful whether IVC filter placement represents a useful option for the vast majority of orthopedic patients. Until well-designed studies have proved the usefulness of vena caval filters for this purpose, this indication for filter placement should be considered one that is primarily of historical significance. As with any major surgical procedure, IVC filters, in particular, retrievable filters, remain a useful option for patients who develop VTE during the immediate perioperative period, when full-dose anticoagulant therapy might be contraindicated.¹¹⁸

Bariatric Surgery

PE is considered the leading cause of perioperative death in bariatric surgical patients.²⁰¹ Although the reported

incidence of VTE during the immediate (30 days) postoperative period is 0% to 3%, nearly one third of patients who develop PE die.²⁰² This finding may reflect the lack of cardiac and pulmonary reserves in those who may have cor pulmonale resulting from obesity hypoventilation syndrome.²⁰¹ A survey of the members of the American Society of Bariatric Surgery found that of the 31% who responded, 95% routinely used VTE prophylaxis. The most commonly used method was low-dose heparin (50%), followed by sequential compression devices (SCDs) (33%), LMWH (13%), and other methods (4%). Thirty-eight percent of respondents used two or more methods in combination. Despite this practice, 48% of respondents reported at least one patient death that was due to PE.²⁰³ As a result, placement of IVC filters has become a popular prophylaxis strategy among some bariatric surgeons.

Nevertheless, few data exist to support this practice or any VTE prophylaxis strategy in this patient population. In a prospective study of 106 consecutive Roux-en-Y gastric bypass patients, Prystowsky and associates²⁰⁴ performed bilateral lower extremity duplex scans preoperatively and postoperatively. All patients were given 5000 U of heparin subcutaneously every 12 hours, as well as SCDs, and were ambulatory on postoperative day 1. Patients with a prior history of DVT received temporary vena caval filters. Of 100 patients without a history of DVT, 1 patient was found to have a DVT on a duplex scan performed on postoperative day 14. In contrast, 2 of 6 patients with a prior history of DVT developed a new thrombus DVT postoperatively. Although duplex ultrasonography represents a suboptimal study for assessing the incidence of DVT in an asymptomatic patient population, this study suggests that low-dose heparin combined with SCDs may represent a useful approach to DVT prevention in this patient population. Given that the mean body mass index of the subject population was greater than 51 kg/m², one wonders whether more intensive pharmacologic DVT prophylaxis would be even more effective and thus would obviate the use of IVC filters in high-risk bariatric surgery patients. One observational cohort study found that enoxaparin administered at 40 mg twice daily was significantly more effective than enoxaparin 30 mg given twice daily.²⁰⁵

At the present time, no firm recommendations for VTE prophylaxis can be made for this patient population. Until appropriate clinical trials are performed to address this deficiency in the literature, methods of VTE prophylaxis used for other high-risk populations, such as orthopedic surgery patients, should be used. Given the influence of weight on total blood volume and consequently on plasma heparin concentrations, higher dose regimens (e.g., enoxaparin 40 mg subcutaneously given every 12 hours) or doses adjusted by measured drug levels should be considered to reduce the chances of prophylaxis failure in this challenging patient population.

Other Indications

Vena caval filter placement has been proposed for the treatment of pregnant patients with VTE. Intrinsic (reductions in protein S activity, increases in factor VIII, fibrinogen, and von Willebrand factor activity) and environmental

(reduced activity, IVC compression) factors make pregnancy a high-risk period for thrombotic events (see Chapter 36).^{206–208} Several case series and case reports have documented the use of vena caval filters during pregnancy.^{209–214} Although some researchers have claimed that anticoagulant therapy alone may be insufficient therapy for pregnant patients with VTE, substantial evidence indicates that appropriately monitored anticoagulant therapy is effective for the vast majority of patients.^{215,216} Therefore, IVC filters should be reserved strictly for situations in which anticoagulation is contraindicated. In these instances, retrievable filters should be strongly considered, given the young age of potential recipients and thus the prolonged duration of time during which they will be at risk for complications associated with permanent filters.

Small clinical series have described the use of vena caval filters in pediatric patients,^{217,218} transplant recipients,^{219,220} and those with severe chronic obstructive pulmonary disease.²²¹ Because none of these conditions intrinsically precludes anticoagulant therapy, the use of filters in these populations should be restricted to patients who have absolute contraindications to anticoagulant therapy or those enrolled in well-designed studies. Prophylactic IVC filter placement has been described in a small number of thermally injured patients.²²² Further research to determine the efficacy of conventional VTE prophylactic methods and to identify the subsets of the burn patient population at highest risk for VTE should be performed before wider application of IVC filters is considered for this indication.

APPROPRIATE PREVENTIVE HEALTH CARE AND FOLLOW-UP FOR PATIENTS WITH PERMANENT VENA CAVAL FILTERS

Vena caval filters are associated with an increased incidence of DVT and IVC thrombosis⁷⁰; therefore, routine clinical and objective radiologic follow-up evaluations have been recommended by consensus guidelines.²²³ Clinical evaluation should include an assessment of subsequent episodes of VTE, physical findings of PTS, and current use of anticoagulant therapy, as well as any complications resulting in the discontinuation of anticoagulation. Useful objective radiologic studies include abdominal radiographs to determine placement stability, duplex ultrasound examination of the lower extremities to identify recurrent DVT or chronic venous insufficiency, and CT or MR imaging to identify extracaval filter extension and caval thrombosis. In addition, all patients with lower extremity DVT and a vena caval filter should be prescribed graduated compression stockings (30 to 40 mm Hg) to reduce the incidence of PTS. Anticoagulation should be continued for as long as dictated by the underlying thrombotic event. The benefits of indefinite anticoagulant therapy should be weighed against the risk of hemorrhagic complications, and a decision must be made on a case-by-case basis. Ideally, patients should carry identification to alert physicians to the presence of the filter, so that episodes of guidewire entrapment can be avoided.

CONCLUSIONS

Despite improvements in VTE prophylaxis and increasing acceptance of its importance among physicians, the incidence of VTE remains relatively stable. Therefore, the treatment of patients with VTE will remain an important issue for many physicians. An unprecedented number of new antithrombotic medications are under development or are currently in clinical trials. Although it is likely that these new medications will provide even safer and more effective pharmacologic options for the treatment of VTE, patients with firmly established contraindications to anticoagulant therapy will remain a challenge for medical and surgical practitioners. For these patients, IVC filters will remain an important therapeutic alternative. Similar to the evolution of pharmacologic antithrombotic therapy, IVC filter technology has advanced dramatically. In addition to a wide assortment of permanent IVC filters, several promising retrievable filters are now available for clinical use. If these devices prove to be as efficacious as permanent filters and are actually removed, they will likely represent the future of IVC filters, providing the clinician with greater flexibility to meet the demands of a broad array of different clinical situations. Ideally, these filters will offer the benefits of permanent filters without their long-term thrombotic consequences. Published clinical evaluations of filter performance up to the present, however, have consisted almost exclusively of clinical case series, which lack the rigor required to establish clinical efficacy. It is the fervent hope of the authors of this chapter that a serious effort will be made to rigorously evaluate these new devices to establish their true benefits and risks. Without these studies, IVC filters are destined to remain a subject of clinical controversy.

Thrombosis Related to Venous Access Devices

McDonald K. Horne, III, MD • Richard Chang, MD

INTRODUCTION

Central venous access devices (VADs) are widely used to administer chemotherapy, blood components, and nutrition to patients, as well as for hemodialysis. These devices are typically inserted into the subclavian or internal jugular vein, either directly or after tunneling through subcutaneous tissue, or they may be threaded through peripheral arm veins. Less frequently, they are inserted into femoral veins or the inferior vena cava.¹ The catheters of most VADs are made of silicone rubber, which is highly flexible, although polyurethane, which is somewhat stiffer, is also used to prevent collapse of the lumen when particularly high flow is needed.² The most common complication associated with the use of VADs is infection. The second is thrombosis.

PATHOGENESIS AND INCIDENCE

VAD-related thrombus may be limited to the surface of the catheter itself or may involve the vein wall. Thrombogenesis at both sites starts soon after catheters are inserted and typically becomes clinically manifest within a few days or weeks.³⁻⁶

Catheters regularly begin accumulating a layer of fibrin as soon as they are inserted into a vein.⁷ In particularly hypercoagulable patients, this initial “fibrin sheath” can become so robust at the catheter tip that it acts as a one-way valve to prevent withdrawal of blood through the lumen (Fig. 32-1).⁸ In extreme cases, a sheath may encase the entire intravenous portion of the catheter from its tip to the venipuncture site.⁹

Thrombi involving the vein wall generally arise at two locations: the venipuncture site and anywhere that the catheter tip chronically rubs the venous endothelium. The venipuncture site is vulnerable because there the lumen of the vein is relatively narrow and may be significantly occluded by the catheter itself, leading to local venous stasis. Also present is the risk that the venipuncture itself will damage the venous wall sufficiently to make it prothrombotic. In a study of children, the incidence of VAD-related subclavian vein thrombosis was much greater when the catheter was inserted percutaneously (53% deep venous thrombosis [DVT]) than by the cut-down technique (17% DVT), presumably because the cut-down method was less traumatic to the vein.¹⁰ Evidence of obstruction

at the venipuncture site generally can be found by venography in about one third of catheterized subclavian veins, but usually only 5% to 10% of veins develop symptomatic occlusion.^{3-5,10-12} The risk of thrombosis is greater when VADs are inserted into the femoral veins.^{13,14}

The likelihood that a catheter will cause thrombus remote from the venipuncture site varies according to the location of its tip.^{11,15,16} If the tip resides in the lower one third of the superior vena cava (SVC), repetitive trauma to the vein wall by the mobile catheter will be minimal, and the risk that a mural thrombus may develop is very low. If the tip remains in the upper part of the SVC, however, its movement may be restrained by the ipsilateral innominate vein, and the catheter may contact the SVC wall frequently and in the same location. This creates endothelial damage and a nidus for thrombosis and potential SVC occlusion (Fig. 32-2). Furthermore, a small risk of vascular erosion and perforation exists.¹⁷ If the catheter tip does not advance out of the innominate vein, it will likely abrade this vein's wall, leading to thrombosis. Access through the right internal jugular vein into the SVC provides the straightest route for the catheter with the least risk of chronic venous wall trauma.^{10,18}

CLINICAL PRESENTATION AND MANAGEMENT

Catheter Occlusion

The most common clinical manifestation of VAD-related thrombosis is the inability to withdraw blood from the catheter because of clot at its tip.^{6,8} This problem must be distinguished from blockage caused when the catheter tip abuts against the vein wall. The latter blockage can usually be relieved by having the patient change position. When blood can be neither withdrawn nor infused through a catheter, the cause is more likely to be a kink in the tubing or intraluminal precipitation of medications rather than thrombus.^{19,20}

Withdrawal occlusion related to thrombus is usually relieved by instillation of 2 mg (2 mL) of alteplase (recombinant tissue plasminogen activator; Genentech, South San Francisco, Calif, USA) that is left in for as long as 2 hours.²¹ A similar regimen with urokinase is also effective.²² If this treatment fails, it is wise to investigate the problem by injecting x-ray contrast material through the

Figure 32-1 A fibrin sheath shown by injection of x-ray contrast material into the lumen of a vascular access device (VAD). The arrow indicates where the contrast has become trapped within the sheath that encases the catheter. Contrast does not extend to the tip of the catheter because the luminal opening is distal to the tip.

Figure 32-2 Thrombus (arrow) forming on the wall of the superior vena cava at a site where a poorly positioned catheter has chronically abraded the endothelium.

affected lumen while observing fluoroscopically. If a mural thrombus or a fibrin sheath is blocking the catheter tip, the problem can often be resolved by continuous infusion of a thrombolytic agent given at low doses for several hours. Successful regimens with urokinase and alteplase have been published.^{23–25} We have used infusions of alteplase at 1 mg per hour for 6 to 12 hours (unpublished).

Occlusive Venous Thrombosis

This usually manifests as swelling and/or moderate pain in the shoulder, arm, or neck on the affected side. Rarely, the first sign will be symptoms of pulmonary emboli. Appropriate management of VAD-related thrombosis depends on the clinical state of the patient. Because VADs are used only in patients with major medical disorders, the risks of some available treatment options may be unacceptably large.

Goals of treatment include resolution of acute symptoms, prevention of pulmonary emboli, avoidance of long-term sequelae, and, in some cases, restoration of the vein so that it can be used again in the future for catheterization or hemodialysis. Simple removal of a VAD from a thrombosed vein usually relieves acute pain and swelling.²⁶ Before this is done, however, careful consideration must be given to the patient's current and future needs for central venous access. If these are nil, explantation of the catheter is the treatment of choice. A period of anticoagulation does not seem to be necessary for resolution of symptoms, but it is often prescribed.²⁶ Sometimes, because of concern about pulmonary emboli, anxiety is expressed about pulling a catheter through an occlusive thrombus. Although bits of thrombus are probably sheared off most catheters as they are removed, only one fatal embolus has been reported in this setting, and that occurred in a 1-year-old child.^{27,28} Therefore, the practice of removing VADs through a thrombus rarely has adverse consequences.

If a VAD is still necessary for a patient's care, it does not need to be removed simply because it is in a thrombosed vein. Arm elevation alone will likely yield significant symptomatic relief.²⁹ Standard anticoagulation with unfractionated or low molecular weight heparin for 5 to 7 days may be even more effective.^{26,30,31} This is followed by an extended period of prophylactic anticoagulation with warfarin (international normalized ratio [INR], 2 to 3) or low molecular weight heparin (e.g., 1 mg per kilogram enoxaparin per day).³² Neither the optimal intensity nor the duration of prophylactic anticoagulation has been established in clinical trials; whether it is even necessary remains unknown. However, the presumption is that long-term anticoagulation reduces the risk of pulmonary emboli.^{33,34} It may also prevent clot propagation into developing collateral veins and may reduce long-term symptoms. Therefore, it is reasonable to continue anticoagulation for the lifetime of the catheter, or at least until clinical circumstances make the risk of bleeding unacceptable.

The reported incidence of clinically apparent pulmonary embolus (PE) caused by VAD-related thrombosis is variable. Asymptomatic PEs are the most common. In one series, for example, four of 79 evaluable patients ($\approx 5\%$) with VAD-related DVT had symptoms of PE and positive lung scans.³⁵ Two of these patients died of PE despite heparin therapy. Nine other patients ($\approx 11\%$) had positive lung scans but no symptoms. In another report, symptomatic PEs were confirmed by imaging in 7 of 41 (17%) patients with catheter-related DVT.³⁶ However, in larger populations of patients at cancer centers, VAD-related PEs are rarely recognized.^{26,29}

Chronic symptoms are uncommon in patients who develop acute VAD-related DVT.^{26,37} However, even asymptomatic thrombosis, which is much more common than the symptomatic type, often permanently damages

Figure 32-3 Left panel, Venogram shows thrombotic occlusion of the right axillary-subclavian vein (arrow). The intravenous catheter responsible for the thrombus can be seen proximally. Right panel, Venogram of the same patient after lysis of the thrombus with intracatheter alteplase. The arrow shows the previously occluded axillary-subclavian vein. The vein that is more cephalad is the right cephalic vein.

an involved vein.^{12,38,39} This outcome is clinically unimportant unless the vein is needed for a catheter at a later time, in which case reinsertion becomes difficult if not impossible. For patients who require multiple catheters over a long period, the loss of central venous access sites represents a significant clinical dilemma. Aggressive efforts to recanalize an acutely thrombosed vein are justified when a future need to recatheterize that vein is anticipated. The use of thrombolytic agents in combination with anticoagulation can produce satisfactory long-term results.^{40–43}

Although thrombolytic therapy for VAD-related DVT is not standardized, we have developed a successful protocol by using recombinant tissue plasminogen activator (alteplase) in combination with anticoagulation (Fig. 32-3).^{42,43} By “pulse-spraying” the drug directly into the thrombus, we achieve high local concentrations, and by choosing a thrombolytic agent that has binding affinity for fibrin, we maximize the chance that a significant amount of the drug will be retained in the thrombus.⁴⁴ Although we originally used alteplase in a concentration of 1 mg per milliliter and injected approximately 1 mL into each centimeter of clot, recently we reduced the concentration of alteplase to 100 µg per milliliter and injected no more than 4 mg into a thrombus associated with a VAD in the axillary-subclavian vein, regardless of its length. So far, our results are as good as those attained with higher doses (unpublished). We avoid treating thrombi that are known to have been symptomatic for over a month because these are relatively resistant to lysis. Usually, more acute thrombi partially lyse within 24 hours after the first treatment; then, we administer a second dose of alteplase. By the third day, antegrade flow typically has been well established. Throughout this time, we fully anticoagulate with unfractionated or low molecular weight heparin. We recommend removal of the catheter because in our experience, its continued presence increases the risk of rethrombosis. However, we always delay removal of the catheter until at least 24 hours after the last dose of alteplase is given. We are concerned that if we remove the catheter before giving the alteplase, the newly opened venipuncture wound in the region will bleed when high concentrations of thrombolytic

drug are deposited nearby. We continue prophylactic anticoagulation with warfarin or low molecular weight heparin for 6 weeks after the time the catheter is removed. In our experience, this regimen produces the greatest chance for long-term venous patency.

Although thrombolysis and anticoagulation generally produce good long-term venous patency, the addition of venous dilatation (angioplasty) and venous stents appears not to increase the benefit significantly. The need for repeated procedures is great.^{45–47}

Superior Vena Cava Occlusion

A particularly distressing complication of VAD use is superior vena cava (SVC) occlusion, which originates at the site of trauma to the wall of the SVC (see Fig. 32-2). Rarely, if ever, does SVC obstruction result from propagation of clot from the subclavian veins. Symptoms of venous obstruction are often preceded by a period of catheter withdrawal occlusion that occurs as the catheter tip becomes embedded in mural thrombus.⁴⁸ Unless the bleeding risk is unacceptable, thrombolytic therapy, in combination with anticoagulation, is the treatment of choice.

Although peripheral intravenous administration of thrombolytic agents may be effective in lysing SVC thrombi, symptoms typically do not ameliorate before 12 to 72 hours, and the quantities of drug required produce hypofibrinogenemia and an increased risk of bleeding.^{49,50} If the tip of the VAD catheter is embedded in the thrombus, as it often is, thrombolytic agents can also be delivered through the VAD itself directly into the thrombus.^{51,52} If the tip of the VAD is not embedded in the thrombus, a second catheter must be inserted and positioned just distal to the obstruction so that the clot is bathed in the drug. Despite high local concentrations of a lytic agent, however, continuous infusions may be necessary for several days to remove the thrombus. If standard intravenous doses of drug are used (e.g., 4400 U/kg/hr urokinase), the patient will likely remain at an increased risk of bleeding for a protracted period. However, we have found that lower doses may be sufficient,

and that treatment may be interrupted without rethrombosis, as long as anticoagulation is continued.⁵³ In theory, an agent with binding affinity for fibrin, such as alteplase, would be even more effective at low doses and could be given intermittently because it would not completely diffuse from the clot between treatments.⁵⁴ Alteplase 0.02 mg/kg/hr has been suggested for lysing of SVC thrombi.⁵⁵

After maximal thrombolysis has been achieved, underlying stenosis of the SVC may be discovered. Although this can be relieved with balloon angioplasty, the benefit of this is usually temporary because of the elastic recoil of the vein.⁵⁶ Angioplasty followed by placement of metal venous stents is much more effective in preserving long-term patency.^{55–57} However, a risk of rethrombosis is present because of small amounts of residual thrombus, and because the stents themselves are thrombogenic. Anticoagulants are usually prescribed for several months after stent placement, but the optimal duration and intensity of anticoagulation have not been established. Antiplatelet agents are also sometimes prescribed, although evidence suggesting that these are marginally antithrombotic in the venous circulation makes it unlikely that they are helpful.^{57,58}

Right Atrial Thrombi

Although the optimal location for the tip of a VAD is the lower third of the SVC, precise placement of the catheter tip in that location is complicated by the fact that the catheter tip tends to move cephalad when a patient sits upright, thereby withdrawing into the upper SVC or even into the innominate vein.^{15,59} One way to compensate for this is to purposely place the catheter tip in the right atrium (RA), but this practice remains controversial.⁶⁰ A U.S. Food and Drug Administration (FDA) bulletin from 1989 states that the catheter tip should not be intentionally inserted into the RA, nor positioned so that it might migrate there.⁶¹ However, the FDA's major concern at the time appears to be catheter placement by improperly trained personnel; this worry is based on experience from the 1970s and 1980s before fluoroscopic guidance was routinely used during catheter insertion. Because the function of large bore, high-flow catheters used for dialysis and apheresis is better if their tips are located in the right atrium, the 2001 Kidney Disease Outcomes Quality Initiative Clinical Practice Guidelines advocate placement of the catheter tips at the SVC/right atrial junction or into the right atrium.⁶² However, this is presumably why many reports of VAD complications involving the right heart describe patients on renal dialysis.

Wherever a catheter tip repetitively abrades the atrial endocardium, a mural thrombus is likely to develop.⁶³ Such a clot may remain sessile or may detach with motion of the heart and embolize or remain adherent to the catheter. By echocardiography, 6 of 13 adults and 13 of 55 children whose catheter tips were in the RA were seen to have developed RA thrombi that were attached to the atrial wall or that moved with the tip of the catheter.^{64,65} In another study of children, the catheter tip in 31 of 85 patients (36%) was found in the RA, although only three RA thrombi were identified by echocardiography; all patients were asymptomatic.¹⁰ Therefore, in general, the natural history of these thrombi is benign. They start to develop within a week of catheter placement; they then become

stabilized, without causing symptoms, and begin to calcify.^{64,65} Incidental discovery of an RA thrombus does not necessarily mandate removal of the catheter. One option is to follow the thrombus with serial echocardiograms to be sure about whether it is enlarging; however, this usually causes significant anxiety for the patient and the medical staff. Therefore, anticoagulation (heparin followed by warfarin) is often prescribed for the lifetime of the catheter, with follow-up echocardiograms performed to confirm that the thrombus is stable or regressing.

If an RA thrombus is discovered during the course of investigation of pulmonary emboli or bacteremia or a new heart murmur, more aggressive management is required.^{66–69} Similar to all thrombi, RA thrombi may become infected, thereby releasing clinically significant emboli. In addition, RA thrombi may impinge on the tricuspid valve or prolapse through it, in this way causing tricuspid regurgitation. In situations such as these, the catheter must be removed, but the concern involves whether this can be done without causing a significant embolus. If the thrombus moves with the atrial wall and is clearly adherent to it, there is little risk that it will dislodge when the catheter is retracted.⁷⁰ Once the catheter is out, the patient should be anticoagulated and treated with antibiotics, if appropriate, while the status of the thrombus is monitored periodically with the use of echocardiography. On the other hand, if the clot moves with the catheter and is clearly not attached to the atrial wall, it may be stripped off when the catheter is removed and may become an embolus. Removal of a large thrombus attached only to the catheter, therefore, requires surgery if it is likely to be infected or is damaging the tricuspid valve.⁶⁶ Otherwise, it also can be treated with anticoagulation followed by echocardiography.⁷⁰ Thrombolytic therapy is sometimes considered.⁷¹ However, if this is delivered locally through the VAD, the clot may adhere to the catheter and may detach en masse, causing significant pulmonary artery obstruction. If thrombolytic therapy is given systemically, the usual risk of bleeding is associated.

PROPHYLAXIS AGAINST VENOUS ACCESS DEVICE-RELATED THROMBOSIS

Two types of prophylactic anticoagulation are used: periodic flushes of saline and heparin through the catheter lumen to prevent clot at the tip and catheter malfunction, and systemic anticoagulation to prevent thrombotic occlusion of the vein.

Although no evidence indicates that instillation of a catheter lumen with any concentration of heparin less than 500 U per milliliter is more effective than saline flushes alone in preventing catheter malfunction, lower concentrations are commonly used because, should multilumen catheters be flushed several times daily, the patient may achieve significant systemic anticoagulation.^{72,73} Another problem with heparin flushes is that blood samples for reliable coagulation tests are difficult to obtain from a heparinized catheter, even after a discard.⁷⁴ A low risk of heparin-induced thrombocytopenia/thrombosis occurs, which may lead to thrombosis in the catheterized vein.^{75–77} An alternative to heparin that appears to be at least modestly

successful is the instillation of urokinase or alteplase into each lumen between catheter uses.^{78,79}

Both warfarin and low molecular weight heparins have been tested in various regimens for their effectiveness in preventing catheter-induced vein thrombus. Bern and co-workers⁸⁰ published a randomized trial of 1 mg per day of warfarin to prevent symptomatic DVT related to subcutaneous ports in patients with cancer, about three quarters of whom had metastatic adenocarcinoma.⁸⁰ Four of 42 patients (9.5%) who were given warfarin and 13 of 40 patients (32.5%) who were given placebo developed symptomatic VAD-related DVT. However, this success was not reproduced in later studies in which the rate of symptomatic thrombosis in control groups (3%–12%) was substantially lower.^{81–83} A randomized controlled trial of 1590 patients that is currently under way should clarify the role of warfarin in preventing VAD-related DVT.⁸⁴

Impressive results were also published by Monreal and associates,⁸⁵ who used 2500 IU per day of dalteparin given systemically, although again the rate of symptomatic thrombosis in the control group was extraordinary (62%).⁸⁵ The efficacy of dalteparin seemed to be confirmed, however, in less thrombotic patients (14.6% symptomatic DVT in the control group, 1.9% in the treated group) in a subsequent, nonrandomized trial in which a larger dose of the drug (5000 IU per day) was used.⁸⁶ A recent randomized, placebo-controlled trial of 40 mg per day of enoxaparin for prophylaxis failed to significantly lower the risk of symptomatic DVT, but the incidence of this condition in the placebo group was only 3.1%.⁸⁷

Therefore, use of the studied prophylactic anticoagulant regimens does not appear warranted in patient populations with a low rate of VAD-related DVT; however, in high-risk patients this may not be true. Because even the lowest dose regimens are not provided without bleeding risk in patients with advanced disease, our practice is to reserve prophylactic anticoagulation for patients with VAD who have previously had a catheter-related DVT. We prefer anticoagulant regimens (e.g., warfarin with an INR 1.5 to 2.0, 1 mg/kg/day enoxaparin) that have proved efficacious in other settings, and we accept the added rate of complication associated with patient care.

VASCULAR ACCESS FOR HEMODIALYSIS

Vascular access for hemodialysis must support flow rates of at least 400 mL per minute.^{62,88} This is best achieved with an arteriovenous fistula (AVF) in the wrist (radial artery/cephalic vein) or, if the vessels are too small there, at the elbow (brachial artery/cephalic vein) or in the thigh (popliteal artery/saphenous vein).⁶² Although AVFs have the best patency rates, about a quarter of them become occluded with a thrombus during the first year; this is usually promoted by the development of stenosis in the venous outflow.^{89,90} When sites for AVFs have become depleted, arteriovenous grafts offer the next best prospect for hemodialysis, but these are even more prone to thrombose, again due to developing venous stenosis. Unfortunately, antiplatelet agents and warfarin do not improve the patency rates of grafts but are associated with excessive bleeding complications.^{91,92} Venous catheters are the last choice for hemodialysis because the large

bore required is associated with a high rate of venous damage and thrombosis, but placement of the catheter in the right internal jugular vein maximizes the likelihood of long-term success.⁹³

Hemodialysis flow rates are regularly measured. When they begin to fall, an x-ray contrast study (fistulogram) should be performed to assess venous stenosis which, if found, requires angioplasty. If thrombosis occurs despite regular monitoring, the problem must be addressed immediately so as not to delay dialysis.⁹⁴ Biding of time through insertion of a VAD is undesirable because of the high complication rate associated with this approach. A thrombosed AVF or graft can be treated with surgical thrombectomy or thrombolysis with percutaneous devices that mechanically break up and remove the clot, with or without the help of a thrombolytic drug, usually alteplase.^{94–96} Thrombolysis is generally faster (lasting less than an hour), less traumatic for the patient, and less expensive than surgical thrombectomy. After the clot has been removed, any underlying venous stenosis must be dilated. Metallic stents can be used to maintain patency if dilatation alone fails, but maintaining long-term patency is difficult.^{97,98}

Dietary Supplements and Hemostasis

Tieraona Low Dog, MD • Merry Jennifer Markham, MD

INTRODUCTION

Complementary and alternative medicine (CAM) consists of various medical therapies and health care products, including dietary supplements. In addition to natural products, other CAM treatments include prayer, hypnosis, chiropractic care, massage therapy, relaxation techniques, biofeedback, and acupuncture. This review focuses on the hemostatic effects of dietary supplements.

According to the Dietary Supplement Health and Education Act of 1994 (DSHEA), a dietary supplement is a product that is meant to supplement one's diet. Dietary supplements contain one or more of the following ingredients: a vitamin, a mineral, an herb or other botanical, an amino acid, or another dietary substance, or a combination of these ingredients or their extracts.¹ By definition, the dietary supplement is intended for ingestion in pill, capsule, tablet, or liquid form, but it is not for parenteral use.

DSHEA exempted this industry from the strict regulations of the U.S. Food and Drug Administration (FDA) for drug approval. Currently, no FDA regulations provide a minimum standard of practice for manufacturing; however, the FDA has developed guidelines for dietary supplement good manufacturing practices that are to be implemented in the future. These regulations focus on mandating practices to ensure the purity, quality, strength, and composition of supplements. Numerous articles in the literature have reported the presence in supplements of heavy metals, undeclared pharmaceuticals, and contaminants, and the inaccurate labeling of dietary ingredients. Accordingly, reviews of "drug effects" of unknown agents in unknown quantities containing unknown adulterants are essentially doomed to incompleteness and uncertainty.² Nonetheless, the ubiquitous use of these agents, often in conjunction with prescribed agents, justifies this effort. Note that the labels on these supplements are required to contain this disclaimer: "This product is not intended to diagnose, treat, cure, or prevent any disease."

A national survey conducted in 2002 found that 19% of adults in the United States had used natural products, including herbal and animal-based supplements (such as glucosamine) during the previous year.³ Use of these products continues, although the specific agents used change in response to research, fad, popularity, and advertisements.⁴ The top ten most commonly used supplements have been identified as echinacea, ginseng, ginkgo, garlic supplements, glucosamine, St. John's Wort, peppermint, fish oil or omega-3 fatty acids, ginger supplements, and soy supplements. The most likely user of natural products

is a woman with an advanced education and a high income.² Although some of these agents have no known effects on coagulation, others have been associated with alterations in hemostasis (Table 33-1).

Most case reports suggesting a relationship between a hemorrhagic event and the use of a dietary supplemental agent do only that, as causation is difficult to prove and definitive studies are hard to find. The presence of the agent often gets the blame for the event. On the other hand, although it is highly unlikely that these supplemental agents produce hemostatic effects sufficient to cause clinical concern, they well may offer the "second hit" that, when combined with another hemostatic defect such as von Willebrand disease, thrombocytopenia, mild hemophilia, or anticoagulant use, may result in observable, even significant, laboratory or clinical changes. Accordingly, attempts to study these agents with the use of normal young volunteers who are taking no other drugs may not have been appropriately designed to detect such subtle alterations.

THE TEN MOST COMMONLY USED DIETARY SUPPLEMENT PRODUCTS

Echinacea

Echinacea (*Echinacea purpurea*, *Echinacea angustifolia*, *Echinacea pallida*) is commonly used for the prevention of colds and other respiratory tract infections. Orally, it is also used as an antiseptic, antiviral, and immune stimulant. It is frequently found in combination preparations with other vitamins, herbs, and minerals. Currently, no reports have documented effects of echinacea on hemostasis.

Ginseng

Another very popular dietary supplement, ginseng, may be found alone, in combination supplements, and in popular energy drinks. Two common species are available to consumers—American ginseng (*Panax quinquefolius*) and Asian or Chinese ginseng (*Panax ginseng*). Siberian ginseng (*Eleutherococcus senticosus*), also available on the market, is not a true ginseng (i.e., not of the *Panax* genus) but is reported to have similar health benefits. All three are used as a general tonic for promoting well-being, for increasing resistance to environmental stress, and for enhancing physical endurance. Siberian ginseng has not been reported to affect hemostasis or to interact with anticoagulant medications.

Table 33-1 The Ten Most Commonly Used Supplements and their Effects on Coagulation

Dietary Supplement	Effects on Coagulation
Echinacea	None reported
Ginseng	Possible antiplatelet activity May increase or decrease INR when taken with warfarin
Ginkgo biloba	Possible antiplatelet activity May increase risk of bleeding when taken with warfarin
Garlic	Possible antiplatelet activity May increase INR when taken with warfarin
Glucosamine	When taken alone, no reported effects on coagulation When combined with chondroitin, may increase INR when taken with warfarin
St. John's wort	May cause irregular menstrual bleeding when taken with oral contraceptives May decrease INR when taken with warfarin
Peppermint	None reported
Fish oils/omega-3 fatty acids	Possible antiplatelet activity May increase INR when taken with warfarin
Ginger	Possible antiplatelet activity May increase INR when taken with warfarin
Soy	Possible antiplatelet activity May decrease INR when taken with warfarin

INR, international normalized ratio.

When taken alone, American or Asian ginseng may increase the risk of bleeding through their antiplatelet activity.⁵ When American or Asian ginseng is taken with warfarin, an altered international normalized ratio (INR) may result. Both a decrease and an increase in INR have been reported; however, the most commonly reported effect is a decrease in the effectiveness of warfarin.^{6,7} In a randomized, controlled trial by Yuan and associates,⁸ American ginseng administered for 2 weeks to subjects on warfarin significantly reduced the INR when compared with placebo. However, a pharmacokinetics study in rats revealed no alterations in warfarin levels and no impact on prothrombin time after *P. ginseng* was administered.⁹ Although these herbs are related, they contain different constituents, which may, in part, account for the differences noted in laboratory data.

Ginkgo

Ginkgo biloba is commonly taken to improve dementia and memory loss, mood disturbances, difficulty concentrating, and sexual dysfunction. Ginkgo has been shown to decrease platelet function by inhibiting platelet aggregation.¹⁰ Reports of four individual cases indicated that spontaneous bleeding may be associated with ginkgo use.^{7,11} However, a prospective, double-blind, randomized, placebo-controlled study was carried out in 32 young, healthy male volunteers as a means of evaluating the effects of three dosages of ginkgo (120, 240, and 480 mg per day) on hemostasis, coagulation, and fibrinolysis. After 14 days of administration, ginkgo did not induce significant modifications in bleeding time, platelet function, or coagulation factors at any dosage when compared with placebo.¹² When combined with warfarin, an increased risk of bleeding is seen owing to the effect of the herb on platelet function. However, a recent study in healthy adults showed that ginkgo, when taken at recommended doses, did not alter the INR or the pharmacokinetics or pharmacodynamics of warfarin when patients were given a single large dose of

warfarin (25 mg) after 1 week of pretreatment with ginkgo.¹³ Kohler and colleagues,¹⁴ using 50 healthy male volunteers, were unable to find evidence suggesting any effect of ginkgo on these subjects' platelet function. At this time, the true effect of ginkgo on hemostasis or interaction with warfarin is not clear.

Garlic

Garlic (*Allium sativum*) is used as a flavoring ingredient in food preparations and is promoted as a dietary supplement for the treatment of patients with hypertension and hyperlipidemia, and for the prevention of cardiovascular disease. Garlic is used to prevent various cancers, including colorectal, gastric, breast, and prostate cancers. Garlic administration has been shown to inhibit platelet aggregation in several studies, possibly explaining the rationale for its use in the prevention of cardiovascular disease.^{15–17} After 26 weeks of garlic consumption, roughly an 80% reduction was observed in serum thromboxane in healthy male volunteers who had eaten 3 g (roughly 1 clove) of fresh garlic daily.¹⁸ Cooked garlic has a lower inhibitory effect on platelet aggregation than that attained with raw garlic.¹⁹ Cases of postoperative bleeding during augmentation mammoplasty²⁰ and transurethral resection of the prostate²¹ have been reported in patients taking garlic prior to surgery. Spontaneous spinal epidural hematoma has also been reported.²² Evidence is lacking for a direct interaction of warfarin with garlic. A small, controlled study failed to find any significant change in INR values among patients stabilized on warfarin therapy (INR target, 2 to 3) who were started on 1200 mg of aged garlic extract (AGE) for 2 months in comparison with a placebo group.²³

Glucosamine

Sometimes sold in combination with chondroitin sulfate, glucosamine is widely sold as an arthritis remedy; it is useful for osteoarthritis and temporomandibular joint

arthritis. A meta-analysis supported the claims that glucosamine is at least modestly effective when used to relieve osteoarthritis symptoms.²⁴ Although no cases of spontaneous bleeding or interaction with antiplatelet drugs have been reported, one case report describes a possible interaction with warfarin.²⁵ A patient who had been on a stable dose of warfarin with therapeutic INR values developed supratherapeutic values after 4 weeks of taking a glucosamine-chondroitin supplement (3000 mg glucosamine and 2400 mg chondroitin daily).²³ It is possible that augmentation of the warfarin effect was due to the glucosamine, the chondroitin, or both, when taken at higher than recommended doses.²⁶ Recommended daily doses are 1500 mg per day of glucosamine and up to 1200 mg per day of chondroitin.⁶

St. John's Wort

St. John's wort (*Hypericum perforatum*) is taken for depression, anxiety, obsessive-compulsive disorder, attention deficit-hyperactivity disorder, and other mood disorders. Irregular menstrual bleeding and breakthrough bleeding have been reported in women who were taking St. John's wort concomitantly with oral contraceptives.²⁷ Clinical trials have confirmed this finding and suggest that the increase in breakthrough bleeding is due to an induction of cytochrome P450 3A enzyme activity, with resultant induction of the metabolism of the oral contraceptive and reduction in the contraceptive's effectiveness.^{28,29} St. John's wort is known to reduce the effects of warfarin and is associated with decreased INRs. Warfarin binds to certain St. John's wort constituents in vitro, which may reduce the bioavailability of warfarin.³⁰ St. John's wort also induces the metabolism and clearance of warfarin by the cytochrome P450 system.³¹ Reduction in INR in patients who are stable on warfarin suggests a possible induction of cytochrome P450 2C9.³²

Peppermint

Peppermint leaf (*Mentha piperita* X) or oil is used for dyspepsia, colds, cough, nausea, irritable bowel syndrome, and tension headache. This herb has not been reported to alter hemostasis or to interact with anticoagulant or antiplatelet medications.

Fish Oils/Omega-3 Fatty Acids

Fish oil is taken orally for the treatment of patients with hypertriglyceridemia, coronary heart disease, hypertension, age-related maculopathy, bipolar disorder, obesity, stroke, rheumatoid arthritis, and various other disorders. Fish oil is typically derived from cold-water fish such as herring, mackerel, sardine, trout, or salmon. The oils have high concentrations of long-chain, polyunsaturated fats called omega-3 fatty acids. Fish oil-derived omega-3 fatty acids possess anti-inflammatory and antithrombotic properties because they compete with arachidonic acid in the cyclooxygenase and lipoxygenase pathways of platelet metabolism. Omega-3 fatty acids decrease platelet aggregation.^{33,34} Some evidence suggests that excessive consumption of fish oils may increase the risk of hemorrhagic stroke.^{35,36} A randomized, placebo-controlled study of 11 patients on

chronic anticoagulation with warfarin found no alteration in INR values after they had taken 3 or 6 g of fish oil daily for 4 weeks.³⁷ Since the time of that trial, an increase in INR was reported after a patient on long-term warfarin anticoagulation doubled her dose of fish oil from 1000 mg to 2000 mg per day.³⁸

Ginger

Orally, ginger (*Zingiber officinale*) is used for nausea, vertigo, dyspepsia, arthritis, loss of appetite, and migraine headache. Ginger is believed to decrease platelet aggregation via the arachadonic acid pathway.^{11,39,40} One study reported a decrease in serum thromboxane B₂ when ginger was administered orally to rats.⁴¹ Given this potential antithrombotic property, ginger should be used with caution in patients taking antiplatelet medications. When taken with warfarin, the herb may lead to an increased warfarin effect and elevated INR. A published case report describes a 76-year-old woman on long-term anticoagulation with warfarin who began having supratherapeutic INR values after she started to ingest raw ginger and tea made from ginger powder.⁴² Her INR returned to stable values once she had discontinued the herb. An elevation in INR as a result of initiation of consumption of ginger products was documented in another patient on long-term phenprocoumon,⁴³ an oral vitamin K inhibitor in the coumarin class of drugs. In a recent clinical trial, 12 patients were pretreated with ginger for 1 week at recommended daily doses.¹³ Patients were then administered a single 25-mg dose of warfarin. No association was found between consumption of ginger and INR or the pharmacokinetics and pharmacodynamics of warfarin.

Soy

Soybeans (*Glycine max*) are the most significant dietary source of isoflavones, which are naturally occurring plant compounds commonly referred to as "phytoestrogens" and named for their similarity in structure to the estrogen molecule and ability to bind to the estrogen receptor.^{5,44} Phytoestrogens have been publicized as a therapeutic alternative for a variety of hormone-dependent conditions, including breast and prostate cancer, menopausal symptoms, osteoporosis, and cardiovascular disease.

Whether soy affects coagulation parameters is controversial. Dent and colleagues⁴⁵ found that 40 g of soy protein did not alter fibrinolytic or coagulation factors in perimenopausal women. In animal studies and in vitro, however, soy and soy isoflavones have been found to potentially inhibit platelet aggregation.^{46–49} Schoene and Guidry⁴⁶ demonstrated that, when fed an isoflavone-rich soy protein (containing 1.45 mg per gram of the isoflavone genistein), rats developed alterations in their platelet function that could lead to decreased platelet activation and aggregation. When taken in combination with warfarin, soy may decrease anticoagulant effects and INR.⁵⁰

COUMARIN-CONTAINING PLANTS

Coumarins belong to a group of compounds known as benzopyrones. They are fairly ubiquitous in the plant kingdom; more than 3400 naturally occurring coumarins

have been identified. Some commonly ingested coumarin-containing foods include strawberries, apricots, and cherries, as well as spices such as cinnamon. Confusion seems to pervade the medical literature regarding the anticoagulant activity of this class of compounds. Although it is true that some coumarins have anticoagulant activity because of their chemical structure, the overall effect in vivo is quite weak. The parent compound, coumarin, does not possess any anticoagulant activity because it lacks a 4-hydroxy group with a carbon at the 3 position. Pharmacologic activities are all dependent on side chains and substitution around the central coumarin ring structure.

Part of the confusion may be in the very word itself. Ranchers in the northern United States reported an outbreak of lethal hemorrhage in their cattle during the 1920s. In 1922, Schofield, a Canadian veterinarian, determined that bleeding was due to a toxin from moldy feed made from sweet clover that acted as a potent anticoagulant. In 1939, Campbell and Link, two researchers working at the University of Wisconsin, identified that the toxin was bishydroxycoumarin (dicoumarol), which is formed when fungi in moldy sweet clover (*Melilotus officinalis*) oxidize coumarol to 4-hydroxycoumarin. The discovery of dicoumarol led to the development of modern anticoagulant drugs such as warfarin. Because the base molecule for warfarin (Coumadin; Bristol-Myers Squibb, Princeton, NJ, USA) and related drugs is coumarin, these drugs are often referred to as coumarin drugs, although the parent molecule coumarin showed no anticoagulant activity in a human clinical trial.⁵¹ Generalizations that warn physicians to be cautious about coumarins in foods and botanical remedies are not helpful.

MISCELLANEOUS SUPPLEMENTS

Many other popular dietary supplements have been the subjects of reports of altered hemostasis. Cranberry juice is used for the prevention and treatment of urinary tract infection. Several reports have documented interactions between warfarin and cranberry juice that led to elevations in INR values.⁵² In one fatal case, a man's INR increased to greater than 50 after he began consuming an unknown quantity of cranberry juice.⁵³ Cranberry contains compounds that can be converted to salicylic acid in the body; thus, antiplatelet activity is possible. Duthie and coworkers⁵⁴ determined that consumption of cranberry juice was associated with a significant increase in salicylic acid in the urine, as well as elevated plasma levels.

Noni juice from *Morinda citrifolia* fruit is marketed as an immune booster, a digestive aid, and an antioxidant. At least one case report has described an interaction between Noni juice and warfarin that led to a decrease in INR.⁵⁵ Noni juice is reported to consist of multiple vitamins; however, it is unclear whether it contains vitamin K.

Quinine, a drug extracted from cinchona tree bark, has been marketed for several uses, including leg cramps, varicose veins, fever, and malaria. In the late 1990s, the FDA acted to limit the marketing of quinine on the basis of safety concerns, one of which includes drug-induced thrombocytopenia.^{56,57} Several cases of rapid-onset thrombocytopenia caused by ingestion of quinine have been reported.^{57,58}

Additionally, quinine is known to be associated with thrombotic thrombocytopenic purpura–hemolytic-uremic syndrome (TTP-HUS).⁵⁹

Willow (*Salix* spp) has been used since ancient times to relieve pain. *Salix* species contain several prodrugs of salicylate, principally salicin, from which acetylsalicylic acid is derived to be marketed as aspirin. Although some impact has been noted on platelets, oral consumption of 240 mg per day of willow bark extract—the amount typically recommended for musculoskeletal pain—was found have a lesser effect on platelet aggregation than was observed with 100 mg per day of aspirin ($P = .001$).⁶⁰

Coenzyme Q10 (also known as ubiquinone), flaxseed, and green tea have been reported to result in a decreased INR when taken with warfarin.^{7,60} Dong quai, devil's claw, papaya, bromelain (an enzyme found in pineapple), cayenne, and feverfew may potentiate warfarin's effect.^{61–64}

Vitamin E is taken for the treatment and prevention of Alzheimer disease and other dementias, macular degeneration, and cardiovascular disease. It is also used for cancer prevention and for the prevention of preeclampsia in pregnant women. Vitamin E is known to have an anticoagulant effect. This supplement inhibits platelet aggregation and adhesion,⁶⁵ as well as vitamin K–dependent clotting factors.^{66,67} Given these properties, vitamin E may increase the risk of bleeding in patients taking other anticoagulants, including warfarin, and may enhance bleeding in patients with von Willebrand disease.

Patients on long-term anticoagulant therapy are sometimes told to avoid foods, such as broccoli and spinach. Schurges and colleagues⁶⁸ set out to study these foods in a vigorous and systematic way. Using healthy volunteers who were stabilized long term on warfarin to an INR of 2.0, investigators studied the effects of those foods taken with calculated incremental doses of vitamin K ranging from 50 µg to 500 µg. They deduced that no significant change in INR occurred until at least a total of 150 µg of available vitamin K was added to the diet; they further deduced that food supplements such as broccoli or spinach, which contain an aggregate of less than 100 µg per day of available vitamin K, do not significantly interfere with long-term oral anticoagulant therapy. They also studied the effects of a single large meal of vitamin K in the form of large quantities of broccoli or spinach containing 700 µg to 1500 µg of available vitamin K and found that each of those foods lowered the INR from a baseline of approximately 2.0 down to 1.6–1.7, but only for about 24 hours.

The applicability of these observations to patient care is not exactly clear in that these were all very young healthy patients who were taking no other medications. Additionally, the effects observed were at the lowest therapeutic INR target, namely, 2.0. The effect of a “therapeutic” menu of broccoli or spinach on an elevated INR such as 7 or 8 is unknown. It is clear that foodstuffs containing vitamin K can alter the INR. On the other hand, investigators found that a single meal of natto, a traditional Japanese soybean food, decreased the INR in volunteers for several days.⁶⁸ This finding probably is due to the fact that this food is moldy because of *Bacillus natto*, an organism on soy meal that produces significant amounts of vitamin K and presumably resides in the gut of those who eat this food, all the while elaborating vitamin K in the host's gastrointestinal tract.

Table 33-2 Unexpected Sources of Vitamin K that may Alter INR When Taken with Warfarin

Source	Amount of Vitamin K
Viactiv (McNeil Nutritionals LLC, Fort Washington, Pa, USA) soft calcium chews	40 µg per chew*
Boost (Novartis Nutrition Corporation, Fremont, Mich, USA)	30 µg per 8 fl oz*
Ensure (Abbott Laboratories, Abbott Park, Ill, USA)	30 µg per 8 fl oz*
Some energy or protein bars	40 to 65 µg per bar*
Olestra-containing "light" potato chips	80 µg per 1-ounce serving†
Natto (fermented soybean)	1000 µg per 100 g natto‡
Condiments such as mayonnaise	11 µg per 1 tablespoon
Soy bean emulsions (e.g., Intralipid 10% [Pharmacia & Upjohn AB, Sweden], Liposyn [Abbott Laboratories, Montreal, Canada]) and drugs (e.g., propofol) that use these emulsions or delivery vehicles	13 to 31 µg/dL§

§Lennon C, Davidson KW, Sadowski JA, Mason JB: The vitamin K content of intravenous lipid emulsions. *J Parenter Enteral Nutr* 17:142–144, 1993.

INR, international normalized ratio.

Portions of these variables are due not only to the specific food and vitamin K contained in the food but to the bioavailability of vitamin K, which ranges from a few percentage points to a very high level. The authors concluded that consistency is probably more important than content in terms of dietary intake of vitamin K in patients anticoagulated on a long-term basis.

Table 33-2 lists some unexpected food sources of vitamin K that may interfere with therapeutic administration of warfarin.

RECOMMENDATIONS

Because the list of dietary supplements is long yet incomplete, and because even their alleged contents may be in dispute, it would be daunting to master lists of these agents and their potential effects on hemostasis. Probably a more functional approach would be to remember that these supplements may alter hemostasis; therefore, should such agents be encountered in patients, inquiry regarding them is clearly justified. More important in long-term care such as chronic anticoagulation therapy is stability of the use of supplements. Frequent starting and stopping of supplement use is likely to more be harmful than is consistent use.

Chapter 34

Thrombotic Risk of Contraceptives and Other Hormonal Therapies

Suman Sood, MD • Steven Stein, MD • Barbara A. Konkle, MD

INTRODUCTION

Hormones are used in various forms for contraception, postmenopausal symptom management, treatment of patients with hormone-responsive cancers, and breast cancer risk reduction. This chapter focuses on the association of hormone therapy with thromboembolic disease. The benefits of these drugs are discussed in some detail. In deciding whether to prescribe hormone therapy, one must try to assess the risk:benefit ratio for that individual. Although much still needs elucidation, the goal of this chapter is to provide data on which clinicians can base these decisions.

BASIC SCIENCE

The increased risk of thrombosis in association with the use of hormones has been well established. In general, the effects of oral contraceptives (OCs) and hormone replacement therapy (HRT) on coagulation variables are modest, and reports suggest that the use of OCs induces changes in the procoagulant and anticoagulant pathways that may counterbalance each other.¹ Baseline epidemiologic studies in healthy women undergoing menopause have demonstrated increased levels of several coagulation factors, including factors VII and VIII and fibrinogen. These changes are due to estrogen status and to aging.²

Several studies have shown that estrogen activates the coagulation system. Caine and coworkers³ showed that administration of 0.625 mg or 1.25 mg of conjugated equine estrogen to 29 healthy postmenopausal women (average age, 57 yr) for 3 months increased an index of thrombin generation (prothrombin fragments 1+2) in a dose-dependent manner. Thrombin activity, as indicated by the generation of fibrinopeptide A, was also increased. Furthermore, levels of inhibitors of thrombin generation (protein S) and activity (antithrombin III) were decreased relative to placebo. A similar study in which blood samples at baseline and after 3 months of therapy with unopposed estrogen therapy were tested versus placebo in 26 healthy postmenopausal women additionally showed significantly reduced concentrations of tissue factor pathway inhibitor (TFPI), an important inhibitor of the extrinsic pathway of coagulation.⁴ These findings are similar in users of OCs, with increased levels of factors VII, VIII, and X and

decreased antithrombin III and protein S levels contributing to an overall procoagulant state.⁵

One of estrogen's procoagulant mechanisms of action may occur through first-pass hepatic metabolism. Estrogen has been found to increase hepatic production of several plasma proteins involved in coagulation, including factor VII, factor X, and fibrinogen, and it has been implicated in the acquisition of a deficiency in plasma glucosylceramide levels, an activated protein C (APC) anticoagulant cofactor.⁶ Moreover, use of OCs and HRT has been associated with higher levels of C-reactive protein (CRP).^{7,8} Because it avoids first-pass hepatic metabolism, it has been suggested that transdermal hormone therapy may be a safer alternative to oral therapy in that it induces less activation of the coagulation system, including less APC resistance.^{9–12} However, a decreased risk of thrombosis with the currently available transdermal contraceptive (norelgestromin/ethinyl estradiol) (Ortho Evra; Ortho-McNeil Pharmaceutical, Inc., Raritan, NJ, USA) has not been demonstrated.

Data about the effects of estrogen on the fibrinolytic system are conflicting, but on the whole, estrogen seems to induce heightened fibrinolytic activity.¹³ This may be due at least in part to a decrease in fibrinogen and plasminogen activator inhibitor-1 (PAI-1) concentrations and increased plasminogen levels.⁴ Levels of PAI-1, a critical inhibitor of fibrinolysis, are generally higher in postmenopausal women.¹⁴ This hyperfibrinolysis may counterbalance the procoagulant effects of estrogen and may explain the low absolute risk of thromboembolism seen in women who are taking HRT.

Estrogens have both rapid and longer-term effects on the blood vessel wall. Estrogen influences the bioavailability of endothelially derived nitric oxide and causes relaxation of vascular smooth muscle cells.¹⁵ The longer-term effects of estrogen are due, at least in part, to changes in vascular cell gene and protein expression, which may lead to inhibition of the response to vascular injury, reduced oxidation of low-density lipoprotein, and reduced levels of lipoprotein(a) (Lp[a]). However, the decrease in cholesterol levels seen with HRT has not been shown to correlate with a decreased risk of cardiovascular disease. Once atherosclerotic disease exists, estrogens may exacerbate the proinflammatory state by increasing CRP levels and matrix metalloproteinase activity.¹⁶ In the future, genetic screening may play a role in determining who would benefit from

estrogen therapy. Estrogen receptor polymorphisms in intron 1 have been associated with the magnitude of response of high-density lipoprotein cholesterol levels to estrogen or combination HRT, although the underlying mechanism remains unknown. It is unclear whether this population of women may benefit clinically from HRT.¹⁷

Recent data have shown a higher incidence of thrombotic risk in women who use third-generation combined oral contraceptives (e.g., desogestrel, gestodene, norgestimate, drospirenone) compared with second-generation progestones (e.g., levonorgestrel, norethisterone).¹⁸ It has been postulated that this may be explained by differential effects of progestins on plasma sensitivity to APC.^{6,19} One explanation involves a differential increase in FVIII levels and a decrease in protein S activity (free protein S decreases with desogestrel and increases with levonorgestrel; the increase in free protein S with levonorgestrel may be due to a decrease in C4b-binding protein).^{20,21} This suggests that the prothrombotic effects of estrogen may be inadequately counteracted by the lower androgenicity of the progestin component present in third-generation OCs but not in second-generation OCs, thus inducing APC resistance.

ORAL CONTRACEPTIVE USE AND THROMBOSIS

Venous Thromboembolism

Since their introduction, the use of OCs has been linked to an increased incidence of thromboembolic events.²² First-generation OCs consisted of at least 50 µg of ethinyl estradiol or mestranol and a progestin, typically norethindrone. Because estrogen was suspected of increasing the risk for thromboemboli, contraceptives that contained less than 50 µg of estrogen and a new progestin, levonorgestrel, were introduced—second-generation OCs (see Table 34-1 for available combined hormonal contraceptives). Initial efforts to reduce the risk of venous thromboembolism (VTE) by reducing estrogen content have proved successful.^{23–25} Bottiger and colleagues²⁴ noted a marked decline of approximately 80% in reports of nonfatal VTE per 100,000 users when low-dose estrogen OC replaced high-dose preparations. In the Oxford planning study, lower incidence rates were noted among users of low-dose contraceptives (39 per 100,000 person-years) compared with users of high-dose contraceptives (62 per 100,000 person-years).²⁵ Compared with non-OC users, women who take second-generation OCs have a risk of VTE that is increased about fourfold.²⁶

The progestins desogestrel, gestodene, and norgestimate, in combination with no more than 35 µg of ethinyl estradiol, constitute third-generation OCs (see Table 34-1). Third-generation OCs increase the risk of VTE approximately twofold over second-generation products.²⁶ The risk of VTE with oral preparations for the newer progestins has been less well studied but should not be presumed to be less than that seen with third-generation products. VTE with OCs that contain drospirenone (Yasmin; Berlex, Montville, NJ, USA) or cyproterone acetate (Diane 35; Berlex, Pointe-Claire, Quebec, Canada, Estelle 35; Douglas, Auckland, New Zealand) has been reported,^{27,28} and it produces acquired APC resistance similar to that found in women

taking third-generation products.²⁹ Because of the increased risk of thrombosis associated with cyproterone acetate-containing preparations, these are not recommended for routine contraception. On the basis of postmarketing adverse event reporting to the U.S. Food and Drug Administration (FDA), transdermal hormonal contraception (norelgestromin and ethinyl estradiol as Ortho Evra) cannot be assumed to carry a lower risk of VTE than is seen with oral preparations. The VTE risk associated with use of the vaginal ring (ethinyl estradiol and etonorgestrel) (NuvaRing; Organon Inc., Roseland, NJ, USA) is unknown.

The VTE-associated risk of progesterone-only containing contraceptives has been studied in eight case-controlled studies,^{30–37} and none has shown a statistically significant increased risk of VTE in women who use these for contraception, although an increased risk has been found for other indications.³²

Myocardial Infarction

Current use of OCs increases the risk of myocardial infarction, but most of the excess risk is attributable to an interaction with cigarette smoking.³⁸ Taken together, case-controlled and cohort studies suggest that current users of OCs who are younger than 40 years of age and who do not smoke have little or no increased risk for myocardial infarction. In general, young women (the primary users of OCs) have a low incidence of myocardial infarction. In the United States, the baseline annual risk for fatal ischemic heart disease ranges from 1 to 2 per 100,000 persons in women younger than 35 years of age to 4.1 per 100,000 persons in women 35 to 39 years of age, and to 10 to 21 per 100,000 persons for women in their 40s.³⁹ Thus, most studies have been too small to address whether the risk for myocardial infarction from OCs differs according to coronary risk factors other than smoking. The data consistently show that past use of OCs is not associated with increased risk. In a meta-analysis of 13 studies, Stampfer and coworkers⁴⁰ estimated that past users of OCs had a pooled relative risk for myocardial infarction of 1.01 (95% confidence interval [CI], 0.91 to 1.13). These findings suggest that any increase in risk for myocardial infarction due to OC use occurs only with current use and probably acts through an acute prothrombotic interaction with cigarette smoking. This statement is supported by the finding that angiographic studies of young women with myocardial infarction tend to show an absence of atherosclerosis in cases associated with current or recent use of OCs.⁴¹

Stroke

Prospective studies have not shown an increased risk for stroke among past users of OCs, and studies of stroke in current users have yielded inconsistent results.³⁸ Reported studies are often small, do not differentiate between hemorrhagic and thromboembolic strokes, and often do not control for other major risk factors. In studies that have shown an increased risk, the interaction with smoking does not seem to be as great as that associated with myocardial infarction.

The Nurses' Health Study⁴² found no statistically significant increase in risk for stroke among past users of OCs (ischemic stroke and subarachnoid hemorrhage were

Second-generation OC: Levonorgestrel and norethindrone containing.

Third-generation OC: Norgestimate and desogestrel containing.

combined in the study). In the Royal College of General Practitioners' Study,⁴³ past users who were smokers had an increased relative risk for stroke of 1.8 (95% CI, 1.1 to 2.8). The World Health Organization case-controlled study⁴⁴ also suggested that an interaction between smoking and contraceptives was associated with ischemic stroke.

Taken together, studies of low-dose OCs suggest that these drugs produce little increase in risk for ischemic stroke.⁴⁵ Occlusive stroke in young women occurs at an estimated annual rate of 5.4 per 100,000 person-years.⁴⁶ Fatal occlusive stroke is even rarer, with annual rates lower than 0.5 per 100,000 for women younger than 45 years of age.³⁹ Therefore, any attributable risk for death from occlusive stroke associated with the use of OCs is small at most, although smokers may be more susceptible. Current studies provide no persuasive evidence of any increase in risk for hemorrhagic stroke among young women without risk factors who use low-dose OCs.³⁸

Hormonal Contraception and Thrombophilia

Inherited and acquired factors interact to modulate the risk of VTE in women who use OCs. Carriers of the factor V Leiden mutation have been studied most extensively. Early studies documented that the risk of VTE in women with

FV Leiden who use OCs was greater than the additive risk of these two factors. Initial reports of VTE risk in women who use OCs described a greater than 30-fold increased risk,^{47,48} although a pooled analysis of eight case-controlled studies found an odds ratio of 10.25 (95% CI, 5.69 to 18.45) for OC use in FV Leiden and of 7.14 (95% CI, 3.39 to 15.04) in women with the prothrombin 20210 mutation.⁴⁹ The risk appears to be greater in FV Leiden carriers who use third-generation OCs compared with second-generation products.⁴⁸ In a prospective cohort study of 236 asymptomatic female carriers of FV Leiden, almost all of whom were heterozygotes, the risk of VTE was 1.8% per year of OC use.⁵⁰

Thrombophilic women are more likely to develop thrombosis early in their OC use, with a 19-fold (95% CI, 1.9 to 175.7) increase reported in the first 6 months, and an 11-fold (95% CI, 2.1 to 57.3) increase noted during the first year, based on a case-controlled study.⁵¹ This study included women with a deficiency of protein C, protein S, or antithrombin III, or heterozygosity for the FV Leiden or prothrombin 20210 mutation.

Hormonal therapy and pregnancy have been associated with an increased risk of cerebral vein thrombosis. The use of OCs is strongly and independently associated with this disorder. The risk is increased in individuals with prothrombin 20210 and FV Leiden mutations.⁵² A marked predominance in women with the prothrombin mutation

who use OCs has been reported in two studies.^{52,53} These findings are based on a small number of women, given that cerebral venous thrombosis is a rare event (see Chapter 16).

Other acquired or inherited factors modulate the risk of thrombosis in women who use OCs. In a case-controlled analysis, thrombophilic women who had a history of air travel of at least 8 hours duration had an increased risk of VTE (odds ratio [OR], 13.9; 95% CI, 1.7 to 117.5).⁵⁴ A synergistic effect of obesity (body mass index [BMI] > 25 kg/m²) with OC use has been reported with tenfold increased risk.⁵⁵ Data from the Leiden Thrombophilia Study showed an increase in VTE risk with OC use in the setting of elevated factors II, V, and XI and with a decrease in factor XII.⁵⁶ Researchers did not find an increased risk with elevated FVIII levels, which has been shown to be a risk factor for initial and recurrent VTE in other settings.

COUNSELING THROMBOPHILIC WOMEN ON THE USE OF HORMONAL CONTRACEPTION

More and more people are undergoing testing to identify thrombophilic disorders related to family or personal medical issues. The physician is often asked about the use of hormonal contraception in women with thrombophilia. Combined hormonal contraception is believed to be contraindicated in women with a personal history of VTE. In such women, postmenopausal HRT is associated with an unacceptable risk of recurrent events.⁵⁷ Whether concomitant anticoagulation therapy decreases the risk sufficiently to compensate for this strategy is unknown, but such an approach is commonly used.

Information on the use of progestin-only contraceptives in this setting is limited. Conard and associates⁵⁸ evaluated the progestin chlormadinone acetate in 102 women, 71 of whom had a prior deep venous thrombosis (DVT) and 31 of whom had an identified thrombophilia. The occurrence of new or recurrent DVT was evaluated in a case-controlled manner in women with similar risk factors as controls. No significant difference in events was found.⁵⁸ Given these data, along with other data from women without diagnosed thrombophilia, progestin-only contraception may be an option in women with a low risk of recurrence, such as those with a past nonhormonal precipitated DVT.

A common consultation question involves the use of hormonal contraception in asymptomatic carriers of thrombophilic defects. In this setting, one must be sure that effective contraception is not refused as the result of an overestimation of VTE risk. Increases in the number of women seeking pregnancy termination have been noted after media-promoted fear of health risks associated with hormonal contraceptives.⁵⁹ When considering alternative contraception, one must take into account the efficacy of other methods, which is generally inferior, and the woman's acceptance of pregnancy termination if contraception should fail. Pregnancy itself is associated with an approximately fivefold increased risk of thrombosis. This risk is increased further in thrombophilic women, as are some pregnancy complications. It is assumed that women with inherited thrombophilias that carry a higher risk of VTE, such as antithrombin III deficiency, are at greater risk

Table 34-2 Estimated Risk of Venous Thromboembolism (VTE) per Year of Oral Contraceptive Use in Women Without Prior VTE*

	Age, 20 yr [†]	Age, 50 yr [†]
No defined thrombophilia [‡]	0.04%	0.4%

[†]Underlying risk increases with age.⁶⁰

[‡]Presume relative risk of VTE with OC use = 4.
FV, factor V; PT, prothrombin.

than those with milder defects, although this has not been proved in a clinical study.

The risk of DVT increases with increasing age. Women at age 20 have an approximately tenfold lower risk than women at age 50.⁶⁰ Thus, the absolute risk of developing a DVT in a young woman who uses OCs is significantly less than that in a woman who is approaching menopause, even with identical genetic risk factors (Table 34-2). Counseling must take this into account. In the Leiden Thrombophilia Study, a 1.8% per year risk of VTE was reported in asymptomatic carriers of FV Leiden who used OCs. This included all age groups, but the risk should be less in a young adult. The European Prospective Cohort on Thrombophilia Study evaluated the risk of first venous thrombosis in asymptomatic carriers of a familial thrombophilic defect.⁶¹ It was found that fewer women with thrombophilia than controls used OCs, but VTE was only slightly more likely to occur in those with (0.5% per year [95% CI, 0.0 to 2.9]) than in those without thrombophilia (0.4% per year [95% CI, 0.1 to 0.9]).

Because VTE is a manifestation of multiple known and unknown genetic and environmental factors, family history may provide a clue as to thrombophilic tendency within the family, which may influence counseling. VTE-associated risk with hormonal contraception may be acceptable to many asymptomatic women with a low risk for thrombophilia when this and other factors are considered. Levonorgestrel-containing OCs produce the least APC resistance; thus, the least thrombogenic OC may be the one with the lowest estrogen dose and that includes levonorgestrel as the progestin.

HORMONE REPLACEMENT THERAPY AND THROMBOSIS

In the United States and other developed countries, more women die from cardiovascular disease than from any other disease. The Nurses' Health Study, among other observational studies, suggested that postmenopausal women who take estrogen therapy have fewer cardiovascular events (range, 40% to 50%) over time compared with untreated women.⁶² After cessation of menses (menopause), average circulating estrogen levels eventually fall to less than 10% of premenopausal levels. This state of estrogen deficiency has been believed to contribute to the acceleration of

several age-related health problems in women, including cardiovascular disease, osteoporosis, and possibly dementia. Despite a large and growing body of information, including the results of several well-conducted randomized trials on the risks and benefits of long-term HRT in preventing or treating some of the disorders associated with menopause, whether to take postmenopausal hormones remains a difficult decision and an area of therapeutic controversy.

HORMONE REPLACEMENT THERAPY AND CARDIOVASCULAR DISEASE

Atherosclerosis increases after menopause, especially among women who have undergone surgical oophorectomy.⁶³ More than 40 observational studies have suggested that HRT reduced cardiovascular morbidity and mortality in postmenopausal women.^{64,65} Most of these studies were conducted in healthy postmenopausal women who used unopposed estrogen replacement therapy.

In the Heart and Estrogen/Progestin Replacement Study (HERS), the first large clinical trial undertaken to examine the effects of HRT on risk for cardiovascular disease, 2763 women with established coronary disease were randomly assigned to receive daily conjugated equine estrogen plus medroxyprogesterone acetate or placebo (Table 34-3).^{66,100} After a mean of 4.1 years of follow-up, no differences were seen in the primary composite outcome of nonfatal myocardial infarction or death from coronary heart disease (HRT group, 179 events; placebo group, 182 events; relative hazard, 0.99 [95% CI, 0.81 to 1.22]) or any of the secondary clinical outcomes. This null result shook the foundation on which recommendations for widespread use of estrogen replacement had been built—that estrogen reduces a woman's risk for heart disease. On the basis of these results, assertions regarding secondary prevention of coronary heart disease could no longer be made with confidence. Initially, more detailed analysis of HERS results tantalizingly revealed that within the overall null effect, risk for coronary heart disease was reduced during years 3 to 5,

but this reduction was offset by the unexpected 50% increase in risk observed during year 1. However, data from 2.7 additional years of unblinded follow-up failed to show persistence of this promising trend in reducing cardiovascular risk despite the fact that 45% of women continued to take the original assigned therapy. At the end of 6.8 years, the relative hazard remained 1.00 (95% CI, 0.77 to 1.29).⁶⁷ In other secondary prevention trials, such as the placebo-controlled Estrogen Replacement for Atherosclerosis (ERA) trial, neither estrogen alone nor estrogen in combination with progestin affected the angiographically determined progression of coronary atherosclerosis in women with established coronary artery disease over a 3-year period.⁶⁸

The National Institutes of Health (NIH)-sponsored Women's Health Initiative (WHI), a recent large-scale randomized, double-blinded trial of primary prevention of coronary heart disease, demonstrated an overall lack of benefit of long-term HRT. The WHI was a placebo-controlled long-term trial of HRT, calcium/vitamin D supplementation, and dietary modification that was conducted in 16,608 mostly healthy, ethnically diverse postmenopausal women; investigators explored the effects of these interventions on many end points, including the incidences of cardiovascular disease, osteoporotic fractures, and breast cancer.⁶⁹ Only 7.7% of participating women reported a prior history of cardiovascular disease. Women with an intact uterus at baseline were randomly assigned to receive daily conjugated equine estrogens plus medroxyprogesterone acetate versus placebo. The study was stopped early in 2002 by the Data Safety and Monitoring Board after an average follow-up time of 5.2 years because of an increase in coronary heart disease (CHD), stroke, and pulmonary embolism (PE), as well as evidence of breast cancer harm that outweighed the potential benefit of hormone use in terms of reducing fractures and preventing colon cancer. The estimated hazard ratio for CHD was 1.29 (95% CI, 1.02 to 1.63) with 286 total cases. The absolute risk excess per 10,000 women attributable to estrogen plus progestin was seven additional CHD events. As in the HERS trial, the difference between treatment groups began soon after randomization but in this trial was found to persist.

Table 34-3 Risks of Thrombosis and Other Events from the HERS and WHI Studies*†

Clinical Event	HERS ⁶⁶ (Estrogen + Progestin)	WHI ⁶⁹ (Estrogen + Progestin)	WHI ⁷⁰ (Estrogen alone)
CHD events	0.99 (0.80–1.22)	1.29 (1.02–1.63)	0.91 (0.75–1.12)
Stroke	1.23 (0.89–1.70)	1.41 (1.07–1.85)	1.39 (1.10–1.77)
Pulmonary embolism	2.79 (0.89–8.75)	2.13 (1.39–3.25)	1.34 (0.87–2.06)
DVT	2.80 (1.30–6.00)	2.07 (1.49–2.87)	1.47 (1.04–2.08)
Total VTE	2.70 (1.40–5.00)	2.11 (1.58–2.82)	1.33 (0.99–1.79)
Breast cancer	1.30 (0.77–2.19)	1.26 (1.00–1.59)	0.77 (0.59–1.01)
Colon cancer	0.69 (0.32–1.49)	0.63 (0.43–0.92)	1.08 (0.75–1.55)
Hip fracture	1.10 (0.49–2.50)	0.66 (0.45–0.98)	0.61 (0.41–0.91)
Death	1.08 (0.84–1.38)	0.98 (0.82–1.18)	1.04 (0.88–1.22)
Global index‡	–	1.15 (1.03–1.28)	1.01 (0.91–1.12)

*Hazard ratios with 95% confidence intervals given.

†Data are based on the intent-to-treat analysis. For the primary CHD events outcome (myocardial infarction plus CHD death), the three trials had similar numbers of events and thus similar power. For other outcomes, the smaller HERS trial had fewer events and less precise hazard ratios.

‡The global index was composed of the first occurrence of any of the events listed in the table.

HERS, Heart and Estrogen/Progestin Replacement Study; WHI, Women's Health Initiative; CHD, coronary heart disease; DVT, deep venous thrombosis; VTE, venous thromboembolic events.

Conjugated equine estrogen is by far the most widely used estrogen in the United States, and it is the treatment for which epidemiologic data are most readily available. Because of the increased risks of endometrial hyperplasia and carcinoma associated with estrogen alone, most women who have not undergone hysterectomy are treated with a progestin in addition to estrogen. The addition of progestin provides a more nearly physiologic replacement regimen, but this agent may oppose some of the benefits of estrogen, particularly with respect to cardiovascular disease. In 10,739 women without a uterus, the WHI trial revealed that estrogen given alone did not increase CHD risk but failed to significantly reduce it.⁷⁰ The hazard ratio for CHD events was 0.91 (95% CI, 0.75 to 1.12) with an average of 6.8 years of follow-up. Without progestin, the effect of harm was less pronounced; this trend was especially noted in younger participants (hazard ratio [HR], 0.56; ages, 50 to 59 years vs HR, 1.04; ages 70 to 79 years).

As a result of these findings, thousands of women throughout the world have stopped taking HRT. Other prospective primary prevention trials, such as the United Kingdom-based Women's International Study of Long Duration Oestrogen after Menopause (WISDOM), were cancelled. However, the controversy about HRT continues. Many have argued that the methods used in observational studies were inherently confounded by a "healthy user bias," by which women for whom estrogens are prescribed are often healthier initially, and those who continue to take hormones tend to be free of disease. Thus, lower mortality among hormone users may have been attributed erroneously to the hormone itself.

Others have believed that it is the timing of the initiation of HRT that is the problem: most women in observational studies began to receive therapy at or near the menopausal transition, whereas in the WHI study, older women with a mean age of 62.7 years, averaging 12 years postmenopausal, were treated.⁷¹ Theoretically, younger women have little to no atherosclerosis compared with the older cohort studied in the WHI; substantial preclinical data have suggested that the atheropreventive effects of estrogen exist before vascular damage occurs versus the possibility that adverse effects of estrogen in promoting thrombosis and inflammation are present once complex atheromas occur. The WHI found a nonsignificant trend toward lower risk with less passage of time since menopause; for women in whom menopause had begun less than 10 years previously, 10 to 19 years previously, and 20 or more years previously, the hazard ratios for CHD associated with postmenopausal hormone therapy compared with placebo were 0.89, 1.22, and 1.71, respectively.⁷² Such findings are consistent with animal studies showing that the benefits of estrogen in preventing atherosclerosis were reversed in the presence of endothelial injury in rabbits.⁷³ Similarly, ovariectomized monkeys that began hormonal therapy at the time of surgery have a reduced incidence of atherosclerosis compared with monkeys that began therapy years after ovariectomy.⁷⁴ The Estrogen in the Prevention of Atherosclerosis (EPAT) trial, conducted in 222 healthy menopausal women without preexisting cardiovascular disease, found the average rate of progression of subclinical atherosclerosis, as measured by carotid intima media thickness (one of the earliest detectable

anatomic changes in the development of atherosclerosis), to be lower in those taking unopposed estrogen versus those taking placebo (-0.0017 mm per year vs 0.0036 mm per year).⁷⁵ Of note, this protective effect disappeared in women placed on lipid-lowering medications. The question remains whether HRT initiated during the perimenopause may decrease the risk of coronary heart disease.

Other difficulties with earlier studies may have involved different formulations and schedules of HRT, incomplete follow-up and compliance, and other considerations such as the use of surrogate end points in trials that may have addressed the wrong mechanisms. Another area of controversy relates to the route of administration of estrogen. Some data suggest that transdermal patches are less likely to produce a hypercoagulable state because of reduced hepatic processing, inducing less production of various proinflammatory molecules, including CRP.⁷⁶ The Papworth Hormone-Replacement Therapy Atherosclerosis Trial, which compared transdermal estrogen given alone or in combination with norethindrone, also showed no cardiovascular benefit of HRT for secondary prevention in women with angiographically proved coronary heart disease, but no studies have been conducted as yet on primary prevention.⁷⁷

To answer these lingering questions, trials such as the Kronos Early Estrogen Prevention Study (KEEPS) are currently recruiting subjects to study the effects of HRT in a younger population of women.⁷⁸ KEEPS is designed as a 5-year, randomized, placebo-controlled, double-blinded trial in 720 healthy perimenopausal women aged 42 to 58 years. Participants will have had cessation of menses after age 40 and no menses for 6 to 36 months prior to randomization. They will be divided into three groups and will receive transdermal estrogen, oral estrogen, or placebo. Women receiving estrogen will also be treated with a progestin. Participants will be followed for the development of atherosclerotic disease via carotid intimal medial thickness as a surrogate for cardiovascular end points. Studies such as these will be very helpful in elucidating the potential role of HRT in the prevention of coronary heart disease in perimenopausal women.

At this time, with the results of several large, well-conducted randomized trials suggesting a lack of net benefit and the presence of serious risk, it is recommended that HRT should not be initiated or continued in postmenopausal women for the purposes of primary or secondary prevention of coronary heart disease.⁷⁹

HORMONE REPLACEMENT THERAPY AND STROKE

Data on increased risk of stroke with HRT have been clarified by the findings of recent large, randomized trials. A meta-analysis of nine observational primary prevention studies suggests that hormone therapy is associated with a small increase in stroke incidence (relative risk [RR], 1.12; 95% CI, 1.01 to 1.23), primarily caused by an increase in thromboembolic stroke (RR, 1.20; 95% CI, 1.01 to 1.40).^{79,80} These results are consistent with findings from the WHI, which revealed an increased risk of stroke with a hazard ratio (HR) of 1.41 (95% CI, 1.07 to 1.85) in 212

cases. The absolute risk excess per 10,000 women attributable to estrogen plus progestin was small, at only eight additional strokes.⁶⁹ In contrast to CHD, excessive risk of stroke was not present in the first year, but it occurred during the second year and persisted. In the WHI study of women without a uterus who were receiving estrogen alone, the HR was 1.39 (95% CI, 1.10 to 1.77), suggesting that this adverse effect is attributable to the estrogen component of the hormone regimen.⁷⁰ It is interesting to note that in the WHI, 79.8% of strokes were ischemic. The adjusted HR for HRT versus placebo was significant for ischemic (HR, 1.44; 95% CI, 1.09 to 1.90) but not hemorrhagic or combined stroke, suggesting an increased risk for thromboembolic disease. In HERS, the risk of stroke was found to be nonsignificant with an HR of 1.23 (95% CI, 0.89 to 1.70).⁸¹

For secondary prevention, the Women's Estrogen for Stroke Trial (WEST) studied HRT provided after ischemic stroke and transient ischemic attacks (TIAs) among postmenopausal women. After a mean of 2.8 years of follow-up, no net benefit was found for the use of estrogen therapy in 664 women randomly assigned to unopposed estrogen or placebo. Secondary analysis revealed an increase in the risk of stroke-related death, along with evidence of an increased early risk of death. During the first 6 months after randomization, three fatal strokes and 18 nonfatal strokes were reported in the group assigned to estradiol, compared with one fatal stroke and eight nonfatal strokes in the placebo group (RR, 2.3; 95% CI, 1.1 to 5.0). Evidence also suggested that women randomly assigned to estradiol had more severe strokes. Among those with recurrent strokes, complete or near complete recovery was half as likely to occur among those randomly assigned to estrogen therapy.^{82,83} On the basis of these results, HRT should not be initiated to reduce the risk of stroke or other cardiovascular disease in postmenopausal women.

HORMONE REPLACEMENT THERAPY AND VENOUS THROMBOEMBOLIC DISEASE

In general, observational studies have reported a two- to threefold increase in relative risk for thromboembolic events with the use of HRT.^{84,85} This number has been confirmed by clinical trial data from the HERS⁶⁶ and WHI studies. In the HERS trial, confirmed venous thromboembolic events occurred in 34 women in the hormone group (6.2 per 1000 woman-years) and in 13 women in the placebo group (2.3 per 1000 woman-years). This translated to a relative HR of 2.7 (95% CI, 1.40 to 5.00) for users of the estrogen/progestin combination. The excess risk was 3.9 per 1000 woman-years (CI, 1.4 to 6.4 per 1000 woman-years), and the estimated number needed to treat for harm was one excess thromboembolic event for every 65 women taking hormones for 5 years. More women in the hormone group experienced deep venous thromboses (25 vs 9; relative hazard, 2.80; CI, 1.30 to 6.00; $P = .008$) and pulmonary emboli (11 vs 4; relative hazard, 2.79; CI, 0.89 to 8.75; $P = .08$); for three women, all in the hormone group, pulmonary embolism proved fatal. Similar to other studies, the risk appeared to be highest during the first 2 years of use and tended to decline with time (RR, 1.40; 95% CI, 0.64 to 3.05; $P = .08$).^{79,86,87}

The WHI initially reported an overall HR for VTE of 2.11 (95% CI, 1.58 to 2.82), with 151 cases in treated participants versus 67 cases in the placebo group.⁶⁹ A slightly extended follow-up period revealed that venous thrombosis occurred in a total of 167 women who were taking estrogen plus progestin (3.5 per 1000 person-years) versus 76 women who were taking placebo (1.7 per 1000 person-years).⁸⁶ The HR for DVT was 2.07 (95% CI, 1.49 to 2.87) with 167 cases, and for PE, it was 2.13 (95% CI, 1.39 to 3.25) with 101 cases. The estimated excess number of events per 1000 women taking estrogen plus progestin for 10 years was 18. In women with a hysterectomy who received estrogen alone, the risk was attenuated, with an HR of 1.33 and a 95% CI of 0.99 to 1.79.⁷⁰ Only the increased risk of DVT reached statistical significance. The HR for DVT was 1.47 (95% CI, 1.04 to 2.08), and for PE, it was 1.34 (95% CI, 0.87 to 2.06).

An additional nested case-controlled study examining the association of various biomarkers, treatment assignment, and the risk of vascular outcomes was conducted during the WHI study.⁸⁶ All validated cases of VTE that occurred between randomization and a selected 2-year follow-up time point ($n = 147$) were paired with control cases matched for age, follow-up time, and baseline vascular disease. Analysis revealed that the risk associated with HRT increased with age: HR was 4.28 (95% CI, 2.38 to 7.72) in women aged 60 to 69 years and 7.46 (95% CI, 4.32 to 14.38) in women aged 70 to 79 years as compared with women aged 50 to 59 years who were taking placebo. The risk was also increased in overweight (BMI 25 to 30) and obese (BMI > 30) women with a HR of 3.80 (95% CI, 2.08 to 6.94) and 5.61 (95% CI, 3.12 to 10.11), respectively. Factor V Leiden positivity increased the hormone-associated risk of thrombosis by 6.69-fold over that reported in women on placebo without the mutation (95% CI, 3.09 to 14.49). A 2.6-fold increase was seen among heterozygotes and a 7.5-fold increase was noted among homozygotes, leading to an estimated absolute risk of VTE of 0.8% per year among women carrying an FV Leiden mutation and taking HRT. Estimates range from 795 unselected healthy women to 376 women with coronary heart disease who needed to be screened for FV Leiden mutations prior to initiation of HRT to prevent one episode of VTE over 5 years of treatment.⁸⁸ Different from users of OCs, other measured genetic variants, including prothrombin 20210, methylenetetrahydrofolate reductase mutation C677T, factor XIII Val34-Leu, PAI-1 4G/5G, and factor V HR2, were not found to modify the association of HRT with venous thrombosis. It is possible that the lower estrogen dose in HRT versus that in OCs explains this difference, rather than simply a higher baseline level of VTE in postmenopausal women compared with younger women that obscures the interaction.

Some data suggest that the mode of supplying estrogen may be crucial to the risk of VTE; it is intimated that transdermal estrogen may not be associated with an increased risk of thromboembolic events. In contrast to three very small prior case-controlled studies that showed a nonsignificant increased risk of VTE in users of transdermal HRT, Scarabin and colleagues⁷⁶ recently performed the hospital-based case-controlled Estrogen and Thromboembolism Risk (ESTHER) study in France to assess women

with a first documented episode of idiopathic VTE. Overall, 32 patients (21%) and 27 controls (7%) were found to be current users of oral estrogen only replacement therapy versus 30 patients (19%) and 93 controls (24%) who were current users of transdermal HRT. The estimated risk of VTE in users of oral HRT was 3.5 (95% CI, 1.8 to 6.8); in users of transdermal HRT, it was 0.9 (95% CI, 0.5 to 1.6) compared with nonusers. When users of estrogen-only HRT were compared with users of transdermal HRT, the estimated risk of VTE was 4.0 (95% CI, 1.9 to 8.3).^{76,85} This finding is biologically plausible in that oral but not transdermal estrogen has been found to enhance *in vivo* thrombin generation and induce an acquired resistance to protein C.^{9,12} In addition, a lower antithrombin III concentration has been found in women on oral but not transdermal HRT.⁸⁹ It is possible that although oral HRT induces a procoagulant environment caused by an increase in general hepatic protein synthesis, transdermal estrogen replacement therapy has little effect on hemostasis. However, several confounding variables may exist in this observational study, including recall bias, preferential referral of cases, and in appropriateness of the selection of controls (they had more illnesses such as diabetes and were potentially unequally likely to be taking HRT). Data from large studies such as KEEPS will be instrumental in helping clinicians to prospectively determine the safety of transdermal estrogen therapy.

HRT is generally believed to be contraindicated in women with a history of DVT because of the unacceptable risk of recurrent events. Before the results of large trials such as HERS and WHI were known, Hoibraaten and coworkers⁵⁷ studied the risk of giving HRT to 140 postmenopausal women with a history of DVT or PE. The study was terminated prematurely for ethical reasons after the findings of the HERS trial were published. Despite the limited duration of the trial, a high incidence of recurrent VTE in women randomly assigned to hormonal therapy was found: eight women in the HRT group (10.7%) versus one woman in the placebo group (2.3%) developed VTE. Furthermore, all those in the HRT group experienced a thrombotic event within the first 261 days after inclusion in the study. Treatment groups were similar with regard to other risk factors for VTE, including time from previous VTE and rates of inherited thrombophilia (28% of women on HRT and 22% of women in the placebo group), suggesting that the bulk of the excess risk of thrombosis found in this study could be attributed to HRT. Few women with a prior history of VTE were enrolled in the WHI because of the eligibility criteria, but data also suggest an increased risk in this population: with HRT, HR 3.87 (95% CI, 0.45 to 33.34) versus those without a history of VTE, HR 2.06 (95% CI, 1.54 to 2.76).

In women who need to take HRT but who are at high risk of VTE, anticoagulation with warfarin or low molecular weight heparin may be considered, but no clinical trials have been performed to date to confirm the safety of this approach. This group includes women with a prior history of VTE, as well as those who carry an inherited thrombophilic state such as FV Leiden. In the HERS study, a trend toward the beneficial effects of baseline aspirin use was noted to attenuate the risk of thromboembolic disease (HR, 1.68; 95% CI, 0.96 to 2.92 for aspirin users vs HR, 4.23; 95% CI, 1.41 to 12.7 for nonusers),⁸⁷ although this was not seen in the WHI.

The decision regarding whether a woman should initiate or continue short-term hormonal therapy for menopausal symptom control must be made by weighing her individual risk:benefit ratio. The risk of VTE is unknown in women who take HRT for only a few months, although observational evidence suggests that the risk seems greatest during the first several months to 1 year after initiation of HRT. Phytoestrogens have also been used to relieve postmenopausal symptoms; the few prospective studies performed to date have not yet found any potential adverse effects of soy products on the coagulation system.⁹⁰

SELECTIVE ESTROGEN RECEPTOR MODULATORS/SELECTIVE ESTROGEN RECEPTOR DOWN-REGULATORS, AROMATASE INHIBITORS, AND THROMBOSIS

Tamoxifen is one of the most effective treatments for patients with breast cancer because of its ability to antagonize estrogen-dependent growth by binding estrogen receptors and inhibiting proliferation of breast epithelial cells. However, tamoxifen has estrogenic agonist effects in other tissues such as bone and endometrium. Several novel anti-estrogenic compounds have been developed that have a reduced agonist profile in breast and gynecologic tissue; they thus offer the potential for enhanced efficacy and reduced toxicity compared with tamoxifen. In advanced breast cancer, clinical data are available for two groups of agents: selective estrogen receptor modulators (SERMs—further divided into “tamoxifen-like,” namely, toremifene, droloxifene, and idoxifene, and “fixed-ring” compounds, namely, raloxifene, arzoxifene, and EM-800) and selective estrogen receptor down-regulators (SERDs—fulvestrant, SR 16234, and ZK 191703).

The estrogen agonist/antagonist tamoxifen is widely used in the management of breast cancer. Currently, this drug is used in the adjuvant setting after local therapy is provided for early-stage breast cancer that is hormone receptor positive, in the treatment of patients with metastatic breast cancer that is hormone receptor positive, and prophylactically in women deemed at high risk for the development of invasive breast cancer. In a meta-analysis of four major primary prevention trials of tamoxifen involving 28,406 subjects, the use of tamoxifen was associated with 118 serious VTEs versus 62 in the placebo group, with a relative risk of 1.9 (95% CI, 1.4 to 2.6), including six versus two cases of fatal pulmonary emboli. The risk of superficial thrombophlebitis was doubled with tamoxifen relative to placebo (68 vs 30 events).⁹¹

Saphner and associates⁹² retrospectively analyzed the 10-year experience of 2673 women with breast cancer in multicenter trials conducted by the Eastern Cooperative Oncology Group (ECOG); an increase in VTE was associated with tamoxifen therapy alone, as well as with a substantial increase in patients allocated to combined treatment with tamoxifen plus chemotherapy compared with untreated controls or those who received chemotherapy alone. Specifically, the data showed that premenopausal patients who received chemotherapy and tamoxifen had a greater number of venous events than did those who received chemotherapy

without tamoxifen (2.8% vs 0.8%; $P = .03$). Postmenopausal patients who received tamoxifen and chemotherapy had a greater number of venous thrombi than did those who were given tamoxifen alone (8.0% vs 2.3%; $P = .03$) or those who were observed (8.0% vs 0.4%; $P < .0001$). These findings and data from other studies suggest that chemotherapy contributes to thrombosis in patients with breast cancer.⁹³ A large United Kingdom–based General Practice Research Database study concluded that the relative risk estimate for VTE with current tamoxifen exposure, as compared with those who were never exposed and past use as a reference group, was 7.1 (95% CI, 1.5 to 33).⁹⁴

In the breast cancer prevention trial, the National Surgical Adjuvant Breast and Bowel Project B-24 (NSABP P-1),⁹⁵ a randomized clinical trial of 13,388 women to evaluate the effectiveness of tamoxifen in the prevention of breast cancer in women considered to be at increased risk of the disease, the use of tamoxifen was associated with an increased risk of VTE. Pulmonary emboli were observed in almost three times as many women in the tamoxifen group as in the placebo group (18 vs 6; RR, 3.01; 95% CI, 0.15 to 9.27). A greater number of women who received tamoxifen developed DVT compared with women who received placebo (35 vs 22 cases, respectively). Average annual rates per 1000 women treated were 1.34 versus 0.84 (RR, 1.60; 95% CI, 0.91 to 2.86). (See Table 34-4 for a summary of tamoxifen breast cancer prevention studies.)^{101–103}

In the NSABP B-24 randomized trial, in which the use of tamoxifen after lumpectomy and radiation therapy for ductal carcinoma in situ was compared with the use of placebo, one extra pulmonary embolism and seven extra deep venous thromboses were noted in the treatment arm.⁹⁶ A total of 891 women in the tamoxifen group had nine deep venous thromboses (1%) and two pulmonary emboli (0.2%). The placebo arm consisted of 890 women who had two deep venous thromboses (0.2%) and one pulmonary embolus (0.1%).

Relative risk estimates from studies published to date on the use of tamoxifen range from no effect up to a 7-times increased incidence of VTE. Most authorities in the field quote a 2- to 4-times increased relative risk for VTE with the use of tamoxifen versus that in patients who were not receiving the drug. Again, as has often been discussed in this chapter, the absolute risk of VTE in a patient on tamoxifen may be so low as to not influence the decision to use the agent in the management of any individual patient's breast cancer. Known thrombophilic mutations, such as FV Leiden and prothrombin 20210, do not appear

to interact with tamoxifen to impose an increased risk for VTE. A case-controlled study conducted by the National Surgical Adjuvant Breast and Bowel Project's Breast Cancer Prevention Project (BCPT) in 371 subjects compared the rate of FV Leiden and prothrombin 20210 mutations in women who experienced a VTE while receiving tamoxifen versus placebo. No statistical evidence of an additive effect of tamoxifen use to these two genetic mutations on the rate of thromboembolic events was found. They concluded that screening women at risk for breast cancer for FVL and/or prothrombin 20210 appears to offer no benefit in determining the risk of tamoxifen-associated thromboembolic events.⁹⁷

Raloxifene hydrochloride is a SERM that is chemically distinct from tamoxifen and estradiol and that has antiestrogenic effects on breast and endometrial tissue and estrogenic effects on bone, lipid metabolism, and the coagulation system. Currently, raloxifene is FDA approved for the treatment of patients with postmenopausal osteoporosis. The Multiple Outcomes of Raloxifene Evaluation (MORE) study, which treated a total of 7705 postmenopausal women with osteoporosis, was the pivotal trial that led to the drug's approval.⁹⁸ In the MORE study, the use of raloxifene increased the risk of VTE (relative risk, 3.1; 95% CI, 1.5 to 6.2). After 40 months of follow-up, higher rates of DVT (38 cases) and PE (17 cases) were observed in the combined raloxifene groups (60-mg and 120-mg doses were used) than in the placebo groups (5 and 3 cases, respectively). One case of VTE occurred per 155 women treated with raloxifene for 3 years.

Raloxifene and tamoxifen both appear to increase the risk of VTE but to different degrees. The Study of Tamoxifen and Raloxifene (STAR) trial, one of the largest breast cancer prevention trials ever undertaken, randomized 19,747 postmenopausal women at high risk for breast cancer to receive either tamoxifen or raloxifene for 5 years. The investigators found no difference in the number of invasive breast cancers in each group, but fewer noninvasive breast cancers in the tamoxifen arm. Thromboembolic events occurred less often in the raloxifene group (RR, 0.70; 95% CI, 0.54 to 0.91). The cumulative incidence at 6 years was 21 per 1000 in the tamoxifen arm and 16 per 1000 in the raloxifene arm. PE and DVT occurred in 54 versus 35 women (RR, 0.64; 95% CI, 0.41–1.00) and in 87 versus 65 women (RR, 0.74; 95% CI, 0.53–1.03) assigned to tamoxifen and raloxifene, respectively. Fewer cases of uterine cancer and cataracts occurred in the raloxifene arm.

Table 34-4 Tamoxifen Breast Cancer Prevention Trials*

	Royal Marsden Trial ¹⁰¹		NSABP P-1 ⁹⁵		Italian Tamoxifen Study ¹⁰²		IBIS-1 ¹⁰³		All Trials	
	T	P	T	P	T	P	T	P	T	P
Total patient no.	1238	1233	6681	6707	2700	2708	3573	3566	14192	14214
Breast cancers	62	75	124	244	34	45	69	101	289	465
DVT and PE	12	8	53	28	10	9	43	17	118	62
Superficial thrombophlebitis	8	5	NA		33	16	27	9	68	30

*The number of patients who experienced each end point is shown in the table.

DVT, deep venous thrombosis; IBIS-I, International Breast Cancer Intervention study I; Italian, Italian Tamoxifen Prevention study; Marsden, The Royal Marsden Hospital Tamoxifen Randomized Chemoprevention trial; NSABP P-1, National Surgical Adjuvant Breast and Bowel Project P-1 study; P, placebo; PE, pulmonary embolism; T, tamoxifen.

No differences were found in ischemic heart disease events, stroke, other invasive cancer sites, osteoporotic fractures, or mortality. At present, it is considered prudent not to prescribe either raloxifene or tamoxifen to a woman with a history of VTE, but this decision should be individualized on the basis of the woman's clinical history and known underlying risk factors. Consideration may be given to the use of DVT prophylaxis in combination with raloxifene or tamoxifen if the benefits of treatment are deemed greater than the associated risks.^{98a}

AROMATASE INHIBITORS

At present, the treatment of postmenopausal women with hormone-responsive breast cancer is undergoing a shift toward the use of aromatase inhibitors instead of tamoxifen. In the United States, three aromatase inhibitors are clinically available: anastrozole (Arimidex; AstraZeneca Pharmaceuticals LP, Wilmington, DE, USA), letrozole (Femara; Novartis Pharmaceuticals Corporation, East Hanover, NJ, USA), and exemestane (Aromasin; Pfizer Inc, New York, NY, USA). The former two are nonsteroidal compounds with reversible binding properties, and the latter one is a steroidal compound with irreversible binding properties. Emerging data indicate that in terms of VTE risk, these agents are safer than tamoxifen. In the Arimidex, Tamoxifen, Alone or in Combination (ATAC) trial, patients experienced 73 total venous thromboembolic events on anastrozole (2%) versus 120 events on tamoxifen (4%), with an odds ratio of 0.60 (95% CI, 0.44 to 0.81).⁹⁹ Specifically, for deep venous thromboembolic events, patients on anastrozole experienced 40 events (1%) versus 60 events on tamoxifen (2%), with an odds ratio of 0.66 (95% CI, 0.43 to 1.00). In other words, anastrozole users experienced half the venous thromboembolic events that tamoxifen users reported, that is, 2% versus 4%.

Aromatase inhibitors are now the agents of choice in postmenopausal women with hormone-responsive breast cancer, both in the metastatic setting and alone or in sequence with tamoxifen in the early/adjuvant setting. They are currently being tested in breast cancer prevention trials, where the toxicity profiles of these agents have increased importance because of the otherwise healthy nature of the population.

SUMMARY

Although numerous studies have explored the thrombotic potential of the agents discussed in this chapter, data in many areas are insufficient to confirm true risks of VTE. Often, the absolute risks for adverse events are so low that they do not affect the risk:benefit calculations that go into the decision of whether or not to use these agents. It is conceivable that in the future, more comprehensive pharmacogenomic studies will lead to individualization of hormonal contraception and HRT recommendations. As is almost always the case in clinical medicine, decisions must be highly individualized, because the benefits of these agents to the patient and to society may be large, and the risks may be small. With continued use of hormonal therapies, the need to better define risks for thrombotic

events in women with a remote history of thrombosis or a laboratory-defined thrombophilia is clear. Additionally, improved understanding of the pathogenesis of hormonally induced thrombosis would aid in the development of new therapies without this adverse effect.

Management of Bleeding Disorders in Pregnancy

Stephanie Seremetis, MD • Victoria Afshani, MD

INTRODUCTION

Bleeding disorders during pregnancy and the puerperium pose specific and sometimes difficult management problems for the obstetrician and the consulting hematologist. Issues associated with diagnosis and management may be related to the mother and her unborn child. Various bleeding disorders can be categorized into several distinct categories. The first includes the inherited disorders, including the relatively common von Willebrand disease (VWD), the less common factor deficiencies, and inherited platelet disorders. The second category comprises acquired disorders that typically manifest prior to pregnancy, including immune thrombocytopenic purpura (ITP) and clotting factor inhibitors, but may also first occur in the context of pregnancy. Finally, disorders related directly to physical or pathophysiologic mechanisms may occur during pregnancy. Alterations in the normal hematologic responses to pregnancy that lead to dysregulation of the clotting cascade include disseminated intravascular coagulation (DIC) and hemolysis with elevated liver function and low platelets (HELLP) syndrome. Obstetric and anatomic causes include placental issues such as placenta previa, placenta accreta, and abruptio, ectopic pregnancy, abortion and miscarriage, uterine atony due to twins or prolonged delivery, and retained products of conception. For management of these presentations, the reader is referred to textbooks on obstetrics and gynecology. Occasionally, medications are implicated when a bleeding tendency develops during pregnancy. The use of aspirin and heparin in women who have cardiac disease, including coronary artery disease and cardiac valve replacement with mechanical prostheses, as well as in women with systemic lupus erythematosus (SLE) with or without circulating anticoagulants or with known venous or arterial thromboses, have the potential to cause increased bleeding during pregnancy.

INHERITED DISORDERS OF BLEEDING IN PREGNANCY

Coagulation Factor Changes During Normal Pregnancy

Normal pregnancy is a relatively procoagulant state in that coagulation and fibrinolytic pathways undergo major changes that lead to a net increased propensity for hemostasis.

Concentrations of some coagulation factors increase significantly, as do concentrations of plasminogen activation inhibitors, which reduce the activity of the fibrinolytic system. Both factor VIII and von Willebrand factor (VWF) increase steadily throughout gestation.^{1–5} Factors VII and X and fibrinogen also rise significantly.^{4,6} Other factors in the clotting cascade—factors II, IX, XII, and XIII—show no differences in levels throughout pregnancy.⁶ Controversial data regarding factor XI levels have been published, with reports of either an increase or a fall in levels associated with advancing gestation.^{6,7} Additionally, platelet count may decrease slightly during the third trimester because of dilution caused by hydremia during normal pregnancy but not to a degree that will pose a risk of bleeding during delivery.^{8,9} Bleeding time, which reflects primary hemostasis, remains normal throughout pregnancy or may shorten, reflecting the increased platelet–endothelium interactions of pregnancy. Prothrombin time (PT) and partial thromboplastin time (PTT) may decrease to the lower limits of normal or may be slightly shortened in plasma from women in the third trimester, suggesting a low-grade process of intravascular coagulation.⁹

Coagulation Factor Changes in Inherited Bleeding Disorders

In pregnant women with inherited bleeding disorders, the data regarding coagulation factor levels are less certain. Women with type 1 VWD or who are carriers of hemophilia A sustain a significant rise in levels of factor VIII and in the antigen and activity of VWF during the second half of pregnancy. These women therefore rarely need hemostatic treatment later in pregnancy or during delivery. Factor IX levels, in contrast, remain relatively constant during gestation. Factor XI levels have not been measured prospectively during pregnancy in patients who are deficient in factor XI.

von Willebrand Disease

VWD is the most common inherited bleeding disorder, with prevalence in the general population estimated at 1% to 3%⁴ (see Chapter 7 for a detailed discussion of VWD). The precise frequency of VWD is difficult to determine because there is considerable genotypic and clinical heterogeneity in this disorder. Most cases of VWD are inherited in an autosomal dominant pattern; thus, the

implications for women of childbearing age are significant. The disorder is classified into three major types—types 1, 2, and 3—on the basis of the specific pathophysiologic mechanisms involved. The classification of VWD was recently the subject of a consensus committee of the International Society on Thrombosis and Haemostasis,¹⁰ which proposed a revised system that retains the three major types of VWD and further classifies type 2 into four subtypes on the basis of laboratory and clinical data. Type 1 VWD, which accounts for 70% to 80% of all cases, usually causes only mild bleeding. Type 2 occurs in 10% of cases. Type 3 VWD, which is the only form that is inherited in an autosomal recessive pattern, accounts for an additional 10% of cases and causes the most severe bleeding manifestations. Correct determination of the specific subtype of VWD becomes important for counseling and therapy during pregnancy and delivery.^{10,11}

Clinical Manifestations of VWD at Diagnosis

The clinical manifestations of VWD classically consist of mucocutaneous hemorrhage, which contrasts with the deep-tissue hemorrhage associated with hemophilia A. Many cases, particularly of milder forms, remain undiagnosed until the pathways of coagulation are exposed to the stress of trauma, surgery, or administration of antiplatelet agents. Increasingly, menorrhagia has been identified as a sentinel symptom of an inherited coagulopathy in menstruating women.¹² Menorrhagia of long-standing duration, specifically from onset of menarche, recently has been shown to be a valuable predictor of a systemic bleeding disorder and may provide the first clue to milder forms of these disorders.¹³ In one study, menorrhagia was defined objectively and was measured as a method of screening for bleeding disorders; 17% of women with this problem were subsequently diagnosed as having a coagulopathy. Conversely, almost 75% of women with a defined coagulopathy reported menorrhagia as a symptom.^{12,13}

Changes in Factor Levels with Gestation

Among the original observations made by von Willebrand regarding the disease named for him was that obstetric patients with this disorder were at less risk of hemorrhage during pregnancy than at any other time. He also observed that these patients were at increased risk for postpartum bleeding episodes.¹⁴ Type 1 VWD, which is a quantitative disorder that results from an absolute deficiency of VWF, typically has equivalently low plasma levels of all three aspects of the factor VIII complex: factor VIII coagulant activity (FVIII:C), VWF antigen (VWF:Ag), and VWF activity (VWF:Ac), usually in the range of 5 to 40 IU per deciliter. During pregnancy in type 1 patients, factor levels of VWF and factor VIII increase steadily, beginning in the second trimester, to levels that reach three to four times nonpregnant baseline levels by the time of delivery in most women. Levels may increase even further during active labor.² Immediately postpartum, levels begin to fall rapidly, and within several weeks, they reach prepregnancy status.

Type 2A VWD is a qualitative disorder caused by mutations in the VWF gene that result in a variable decrease in plasma VWF:Ag, a marked decrease in VWF:Ac measured as the VWF ristocetin cofactor (RcoF), and the absence of high and intermediate molecular weight VWF forms on gel electrophoresis.¹⁵ The severity of the bleeding risk is

proportionate with the level of vWF:RcoF.¹⁶ VWF levels increase throughout pregnancy, but the abnormal multimers remain; thus, the benefit of this increase may not be as significant as for type 1 disease. Type 2B is further characterized by a mutation in the VWF gene that causes increased affinity for the platelet membrane glycoprotein Ib. Thrombocytopenia results from enhanced binding of platelets to VWF, and as VWF levels rise during pregnancy, thrombocytopenia may worsen.¹⁷ Increased platelet aggregation, even in the setting of thrombocytopenia, may paradoxically predispose to thrombosis.

Type 3 VWD, the most severe and least common form, results from total absence of VWF:Ag and VWF:Ac caused by gross mutations of the VWF gene, with a resultant severe decrease (i.e., 2% to 5% of normal) in FVIII:C. Levels do not rise during pregnancy; therefore, pregnant women with this form of VWD remain at severe risk of hemorrhage throughout pregnancy, as well as during the postpartum period.

General experience suggests that low RcoF levels are the most important determinant of abnormal surgical or peripartum bleeding. Bleeding risk for most women with VWD appears to be greatest during the immediate postpartum or postabortion period, when factor VIII and VWF levels may drop precipitously.³ Monitoring of factor levels should occur at least every 8 to 12 weeks, beginning at the confirmation of pregnancy and continuing for 6 to 8 weeks postpartum.¹⁸ More frequent testing may be necessary during the puerperium. Factor levels of 50 IU per deciliter, which reflect the lower end of the normal range, generally are considered to be a safe threshold above which the risk of bleeding complications is not increased; they are the usual therapeutic goal for replacement therapy when such intervention is indicated.

First-trimester vaginal bleeding occurred in women with VWD at a rate of 33% in one study, which is twice the observed incidence of 16% in all pregnant women. However, the overall spontaneous miscarriage rate is the same (21%) in both groups, reflecting no evidence of increased pregnancy loss in this population. Increased documentation of even minor vaginal bleeding may reflect a reporting bias in women who have a heightened awareness of the significance of gestational bleeding in their circumstances. Furthermore, the incidence of antepartum hemorrhage was not increased in VWD.⁵

Therapy During Labor and Delivery

It is useful to recheck factor levels at 34 to 36 weeks gestation in preparation for delivery. At coagulation factor levels of 50 IU per deciliter and above, uncomplicated vaginal deliveries are unlikely to be associated with abnormal bleeding. If labor is prolonged, or if a cesarean section is planned or becomes necessary, factor levels should ideally exceed 50 IU per deciliter to minimize bleeding. A planned date of delivery by induction or by cesarean section may facilitate the timing of administration of factors. Many patients with type 1 VWD and some with type 2A do not require additional intervention prior to delivery because their factor levels have increased. Table 35-1 outlines therapies for various procedures that are performed during pregnancy or at parturition. Typically, factor concentrates such as Humate-P (ZLB Behring GmbH, Marburg, Germany), Alphanate (Grifols Biologicals, Inc., Los Angeles, Calif, USA), or

Table 35-1 Suggested Treatment During Pregnancy of Patients with Von Willebrand Disease

Type	1	2A	2B	3
Change expected with pregnancy	Usually normalize	May normalize	Von Willebrand factor rises, platelets fall	No change
Therapy for antenatal procedures (<50 IU per deciliter)	Humate-P, Alphanate, or Koate-DVI for 2–3 days	Humate-P, Alphanate, or Koate-DVI for 2–3 days	Humate-P, Alphanate, or Koate-DVI for 2–3 days	Humate-P, Alphanate, or Koate-DVI for 2–3 days
Vaginal delivery	No replacement if >50 IU per deciliter*	No replacement if >50 IU per deciliter*	Factor concentrate	Factor concentrate
Cesarean section	No replacement if >50 IU per deciliter*	No replacement if >50 IU per deciliter*	Factor concentrate for 7 days	Factor concentrate for 7 days
Postpartum	DDAVP/factor concentrate 3–4 days	DDAVP/factor concentrate 3–4 days	Factor concentrate for 3–4 days	Factor concentrate for 3–4 days

*If no factor replacement, monitor factor levels for 2 to 4 days after delivery.

Humate-P is manufactured by ZLB Behring GmbH, Marburg, Germany.

Alphanate is manufactured by Grifols Biologicals, Inc., Los Angeles, Calif, USA.

Koate-DVI is manufactured by Talecris Biotherapeutics, Inc., Research Triangle Park, NC, USA.

Koate-DVI (Talecris Biotherapeutics, Inc., Research Triangle Park, NC, USA),^{19,20} which contain both factor VIII and VWF, are used to replace deficient factors in type 2B and type 3 VWD, as well as in those few patients with type 1 or 2A who do not reach acceptable factor levels. Parturient women with type 2B or type 3 VWD probably should receive factor replacement to a level greater than 50 IU per deciliter for at least 3 to 4 days to minimize hemorrhage. Specific dosing with clotting factor concentrates during pregnancy has not been established as distinct from other surgical prophylaxis in VWD. Data are available only from anecdotal reports and must be generalized from larger experience in the use of these clotting factor concentrates in surgery.¹⁶ Dosing recommendations are made in terms of RcoF units, with the caution that only one of the currently available clotting factor concentrates that contain VWF (Humate-P) is labeled specifically with reference to RcoF units (see product insert, ZLB Behring). Delivery should be regarded as a moderate or severe challenge to hemostasis and should be treated by analogy as minor or major surgical episodes are treated. Thus, in major hemostatic challenge (e.g., cesarean section), a dose of 50 to 75 IU per kilogram VWF should be given, with subsequent dosing at 40 to 60 IU per kilogram every 8 to 12 hours for 3 days; the goal is to maintain the nadir level of RcoF at greater than 50 IU per deciliter.¹⁶ Therapy can be changed to daily administration of 50 IU per kilogram for a total of up to 7 days of treatment. Again, it is difficult to establish clear norms for use of this intervention, in that very few to no data are available. It is widely assumed that cesarean section introduces the same stresses as a major surgical procedure, and episiotomy or a low-degree tear during delivery presents a minor surgical stress.

DDAVP in Pregnancy

Intravenous administration of 1-deamino-8-D-arginine vasopressin (DDAVP; desmopressin) increases FVIII:C and VWF concentrations by stimulating V-2 receptors. This elevation lasts for longer than 6 hours, and the biologic half-life is only marginally shorter than that of exogenous factor VIII and VWF from plasma concentrates.²¹ DDAVP has also been shown to prevent bleeding in mild or moderate hemophilia or VWD. Some hematologists and obstetricians are reluctant to use it during pregnancy

because of the risk of inducing uterine contractions and preterm labor. However, DDAVP is very specific to V-2 receptors and has little effect on smooth muscle V-1 receptors and consequently does not cause uterine contractions.²² The other concern regarding antenatal use of DDAVP involves a possible decrease in blood flow from the placenta and subsequent intrauterine growth retardation; however, the vasopressor effect of DDAVP is weak.²² Several publications have discussed the management of diabetes insipidus²³ and Ehlers-Danlos syndrome²⁴ in pregnant women with no harm to the fetus. Although the theoretical risk of uterine contraction may be a contraindication to use during pregnancy, this should not be a problem for a patient in labor. The use of DDAVP is indicated during the immediate postpartum period in type 1 and type 2A VWD, generally for a period of 3 to 4 days, to minimize the risk of postpartum hemorrhage, which has occurred in as many as 25% of parturients in some series.²⁵ When DDAVP is used during the postpartum period, hyponatremia has been reported; thus, serum sodium concentration should be monitored during DDAVP therapy. The use of hypotonic intravenous fluids should be minimized, and oral fluids should be somewhat restricted. Women who present with spontaneous miscarriage or elective termination are also at increased risk for hemorrhage and should empirically receive DDAVP therapy (if type 1 or 2A) or clotting factor concentrate for several days after the event. Women who exhibit evidence of bleeding despite DDAVP therapy should also receive a factor concentrate such as Humate-P.

Therapy During Prenatal Diagnostic Testing and for Anesthesia

Prenatal diagnosis of the fetus usually occurs within the first trimester of pregnancy, either by chorionic villous sampling or by amniocentesis. It is therefore possible, but less likely than would be the case later in pregnancy, that the coagulation factors involved will have increased to a safe range for invasive procedures. Measurement of maternal FVIII:C should be performed within 1 week of the procedure, and adequate therapy administered for factor VIII levels significantly below 50 IU per deciliter. Because this procedure represents a minor hemostatic challenge, correction should continue for 48 to 72 hours after it is

completed. Clotting factor concentrates may be used; in this instance, too, researchers disagree about the role of DDAVP. Anecdotes describe its use, and the literature provides no evidence of a specific contraindication in early pregnancy. It is our practice to have a comprehensive discussion with the patient about the risks and benefits of each of the approaches, and to individualize therapy.

The use of regional anesthesia must be considered for each woman because recommendations remain controversial. In one series, patients with type 1 or 2A VWD underwent epidural catheter placement when factor VIII levels measured 50 IU per deciliter or higher without untoward consequences.²⁶ Some centers recommend that bleeding time should also be checked, and they specify that if it is less than 15 minutes, the risk for hemorrhagic complications is not increased.

Hemophilias

Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are both inherited in an X-linked recessive pattern. Women from hemophilia-affected families are most commonly asymptomatic carriers. However, 10% to 20% of female carriers may be at risk for significant bleeding complications caused by extreme lyonization and subsequent reduction of factor VIII or IX to levels below the minimal amount needed to maintain hemostatic equilibrium. Because only one chromosome is affected, hemophilia carriers would be expected on average to have factor levels that are 50% of normal, with normal defined as ranging from 50 to 150 IU per deciliter. However, levels as low as 5% have been reported to occur as a result of lyonization—the random inactivation of one of each pair of X chromosomes.²⁷ Factor levels below 30 IU per deciliter may lead to clinical bleeding analogous to that seen in mild hemophilia A.²⁸

Two unusual conditions may result in factor VIII levels low enough to cause concern during pregnancy. The first, VWD type 2N (Normandy), consists of distinct missense mutations that inactivate the binding site of factor VIII on VWF. Platelet function and multimer patterns are normal, but FVIII:C levels are low—frequently less than 10%—which causes patients' laboratory results to resemble those of patients with mild hemophilia A. Because of the qualitative defect in the VWF protein, these patients have short-lived factor VIII response to DDAVP or to highly purified or recombinant factor VIII products. The agent of choice during pregnancy is a plasma-derived VWF product such as Humate-P, which contains normal VWF along with factor VIII.^{29,30}

In the second condition, Turner syndrome (gonadal dysgenesis), the 45,X karyotype seen in 50% of cases produces streak gonads and infertility. However, 25% of affected individuals have (46,XX/45,X) mosaicism, and 25% have a (46,XX) structurally abnormal X chromosome.³¹ A small number of these women have sufficient follicles to become pregnant, and if they are from hemophilia A-affected families, patients may exhibit severe factor deficiencies that must be managed appropriately during pregnancy.

The literature is limited regarding changes in clotting factors during pregnancy in patients with bleeding disorders. However, a significant rise in FVIII:C, vWF:Ag, and

VWF:Ac has been reported in normal women, in carriers of hemophilia A, and, as previously discussed, in patients with VWD of various subtypes. These increases generally begin during the late first trimester, and gradually, levels continue to increase until the end of pregnancy. It is therefore extremely rare for women, even those who have low factor VIII levels at baseline as a consequence of extreme lyonization, to require treatment during late pregnancy or at parturition. However, prophylaxis for bleeding must be considered at the time of prenatal diagnostic testing; carriers with low factor VIII levels (whose levels may still be lower than 50 IU per deciliter at term) are at considerable risk of bleeding and require prophylactic treatment. In contrast to factor VIII and VWF, factor IX levels do not increase throughout pregnancy, although controversial results have been published regarding changes in this plasma protein. Hemostatic challenges of pregnancy, such as invasive prenatal diagnostic techniques, termination of pregnancy, spontaneous abortion, normal spontaneous vaginal delivery, and delivery by cesarean section, are all complicated by excessive and prolonged hemorrhage. Therefore, it is important that factor levels are checked before any of these procedures are undertaken, and that prophylactic treatment is arranged when factor levels are lower than 50 IU per deciliter for factors VIII and IX.³² Because it may not be possible to measure factor levels in emergency situations, we recommend that these should be assayed at regular intervals during gestation—at least once per trimester. Usually, carriers of hemophilia A normalize factor VIII levels during pregnancy to well above 50 IU per deciliter and thus do not require therapeutic intervention. However, women who are carriers of factor IX deficiency often require prophylactic treatment with clotting factor concentrate because levels do not significantly change during pregnancy.

For women who are carriers of hemophilia A, DDAVP may be considered as an appropriate pharmacologic intervention to increase the level of factor VIII to above 50 IU per deciliter. Provisions regarding the use of this agent were outlined in the section on treatment of VWD during pregnancy and are not repeated here. If response to DDAVP is inadequate, or if the physician or the patient is uncomfortable about the use of DDAVP after the risks and benefits of this therapeutic approach have been comprehensively discussed, then treatment with recombinant factor VIII concentrates should be considered in the context of prophylaxis of excessive bleeding during invasive procedures or at the time of delivery (Table 35-2). Again, interventions at the time of prenatal diagnostic testing generally involve minor surgical procedures that require 3 days of therapy at levels that allow the attainment of a nadir of 50 IU per deciliter. Calculations of the dose to be administered are based on the baseline clotting factor available and the desired goals of therapy. Women who are carriers of hemophilia B are at increased risk of bleeding when diagnostic interventions are provided during pregnancy or at the time of labor and delivery. If the patient requires correction of the baseline concentration of factor IX, the use of recombinant factor IX concentrates is indicated (see Table 35-2). The goal is to maintain a nadir of 50 IU per deciliter or higher. Most diagnostic interventions are viewed as minor surgical procedures; cesarean section is considered a major surgical procedure.

Table 35-2 Suggested Factor Replacement for Selected Inherited Bleeding Disorders

	Prenatal Procedure/Labor and Delivery	Postpartum Care
Hemophilia A carrier	Factor >50 IU per deciliter: No therapy Factor <50 IU per deciliter: DDAVP or rFVIII × 3 days	No therapy DDAVP or factor VIII concentrate for 3–4 days
Hemophilia B carrier	Factor >50 IU per deciliter: No therapy Factor <50 IU per deciliter: rFIX concentrate × 3 days	No therapy rFIX concentrate 3–4 days
Factor VII deficiency	rFVIIa 15–30 mg per kilogram every 6 hours × 3 days	rFVIIa 15–30 mg per kilogram every 6 hours × 3 days
Factor XI deficiency	Factor XI concentrate to goal 40 IU per deciliter × 1 dose (10–15 mL per kilogram) or FFP	Factor XI concentrate every 48 hours × 3–5 days (10–15 mL per kilogram) or FFP
Factor XIII deficiency	Treatment throughout pregnancy with cryoprecipitate or factor XIII concentrate	3–4 days of cryoprecipitate or factor XIII concentrate

DDAVP, 1-deamino-8-D-arginine vasopressin; FFP, fresh frozen plasma; rFVIIa, recombinant factor VIIa; rFVIII, recombinant factor VIII; rFIX, recombinant factor IX.

Factor XI Deficiency

Factor XI deficiency is a genetic disorder that is prevalent among Ashkenazi Jews, with a heterozygous frequency of 8%.³³ Its frequency in non-Jews is unknown. The inheritance pattern is autosomal; severe deficiency occurs in homozygotes, and partial deficiency has been noted in heterozygotes. Normal plasma levels are 70 to 150 IU per deciliter. Homozygotes typically have factor levels below 15 IU per deciliter, and the range for heterozygotes is 15 IU per deciliter to the lower level of normal.³⁴ In contrast to those with VWD and hemophilia, factor XI-deficient patients do not have spontaneous pathologic bleeding but may experience significant hemorrhage after a hemostatic challenge. Menstruation may represent the first such challenge for women of childbearing age. A poor correlation between factor XI level and bleeding tendency has been noted,^{34–36} and homozygotes with undetectable levels may have never experienced hemorrhage, even with surgery, trauma, or previous pregnancies. Such patients are usually discovered during family studies or through evaluation of a prolonged PTT. Additionally, the tendency to bleed after hemostatic challenge may vary over time in individuals with this deficiency. The presence of additional coagulation defects, the most common of which is VWD, in a factor XI-deficient patient can further influence bleeding risk.

Factor XI Deficiency in Pregnancy

Changes in plasma factor XI levels during pregnancy in factor XI-deficient women have not been studied extensively. Results in normal women have been conflicting, with some studies showing an increase⁶ and others a fall in levels during pregnancy.^{7,37} A single available study in which investigators studied factor XI-deficient women showed inconsistent changes during the second and third trimesters of pregnancy. Four women showed some increase and four exhibited a slight decrease from baseline in factor XI levels.³⁸ Prospective studies of changes in factor XI levels during pregnancy and the postpartum period are needed.

Therapy During Pregnancy

Conventional treatment for patients with factor XI deficiency includes the use of fresh frozen plasma. This therapy

is potentially problematic in terms of the usual risks of transmission of infectious agents and volume challenge, the latter of which is partially balanced by the long half-life of infused factor XI (50 hours). Factor XI concentrate, currently in development but not available in the United States, permits correction of isolated factor deficiency with little risk of viral exposure.³⁹ Several case reports of factor XI-related thrombosis have been reported. This complication occurred only in a population with known preexisting thrombotic or vascular disease.^{36,40} Although potential risk is due to the hypercoagulable state induced by pregnancy, no thrombotic complications have been reported in pregnant women who are deficient in factor XI. If factor XI replacement is prescribed, the goal of therapy should be to attain a factor level of approximately 40 IU per deciliter³⁸ to minimize bleeding; this should be sustained for a period of 3 to 4 days after a vaginal delivery and 4 to 5 days after a cesarean section (see Table 35-2). It is important that factor levels be maintained at levels as close as possible to the target level of 40 IU per deciliter, and that levels in excess of 100 IU per deciliter are avoided because levels this high theoretically may enhance thrombotic risk. The dose should not exceed 30 IU per kilogram.³⁹ When a woman has risk factors for a hypercoagulable state besides pregnancy (e.g., obesity, increased age, vascular disease), fresh frozen plasma should be used. In patients with no prior hemorrhagic history, regardless of factor XI level (even to 0% to 3%), it is reasonable to refrain from infusing any fresh frozen plasma or factor XI concentrate but to be prepared to do so should hemorrhage occur.

Preconception Counseling

Once the factor XI level has been discerned in a patient who is suspected of having factor XI deficiency, the probability of heterozygosity may be considered, and pedigree analysis should be performed to assess prior probability with the use of an available chart.³⁴ Prior to conception, patients from factor XI-deficient families may receive genetic counseling on the risks of vertical transmission of severe deficiency. Factor XI-deficient patients who are attempting to conceive should be counseled properly in advance about the risks of pregnancy and delivery, and

they should be informed of the usefulness of hepatitis B vaccination should blood products become necessary. If pregnancy occurs prior to immunization, the vaccine can be given safely during pregnancy. Once a factor XI-deficient woman has become pregnant, the potential risks and benefits of prenatal testing must be addressed. Invasive procedures during pregnancy may be desirable for individual patients, but these must be evaluated on an individual patient basis because of the potential for significant accidental maternal, fetal, or placental bleeding.

Rare Inherited Bleeding Disorders

Rare inherited bleeding disorders include several other hereditary disorders of blood coagulation that may be associated with excessive bleeding in pregnancy. These include deficiencies in prothrombin, fibrinogen, and factors V, VII, X, and XIII (see Chapter 5). These disorders occur at a frequency of 1 to 2 per million persons and usually become manifest during childhood.⁴¹ Because of the rarity of these conditions, experience in the specific management of obstetric problems in women with these bleeding disorders is very limited. Factor XIII-deficient women routinely spontaneously miscarry if they are not treated throughout pregnancy; thus, factor XIII seems necessary for successful and durable implantation of the fertilized ovum in the uterus. In addition, hereditary afibrinogenemia and hypofibrinogenemia (especially if the level is below 50 mg per deciliter), if untreated, also have been reported to be associated with recurrent pregnancy loss. Therapy for patients with rare inherited bleeding disorders is based on knowledge of the half-life and volume of distribution of the factor in question, as well as on the replacement therapy that is currently available. Factor VII-deficient patients may now be treated with recombinant factor VIIa. Dosing at 15 to 30 µg per kilogram given every 6 hours should be used during the peripartum and postpartum periods in those women with a significant bleeding history. Factor V-deficient patients, factor X-deficient patients, prothrombin-deficient patients, and those with factor XIII deficiency may be treated with fresh frozen plasma.⁴¹ Cryoprecipitate is useful for the treatment of patients with hypofibrinogenemia, dysfibrinogenemia, or factor XIII deficiency; factor XIII concentrates, when available, may be used prophylactically throughout pregnancy and at the time of delivery (see Table 35-2).⁴² Again, in none of these cases are specific recommendations available for the prophylaxis of bleeding during pregnancy and delivery. Therapeutic recommendations are based entirely on experience with the generic treatment of patients with these disorders during surgery and other bleeding episodes.

Preconception Counseling

Women from families with known inherited bleeding disorders should be assessed whenever possible prior to pregnancy to ascertain carrier status for the particular disease in question. The purpose of early identification is severalfold. First, the degree to which a woman is affected by a bleeding disorder is a major factor in decisions regarding the safety of conceiving and carrying a pregnancy to term, as well as in the development of appropriate and realistic expectations. Management of the disorder during pregnancy may require serial monitoring of factor levels, with baseline

levels attained prior to conception. Immunization against hepatitis A and B should be undertaken in patients who may require blood product transfusion during pregnancy or delivery. In certain disorders (e.g., VWD), it may be appropriate to treat patients and monitor response of plasma levels prior to pregnancy, to confirm the efficacy of therapy. Genetic counseling should be offered to all affected women and carrier women from affected families so that they may be given adequate information regarding inheritance to make decisions regarding pregnancy and prenatal diagnosis.

THROMBOCYTOPENIA

Normal platelet counts in nonpregnant women range from 150,000 to 300,000/µL. Relative thrombocytopenia is a normal physiologic response to pregnancy, and mean platelet count has been found to decrease successively at each trimester of normal, uncomplicated pregnancies. Maternal plasma volume expansion with increasing gestational age is believed to be the principal factor that causes a decrease in platelet count. In one study of healthy gravidas, mean platelet counts for successive trimesters were 322,000 ± 75,000, 298,000 ± 55,000, and 278,000 ± 75,000/µL.⁴³ Although mild relative thrombocytopenia is common and even expected in pregnancy, bleeding is rare with platelet counts above 50,000 to 75,000/µL, unless a qualitative platelet defect is also present. Generally, platelet counts below 100,000/µL should prompt a hematologic evaluation that is undertaken to exclude reversible or potentially life-threatening causes of thrombocytopenia.^{43–45} Events and platelet counts of prior pregnancies very accurately predict the course of future pregnancies.

The most frequent cause of thrombocytopenia that occurs during pregnancy is incidental thrombocytopenia of pregnancy, also referred to as gestational thrombocytopenia. In one large series of pregnant women, 74% of patients with thrombocytopenia had incidental thrombocytopenia; the second most common cause was hypertensive disorders of pregnancy (in 21%). An immune disorder such as ITP or SLE was implicated in less than 5% of thrombocytopenic gravidas, and in less than 2%, DIC, thrombotic thrombocytopenic purpura (TTP), HELLP syndrome, or other related syndromes were found to be the cause of thrombocytopenia.⁴⁶

Incidental thrombocytopenia of pregnancy was first described in 1988, when pregnant women considered to have ITP were distinguished from typical patients with ITP on the basis of their clinical course and that of their infants. In women for whom prepregnancy data were available, platelet counts were in the normal range. When platelet counts in these women were followed during the puerperium, counts returned to normal within 6 weeks of delivery,⁴⁷ consistent with normalization of plasma volume and other hemostatic factors that had been altered during pregnancy. The mechanism for decreased platelet count after pregnancy remains unknown, but it has been reported that mean platelet volumes are higher than in pregnant women with platelet counts in the normal range—a fact that suggests a nonimmunologic destructive process.⁴⁸

Incidental thrombocytopenia of pregnancy typically is mild, with platelet counts usually ranging from 100,000

to 150,000/ μ L; counts as low as 70,000/ μ L are less commonly seen. The diagnosis is considered after a prior history of bleeding or known thrombocytopenia has been excluded, and in the absence of other hemostatic or systemic abnormalities that may alter platelet count. Laboratory studies that may be helpful include liver function tests, coagulation tests, and human immunodeficiency virus (HIV) testing. A recent normal platelet count that was obtained prior to conception or a mild thrombocytopenia that occurred during a prior pregnancy but resolved spontaneously in the postpartum period may be very useful in ascertaining the diagnosis of incidental thrombocytopenia. The definition of incidental thrombocytopenia that has been established is a platelet count of 70,000 to 150,000/ μ L in an otherwise healthy gravida.⁴⁷ It is recognized that platelet counts lower than 70,000/ μ L may represent incidental thrombocytopenia, and that patients with mild ITP may have platelet counts in the 70,000 to 100,000/ μ L range. The implications of confusion in the diagnosis of these two disorders are generally not clinically significant, in that obstetric management of the patient with mild ITP or gestational thrombocytopenia remains the same as that provided for a hematologically normal patient. Epidural anesthesia is not contraindicated for patients with platelet counts above 70,000/ μ L, and for these women, no benefit is derived from choosing cesarean section over vaginal delivery. Transfusion of platelets, likewise, is not indicated in the absence of overt bleeding.

The hypertensive disorders of pregnancy, which are the second most common cause of a low platelet count during pregnancy, are discussed in greater detail elsewhere in this chapter. Serial measurements of blood pressure (as well as tests of liver function and coagulation) should be attained at the time of diagnosis of thrombocytopenia, as well as at suitable intervals during the remainder of the pregnancy (determined by clinical course and the presence of continued platelet decline).

As with nonpregnant individuals, causes of thrombocytopenia in the gravida may be categorized as problems of decreased production, increased destruction, or sequestration. Initial evaluation of thrombocytopenia must include a review of the peripheral smear. The laboratory platelet count should be confirmed manually, and platelet and red blood cell morphology should be evaluated for clues to the cause of the thrombocytopenia. Pseudothrombocytopenia is a laboratory artefact that results from platelet clumping of normal platelets at the time of collection; it is of no clinical significance, except for the confusion and inappropriate treatment it may produce (see Chapters 9 and 10). The presence of megathrombocytes in the peripheral smear suggests compensation of the bone marrow for a state of increased peripheral removal of platelets. If the process is one of immune-mediated platelet removal, the red blood cell morphology is typically normal. Evidence of erythrocyte trauma in combination with decreased platelet counts may be indicative of a microangiopathic process, such as DIC, HELLP, or ITP. The presence of teardrop or nucleated red blood cells on the smear suggests a problem with primary bone marrow production. Leukocytes may also provide information on the cause of thrombocytopenia, suggesting a nutritional deficiency or a malignant process.

Initial corroborative laboratory studies that should be obtained in all pregnant women with confirmed thrombocytopenia include blood coagulation studies to evaluate for the presence of DIC. PT, PTT, fibrinogen, and fibrin split product (FSP) levels provide information that may help the clinician to rule out DIC. Liver function studies aid in the evaluation of the HELLP syndrome, which is discussed later in this chapter. Other laboratory evaluations that should be performed depend on the clinical history and may include tests for collagen vascular disease, including SLE and rheumatoid arthritis (RA), as well as testing for HIV infection.

A careful drug history may exclude possible toxic exposures. The possible offending agent should be discontinued and the platelet count monitored for recovery.

IMMUNE THROMBOCYTOPENIC PURPURA

Diagnosis

Immune thrombocytopenic purpura (ITP) is a relatively uncommon cause of thrombocytopenia in pregnancy; it occurs in less than 4% of thrombocytopenic gravidas, or in 1 to 2 per 1000 live births overall (see Chapter 9).⁴⁶ ITP is typically a chronic condition in adults. A long clinical history of easy bruising suggestive of a mild hemostatic impairment already may have led to the discovery of a mild thrombocytopenia that was diagnosed as ITP prior to pregnancy. Routine complete blood cell counts attained early in pregnancy identify most cases of ITP that were undiagnosed prior to pregnancy. The finding of a moderate asymptomatic thrombocytopenia as low as 50,000 to 70,000/ μ L in the absence of a hypertensive disorder of pregnancy during the first trimester is most likely to represent chronic ITP.⁴⁷ ITP is three times more prevalent in women than men, and it typically affects women during the second and third decades of life. Because ITP is a condition of young women, it is not an uncommon diagnosis during pregnancy. Practice guidelines recently set forth by the American Society of Hematology on the management of ITP include specific recommendations for the care of pregnant women and their newborn infants.⁴⁸ No reliable basis has been established for distinguishing ITP from incidental thrombocytopenia of pregnancy. The diagnosis is made on the basis of a review of clinical data for each patient. A history of thrombocytopenia or bleeding consistent with ITP (petechiae or epistaxis) prior to conception suggests the diagnosis of ITP. Platelet counts lower than 50,000/ μ L also are commonly found to be the result of ITP. Current recommendations of confirmatory testing include measurement of blood pressure and urinary protein to rule out preeclampsia, performance of liver function tests to exclude HELLP, and HIV testing. As in the case of nonpregnant women, the diagnosis of ITP rests on the exclusion of other systemic disorders as the cause of low platelets, the presence of normal white and red blood cell indices, the absence of splenomegaly, and the absence of toxic or drug exposures. Antiplatelet antibody testing is not routinely recommended because the assay has high rates of false-positive and false-negative results.

Management During Pregnancy

Management of ITP during pregnancy is distinguished from that provided to nonpregnant women in several ways.⁴⁸ First, attention must be paid to the potential adverse effects of standard ITP treatments on fetal development and on the course of pregnancy. Second, the incidence of thrombocytopenia is increased in newborns of mothers with documented ITP, which may affect obstetric management. The most commonly used initial therapy in nonpregnant individuals with a diagnosis of ITP is glucocorticoid administration, which is nonteratogenic to fetuses but may induce or exacerbate gestational diabetes mellitus and postpartum psychiatric disorders. Intravenous immunoglobulin (IVIg) is considered safe for the fetus but may cause maternal adverse effects. The use of immunosuppressive or cytotoxic agents, including cyclophosphamide, the vinca alkaloids, and azathioprine, is relatively contraindicated because effects on the fetus are unpredictable. As with any intra-abdominal surgical procedure, the use of splenectomy in refractory cases of ITP has been reported to increase preterm labor and loss of pregnancy during the first trimester; this procedure may be technically difficult to perform during the third trimester because of the size of the uterus. Last, adequate hemostasis is required at the time of delivery to reduce the risk of maternal postpartum bleeding complications.

Timing of Intervention

Gravidas with the diagnosis of ITP (confirmed as chronic or presumed to be a first presentation, given the timing of detection during the pregnancy and the absence of other causes) with platelet counts greater than 50,000/ μ L at any time during pregnancy and those with platelet counts of 30,000 to 50,000/ μ L during the first two trimesters and no evidence of bleeding should be observed. For women with platelet counts lower than 10,000/ μ L at any time during pregnancy, or with counts of 10,000 to 30,000/ μ L during the latter two trimesters, or with bleeding, intervention should be undertaken. The goal of therapy for the gravida with ITP is to maintain a safe (as distinct from normal) platelet count, particularly with regard to labor and delivery.

In gravidas who require treatment for thrombocytopenia, prednisone given at a dose of 1 mg/kg/day is the first choice of therapy when platelet counts are between 10,000 and 30,000/ μ L. The platelet count should rise to greater than 50,000/ μ L within approximately 1 week of initiation of therapy. The dose should then be tapered slowly to the minimum effective dose required to maintain platelet count in an acceptable range. Too rapid lowering of the steroid dose often results in recurrence of the thrombocytopenia. Women with severe thrombocytopenia (<10,000/ μ L) should receive IVIg as initial treatment, at a dose of 0.4 g/kg/day for 5 days or 1 g per kilogram daily for 2 days, and platelet transfusions should be administered if significant bleeding is present. IVIg often requires repeat administration every 2 to 4 weeks to maintain platelet count at an acceptable level, particularly near term. IVIg is also appropriate second-line treatment for women in whom glucocorticoid therapy has been unsuccessful. Splenectomy is rarely undertaken in gravidas because of

the increased risks of surgery for both mother and fetus as compared with a nonpregnant individual. Current recommendations for the use of surgical intervention are the presence of ITP that is refractory to steroids and to IVIg, with platelet counts determined to be 10,000/ μ L in the second trimester and the occurrence of overt bleeding. When possible, pneumococcal vaccine should be administered 2 weeks prior to splenectomy.

Because of increased maternal and fetal risks associated with surgery, medical management recommendations for ITP in the pregnant woman differ from those for non-gravidas in terms of the lower threshold required for the use of IVIg in pregnancy and the less frequent use of splenectomy.

Impact of Maternal Immune Thrombocytopenic Purpura on Fetal Platelet Count

Autoantibodies produced in ITP are of the immunoglobulin (Ig)G class; therefore, they readily cross the placenta. The manifestation of this phenomenon is variable in terms of fetal platelet count. The severity of maternal thrombocytopenia does not correlate with that of thrombocytopenia in the fetus^{49,50}; moreover, the pharmacologic interventions used to raise maternal platelet count may not necessarily result in an elevated fetal platelet count.^{51,52} Refractory severe maternal thrombocytopenia despite splenectomy and a previous history of delivery of a thrombocytopenic infant are predictors for neonatal thrombocytopenia in the current pregnancy.⁵³

Currently, two methods are available by which fetal platelet counts can be determined (in utero), and both are problematic. Fetal scalp sampling, which involves removal of blood via a heparinized capillary tube from a small scalp laceration, requires that the woman must be in active labor and must have ruptured membranes and a dilated cervix. The fetal head must be engaged in the pelvis to allow access to the scalp. Platelet counts attained in this fashion may be grossly inaccurate because of contamination with amniotic fluid or maternal blood, or because of platelet clumping. Additionally, scalp hematoma may occur. A platelet count above 50,000/ μ L that is attained in this fashion is reassuring for a vaginal delivery. The second method, cordocentesis, or percutaneous umbilical blood sampling (PUBS), provides a more accurate platelet count but requires experience with the technique to minimize the potential risks to the fetus of postpuncture bleeding; this is usually self limited but may necessitate emergency cesarean section or may result in fetal death (in 1% of cases)—a figure similar to the fetal death rate without PUBS testing.⁵⁴ Risks to the fetus appear to be least problematic after 35 weeks gestation.⁴⁹ For women at term who have maintained a platelet count above 50,000/ μ L, cordocentesis may guide the decision to permit a vaginal delivery by ensuring that the fetal count is also adequate for that method of delivery. Infants born to mothers with ITP may experience further decline in platelet count during the first postpartum week.⁴⁹ If thrombocytopenia is severe, IVIg is recommended, along with the provision of platelet transfusional support with evidence of active bleeding.

ALLOIMMUNE THROMBOCYTOPENIA

Alloimmune thrombocytopenia (AIT) is a clinical entity that is distinct from ITP in that maternal platelet counts are usually normal or only mildly decreased, yet the fetus may experience a severe, life-threatening thrombocytopenia.⁵⁵ It results from maternal sensitization to fetal platelet antigens and may be considered the platelet equivalent to red blood cell Rh sensitization and hemolytic disease of the fetus and neonate. Fetal platelets apparently cross the placental barrier and are recognized as foreign by the maternal immune system. IgG antiplatelet antibodies are directed against platelet-specific antigens inherited from the father but absent from the mother's platelets. The incidence of this is approximately 1 in 1000 fetuses.⁵⁵ The abnormality that most frequently causes this disorder is an incompatibility in the polymorphism affecting the PLA (HPA-1) antigen encoded on the gene for platelet glycoprotein IIIa. Alloantibodies from a sensitized PLA1-negative mother cross the placenta and cause immune-mediated thrombocytopenia in a PLA1-positive fetus. The PLA antigen polymorphism also reportedly causes the most severe form of alloimmune thrombocytopenia.⁵⁶ The diagnosis is usually first made after the birth of a child with unexpected severe thrombocytopenia.

The chief complication of AIT is intracranial hemorrhage (ICH), which occurs in 10% to 20% of such severely affected neonates; 25% to 50% of cases occur in utero.⁵⁶ In contrast to Rh sensitization of red blood cells, AIT may occur during a first pregnancy. Efforts to screen mothers at risk to deliver affected infants are complicated by the fact that only 1 in 20 PLA1-negative mothers with antigen-incompatible partners ever become sensitized, despite repeated pregnancies. Thus, the incidence is not well predicted on the basis of antigen screening tests. However, once an affected fetus or neonate has been identified, the maternal risk of subsequent affected pregnancies ranges from 50% to 100%, dependent on the homozygosity or heterozygosity of the father for the allele, even with different mates. It is suggested that in cases of paternal heterozygosity for the PLA1 allele, amniocentesis should be performed at 15 to 18 weeks to allow platelet-antigen genotyping of the fetus. If the incompatible antigen is not present, fetal platelet count will be unaffected, and normal delivery may occur without further intervention. If the antigen is present, then PUBS at 20 to 24 weeks should be undertaken, with transfusion of maternal platelets provided to minimize risk to the fetus of hemorrhage during this procedure. If the fetus is found to be thrombocytopenic with a platelet count lower than 100,000/ μ L, maternal treatment with IVIg at a dose of 1 g/kg/wk should be instituted immediately and continued for the duration of the pregnancy; an increase or lack of further decrease in the fetal platelet count has been documented in 62% to 85% of affected fetuses when this therapy was provided.

Addition of low-dose steroid therapy has not been proved to increase response rates over those seen with IVIg alone. Repeat PUBS should be undertaken 3 to 6 weeks after therapy is begun, to document improvement in the platelet count. If the counts remain low, high-dose prednisone (60 mg/day) added to weekly IVIg will result in

a rise in the platelet count in approximately half of remaining cases.⁵⁷ PUBS should again be performed in 3 to 6 weeks so that the platelet count can be determined. If the count remains below 50,000/ μ L, cesarean section should be performed. Delivery prior to 34 weeks for severe thrombocytopenia (<20,000/ μ L) is of questionable usefulness in that prematurity alone may also lead to ICH.

THE HELLP SYNDROME

The HELLP syndrome was first described in 1954 by Pritchard and coworkers, and it was given the acronym in 1982 by Weinstein on the basis of the three cardinal manifestations of the syndrome.⁵⁸ The "H" stands for Hemolysis, the "EL" for Elevated Liver enzymes, and the "LP" for Low Platelets. It is considered in conjunction with disorders of preeclampsia and eclampsia to constitute a spectrum of heterogeneous hypertensive disorders that may occur during the latter half of pregnancy, and it is one of the leading causes of maternal morbidity and mortality in the Western world. The diagnosis of the HELLP syndrome is based on hematologic and serum chemistry abnormalities, but variation among centers regarding criteria that establish the diagnosis is ongoing. The University of Tennessee uses strict laboratory criteria, which include an abnormal peripheral smear with evidence of microangiopathic hemolytic anemia, total bilirubin above 1.2 mg per deciliter, lactate dehydrogenase (LDH) above 600 IU per liter, aspartate aminotransferase (AST) above 70 IU per liter, and platelet count below 100,000/ μ L.⁵⁹ A recent study of uncomplicated singleton pregnancies followed to delivery found that a small number of gravidas experienced an asymptomatic gradual decline in the platelet count to less than 150,000/ μ L. These women were more than seven times as likely to develop AST elevation as were those without thrombocytopenia; this suggests that the fall in platelets precedes the elevation in liver enzyme test results.⁶⁰

The earliest clinical signs and symptoms of this disorder are protean; thus, it may be mistaken for other conditions, ranging from the benign to the life-threatening. This diagnosis may often be delayed if symptoms, including shoulder, neck, and upper body pain, malaise, nausea, vomiting, and headache, are attributed to a viral syndrome, gastritis, or a musculoskeletal problem. The disorder, in its more severe presentation, may be difficult to distinguish from other severe hepatic or hematologic syndromes seen in pregnancy. Severe preeclampsia, hemolytic-uremic syndrome (HUS), TTP, SLE, and acute fatty liver of pregnancy all may produce clinical manifestations and laboratory studies similar to those seen with the HELLP syndrome. Target organs in all the diseases listed here include the kidneys, the liver, and the vascular endothelium. Because it is possible for two syndromes to occur in the same individual, the diagnosis can be extremely difficult to confirm. Subtle differences between these conditions can be used to guide diagnosis of the correct clinical entity; correct diagnosis is essential because management of the condition during pregnancy may be significantly different for each disorder.

Table 35-3 Differentiation of HELLP from Similar Diseases*

	Platelets	PT/PTT	LDH	Bilirubin	Glucose	SBP	Proteinuria
HELLP	↓↓	N	↑↑↑	N	N	N/↑	↑
AFLP	↓	↑↑	N/↑	↑↑↑	↓	N	N
Preeclampsia	N	N	N	N	N	↑↑	↑↑
TTP	↓↓	N	↑↑	N	N	N	↑
HUS	N	N	↑	N	N	↑	↑↑

*Early in disease course.

AFLP, acute fatty liver of pregnancy; HELLP, Hemolysis, Elevated Liver Tests, Low Platelets; HUS, hemolytic-uremic syndrome; LDH, lactate dehydrogenase; N, normal or no change; PT, prothrombin time; PTT, partial thromboplastin time; SBP, systemic blood pressure; TTP, thrombotic thrombocytopenic purpura. ↑, implies mild change, ↑↑, moderate change, ↑↑↑, severe change.

Several key characteristics have been identified for each of these disorders that may be useful in differentiation of the various syndromes. These features are presented in Table 35-3.⁶¹ Thrombocytopenia is the earliest and most common hemostatic abnormality associated with the HELLP syndrome; it is seen in all gravidas with this diagnosis. Abnormalities of the coagulation cascade, manifested by elevated PT and PTT and decreased fibrinogen, and derangement of liver enzymes do not occur until very late in the course. LDH is frequently elevated much earlier than any liver abnormalities become apparent, suggesting that the initial source of the problem is hemolyzed red cells. In contrast, acute fatty liver of pregnancy typically displays high serum bilirubin concentrations, prolongation of PT and PTT, hypoglycemia, and only modestly diminished platelet counts. Both TTP and HUS can imitate HELLP in many of its clinical features. All three syndromes share microangiopathic hemolytic anemia, thrombocytopenia, proteinuria, increased serum LDH, and renal compromise. However, TTP typically does not cause marked derangement of hepatic function as manifested by elevations in AST and alanine aminotransferase (ALT). In HELLP, the degree of renal dysfunction is usually correlated with the level of hepatic impairment, whereas in HUS, renal failure is elevated to an extent that is out of proportion to the liver enzyme levels. Both TTP and HUS are managed through plasma exchange.

Preeclampsia is a well-defined clinical triad of hypertension, proteinuria, and nondependent edema; it can be mild or severe. The criteria for mild and severe disease have recently been established by the American College of Obstetrics and Gynecology.⁶¹ The presence of grand mal seizures is classified as eclampsia, which is a life-threatening condition that is associated with a high risk of maternal and fetal mortality. The most efficacious treatment is prevention in a woman with identified preeclampsia. Immediate delivery of the fetus is mandatory once the syndrome has progressed to eclampsia. Measures that may be used to mitigate the sequelae of preeclampsia include control of blood pressure with intravenous hydralazine at doses of 5 to 10 mg given every 30 minutes, or labetalol, or less commonly, sodium nitroprusside, because of concern for fetal cyanide toxicity at doses above 10 µg/kg/min.⁶¹ Seizure prophylaxis should be initiated in patients with preeclampsia who are in active labor and in patients with HELLP who are in labor, or at any time that epigastric pain is present. Intravenous magnesium sulfate administered as a bolus and then by continuous infusion

is the treatment of choice; toxicity is monitored with the use of patellar reflexes and serum magnesium levels. Infusion may need to continue into the postpartum period until evidence indicates that the hypertensive disorder has been resolved.⁶¹

Once the diagnosis of the HELLP syndrome has been considered, some centers find it useful to further classify the disorder by severity to assist in prognosis and management during the peripartum period. A three-class system, based on maternal platelet count nadir, was devised. Class 1 is a platelet count below 50,000/µL, class 2 includes platelet counts between 50,000 and 100,000/µL, and class 3 consists of platelet counts above 100,000 but less than 150,000/µL. Regardless of the course during pregnancy and the immediate peripartum period, HELLP syndrome may further worsen during the postpartum period, resulting in pathologic thrombosis. Prophylactic administration of heparin is probably reasonable at this time in most cases of HELLP syndrome; no articles have documented the use of low molecular weight heparin in this clinical situation.

Management of Thrombophilia and Antiphospholipid Syndrome During Pregnancy

Jody L. Kujovich, MD • Barbara M. Alving, MD

INTRODUCTION

Thromboembolic events that occur during pregnancy or during the postpartum period present unique diagnostic and therapeutic challenges that may affect both mother and fetus. Such events are not rare; venous thromboembolism (VTE) occurs in approximately 1 in 1000 pregnancies, and pulmonary embolism is a leading cause of maternal death.¹⁻⁴ This chapter discusses the prevention, diagnosis, and treatment of VTE in pregnant women, the role of inherited and acquired thrombophilia (i.e., antiphospholipid syndrome [APLS]) in inducing VTE and other complications that affect fetal development, and treatment approaches to pregnancy-related stroke. Benefits and risks of anticoagulant therapy in these different clinical settings are also reviewed.

Pregnancy is a prothrombotic state that involves all three components of Virchow's triad: venous stasis, endothelial damage, and alteration of circulating coagulation factors (Table 36-1). Venous stasis results from a hormonally induced increase in venous distensibility and obstruction of venous flow by the enlarging uterus. Pelvic vascular endothelial injury may occur at the time of delivery or as a result of venous hypertension. Pregnant women may have increased levels of several procoagulant factors, a progressive fall in protein S levels, acquired resistance to activated protein C, and impaired fibrinolysis.^{1,3,5-10}

Evidence for thrombophilia is found in more than 50% of women with pregnancy-related VTE. The most common inherited thrombophilic disorders include factor V Leiden (FV Leiden), prothrombin 20210 gene mutation, and deficiencies of antithrombin III, protein C, or protein S. The most common acquired thrombophilic disorder is immune-mediated APLS. Elevated levels of homocysteine, which may be associated with an increased risk for thrombosis, may be due to environmental factors and/or to an underlying gene polymorphism (e.g., methylenetetrahydrofolate reductase [MTHFR] 677).

VENOUS THROMBOEMBOLISM IN PREGNANCY

The risk of VTE is four- to tenfold higher in pregnant than in nonpregnant women of similar age (Table 36-2).^{3,11} This

increased risk, which begins during the first trimester and continues throughout pregnancy, is greatest during the postpartum period.^{3,12-15} According to one meta-analysis, more than 50% of cases of VTE that develop during pregnancy occur in the first two trimesters, and the risk for VTE is increased by 15-fold during the postpartum period.¹⁵

THROMBOPHILIA AND VENOUS THROMBOEMBOLISM DURING PREGNANCY

The risk of VTE during pregnancy is greater in women with thrombophilia than in those without this condition and is exacerbated by additional prothrombotic factors. FV Leiden is associated with a 5- to 16-fold increased thrombotic risk during pregnancy and the puerperium over that seen in nonpregnant women without thrombophilia (see Table 36-2).¹⁶⁻²⁰ Heterozygous carriers of the prothrombin 20210 mutation have a 3- to 15-fold higher risk of pregnancy-associated VTE than do unaffected women.^{16,17,19,21} The widely varying prevalences and risks that have been reported may reflect the relatively small sample sizes and different cut-off levels used to define a deficiency. In a single family study, antithrombin III-deficient women had a nearly 50-fold higher risk of VTE during pregnancy and the puerperium than was noted in nonpregnant women, with the highest risk reported during the postpartum period.²² In the absence of prophylactic anticoagulation, postpartum VTE occurred in 15% of previously asymptomatic deficient women, and in 50% of those with a prior history of VTE.

Homozygosity for the common MTHFR 677 mutation predisposes to mild hyperhomocysteinemia, usually in the setting of suboptimal folate levels. No consistent evidence suggests that the MTHFR 677 mutation increases the risk of VTE, independent of homocysteine levels. Therefore, laboratory testing for this gene mutation is not indicated. Hyperhomocysteinemia and high levels of several clotting factors are independent thrombotic risk factors, but their contributions to VTE during pregnancy are not well defined. High FVIII levels (>170% of normal) may also serve as a risk factor for thrombosis during pregnancy.¹⁷

Women with multiple or homozygous thrombophilic defects have the greatest risk of pregnancy-associated VTE.

Table 36-1 Risk Factors for Pregnancy-Related Venous Thromboembolism**Physiologic Changes During Pregnancy**

Venous stasis

- Obstruction of venous return by enlarging uterus
- Increase in venous distensibility due to hormonal effects

Pelvic vascular injury due to venous hypertension or delivery

Alteration of circulating coagulation factors

- Increased procoagulant factors
- Decreased protein S levels
- Acquired resistance to activated protein C
- Impaired fibrinolysis

Risk Factors

- Advanced maternal age
- Obesity
- Immobilization
- Multiple gestations
- High parity
- Preeclampsia
- Cesarean section
- Prior venous thrombosis
- Thrombophilia

This risk is increased 20- to 40-fold in homozygous FV Leiden women.^{11,17} In one study, the risk of pregnancy-associated VTE was increased ninefold in women who were heterozygous for FV Leiden and 15-fold in those who were heterozygous for the prothrombin 20210 mutation. In contrast, this risk was increased >100-fold in women with both mutations, illustrating the dramatic increase in overall risk when thrombophilic mutations are combined.¹⁶ In another retrospective study, VTE occurred in 18% of pregnancies in double heterozygous carriers of FV Leiden and the prothrombin 20210 mutation, compared with 6% of those with only the prothrombin 20210 mutation, suggesting that the combination of the two mutations confers a nearly threefold greater risk than is conferred by the prothrombin 20210 mutation alone.²³ In studies of thrombophilic families, VTE complicated 4% of pregnancies in double heterozygous carriers of

FV Leiden and the prothrombin 20210 mutation and 16% of pregnancies in women with homozygous FV Leiden, compared with 0.5% of pregnancies in unaffected relatives.^{11,24,25} A recent meta-analysis found that the risk of pregnancy-related VTE was increased 34-fold and 26-fold in homozygous patients of FV Leiden and the prothrombin 20210 mutation, respectively.²⁶

Although thrombophilia increases the relative risk of pregnancy-associated VTE, the absolute risk in asymptomatic carriers has not been well defined. Retrospective observational data and studies of thrombophilic families probably overestimate the risk in unselected asymptomatic women. Two prospective studies of unselected pregnant women screened for FV Leiden reported very low rates of VTE in heterozygous carriers (1% and 0%, respectively).^{27,28} No thrombotic complications occurred during pregnancy or the puerperium among a large cohort of FV Leiden carriers identified by general population screening.²⁹ Several retrospective studies estimated the probability of VTE in FV Leiden carriers in the range of 2.5 to 3 per 1000 pregnancies.^{2,16,17} This risk in women with the prothrombin 20210 mutation is approximately 1 in 200 to 300 pregnancies.¹⁷ These estimates suggest that asymptomatic women with a single thrombophilic defect and no other predisposing factors have a relatively low absolute risk. In contrast, women with homozygous or combined thrombophilia have a much higher probability of VTE—in the range of 10 to 50 per 1000 pregnancies.^{11,17} Women with antithrombin III deficiency also are at greater risk, although estimates range from 1 in 3 to 1 in 250 pregnancies, depending on the type and severity of deficiency.^{2,16}

DIAGNOSIS OF VENOUS THROMBOEMBOLISM DURING PREGNANCY

Signs and symptoms of deep venous thrombosis (DVT), such as lower extremity pain and edema, and of pulmonary embolism (PE), such as dyspnea and tachypnea,

Table 36-2 Thrombophilia and Risk of Pregnancy-Associated Venous Thromboembolism

Thrombophilic Disorder	Prevalence in Women with Pregnancy-Associated VTE	Risk of Pregnancy-Associated VTE (odds ratio)*	Probability of Pregnancy-Associated VTE [†] (VTE/1000 pregnancies)
None	<50%	4–10	1
FV Leiden (heterozygous)	20%–46%	5–16	2–3
FV Leiden (homozygous)	2%–4%	20–40	40
PGM 20210 heterozygotes	6%–26%	3–15	3–5
PGM 20210 homozygotes	NA	26	NA
FVL/PGM (double heterozygotes)	7%–9%	9–107	10–50
ATIII deficiency [‡]	1%–19%	7–64	4–333
PC deficiency [§]	2%–14%	4–7	1–9
PS deficiency [¶]	1%–12%	2–3	1–3
High FVIII levels ^{**}	18%	4–5	2–3

*Risks relative to nonpregnant women without thrombophilia.

[†]Assuming baseline incidence of 1 VTE per 1000 to 1500 pregnancies.

[‡]Variably defined as <60% or <80% of normal activity.

[§]Variably defined as <50% or <70% of normal activity.

[¶]<53% to 55% of normal activity.

^{**}>170% of normal activity.

VTE, venous thromboembolism; FV Leiden, factor V Leiden; PGM, prothrombin gene mutation; ATIII, antithrombin III; PC, protein C; PS, protein S; FVIII, factor VIII; NA, not applicable (data not sufficient).

may be attributed to pregnancy, thus causing a delay in diagnosis.³⁰ Approximately 80% to 85% of DVT sites in pregnant women are found in the left lower extremity; most involve the iliofemoral veins, which are associated with an enhanced likelihood of PE. Isolated calf vein DVT is uncommon, accounting for <10% of cases.^{12,14,15} The striking predilection for the left leg is believed to be due to compression of the left iliac vein by the right iliac artery, which is exacerbated by the enlarging uterus. The risk for isolated iliac vein thrombosis is increased during pregnancy, although its true incidence is unknown. More than 66% of women with a pregnancy-related DVT exhibit symptoms of a post-thrombotic syndrome, perhaps reflecting the high frequency of iliofemoral vein involvement.^{31,32}

In nonpregnant patients, the combination of a negative D-dimer assay and a low clinical probability safely rules out VTE. However, no studies have established the negative predictive value of D-dimer testing during pregnancy. The role of D-dimer testing is limited during pregnancy in that concentration increases with gestational age.³³ By the third trimester, D-dimer levels exceed conventional cut-off values for excluding VTE in nearly all women, and they do not return to normal levels until 4 to 5 weeks after delivery.³⁴ Higher D-dimer levels are found in women with preterm labor, placental abruption, and preeclampsia.

Because of the unreliability of clinical assessment and the uncertainty of D-dimer testing, an objective diagnosis is required in pregnant patients with suspected VTE. Compression ultrasound is the first-line diagnostic test for DVT because it does not involve radiation exposure. Ultrasound is highly sensitive and specific for proximal DVT in nonpregnant patients, but it is not known whether available data are applicable to pregnant women. Because a normal ultrasound does not reliably exclude calf vein DVT, serial testing over 7 to 14 days is recommended to rule out propagation of undetected calf vein thrombosis.^{35–37} Compression ultrasound is inadequate for diagnosis of isolated iliac vein thrombosis and may not detect extension of proximal DVT into the iliac vein or inferior vena cava (IVC). Because of its high sensitivity and specificity for thrombosis in this location, magnetic resonance venography is recommended when clinical suspicion of iliac vein involvement is high.³⁸ Because of an uncertain natural history of superficial vein thrombosis below the knee during pregnancy, serial ultrasounds should be considered to exclude extension into the deep venous system.

The diagnosis of pulmonary embolism during pregnancy is complicated by concerns about fetal exposure to ionizing radiation. Most experts agree that the risks of undiagnosed PE far outweigh the theoretical risks of radiation exposure from diagnostic imaging.^{35–37} With appropriate precautions, radiation exposure resulting from radionuclide lung or helical computed tomography (CT) scans is far below the threshold associated with an increased risk of teratogenesis.^{37,39,40} A lower extremity ultrasound examination is appropriate for women with suspected PE in that a diagnosis of DVT allows treatment and thus avoids the need for further imaging. However, lower extremity DVT is detected in less than 50% of women with PE during pregnancy.¹³ If the initial ultrasound examination is negative or nondiagnostic, a ventilation/perfusion (V/Q) or helical CT scan should be performed. The distribution of results of V/Q

scanning in pregnant women with suspected PE differs from that in nonpregnant women; a much higher prevalence of normal scans and fewer high-probability and non-diagnostic studies are noted.³⁶ An initial perfusion scan with reduced dose reduces the radiation exposure in that a normal study excludes PE, obviating the need for a ventilation scan. Limited available evidence suggests that withholding anticoagulation in pregnant women with a normal perfusion scan is safe. The accuracy of helical CT scanning has not been evaluated in pregnant women with suspected PE. Although the role of helical CT in pregnancy is not addressed in published guidelines, it is emerging as the first-line imaging study for use in patients with suspected PE.⁴¹ Pulmonary angiography is rarely performed because it is invasive and requires a significantly higher radiation dose; it is not more accurate than helical CT scans.³⁷

MANAGEMENT OF THROMBOSIS AND THROMBOPHILIA DURING PREGNANCY

Antithrombotic Therapy During Pregnancy

Because of the paucity of well-controlled trials, guidelines for anticoagulation during pregnancy are based largely on case series and studies in nonpregnant patients.⁴² Although unfractionated heparin (UFH) or low molecular weight heparin (LMWH) is recommended during pregnancy, LMWH has generally replaced UFH in the management of VTE, on the basis of data that have established its safety and efficacy.^{35,42–45} Despite widespread endorsement in consensus guidelines, LMWH has not yet been approved by the U.S. Food and Drug Administration (FDA) for use during pregnancy. LMWH has several advantages over UFH, including a more predictable dose response (obviating the need for frequent laboratory monitoring), a longer half-life (allowing once- or twice-daily dosing), and an improved safety profile with a probable lower risk of osteoporosis and heparin-induced thrombocytopenia (HIT). Because LMWH does not cross the placenta, no risk of fetal bleeding or teratogenicity is present, although bleeding at the uteroplacental junction may occur rarely. Potential maternal complications include bleeding, osteoporosis, HIT, and allergic skin reactions. One review of LMWH use during 2777 pregnancies found that rates of VTE and bleeding were comparable with those reported in nonpregnant patients.⁴⁴ Recurrent VTE occurred in <1% and major bleeding in approximately 2% of women who were given LMWH for prophylaxis or treatment during pregnancy. The rate of postpartum hemorrhage was similar to that reported in women who were not receiving anticoagulants, and most cases of bleeding were associated with an obstetric cause.^{44,46}

Osteoporosis

Osteoporosis is a particular concern for pregnant women who may require LMWH (or UFH) over the course of gestation. In two studies, prolonged treatment with UFH reduced bone mineral density in up to 30% of patients and resulted in vertebral fracture in 2% to 3% of women receiving long-term prophylaxis during pregnancy.^{47,48} Convincing evidence from animal models and clinical studies suggests that LMWH use is associated with a significantly

lower risk of osteoporosis than is use of UFH.^{49,50} One study measured bone mineral density at various time points after delivery in women randomly assigned to prophylactic doses of UFH or LMWH during pregnancy. Women who received UFH had significantly lower bone mineral density up to 3 years postpartum, consistent with animal data suggesting that adverse effects may not be reversible. In contrast, no difference in bone mineral density was observed between women who received LMWH and a group of untreated control women.⁵⁰ Other data also suggest that long-term treatment with LMWH, at least in prophylactic doses, does not adversely affect bone mineral density.⁵¹ The effects of higher therapeutic doses have not been adequately studied.

Heparin-Induced Thrombocytopenia

HIT is extremely rare in pregnant women, even among those receiving long-term UFH.^{52,53} The estimated incidence of HIT is <0.1% in obstetric patients who are given LMWH.⁴⁴ Recent American College of Chest Physicians (ACCP) guidelines suggest that platelet count monitoring is not required in pregnant women who are treated exclusively with LMWH.⁵⁴

Skin Reactions

Allergic skin reactions to UFH and LMWH may complicate the management of pregnant women who require anticoagulation. Allergic skin reactions are reported in 0.6% to 29% of pregnant women given LMWH for prophylaxis or treatment of VTE.^{43,44,55} The wide range in reported incidence likely reflects the varying types and severity of skin reactions described. Although several types of allergic reactions may occur, delayed type IV hypersensitivity reactions are the most common and show a striking predilection for women.⁵⁶ These reactions are characterized by erythematous plaques that are often pruritic. Such plaques typically develop at the sites of subcutaneous injection 10 days after initiation of therapy; however, they may also occur after several months of heparin administration.⁵⁵ When these plaques first appear, the patient should be evaluated for possible HIT because similar-appearing isolated skin lesions may progress to skin necrosis as a rare but documented manifestation of this condition.⁵⁷ Severe HIT-associated skin reactions may occur in the absence of thrombocytopenia.⁵⁸

Allergic skin reactions to LMWH require a change in therapy in most cases.⁵⁵ Heparin-like compounds should be avoided in patients with HIT, skin necrosis, or type I immediate hypersensitivity reactions. Delayed type IV hypersensitivity reactions may resolve with a change in preparation, although cross-reactivity with other LMWHs is common. Cutaneous testing is occasionally useful in confirming the diagnosis and in screening for cross-reactivity with other LMWH preparations.⁵⁶

Warfarin

In contrast to heparins, warfarin and other coumarin derivatives cross the placenta with the potential for fetal bleeding and teratogenicity.⁴² Although warfarin may be safe during the first 6 weeks, the risk of embryopathy is highest between 6 and 12 weeks gestation.⁴² Embryopathy, which is estimated to occur in the fetuses of 2.4% to 6.4% of

women receiving coumarin derivatives during the first trimester,^{59–61} is characterized by nasal and limb hypoplasia, stippled epiphyses, and vertebral abnormalities.^{42,59} Central nervous system abnormalities due to fetal intracerebral hemorrhage may occur after warfarin exposure at any time during pregnancy. Therapeutic maternal levels of anticoagulation may produce supratherapeutic effects on the fetus, caused in part by immaturity of the fetal liver. Fetal bleeding may occur at any time, especially at the time of birth, because of the combination of the anticoagulant effect and the trauma of delivery.⁶⁰ Children exposed in utero to warfarin during the second and third trimesters are reported to have a higher incidence of long-term neurodevelopmental problems.⁶²

Women who receive warfarin therapy should be counseled prior to pregnancy about potential fetal risks.⁴² Two strategies are recommended for women on long-term warfarin who are contemplating pregnancy. One option is to continue warfarin with frequent pregnancy testing, substituting LMWH or UFH as soon as pregnancy has been confirmed. Testing must be performed prior to the sixth week of gestation to minimize the risk of warfarin-induced embryopathy. Alternatively, the patient may be switched to LMWH prior to attempts at conception. Because warfarin is probably safe during the first 4 to 6 weeks of gestation, the former approach may be more convenient in reliable patients.⁴² Personal preference and medicolegal concerns may also factor into the decision.

Other Antithrombotic Agents

Treatment options for pregnant women who are unable to receive heparin are limited. Danaparoid, which is not available in the United States, has low cross-reactivity with heparin-induced antibodies and has been used safely in pregnant women.⁴² It does not appear to cross the placenta, and on the basis of measurements of anti-FXa levels in fetal cord blood and breast milk in a small number of women, it is believed to be safe for breastfeeding mothers.⁶³

Direct thrombin inhibitors, such as lepirudin and argatroban, do not cross-react with heparin-induced antibodies and are recommended for nonpregnant patients with HIT.⁵⁴ A few case reports have described lepirudin use during pregnancy without maternal or fetal complications.^{64,65} However, lepirudin and argatroban have not been adequately evaluated in pregnant women, and the extent of placental transfer is unknown.

Fondaparinux is a synthetically derived pentasaccharide that binds to antithrombin III, potentiating antithrombin III-mediated inactivation of factor Xa. It does not cross-react with HIT antibodies in vitro and is a potentially useful therapeutic agent for HIT, although it has not yet been approved for this indication.⁶⁶ Anecdotal reports have described the successful use of fondaparinux in pregnant women who were unable to receive heparin.^{67,68} Fondaparinux was used in a small number of pregnant women with severe cutaneous reactions to LMWH without evidence of cross-reactivity or other adverse effects.⁶⁷ An ex vivo model in which perfused placentas were used indicated that fondaparinux was not transferred across the placenta.⁶⁹ A clinical study involving five pregnant women who were given prophylactic doses reported that fondaparinux

activity was detectable in cord blood samples in concentrations that were approximately one tenth of those in maternal plasma.⁶⁷ Although these concentrations are not likely to be clinically significant, the extent of placental transfer with higher therapeutic doses is unknown.

At present, clinical experience with lepirudin or fondaparinux is insufficient to confirm their safety during pregnancy or breastfeeding. The use of these newer antithrombotic agents should be reserved for women for whom no other therapeutic alternatives are available. In these situations, the physician should discuss the risks and benefits of therapy in detail with the patient and her family. This discussion should be well documented in the medical records. Danaparoid, lepirudin, argatroban, and fondaparinux are classified as FDA pregnancy risk category B, meaning that no well-controlled studies in pregnant women have validated the findings of studies that were done with animals.

Laboratory Monitoring

In pregnant women receiving treatment doses of UFH, the partial thromboplastin time (PTT) may not reflect the true degree of anticoagulation, in part because of elevated levels of factor VIII.⁷⁰ Monitoring the anticoagulant activity of heparin with the use of the PTT in pregnant women may result in administration of inappropriately high doses, leading to an increased risk of bleeding for the patient. Measurement of anti-FXa activity levels is recommended for patients who appear to be “heparin resistant.”³⁵ Doses of subcutaneous UFH are adjusted so that a midinterval anti-FXa level in the therapeutic range of 0.3 to 0.7 U per milliliter is achieved.³⁵

For women receiving LMWH, a chromogenic anti-FXa assay is used to monitor the anticoagulant effect, although no consistent evidence suggests that anti-FXa levels correlate with efficacy or bleeding.^{46,71} Currently, no consensus has been reached regarding laboratory monitoring of LMWH during pregnancy. Some experts recommend periodic

checking of anti-FXa levels (e.g., shortly after initiation, and then every 1 to 3 months) when treatment doses are used in pregnant women.^{42,72–74} Peak anti-FXa levels are measured approximately 4 hours after a subcutaneous injection is given. LMWH doses are adjusted to maintain levels in the therapeutic range for nonpregnant patients receiving twice-daily doses (0.5 to 1.2 U per milliliter).⁴² The therapeutic range for once-daily dosing is less well defined but likely exceeds 1.0 U per milliliter for most LMWHs.⁷¹ Measurement of anti-FXa levels is usually unnecessary when LMWH is administered in prophylactic doses.⁴⁶

Primary Prophylaxis of Venous Thromboembolism in Asymptomatic Women

Because the probability of VTE during pregnancy is low, prophylactic anticoagulation is not routinely recommended for asymptomatic women with a single thrombophilic defect (Table 36-3). Clinical surveillance with prompt investigation of signs and symptoms of VTE may be adequate in low-risk women without other risk factors.⁴² However, risk assessment must be individualized. Thrombophilic women should be counseled on the increased thrombotic risk during pregnancy and on the need for prompt evaluation of signs or symptoms suspicious for VTE. Women who do not receive antepartum anticoagulation should be offered a 4- to 6-week course of warfarin postpartum because the highest risk of VTE (especially PE) occurs during this period.^{3,42} Prophylactic LMWH (or UFH) during pregnancy followed by 4 to 6 weeks of postpartum anticoagulation is recommended for women who are homozygous for FV Leiden or the prothrombin 20210 mutation, who are doubly heterozygous for both mutations, who may be deficient in antithrombin III, or who have been identified as having other combined thrombophilic defects.^{42,74} The indications for prophylaxis are stronger in women with coexisting risk factors.

Table 36-3 Recommended Prophylaxis Against Venous Thromboembolism for Pregnant Women

Primary Prophylaxis—Asymptomatic Women	Antepartum	Postpartum
Low risk thrombophilia (single defect, no other risk factors)	Clinical surveillance	6 wk warfarin
Homozygous FV Leiden or prothrombin 20210	Prophylactic dose* LMWH	6 wk warfarin
FV Leiden/prothrombin 20210		
Antithrombin III deficiency		
Multiple thrombophilic defects		
Secondary prophylaxis—Women with previous VTE		
Single provoked VTE, no thrombophilia	Clinical surveillance	6 wk warfarin
Prior estrogen-related VTE ± thrombophilia	Prophylactic dose* LMWH	6 wk warfarin
Prior unprovoked VTE, no thrombophilia	Prophylactic dose* LMWH or clinical surveillance	6 wk warfarin
Prior VTE and thrombophilia (not on long-term warfarin)	Prophylactic* or intermediate dose† LMWH	6 wk warfarin
Prior VTE and thrombophilia (on long-term warfarin)	Adjusted dose‡ LMWH	Resume long-term warfarin

*Prophylactic dose = enoxaparin 40 mg SC q 24 hr or dalteparin 5000 U SC q 24 hr.

†Intermediate dose = enoxaparin 40 mg SC q 12 hr or dalteparin 5000 U SC q 12 hr.

‡Adjusted dose = enoxaparin 1 mg/kg SC q 12 hr or dalteparin 100 U/kg SC q 12 hr.

FV Leiden, factor V Leiden; VTE, venous thromboembolism; LMWH, low molecular weight heparin.

Secondary Prophylaxis in Women with Previous Thrombosis

The risk for VTE in pregnancy and especially during the postpartum period is generally increased for women with a prior history of VTE, although according to published studies, recurrence rates range from 0% to 15%. This risk appears to be higher in women with a prior unprovoked event and/or other coexisting inherited or acquired thrombotic risk factors.⁷⁵ The risk of recurrent VTE is increased after miscarriage and terminations and is particularly high after stillbirth.⁷⁶ This risk also appears to be increased for women with a prior estrogen-related thrombosis.⁷⁶

When considering therapy for a patient who is currently pregnant, the physician should review the numbers and types of previous episodes (spontaneous or provoked by a transient risk factor), the requirements for long-term anticoagulation, thrombophilic defects, and concurrent risk factors, such as obesity, immobilization, and multiple gestation.^{42,72}

Management options during pregnancy include clinical surveillance or active prophylaxis with LMWH or UFH (see Table 36-3). LMWHs are preferred for prophylaxis during pregnancy, although no consensus has been reached on the optimal dosing regimen. The use of UFH requires more frequent injections, and standard prophylactic doses (e.g., 5000 U every 12 hours) may be inadequate in women with a high-risk pregnancy. Thus, higher doses (7500 to 10,000 U every 12 hours) and/or doses that provide detectable prophylactic anti-FXa levels (0.1 to 0.3 U per milliliter) are often recommended.⁴² Although no randomized controlled trials have confirmed efficacy during pregnancy, low recurrence rates were reported in all studies in which LMWH was used for prophylaxis of VTE.⁴⁴ Prophylaxis, when indicated, should be initiated as soon as pregnancy is confirmed.¹³⁻¹⁵

Available evidence suggests that women with a single prior provoked VTE who do not have thrombophilia or other persistent risk factors have a low rate of recurrence during pregnancy and may be safely followed without antepartum anticoagulation.⁷⁵ Prophylaxis during pregnancy should be considered, however, in women with a prior estrogen-related VTE.⁴² Women with a history of VTE who do not receive prophylactic anticoagulation during pregnancy should be given a postpartum course of warfarin. Graduated elastic compression stockings are recommended for all women with a prior DVT.⁴²

Women with a prior unprovoked VTE who do not have thrombophilia and who are not receiving long-term anticoagulation therapy may be treated with prophylactic LMWH (or UFH) or clinical surveillance. LMWH should particularly be considered for women with a prior PE because the risk of recurrence in these patients is relatively high.^{77,78}

Women with a history of VTE and confirmed thrombophilia who are not receiving long-term anticoagulation should be given prophylactic LMWH during pregnancy, followed by a 6-week postpartum course of warfarin. Standard prophylactic doses (e.g., enoxaparin 40 mg every 24 hours) or intermediate doses (enoxaparin 40 mg twice daily) are appropriate, depending on the thrombophilic profile. For example, although prophylactic doses are adequate for most women with heterozygous FV Leiden, an intermediate dose of LMWH is recommended for those

with homozygous or combined defects, antithrombin III deficiency, or APLS.⁴² Women with a prior VTE who are on long-term anticoagulant therapy usually require adjusted therapeutic doses of LMWH during pregnancy, followed by resumption of warfarin postpartum.⁴²

The pentasaccharide fondaparinux has been successfully used for this indication.⁶⁸

Treatment of Acute Thrombosis During Pregnancy

Women who develop acute VTE during pregnancy should receive therapeutic doses of LMWH or UFH. LMWHs are preferable because of their ease of administration, more predictable antithrombotic effects, and excellent safety profile.⁴² Because of the increased clearance rate of LMWH during pregnancy, twice-daily regimens provide a more consistent anticoagulant effect than is attained with once-daily dosing. If UFH is administered, the initial dose is given intravenously as a bolus, followed by a continuous infusion adjusted to prolong the mid-interval PTT into the therapeutic range for at least 5 days. Adjusted subcutaneous doses of UFH or LMWH are substituted for the remainder of pregnancy. Multiple randomized trials and meta-analyses have confirmed that LMWH is at least as safe and effective as UFH for the treatment of nonpregnant patients with acute DVT and PE.⁷⁹⁻⁸¹

Therapeutic doses of LMWH are usually continued throughout pregnancy because of the high risk of recurrent thrombosis. It is unknown whether the dose of LMWH can be safely reduced after an initial period of full anticoagulation because no studies have compared different dosing regimens in pregnant women. However, lowering of the dose of LMWH after an initial phase of therapeutic anticoagulation was effective in patients with malignancy, who are also at high risk for recurrence.⁸² Therapeutic doses of LMWH should be continued for at least 4 to 6 weeks after diagnosis of acute VTE. Switching to an intermediate dose for the remainder of pregnancy may reduce the risks of bleeding and osteoporosis. Until evidence-based guidelines become available, decisions about dosing should be based on assessment of the risks of recurrence and adverse effects in each individual case.

Delivery

In general, therapeutic doses of LMWH or subcutaneous UFH should be discontinued 24 hours prior to elective induction of labor or cesarean section so that the risk of hemorrhage may be reduced and safe epidural anesthesia provided (Table 36-4).⁴² Therapeutic doses of subcutaneous UFH may cause a persistent anticoagulant effect at the time of delivery.⁸³ Preliminary data suggesting that LMWH may be safely discontinued 12 hours before delivery of epidural anesthesia require confirmation in larger groups of women receiving therapeutic doses.⁸⁴ Reinitiation of LMWH should be delayed for at least 2 hours after the epidural catheter is removed. Women who are given LMWH should be instructed to discontinue their injections at the onset of spontaneous labor. If an unacceptable anticoagulant effect is expected at the time of delivery on the basis of the timing of the last dose or current anti-FXa levels, epidural anesthesia should be avoided. Protamine sulfate may partially reverse

Table 36-4 Management of Peripartum Antithrombotic Therapy

Discontinue LMWH 24 hours before elective induction or cesarean section or at onset of spontaneous labor.

High-risk women with recent VTE:

- Consider substituting IV UFH until 4 to 6 hours before expected time of delivery and/or retrievable IVC filter.
- Avoid epidural anesthesia if last dose LMWH within 12 hours or detectable anti-FXa levels.
- Consider protamine for excessive anticoagulation or bleeding at delivery if last dose of LMWH within preceding 8 hours.
- Consider antithrombin III replacement for antithrombin III-deficient women. First dose prior to delivery. Maintain antithrombin III level at 80% to 120% of normal until restarting LMWH postpartum

Postpartum

- Start LMWH and warfarin as soon as hemostasis is confirmed after delivery (within 12 hr).
- Delay at least 2 hours after epidural catheter removal.
- Continue LMWH until warfarin therapy adequate (INR 2–3 for 48 hr).

LMWH, low molecular weight heparin; VTE, venous thromboembolism; IVC, inferior vena caval; FXa, factor Xa; INR, international normalized ratio.

excessive anticoagulation at the time of delivery, especially if LMWH has been administered within the preceding 8 hours.^{35,71} In women at very high risk of recurrence, intravenous UFH may be substituted and discontinued 4 to 6 hours before the expected time of delivery, to minimize the period of subtherapeutic anticoagulation.^{42,85} Women with inherited antithrombin III deficiency might be considered for peripartum replacement therapy with purified antithrombin III concentrates. An initial dose of 50 U per kilogram is given prior to delivery. Plasma antithrombin III levels should be maintained in the optimal range of 80% to 120% until LMWH therapy is reinitiated postpartum. The shorter half-life of antithrombin III during pregnancy (approximately 29 hours) may necessitate daily dosing.

Postpartum Treatment

LMWH (or UFH) should be restarted postpartum as soon as adequate hemostasis has been confirmed, optimally within 12 hours after an uncomplicated delivery. Warfarin can be started at the same time. LMWH/UFH should be continued until the international normalized ratio (INR) is within the therapeutic range (2–3) for at least 48 hours. Postpartum anticoagulation should be continued for at least 6 weeks, or until a minimum total 3-month course is completed in cases of VTE occurring late in pregnancy.⁴² The optimal duration of anticoagulation after pregnancy-related VTE is unknown. The decision regarding treatment duration should be based on the extent and timing of VTE during pregnancy, thrombophilic defects, prior thrombotic history, and coexisting risk factors. Women with APLS or antithrombin III deficiency are at high risk for recurrence and usually require long-term anticoagulation. LMWH, UFH, fondaparinux, and warfarin are not secreted into breast milk and are safe for women who plan to breast-feed.⁴²

Inferior Vena Caval Filters

Indications for placement of filters in the IVC during pregnancy are the same as in nonpregnant patients, that is, acute VTE with a strong contraindication to anticoagulation, recurrent VTE despite adequate anticoagulation, and selected critically ill patients at high risk of recurrent fatal PE (see Chapter 31). Filter insertion into the IVC appears to be technically safe during pregnancy, as noted in case reports and case series.⁸⁶ The newer retrievable filters are as effective as permanent filters and have a similar complication rate.⁸⁷ Continued anticoagulation while the filter is in place is recommended unless the risk for bleeding outweighs the risk of thrombosis. Although the use of retrievable filters during pregnancy has not been systematically studied, multiple case reports describe their efficacy and the lack of associated maternal or fetal complications.⁸⁸ A retrievable filter inserted into the IVC prior to delivery provides protection against PE in high-risk women with proximal DVT who are given a diagnosis near term; the filter can be removed postpartum.

Thrombolytic Therapy

Current data on the use of thrombolytic therapy in pregnant women are limited to case reports and case series.^{89–91} Thrombolytic agents have been used safely in small numbers of pregnant women with massive PE, thrombosed cardiac valves, acute stroke, large DVTs and renal vein thrombosis.^{90–93} Information on their use has recently been collected and reviewed.⁹³ Systemic thrombolysis and local catheter-directed thrombolysis have both been performed successfully in pregnant women. Maternal hemorrhage and fetal loss are estimated to occur in approximately 6% of pregnant women receiving systemic thrombolysis, although the complication rate has not been well defined.⁹¹

Thrombolytic therapy should be reserved for pregnant women with life-threatening VTE (e.g., unstable PE with circulatory compromise) who require rapid clot lysis. When thrombolysis is required, recombinant tissue plasminogen activator and streptokinase are favored over urokinase because both are large molecules that do not cross the placenta in significant amounts.^{91,93,94}

ANTIPHOSPHOLIPID ANTIBODIES AND THE ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid antibodies (APLAs) comprise a heterogeneous group of autoantibodies directed against proteins bound to phospholipid. APLAs are found in 1% to 10% of healthy individuals, 4% to 14% of patients who present with VTE, and approximately 30% of those with lupus. Patients with APLA identified on two occasions of testing are given a diagnosis of APLS if they also have a history of arterial, venous, and/or small vessel thrombosis, or a history of pregnancy morbidity. Adverse pregnancy outcomes that are diagnostic of the syndrome include three or more unexplained spontaneous miscarriages before 10 weeks, one or more unexplained fetal deaths at or after 10 weeks, and premature birth (before 35 weeks) due to severe preeclampsia or placental insufficiency.⁹⁵ Women with APLS may have obstetric complications in the absence

of a history of arterial or venous thrombosis. Laboratory criteria require demonstration of moderate or high levels of immunoglobulin (Ig)G or IgM anticardiolipin antibodies or a lupus inhibitor on two occasions at least 6 weeks apart. Lupus inhibitors and high-titer IgG anticardiolipin antibodies are most strongly associated with thrombotic complications of the syndrome.⁹⁶ A lupus inhibitor may also be a strong predictor of thrombosis during pregnancy.⁹⁷ It is unclear whether measurement of anti- β_2 -glycoprotein (GP) I antibodies provides additional information about pregnancy complications beyond that attained through anticardiolipin antibody and lupus inhibitor testing.⁹⁸

Implications of a Positive Test for APLA

The prevalence of APLA in unselected obstetric populations is similar to that in healthy nonpregnant individuals; it ranges from 2% to 9%.^{99,100} APLAs are found in up to 20% of women with recurrent pregnancy loss (RPL); they are risk factors for fetal loss and other pregnancy complications.¹⁰¹ In several studies, consistently lower live birth rates have been noted in low-risk women with APLA compared with women without these antibodies.^{100,102–104} The association between APLA and fetal loss is strongest for unexplained losses that occur during the second or third trimester.^{105,106} However, a recent meta-analysis reported a significant overall threefold increased risk of early and late pregnancy loss.²⁶ Pregnancy is assumed to markedly increase the risk of VTE in patients with APLA, but no large studies have estimated the risk. This assumption is based on the marked increase in overall thrombotic risk that occurs when multiple predisposing factors are combined. A small case-controlled study found that APLAs occurred in 27% of women with pregnancy-associated VTE compared with 3% of control women with uneventful pregnancies.¹⁰⁷

Management During Pregnancy

During pregnancy, women with APLS are at risk for thrombosis, fetal loss, and possibly other maternal and fetal complications. Women with APLA should be counseled regarding potential thrombotic and obstetric complications. High-risk women should be evaluated prior to conception so that a plan for management during pregnancy can be formulated. Testing for other thrombophilic disorders should be considered, especially if patients report a prior history of VTE.¹⁰⁸ Coexisting prothrombotic risk factors enhance the risk for thrombosis in patients with APLA, underscoring the importance of a careful assessment in each individual case.¹⁰⁹ Pregnant women with APLS require close maternal and fetal monitoring, including frequent surveillance of fetal growth and development and periodic platelet counts, especially if they have had a history of thrombocytopenia. However, serial measurement of APLA is unnecessary because fluctuations in titer will not affect management.

Primary Prophylaxis in Asymptomatic Women

Treatment for asymptomatic women with APLA and no prior history of thrombosis or fetal loss is controversial (Table 36-5). Therapeutic strategies include clinical surveillance or low-dose aspirin given alone or in combination

Table 36-5 Management of Pregnant Women With Antiphospholipid Antibodies (APLA) in the Presence or Absence of Antiphospholipid Syndrome (APLS)

Monitoring

Monitor fetal growth and development as well as maternal platelet count

Primary prophylaxis: Asymptomatic women with APLA

Antepartum: Clinical surveillance or low-dose aspirin (80–100 mg/d) and/or prophylactic dose LMWH or UFH*
Postpartum: Warfarin (INR 2–3) for 6 weeks

Secondary prophylaxis: Women with APLS (prior thrombosis)

Women receiving long-term warfarin
Antepartum: Adjusted dose LMWH or UFH $\pm$ low-dose aspirin (80–100 mg/d)
Postpartum: Resume long-term warfarin (INR 2–3)
Women not receiving warfarin
Antepartum: Prophylactic or intermediate dose LMWH or UFH $\pm$ low-dose aspirin (80–100 mg/d)
Postpartum: Warfarin (INR 2–3) for 6 weeks or longer

Secondary prophylaxis: Women with APLS (prior recurrent or late fetal loss)

Antepartum: Prophylactic dose LMWH or UFH and low-dose aspirin (80–100 mg/d)
Postpartum: Warfarin (INR 2–3) for 6 weeks

Treatment of acute thrombosis

Antepartum: Adjusted dose LMWH or UFH throughout pregnancy
Postpartum: Warfarin (INR 2–3) for extended period

*Heparin doses are defined in Table 36-3.

LMWH, low molecular weight heparin; UFH, unfractionated heparin; INR, international normalized ratio.

with prophylactic doses of heparin. No prospective trials have been conducted to evaluate prophylactic anticoagulation in women with APLA without clinical manifestations of the syndrome. In the absence of evidence-based recommendations, some experts suggest low-dose aspirin,⁹⁸ whereas others favor withholding of pharmacologic therapy because of the high probability of a successful pregnancy outcome.¹¹⁰ The guidelines of the ACCP endorse surveillance, prophylactic doses of heparin (LMWH or UFH) and/or low doses of aspirin for asymptomatic women with persistent APLA.⁴² The same approach is appropriate for women with one or two prior early pregnancy losses (before 10 weeks gestation). Treatment decisions should take into account the APLA profile and other thrombotic risk factors. In asymptomatic women with persistent APLA, a 6-week course of warfarin might be considered postpartum.

Secondary Prophylaxis in Women with Prior Thrombosis

Women with APLS based on persistent APLA and a history of thrombosis should receive prophylactic anticoagulation throughout pregnancy and during the postpartum period. Most experts favor low-dose aspirin given in combination with heparin, despite the lack of evidence of additional benefit.^{42,98} Indications for aspirin may be stronger in women with prior arterial thrombosis and/or pregnancy complications. It is unknown whether a history of thrombosis enhances the risk of an adverse pregnancy outcome. The dose of heparin depends on previous thrombotic

history and indications for long-term therapy. Therapeutic doses of LMWH or UFH are recommended for women on long-term anticoagulation prior to pregnancy, followed by resumption of warfarin postpartum. Women with APLA and a single prior VTE episode who are not receiving long-term anticoagulation may be treated with prophylactic or intermediate doses of LMWH (or UFH), followed by a 6-week postpartum course of warfarin.⁴² LMWH is restarted after delivery, along with warfarin, and is continued until a therapeutic INR is attained.^{2,3}

Secondary Prophylaxis in Women with Previous Fetal Loss

Women with APLS who have a history of recurrent and/or late fetal loss may require antithrombotic therapy during subsequent pregnancies. Available evidence suggests that aspirin alone is ineffective in preventing pregnancy loss in this population.¹¹¹ Two small, randomized trials showed that low-dose aspirin and prophylactic doses of UFH reduced the risk of pregnancy loss by 54%, compared with aspirin alone. Live birth rates were 71% and 80% with combination therapy, compared with 42% and 44% with aspirin alone.^{111–113} Live birth rates were similar with high (16,000 to 40,000 U per day) and low (10,000 to 25,000 U per day) doses of UFH (80% and 76%, respectively).¹¹⁴ The superiority of aspirin given together with heparin has established combination therapy as the standard of care for women with APLS characterized by APLA and fetal loss.

No large randomized trials have compared LMWH with UFH in the prevention of pregnancy complications in women with APLS. Prophylactic LMWH given alone or in combination with aspirin produced live birth rates ranging from 84% to 93% in several small comparative trials and prospective cohort studies.^{97,115–118} A uniform treatment protocol tailored to the complete spectrum of APLA-associated obstetric complications resulted in the highest live birth rate (93%), underscoring the value of clinical pathways and comprehensive multidisciplinary care.⁹⁷ Despite the lack of randomized trials, most experts favor the use of LMWH because of its multiple advantages over UFH and evidence of equivalent efficacy in all other settings studied.^{42,110} ACCP and other consensus guidelines recommend low-dose aspirin and prophylactic doses of heparin (LMWH or UFH) throughout pregnancy for women with APLS who have a history of two or more early miscarriages, or one or more late fetal losses, preeclampsia, fetal growth restriction (FGR), or placental abruption.^{42,98,119} Aspirin therapy is started prior to conception or at the time of a positive pregnancy test. LMWH (or UFH) should be started as soon as pregnancy has been confirmed.¹¹⁰ A postpartum course of anticoagulation is also recommended because women with APLA and fetal loss have an increased risk of subsequent thrombosis.^{42,98,120} Women with previous thrombosis and pregnancy loss usually require higher adjusted doses of LMWH (or UFH) in combination with aspirin. No role for immunomodulatory agents (e.g., corticosteroids or IVIg) in the treatment of pregnant women with APLS has been established.¹¹⁸

Treatment of Acute Thrombosis

Pregnant women with APLS who develop acute thromboembolism require therapeutic doses of LMWH (or UFH)

throughout pregnancy, followed by a minimum 6-week course of warfarin postpartum. Reevaluation of APLA status postpartum is useful in newly diagnosed women because persistent APLAs are an indication for long-term anticoagulation. The general consensus favors indefinite anticoagulation on the basis of evidence that patients with APLS are at high risk for recurrent thrombosis if anticoagulation is stopped.^{121,122} Two randomized trials showed that moderate-intensity warfarin (INR, 2 to 3) is as effective as high-intensity warfarin (INR, 3 to 4.5) in preventing recurrent thrombosis in patients with APLS.^{123,124}

APLA and Other Pregnancy Complications

The association of APLA with other obstetric complications such as preeclampsia, FGR, and placental abruption is controversial, with conflicting results reported in different studies. High rates of preeclampsia and FGR (up to 50% and 30% of pregnancies, respectively) were reported in a series of women with known APLS that included a substantial number of women with lupus and/or prior thrombosis.^{125,126} Unselected low-risk pregnant women with APLA identified by first-trimester screening had a higher incidence of preeclampsia in some^{102,104,127} but not all studies.^{101,103} APLAs were not associated with mild, severe, or early onset of preeclampsia in several series of unselected women who presented with the disorder,^{128,129} and they did not predict a recurrence during a subsequent pregnancy.¹³⁰ However, in a recent meta-analysis, APLAs were associated with a nearly threefold increased risk of preeclampsia.²⁶ APLAs were associated with FGR or low-birthweight infants in several¹⁰⁴ but not other studies.¹⁰³

Despite evidence of an improved live birth rate for women with APLS, it remains unclear whether the frequency of other pregnancy complications is reduced by antithrombotic therapy. No association has been found between the antithrombotic regimen and the frequency of preeclampsia, prematurity, or FGR in randomized trials of prophylaxis in women with fetal loss. Despite the higher live birth rates achieved with heparin and aspirin, a substantial number of successful pregnancies were complicated by preeclampsia, prematurity, and low-birthweight infants.^{131,132} No trials have evaluated the efficacy of antithrombotic therapy in preventing these other complications in pregnant woman with APLS. Expert opinion and consensus guidelines suggest that antepartum low-dose aspirin and LMWH (or UFH) should be used for pregnant women with APLA and prior severe or recurrent preeclampsia, abruption, or FGR.^{42,133}

PREGNANCY-ASSOCIATED STROKE

The estimated incidence of ischemic stroke associated with pregnancy is in the range of 4 to 18 events per 100,000 deliveries.^{134–136} The time of greatest risk is the postpartum period.^{135–138}

Most cases of embolic stroke are associated with a cardiac source in women with damaged or prosthetic valves. Peripartum cardiomyopathy, a rare complication of pregnancy, may result in a left ventricular thrombus and embolic stroke in up to 10% of cases.¹³⁹ Arterial thromboembolism may occur “paradoxically” through a patent

foramen ovale (PFO) in patients with venous thrombosis.^{140–142} Predisposition to venous thrombosis and hemodynamic changes associated with pregnancy may make paradoxical embolism through a PFO likely, especially with intense Valsalva maneuvers during labor and delivery (see Chapter 44). Cerebral vein thrombosis is another potential cause of pregnancy-related stroke.^{134,138} Preeclampsia is the most common pregnancy-associated risk factor for stroke.^{135,137}

The contribution of thrombophilia to pregnancy-related stroke is unclear; hyperhomocysteinemia and APLS are established risk factors for arterial thrombosis in nonpregnant patients. Inherited thrombophilic disorders are not major risk factors for stroke, and the cause remains unknown in as many as 22% to 32% of reported cases.^{134,135}

Diagnostic evaluation of suspected stroke during pregnancy is similar to that performed in nonpregnant patients, although cerebral vein thrombosis and paradoxical embolism warrant special consideration. Routine head CT scanning with abdominal shielding results in an acceptably low fetal radiation exposure, and magnetic resonance imaging (MRI) is considered safe, especially in later trimesters.¹³⁹ Evaluation of pregnancy-related stroke should include an echocardiogram to look for a cardiac source of embolism and a PFO. Patients with a PFO and/or known thrombophilia should be evaluated for DVT, which is an indication for anticoagulation. Paradoxical emboli may also originate from pelvic veins in pregnant and postpartum women. The diagnosis of cerebral vein thrombosis requires a high index of suspicion; it is confirmed by MR venography because routine CT is so frequently falsely negative.

No controlled studies have investigated thrombolytic therapy during pregnancy, and pregnant women were excluded from the stroke trials. Although thrombolytic agents are generally avoided because of the risk of maternal and fetal complications, multiple reports have described their successful use in pregnant women with acute stroke.^{92,93,143} Anticoagulation with LMWH or UFH is recommended for cerebral vein thrombosis, even in the presence of hemorrhagic infarction^{144,145} (see Chapter 16).

No randomized trials of antithrombotic therapy have explored stroke prevention in pregnant women. Low-dose aspirin is recommended for women with a history of non-cardioembolic stroke with no other risk factors.¹⁴⁵ Available evidence suggests that low-dose aspirin given during the second and third trimesters is safe for mother and fetus.⁴² Other antiplatelet agents should be avoided because their safety during pregnancy has not been confirmed. LMWH or UFH throughout pregnancy is suggested for women with a history of ischemic stroke and known thrombophilia or with a potential cardiac source of embolism.¹⁴⁵ Women with mechanical heart valves are at high risk for arterial thromboembolism and frequently require therapeutic dose anticoagulation throughout pregnancy. Adjusted doses of LMWH or UFH with laboratory monitoring are favored over second- and third-trimester warfarin, although the optimal antithrombotic regimen is controversial.⁴² LMWH or UFH is also recommended for women who have had a recurrent transient ischemic attack (TIA), or who have sustained a stroke despite receiving aspirin therapy.

No consensus has been attained regarding the treatment of women with a history of stroke and APLS during

pregnancy. Clinical studies in nonpregnant patients have shown that patients with APLS have a high risk of recurrent thrombosis, which tends to occur in the same vascular distribution as the original event. Thus, LMWH or UFH, with or without low-dose aspirin, should be considered for pregnant women with high-titer antibodies and multiple complications of APLS.

Women with a history of stroke may seek counseling regarding the risks associated with pregnancy. Extremely limited data are available on maternal and fetal outcomes of subsequent pregnancies in women with prior stroke. Two retrospective series have reported a low risk of recurrent stroke during subsequent pregnancies (0% and 1% of pregnancies, respectively).^{146,147} None of the women with an initial pregnancy-related stroke experienced recurrence during subsequent pregnancies. The risk of recurrent stroke was increased during the postpartum period (relative risk, 9.7), but not during pregnancy itself.¹⁴⁷ Although these results should be interpreted with caution, the observed low risk of recurrence suggests that a history of stroke is not a contraindication to a future pregnancy.

THROMBOPHILIA AND OBSTETRIC COMPLICATIONS

Serious obstetric complications, including RPL, preeclampsia, FGR, and placental abruption, occur in 1% to 5% of pregnant women and are believed to involve impaired placental perfusion. Thrombophilia may enhance susceptibility to placental thrombosis and gestational vascular complications. In addition to APLS, most inherited thrombophilic disorders have been linked to fetal loss and other complications. Thrombophilic defects were identified in 49% to 65% of women with obstetric complications, compared with 18% to 22% of women with normal pregnancies, suggesting a three- to eightfold increase in risk (Table 36-6).^{148,149}

Available evidence suggests that FV Leiden is a risk factor for recurrent pregnancy loss. A large number of case-controlled studies found a high prevalence of FV Leiden in women with unexplained RPL (up to 30%), compared with 1% to 10% of control subjects, with odds ratios ranging from 2 to 5.^{150–154} Several other studies, however, found no association.^{155–157} Most of these studies were smaller and primarily included women with first-trimester fetal losses that are often caused by nonthrombophilic factors.

The prothrombin 20210 mutation was linked to fetal loss in some but not all studies. This mutation was found in 4% to 9% of women with RPL (most during the first trimester), compared with 1% to 2% of those with uncomplicated pregnancies, with odds ratios ranging from 2 to 9.^{150,158–162} A large case-controlled study identified FV Leiden and the prothrombin 20210 mutation as independent risk factors for a first unexplained fetal loss after 10 weeks gestation, with odds ratios of 3.5 and 2.6, respectively.¹⁵⁰ Two other studies found the prothrombin 20210 mutation in 9% to 13% of women with a first unexplained third-trimester loss, compared with 2% to 3% of control subjects, suggesting a two- to threefold increase in risk.^{153,161} Several other studies found no significant association with fetal loss.^{151,154} In several meta-analyses, FV Leiden and the prothrombin 20210 mutation each conferred

Table 36-6 Thrombophilia and Risk of Pregnancy Loss*

Thrombophilic Disorder	Prevalence in Women with Fetal Loss	Prevalence in Controls	Risk of Fetal Loss (odds ratio)
Factor V Leiden	8%–30%	1%–10%	2–5
Prothrombin 20210	4%–13%	1%–2%	2–9
Antithrombin III deficiency	0%–2%	0%–1.4%	2–5
Protein C deficiency	6%	0%–2.5%	2–3
Protein S deficiency	5%–8%	0%–0.2%	3–40
Hyperhomocysteinemia	17%–27%	5%–16%	3–7
Combined thrombophilia	8%–25%	1%–5%	5–14
APLA	20%	5%	3–5

*Variably defined as first or recurrent early and/or late pregnancy loss. APLA, antiphospholipid antibody.

a two- to threefold increased risk of recurrent first-trimester and later fetal loss.^{163–165}

Deficiencies in the natural anticoagulant proteins C, S, and antithrombin III increased the risk of fetal loss according to most,^{166,167} but not all, of the limited number of studies.^{154,160} These conflicting results may reflect the relative rarity of these disorders and the small numbers of women studied. In a report on thrombophilic families, 22% of pregnancies in women who were deficient in protein C, protein S, or antithrombin III ended in fetal loss, compared with 11% of those in unaffected family members, suggesting a twofold increase in risk.¹⁶⁷ An increased risk of stillbirth was reported in women with antithrombin III or protein S deficiency but not in those with protein C deficiency.¹⁶⁶ A prospective cohort study found no significant increase in risk of fetal loss, but only a small number of women were included in the trial.¹⁶⁸

Hyperhomocysteinemia was found in 17% to 27% of women with first or recurrent fetal loss, compared with 5% to 16% of control women, with odds ratios ranging from 3 to 7.^{169–171} Interpretation of these studies is complicated by varying definitions of hyperhomocysteinemia, timing and method of testing, and use of supplemental vitamins. One study suggested that homocysteine levels have a graded effect on risk, with levels greater than 15 μmol per liter conferring a sevenfold increased risk of a first fetal loss at 8 to 9 weeks gestation.¹⁶⁹ A meta-analysis found a three- to fourfold increased risk of recurrent early pregnancy loss in women with hyperhomocysteinemia.¹⁷² In contrast, no convincing evidence suggests that a homozygous MTHFR 677 mutation is a risk factor for pregnancy complications independent of homocysteine levels. This mutation was not associated with an increased risk of early or late fetal loss in a large number of observational studies, a prospective study of primigravid women, and a large meta-analysis.^{151,153,154,163,173}

Women with multiple thrombophilic defects have approximately a ninefold to 14-fold increased risk of late pregnancy loss compared with a fourfold higher risk with only a single defect.^{151,166,174} Although most pregnancy losses occur during the first trimester, evidence suggests that thrombophilic women may have a higher risk of loss at later stages of gestation.¹⁷⁵ Multiple studies, including two meta-analyses, have suggested that FV Leiden carriers have a greater risk of late pregnancy loss than early first-trimester loss.^{150,163,166,176} Other data suggest that women

with other thrombophilic defects also have a greater risk of late pregnancy loss.^{151,166} One possible explanation is that late pregnancy loss reflects thrombosis of placental vessels, in contrast to first-trimester losses, which are more commonly due to other causes. However, thrombophilia also increases the risk of an early first-trimester fetal loss.^{162,163,169,177}

Although preeclampsia, FGR, and placental abruption may also involve impaired placental perfusion, their association with thrombophilia remains controversial. This may reflect the varying diagnostic and selection criteria, different ethnic groups, and small number of cases included. Multiple case-controlled studies have found at least one thrombophilic defect in 40% to 72% of women with preeclampsia, compared with 8% to 20% of control women with normal pregnancies.^{148,178,179} In contrast, other studies have not demonstrated an association.^{157,180,181} The prevalence of FV Leiden was significantly higher in women with preeclampsia than in women with normal pregnancies, with odds ratios ranging from 2 to 6.^{148,178,182,183} Several other studies found no difference in prevalence of the mutation between preeclamptic and control women.^{157,180,181} A FV Leiden mutation did not increase the risk of preeclampsia in three prospective studies of unselected pregnant women who were screened during the first trimester.^{27,28,173} Several large meta-analyses found an overall twofold to threefold increased risk of preeclampsia.^{184–186}

The role of other thrombophilias in the pathogenesis of preeclampsia remains uncertain. Most studies, including two meta-analyses, have found no association with the prothrombin 20210 mutation.^{157,181,185,187} A large number of studies have suggested that hyperhomocysteinemia increases the risk of preeclampsia. Women with second-trimester homocysteine levels greater than 5 to 10 μmol per liter had a three- to fourfold greater risk of developing preeclampsia, suggesting that hyperhomocysteinemia may reveal a high-risk group.^{188,189} Most studies found no association between a homozygous MTHFR 677 mutation and preeclampsia, underscoring once again the importance of measuring homocysteine levels rather than MTHFR genotypes.^{157,173} Conflicting results reported may be due at least in part to major differences in the severity of preeclampsia.^{181,182} Thrombophilic women with severe preeclampsia may have a higher risk of serious maternal complications and adverse perinatal outcomes than those

without thrombophilia.^{179,182} Thrombophilia was also linked to an earlier onset of severe preeclampsia in several studies.^{182,187}

Data on the risk of FGR and placental abruption are more limited but also conflicting. In a recent meta-analysis, FV Leiden and the prothrombin 20210 mutation were both found to be associated with a significant two- to threefold increased risk of FGR.¹⁹⁰ In contrast, two larger case-controlled studies found no association between maternal or fetal thrombophilia and FGR.¹⁹¹

FV Leiden, the prothrombin 20210 mutation, and hyperhomocysteinemia were associated with an increased risk of placental abruption in some^{148,192–194} but not other studies.^{157,195}

Antithrombotic Therapy for Preventing Obstetric Complications

The high prevalence of thrombophilia in women with gestational vascular complications and the tendency for recurrence provide a rationale for trials of prophylactic anticoagulation to improve pregnancy outcomes. Current data on antithrombotic therapy in women with hereditary thrombophilia and pregnancy loss are limited to several observational studies and two randomized trials. In one study, 50 thrombophilic women with recurrent pregnancy loss received enoxaparin throughout 61 subsequent pregnancies. The live birth rate was 75% with enoxaparin prophylaxis, compared with 20% in prior untreated pregnancies.¹⁹⁶ Another study reported a similar live birth rate of 70% with enoxaparin prophylaxis compared with 44% in untreated historical control women.¹⁹⁷ A prospective randomized trial compared prophylactic doses of enoxaparin with low doses of aspirin in women with the prothrombin 20210 mutation, FV Leiden or protein S deficiency, and a single unexplained fetal loss. Enoxaparin prophylaxis was associated with a significantly higher live birth rate of 86% compared with 29% with aspirin, suggesting a 15-fold greater likelihood of a successful outcome.¹⁹⁸ The LIVE-ENOX trial randomly assigned thrombophilic women with a history of recurrent pregnancy loss to two different doses of enoxaparin. Prophylactic doses (40 mg per day and 80 mg per day) resulted in similar high live birth rates of 84% and 78%, respectively. These rates were substantially higher than the 23% live birth rate reported in prior untreated pregnancies.¹⁹⁹ No prospective randomized trials included an untreated control group, confirming the benefit of LMWH in this setting. However, the concordant results of these studies strongly suggest that anticoagulation therapy may improve pregnancy outcomes in thrombophilic women. Until additional studies are completed, antithrombotic prophylaxis should be considered in selected thrombophilic women with unexplained recurrent pregnancy loss after an informed discussion of the risks and potential benefits. The evolving consensus in favor of prophylactic anticoagulation is reflected by recent ACCP guidelines, which recommend prophylactic doses of LMWH or UFH and low doses of aspirin for thrombophilic women who have had recurrent pregnancy loss or a single loss during the second or third trimester.⁴²

It is unknown whether lowering high homocysteine levels with supplemental vitamins will improve pregnancy outcome. In a small, uncontrolled series, 20 of 22 women

with a history of hyperhomocysteinemia and RPL had a subsequent successful pregnancy after their homocysteine levels were normalized with folic acid and vitamin B₆.²⁰⁰ ACCP guidelines recommend supplemental folic acid throughout pregnancy for women who are homozygous for the MTHFR 677 mutation.⁴² High homocysteine levels should be lowered with folic acid (1 to 2 mg per day), optimally given prior to conception.

Few data support the benefit of antithrombotic therapy in thrombophilic women with other pregnancy complications. A few uncontrolled studies of thrombophilic women with preeclampsia, FGR, or placental abruption reported improved pregnancy outcomes with UFH or LMWH given with or without aspirin.^{201–203} However, these studies were small (total, 71 cases), and preeclampsia recurred in 38% of treated women in one study.²⁰² In the LIVE-ENOX study, incidences of preeclampsia, placental abruption, and FGR were substantially lower with enoxaparin prophylaxis than in prior untreated pregnancies.²⁰⁴ A study of thrombophilic women with prior fetal loss who received enoxaparin or aspirin during a subsequent pregnancy showed that those who were given enoxaparin had newborns with significantly higher birth weights, and fewer were classified as small for gestational age.¹⁹⁸ However, neither study was designed to evaluate these complications as primary outcomes. ACCP guidelines recommend low doses of aspirin and prophylactic doses of LMWH or UFH for thrombophilic women with a history of severe or recurrent preeclampsia or placental abruption.⁴² Decisions about antithrombotic therapy should be based on an individual risk:benefit assessment. Assessment of maternal thrombotic risk during pregnancy should also be incorporated into the clinical decision.

SCREENING FOR THROMBOPHILIA

It is widely agreed that routine laboratory screening for thrombophilia in pregnant women or women who might become pregnant is not warranted. Most experts favor a risk-stratified approach to testing—a strategy that is also cost effective.^{42,74,205} Evaluation for thrombophilia is recommended in women with a personal history of VTE. Testing should also be considered in asymptomatic women with a family history of thrombophilia and/or thrombosis, particularly if a positive result will affect management.^{42,74} Thrombophilic defects are found in up to 20% of women with normal pregnancies, suggesting that additional risk factors are required for the development of VTE or other complications. Selective thrombophilia screening requires an accurate patient history, focused on personal and family histories of thrombosis and prior exposure to circumstantial risk factors such as oral contraceptives.

Thrombophilic women have an increased risk of fetal loss and possibly other obstetric complications. Because the probability of a successful pregnancy outcome remains high, universal screening of pregnant women is not recommended. Women with unexplained fetal loss (≥ 3 miscarriages, intrauterine fetal death, or stillbirth), severe or recurrent preeclampsia, FGR, or placental abruption should be screened for APLAs. Recent ACCP guidelines also suggest that testing should be performed to identify inherited thrombophilias in light of accumulating evidence that prophylactic anticoagulation therapy may improve

pregnancy outcomes.⁴² Screening of women with a history of recurrent fetal loss or other unexplained severe pregnancy complications is reasonable after the implications of a positive test have been discussed, especially when a trial of LMWH is under consideration. Because of the risk of VTE, thrombophilic women may benefit from prophylaxis and counseling about present and future thrombotic risks.

Testing for patients with suspected thrombophilia includes a DNA assay for FV Leiden and for the prothrombin 20210 mutation, antithrombin III and protein C activity assays, free protein S antigen or activity assay, anticardiolipin antibody assay, multiple clotting tests for a lupus inhibitor, and measurement of plasma homocysteine level. Laboratory evaluation for thrombophilia can be performed during pregnancy with several caveats. Protein S antigen and activity levels decline during normal pregnancy (by $\geq 40\%$), making it difficult for clinicians to confirm or reliably exclude the diagnosis of an inherited deficiency. Homocysteine levels also decrease, especially with folic acid supplementation. Levels of antithrombin III, protein C, and protein S obtained immediately after an acute VTE may be misleadingly low, as has been noted in nonpregnant patients. DNA-based assays are reliable during pregnancy and acute thrombotic episodes; these are not affected by anticoagulant therapy. A complete laboratory evaluation should be performed, even after a single defect has been identified because combined thrombophilias are common.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA (PNH)

Paroxysmal nocturnal hemoglobinuria (PNH) is a special thrombophilic disorder that presents particular problems during pregnancy. PNH with and without pregnancy is discussed in Chapter 14.

Part VI

Special Issues

By observing and studying the effects of surgery and trauma on hemostasis—including physiologic as well as hypocoagulable and hypercoagulable situations—our understanding of the interrelationship between hemostasis and surgery has been advanced.

The following topics will be addressed in this chapter:

- Surgery for patients with congenital hemostatic defects
- The effects of surgery on hemostasis (with particular reference to cardiopulmonary bypass and orthotopic liver transplantation)
- Preoperative hemostatic testing
- Invasive procedures for patients with abnormal coagulation tests
- Invasive procedures for patients on anticoagulant therapy
- Consultation on patients with intraoperative or postoperative hemorrhage

Blood coagulation exists to halt excessive blood loss. It is paradoxical that surgery and trauma simultaneously represent major risk factors for both hemorrhagic and thrombotic complications. Although Kearon and Hirsh estimated that surgery and trauma increase the baseline risk of thrombosis up to a hundred-fold,¹ patients with mild hemophilia who have never bled from stresses of everyday life may bleed vigorously from surgical procedures.²

The history of the discovery of blood coagulation has been well reviewed by Ratnoff,³ whereas the maturation of our understanding of and management of traumatic and surgical wounds has been reviewed thoroughly by Majno.⁴ The concept of pressure dressings and ligation of blood vessels to control excessive bleeding was not described until 300 to 200 BC by physicians in Alexandria. It was not until the 18th century that the French surgeon Petit deduced that the clotting of blood had something to do with the control of hemorrhage following surgery; before that time, it was believed that constriction and retraction of vessels were the only mechanisms of hemostasis.⁴ Not until the end of the 19th century did Wright observe that blood from hemophiliacs clotted more slowly than normal blood and that perhaps this observation was causally related to the hemorrhage characteristics of hemophilia.³

SURGERY FOR PATIENTS WITH CONGENITAL HEMOSTATIC DEFECTS

That hemophiliacs bleed abnormally has been known since antiquity.⁵ Because uncontrolled bleeding occurred in the

hemophiliac's daily life, surgical procedures were generally avoided. Any surgery that was performed on hemophiliacs was usually done as a heroic measure; the results were expectedly disastrous and many patients bled to death.

Transfusion science was essentially nonexistent until World War II. Whole blood was available for hemophiliacs but it is now clear that although whole blood improved the hematocrit value, it was unable to raise the level of either factor VIII or factor IX by more than about 10% to 20%. With the development of blood banking following World War II, acute surgical hemorrhagic mortality dropped from 50% before any blood banking to about 25%. Cryoprecipitate was discovered by Dr. Judith Pool in the 1960s, allowing factor VIII levels to reach briefly any level desired. Hemorrhagic mortality dropped to 2%. After factor VIII and factor IX concentrates became available in the 1970s, factor VIII and factor IX levels could be raised to any level desired, theoretically indefinitely, and surgical mortality approached zero.⁶ Patients still experience nonfatal hemorrhage at an overall rate of approximately 18%.⁶⁻⁹ Elective diagnostic procedures such as liver biopsy have been reported to be both safe and effective in directing subsequent therapeutic decision making.¹⁰⁻¹²

Extracorporeal shock-wave lithotripsy (ESWL) can be performed safely using factor replacement levels of 50% to 60% before the treatments and for 3 to 5 days posttreatment. As in normal patients undergoing ESWL, hematuria is common, but serious (capsular or retroperitoneal) hematomas were not encountered in a series of 11 hemophiliacs so managed.¹³

Factor levels should be maintained in the patient undergoing surgery as high and as long as indicated. The prescribed factor is infused the morning prior to surgery and the factor level is measured before anesthesia induction to confirm that the factor has been appropriately administered and that no unexpectedly low increment of factor resulted (i.e., less than about 60% calculated), which could be the first and only sign of an occult inhibitor.

For fairly minor surgical procedures (including procedures such as endoscopy with biopsy, arthroscopic surgery, skin or breast biopsies, lymph node biopsies, and complicated dental work), the factor level is customarily kept at a "trough" of approximately 30% and a "peak" of about 60% for 3 to 4 days, with longer amounts being necessary if there is significant traction along the incision line. For more invasive surgery such as open abdominal or orthopedic surgery and particularly cardiovascular or neurologic surgery, a targeted "trough" concentration of 80% with a "peak" of 150% is advised. Although these levels are

clearly higher than physiologically required for hemostasis, the higher levels provide a cushion for missed doses or other logistic problems. “Peak and trough” levels are followed once a day for several days and can probably be gradually lowered as surgical hemostasis becomes more secure after about the fourth or fifth day. Most hemostatic wounds are well healed from a hemostatic point of view by the fourth or fifth day and, therefore, after that time factor levels can be allowed to drift down to about one half the levels required at the time of surgery. The most notable exceptions to these are procedures that are characterized by significant tension along the incision line such as open abdominal operations or operations through the muscles of posture (e.g., nephrectomy position). Therapy is often quite prolonged at a slightly lower level (50% to 60%) following major orthopedic surgery during rehabilitation and aggressive physical therapy. Otherwise, we rarely give factor longer than 7 to 10 days following surgical procedures. Table 37-1 provides general guidelines for surgical procedures in hemophiliacs.

If one wishes to use continuous infusion of factor concentrates, a more even level of factor concentration results with less severe peaks and troughs. Less factor administration is possible and overall costs are decreased as less factor is consumed. Therapeutic levels closer to 60% to 70% are sufficient accordingly.^{14,15}

Cardiovascular surgery can be done successfully in hemophiliacs. Best results are obtained if the surgeons, anesthesiologists, and perfusion technicians all use their routine protocols based on the dictum that a hemophiliac with near 100% replacement therapy can and should undergo diagnostic and therapeutic cardiac catheterization receiving heparin, protamine, and aprotinin as would any other patient. Monitoring the appropriate factor concentration, probably best managed by the hematologist so that others can focus on their tasks, is the only difference.^{16,17} An advantage of placing bioprosthetic heart valves in those

patients requiring valve replacement is that the dilemma presented by the chronic use of warfarin postoperatively can be avoided. The use of aspirin chronically for ischemic heart disease is uncertain and must be approached on a case-by-case basis,¹⁷ although its low-dose (81 mg/day orally) use following coronary artery bypass grafting (CABG) appears rational and safe.

In the rarer contact factor deficiencies (factor XII, high-molecular-weight kininogen, and prekallikrein), replacement therapy for surgery is not indicated. In order to monitor adequate heparin levels during cardiopulmonary bypass, the patient's baseline activated clotting time (ACT) cannot be used because it is 600 to 800 seconds before heparin infusion and is not “corrected” by factor replacement therapy. Davidson and coworkers successfully used heparin levels to monitor a patient with such a deficiency and also documented typical levels of thrombin generation during the CABG despite the inherited defect.¹⁸ It is essential to discuss with the surgeon (or other clinicians) that during treatment, hemostasis will be normal and, therefore, the surgical procedure should be carried out as completely and fully as it would be in a normal patient.

Bleeding may be more obstinate following oral surgical procedures or following prostate surgery because of profibrinolytic agents in saliva and urine that bathe the wounds dissolving hemostatic clots. For patients undergoing either prostate or oral surgery, an antifibrinolytic agent (ϵ -aminocaproic acid, [EACA], 2 g every 8 hours orally, or tranexamic acid, 20 mg/kg orally every 8 hours for approximately a week) helps prevent otherwise stable clots from being lysed.¹⁹ These agents can be administered intravenously for patients taking nothing by mouth.

Special attention may be required in patients with von Willebrand disease (VWD) (see Chapter 7) undergoing invasive procedures. In patients undergoing fairly minor procedures (such as dental procedures, colonoscopies, arthroscopic examinations, and most biopsies) DDAVP, 0.3 μ g/kg intravenously, suffices for patients with type 1 VWD. This dose of DDAVP can be given daily or twice daily for about 3 days before the agent typically becomes ineffective because of tachyphylaxis. Hyponatremia can be troubling and can cause seizures; accordingly, free water intake must be minimized during DDAVP therapy. However, this brief period usually suffices for hemostasis with such procedures. Antifibrinolytic agents in doses mentioned earlier are advised concomitantly for mucosal procedures.

In patients with type 2 or type 3 VWD or in patients with type 1 VWD who are undergoing more extensive procedures requiring hemostatic control longer than the 3 days that can be provided by DDAVP, factor VIII concentrates (Alphanate or Humate P) containing von Willebrand factor (VWF) work well. Cryoprecipitate is an effective agent and should be considered in certain settings. Many clinicians have noticed that it is much easier to correct the factor VIII clotting activity or VWF level to desirable levels (i.e., 30% to 50% or higher) than it is to correct the bleeding time or platelet function assay (PFA). Most experts have deduced that it is preferable to monitor the factor VIII activity or VWF level rather than the bleeding time or PFA because typically neither of the latter two tests correct with otherwise appropriate therapy and failure of the bleeding time or PFA to correct does not predict bleeding.^{20,21,22}

Table 37-1 Guidelines for Successful Surgery in Patients with Congenital Hemostatic Disorders

- Establish the correct hemostatic diagnosis
- Confirm the inhibitor, hepatitis, and human immunodeficiency virus status of the patient
- Assume that surgical indications are the same as those in hemostatically normal patients
- Develop and follow a surgical plan
- Consult with the blood bank concerning logistics
- Expose patient to minimal amount of factor lot numbers
- Consult with the anesthesiologist
- Prohibit intramuscular medications, especially preoperatively
- Avoid aspirin, aspirin-containing medications, and other platelet-inhibiting medications
- Determine and administer the appropriate preoperative clotting factor dosage, and measure the plasma level before induction of anesthesia
- Monitor appropriate hemostatic tests frequently
- Sustain a hemostatic level of the patient's deficient factor as long as needed by repeated intravenous infusions of the appropriate agent
- Consider whether adjunctive agents, e.g., antifibrinolytic drugs or hypotensive anesthesia, might enhance hemostasis

For patients with inhibitors who need surgery, it is advisable to be cautious, especially regarding elective surgery. Refer to Chapter 6 for general comments regarding hemorrhage in patients who have inhibitors. Porcine factor VIII has been effectively employed for hemostasis²³ as has activated prothrombin complex concentrate (FEIBA).²⁴ Typical doses are an initial IV bolus infusion of 100 IU/kg followed by 50 IU/kg every 8 to 12 hours. There is no laboratory test to monitor for efficacy. Recombinant factor VIIa (NovoSeven)²⁵ has proved effective for surgical procedures in patients with factor VIII or factor IX inhibitors, usually infused initially at 90 µg/kg intravenously every 2 to 3 hours for 48 hours followed by dose reduction during a total of 5 days of treatment.^{26,27,28} No laboratory testing is agreed on as being highly effective to monitor therapy.

EFFECT OF SURGERY ON HEMOSTASIS

Large-vessel hemorrhage (in general, named arteries or veins) tends to require physical methods such as cautery, pressure, ligation, or tamponade to control blood loss, whereas microcirculatory hemorrhage depends on an intact hemostatic system. Tissue factor (TF) is released from damaged blood vessels and with native plasma activated factor VII vigorously initiates the extrinsic arm of the coagulation system.^{29,30} Thrombin generation should be sufficient that enough platelets are stimulated to adhere to denuded areas of the open endothelium and then recruit, through release of their attractants, enough platelets to begin aggregation to breach the leak. Any compromise in this elaborate system, such as a factor deficiency, thrombocytopenia, or excessive anticoagulation therapy might well result in hemorrhage. This schema physiologically regains hemostatic control of an open vascular system, yet may potentially result in an equally devastating thrombotic condition if not properly controlled.

Thrombotic Signals as a Result of Surgery

Initiators of coagulation include TF and other cytokines, particularly tumor necrosis factor (TNF) and interleukin 6 (IL-6) if inflammation or infection are present.^{31,32} These cytokines rapidly accelerate the extrinsic system. Tissue destruction and TF release also occur in medical situations such as myocardial infarction,³³ sepsis,³⁴ and malignancy (see Chapters 15 and 23). During the first several hours following surgery or significant trauma, there is an increase to approximately twice normal in circulating tissue plasminogen activator (tPA) levels and a rapid decrease toward normal levels by the end of the first 24 hours. Beginning approximately 2 hours after trauma, levels of plasminogen activator inhibitor type I (PAI-1) begin to rapidly rise, approaching levels 4 to 5 times normal, and then gradually decrease over a day or so—only to have a secondary peak at about day seven.^{31,32,35,36} During that period, these high levels of PAI-1 dampen the fibrinolytic system, a process that has been termed “fibrinolytic shutdown.”³⁵ Of interest, it has been observed that warfarin administration dampens the increase in the PAI-1 reflex and thus may attenuate fibrinolytic shutdown which could explain, in part, its net antithrombotic effect.³⁷

While thrombin is being generated, antithrombin III is consumed as it neutralizes thrombin by forming thrombin:

antithrombin (TAT) III complexes.³⁸ Antithrombin III levels acutely can become severely reduced during surgery, particularly with trauma and especially after burns.³⁹

Levels of these mediators fluctuate rapidly and their degree of perturbation as measured by static laboratory tests will be a function not only of the type, degree, and duration of trauma, but also of the timing of blood sample collection. Experimental evidence in reproducible trauma in animals validates that graduated degrees of trauma result in graduated degrees of hypercoagulability.⁴⁰

Shock and stasis often follow trauma. Stasis and venodilation may be induced in surgery by various anesthetic agents. General anesthetics cause more systemic venostasis than local anesthetics used in epidural anesthesia. General anesthesia is associated with higher levels of PAI-1 generation 24 hours after the surgery and a higher incidence of thrombosis when compared in a controlled manner with patients undergoing the same procedure using epidural anesthesia. These higher levels of PAI-1 correlated well with subsequent thrombosis.⁴¹ Hamer and colleagues^{41a} demonstrated that venous stasis is associated with hypoxia in venous valve pockets and may account in part for these pockets serving as loci of thrombosis generation. In endothelial cell cultures, hypoxia is associated with release of P-selectin from the endothelial cells, which may contribute to local inflammation.^{41b} Comerota and colleagues⁴² studied the degree of venodilation of arm veins in patients undergoing total hip replacement. In patients who experienced a postoperative DVT, the mean degree of venous dilation was 29% over presurgical diameters, whereas the mean dilation of those who did not experience DVT was only 12%. All patients who experienced more than 20% dilation of their arm veins experienced a DVT. Venodilation created “microtears” in the endothelial lining that exposed underlying collagen and may very well have served as the nidus or trigger for thrombosis associated with surgery.

One of the newer concepts in the initiation and perpetuation of thrombosis involves “microparticles.” Microparticles (MP) are of ubiquitous origin, derived from the membranes of platelets, erythrocytes, leukocytes, and endothelial cells.⁴³ They are present in normal human blood but they increase in response to several disease states, trauma, and surgery.^{44–47} By virtue of their high surface-to-volume ratios they act as effective portages for various mediators such as TF, components of platelet membrane receptors, VWF, and other constituents^{47–49} that seem active in stimulation, proliferation, and apoptosis of various cells.⁵⁰ Our understanding of this new area in vascular physiology, disease, and injury will rapidly proliferate. These theories of surgically induced hypercoagulability are listed in Table 37-2.

Various other situations and events might have an impact on the effects of surgery on hemostasis and thrombosis. In major orthopedic surgery, epidural anesthesia seems to result in comparatively less hypercoagulability than does general anesthesia.^{51,52} The use of tourniquets in total knee replacement seems to lessen the hypercoagulability while increasing the net fibrinolysis in that operation when compared with not using a tourniquet.⁵³ Boldt and colleagues⁵⁴ deduced that there was no net difference between use of normal saline or lactated Ringer's solution as replacement strategies with respect to input on hemostasis. Coronary artery bypass graft (CABG) appears less

Table 37-2 Putative Causes of Hypercoagulability in Surgery and Trauma

- Generation of large amounts of procoagulant factors
- Generation of high concentrations of PAI-1 ("fibrinolytic shutdown")

- Pooling of blood
- Venous microtears
- Microparticles

PAI-1, plasminogen activator inhibitor-1.

hypercoagulable when performed on-pump rather than off-pump according to Quigley and colleagues.⁵⁵ The use of hetastarch was found to be associated with increased post-CABG hemorrhage in a dose-response manner.⁵⁶ Mild hypothermia (32° C to 36° C) did not affect hemostasis in one study⁵⁷ but more severe and prolonged hypothermia,⁵⁸ as well as acidosis, grossly impeded hemostasis (see Chapter 46). In a recent randomized trial, normothermic off-pump CABG resulted in less hemorrhage and fewer transfused blood products than did relative hypothermia.⁵⁹ It is of interest that harboring the gene for factor V Leiden mutation is correlated with decreased blood loss in cardiopulmonary bypass (CPB).⁶⁰

White and associates⁶¹ have prepared a useful database regarding varying degrees of apparent hypercoagulability of various surgical procedures, demonstrating the higher incidence of thrombosis following vascular, orthopedic, and central nervous system parenchymal surgeries compared with a lower incidence following minor orthopedic, urologic, and head and neck surgery cases.

Prophylaxis Against Thrombosis

Prophylaxis against DVT and pulmonary embolism (PE) are discussed thoroughly in Chapter 14, as well as in a recent consensus.⁶² The role of mechanical and similar adjuncts in prophylaxis against venous thromboembolism (VTE) verifies their use. Westrich⁶³ demonstrated that intermittent pneumatic compression (IPC) in total knee replacement surgery was, in their hands, more effective than low molecular weight heparin (LMWH) and far more effective than aspirin alone in reducing both DVT and PE. However, they did note only a 33% compliance rate with patients for whom IPC was prescribed. Others have demonstrated not only the effectiveness of IPC and similar devices but the additive effect of this methodology with chemical (heparin) prophylaxis.^{64,65} The efficacy is theoretically due to a decrease in cross-sectional area of capacitance veins, thus generating both an increase in linear blood flow as well as protection of venous valve competency. There are clinical data supporting the theory that IPCs work in part by release of endogenous tPA.⁶⁶ Additionally, because the vein wall is less distended, one might speculate a decrease in microtears in the venous wall.⁶⁵

Whereas there has been a general and increasing acceptance of chemical prophylaxis in surgical patients, there remains a reticence on the part of neurosurgeons for understandable fear of possible additional risk of hemorrhage. For many indications, IPC is probably effective.^{64–67} However, several recent analyses of VTE prophylaxis in neu-

rosurgical patients^{68–70} have indicated that not only is LMWH itself safe but, when combined with IPC, it adds to the efficacy of VTE prophylaxis either without any additional risk of hemorrhage^{68,69,71,72} or with such a small amount of increased risk that such risk of hemorrhage is easily absorbed by the decrease in overall morbidity and mortality from VTE.⁷² In these studies, all prophylactic doses of LMWH were initiated postoperatively. In one small study involving only patients undergoing brain tumor surgery, LMWH was given preoperatively with an increased risk (5 of 46 patients) of intracranial hemorrhage.⁷³ rFVIIa has been employed in some neurosurgical cases with recalcitrant hemorrhage, although the risk:benefit ratio has not yet been determined.⁷⁴

There is considerable debate regarding the need for VTE prophylaxis in patients undergoing laparoscopic surgery⁷⁵ with arguments for⁷⁶ it and against it.⁷⁷ In patients with prior VTE, prophylaxis seems indicated and rational. The reduction in net tissue damage afforded by laparoscopic surgery seems counterbalanced by the effects of the use of pneumoperitoneum and the Trendelenburg position.

The coagulation challenges associated with two surgical procedures, *cardiopulmonary bypass* and *orthotopic liver transplantation (OLT)*, are multiple with many various abnormalities noted; however, more likely than not the changes leading to significant hemorrhage are mediated by surges of endogenous tPA resulting in a brisk hyperfibrinolytic state.

Cardiopulmonary Bypass Surgery

The effects of CPB on blood have been thoroughly reviewed.^{78–80} Whereas platelet defects have been ascribed to CPB,⁸¹ these are mostly multiple, minor, and transient.^{82,83} These aberrations are produced, in part, by partial activation of platelets coming in contact with the nonbiologic material of the CPB pump and oxygenator apparatus as well as binding and agglutination of platelets to such material. Platelet glycoprotein Ib (GpIb) is decreased on these platelets but it is doubtful whether this change itself is sufficient to cause a significant hemostatic challenge. Of interest, through some mechanisms differing from its anti-fibrinolytic effects, aprotinin seems to restore normal platelet activity.⁸⁴ Hemorrhage may be serious enough to result in re-exploration in 3% to 7%⁸⁵ of cases of CABG and is associated with a 30% increase in mortality.⁷⁸

Patients with acute coronary syndrome (ACS) are frequently administered antiplatelet agents because of their efficacy. However, because of clinical uncertainty regarding the timing of necessary operative intervention, patients frequently may be taken to the surgery suite while being administered such agents. Exposure to clopidogrel within three days of CABG results in excessive postoperative bleeding and reoperation;⁸⁶ therefore, its use ideally should be withheld prior to elective or semi-elective CABG. Administration of ASA up to the time of CABG is common. Although blood loss in patients undergoing this procedure while on aspirin is statistically higher than for those patients stopping aspirin use a week before surgery (410 mL compared with 539 mL, $p = 0.01$), these differences are of questionable clinical importance and did not lead to more transfusions in the patients who were given aspirin.⁸⁷

There is considerable growing opinion that the amount of bleeding encountered in CABG may be of less total clinical outcome significance than the total amount of blood products transfused, and, that increased use of blood products seems to be associated with less favorable long-term outcome.^{82,87} For instance, in the above ASA study, although patients received ASA blood slightly more often, they were transfused the same amounts yet had better oxygenation and shorter ventilation times than patients off aspirin for the week preceding CABG surgery.⁸⁷

When excessive hemorrhage in CPB patients was believed to be caused by acquired platelet defects, many studies examined the efficacy of routine use of DDAVP in managing those defects.^{88,89} DDAVP was not uniformly efficacious in reducing mortality, re-exploration, and blood use, and may have even contributed to a twofold risk of perioperative acute myocardial infarction (Table 37-3). These data suggest that hemorrhage in the majority of CPB patients is not primarily due to a platelet defect or at least a platelet defect that could be reversed by the administration of DDAVP. DDAVP should not be used routinely in CPB patients but employed only when it is apparent that a patient is hemorrhaging and then it should be given in the routine dosage (0.3 µg/kg intravenously).^{90,91} This approach may minimize hemorrhage in patients taking aspirin prior to their surgery.⁹²

Similarly the routine nonspecific use of platelet transfusions, as well as fresh frozen plasma (FFP) infusion, is not indicated.^{93,94} Indeed, using the large aprotinin database, Spiess and coauthors⁹⁵ demonstrated that use of platelet transfusions was associated with multiple types of poor outcome, including infection, vasopressor use, stroke, and death.

Meta-analysis of six studies found neither rationale for nor reduction in blood loss with routine prophylactic use of FFP in CABG.⁹⁶ Autotransfusion of shed blood during CABG using cell saver techniques was found in a randomized trial to be safe, resulting in no apparent clinical or laboratory aberrations while decreasing significantly the use of any homologous transfused blood or blood products.⁹⁷ Two studies comparing preoperative use of LMWH with UFH in ACS patients undergoing CABG demonstrated more re-exploratory surgery for hemorrhage⁹⁸ and a higher transfusion rate for those patients receiving LMWH.⁹⁹

There is now general consensus that the majority of excessive bleeding following CPB is due to the surge of

tPA that occurs during rewarming of the patient, which temporally correlates with coming off the CPB apparatus and closure of the mediastinum.^{100,101} Until that time, circulating levels of tPA are not particularly high as the surge does not begin until the rewarming phase. Of interest, patients who undergo cardiothoracic surgery without CPB do not experience this tPA surge.¹⁰⁰ Patients undergoing “off-pump” CABG do not lose as much blood as those “on-pump”^{102,103} and use of ASA off-pump did not increase shed blood.¹⁰⁴

Pharmacologic agents block the effects of tPA. Aprotinin is a serpin isolated from bovine pancreas. It is a powerful inhibitor of plasmin and thus an effective blocker of fibrinolysis. It has little or no anti-tPA or platelet activity.^{105,106} A meta-analysis of 72 trials including 8409 CPB patients concluded that of multiple hemostatic agents, aprotinin was associated with the greatest decrease in blood loss, mortality, rate of re-exploration, and overall blood use⁸⁹ whether the routine-dose aprotinin (2 million KIU as an IV bolus followed by 500,000 KIU IV every hour) or lower doses was employed. Others^{79,107–112} have stated that other fibrinolytic agents are as good as and particularly less expensive than aprotinin.

Perioperative myocardial infarction occurred in 4% of patients receiving lower-dose aprotinin and in 8% of those receiving the conventional dose; however, the overall mortality rate was still half that of patients not receiving aprotinin. The overall perioperative myocardial infarction rate was essentially the same as placebo.⁸⁹

Aprotinin has also been shown in both case reports and small studies to be efficacious in special situations requiring CPB such as patients undergoing hypothermic surgery,¹¹³ heart transplantation,¹¹⁴ aortic surgery,¹¹⁵ CABG in patients with ITP,¹¹⁶ or lung transplantation,¹¹⁷ and in patients requiring a left ventricular assist device (LVAD) as a bridge while awaiting transplant.¹¹⁸

Re-exploration to assess hemorrhage is necessary in 3% to 7% of cases following CPB,⁸⁵ and 67% of the time a specific bleeding site responding to local measures is found.⁷⁸ Of interest, Pelletier⁸⁵ found for the 33% of cases in which they did not find a surgical or anatomic correctable reason for hemorrhage, most hemorrhage simply stopped as though the re-exploration itself had a net hemostatic effect. Studying their hypothesis, various coagulation components of mediastinal blood were measured and compared with

Table 37-3 Meta-Analysis of Efficacy of Hemostatic Agents Compared with Placebo for Perioperative Hemorrhage Associated with Cardiopulmonary Bypass Surgery

	Mean Decrease in Blood Loss, mL	Odds Ratio			
		Mortality	Re-exploration	Blood Product Use	Perioperative AMI ^a
Aprotinin ^b	446	0.55	0.37	0.37	1.13
Antifibrinolytic agents ^c	264	0.78	0.44	0.46	0.48
DDAVP ^d	114	1.02	0.67	0.79	2.4

^aAMI, acute myocardial infarction.

^cEither EACA or tranexamic acid.

^dDDAVP, 1-deamino-8-D-arginine vasopressin. Data from Laupacis A, Fergusson D: Drugs to minimize perioperative blood loss in cardiac surgery: Meta-analyses using perioperative blood transfusions as the outcome. *Anesth Analg* 85:1258–1267; and Levi M, Cromheecke ME, deJonge E, et al: Pharmacological strategies to decrease excessive blood loss in cardiac surgery: Meta-analysis of clinically relevant endpoints. *Lancet* 354:1940–1947, 1999.

systemic levels in the same patient. The fibrinogen and α_2 -plasmin inhibitor levels were both significantly lower ($p = 0.05$), whereas the levels of PAI-1 and fibrin degradation products (FDPs) were both significantly higher ($p = 0.05$) in the shed mediastinal blood than in systemic blood. They used these data as evidence for increased fibrinolytic activity primarily in the mediastinal cavity itself and that drainage via exploration may have eliminated self-perpetuating local hyperfibrinolysis. Khalil and colleagues have reproduced similar findings and additionally showed the efficacy of the installation of aprotinin into the pericardial sac.¹¹⁹

Although operative and postoperative hemorrhage experienced in modern CABG surgery is largely controlled by advances in technical skills, cell saver techniques, improved equipment, and the use of antifibrinolytic agents, occasionally hemorrhage can be significant. Several small series^{120–124} have reported late use of “last-effort” recombinant human activated factor VII (rFVIIa) to control hemorrhage with apparent efficacy, although thrombotic events have been reported.^{124–125} One consensus group recognized that off-label use of rFVIIa in cardiothoracic surgery patients was feasible as rescue therapy in actively hemorrhaging patients for whom all routine hemostatic measures have failed although the risk:benefit ratio has yet to be determined in any randomized trials.¹²⁶ A recent editorial^{126a} has called into question these off-label uses citing the heavy reporting bias against experiences having negative results and major or fatal complications. A summary of the few available controlled trials with use of rFVIIa in these off-label situations suggests a less favorable outlook than that reached by the census group.

Aprotinin, EACA, and tranexamic acid^{127,128} exert their primary procoagulant effects by blocking the action of plasmin, thereby greatly impeding fibrinolysis. Thrombotic events to include either arterial (myocardial infarction or stroke) or venous (DVT or PE) events do not appear increased using these agents.^{101,129,130} Two recent publications^{111,130a} have questioned the continued use of aprotinin in CABG surgery citing apparent acute and chronic complications (respectively) in patients who were administered aprotinin when compared with either control CABG patients or CABG patients administered EACA or tranexamic acid as alternative antifibrinolytic agents. An accompanying editorial^{130b} reviews the latter report, pointing out the limitations of epidemiologic non-randomized studies. Before one reaches conclusions from these two publications, one has to also consider the multiple reports showing that aprotinin was associated with less blood loss, fewer transfusions of blood and blood products, and seemingly better outcomes.^{79,87,89,95,112} This contentious area is rightfully under intense review and debate and will probably not be decided until head-to-head randomized studies are used in CABG patients comparing aprotinin with other antifibrinolytic agents for both short-term and long-term results.

Because aprotinin is prepared from bovine pancreas, it could be expected to cause immunologic reactions, including anaphylaxis.¹³¹ Dietrich and colleagues¹³² studied 248 cases of re-exposure to aprotinin and found a 3% incidence of adverse reactions, which typically occurred on initiation of aprotinin administration and were characterized by an acute fall in blood pressure. All survived the reaction. Only 1.5% of patients experienced adverse reaction on

re-exposure if more than 6 months had lapsed since their last exposure. Patients who had had re-exposure within 6 months had a reaction rate of 4.5%.

Drugs that block the platelet glycoprotein IIb-IIIa (GP-IIb/IIIa) platelet receptor (see Chapter 20) are used in patients with ACS, a population that may undergo emergent CABG with CPB and attendant extra risk for hemorrhage. Following abciximab, the GP-IIb/IIIa receptor blocker with the longest half-life, a 12-hour hiatus after the last infusion is recommended.¹³³ Because abciximab is very tightly bound to platelet membranes with negligible amounts of unbound circulating abciximab in the plasma, use of platelet transfusions is rational for preparation of patients requiring emergent surgery before 12 hours have lapsed since the last abciximab infusion.

Hyperfibrinolysis following CPB is associated with a tPA surge that may occur in response to enhanced procoagulant activity. Dietrich and colleagues¹³⁴ operated on patients at risk for post-CPB hyperfibrinolysis by first treating them with warfarin to a mean international normalized ratio (INR) of 2.4; their control group had an INR of 1.1. Those patients undergoing CPB at the therapeutic INR required less heparin to reach appropriate anticoagulation as determined by the activated clotting time (ACT) and in particular required less heparin during the operation to maintain an appropriate ACT value. These data suggest that warfarin pretreatment resulted in less thrombin (and therefore less fibrin) generation during CPB with a subsequent diminished tPA surge. Blood loss at 6 and 12 hours with warfarin-treated patients was 381 and 505 mL, respectively, whereas the control group lost 472 and 527 mL, respectively—reaching statistical significance ($p < 0.05$). They noticed no correlation with blood loss even with patients at the highest INRs, including up to 6.0. They neither reversed the warfarin nor administered FFP during the operation.¹³⁴ Similarly, higher—as opposed to lower—heparin levels during CABG were found to be associated paradoxically with less blood loss. This enhanced anticoagulation is believed to result in decreased thrombin generation, which, in turn, translates into less thrombosis, less rebound hyperfibrinolysis, less bleeding, fewer transfusions, and better immediate and long-term outcomes.⁷⁹

Orthotopic Liver Transplantation

Orthotopic liver transplantation (OLT) historically has been complicated by massive hemorrhage and heavy demands on the transfusion service. In the past several years our understanding of the hemorrhagic nature of OLT has increased to the point that effective therapy has greatly reduced both the incidence and severity of hemorrhage as well as impact on the blood bank (see Chapter 39).

OLT often is performed in patients with profound deterioration of their hemostatic system, even preoperatively, given the role of the liver in coagulation and fibrinolysis. The platelet count is often low because of hypersplenism. Accordingly, it previously had been regarded that these preoperative changes were the primary cause(s) of hemostatic failure in OLT.

Our understanding of hemostatic failure has been assisted by dividing OLT into four phases: the preoperative, anhepatic, and reperfusion phases with a convalescent phase occurring in the week or two following the transplantation.

The hemostatic changes characteristic of OLT have been described by many.^{135–140}

In brief summary, the patient has impaired hemostasis that deteriorates during the anhepatic phase because there is not even an impaired liver attempting to clear activated coagulation products or any released tPA. During the reperfusion phase, the surge of tPA results from washout from the donor liver following anastomosis with the recipient. This release of tPA is enhanced by shock, acidemia, and probably hypothermia. It is also during this phase that hemorrhage can become excessive. Those using thromboelastography (TEG) were instrumental in the discovery of reperfusion hyperfibrinolysis.¹³⁵ In the convalescent period from postoperative days 1 through 14, procoagulant factors appear to replenish faster than anticoagulant factors. This may, in part, explain acute hepatic artery thrombosis that, if it happens, does so in this period.

Several groups infused aprotinin (using 2 million KIU as a loading dose followed by 500,000 KIU every hour until skin closure) at the time of reperfusion noting marked decreases in blood loss and transfusion requirements of red cells, FFP, and platelets.^{141,142} Patients who did not require transfusion of any blood product increased from 17% in patients not receiving aprotinin to 39% in those who did receive aprotinin.¹⁴³ Although some studies have shown no benefit using the same aprotinin regimen,^{143,144} a double-blind study¹⁴⁵ supports the use of aprotinin in OLT.

In OLT patients who experienced hemorrhage despite all surgical and pharmacologic corrective efforts, rFVIIa seemed effective in a small number of patients over a broad range of rFVIIa dosage.¹⁴⁶ However, rFVIIa was not effective in reducing blood loss when prophylactically administered to OLT patients.¹⁴⁷ One recent consensus study regarding off-label use of rFVIIa deemed its use “appropriate” following failure of all routine measures, although randomized studies are needed to determine the risk:benefit ratio.^{126,126a}

Aprotinin use may also decrease blood loss and transfusion needs in patients undergoing total hip replacement,¹⁴⁸ total knee replacement,¹⁴⁹ orthopedic tumor surgery, or removal of infected orthopedic hardware.¹⁵⁰ Doses were less than those used with CPB or OLT—yet blood loss was decreased by 40% to 60% without a major increase in DVT (although all patients received LMWH for these procedures). Aprotinin has not gained universal acceptance in orthopedics, perhaps because blood loss usually is much less for these surgical procedures than with CPB or OLT and a majority of orthopedic blood loss can be recovered by use of cell savers.¹⁵¹

PREOPERATIVE HEMOSTATIC TESTING

Screening for Hemostatic Defects

Approximately 3% of all surgical procedures will be accompanied by a degree of hemorrhage deemed by the surgeon to be excessive. In their large meta-analysis of more than 50 randomized double-blinded studies comparing low-dose heparin with placebo in DVT prophylaxis, Collins and colleagues noted that among the 7486 controls receiving placebo, 3.3% of patients were judged to have bled excessively by the surgeon and that 0.1% succumbed to

bleeding.¹⁵² Three papers^{153–155} rendered a similar rate of hemorrhage among patients who are undergoing surgical procedures during studies of appropriateness of preoperative hemostatic testing. Of 4499 patients, 2% were deemed to bleed excessively. The sensitivity of hemostatic screening tests in these 4499 patients was 18%, the specificity was 90%, the positive predictive value was 3%, and the negative predictive value was 98%. There was no correlation between results of these preoperative screening tests for hemostatic competence and surgery-related hemorrhage. Of the 85 patients who bled,^{153–155} 70% had completely normal tests. Of the 435 patients who had abnormal tests, only 15 bled, implying that 97% of patients potentially identified as those likely to bleed did not bleed. Nonetheless preoperative prothrombin time (PT), partial thromboplastin time (PTT), and platelet counts are almost as common as a routine admission order and their use seems to have become a habit.^{156–158}

Approximately \$30 billion are spent in the United States for preoperative testing of all types,¹⁵⁹ yet the clinical value of these tests is extremely limited. In studying over 1000 patients at the Mayo Clinic who underwent surgery without *any* preoperative tests, outcome analyses show that the death or major operative mortality rate was 0%. None required blood transfusion.¹⁶⁰

Multiple studies continue to support the agreed-on conclusion that obtaining routine preprocedural coagulation study is without merit. That abnormal hemostasis exists and is identifiable is irrefutable, but repeated studies fail to document the role of laboratory testing in identifying such patients because those with abnormal hemostasis are best discovered by a thorough history and physical examination. This is true for general surgical patients,¹⁶¹ those undergoing tonsillectomy and adenectomy,¹⁶² cataract surgery,¹⁶³ and neurosurgical procedures.¹⁶⁴

To contrast with the dozen or so studies reaching exactly the same conclusions, there is no study offering contradictory evidence or opinion. Accordingly, the statistical weight garnered by this unanimous thrust is so considerable that further studies of the general population seem without merit. This conclusion was arrived at in four of four overviews^{165–168} on this subject.

Why do physicians continue these practices? One reason is habit.^{156,158} One survey¹⁶⁸ found habit offered as an explanation in 52% of such practices, whereas 45% used “defensive medicine” as their rationale.

The routine use of the bleeding time as a predictor of hemostatic competency in patients without a bleeding history is without foundation.¹⁶⁹ However, if patients do have a bleeding history, the bleeding time is held as worthwhile in sorting out whether the abnormal bleeding is associated with platelet:endothelial dysfunction. The bleeding time is not even effective to predict among patients taking aspirin preoperatively which patients are likely to bleed.¹⁶⁹ The platelet function assay (PFA) has replaced the bleeding time (see Chapter 41) for platelet function analysis, although a prolonged PFA does not necessarily imply enhanced hemorrhagic risk.

The best method to determine hemorrhagic risk with surgery is an adequate history and physical examination (Table 37-4).^{160,169,170} What is the role of hemostatic testing among individuals who have undiagnosed disorders of hemostasis? This small group of patients may or may not

Table 37-4 Appropriate Questions to Screen for Possible Abnormal Hemostasis

- Have you or anyone in your family ever been labeled a "bleeder"? Has someone in the family ever sustained abnormal bleeding?
- Have you ever bled with surgery or following childbirth? What surgical procedures have you had, including major surgery, minor surgery, biopsies, and dental extractions?
- Did a surgeon or dentist ever have to re-explore the wound site or did you ever have to return to the operative suite for hemorrhagic control?
- Have you ever had excessive menstrual periods? How long do your periods last? How many pads or tampons are needed each day? Have you ever required iron supplementation for anemia due to a menstrual blood loss?
- Do you bruise excessively? Are these bruises multiple? Are they confined only to the outer thighs or other areas that are subject to trauma? Are any of these bruises palpable (i.e., are they true hematomas) or are they level with the surface of the skin?
- Do you have nosebleeds now or was there ever a time in your life when you did have spontaneous nosebleeds?
- Have you ever required a blood or plasma transfusion and, if so, why?
- Have you ever bruised or experienced hemorrhage following trauma, car accidents, falls, organized or unorganized sports, altercations, or any acts of violence?

show abnormal hemostatic testing. However, far more specific and sensitive is the history of bleeding. Three papers have examined the presentation of patients harboring mild hemophilia at risk for hemorrhage, perhaps even in a major fashion, following operative procedures.^{2,171,172} The patients included in these papers are the very ones who are of concern to surgeons and other persons practicing invasive procedures, yet they represent substantially less than 1% of the population. Of the patients described in these three papers, patients who had undergone dental extraction and/or tonsillectomy without subsequent bleeding, did not harbor an underlying heritable hemorrhagic diathesis indicative of the history's ability to accurately predict adequate hemostasis. A positive medical history of bleeding was found to be 12.5 times more likely to predict the true hemorrhagic potential than any battery of laboratory tests. In using newer tests to identify patients with VWD, Biron and colleagues found that whereas 1% of the population tested true positive, 10% tested false positive.¹⁷³ Naturally, patients may acquire causes of bleeding such as severe or decompensated liver disease, administration of anticoagulant drugs, or the development of a spontaneous inhibitor of a coagulation factor (see Chapter 6).

What if hemostatic screening tests return abnormal? In one report,¹⁵³ abnormal studies were found in 1.9% of screened patients. When another sample was collected and the test was repeated before the surgical procedure, results of half of those abnormal tests returned normal, showing that specimen collection, laboratory error, or laboratory variability explained many abnormalities.

When the cause of persistently prolonged PTTs of unknown etiology¹⁷⁴ was determined, 67% of patients were not at actual risk for hemorrhage because the nature of the process leading to the prolongation (bad laboratory sample, laboratory error, lupus anticoagulant, and pre-laboratory variability) would not be expected to result in

postoperative hemorrhage. However, the other 33% were at very clear risk to bleed; moreover, 81% of these 33% had already given a clear, positive history of a hemorrhagic diathesis even before the nature of their laboratory abnormality was determined. There was a lack of correlation between the degree of prolongation of the PTT and the risk of bleeding, a conclusion made by others¹⁵³; the risk of bleeding rather is a function of the *cause* of the PTT prolongation, not the *degree* of prolongation. Of significant concern is the fact that often an abnormal result frequently is ignored or forgotten by the practitioner who ordered the tests.^{157,175} One might question why such laboratory tests are unable to define precisely which patients are likely to bleed following an invasive procedure. Table 37-5 gives lines of reasoning why this is true.

Hemostatic tests should be ordered much less frequently than they customarily are. They are indicated in patients who answer affirmatively to any of the questions in Table 37-4. Others have stated that indications of screening tests as determined by the history and physical examination should include those with malabsorption, trauma, a history of active hemorrhage, a history of chemotherapy or radiotherapy, purpura, anemia, or the prior use of anti-coagulants.¹⁷⁶ Some¹⁷⁷ have added patients with liver disease, operations characteristically associated with a blood loss of greater than 1500 mL, or highly invasive procedures such as those included in Table 37-6. It would seem rational to include those patients refusing to accept blood or blood product infusion. Using criteria similar to these, four studies indicated that screening was appropriate in 11%,¹⁵³ 8%,¹⁵⁵ 23%,¹⁷⁶ and 19%¹⁷⁸ of patients, giving a mean of 15%, implying that 85% of preoperative hemostatic testing

Table 37-5 Why Hemostatic Testing is Not Usually Sufficient to Detect Those Likely to Experience Operative Hemorrhage

- Patients suffering the worst hemorrhagic disorders, classic hemophilia A or B, are identified very early in life and have established diagnoses for life. Accordingly, preoperative screening is not effective or even warranted as the diagnosis is already known.
- The great majority of postoperative bleeding is not due to hemostatic failure but to a surgical or technical problem more appropriately corrected by surgical maneuvers. Exhaustive preoperative screening cannot predict operative errors.
- Traditional tests to screen for hemostatic disorders (PT, PTT, platelet count) were designed primarily to detect static disorders of hemostasis. As such, they do not reflect accurately ongoing changes in a situation as dynamic as trauma or surgery.
- The most flagrant examples of hemostatic failure—disseminated intravascular coagulation, hyperfibrinolysis, and thrombocytopenia—develop during an operation and cannot be predicted by tests performed before the operation.
- The PT and PTT are expected to give abnormal results approximately 2.3% of the time. If one is screening for mild defects in factor VIII or factor IX, these disorders occur in about 1:20,000 males and, therefore, the ratio of true positives to false positives is on the order of 1:500.*

*From Clarke JR, Eisenberg JM: A theoretical assessment of the value of the PTT as a preoperative screening test in adults. *Med Decis Making* 1:40-43, 1981, with permission. PT, prothrombin; PTT, prothrombin time.

Table 37-6 A Schema for Preoperative Hemostatic Evaluation

Level of Risk*	Screening History		Proposed Surgery	Recommended Tests
Minimal	Negative $\pm$ prior surgery	and	Minor	None
Low	Negative with prior surgery	and	Major	Platelet count, PTT, or none
Moderate	Possible bleeding disorder	or	CNS, CPB, or Prostatectomy	Above tests <i>plus</i> BT (or PFA), PT
High	Highly suspicious or documented bleeding disorder	and	Major or minor	Above tests <i>plus</i> factors VIII, IX, and XI levels, TT If these are negative, pursue diagnosis

*Level of risk is estimated by the product of the risk of bleeding times the clinical consequence of bleeding.

BT, bleeding time; CNS, central nervous system; CPB, cardiopulmonary bypass; PTT, partial thromboplastin time; PT, prothrombin time; TT, thrombin time. The bleeding time may well be replaced by platelet function assays (PFA) (see Chapter 41).

Modified from Rapaport SI: Preoperative hemostatic evaluation: Which tests, if any? Blood 61:229–231, 1983; and Woodman RC, Harker LA: Bleeding complications associated with cardiopulmonary bypass. Blood 76:1680–1687, 1990, with permission.

is without merit. Table 37-6 offers a proposed schema for preoperative hemostatic evaluation that seems rational, defensible, and conscious of cost containment issues.

Screening for Thrombotic Disorders

Bleeding is not the only complication that can follow operative procedures. Venous thromboembolism (VTE) can be a major or fatal complication of a surgical procedure. Whereas risk stratification and prophylactic measures to reduce these risks are covered in Chapter 14, suffice it to say that a history of a VTE places the patient at 30 to 40 times the risk of the normal population to experience yet another VTE and that risk is still further exacerbated perhaps 100-fold by surgery.¹ These patients may well deserve screening for the more common thrombophilic abnormalities, particularly if laboratory findings may alter therapy.

Routine coagulation or special tests (e.g., factor V Leiden and prothrombin 20210 mutations) are not indicated to screen the general population solely for the possibility of VTE following surgery.¹⁷⁹ An abnormally short PTT (less than 23 seconds) has been suggested to predict for poor outcome, including death, thrombosis, or bleeding.¹⁸⁰

In preparation to undergo certain procedures (as in hip or knee replacement, as well as renal transplantation) known to be at high risk for VTE, some^{181–184} have questioned whether preoperative screening for thrombophilic conditions is warranted. Whereas the data are inconclusive, it must be recalled that because the relative risk (RR) of the main recognized thrombophilic disorders ranges only from about 2 (factor V Leiden) to 6 (antithrombin III deficiency), the RR of such surgery as this is closer to 100, bringing into focus the clinical application of the question being asked. As with patients prone to postoperative hemorrhage, an appropriately performed history and physical examination again is the best path to predict the possibility of thrombotic events.¹⁸⁵ Particular attention should be paid to cancer, heart failure, use of estrogens, and especially a history of VTE.¹⁸⁶ These risks are not simply additive but increasing risk factors implies even more rapid escalation of overall risk for VTE following surgery. More than 30 years ago Kakkar and colleagues¹⁸⁷ showed that the risk factors most predictive for VTE were a previous VTE, varicose veins, and operations on patients with a malignancy or patients over 60 years of age. For patients identified to be at very high risk for thrombosis, more aggressive thromboprophylaxis is indicated.¹⁸⁸

Special heed should be paid to those patients who recently experienced a VTE. Sarasin and Bounameaux¹⁸⁹ have determined that patients who recently have had a VTE are at extreme risk for VTE recurrence following an invasive procedure during the first 20 weeks after their VTE with a gradual decrease in this very high rate after that 20-week period. They suggested that patients who are at such high risk for VTE that any elective procedures should be postponed for several months. Similar conclusions were rendered by Kearon and Hirsh.¹

INVASIVE PROCEDURES IN PATIENTS WITH ABNORMAL COAGULATION TESTS

Those practicing invasive procedures typically assume a direct relationship between in vitro routine coagulation tests and the adequacy of in vivo hemostasis. There is little evidence to support this stance as suggested in the previous subchapter on preoperative screening tests. Nonetheless, many view coagulation tests to be touchstones of physiology. Multiple examples exist of abnormal hemostasis with normal routine coagulation tests as well as normal hemostasis in patients with substantially prolonged tests.¹⁹⁰

In severe hepatic disease, the situation is even worse. Most routine coagulation tests are severely altered but hemostatic bleeding may be minimal as most visceral bleeding is from large vessels and due to hemodynamic rather than hemostatic defects. Recently Mannucci's group has shown that total thrombosis generation (probably the best predictor of physiologic hemostasis) is actually normal in those with cirrhosis, despite severe alteration in conventional coagulation tests.¹⁹¹

Invasive procedures such as bronchoscopy, endoscopy, lumbar punctures, paracentesis, and the insertion of lines for central venous access are part of modern medical practice. Although many patients needing these procedures have abnormal coagulation studies, published data underscore the safety and acceptable outcomes of such procedures in cancer patients, transplant patients, and patients in intensive care units. There is no published evidence for increased risks of procedure-related hemorrhage, and there is no controlled study that indicates at what levels the PT, PTT, and platelet count actually represent or predict contraindications to invasive procedures or that prophylactic replacement of blood products reduces risk of hemorrhage resulting from an invasive procedure.^{192,192a–d}

General surgery in patients with thrombocytopenia from acute leukemia was far safer than the preconceived notions of hematologists or surgeons. Bishop and colleagues¹⁹³ performed 130 invasive procedures on patients whose platelet count was less than 50,000/ μ L (and usually remained less than 50,000/ μ L despite platelet transfusion therapy because of refractoriness to platelet transfusion). Only 7% required more than four units of packed red blood cells at the time of major surgery and none died secondary to the operation or from resultant bleeding. They concluded that major surgery or invasive procedures had a positive risk:benefit ratio in such patients. Studying laparoscopic splenectomy for refractory idiopathic thrombocytopenic purpura, Keidar and colleagues¹⁹⁴ deduced the procedure was hemostatically secure if patient counts were 20,000/ μ L or higher without a need for platelet transfusion. Those with platelet counts of less than 20,000/ μ L bled more and required more platelet and red blood cell transfusions, but all survived. In cancer patients, gastrointestinal endoscopies and biopsy for investigation of patients with gastrointestinal hemorrhage can be safely performed with platelet counts as low as 20,000/ μ L.¹⁹⁵ It is held that platelets in clinical conditions characterized by high platelet turnover (e.g., ITP) are more hemostatically efficient than platelets in conditions of low production (e.g., aplasia) so this matter can be factored into one's use of platelet transfusions.

Liver Biopsy

It is frequent practice to administer a few units of FFP prior to liver biopsy in patients with liver failure to decrease risk of hemorrhage. There are no data to support the three operative premises (1) that bleeding is likely; (2) that giving FFP improves the PT, and (3) that hemorrhagic risk is decreased by the administration of the FFP. In patients having PTs greater than 3 seconds above normal, administration of three units of FFP failed to correct the PT; however, subsequent liver biopsy did not result in hemorrhage.¹⁹⁶ In a larger study, McGill and colleagues performed 9212 liver biopsies over a 21-year period¹⁹⁷ if patients' ratio of the PT to control (i.e., the prothrombin time ratio [PTR]) was less than 1.5 (corresponding now to an INR of approximately 1.8) and the platelet count was 55,000/ μ L or higher. Among the 32 (0.03%) patients who experienced significant post-biopsy hemorrhage, there was no correlation between any coagulation test results and hemorrhage. McVay and Toy¹⁹⁸ performed a similar study in which they limited liver biopsy to patients whose PT ratio was below 1.5, (estimated INR of 1.8) PTT ratio below 1.5, and platelet count 50,000/ μ L or higher. They found that 6 of 175 (3.4%) patients were judged to have bled abnormally. They found no correlation between the hemorrhage and pre-procedure hemostatic results. Additionally, they showed that of their patients who did experience hemorrhage, the only positive predictor was the presence of liver malignancy. They concluded that the infusion of FFP and/or platelets within these variables was not warranted. Boberg and colleagues questioned whether a prolonged bleeding time heralded increased risk of hemorrhage following liver biopsy. In their study, they were unable to find that the risk of bleeding correlated with the bleeding time except, unex-

plainably, in patients who were bone marrow transplant patients. They also corroborated that there was no correlation between hemorrhage and platelet count, PT, or PTT.¹⁹⁹ Ewe²⁰⁰ studied the "liver bleeding time," meaning that, following laparoscopic liver biopsy, the site was directly observed to determine duration of bleeding. In 200 patients, 10 experienced prolonged bleeding yet the pre-biopsy studies were unable to predict which of their patients would hemorrhage. These biopsies were performed on patients whose platelet counts were as low as 30,000/ μ L, PT ratios as high as 2.2 (implying an INR of at least 2.6), and whole blood clotting times markedly prolonged. Makris and colleagues²⁰¹ in a prospective study measured PT, PTT, TT, fibrinogen concentration, bleeding time, and platelet count prior to liver biopsy. All patients were prospectively screened by computed tomography (CT) scanning 24 hours after the biopsy. Over half the patients had at least one abnormal screening test and many had more than one with PTs as long as 19.5 seconds (INR of approximately 2.0), PTTs as long as 67 seconds (or almost twice their control), and bleeding times as long as 19 minutes with platelet counts as low as 52,000/ μ L. Only two patients out of 104 bled abnormally as determined by the CT scan and these patients had completely normal pre-biopsy screening tests. Bravo and colleagues²⁰² extensively reviewed liver biopsy. They pointed out that the mortality of liver biopsy was 1:10,000 and that the vast majority of such mortality occurred in patients with cirrhosis or, especially, tumors. Inexplicably they listed as absolute contraindications those patients with PTs prolonged greater than 3 seconds, platelet counts less than 50,000/ μ L, and a bleeding time longer than 10 minutes. No data are offered to support these contentions.

Evidence-based methodology has failed thus far to establish cutoff values of hemostatic tests beyond which liver biopsy is unsafe; additionally, no trial has demonstrated that the administration of platelets or FFP before this procedure has clinical efficacy or rationale.^{94,197,198} If one is concerned about hemostatic integrity, this is an indication for performing transvenous liver biopsy because bleeding would be directly into the vascular system.

Esophagogastroduodenoscopy and Colonoscopy

Concurrent aspirin or nonsteroidal anti-inflammatory drug (NSAID) administration increases the risk of minor bleeding following esophagogastroduodenoscopy (EGD) and colonoscopy with biopsy threefold, from 2.1% to 6.3%. However, major bleeding, defined as the need for hospitalization or for treatment directed toward the bleeding, occurred at the same rate, namely 0.6%, whether or not aspirin or a NSAID was used.²⁰³ Guidelines promulgated by the American Society of Gastrointestinal Endoscopy do not suggest cessation of antiplatelet agents prior to endoscopic procedures.²⁰⁴ This consensus panel endorsed the continuation of warfarin therapy for low-risk procedures (EGD or colonoscopy $\pm$ biopsy and biliary or pancreatic stent [without sphincterotomy]) provided the INR is not supratherapeutic. Patients having true high risk for thromboembolism yet requiring endoscopic procedures were not adequately addressed and recommendations for such patients have not been promulgated.²⁰⁵

Paracentesis and Thoracentesis

In 108 patients undergoing either paracentesis or thoracentesis and whose PT and PTT were at least twice normal and platelet counts were as low as 50,000/ μ L, 10% of patients received four units of FFP prior to procedure, while the other 90% did not. There was no correlation between hemorrhage as defined by hemoglobin concentration dropping at least 2 g/dL and any preoperative hemostatic tests or especially the infusion of FFP.²⁰⁶ Similar findings were reported by Webster and colleagues.²⁰⁷ Permanent peritoneal dialysis catheters may be safely inserted or removed in patients with end-stage renal disease without cessation of aspirin therapy.²⁰⁸

Bronchoscopy

Five studies are available regarding the safety of bronchoscopy with transbronchial biopsy in patients with abnormal hemostatic tests. Kozak and Brath²⁰⁹ studied bleeding in such patients and were unable to show any correlation between hemostatic test results and the risk of hemorrhage. In a major bone marrow transplant unit where thrombocytopenia is common, Weiss and colleagues²¹⁰ performed 66 fiberoptic bronchoscopies and bronchioalveolar lavages; only four patients bled, with one event being major but not fatal. Thirteen of their patients underwent these studies with platelet counts less than 20,000/ μ L. Because a diagnosis was secured by their procedure in one half the cases, they concluded that the risk:benefit ratio is strongly in favor of the procedure. In a prospective study, Bjortuft and colleagues²¹¹ performed 105 consecutive biopsies on patients monitoring the PT, PTT, bleeding time, and platelet count. They measured the actual blood loss by repeated suction and defined blood loss greater than 20 mL as worrisome. The mean blood loss for all patients was 7 mL but eight patients (8%) bled more than 20 mL; no losses were life threatening. Of interest, there was no correlation between the pre-biopsy test results and the ability to predict blood loss. They also noted that none of their 17 (16%) patients with bleeding times longer than 10 minutes experienced excessive hemorrhage. Diette and colleagues²¹² determined that bronchoscopy in patients with lung transplants resulted in hemorrhage at a rate higher than in patients without transplants, but found that perturbations in the PT, PTT, or platelet count neither explained nor predicted those who bled. Herth and associates²¹³ reported that concomitant aspirin use was not associated with additional hemorrhage in patients undergoing transbronchial biopsy so pre-procedure cessation of aspirin was not justified.

Lumbar Puncture

Although lumbar puncture has been studied less thoroughly, Howard and colleagues²¹⁴ examined the safety of lumbar puncture, which was commonly done for diagnostic and therapeutic purposes in patients with leukemia and thrombocytopenia. They performed 5223 consecutive lumbar punctures on patients whose platelet counts were below 100,000/ μ L with 941 of those patients having platelet counts ranging from 0 to 50,000/ μ L (29 had counts below 10,000/ μ L). They observed no serious complications and correctly assumed that this procedure was indicated despite

thrombocytopenia because of its favorable risk:benefit ratio. They also concluded prophylactic platelet transfusions may not be indicated for a lumbar puncture if the platelet count is 10,000/ μ L or higher.

Central Venous Access Devices

Six studies have addressed the role of pre-procedure coagulation studies and outcome of insertion of central venous access devices, typically either subclavian vein (SC) or internal jugular vein (IJ) cannulation. Ray and Shenoy²¹⁵ divided a large cohort of patients into three groups—those having platelet counts of less than 50,000/ μ L, those with platelet counts between 50,000 and 100,000/ μ L, and patients whose platelet count was greater than 100,000/ μ L. They observed no differences in bleeding or other complication rates, although it was their practice to administer platelets routinely prior to insertion of such devices in patients with platelet counts less than 50,000/ μ L. Although the average platelet count increased by only 12,000/ μ L following transfusion, they proceeded with the cannulation, which caused them to question whether platelet transfusion improved the patient's risk-to-benefit ratio. Four patients having platelet counts less than 50,000/ μ L did not receive platelet transfusions yet did not experience abnormal bleeding.

Goldfarb and Lebrech²¹⁶ performed 1000 consecutive IJ cannulations in patients with "coagulopathies" and experienced a bleeding rate of 1%. Fisher and Mutimer²¹⁷ performed either IJ or SC cannulation in 658 patients with severe liver disease whose INR averaged greater than 1.5 (median 2.4, range 1 to 16) and/or had platelet counts less than 150,000/ μ L (median 10,000, range 9000 to 1,088,000/ μ L). Patients received neither prophylactic FFP nor platelet transfusions. Among these 658 patients, there was one major event (a hemothorax occurring in a patient whose INR was 1.5 and platelet count was 68,000/ μ L), which was deemed due to inadvertent laceration of the subclavian artery. The risk of local hematoma formation (which rarely requires any treatment other than pressure) was 6% in patients whose INR was 5 or less and 12% in patients whose INR was above 5. Four risk factors predicted minor bleeding: (1) the IJ site tended to bleed more than the SC site; (2) a procedure requiring more than one pass with the needle to cannulate the vein; (3) failure to easily insert the guidewire; and (4) patients whose INR was above 5. Values of the INR or other coagulation factors were not contraindications to a central line placement, particularly if it was deemed that such placement was beneficial for the patient's overall care.

Foster and colleagues²¹⁸ examined the advisability and safety of central venous catheterization insertion in 259 patients awaiting or having just undergone OLT. Their patients' mean platelet count was 47,000/ μ L (range 8000 to 79,000/ μ L), mean PTT of 97 seconds (range 78 to 100 seconds) and estimated mean INR 2.0 (range 1.5 to 8.0). They administered no pre-procedure FFP or platelets, yet noted no serious bleeding using their most experienced operator. They concluded that there are no data supporting fear of increased bleeding complications in central venous cannulation in patients with coagulopathy.

DeLoughery and colleagues²¹⁹ examined the outcome of central line placement as a function of hemostatic testing in

critically ill patients. They performed 938 procedures with 41% of the patients having at least one abnormal test, 27% having several abnormalities, and 17% having undergone no testing prior to the procedure. Thirty-seven percent of their patients received some blood product prior to the procedure. They found that 16 (1.7%) of patients experienced minor bleeding and that only 2 (0.2%) experienced serious bleeding (neither was fatal). They concluded that laboratory data did not predict bleeding and that, in retrospect, the infusion of blood products, particularly FFP, was inappropriate.

Doerfler and colleagues²²⁰ inserted 104 central lines in patients with abnormalities of coagulation. They judged that seven (6.5%) had some abnormal bleeding; all seven had a platelet count of 37,000/ μ L or less. They had not infused platelets into patients prior to the procedure but used their most experienced operator. There was no predictive value of routine coagulation testing.

In summary, all these studies show that there is no predictive value of routine tests prior to the insertion of central lines. FFP and platelets should not be administered routinely and the most experienced operator seems most appropriate to insert lines in these challenging cases. Thus, there is no reproducible laboratory value that serves as a cutoff for safe insertion and there is no value in delay caused by testing and costly, time-consuming infusion of blood or blood products. The bleeding rate appears to be extremely low, on the order of 1% to 2% and with no report of any fatality in these series. When one considers the benefit of such access, it is clear that the risk:benefit ratio favors performing the procedure. Especially noticeable is that no study has shown that the pre-procedure infusion of FFP or platelets decreases any real or hypothetical increase in hemorrhage.^{219,220}

Arteriotomy

Examining the courses of 1000 cases of femoral artery puncture, Darcy and coworkers²²¹ reported that neither the pre-procedure PT nor the PTT was predictive for arterial hematoma formation in a cohort of patients undergoing femoral arteriotomy. They had arbitrarily limited the study to patients whose PTs were 18 seconds or less. Hematomas formed at a rate of 8% to 10% independent of any of these test results.

INVASIVE PROCEDURES FOR PATIENTS ON ANTICOAGULANT THERAPY

Many patients are receiving chronic oral anticoagulant therapy that was prescribed for clear indications. Accordingly it is not advisable for another practitioner preparing a patient for surgery or an invasive procedure to unilaterally stop warfarin therapy because of fear of bleeding. Should the risk of bleeding be considerably less than the operator perceives (which is almost always the case), then the risk:benefit ratio of withholding warfarin might very well be unfavorable for the patient's overall care. The risk of stopping anticoagulant therapy obviously varies from patient to patient with the risks of thrombosis being often at a fairly low risk (such as patients with atrial fibrillation who are on warfarin for primary prophylaxis of a stroke) to moderate risk (such as patients with modern prosthetic heart

valves), to those with extremely high risk (such as patients who have had thromboses or have active antiphospholipid syndrome). There is substantial evidence^{1,222} that a thromboembolic event (such as may result from withholding anticoagulants) has a 30-fold higher incidence for death or permanent sequelae than does a hemorrhagic event that may occur from continuing a patient on anticoagulant therapy for a procedure.

Kearon and Hirsh estimated that major surgery itself increases the risk of a thromboembolic event up to 100 times, a factor to be incorporated in estimating the risk:benefit ratio regarding the wisdom of stopping or continuing anticoagulant therapy for a procedure.¹ It is especially dangerous to perform any elective surgery in someone who has had a thrombotic event within the previous 20 weeks;¹⁸⁹ in nearly all such cases, elective invasive procedures should be withheld unless anticoagulation is carried out at the lowest therapeutic intensity. This topic is specifically addressed in Chapter 38, but some general comments seem appropriate in this chapter also.

A 1979 paper by Katholi and colleagues²²³ is frequently cited claiming that for patients with older prosthetic heart valves undergoing noncardiac surgery while remaining on anticoagulant therapy (estimated INRs in that time period of 2 to 7) 50% experienced some bleeding, with 10% having serious bleeding, yet none fatal. However, they also reported that of 35 patients with prosthetic heart valves, for whom anticoagulants were withheld, there were two fatal thromboembolic events. Stopping anticoagulant therapy in this small cohort was unfavorable. The hemorrhagic rate of procedures done at modern therapeutic range INRs (2 to 3) has yet to be scientifically and thoroughly determined.

A survey of ophthalmologists²²⁴ showed that although most of them unilaterally stopped anticoagulant therapy before lens implantation, there were no hemorrhagic consequences reported by those who did not stop anticoagulant therapy. However, among those ophthalmologists who did discontinue therapy, there were nine thromboembolic events, including two fatal events.

Until recently it was standard dentistry practice to stop anticoagulant therapy for extractions or similar procedures. This practice was reviewed by Weibert,²²⁵ who concluded that modern therapy with INRs of 2 to 3 does not result in any appreciable increased bleeding or, that if any bleeding occurred, it was never serious and was easily controlled by local measures. In a recent study²²⁶ of dental patients on warfarin therapy, all patients continued their medication. Patients were randomized to receive Gelfoam sponges and sutures, those two measures plus tranexamic acid, or all three of these efforts plus fibrin glue. All patients fared the same and none bled significantly. Because the first option, namely Gelfoam sponges and suture, was the easiest to carry out, that was the method recommended. This entire subject has been thoroughly reviewed by Wahl,²²⁷ who concludes that the risk:benefit ratio of maintaining patients on oral anticoagulants for any oral procedure greatly favors the patient remaining on warfarin and the risk for bleeding is greatly exaggerated or misunderstood. Recent editorials in the dental literature support these tactics.²²⁸

Hip surgery for fractured hips or total hip replacement has always been an operation fraught with thromboembolism, which is the major cause of death in such patients.

In a very early (1959) controlled study, Sevitt and Gallagher²²⁹ reported pinning fractured hips in patients on no anticoagulant therapy or on the vitamin K antagonist phenindione. One hundred fifty patients were in the control group and 150 patients received full-dose phenindione. Although it is impossible to precisely reconstruct what those patients' INRs were, they were likely in the range of 5 to 8. Whereas one could have predicted at such INRs some major bleeding would occur (five in the phenindione group and two in the control group), deaths from pulmonary embolism were decreased by 80%.

Later, in 1971, Salzman and colleagues²³⁰ used warfarin anticoagulation to an estimated INR of 2.5 to 4.5 in a similar study and showed a 20% risk of bleeding, which was about the same as patients receiving aspirin or dextran as their control group yet with a decrease in VTE in the group on warfarin. In 1983, Francis and coworkers²³¹ began warfarin anticoagulant therapy to an estimated INR of 1.8 several days prior to total hip replacement or total knee replacement. Four percent of their patients bled, which was the same incidence as controls receiving dextran. Of the patients who were treated with warfarin compared with dextran, there was a 60% reduction in DVT and an 88% reduction in large proximal vein thrombosis. These papers showed that major surgery is feasible with very acceptable bleeding, with INRs that are not so high as to provoke bleeding but high enough to result in excellent prophylaxis of VTE in very high-risk patients.

In a cohort of 100 consecutive patients at high risk for thromboembolism who underwent major surgery, an INR of 1.8 ± 0.2 was associated with acceptable bleeding and a low risk of thromboembolism. Additionally, the time required for reconstituting a full therapeutic INR averaged only 2 days.²³² In a recent editorial, Sandset and Abildgaard²³³ point out that surgical procedures are carried out in many European centers in patients on warfarin therapy with INRs up to 2.0 with acceptable bleeding risk. Torn and Rosendaal²³⁴ found an odds ratio of only 1.3 when invasive procedures were carried out with INRs > 3.0 when compared with those procedures on patients whose INRs were < 2.0 .

These data appear highly consistent with the hypothesis that perceived hemorrhagic risks in patients operated on with INRs > 1.5 are greatly overestimated, and that although randomized controlled trials are lacking, that surgery with higher INRs is feasible, safe, and rational. Clearly each patient needs an individual estimate of their unique risk:benefit ratio depending on their risk and consequence for hemorrhage or thrombosis.

A growing list of varying procedures in addition to dental, ophthalmic, and hip surgery reveals no additional hemorrhagic risk for patients on warfarin, provided the INR is not supratherapeutic and, based on risk:benefit analysis, does not justify discontinuing warfarin for these procedures; this list includes hand surgery,²³⁵ transrectal prostate biopsy,²³⁶ and extensive cutaneous surgery.^{237,238} The rigorous logic employed in the extensive review by Otley²³⁸ is particularly clear and useful, even for those in disciplines different from cutaneous surgery and is strongly recommended reading for anyone wishing to frame a risk:benefit profile. Perhaps as important as the growing list of disciplines, procedures, and varying INRs in these referenced reports is the total unanimity of these opinions with no known studies suggesting otherwise.

If a patient on chronic oral anticoagulant therapy undergoes surgery without warfarin, many practitioners will use a "heparin bridge" to protect the patient during the brief period of subtherapeutic INR during the surgery and particularly after the surgery while the INR returns to therapeutic levels. LMWH may be used for this purpose (See Chapter 38).^{239,240}

As more patients are administered chronic oral anticoagulation, it should be expected that more cases of trauma will occur in such patients. The fate of trauma patients who are on chronic oral anticoagulant therapy as a pre-injury condition has been addressed.^{241–243} Surprisingly, there appears to be little if any extra morbidity or mortality in such patients when compared with similar trauma patients lacking the pre-injury condition of warfarin therapy, with the possible exception of those patients experiencing closed head injuries.²⁴³

Should a patient need emergent surgery (such as for trauma or an acute abdominal process), it may be advisable to reverse, or at least partially reverse, the effect of the warfarin prior to surgery. This can be done quite safely with very small doses of intravenous vitamin K, which will decrease the INR within 6 hours.²⁴⁴ Intravenous administration is safe when small amounts, such as 0.5 to 1.0 mg, are administered in a diluted solution over approximately 30 minutes. Not only do higher doses far too often result in total reversal of the warfarin (which may not be desirable) but also doses greater than 1 to 2 mg frequently lead to warfarin resistance, making it difficult to re-achieve a therapeutic INR. When vitamin K is given intravenously it is safe while being faster and more reliable than giving it subcutaneously or orally.^{245–247} Should one overshoot and the INR become unacceptably subtherapeutic, a heparin, LMWH, or pentasaccharide bridge method can be employed until the patient's INR returns to therapeutic range.

CONSULTATION ON PATIENTS WITH INTRAOPERATIVE OR POSTOPERATIVE HEMORRHAGE

Hematologists and transfusion medicine specialists are called by surgeons, anesthesiologists, and critical care personnel for the evaluation of bleeding either during an operation or afterward. Surgery or major trauma is the ultimate test of the hemostatic system. Accordingly, it is possible for patients who have never hemorrhaged to any significant degree to bleed excessively.

Nearly all reviews of intraoperative and early postoperative bleeding^{78,248} point out that 75% to 90% of all such bleeding is technical in nature because of a structural problem such as an undone ligature, failed clamp, or partially secured vessel. It is very important to work with the surgeon because the cause of bleeding must be either surgical or hemostatic failure. Early in the consultation process it is advisable to have personnel draw blood samples for routine available coagulation tests. A sample of blood must be drawn from a fresh peripheral venipuncture. This may seem counterintuitive to the anesthesiologist, who may have several vascular devices from which blood could be drawn. Too frequently samples are adulterated by the infusion of heparin or even saline, erythrocytes, or plasma.²⁴⁹

Therefore, the very sample that one needs for critical decision-making must not be suspect from the very beginning. It is advisable to call the coagulation laboratory so that technicians can be alerted to both the seriousness of these particular tests as well as to work with the hematologist in a sequential manner regarding subsequent tests, the indications for which will unfold as the laboratory consultation progresses. Assessment of all patients experiencing substantial hemorrhage usually includes a PT, PTT, TT, platelet count, and measurements for D-dimer (or other FSPs). If the PT, PTT, and TT are all prolonged with decreased plasma fibrinogen levels and decreased platelets with positive assays for D-dimers, disseminated intravascular coagulation (DIC) is very high on the list for hemorrhage. If the FDPs are high but with the PT, PTT, and platelet count fairly well preserved with a very long TT, hyperfibrinolysis is strongly suggested. Conversely, if the TT is the sole test that is relatively the most prolonged, the culprit more often than not is excessive heparin either systemically administered or possibly from a contaminated sample from an intravenous line containing heparin. It must be recalled that neither LMWH nor the newer pentasaccharides prolong the PT, PTT, or TT so their involvement cannot be eliminated by those tests being normal.²⁵⁰ The coagulation laboratory can set up a 1:1 mix of patient plasma with normal plasma to repeat the PT, PTT, and TT if any of these three tests are abnormal on initial testing of the patient's plasma. If the 1:1 mixture results in a previously abnormal test becoming normal, it strongly suggests a deficiency that can occur either congenitally, because of vitamin K deficiency or warfarin therapy, or from severe liver disease. Should the 1:1 mixture not correct the abnormal test(s), then an inhibitor, to include heparin, FDPs or D-dimers, or spontaneous acquired inhibitor,²⁵¹ is strongly suggested. The use of the thromboelastogram (TEG) by anesthesiologists has been discussed vigorously.^{252,253} Whereas this test does not traditionally fit into hematologists' thinking, it clearly is one of the most accurate and rapid ways to detect hyperfibrinolysis especially in situations that are characterized by hyperfibrinolysis, namely CPB and OLT.

PFA, especially at the point of care, would seem to be able to quickly reveal platelet dysfunction. Two studies^{254,255} address this situation in CPB patients. In one study, although platelet dysfunction could be demonstrated, there was only a poor correlation between PFA abnormalities and hemorrhage following CPB and the PFA abnormalities were not substantiated by the more traditional but cumbersome platelet aggregation studies.²⁵⁴ The other study failed to demonstrate significant PFA studies in post-CPB patients; some patients with mild platelet aggregation abnormalities did not experience abnormal hemostasis,²⁵⁵ and TEG appeared to better predict bleeding and guide therapy. These findings are consistent with the notion that although platelet abnormalities are commonly detected following CPB, they are brief and of questionable overall importance. While agreeing that point-of-care testing was of marginal diagnostic significance, Avidan and associates²⁵⁶ pointed out that its use within a protocol for hemorrhage following CPB patients resulted in more focused transfusion practice than in post-CABG hemorrhage patients whose care was under traditional clinical discretion, which overall resulted in overall fewer transfused blood products.

Next the consultant should ascertain if any preoperative coagulation tests were done and what the results were. Often preoperative tests were abnormal yet were either not seen or not acted on. A slight prolongation of the PTT could very well represent a mild, previously undetected deficiency of factor VIII, IX, or XI, or if the PT and PTT are both prolonged while the level of albumin is low and bilirubin is elevated, significant liver disease is suggested. If the preoperative and intraoperative coagulation tests mentioned are all normal, a local structural or technical problem is likely to be at fault.

Once laboratory studies are initiated, attention must be paid to the clinical features of hemorrhage. As Table 37-7 depicts, the nature of bleeding is very helpful. The concept that bleeding is due to a structural defect is greatly strengthened if there is bleeding from a single site while other potential sites are not bleeding. If bleeding is sudden and massive with bright red, pulsatile blood, arterial bleeding is probable. Clinical features that favor a basic hemostatic defect are multiple concurrent bleeding sites. Concomitant hemoglobinuria and hemoglobinemia strongly implicates transfusion reaction-induced DIC. Slow and persistent oozing, particularly several days after surgery, suggests a hemostatic defect. Table 37-8 lays out an overall evaluation. Appropriate questions asked of the treatment team and review of the chart or any pre-existing data often are the best sources of information.

Table 37-9 lists several hemostatic details that may or may not affect postoperative hemorrhage. Low-dose prophylactic use of heparin does not increase bleeding according to comprehensive meta-analyses.¹⁵² Agents that may substantially impair platelet function are aspirin and NSAIDs (particularly ketorolac) in the postoperative period. Recalling that perhaps 1% of the population may have von Willebrand syndrome, it is highly possible that the addition of aspirin or NSAIDs is enough to expose the underlying nature of that heretofore stealth bleeding diathesis.²⁵⁷ Increasingly, antiplatelet agents, not only clopidogrel but GP-IIb/IIIa inhibitors are used in clinical practice and may be associated with hemorrhage. Of the three GP-IIb/IIIa inhibitors, only abciximab-related hemorrhage is reversed by platelet transfusion owing to the extreme protein binding of abciximab. Platelet transfusions are not acutely effective due to extant plasma levels for both

Table 37-7 Clinical Features of Hemorrhage

Clinical Features Favoring Structural or Technical Defects

- Bleeding from a single site while other candidate sites are not bleeding
- Sudden onset of massive and/or rapid bleeding
- Bright red or pulsatile bleeding from an identifiable source

Clinical Features Favoring Hemostatic Defect

- Multiple simultaneous bleeding sites
 - Surgical incision
 - Vascular access sites
 - Mucosal membranes
 - Skin
 - Hematuria
 - Hemoglobinuria or hemoglobinemia
- Slow persistent ooze of blood from a non-identifiable source
- Delayed hemorrhage following adequate hemostasis

Table 37-8 Evaluation of Postoperative Hemorrhage

- Obtain fresh venipuncture sample of blood for:
 - Thrombin time
 - Prothrombin time
 - Partial thromboplastin time
 - 1:1 mix with normal plasma of the above, if any are abnormal
 - Blood smear for schistocytes and platelet count estimation
 - Signs of sepsis such as leftward shift, toxic granulation, or vacuolization of granulocytes
- Note features of bleeding (see [Table 37-7](#))
- Repeat directed history and physical examination
- Review patient's chart:
 - Were preoperative liver and renal tests normal?
 - Were preoperative coagulation screening tests normal?
 - Were aspirin or NSAIDs administered?
- Is the patient septic?
- Was the patient transfused? With what? When?
- Was bovine thrombin or fibrin glue containing bovine thrombin used as hemostatic agent?
- What surgical procedure was performed?
- Was anesthesia time prolonged?
- Note type and rate of bleeding
- Estimate consequences of continued bleeding

NSAIDs, nonsteroidal anti-inflammatory drug(s).

Table 37-9 Details that Affect Intraoperative or Postoperative Hemorrhage**Does Not Affect**

- Low-dose heparin prophylaxis
- Low-dose warfarin prophylaxis
- Osler-Weber-Rendu syndrome
- Mild thrombocytopenia ($\geq 60,000/\mu\text{L}$)

Occasionally Affects

- Aspirin or NSAID administration
- Adjusted-dose heparin prophylaxis
- Poor metabolic/nutrition states*
- Moderate thrombocytopenia (30,000–60,000/ μL)

Frequently Affects

- Ticlopidine, clopidogrel, or GP-IIb/IIIa inhibitors
- Platelet defects, especially with concomitant aspirin or NSAID administration
- Factor VIII or IX levels <30% of normal
- Fibrinogen <60 mg/dL
- Severe thrombocytopenia (<30,000/ μL)
- Multiorgan failure

NSAID, nonsteroidal anti-inflammatory drug.

*Prolonged use of glucocorticosteroids, malnutrition, inanition, bedridden state from chronic illness, septicemia, and chronic renal or hepatic failure.

eptifibatide and pirofiban.²⁵⁸ By far, the rarest abnormality is mild, previously undiagnosed hemophilia,² which is characterized by a slow ooze that usually starts on postoperative days 1 to 3 and is rarely of a brisk or alarming nature initially. Characteristically, hemostasis in mild hemophiliacs undergoing surgery is surprisingly normal for the first day or so during high levels of wound-induced TF generation. The nature of hemophilic bleeding has been described exquisitely in the older literature; the interested reader is referred to such descriptive papers.^{259–263}

[Table 37-10](#) presents various causes of postoperative bleeding. The differential diagnosis is, in part, a function of time from the operation. Hyperfibrinolysis, although not limited to patients undergoing CPB or OLT, characteris-

Table 37-10 Causes of Intraoperative or Postoperative Hemorrhage**Intraoperative Hemorrhage***

- Structural/technical defects
- Disseminated intravascular coagulation
- Heparin overdosage
- Hyperfibrinolysis

Early Postoperative (Days 0 to 2)*

- Structural/technical defects
- Thrombocytopenia
- Qualitative platelet disorders
- Mild/moderate hereditary coagulation disorder

Delayed Postoperative Bleeding (Days 2 to 7)*

- Thrombocytopenia
- Aspirin or NSAID administration
- Vitamin K deficiency
- Multiorgan failure
- Antibodies to factor V following use of bovine thrombin in fibrin glue

NSAID, nonsteroidal anti-inflammatory drug.

*These times are those commonly encountered but are used only as approximations.

tically is very brisk but usually of short duration. In CPB and OLT in which the index of suspicion and prevalence is high, prompt administration of aprotinin or another fibrinolytic agent as discussed earlier in this chapter is strongly indicated. Thrombocytopenia that begins postoperatively and becomes worse, particularly if it is associated with thrombosis, is highly suggestive of heparin-induced thrombocytopenia (see Chapter 25). Vitamin K deficiency of an acquired nature is surprisingly common in intensive care situations, particularly if the patient has been ill for some time and, therefore, malnourished from the onset; after several days/weeks in the intensive care unit, one becomes depleted of vitamin K-dependent factors. One clinical hallmark of this situation is that the PT tends to prolong comparatively earlier than the PTT. Vitamin K deficiency is diagnosed and treated by the suspicion of this problem and the response of the patient to vitamin K administration.²⁶⁴

[Table 37-11](#) offers several therapeutic options. Watching and waiting with the appropriate administration of red blood cells and fluid is often appropriate, particularly if the rate of bleeding seems to be decreasing. Re-exploration of the surgical site not only often will identify the bleeding site but also may be therapeutic in itself because it may remove thromboplastic as well as fibrinolytic agents released from large collections of clotted blood.⁸⁵ If a specific diagnosis is made, therapy obviously is addressed toward that cause.

Table 37-11 Therapeutic Options in Intraoperative or Postoperative Hemorrhage

- Acute volume and red cell administration as indicated
- Angiography with or without arterial embolization
- Watchful waiting
- Re-exploration of bleeding site
- Limited use of FFP, cryoprecipitate, and platelet transfusion, except for precise diagnoses and indications
- DDAVP
- Antifibrinolytic agents
- Use rFVIIa in select cases

DDAVP, 1-deamino-8-D-arginine vasopressin; FFP, fresh frozen plasma.

In desperate situations in which more traditional methods have failed and even without a specific diagnosis, many have employed rFVIIa reporting reasonable results. We are learning how to use this new and valuable tool in our therapeutic armamentarium. Consensus recommendations for use¹²⁶ and complications¹²⁵ exist but have yet to be verified with appropriately done studies, which are clearly needed. Dosage is usually initially 40 to 90 µg/kg which may be repeated every 2 hours for 8 to 12 hours total if hemostasis is not achieved earlier.

The use of topical surgical adjuvants including fibrin glue is covered thoroughly in Chapter 29. Bleeding that begins 4 to 14 days or even longer after surgery in which fibrin glue was employed raises the possibility of the induction of anti-bovine factor II and/or factor V, which may have cross-reactivity to their human counterparts. Management of such problems has been recently reviewed.²⁶⁵

The administration of DDAVP is effective for platelet dysfunction due to aspirin or NSAIDs. Administration of 0.3 µg/kg intravenously over 30 minutes is effective in bleeding due to platelet dysfunction.

The tempo, depth, and thoroughness of evaluation will be a function of the potential consequences of continued bleeding. A small amount of bleeding in a confined space

on which pressure cannot be applied (such as the brain or internal organ) is obviously of more immediate concern than bleeding outside the body such as from a wound on an extremity. Accordingly, a more conservative approach may be indicated for the latter. Attempts at surgical techniques to stop true hemostatic defects are not successful; suturing to replace the hemostatic function of a missing coagulation factor will not work. In fact, the tighter one attempts to suture, the more inward the bleeding becomes, which continues and can dissect internally at an alarming rate and actually cause more damage than had the blood been allowed to escape the confines of the body.

Not all excessive hemorrhage is necessarily due to hemostatic failure. Bleeding in large, named vessels—particularly arteries—requires surgical repair. Bleeding from those vessels is rarely, if ever, due to a defect in the hemostatic system. Massive amounts of clotting factors, plasma, and platelets will not correct large structural lesions but can result in dilutional coagulopathy, which can mimic or actually result in DIC (See Chapter 46).^{266,267} Table 37-12 offers some suggestions, if not hypotheses, regarding advice and hints on how to construct a reasoned risk:benefit stratification. There is much work to do. Studies providing data or answers to these points are needed.

Table 37-12 Observations Concerning Bleeding and Thrombosis in Risk:Benefit Stratification*

1. Evidence-based medicine (EBM) teaches us with statistical power what to expect from a population with a specific question, yet tells us little of what will happen to an individual patient within that population, given one's ultimate unique condition. Although EBM is a valuable guideline, final determinations are clinically based.
2. Given that either bleeding or thrombosis can be serious if not catastrophic, outcomes are nearly always better following a hemorrhagic event than a thrombotic event. In 21st-century medicine, far more patients experience thrombotic than hemorrhagic death.
3. Structural disorders, such as esophageal varices, tumors, and fresh postoperative sites, do not require the presence of anticoagulants to bleed, but any anticoagulants (heparin, warfarin, or antiplatelet agents) administered will invariably be blamed for any hemorrhage, regardless of its size, nature, or location.
4. Because bleeding is perceived as abnormal in 3–5% of all procedures, one should expect, and tolerate, a similar baseline occurrence for procedures carried out with concurrent anticoagulant therapy.
5. In patients experiencing macrovascular hemorrhage who have abnormal hemostatic tests, it is more important to address the cause or site (lacerated organs, unsuccessfully ligated vessels, or blunt trauma) than to spend time addressing and “correcting” the laboratory abnormalities with infusion of fresh frozen plasma (FFP), platelets, and the like.
6. True hemostatic failure with microvascular bleeding typified by classic hemophilia A or B patients inadvertently undergoing trauma or surgery without factor replacement is ONLY corrected by replacement of the missing factor—regardless of one's surgical expertise.
7. Microvascular bleeding is due to hemostatic failure resulting from inadequate thrombin generation, thrombocytopenia, or excessive fibrinolysis (disseminated intravascular coagulation [DIC], hyperfibrinolysis). Such bleeding is diffuse and typically oozes up from vascular beds without any clear physical site of origin, thereby largely eliminating the possibility of hemostatic success with a ligature or other physical measures. Macrovascular bleeding, on the other hand, typically emanates from lesions or vessels large enough to see the bleeding point. Such vessels are usually large enough to have been named. Classic hemostasis resulting in fibrin generation has little to offer; mechanical means such as pressure, suture, cautery, or ligation are the most effective.
8. To date, nearly all studies concerning invasive procedures for patients on chronic anticoagulant therapy begin with the premise that anticoagulant therapy must be stopped or modified, despite no evidence that demonstrates the correctness of that premise. No study has proved—or even strongly implied—at what INR patients on warfarin are statistically more likely to bleed than patients not on warfarin undergoing similar procedures. A few studies suggest that a cutoff INR is clearly above 2.0 and probably close to 3.5.
9. Determining risk:benefit ratio requires an accurate assessment of risk for bleeding with or without anticoagulant therapy, as well as the risk for thrombosis with or without concurrent anticoagulant therapy. This is not always apparent in the extant literature on this subject. For instance, some guidelines consider polypectomy or fine needle aspiration to be procedures of high risk for bleeding, whereas others deem brain tumor surgery or cardi thoracic surgery to be high-risk procedures. High-risk patients for one group may consist of mechanical heart valves in the mitral position, yet no mention is made of patients with much higher thrombotic risk, such as those with anticardiolipin syndrome, prior life-threatening thrombosis, thrombosis within 6 months of an invasive procedure, or patients who have already experienced thrombosis when anticoagulation has been held for a prior procedure.
10. Performing invasive procedures on patients with either severe thrombocytopenia or patients with therapeutic or anticoagulant therapy-induced prolongation of standard coagulation tests will occasionally be associated with hemorrhage, despite one's best efforts to construct a risk:benefit ratio as favorable as possible for an individual patient. Such events must not dissuade one from further efforts on behalf of our patients.

INR, International Normalized Ratio.

Anticoagulation in the Perioperative Period

Bundarika Suwanawiboon, MD • Thomas L. Ortel, MD, PhD*

Hematologists are frequently consulted to evaluate patients who receive long-term oral anticoagulant therapy and may require temporary interruption of warfarin prior to surgery or an invasive procedure. In general, these patients are maintained on chronic anticoagulation for clinical conditions associated with an increased thrombotic risk, including mechanical prosthetic heart valves, chronic atrial fibrillation, or venous thromboembolism, making perioperative management problematic. On the one hand, disruption of oral anticoagulation will expose the patient to an increased risk of thromboembolism, but the degree of risk is clearly variable among such patients. On the other hand, there is a legitimate, but often exaggerated, risk of hemorrhagic complications if anticoagulant therapy is continued. Prior to formulating a management recommendation, these issues must be individually addressed using risk:benefit ratio formulations as best as possible. These considerations are best managed by a hematologist with experience in the management of antithrombotic therapy and perioperative hemorrhage.

Presently, there is little consensus on the optimal management of anticoagulant therapy in this particular scenario. In addition, there are no randomized prospective clinical studies to evaluate the efficacy and safety of different perioperative anticoagulation approaches. Most recommendations are based largely on empirical data and the extrapolation of anticoagulant benefit estimated from thrombotic and bleeding risks identified in certain procedures and patient groups, which may not be entirely applicable to patients in different clinical settings. This chapter provides a summary of currently available evidence and suggests a management framework concerning the perioperative and postoperative management of patients on chronic anticoagulation. Nevertheless, clinicians must keep in mind that the recommendation for each patient should be individualized to maintain a balance between efficacy of anticoagulant therapy in the prevention of thromboembolic events and safety of the treatment to minimize potential hemorrhagic complications.

When considering the rates at which complications occur, it is also important to bear in mind the clinical consequences of these complications. For example, approximately 20% of arterial thromboembolic events are fatal, and 40% result in serious permanent disability.¹ Additionally, up to 6% of

recurrent venous thromboembolic events are fatal.¹ In contrast, several studies have demonstrated that ~3% of major postoperative bleeding events are fatal with most patients making a full recovery after hemorrhagic complications.¹ These observations suggest that a hemorrhagic complication may not be as devastating as a thromboembolic event, and should also be taken into consideration when making a recommendation for the individual patient.

PREOPERATIVE ASSESSMENT

Prior to considering discontinuation of oral anticoagulation and selecting an alternative anticoagulant agent, several issues need to be addressed: (1) Perioperative thromboembolic risk; (2) Perioperative and postoperative bleeding risk; and (3) Potential benefit of perioperative anticoagulation.

These issues will be discussed in more detail subsequently. Other variables that may play a role in the decision-making include patient preference and the cost of supplemental perioperative anticoagulation, particularly in the case of intravenous unfractionated heparin, which generally requires hospitalization for drug administration and laboratory monitoring.

Perioperative Thromboembolic Risk

The assessment of perioperative thromboembolic risk can be stratified based on the indication for anticoagulation. Most patients require long-term oral anticoagulant therapy because of a mechanical prosthetic heart valve, chronic atrial fibrillation, or venous thromboembolism. Specific patient populations will be considered separately.

Patients with a Mechanical Prosthetic Heart Valve

Long-term anticoagulant therapy is indicated in patients with a mechanical prosthetic heart valve because of the risk of systemic thromboembolism and valve thrombosis. In the absence of anticoagulant therapy, the incidence rates of prosthetic valve thrombosis and major embolism (resulting in death, residual neurologic deficit, or peripheral ischemia requiring surgery) are approximately 1.8% per patient-year and 4% per patient-year, respectively (derived from a meta-analysis of 46 studies including 13,088 patients, combining patients with prosthetic valves in the aortic and/or mitral

*TLO is supported by a cooperative agreement (U18 DD00014) with the Hematologic Diseases Branch, the Centers for Disease Control and Prevention.

positions, as well as all types of prosthetic valves, predominantly Starr-Edwards, Björk-Shiley, Medtronic-Hall, and St. Jude).² The rate of these complications decreased to 1% per patient-year with warfarin therapy.²

In general, a prosthetic valve in the mitral position is considered to have higher thrombogenicity and is associated with a greater risk for valve thrombosis and systemic embolization than a prosthetic valve in the aortic position,^{2,3} owing to increased vascular stasis around the mitral valve.⁴ Risk of thrombotic complication is also affected by the design and construction materials of the valve prosthesis. The risk is highest in patients who have a caged-ball type of valve (e.g., Starr-Edwards), followed by the single-leaflet tilting disc type (e.g., Björk-Shiley, Medtronic-Hall) and the bileaflet tilting disc type (e.g., St. Jude, Carbomedics), which is the least thrombogenic.^{2,4-6}

In patients who have more than one prosthetic valve, the risk for thromboembolic complication is higher than that of patients with a single valve prosthesis.²⁻⁴ Furthermore, the presence of concomitant atrial fibrillation also increases the risk of thrombogenicity of a prosthetic valve.²

When anticoagulation therapy is transiently discontinued, the principal concern is the risk of thrombosis. However, it is difficult to estimate the daily risk of thromboembolism in the absence of anticoagulation therapy due to limited data and the fact that most studies involve patients with first-generation prosthetic heart valves. Recent data from patients with newer generation mechanical heart valves (e.g., St. Jude and Björk-Shiley valve prostheses) provide the estimation of an annualized risk of any thrombotic complication varying from 10% to 23%.⁷ The summary of annual thrombotic risk associated with prosthetic heart valves in the absence of antithrombotic therapy is listed in Table 38-1.

Patients with Chronic Atrial Fibrillation

Patients with atrial fibrillation are at increased risk for systemic embolism. The risk is highest in patients with a prior transient ischemic attack or stroke, particularly if the embolic event occurred within the preceding month (high-risk group), with an incidence of 12% to 15% per year.^{5,8,9} The thromboembolic risk is also modified by the presence of additional risk factors, including hypertension, diabetes mellitus, increasing age (age >65 years) and impaired left ventricular function (Table 38-2).¹⁰⁻¹²

Patients with lone atrial fibrillation who are 65 years in age or younger and have none of the additional stroke risk factors listed in Table 38-2 have the lowest risk of stroke, with an

Table 38-2 Additional Risk Factors for Stroke in Patients with Chronic Atrial Fibrillation

Condition	Relative risk*
Prior TIA/stroke	2.5–2.9
Left ventricular dysfunction	2.5
Hypertension [†]	1.6–2.0
Increasing age [‡]	1.6–1.8
Diabetes mellitus	1.6–1.7

Risk factors for stroke and efficacy of antithrombotic therapy in atrial fibrillation: Analysis of pooled data from five randomized controlled trials. Arch Intern Med 154:1449–1457, 1994.

Compiled from Hart RG, Pearce LA, McBride R, et al: Factors associated with ischemic stroke during aspirin therapy in atrial fibrillation: Analysis of 2012 participants in the SPAF I-III clinical trials. The Stroke Prevention in Atrial Fibrillation (SPAF) Investigators. Stroke 30:1223–1229, 1999.

[†]Hypertension is defined as systolic blood pressure >160 mm Hg

[‡]Age >65 years

Adapted from Douketis JD: Perioperative anticoagulation management in patients who are receiving oral anticoagulant therapy: A practical guide for clinicians. Thromb Res 108:3–13, 2002; and Heit JA: Perioperative management of the chronically anticoagulated patient. J Thromb Thrombolysis 12:81–87, 2001.

incidence of less than 1% per year.^{5,11,13} Nevertheless, most patients with atrial fibrillation fall into a moderate-risk group (atrial fibrillation with the presence of stroke risk factors as listed in Table 38-2, but without history of stroke or transient ischemic attack [TIA]) with an incidence of stroke of 3% to 7% per year.^{5,9} Unfortunately, the data concerning the perioperative thromboembolic risk during the temporary interruption of oral anticoagulation in patients with atrial fibrillation are sparse. Nonetheless, it has been estimated that the daily risk of systemic embolism, interpolating from the aforementioned data, are roughly 0.28% to 0.38% in the high-risk group, followed by 0.06% and 0.15% in the moderate-risk group, and 0.02% to 0.04% in the low-risk group.^{5,11,12}

Patients with Venous Thromboembolism

The risk of additional thromboembolic complications is highest in patients who present with acute venous thromboembolism (within the preceding month), with an estimated thrombotic rate of 40% per year in the absence of anticoagulant therapy.^{1,14,15} The risk of recurrent events then declines rapidly over the following 3 months to approximately 10% per year.^{1,14} In patients with recurrent venous thromboembolism, an estimated risk of 15% per year is speculated if anticoagulant therapy is discontinued.^{1,14} The risk of venous thromboembolism based on time of onset is summarized in Table 38-3.

There are no data regarding the risk of recurrent disease if oral anticoagulant therapy is temporarily interrupted.⁵ The presence of additional independent risk factors also modifies the probability of disease recurrence. These factors include increasing age and body mass index, malignant neoplasm, chronic disease such as neurologic disease with extremity paresis, antiphospholipid syndrome, homozygosity for factor V Leiden polymorphism, and combined heterozygosity for the factor V Leiden and prothrombin 20210 polymorphism.^{1,5,16–20} Furthermore, patients with previous postoperative venous thromboembolism will be more likely to develop recurrent disease after surgery, although there are no data to

Table 38-1 Thrombotic Risk Associated with Prosthetic Valves in the Absence of Antithrombotic Therapy

Prosthesis Type	Rate of Thrombosis (% per year)
Multiple (St. Jude) prosthetic valves	91
Dual-leaflet (St. Jude) mitral valve	22
Single-leaflet (Björk-Shiley) aortic valve	23
Dual-leaflet (St. Jude) aortic valve	10–12

Table 38-4 Risk Stratification for Perioperative Thromboembolism**High Risk of Thromboembolism**

Recent (<3 months) history of venous or arterial thromboembolism

Mechanical valve in mitral position and/or older model of prosthetic valve (e.g., single-disc or caged-ball type)

Recent mechanical valve placement (<3 months)

Atrial fibrillation with history of systemic embolization

Atrial fibrillation in the presence of mechanical heart valve

Acute intracardiac thrombus confirmed by echocardiography

Rheumatic atrial fibrillation

Presence of hypercoagulable state

 Recurrent episodes of (≥ 2) arterial* or idiopathic venous thromboembolism

 Life threatening venous thromboembolism (e.g., mesenteric or cerebral vein thrombosis, Budd-Chiari syndrome)

 Protein C or protein S deficiency

 Antithrombin III deficiency

 Homozygous factor V Leiden mutation

 Antiphospholipid-antibody syndrome

Moderate Risk of Thromboembolism

Newer model of prosthetic valve (e.g., St. Jude) in mitral position

Older model of mechanical valve in aortic position

Cerebrovascular disease with multiple (≥ 2) strokes or transient ischemic attacks without risk factors for cardiac embolism

Atrial fibrillation with risk factors for cardiac embolism[†] but without history of stroke or transient ischemic attack

Low Risk of Thromboembolism

Remote history of venous thromboembolism (>3–6 months)

Atrial fibrillation without a history of stroke or other risk factors for cardiac embolism[†]

Bileaflet mechanical valve in aortic position

*Risk not including primary atherosclerotic events, e.g., stroke or myocardial infarction due to intrinsic cerebrovascular or coronary disease.

[†]Risk factors for cardiac embolism such as ejection fraction <40%, diabetes, hypertension, non-rheumatic valvular heart disease, transmural myocardial infarction within preceding month. Adapted from Ansell J, Hirsh J, Poller L, et al: The pharmacology and management of the vitamin K antagonists: The Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. *Chest* 126:204S–233S, 2004; and Jaffer AK, Brotman DJ, Chukwumerije N: When patients on warfarin need surgery. *Cleve Clin J Med* 70:973–984, 2003.

provide a reliable estimate of this risk.⁵ Table 38-4 summarizes a risk stratification scheme for thromboembolism based on patient-related characteristics when assessing the need for perioperative anticoagulant therapy.

Preoperative and Postoperative Bleeding Risks***Risk of Bleeding Associated with Patient Characteristics***

The first step to evaluate perioperative and postoperative bleeding risk is to obtain a thorough patient history to rule out the possibility of an underlying coagulopathy. Other pertinent information that will help determine the surgical bleeding risk includes history of aspirin, nonsteroidal anti-inflammatory drug (NSAID) or other antiplatelet therapy; history of blood transfusion; bleeding during previous invasive procedures, (e.g., dental cleaning/extraction, childbirth, surgery, or trauma), and other medical problems. Certain medical conditions may also increase the risk of bleeding. Examples include hepatic or renal insufficiency, dysproteinemias, myeloproliferative disorders, or malignancy/sepsis-associated disseminated intravascular coagulation. Preoperative laboratory screening tests should be obtained, if clinically indicated, to further evaluate for an underlying bleeding disorder.

Generally, a routine complete blood count is ordered to screen for anemia or thrombocytopenia, regardless of a bleeding history. Coagulation screening tests other than prothrombin time/INR on the morning of the procedure are seldom indicated.¹⁶ It has been suggested that patients who undergo surgery with an INR > 1.5 have an increased risk of postoperative hemorrhagic complications.⁵ Additional coagulation testing may be required in the patient who has a history of a bleeding diathesis, an underlying medical disease that may increase the risk of bleeding, and in patients with positive family history of abnormal bleeding.

Risk of Bleeding Associated with Type of Surgery or Procedure

Several procedure-specific factors significantly influence the perioperative and postoperative hemorrhagic outcomes and the decision for anticoagulant management. These include the location and extent of surgery and the accessibility of bleeding to compression or other physical means of control (e.g., packing, suturing, cautery, topical hemostatic or antifibrinolytic agent).^{16,21} Procedures that appear to have a low risk of bleeding despite the continuation of oral anticoagulation include most outpatient dental procedures,^{22–29} cataract extraction,^{30–35} and most cutaneous surgery, including Mohs micrographic surgery.³⁶ Examples of moderate-risk procedures include major intra-abdominal surgery and orthopedic surgery.⁵ High-risk procedures include cardiac and major vascular surgery,³⁷ prostatectomy,^{38,39} bladder surgery,⁵ and renal biopsy.⁴⁰

The incidence of excessive perioperative blood loss in patients undergoing cardiac surgery with cardiopulmonary bypass is approximately 13% to 16% when abnormal bleeding is defined as more than 10 units of perioperative blood transfusion. This incidence drops to 5% to 7% if excessive bleeding is defined as greater than 2 L blood loss within the first 24 postoperative hours.^{37,41} For

patients undergoing an elective general or orthopedic surgery, results from a meta-analysis of 52 randomized controlled trials (29 in general surgery and 23 in orthopedic surgery) including a total of 2658 patients in the placebo-control groups demonstrated that the rate of major bleeding was approximately 4%.⁴² This estimate of hemorrhagic complication is obtained from patients who did not receive any anticoagulant therapy and, therefore, can be regarded as a normal and baseline risk for major bleeding anticipated in any patient undergoing a general surgical procedure. A classification scheme of surgical bleeding risk related to the type of procedure is provided in Table 38-5.

Endoscopic Procedures

Among various elective gastrointestinal endoscopic procedures, diagnostic esophagogastroduodenoscopy (EGD), flexible sigmoidoscopy and colonoscopy with or without biopsy, diagnostic endoscopic retrograde cholangiopancreatography (ERCP), biliary stent insertion without endoscopic sphincterotomy, and endosonography (EUS), are categorized as low-risk procedures based on the 2002 guidelines on the management of anticoagulation and antiplatelet therapy for endoscopic procedures by the American Society for Gastrointestinal Endoscopy (ASGE).⁴³

Procedures with an increased bleeding risk include colonoscopic or gastric polypectomy,^{44,45} laser ablation and coagulation,^{46,47} endoscopic sphincterotomy,⁴⁸ and those procedures where bleeding is inaccessible or uncontrollable by endoscopic means such as pneumatic or bougie dilation of benign or malignant strictures and EUS-guided fine needle

Table 38-6 Hemorrhagic Risk Stratification for Endoscopic Procedures

aspiration.⁴³ Table 38-6 summarizes the list of high- and low-risk endoscopic procedures according to the ASGE.

Potential Benefits of Perioperative Anticoagulation

Patients with a Mechanical Prosthetic Heart Valve

The rationale for bridging anticoagulant therapy with unfractionated heparin (UFH) or low molecular weight heparin (LMWH) during the period when oral anticoagulation is temporarily discontinued is to shorten the time when the patient is at risk for thromboembolic events because of subtherapeutic anticoagulation.^{49–51}

Katholi and colleagues reported that there were no thromboembolic events among 25 patients with isolated aortic valve prostheses (Starr-Edwards Model 1200 and MaGovern) who received no perioperative anticoagulation before a procedure, compared with two fatal thromboembolic episodes in ten patients with mitral valve prostheses (Kay-Shiley disc, Starr-Edwards Model 6120 and MaGovern) (Table 38-7).⁵² In contrast, nine patients who underwent noncardiac surgery and continued warfarin therapy, with estimated INRs of 2.5 to 7.0, sustained three major hemorrhages requiring “unanticipated” transfusion support.⁵² Subsequently, a prospective cohort study was performed to evaluate the outcome of patients undergoing noncardiac procedures on two different perioperative anticoagulation protocols (45 procedures in 39 patients).⁵³ In patients with isolated mechanical aortic valves, warfarin was discontinued 3 to 5 days prior to the procedure without bridging anticoagulation. For patients with mitral valve prostheses, warfarin anticoagulation was rapidly reversed by parenteral vitamin K given within 24 hours prior to the surgery and intravenous UFH was initiated 12 hours preoperatively. There were no thromboembolic events in either patient group. However, there was one major bleeding event in a patient with a prosthetic mitral valve (see Table 38-7).

Table 38-7 Thromboembolic Events in Patients with Prosthetic Heart Valves Receiving Perioperative Anticoagulation with Unfractionated Heparin or Continued Warfarin

Author	Type of Study	No. of Patients (No. Procedures)	Valve Replaced ^a	Perioperative Therapy ^b	Thromboembolic Events	Bleeding Events

A, aortic valve prosthesis; M, mitral valve prosthesis; T, tricuspid valve prosthesis; and C, combined prostheses; IV, intravenous; UFH, unfractionated heparin.

^aThe numbers in parentheses refer to the number of procedures performed for the different types of valves. For the first three studies, most patients had Starr-Edwards prosthetic valves. Other valves included the Smeloff-Cutter mitral valve, MaGovern aortic and mitral valves, and the Braunwald-Cutter aortic and mitral valves. The type of valve replacement was not reported in the fourth study.

^bThe numbers in parentheses refer to the number of procedures performed using a particular strategy.

^cNone indicates that anticoagulation was simply discontinued for 3 to 5 days prior to surgery.

^dWarfarin anticoagulation was not discontinued for the surgical procedure.

^eThere were three major perioperative hemorrhages.

^f"Significant bleeding" was noted in one patient in the postoperative setting (no description of bleeding nature).

^gTwenty-three major operations (hysterectomy, 8; pulse generator change, 5; bowel resection, 4; cholecystectomy, 3; subtotal gastrectomy, 2; and craniotomy, 1). 22 Minor operations (biopsy or excision, 9; dental extraction, 5; arteriography, 4; mastectomy, 2; and hemorrhoidectomy, 2).

^hIntravenous unfractionated heparin (unspecified dose) starting 12 hours postoperatively.

ⁱMinor incisional hematoma; heparin was started early after operation (time of onset not specified).

^jOne patient with abdominal incisional hematoma and one patient with vaginal cuff bleeding, requiring blood transfusion.

^kAnticoagulation discontinued 1 to 3 days prior to surgery in 113 operations and 4 or more days in 42 operations.

^lThromboembolic complications occurred from 12 months to more than 2 years after the surgery.

^mIntraoperative difficulties with "hemostasis" were encountered in 24 patients; postoperative bleeding was "prominent" in 7 procedures; and hematomas occurred in 11 cases. Most of the bleeding complications were associated with an elevated prothrombin time at the time of surgery.

ⁿIV UFH started after discontinuation of warfarin and stopped 6 to 12 hrs before surgery.

^oFive bleeding complications; all required re-operation for control of bleeding or evacuation of hematoma.

Similar results were obtained by Tinker and Tarhan in a larger retrospective study. There were six episodes of thromboembolism among 159 patients with prosthetic heart valves undergoing 180 noncardiac operations in which anticoagulation was discontinued an average of 2.9 days preoperatively. The majority of patients had older generations of valve prostheses (Starr-Edwards) in the aortic position, but 36% of patients had mitral valve prostheses and 11% had multiple prostheses (see Table 38-7).⁵⁴

The advantages of perioperative heparin administration have also been described in a small study performed by Madura and colleagues who found no thromboembolic events in 17 patients with prosthetic valves undergoing major surgery. All of the patients received bridging UFH infusions while warfarin was withheld. Five patients (29%) had bleeding complications and required re-operation, however (see Table 38-7).⁴⁹

Carrel and colleagues examined three different approaches of perioperative anticoagulant therapy and outcomes in 235 patients with prosthetic heart valves who required noncardiac surgery. In this study, perioperative treatment included continuation of warfarin, or discontinuation of warfarin with and without intravenous or subcutaneous heparin administration.^{5,55} Overall, the incidence of hemorrhagic complications was 8% (18 of 235 patients)

and that of thromboembolic events was 7% (16 of 235 patients). Interpretation of the results was limited by inadequate follow up information and the questionable adequacy of perioperative anticoagulation.^{5,55}

Since the availability of LMWH, there has been increasing interest in examining the role of these agents in perioperative therapy when oral anticoagulation is discontinued. This option is appealing because LMWH offers a predictable anticoagulant effect and convenient route of drug administration that can be delivered in an outpatient setting. Traditional bridging anticoagulant therapy using intravenous UFH is more costly and labor intensive because it requires inpatient hospitalization for dose adjustment and laboratory monitoring.^{56,57}

Currently, there are several studies evaluating the efficacy of LMWH as bridging therapy in chronically anticoagulated patients who require an invasive procedure. In these studies, mechanical valve patients represent the majority of the study population (50% to 100%). All but one of the studies⁵⁸ are prospective. Results from these studies have suggested that LMWH appears to be at least as effective as UFH in the perioperative setting if the proper dose is used with overall low incidence rates of both thromboembolic events and major bleeding that are comparable with those seen with UFH.^{22,59} The summaries of

Table 38-8 Clinical Studies Using Low Molecular Weight Heparin as Perioperative Anticoagulation in Patients on Chronic Warfarin Anticoagulation

Ferreira et al ⁶⁶	Prospective cohort	82 (100%) ⁱ	Enoxaparin	1 mg/kg bid ^j	0	9 (11%) ^k
Douketis et al ⁵⁹	Prospective cohort	650 (33%)	Dalteparin	100 IU/kg bid	4 (0.6%) ^l	6 (0.9%) ^m

^aThe percentage in parentheses represents the percentage of patients with prosthetic heart valves of the total number of patients studied.

^bDalteparin dose was reduced to 100 IU/kg on the morning before surgery (maximum, 9000 IU).

^cSix of eight episodes of thromboembolism occurred in patients who had warfarin therapy deferred or withdrawn because of bleeding.

^dMajor hemorrhage (overt bleeding with a drop of hemoglobin >2 g/dL within a 24-hour period or transfusion of at least 2 units of blood; intracranial, intraspinal, intraocular, retroperitoneal, or pericardial bleeding; and fatal bleeding).

^ePostprocedure bleeding, all soft tissue bleeding (2 minor bleeding and 1 patient had a drop of Hb of 2 g/dL but did not require blood transfusion).

^fTwo major bleeds (rectus muscle sheath hematoma and bleeding at incision); 17 minor bleeding episodes.

^gDosage used depended on the patient's weight and the INR before starting the treatment.

^hMinor bleeding (hematuria and spotting after a cervical biopsy).

ⁱType of prosthesis: Sorin Bicarbon prosthesis (35%), Carbomedics (33%), Björk-Shiley (27%), Medtronic-Hall (4%), and Starr-Edwards (1%). Fifty-two percent of patients had prosthetic aortic valves.

^jEnoxaparin dose was adjusted to the lowest dose to obtain an anti-Xa level above 0.4 IU/mL in patients with creatinine ≥ 1.5 mg/dL (≥ 133 μ mol/L).

^kEight minor bleeding (only one patient required blood transfusion) and one major bleeding (intracranial bleeding).

^lMean follow up period = 13.8 days. Two deaths due to cardiac arrests possibly due to thromboembolism; one patient with stroke and one patient with TIA.

^mAll major bleeding events (nonfatal upper gastrointestinal tract bleeding, 4 wound hematomas, and a rectus abdominis sheath hematoma).

clinical studies using LMWH as a bridging anticoagulant therapy are shown in Table 38-8.^{58–66}

Patients with Atrial Fibrillation

In patients with chronic atrial fibrillation who are undergoing elective surgery, there are no clinical trials directly assessing perioperative anticoagulation therapy and patient outcome.¹⁶

Patients with Venous Thromboembolism

Patients with a history of acute venous thromboembolism within the preceding month who require temporary interruption of oral anticoagulation should receive preoperative and postoperative intravenous UFH because of an estimated 1% absolute increase in the risk of recurrence per day without anticoagulation and the extremely high incidence of postoperative thromboembolism.^{1,15} Postoperative intravenous UFH was felt to be justified despite doubling the rate of bleeding because of the net reduction in serious morbidity in these patients with perioperative anticoagulant therapy.¹ For patients who require an invasive procedure during the second and third months after an acute episode of venous thromboembolism, preoperative intravenous heparin is not suggested unless the patient has other risk factors for thromboembolism (e.g., hospitalization) because the risk of recurrent thromboembolic events is sufficiently

decreased. Nevertheless, postoperative administration of therapeutic doses of heparin is recommended owing to the expected 100-fold increase in the risk of developing venous thromboembolism after surgery.¹

Three months after the initial presentation of a venous thromboembolic event, preoperative anticoagulation is generally not warranted, and the use of postoperative therapeutic intravenous UFH is debatable. However, exceptions may be considered in patients who have significant residual clot burden, who have had multiple prior thrombotic events, who have had life-threatening events such as mesenteric or cerebral vein thrombosis, or who are not at increased risk of hemorrhage. There is also a role for alternative postoperative venous thromboembolic prophylaxis with subcutaneous low doses of UFH or LMWH in patients with a low risk of bleeding.^{1,67}

MANAGEMENT RECOMMENDATIONS

The following recommendations, divided into preoperative, perioperative, and postoperative settings, are based on previous study results and the Seventh American College of Chest Physicians Conference on Antithrombotic

and Thrombolytic Therapy.⁷ Nevertheless, it must be emphasized that there are guidelines and that the decision for perioperative and postoperative anticoagulation needs to be individualized and made on a case-by-case basis.

Preoperative Anticoagulation Management

Discontinuation of Warfarin Therapy

For procedures typically deemed to require a “normal” prothrombin time (INR < 1.2) at the time of surgery (i.e., for high-risk procedures listed in [Tables 38-5 and 38-6](#)), warfarin should be discontinued at least 3 to 4 days prior to the surgery (in patients with a target INR of 2.0 to 3.0) to allow the INR to return to normal or at least to a near normal range (INR = 1.2 to 1.4).^{68,69} Warfarin might be withheld for an extra 1 to 2 days in patients who are normally maintained at a higher target INR (above 3.0).^{1,5} Caution should be made in elderly patients who sometimes may require a longer time for the INR to normalize after warfarin is stopped.^{5,68} The prothrombin time/INR can be tested on the day prior to the surgery to ensure that it has fallen into the desired target range that is assumed to be safe to perform the procedure. Other investigators also suggest checking the INR on the day warfarin therapy is stopped.⁵

For patients with a low risk of bleeding who are undergoing a low bleeding risk procedure ([Tables 38-5 and 38-6](#)), oral anticoagulation may be continued at the regular dose with no adjustments. An alternative strategy would be to slightly decrease the dose for several days prior to the procedure, to obtain a lower INR (although not a normal prothrombin time) at the time of the procedure.

Reversal of Oral Anticoagulation

If the INR is greater than 1.5 on the day before surgery, administration of low-dose oral vitamin K (2.5 mg) or intravenous vitamin K (e.g., 1.5 mg administered over 60 minutes) will likely normalize the INR without causing a delay in time to therapeutic oral anticoagulation when warfarin is resumed after surgery.^{5,16} Intravenous vitamin K is reserved by some clinicians for patients with malabsorption who require an urgent procedure, and large doses should be avoided as they have been reported to cause anaphylactoid reactions.^{16,70} Another alternative is to give a small dose of vitamin K (1 mg) subcutaneously, although this route of administration may result in erratic absorption.⁷⁰ In patients who need rapid reversal of oral anticoagulation owing to the need for urgent surgery, fresh frozen plasma (FFP) transfusion may be required. The required volume of transfused FFP can be calculated by estimating the plasma volume (plasma volume [in mL] is approximately $40 \times$ body weight [in kg]) and determining the target net increase in plasma coagulant factor activity.¹⁶ In general, average-sized individuals will require approximately 15 or 16 mL/kg of FFP (containing 100% activity of factor II) to significantly reverse a therapeutic INR.¹⁶ The major limitation of FFP therapy is the risk of transfusion-related infection and intravascular volume overload. In addition, concomitant vitamin K therapy is required owing to the short half-life of factor VII in plasma (4 to 6 hours). An alternative for patients at risk of volume overload is prothrombin complex concentrate infusion; current preparations carry a low

risk for thrombotic complications and very low incidence of transfusion-related infections.

Discontinuation of Antiplatelet Therapy

The risk of bleeding complications associated with antiplatelet therapy was recently reported by Serebruany and colleagues in a meta-analysis involving 338,191 patients who were receiving antiplatelet agents.⁷¹ In this meta-analysis, the majority of patients had sustained acute coronary syndromes with 40% of the eligible studies involving percutaneous coronary interventions. Low-dose aspirin (<100 mg) and dipyridamole resulted in the lowest hemorrhagic complications with total bleeding rates of 3.6% and 6.7%, respectively.⁷¹ The majority of these studies used the Thrombolysis in Myocardial Infarction (TIMI) study group criteria, with the total bleeding risk including major, minor, gastrointestinal bleeding, and stroke.⁷¹ A relatively increased risk of bleeding (9.1% to 9.9%) was found to be associated with a higher dose of aspirin (≥ 100 mg), which was comparable with the risk observed in patients taking clopidogrel (8.5%). However, the incidence of hemorrhagic complications was highest among patients receiving intravenous and oral platelet surface glycoprotein IIb/IIIa inhibitors, with total bleeding rates of 49% and 44.6%, respectively.⁷¹

Controversy remains as to whether it is necessary to withhold antiplatelet therapy prior to the surgery, and, if so, when would be the optimal time to discontinue therapy. Theoretically, it would be prudent to discontinue aspirin and other antiplatelet agents at least 7 days prior to the procedure, given that aspirin, ticlopidine and clopidogrel irreversibly inhibit platelet function.^{72,73} Nevertheless, clinical evidence supporting this common practice is sparse, and most of the data are from patients undergoing high bleeding risk procedures, such as cardiothoracic surgery. Furthermore, recent demonstration of considerable recovery of platelet function as early as 3 days after discontinuation of aspirin in cardiac surgery patients raises the question of whether early cessation of aspirin (>7 days before surgery) is necessary.⁷⁴ Data on this topic for other types of surgery are either limited or unavailable. Therefore, clinicians need to individualize their recommendations based on the consideration of risk:benefit ratio involved in the specific type of procedure and the patient's indication for antiplatelet therapy.

Earlier data from a number of studies, including prospective controlled trials, indicate that preoperative aspirin use (usually ≥ 75 mg/day, within 2 days before surgery) in patients undergoing coronary artery bypass graft surgery is associated with increased blood loss, transfusion requirements, and re-exploration for bleeding.^{75–82} Recent evidence, however, suggests that preoperative aspirin within 5 to 7 days before surgery appears to be safe without a significant increase in adverse postoperative hemorrhagic complications.^{83–88} On the contrary, the combination of clopidogrel and aspirin prior to bypass surgery has been shown to increase the risk of postoperative bleeding, particularly if higher doses of aspirin are used (200 to 325 mg/day).^{89–92} To avoid excessive postoperative bleeding and transfusion, the American College of Cardiology/American Heart Association (ACC/AHA) task force has recommended cessation of aspirin and other antiplatelet inhibitors (excluding clopidogrel) 7 to 10 days prior to

elective cardiac operation in certain clinical settings such as chronic stable angina and low-risk plaque morphology.⁹³ For clopidogrel, the ACC/AHA recommended that this medication be discontinued at least 5 days prior to elective bypass surgery.⁹³

Despite the paucity of evidence, several published reports suggest that certain elective interventions may be performed safely on patients who are at low bleeding risk who are taking aspirin and/or other NSAIDs in standard doses without significant increases in the risk of hemorrhage.⁴³ These include EGD with biopsy, colonoscopy with biopsy, polypectomy, biliary sphincterotomy, and transbronchial biopsy.^{48,94–96} In addition, several controlled studies demonstrated that there was no increase in severe bleeding complications in patients undergoing cutaneous surgery regardless of the continuation of aspirin and NSAIDs prior to the procedures (excluding procedures that involved deep tissue resection or dissection).^{36,97–100} Therefore, it may be reasonable to continue aspirin in a low bleeding risk patient requiring antiplatelet therapy for a medically necessary reason (e.g., history of stroke, TIA, or coronary artery disease) who is scheduled for an elective procedure as mentioned earlier.

Perioperative Anticoagulation Management

Patients should be categorized into high-, intermediate-, or low-risk groups based on both personal and procedural thromboembolic and bleeding risks (see [Tables 38–4 to 38–6](#)).^{5,16,101} For patients at high risk for thromboembolism, a therapeutic dose of UFH or LMWH should start within ~ 2 days after warfarin is stopped.^{5,7} UFH can be given as a continuous intravenous infusion as an inpatient or as a subcutaneous injection as an outpatient. If continuous intravenous UFH is used, the drug should be titrated to achieve a targeted partial thromboplastin time (PTT) that correlates with therapeutic heparin levels (0.3 to 0.7 IU/mL by factor Xa inhibition).¹⁰² Intravenous UFH is usually discontinued approximately 5 to 6 hours before surgery with the expectation that the anticoagulant effect (half-life about 1 hour) will have worn off at the time of surgery (providing that the PTT is not supratherapeutic at the time the anticoagulant therapy is stopped).^{1,7,21} For patients taking therapeutic subcutaneous UFH, the last injection should be given 12 to 24 hours before surgery.⁷

Currently, there are several regimens for LMWH bridging therapy as listed in [Table 38–9](#).¹⁶ If once-daily LMWH (half-life about 5 to 6 hours) is used, it should be administered in the mornings, with the last dose given on the day prior to surgery (i.e., 24 hours before surgery).⁵ An alternative strategy for once daily dosing regimen would be to reduce the last dose by 50%.¹⁶ With either regimen (once-daily or twice-daily), LMWH therapy should be stopped 12 to 24 hours (or 20 to 24 hours) before surgery.^{5,7} Importantly, in patients with renal insufficiency, LMWH therapy may need to be stopped more than 24 hours before surgery to allow for prolonged clearance of the drug.

In patients with a moderate risk of thromboembolism (see [Table 38–4](#)) undergoing a moderate or high bleeding risk procedure, a low dose of UFH (5000 units subcutaneous) or a prophylactic dose of LMWH can be given beginning approximately two days preoperatively after warfarin is discontinued.⁷ Some investigators would recommend

Table 38-9 Perioperative Anticoagulant Regimens for Therapeutic Range Low Molecular Weight Heparin (LMWH)

LMWH	Dose	Time of Last Dose*
Enoxaparin sodium (Lovenox)	1 mg/kg SC q 12 hours, or 1.5 mg/kg SC qd	12–24 hours
Dalteparin sodium (Fragmin)	100 anti-Xa IU/kg SC q 12 hours, or 200 anti-Xa IU/kg SC qd	24 hours
Tinzaparin sodium (Innohep)	175 anti-Xa IU/kg SC qd	24 hours
Ardeparin sodium (Normiflo)	130 anti-Xa IU/kg SC q 12 hours	12–24 hours

*Time to last dose given prior to surgery.
SC, subcutaneously.

a higher dose of UFH or a full dose of LMWH in this setting depending on the clinical situation.⁷ For patients with low risk of thromboembolism, preoperative bridging anticoagulant therapy with full dose UFH or LMWH is generally not necessary.^{1,5,7,16,101}

Role of Prophylactic Inferior Vena Cava Filter Placement

Prophylactic inferior vena cava (IVC) filter placement may be considered for patients who are at extremely high risk for recurrent venous thromboembolic disease, for instance, patients who have had an acute episode of pulmonary embolism or extensive proximal deep-vein thrombosis and who have received anticoagulant therapy for less than two weeks after the onset of the thromboembolic events. In addition, prophylactic IVC filter placement may be considered in patients who have a history of pulmonary embolism with limited cardiopulmonary reserve to tolerate another embolic insult, or in the very rare patient in whom anticoagulant therapy is contraindicated.^{1,103} Such patients usually include neurosurgical patients operated on within a few days of a new thromboembolic event, or central nervous system bleeds only a few days old.

Because of the concerns about the possible long-term complications associated with permanent IVC filter placement (e.g., deep venous thrombosis [DVT] and IVC thrombosis at the insertion site),^{104–106} retrievable IVC filters have been developed to provide an alternative to a permanent IVC filter for patients who require only short-term protection against pulmonary emboli while anticoagulant therapy is interrupted. These IVC filters are safe and effective in the prevention of pulmonary emboli.^{107–109} Although there is no available clinical study dedicated to prospectively examining the role of prophylactic retrievable IVC filter in patients receiving chronic anticoagulation who undergo temporary disruption of anticoagulant therapy, previous studies have included subsets of patients with DVT and/or pulmonary embolism in whom anticoagulants were judged to be contraindicated due to planned surgeries.^{107–109} Thus, this type of IVC filter would be ideal for use in the perioperative setting. See Chapter 31 for further discussion.

In patients who are receiving preoperative intravenous UFH, it is stated that anticoagulation should be discontinued at least 3 hours prior to filter insertion and restarted as soon as possible after insertion.¹⁰⁷ Whereas this might be correct, it is yet to be proved; some patients may choose this interval to thrombose again.

Postoperative Anticoagulation Management

Resumption of UFH or LMWH

In general, adequate postoperative hemostasis is usually achieved by 24 to 48 hours after surgical closure in patients who undergo intra-abdominal, intrathoracic, or orthopedic surgery.⁵ However, patients who undergo surgical procedure for infection or malignancy may continue to have an increased risk of bleeding because of the difficulty to control bleeding or oozing from raw surfaces.¹⁶

If there is evidence of ongoing blood loss in the postoperative setting, postoperative anticoagulation should be withheld until the bleeding has subsided. On the contrary, if there is adequate postoperative hemostasis, the decision to resume full-dose anticoagulant therapy may be influenced by the risk of bleeding associated with the specific operation. For instance, in patients undergoing high bleeding risk procedures (see [Tables 38-5 and 38-6](#)), the resumption of therapeutic anticoagulation with LMWH should be deferred for 24 to 48 hours after surgery. However, in select types of surgery, for example neurosurgery and certain orthopedic procedure (e.g., total hip replacement), for which postoperative bleeding associated with anticoagulation can lead to devastating complications,¹⁶ the decision to resume therapeutic dose of LMWH may be delayed to 48 to 72 hours after surgery even with adequate postoperative hemostasis and may not be given at all if there is concern for ongoing bleeding. If the bleeding risk in the postoperative setting is significant, the initial dose of LMWH could be started at a prophylactic dose beginning on the first or second day after surgery.

In patients undergoing moderate bleeding risk procedures, prophylactic dose of LMWH can usually be resumed on the evening after surgery (12 hours) and can be increased subsequently to therapeutic dose, starting 24 to 48 hours after surgery, if the patient tolerates the prophylactic treatment well without bleeding complications.⁵

If UFH is used for bridging anticoagulant therapy, the treatment can usually be resumed 12 to 24 hours after surgery when there is evidence of adequate hemostasis.^{5,110} To minimize the risk of postoperative bleeding, it is recommended that UFH be started without a bolus, at no more than the expected maintenance infusion rate.^{1,111} The PTT should be checked 12 hours after restarting therapy to allow time for a stable anticoagulant response.¹ Alternatively, UFH may be given subcutaneously as twice-daily injections.¹¹² This approach requires daily, mid-interval PTT testing to be performed to monitor the anticoagulant effect and adjust the dose as necessary. If patients develop hemorrhagic complications while receiving UFH, protamine sulfate can be given to reverse the anticoagulant effect.

Resumption of Postoperative Oral Anticoagulation

Warfarin therapy can be restarted the evening after surgery (same day) in the majority of patients, provided that there is no evidence of ongoing bleeding and adequate hemostasis has been achieved. The warfarin dose corresponding to the patient's usual dose on that day of the week can be used as an initial dose⁵ and INR monitoring should be initiated after the first two or three doses of warfarin therapy.⁷ If the patient had received a higher dose of vitamin K (e.g., 5 to 10 mg) in the preoperative setting, it has been suggested to increase the patient's warfarin dose (e.g., doubling) for two consecutive days after surgery, although there are no data supporting this recommendation.⁵ Alternatively in this setting, one could manage the patient on LMWH after surgery as needed before attempting to convert back to warfarin.

Discontinuation of UFH or LMWH Postoperative Bridging Therapy

UFH and LMWH should be continued postoperatively until the INR has been in the therapeutic range for at least two consecutive days.^{5,7}

Management of Specialized Clinical Settings

Patients with Spinal Anesthesia or Continuous Epidural Analgesia

Epidural hematoma is a rare but devastating complication in patients receiving anticoagulant therapy undergoing spinal anesthesia.^{113,114} In patients who have non-traumatic placement of an epidural catheter followed by immediate removal after surgery, anticoagulant therapy may be resumed 12 hours after the operation. However, the resumption of postoperative anticoagulation should be postponed to at least 24 hours after surgery if there is history of trauma ("bloody tap") associated with epidural catheter placement. For patients who have an indwelling epidural catheter for analgesic administration, it has been recommended that anticoagulation should be withheld until the epidural catheter is removed.⁵ Nevertheless, there are certain criteria that allow co-administration of LMWH and continuous epidural analgesia: (1) epidural catheter placement was non-traumatic; (2) low-dose LMWH is used (enoxaparin 30 mg twice-daily or dalteparin 5000 IU once-daily)¹¹⁵; (3) warfarin is not started until after the epidural catheter is removed; (4) the epidural catheter is removed during the trough anticoagulant effect of LMWH (i.e., 18 to 22 hours after the last dose, for daily dosing); and (5) antiplatelet therapy (e.g. aspirin or NSAIDs) is avoided until the removal of the epidural catheter.^{5,115–117}

Patients with Renal Insufficiency

Nearly all of the clinical studies evaluating the role of LMWH as perioperative bridging anticoagulant therapy have excluded patients with renal insufficiency, defined by estimated creatinine clearance less than 30 mL/minute⁶¹; or serum creatinine greater than 1.4 mg/dL⁶⁵ or 2.0 mg/dL.⁵⁹ This is due to the fact that LMWH is primarily excreted by the kidney and significant bioaccumulation of these drugs can occur in patients with impaired renal function. In actual clinical practice, these patients are commonly

encountered. In this regard, LMWH should be avoided in patients with severe renal insufficiency, and UFH would be the anticoagulant of choice.¹⁰² If LMWH is used in this setting, an anti-factor Xa level should be measured to monitor the anticoagulant effect of LMWH. The level should be obtained four hours after the LMWH dose, with a targeted anti-factor Xa level of about 0.3–0.5 up to 1.0–1.2 u/mL (for twice daily dosing) if the intent is therapeutic dosing; prophylactic dosing would have a lower target range of about 0.1–0.3 µ/mL.¹⁰² These patients will likely also require a longer time to eliminate the LMWH in the preoperative setting.

Patients with History of Heparin-Induced Thrombocytopenia

UFH and LMWH are typically avoided in patients with a history of heparin-induced thrombocytopenia (HIT). In this setting, perioperative or postoperative anticoagulant therapy can be attained by one of the following drugs: danaparoid sodium, lepirudin, or argatroban. (Of note, danaparoid sodium is no longer available in the United States). Clinicians must keep in mind that these anticoagulants are not reversible and caution must be used in patients undergoing high bleeding risk procedures. For patients with acute HIT, warfarin should be given when patients are adequately anticoagulated with a drug that reduces thrombin generation in HIT, such as lepirudin, argatroban, or danaparoid sodium because of the risk of causing venous limb gangrene if warfarin is used alone.¹⁰² The role of pentasaccharide therapy in this situation appears to be very promising.

Patients with Particularly High Thromboembolic Risk

Recently, Larson and colleagues have shown that continuation of dose-reduced oral anticoagulation is feasible in patients with high thromboembolic risks (e.g., history of DVT within the past 6 months, prior postoperative DVT or pulmonary embolism, inherited thrombophilia, and antiphospholipid syndrome), who require an invasive procedure.¹¹⁸ In this noncontrolled retrospective study, preoperative warfarin was continued and adjusted to maintain the target INR of 1.5 to 2.0. Heparin (LMWH or UFH) was given as a supplement only if the INR dropped below 1.5 and baseline warfarin dose was resumed on the evening of surgery. Among the 99 operations stratified by the Johns Hopkins Medical Institutions Surgical Classification System¹¹⁹ (moderate risk 47%; major risk 10%; and critical risk 1%),^{118,119} there were only two thromboembolic events (one symptomatic DVT and one fatal embolic stroke). The incidence of major and minor hemorrhagic complications was 2% and 4%, respectively, but nearly one half of the studied patients underwent low bleeding risk procedures. Despite several limitations of this study, it has demonstrated the feasibility of moderate intensity warfarin (INR 1.5 to 2.0) in the perioperative setting for patients at a particularly high-risk for thromboembolism.

Hemostatic Alterations in Liver Disease and Liver Transplantation

Marco Senzolo, MD • Andrew K. Burroughs, MD

The liver plays key roles in blood coagulation being involved in both primary and secondary hemostasis.¹ It is the site of synthesis of all coagulation factors, except for von Willebrand factor (VWF), and their inhibitors.² Liver damage is commonly associated with impairment of coagulation when liver function reserve is poor. The hemostatic system is in a delicate balance between prothrombotic and antithrombotic processes, aiming to prevent excessive blood loss from injured vessels and to prevent spontaneous thrombosis. Liver failure is accompanied by multiple changes in the hemostatic system because of reduced plasma levels of pro-coagulative and anti-coagulative clotting proteins synthesized by the intact liver.³ Vitamin K deficiency may coexist, so that abnormal clotting factors are produced. Moreover, during liver failure, there is a reduced capacity to clear activated hemostatic proteins and protein inhibitor complexes from the circulation. Thus the global effect of liver disease with regard to hemostasis is complex, so that patients with advanced liver disease can experience severe bleeding or even thrombotic complications (Table 39-1). Finally, when marked portal hypertension develops with collateral circulation and secondary splenomegaly, thrombocytopenia develops due to splenic sequestration, but thrombocytopenia may also be due to decreased hepatic thrombopoietin synthesis. There is also impaired platelet function. These hemostatic abnormalities do not always lead to spontaneous bleeding, but the onset of complications of cirrhosis such as variceal bleeding or infection/sepsis may precipitate worsening of coagulation status. The presence of a consumptive coagulopathy, other than secondary to sepsis or other predisposing causes, is disputed.

Usually therapy for coagulation disorders in liver disease is needed only during bleeding or before invasive procedures. When end-stage liver disease occurs, liver transplantation is the only treatment available that can restore normal hemostasis and correct genetic defects, such as hemophilia or factor V Leiden mutation. During liver transplantation, hemorrhage may occur due to the preexisting hypocoagulable state, the collateral circulation caused by portal hypertension, and increased fibrinolysis which occurs during this surgery.

HEMOSTATIC FACTORS

Procoagulant Factors

The liver is the site of synthesis of fibrinogen and factors II, V, VII, IX, X, XI, XII, and XIII.⁴ VWF is synthesized by the

endothelium.⁵ Factor VIII is synthesized mainly by the hepatic sinusoidal endothelial cells,^{6,7} but also by endothelial and non-parenchymal cells in the kidney, spleen, lungs, and brain.⁸ Thus, the plasma concentration of factor VIII is not decreased with liver disease, and may be increased, as many chronic liver diseases are associated with chronic inflammation.⁹ This occurs because of increased endothelial synthesis or a reduced clearance via low-density lipoprotein receptor-related protein, which is synthesized by the liver.⁵ However, the biologic activity of the synthesized molecule is lower than the plasma concentration.¹⁰ Factor VIII is high in fulminant hepatic failure and low in disseminated intravascular coagulation (DIC)¹¹ but this differential diagnosis is seldom an issue in clinical practice.

Vitamin K is an essential cofactor for the production of biologically active forms of the coagulation factors II, VII, IX, and X. It promotes hepatic post-ribosomal conversion of certain glutamic acid residues in the protein precursors to γ -carboxyglutamic acid (Gla). These active forms of the clotting factors chelate calcium at the Gla site, resulting in effective hemostatic function. When γ -carboxylation is impaired due to deficiency or antagonism of vitamin K, inert precursors are synthesized, (known as Proteins Induced by Vitamin K Absence [PIVKA]) and released into the bloodstream.¹² The clinical significance of these precursors is not clear. In the case of prothrombin, a specific and sensitive immunoassay has been developed which is able to detect small decreases in Gla content of this incomplete PIVKA prothrombin before any changes occur in conventional coagulation tests.¹³ In cholestasis, reduction of vitamin K absorption from the small intestine due to decreased bile salt production can be compensated with parenteral administration of vitamin K 10 mg daily for 24 to 48 hours; but in parenchymal liver disease, decreased levels of coagulation factors are dependent on a decreased synthesis—so there is no improvement with vitamin K administration.¹⁴ Nevertheless, 25% of patients with acute liver injury have a subclinical deficit of vitamin K which may benefit from parenteral administration with corresponding improvement of the International Normalized Ratio (INR).¹⁵

In acute liver failure, the first factors in which plasma concentrations fall are those with the shortest half-lives, factors V and VII (12 hours and 4 to 6 hours, respectively), and levels of factors II, VII, and X will subsequently fall.¹⁶ Factor VIII, together with VWF, is usually elevated, whereas

Table 39-1 Hemostatic Alterations Associated with Liver Disease

Favoring Hemorrhage	Favoring Thrombosis
Low platelet count Impaired platelet function and platelet-vessel wall interaction Enhanced platelet inhibition by nitric oxide (NO) and prostacyclin Decreased levels of coagulation factors (II, V, VII, IX, X, and XI) Quantitative and qualitative abnormalities of fibrinogen Low level of α_2 -plasmin inhibitor, TAFI, histidine-rich glycoprotein Increased levels of tPA, with small increase of PAI-1 levels	Elevated levels of factors VIII and VWF Decreased levels of protein C, protein S, antithrombin III, α_2 macroglobulin Heparin cofactor II elevated Decreased levels of plasminogen

TAFI, thrombin activatable fibrinolytic inhibitor.

there is only a slight reduction of factors IX and X. The differential effects on clotting factors levels during acute liver failure occur because high levels of cytokines increase levels of tissue factor (TF) which activate factors II, V, VII, and X, whereas any thrombin generated is inhibited by antithrombin III, preventing activation of factors VIII, XI, and consequently XI, thus preserving their plasma levels.⁹

Higher plasma des- γ -carboxy (PIVKA) prothrombin concentrations are found in patients with hepatocellular carcinoma due to a local production by tumor cells. This abnormal prothrombin is believed to be a growth factor for this tumor and to be associated with a poor prognosis.¹⁷

Prothrombin gene mutation (20210) is the most common thrombophilic defect in patients with portal vein thrombosis without cirrhosis (extrahepatic portal hypertension), accounting for 22% of cases,¹⁸ whereas, factor V Leiden mutation is the most common hereditary thrombophilic disorder associated with 20% of cases of hepatic vein thrombosis in Western countries,¹⁹ and, less commonly, is encountered in patients with portal vein thrombosis.²⁰

von Willebrand Factor

Plasma concentration of VWF is substantially increased in patients with acute liver failure owing to its increased synthesis as an acute phase reactant protein in response to tissue injury.^{21–23} With liver injury this may also be secondary to endotoxemia associated with endothelial dysfunction.⁵ In chronic liver disease, endothelial shear stress related to portal hypertension may also contribute to the high plasma levels of VWF via a nitric oxide (NO) stimulus.²⁴ A correlation between severity of liver disease and VWF plasma antigen levels has been documented. Unfortunately, studies on the function of VWF in patients with liver cirrhosis are conflicting with regard to normal⁵ or reduced²² platelet aggregation in response to ristocetin.

Fibrinogen

Plasma fibrinogen is an acute-phase reactant, and it remains normal or increased in patients with liver disease.²⁵ Lower levels due to decreased synthesis, yet above 100 mg/dL, have been reported only in patients with extremely severe liver disease.²⁶ However, the high fibrinogen concentrations found in patients with chronic

hepatitis, cholestatic jaundice, and hepatocellular carcinoma do not result in increased ability to clot because this synthesized form is a nonfunctional dysfibrinogen. About 60% to 70% of patients with liver disease have this dysfibrinogen due to an increased activity of sialyltransferase expressed by immature hepatocytes generated during hepatic injury. This leads to a low molecular weight fibrinogen with abnormal α chains and higher sialic acid content.²⁷ Clinically, this results in an abnormal thrombin time (TT), despite almost normal PT and PTT, with an apparent normal concentration of total clottable fibrinogen. This abnormality is reversed following recovery of liver function.²⁸

Platelets

Abnormalities in both number and function of platelets are common in patients with liver disease and contribute to the impaired hemostasis seen in these patients. About one third of patients with chronic liver disease develop thrombocytopenia, which is usually mild to moderate (70,000–90,000/ μ L), and worsens parallel to disease progression with associated increased hypersplenism, which furthers platelet sequestration.^{29–31}

Thrombocytopenia has not been associated with an increased risk of bleeding from esophageal varices (i.e., structural bleeding) or other sources, although there are only a few studies evaluating this, but it has been shown to be correlated with blood loss during surgery (i.e., hemostatic bleeding).³² A higher spleen diameter/platelet count ratio has been shown to have a high predictive value for the presence of esophageal varices in patients with liver cirrhosis.³³

The issue of sequestration versus other causes of thrombocytopenia in cirrhosis has been evaluated recently by comparing platelet number in extrahepatic portal hypertension, with that of cirrhotics having a similar-sized spleen. This has shown a less severe thrombocytopenia in the non-cirrhotic patient.³⁴ Synthetic function of the liver is essential for platelet production via thrombopoietin (TPO), which regulates platelet production in the bone marrow.³⁵ Although TPO is increased in patients with thrombocytopenia owing to a homeostatic response,³⁶ this occurs to a lesser degree with severe or chronic liver diseases than in those subjects with a normal liver.³⁷ Lower TPO mRNA levels in cirrhotic liver tissue³⁸ have been shown, confirming impaired TPO synthesis. In addition,

a low platelet production from the bone marrow in cirrhotic patients has been shown.³⁹

Hepatitis C virus (HCV),⁴⁰ acute viral infection, alcohol abuse, and folate deficiency can all result in some myelosuppression⁴¹—further lowering platelet counts. Consumption coagulopathy is not common in cirrhosis and even if DIC is present at a chronic low level, it does not influence platelet count.^{42,43} Thrombocytopenia may also be contributed to by immune-mediated mechanisms owing to an increased production from B cells of antibodies binding platelet surface antigen GPIIb/IIIa and GPIb/I, which has been shown in viral-induced cirrhosis B and C⁴⁴ and cholestatic liver diseases (primary biliary cirrhosis [PBC] and primary sclerosing cholangitis [PSC]).⁴⁵ Among 368 patients with viral-induced cirrhosis, elevated titers of platelet-associated immunoglobulin G were observed in 88% with HCV and 47% with HBV.⁴⁰

Platelet function, as well as decreased platelet number, is impaired in patients with liver disease. Platelet aggregation in response to ADP, arachidonic acid, collagen, and thrombin is subnormal, probably owing to a defective signal transduction mechanism.⁴⁶ Intrinsic defects⁴⁷ and abnormal plasma factors⁴⁸ have also been shown to contribute to platelet function abnormalities. An abnormal content of arachidonic acid in platelet membranes is found in liver disease and induces less aggregation ability mediated by thromboxane A₂.⁴⁹ In plasma from cirrhotic patients, the presence of an abnormal high density lipoprotein (HDL) level may alter NO content in the cell, leading to abnormal aggregability.⁵⁰ Cholestatic liver diseases, which can demonstrate a normal or hypercoagulable state by thromboelastography,⁵¹ have normal or hyperactive platelet function when assessed by platelet function assay (PFA-100) closure time and flow cytometry of receptors.⁵² When the platelet number is too low, both cytometry or aggregation studies may be difficult to interpret; thromboelastography, which is a global test of clot formation and dissolution, measures both platelet function and number by maximum amplitude (ma) parameter,⁵³ and can be used to assess platelet function.

Splenectomy is generally contraindicated in patients with liver cirrhosis because of the high mortality rate and a risk of secondary portal vein thrombosis, leading to increased risk of bleeding from esophageal-gastric varices and more difficult surgery during subsequent liver transplantation.⁵⁴ Splenic embolization with 30% to 50% reduction in flow can normalize or significantly improve platelet number in some patients with liver cirrhosis⁵⁵ and may be helpful if invasive procedures, such as embolization of hepatocellular carcinoma or interferon therapy for viral hepatitis are required. Insertion of a transjugular intrahepatic portosystemic shunt (TIPS) has been shown to increase, but not to normalize, platelet number.^{56,57}

ANTICOAGULANT FACTORS

Antithrombin III

Antithrombin III (ATIII) is a non-vitamin K-dependent glycoprotein synthesized by the liver but also by the endothelium.⁵⁸ It has low concentration in patients with liver disease, probably because of reduced synthesis and/or

increased consumption due to hyperfibrinolysis.⁵⁹ Usually the ATIII deficit is mild and thrombosis as a complication is very rare, reported only sporadically.⁶⁰ ATIII replacement does not correct hyperfibrinolysis in patients with liver cirrhosis.

Protein C and Protein S

Proteins C and S are vitamin K-dependent glycoproteins synthesized mainly by hepatocytes.⁶¹ Therefore, during acute or chronic liver disease, their concentrations can be decreased concomitantly with the other coagulation factors, but usually not below 20% of normal values.⁶² Genetic deficiency of protein C is rare in the general population, but is found in 20% of patients with Budd-Chiari syndrome (BCS). In patients with liver disease who also have genetic deficiency, plasma concentration is often lower than 20%. When there is severe liver disease, it can be difficult to exclude coexistent genetic deficiency because levels may be very low owing to very depressed synthesis.¹⁹ In this situation, a concomitant finding of a normal level of factor II and protein C/factor VII ratio, can help to confirm a coexistent genetic deficit.⁶³ In acquired deficiency of vitamin K, a defective protein C lacking γ -carboxyl (PIVKA) is produced.¹ Protein C deficiency is not associated with extrahepatic portal vein thrombosis.⁶⁴ Genetic deficiency of protein S is rare, yet it accounts for as many as 7% of patients with BCS or portal vein thrombosis (PVT), especially in Asians.⁶⁵

DISORDERS OF THE FIBRINOLYTIC SYSTEM

All the proteins involved in fibrinolysis, except for tPA and PAI-1 are synthesized in the liver, and reduced plasma levels of plasminogen,⁶⁶ α_2 -plasmin inhibitor, histidine-rich glycoprotein (HRG),⁶⁷ factor XIII,⁶⁸ and thrombin activatable fibrinolytic inhibitor (TAFI)⁶⁶ are documented in patients with liver cirrhosis. Conversely, tPA levels are increased in liver disease owing to decreased clearance, whereas its inhibitor, PAI-1, is normal or only slightly increased in plasma. The inhibitor concentrations are insufficient to counteract the increase in tPA accounting for increased fibrinolysis.⁶⁹ In contrast, in patients with acute liver failure, there are high levels of the acute phase reactant PAI-1 leading to a shift toward hypofibrinolysis.⁷⁰

Hyperfibrinolysis is correlated with the severity of liver dysfunction in cirrhosis as assessed by Child-Pugh score.⁷¹ Ascitic fluid has increased fibrinolytic activity: up to 20 liters are reabsorbed daily, with fibrinolysis being correlated with endotoxin levels.⁷² Increased levels of D-dimers, prothrombin fragments 1+2 (F1+2) fibrin degradation products, and plasmin: α_2 -plasmin inhibitor complexes are found.⁷³ Many studies using different methodologies demonstrate hyperfibrinolysis (thromboelastography,⁷⁴ diluted whole blood clot lysis assay,⁷⁵ and euglobin clot lysis time.⁷⁶ Recently, TAFI has been evaluated: it is decreased by an average of 26% in cirrhosis and by 50% in acute liver failure.^{77,78} However, there is some controversy regarding hyperfibrinolytic activity in cirrhotic patients because not all studies have confirmed this. This may be

due to the particular *in vitro* assay used. In contrast, *in vivo* correlation between hyperfibrinolysis and an increased risk of variceal bleeding, compatible with the circadian rhythm of the daily hyperfibrinolytic activity has been shown.⁷⁹ In addition, increased fibrinolytic activity during liver transplantation and hepatic resection correlates with blood loss.⁸⁰

Interestingly, patients with cholestatic liver disease are characterized by a normal or hypercoagulable state: higher PAI-1 concentrations are seen compared with other etiologies, balancing the increased tPA activity. This results in less hyperfibrinolysis in the reperfusion phase during liver transplantation, and antifibrinolytic therapy is not usually administered.⁸¹ Thus, the clinical issue is whether cirrhotic patients when under “stress” (e.g., during infection, during surgery, or during bleeding) exhibit the increased fibrinolysis, resulting in an increased bleeding tendency, which is not manifest in laboratory terms when patients are stable.

Disseminated Intravascular Coagulation and Accelerated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is characterized by intravascular fibrin deposition due to activation of the clotting cascade, which overwhelms the anticoagulation pathway. Secondary to the activation of the coagulation pathway, consumption of coagulation factors and platelets begins and secondary fibrinolysis occurs, causing a net increased bleeding tendency.⁸²

Low-grade DIC and the hemostatic abnormalities that are present in cirrhotic patients share common laboratory features—a prolonged PT and PTT, low fibrinogen level, elevated fibrin-degradation product and D-dimer, and thrombocytopenia get confused with DIC.^{83–85} Thus, diagnosis by laboratory means alone may be confounding. Early reports linked chronic liver disease to low-grade DIC, ascribing the latter to accelerated fibrinolysis. However, the presence of DIC in liver cirrhosis is disputed (see Chapter 12).⁸⁶ Although DIC-like laboratory abnormalities (so called “pseudo-DIC”) are observed, autopsy studies in cirrhotics have shown little evidence for fibrin deposition and clinically evident DIC is rare.⁸³

More highly sensitive tests, quantifying proteolytic cleavage products of the coagulation reaction—that is, fibrinopeptide A, F1+2, and fibrinolysis reactions (fibrin D-dimer, high molecular weight fibrin/fibrinogen complexes, or soluble fibrin), demonstrate an abnormal profile called accelerated intravascular coagulation and fibrinolysis phenomenon (AICF).⁸⁶ The studies demonstrate AICF in about 30% of cirrhotics, depending on the severity of liver disease; in two studies, this correlated with a decrease in levels of ATIII, protein C, and protein S.⁷⁴

However, Ben Ari and colleagues analyzed 52 patients with stable liver disease for F1+2, thrombin:antithrombin III complex (TAT) and D-dimer levels which were no different from controls, yet TEG studies were able to detect hyperfibrinolysis. AICF may be important in the portal venous system because this phenomenon is more pronounced there than in systemic blood.⁷⁴ This could be related to higher levels of endotoxemia in portal blood, which can trigger the release of IL6 and TNF- α , thereby activating intravascular coagulation.⁸⁷

PROGNOSTIC VALUE OF COAGULATION FACTORS

In cirrhosis, plasma coagulation factor levels are indicators of hepatic synthesis and liver function. A prolonged PT, which is not corrected by intravenous vitamin K administration—10 mg daily for 2 days, helps differentiate vitamin K deficiency from parenchymal liver diseases.¹⁴ PT is part of the Child-Pugh score, which is the most commonly used prognostic score assessing the severity of liver disease.⁸⁸ Recently the MELD score, which incorporates INR, has been used to allocate priority for liver transplantation in the United States based on estimated probability of death within 3 months.⁸⁹

Determination of individual coagulation factors adds little prognostic information to measuring PT or INR. Determination of factors V, VII, and VIII are useful indicators of DIC and prognostic indicators in acute liver failure (ALF).⁸² The Clichy criteria indicate poor prognosis and need for liver transplantation for ALF, when factor V activity is below 20% in patients ≤ 30 years of age or below 30% associated with those ≥ 30 years of age.⁹⁰ Factor V activity has less prognostic value in acetaminophen-induced fulminant hepatic failure.⁹¹

In the King's College criteria in acetaminophen-induced liver failure, PT ≥ 100 s is a prognostic indicator on its own for liver transplantation independent of the grade of coma. In patients with non-acetaminophen-induced ALF, PT ≥ 50 s together with two of the following criteria: age < 10 or > 40 years, drug toxicity, interval between jaundice and encephalopathy onset > 7 days and serum bilirubin > 300 $\mu\text{mol/L}$ are indications of poor prognosis and the need for liver transplantation.⁹²

A multivariate analysis of prognostic factors in cirrhotic patients showed that the level of factor VII was an independent predictor of survival: factor VII $< 34\%$ was predictive of a mortality in 93%.⁹³ Plasma concentration of D-dimer > 300 $\mu\text{g/mL}$ has been shown to be correlated with adverse outcome in patients with liver cirrhosis but has only a 20.5% of positive predictive value with a relative risk of 7.5.⁹⁴

ASSESSMENT OF THE RISK OF THROMBOSIS AND ANTICOAGULATION

Thrombotic complications can paradoxically occur in cirrhotic patients even if clinically they are not considered to have hemorrhagic tendencies. Despite prolonged coagulation tests, these patients cannot be viewed as being “auto-anticoagulated.” Wanless and associates advocated portal vein and hepatic vein thrombosis as concomitant causes in disease progression in cirrhotic patients. Hepatic vein and portal vein thromboses were found in at least 70% and 36% of explanted livers and were associated with regions of confluent fibrosis (focal parenchymal extinction).⁹⁵

Portal vein thrombosis complicates liver cirrhosis between 0.6% to 15% of cases, leading to worsening of liver function and mesenteric infarction if the mesenteric vein is involved.⁹⁶ In these patients, early anticoagulation has been shown to recanalize the splanchnic veins in about 50% of

cases and prevent the extension of the thrombus without causing complications.⁹⁷

In BCS, even if a prothrombotic cause is not identified, anticoagulation should be started immediately after this diagnosis because many genetic prothrombotic defects remain to be discovered and acquired disorders common in BCS may be elusive, such as polycythemia vera or paroxysmal nocturnal hemoglobinuria (PNH). Early anticoagulation ameliorates prognosis. Anticoagulation therapy should continue even after liver transplantation because of the high rate of recurrence and thrombotic complications after OLT, and also because multiple prothrombotic disorders may exist not limited to protein deficiencies.¹⁹

The risk of deep vein thrombosis and subsequent complications, such as pulmonary embolism, is not well known in cirrhotic patients, yet is reported in the literature.⁹⁸ Patients with cholestatic disease, such as PBC and PSC, who often exhibit a procoagulant state demonstrated by TEG, may be prone to thrombosis, but this is not documented.⁵¹ No guidelines are available for the management of thrombotic complications or for the prevention of embolic phenomena following atrial fibrillation in cirrhotic patients. Patients must be assessed on their own characteristics. An endoscopic screen for varices must be performed and appropriate prophylaxis against variceal bleeding should be instituted, particularly if there has been recent bleeding. Antiplatelet drugs and NSAIDs should be avoided because they may precipitate bleeding and increase fluid retention with increased risk of renal failure. Anticoagulation is not contraindicated; warfarin in cirrhotic patients with PVT does not increase complications.^{99,99a}

ASSESSMENT OF THE RISK OF BLEEDING

The role played by coagulation defects in the occurrence of bleeding in cirrhosis is still unclear. This is particularly due to the difficulty (and cost) in measuring static procoagulant and anticoagulant activities, and in formulating the balance between the two (see Table 39-1). In addition, there are very few tests that reflect or predict coagulation in vivo. A recent symposium detailed how little is actually known about hemorrhage in severe liver disease as well as the lack of confidence in routine coagulation tests (PT, PTT) and therapeutic efforts.^{99b}

Recently, generation of thrombin has been explored in vitro in patients with liver cirrhosis and found to be normal. In this study, a resetting of the coagulation and anticoagulation system at a lower level was postulated because during liver disease, both procoagulant and anticoagulant pathways are affected in a parallel manner. However, the in vitro technique has some drawbacks, the major one being that platelets are substituted by phospholipids.³

Clinical signs of coagulopathy in liver disease depend on the degree of impairment of the hemostatic system. Commonly, minor signs of bleeding tendency are present, such as gum bleeding and epistaxis, but major bleeding can be encountered (Table 39-2). The role of hemostatic abnormalities in the risk of variceal bleeding is not clear. Impaired laboratory studies may indicate worse hepatic synthesis—serving more as a co-marker of disease rather than as a cause of hemorrhage. Hyperfibrinolysis has been shown to be linked to, but not necessarily a cause of, increased risk

Table 39-2 Clinical Hemorrhage in Patients with Liver Cirrhosis

Microvascular Manifestations

Petechiae
Bruising, purpura, bleeding at venipuncture sites or after minor challenges (brushing teeth, shaving)
Epistaxis
Gingival bleeding
DIC versus pseudo-DIC (see text)

Macrovascular Manifestations

Hemorrhage during surgery or invasive procedures (TIPS, ICP monitoring, liver biopsy, paracentesis, thoracentesis)
Variceal hemorrhage
Portal hypertensive gastropathy
Peptic ulcer disease

DIC, disseminated intravascular coagulopathy; ICP, intracranial pressure; TIPS, transjugular intrahepatic portosystemic shunt.

of variceal bleeding in a cohort of 61 cirrhotics. Higher levels of fibrinogen degradation products were associated with a greater risk of variceal bleeding compared with patients without (odds ratio = 8), but Child-Pugh score and endoscopic characteristics of varices remain the most important prognostic factors.¹⁰⁰

Recently, the roles of infection and endogenous heparin-like substances demonstrated by TEG have been evaluated in variceal bleeding. Infection may be a trigger factor for bleeding¹⁰¹ and both infection and heparin-like substances may be mechanisms responsible for the persistence of bleeding in some.¹⁰² TEG, which is a quick and reliable method to assess clot formation and lysis,⁵³ also allows detection of heparin-like substances. Studies from our group have shown data consistent with worsening coagulation during infection due to heparin-like substances detected by TEG (Fig. 39-1).¹⁰³

INVASIVE PROCEDURES

Historically, PT and platelet count have been used to assess the risk of bleeding prior to invasive procedures. Cirrhotic patients have increased mortality and morbidity during surgery¹⁰⁴ mainly due to increased bleeding in 60% of cases.^{105,106} Early studies linked PT to this risk during surgery (PT prolongation >1.5 and >2.5 seconds associated with 47% and 87% mortality, respectively),¹⁰⁷ hence platelet count <50,000/μL and PT prolongation of > 3s have been considered relative contraindications to elective surgery.¹⁰⁶ In addition, portal hypertension and collateral veins increase the risk of bleeding during surgical dissection.

Hyperfibrinolysis¹⁰⁸ and clotting activation due to increase tPA levels have been described in patients undergoing liver resection.¹⁰⁹ However, another study performed in patients undergoing laparoscopic liver biopsy failed to demonstrate any correlation between the risk of bleeding evaluated at the hepatic puncture site and coagulation tests, so the degree of injury may be the important factor.¹¹⁰

Liver biopsy is widely used diagnostically and to grade the severity of liver disease or fibrosis. Moreover, it is an essential tool after liver transplantation used to diagnose rejection and other causes of graft dysfunction.

Figure 39-1 Presence of heparin-like effect in a patient with cirrhosis and peritoneal infection. Native-TEG (**A**) and heparinase I-TEG (**B**) on sample collected at the onset of spontaneous bacterial peritonitis in a patient with liver cirrhosis. A significant heparin-like effect was found; the slowed rate of coagulation in **A** compared with **B** is shown by the decrease in slope (lower angle of separation, 13.8 degrees vs 59.5 degrees). Treatment of the sample in **B** with heparinases increases the rate of coagulation, thus implying the presence of heparin-like substances.

Bleeding complications occur in 0.35% to 0.5%, leading to mortality in 0.1%.¹¹¹ Despite the evidence that there were no threshold abnormalities of clotting tests associated with risk of bleeding during laparoscopic liver biopsy, INR and platelet count are essential to evaluate the bleeding risk for percutaneous liver biopsy.¹¹² An audit from the British Society of Gastroenterology (BSG) performed in 1991 showed a doubling of the risk of bleeding in patients with $\text{INR} \geq 1.5$, but that only 7.1% of the bleeding occurred with $\text{INR} \geq 1.5$, and 90% occurred with an $\text{INR} \leq 1.3$.¹¹³ Thus, having a normal INR no more excludes the risk of bleeding than an elevated INR suggests it. A cutoff for platelet count is difficult to justify from the literature. Most textbooks in the United Kingdom and BSG guidelines require (without reporting evidence) a platelet count above 80,000/ μL ,¹⁴ whereas a survey from the Mayo Clinic suggested 50,000/ μL as a reasonable cutoff.¹¹⁴ Current recommendations state that a percutaneous liver biopsy can be done safely without support with platelet counts above 60,000/ μL .¹¹² Burroughs and coworkers advocated evaluating the use of bleeding time to assess the risk of bleeding for percutaneous liver biopsy,¹¹⁵ but this is not done in clinical practice. If clotting parameters are outside stipulated ranges, a transjugular liver biopsy can be more safely performed without plasma or platelet therapy.¹¹⁶ A plugged liver biopsy is also said to be safer, but it may cause a greater risk of bleeding in hypocoagulable patients.¹¹¹

During minor procedures such as thoracentesis, paracentesis, or lumbar puncture performed in patients with liver disease, there are no firm guidelines as to the hemostatic threshold for performing these tests. The largest review on 608 patients who underwent paracentesis or thoracentesis with mild coagulation abnormalities showed 0.2% having excessive bleeding requiring transfusion and 0.02% mortality. There was no correlation with PT, PTT, platelet count, and the risk of bleeding.¹¹⁷ In another study performed in 200 cirrhotics with INR of 3 and platelet count 19,000/ μL who underwent paracentesis, no complications were seen, regardless of baseline INR and platelet count.¹¹⁸ A contraindication to the procedure is clinically evident DIC or fibrinolysis.¹¹⁹ It is impossible using evidence-based techniques to establish “safe” coagulation tests for these procedures; it is more important to limit such procedures to circumstances in which the perceived benefit of the procedure is clearly greater than the risk.

COAGULATION DURING INFECTION AND SEPSIS

The overall cumulative incidence of infection in cirrhotic patients is estimated to be at least 30%,¹²⁰ and is possibly associated with increased risk of variceal bleeding.¹⁰¹ Infection is associated with early rebleeding and increased

mortality.^{121,122} Prophylactic antibiotic therapy has led to earlier rebleeding and better control of bleeding in a randomized study.¹²³

Using TEG, 20 cirrhotic patients who experienced early rebleeding were found to have worsening TEG parameters the day before rebleeding.¹⁰² Moreover, patients with bacterial infection have worse TEG parameters, which can be corrected in vitro by heparinase I, which can cleave heparin-like substances (see Fig. 39-1A and B).¹⁰³ The presence of heparin-like substances is associated in some patients with increased anti-Xa activity.¹²⁴ Heparin-like substances have been detected hours after variceal bleeding in cirrhotic patients.¹²⁵ Based on this evidence, it has been postulated that endotoxins and inflammation due to infection can release heparinoids from the endothelium and mast cells.¹⁰³ One study, as yet not repeated, showed increased heparan sulfate concentrations in patients with variceal bleeding compared with patients without variceal bleeding.¹²⁶ Moreover, sepsis can cause impairment of platelet function, decreasing platelet number and aggregability caused by an increase NO production.¹²⁷

Cytokines, in particular IL6 and TNF- α released during infection, can trigger DIC with hyperfibrinolysis.¹²⁸ One study showed a strong association between both fragment F1+2 and D-dimer with endotoxemia. These markers interestingly returned to normal after antibiotic therapy.⁸⁴ Another report recently showed decreased platelet count and levels of factors VII, X, V, and II, in cirrhotic patients and severe sepsis, suggesting consumptive coagulopathy,¹²⁹ whereas a further study found decreased activity of protein C, which is associated with increased fibrinolysis.¹³⁰

THERAPY OF HEMOSTATIC ABNORMALITIES IN LIVER DISEASE

Usually, hematologic abnormalities in liver disease lead to only mild clinical consequences. However, in particular clinical settings, life-threatening bleeding can occur. Chief among these are the structural bleeds of varices and ulcer disease. Significant microvascular hemorrhage is unusual, despite multiple coagulation test abnormalities. Therapy for hemostatic abnormalities of liver disease is needed only during variceal bleeding, surgery, or before invasive procedures. Intravenous vitamin K injection of 10 mg daily for 24 to 48 hours can reverse vitamin K deficiency.¹⁴

Fresh frozen plasma (FFP) contains all the clotting factors and can correct the laboratory finding of an elevated PT effectively, but this correction depends on the volume and the baseline abnormality of PT. Whether this correction of the PT results in increased hemostasis has yet to be proved. In addition, the laboratory correction is short term (24 to 48 hours) because it depends on the half-lives of the clotting factors (especially factor VII).⁸² A commonly used indication for FFP infusion is the presence of persistent bleeding in patients with INR ≥ 2 or PT prolongation greater than 4s.¹³¹ In surgical or invasive procedures, 50% of the normal PT (i.e., INR of 2) is suggested and should be the aim of replacement therapy. For neurologic procedures such as intracranial pressure monitoring during liver failure, 80% of normal PT range (i.e., an INR of about 1.2 to 1.3) is suggested.¹³¹ During massive blood transfusion, to avoid dilutional decrease of clotting factors for every 2 units of

blood, 1 unit of FFP is typically given (See Chapter 46).¹³² To increase the activity of clotting factor by 1% to 2%, a dose of 10 mL FFP/kg of body weight is necessary.¹³³ Because of the high volume required, adequate replacement is difficult in patients with liver cirrhosis, in whom the intravascular plasma volume is already expanded and in whom ascites may be present and in patients with ALF, in whom increasing plasma volume can lead to increases in intracerebral pressure. Moreover, because of the short half-life, infusions every 6 to 12 hours are needed.¹¹ In patients with INR > 1.5 , FFP is typically given at the dose of 12 to 15 mL/kg before liver biopsy, but this practice is not based on evidence. One study showed correction of PT in only 20% of patients receiving such FFP.¹¹² It is unusual to be able to correct the PT by more than 2 to 3 seconds with less than 500 mL of FFP.¹¹ Thus, transjugular biopsy should be used in patients with coagulopathy not sufficiently correctable with FFP.

Platelet transfusion is employed, but this practice lacks any evidence-based support. One unit every 10 kg is typically administered, and platelet count should be checked one hour after the infusion.¹³⁴ However no correlation between amelioration of bleeding time, increase in platelet count, and enhanced hemostasis has been shown.¹¹²

Cryoprecipitate contains factors VIII, fibrinogen, VWF, fibronectin, and factor XIII. Because of the small volume (30 to 50mL/U/10 kg) required during infusion,¹³⁴ it can be useful in liver cirrhosis and ALF, but it lacks some coagulation factors and may worsen the imbalance already present in patients with liver disease. It is recommended in some patients with DIC and severe (i.e., <50 mg/dL) hypofibrinogenemia, otherwise replacement does not correct the underlying hyperfibrinolytic defect.¹³⁵ In a recent randomized trial performed in patients with ALF, 5 units of cryoprecipitate were less effective than 4 units of FFP in improving the PTT, but one patient developed pulmonary edema in the FFP group.¹³⁶

Desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]), an analog of the antidiuretic hormone, increases plasma level of factor VIII and VWF, probably by increasing the release from endothelial storage sites.¹³⁷ It can improve bleeding time, enhancing primary hemostasis at the dose of 0.3 μ g/kg in patients with liver failure.¹³⁸ However, a randomized trial associating terlipressin and DDAVP in patients with variceal bleeding, demonstrated no difference in control of bleeding and maybe a worsening of the terlipressin action in the DDAVP group.¹³⁹ In a recent randomized trial, DDAVP failed to decrease blood loss during hepatic resection, despite increase of factor VIII and VWF.¹⁴⁰

ATIII infusion is not routinely recommended, although some studies showed an increase in the fibrinogen concentration during DIC.¹⁴¹ In liver transplantation, ATIII administration has not been shown to improve blood loss or decrease mortality.¹⁴²

Recombinant activated factor VII (rFVIIa) was first developed for the treatment of patients with hemophilia A or B who developed inhibitors. It may have a promising role in the treatment of coagulation disorders in liver disease.¹⁴³ A single dose of rFVIIa has been shown to correct prolonged PT in a dose-dependent manner in non-bleeding cirrhotic patients.¹⁴⁴ The half-life of rFVIIa is 2.3 hours.¹⁴⁵ The median duration of normalization of PT is 2, 6, and 12 hours following single doses of 5, 20, and 80 μ g/kg, respectively.¹⁴⁴ A randomized study using rFVIIa

in 71 patients undergoing laparoscopic liver biopsy found no differences in liver bleeding time. Two complications occurred in the rFVIIa group (1 DIC and 1 PVT).¹⁴⁶ In ALF, rFVIIa may be useful to normalize PT in the setting of intracranial pressure monitoring because only a small volume of infusion is required. The King's College group reported on seven patients who had normalization of PT after treatment with rFVIIa before ICP monitoring.¹⁴⁷ During variceal bleeding in a randomized trial, a modest reduction of early rebleeding rate was observed in a subgroup of Child B and C patients after rFVIIa infusion, although no difference in control of bleeding or transfusion was shown overall.¹⁴⁸ Another report described initial hemostasis after infusion of rFVIIa in ten patients, but six experienced early rebleeding and all of them died, illustrating the short interval of action of this drug.¹⁴⁹ In a cohort of eight patients with acute variceal bleeding uncontrolled with endoscopic and medical therapy, rFVIIa administration achieved hemostasis in 25% after a single dose.¹⁵⁰

The efficacy of rFVIIa is limited in patients with low fibrinogen (<100 mg/dL) and concomitant administration of low volumes of plasma is required.¹⁴⁶ Safety, especially concerning the possible prothrombotic effect or triggering of DIC, still has to be assessed in large studies in patients with liver disease.¹⁵¹ Secondary hyperfibrinolysis due to DIC can occur and DIC should be excluded before administration of antifibrinolytic drugs because these agents can worsen the thrombotic component of DIC.

ORTHOTOPIC LIVER TRANSPLANTATION

Orthotopic liver transplantation (OLT) is the only cure for end stage liver disease. Improvements in operative management, surgical techniques, and graft preservation have contributed to a significant reduction in transfusion requirements during the last decade.¹⁵² However, blood losses are highly variable, and correlate in most studies, but not all, with a higher mortality, poor graft function, and risk of infections.¹⁵³ In current practice, a significant proportion of patients receive no blood during surgery. Preoperative identification of patients at high risk of surgical blood loss is of interest, but studies have given contrasting results. Most studies failed to define risks related to bleeding, including preoperative coagulation tests or markers of fibrinolysis during liver transplantation,^{154–156} with the exception of the collateral circulation due to portal hypertension and previous abdominal

surgery.¹⁵⁷ Hemostatic abnormalities during liver transplantation are divided according to the surgical phases which are traditionally: pre-anhepatic phase, anhepatic phase and post-reperfusion phase, and postoperative period (Table 39-3).

Pre-Anhepatic Stage

The first operative stage is characterized by extensive surgical trauma, resulting from dissection of adhesions in the abdominal cavity and transection of many collateral vessels. Usually during this phase, mild coagulation abnormalities occur and the blood losses are mainly correlated with the surgical technique and the baseline hypocoagulable state.¹⁵⁷ The etiology of liver disease can influence the blood product requirement in this stage. Hypercoagulability has been demonstrated in patients with hepatocellular carcinoma as well as cholestatic cirrhosis (PBC, PSC). Marked differences have been shown in the pretransplantation coagulation parameters and intraoperative fibrinolytic activity between patients with cholestatic liver diseases (PBC and PSC), and other etiologies.¹⁴² The PBC and PSC patients have a hypercoagulable state by TEG⁵¹ and less fibrinolytic activity during OLT, suggesting that in these patients anti-fibrinolytic drugs should not be used. Moreover, in pediatric liver transplantation for biliary atresia, plasma studies showed fewer coagulation abnormalities during OLT compared with other etiologies.¹⁵⁸ Enhanced fibrinolytic activity contributes to blood loss in the pre-anhepatic phase in only 10% to 20% of patients.¹⁵⁹

Anhepatic Phase

During this phase, no important surgical blood loss is seen because appropriate vessels are clamped. However, bleeding can occur owing to hemostatic changes in this phase. Despite impairment of synthetic and clearance function, early studies failed to show dramatic changes in PT and PTT during this stage.^{80,160} However, hyperfibrinolysis has been demonstrated in many studies owing to a net increase in tPA derived from endothelial cells; this tPA is not cleared because of the absence of the liver at this time.¹⁶¹ The presence of an active fibrinolytic process has been demonstrated by simultaneous decrease of α_2 -plasmin inhibitor and plasminogen activity, and a concomitant increase in fibrin and fibrinogen degradation products.¹⁶² Use of rFVIIa has been tried in patients with severe coagulopathy (INR 5.7 and 6.9). Moderate bleeding was still reported during surgery, but one patient

Table 39-3 Hemostatic Alterations in Orthotopic Liver Transplantation

	Pre-Anhepatic Phase	Anhepatic Phase	Reperfusion and Post-Reperfusion Phase	Postoperative Period* (Days)
Procoagulant factors	↓	↓↓	↓↓	1–2
Anticoagulant factors	↓	→	→	7–14
Hyperfibrinolysis	↑	↑↑	↑↑↑	1–2
Platelet count	→	→	↓	1–7
Platelet function	→	→	↓	1–2
Heparin-like effect	↑→	↑	↑↑	1–2

*The convalescence period is the time after successful transplantation required to return to normal adult levels.

→, indicates no change; ↑, indicates a mild increase; ↑↑, indicates a significant increase; ↑↑↑, indicates a marked increase.

developed hepatic artery thrombosis after transplant.¹⁶³ Studies that evaluated coagulation factors during OLT after rFVIIa infusion showed a sharp increase of thrombin generation, PT, and PTT, but no amelioration of fibrinolysis.^{164,165}

Reperfusion and Post-Reperfusion Phase

Reperfusion of the liver is a crucial point of the operation and leads to profound coagulation abnormalities. Within minutes after reperfusion, uncontrollable diffuse bleeding may occur in some patients.¹⁶⁶ The roles of humoral factors such as hypocalcemia, hypothermia, hyperkalemia, metabolic acidosis,¹⁶⁰ and release of proteinases from donor hepatic lysosomes, are all believed to contribute to the blood loss, but these effects are not yet well defined.¹⁶⁷

Trapping of platelets in the graft may play a role in the bleeding tendency. Experimental studies have shown a 55% gradient in platelet count between arterial and venous blood flow in the new liver. Moreover, some alterations in the bleeding time and platelet function and aggregation have been demonstrated.¹⁶⁸

Signs of DIC after graft reperfusion have been shown by some investigators, mainly correlated with poor quality of the transplanted organ.¹⁶⁹ During ischemic preservation, damage to vascular endothelial cells may occur. This injured endothelial layer may lead to platelet adhesion and activation of the coagulation system.¹⁷⁰ However both ATIII and heparin administration failed to have any benefit, which suggests DIC is not a major component of the bleeding during the anhepatic phase.¹⁴² Moreover, improvements in the preservation techniques have reduced the frequency of DIC in OLT.

Increase in fibrinolysis has been implicated as the most important and significant phenomenon responsible for bleeding during liver transplantation. Hepatic endothelium is a rich source of plasminogen activators and release and washout of these activators from the transplanted liver have been considered responsible for the increased tPA levels at reperfusion.¹⁷¹ In pigs, hyperfibrinolysis has been shown to be related to preservation time. It usually subsides within 60 minutes after graft reperfusion, but in donor livers with poor function, a sustained increased fibrinolytic response can be seen.¹⁷²

After reperfusion, release of heparin or heparin-like substances has been shown in 25% to 95% of cases.¹⁷³ Protamine sulfate (50 mg) has been used in vivo to antagonize this effect. One study has confirmed the presence of heparin-like compounds using heparinase I-modified TEG, which cleaves heparin and heparan sulfate. Increased blood product requirement was correlated with the presence of heparin-like effects in TEG traces. However a baseline heparin-like effect has recently been found before reperfusion in patients undergoing liver transplantation who had not received heparin.¹⁷⁴

Antifibrinolytic therapy is used during liver transplantation to reduce blood loss, time of surgery, and fibrinolytic activity. Aprotinin is a serine protease inhibitor that antagonizes various proteases.¹⁷⁵ Some use an initial dose of 2×10^6 KIU/hour followed by 1×10^6 KIU/hour and an additional dose of 1×10^6 KIU before reperfusion.¹⁷⁶ Recent prospective studies have confirmed that this dose is able to reduce blood requirement and fibrinolysis, but

at a lower dose, there was only an effect on the volume of blood products replaced.^{177–179} Aprotinin also has anti-inflammatory and antioxidant effects which might also be of benefit. Excessive use of aprotinin is not recommended because of the risks of anaphylactic reactions, renal dysfunction, and stroke.¹⁸⁰

ε Aminocaproic acid (EACA) interferes with plasminogen binding to fibrin and thus EACA inhibits the conversion of plasminogen to plasmin.¹⁸¹ In the only prospective randomized trial, an initial dose of 70 mg per kilogram of body weight followed by 16 mg/kg/hour maintenance was shown to reverse TEG fibrinolysis, and reduce blood cell transfusion, without causing thrombotic complications. However this reduction was not statistically significant compared with controls.¹⁸² Similar to EACA, tranexamic acid inhibits fibrinolysis, but it is 6 to 10 times more potent than EACA.¹⁸³ It does not have any effect on the bradykinin-kallikrein complex.¹⁸⁴ Recent trials have shown that at a dose of 2 mg/kg/hour, tranexamic acid reduces fibrinolysis and blood loss. However, different doses have been used in other studies without clear-cut effects.^{183–186}

The routine use of coagulation monitoring during liver transplantation is established. Usually TEG, a near-site rapid method to globally assess the coagulation process, is used. It provides a rational approach to the use of blood component therapy or pharmacologic intervention, but it does not help in addressing blood transfusion *per se*.⁵³ Recently, TEG was used to monitor postoperative coagulation in patients undergoing hepatic resection for living related liver transplantation. In these patients, a hypercoagulable state correlated with the risk of developing thrombotic complications after surgery.¹⁸⁷

Postoperative Period

Thrombocytopenia is common in the early postoperative period, mainly due to platelet activation and consumption following graft reperfusion.¹⁸⁸ If liver function is restored, thrombocytopenia subsides in a few days after OLT. Following normal synthetic function of the liver, thrombopoietin levels increase significantly on the first day, followed by immature bone marrow megakaryocytes after 3 days, and new circulating platelets after 5 days. Normalization of platelet count is seen after 14 days.¹⁸⁹ The peak TPO levels correlate with the pre-OLT platelet count. Levels of bilirubin, cold ischemia time or episodes of rejection do not influence TPO levels.¹⁹⁰ Persistence of thrombocytopenia can be seen in some patients, which can be ascribed to persistent splenomegaly in some, but not all, patients.¹⁹¹

Chapter 40

Outpatient Anticoagulant Therapy

Jack E. Ansell, MD

The coumarin-type oral anticoagulants have been in use for more than 60 years and are well-established weapons in the armamentarium against thrombotic disease.¹ Their discovery evolved from investigations into a hemorrhagic disease of cattle occurring early in the twentieth century attributed to the consumption of spoiled sweet clover. Karl P. Link,² a biochemist at the University of Wisconsin, eventually isolated the responsible agent in spoiled sweet clover, dicumarol (3-3' methyl-*bis*-4-hydroxy coumarin), which quickly entered the clinical arena through work at the Mayo Clinic in 1941. Link subsequently synthesized a related compound (warfarin), initially popularized as a rodenticide in the late 1940s, that entered clinical practice in the 1950s and quickly became the major oral anticoagulant in clinical use. Little has changed in the formulation of the coumarin-type oral anticoagulants. They have remained critically important drugs in the primary and secondary prevention of thromboembolism. In the last 20 years, the use of oral anticoagulants has grown considerably, commensurate with the increased understanding of the important role of thromboembolism in cardiovascular disorders.

MECHANISM OF ACTION

Vitamin K₁ is an essential cofactor in the posttranslational γ -carboxylation of several glutamic acid residues in the vitamin K-dependent coagulation factors II, VII, IX, and X (Fig. 40-1), as well as proteins C and S.³⁻⁵ In the absence of γ -carboxylation, these proteins are unable to bind calcium and phospholipid and, depending on the level of carboxylation, they manifest a reduced coagulant (i.e., enzymatic) potential. Warfarin produces its anticoagulant effect by interfering with the cyclic interconversion and regeneration of reduced vitamin K from its 2,3 epoxide (vitamin K epoxide).³⁻⁵ Warfarin exerts this effect by inhibiting an enzyme, vitamin K oxide reductase complex 1 (VKORC1) responsible for this interconversion (see Fig. 40-1).⁶ Dietary vitamin K₁ enters the body in a partially reduced state bypassing the warfarin-sensitive reductase and replenishing fully reduced vitamin K₁ stores in the presence of warfarin therapy.

PHARMACOKINETICS AND PHARMACODYNAMICS

Because of its excellent bioavailability and favorable pharmacokinetics, warfarin is the most commonly used oral

anticoagulant in North America. It is highly water soluble and rapidly absorbed from the gastrointestinal tract after oral ingestion.^{7,8} Peak absorption occurs in 60 to 90 minutes. Food may delay the rate of absorption but is said not to reduce the extent of absorption.

Warfarin is a racemic mixture of stereoisomers known as the R and S forms; each has distinctive metabolic pathways, half-lives, and potencies. Racemic warfarin has an average plasma half-life of 36 to 42 hours, with ranges from 15 to 60 hours. Variability in warfarin half-life, due either to natural differences in metabolism or to disease and/or drug-induced alterations in metabolic fate, or of the sensitivity of the VKORC1 enzyme to warfarin account for the marked variations in an individual's initial response to, or maintenance requirement for, warfarin. The S enantiomer of warfarin (5 times more potent than the R enantiomer) is metabolized primarily by the CYP2C9 enzyme of the cytochrome P450 system.⁹ A number of genetic polymorphisms (single nucleotide polymorphisms [SNPs]) in this enzyme leads to a reduced activity of the enzyme and may influence both the dose required to achieve a therapeutic level and the bleeding risk with warfarin therapy.¹⁰⁻¹⁴ Specifically, the CYP2C9*2 and CYP2C9*3 alleles are associated with lower dose requirements and higher bleeding complication rates compared with the wild-type enzyme CYP2C9*1.^{8,10-14} The prevalence of these polymorphisms varies in populations as indicated in Table 40-1.

The recent discovery of a number of SNPs in the VKORC1 gene leading to varying sensitivities of the enzyme to warfarin inhibition has been shown to have a major impact on the pharmacodynamics of warfarin.^{15,16} A combination of SNPs leads to various haplotypes of the gene and gene product. Some of these haplotypes result in an enzyme that is sensitive to warfarin inhibition requiring a lower dose of warfarin, whereas others are more resistant, requiring a higher dose (and maintenance dose) of warfarin to achieve a therapeutic International Normalized Ratio.^{15,17-20} The prevalence of these haplotypes varies in different populations as indicated in Table 40-1. A combination of genetic alterations in either the CYP2C9 or VKORC1 genes has been shown to account for as much as 20% to 50% of the variability in warfarin maintenance dosing.^{14,17,19} The effect of warfarin also varies inversely with the amount of vitamin K₁ absorbed (from the diet and from metabolic by-products of gastrointestinal bacteria) and directly with the amount of warfarin absorbed or available to exert its anticoagulant effect.

Figure 40-1 Reduced vitamin K is oxidized in the posttranslational modification of prothrombin (and other vitamin K-dependent coagulation factors) introducing carboxyl groups to several glutamic acid moieties in the prothrombin polypeptide, and forming γ -carboxyglutamic acid. The oxidized form of vitamin K is recycled after a reduction mediated by VKORC (vitamin K oxide reductase complex). VKORC is the target enzyme inhibited by the S isomer of warfarin. S-warfarin is the active portion of warfarin, whereas the R isomer has little effect. S-warfarin is metabolized by the cytochrome P450 oxidase enzyme, CYP2C9.

WARFARIN AND DRUG INTERACTIONS

Drug interactions commonly occur by affecting the pharmacokinetic or pharmacodynamic behavior of warfarin.^{7,21} Drug interactions may interfere with gastrointestinal absorption of warfarin resulting in a reduction in plasma levels, or interfere with the metabolism of warfarin leading to a reduction or increase in clearance, and consequently, higher or lower plasma warfarin levels. The latter effects may be stereospecific in that only one of the enantiomers may be affected or it may be nonspecific in that both enantiomers may be affected. Interference in the metabolism of the S enantiomer, usually by affecting the P450 cytochrome system (CYP2C9 enzyme), is more common and has a greater potential for enhancing the intensity of anticoagulation, because since the S enantiomer is several times more potent than the R enantiomer. Drugs may also decrease plasma warfarin levels by enhancing the metabolic clearance of racemic warfarin.

The pharmacodynamics of warfarin may also be altered when drugs interfere with other aspects of hemostasis or vitamin K₁ homeostasis. Third-generation cephalosporins containing an *N*-methyl-thiotetrazole side chain are an example in that they interfere with the regeneration of reduced vitamin K₁ from the 2,3 epoxide form. Some drugs or disease states (liver disease, hyperthyroidism) can alter the metabolism of coagulation factors, inhibit coagulation factor interactions by other mechanisms (heparin), or inhibit other aspects of hemostasis (aspirin effect on platelet function) and lead to a greater risk of bleeding. In general, such interactions are most problematic when interacting drugs are added or deleted (or a dose change is made) from a patient's regimen. Once a patient is stabilized on warfarin and an interacting medication, there should be little problem in maintaining stability of warfarin dosing.

Assessing the literature for warfarin-drug interactions is problematic because of the poor quality of the reports. Holbrook and colleagues²² recently performed a systematic review of warfarin and food interactions and found serious problems of reporting potential interactions. They reviewed 187 separate reports of interactions involving 120 drugs or foods and found that no report met their quality criteria as an excellent study. There were 33 small randomized controlled trials of fair or good quality. There were 148 reports that were rated poor quality and 130 of these were case reports (96% single case reports). Table 40-2 summarizes these interactions and categorizes them by level of cause and effect on INR.

A new problem of recent development is the widespread use of dietary supplements and herbal preparations.^{23,24} Unlike drug products, dietary supplements are not tested prior to marketing for safety, efficacy, dosing requirements, or interactions with other medications. They are not required to meet quality standards for labeling, nor are they required to meet United States Pharmacopeia standards for tablet content uniformity (see Chapter 33). Consequently, patients may be exposed to different ingredients as well as different doses of those ingredients among similar products produced by different manufacturers and among batches from the same manufacturer. There is a growing number of case reports describing interactions between warfarin and dietary

Table 40-1 Frequency of Genetic Polymorphisms of CYP2C9 and VKORC1 in Different Ethnic Groups

CYP2C9 Polymorphism*			
	CYP2C9*1 (%)	CYP2C9*2 (%)	CYP2C9*3 (%)

supplements, but virtually none of these interactions has been systematically substantiated. Because of the uncertainty that exists, it is wise for patients on warfarin to avoid the use of dietary supplements, or at best, to be carefully observed when beginning or stopping a supplement. For a listing of various drug interactions or reported herbal interactions, the reader is referred elsewhere.²¹

THERAPEUTIC RANGE AND MONITORING OF ORAL ANTICOAGULANTS

The concept of a safe and effective therapeutic range evolved largely as a consequence of trial and error and clinical empiricism in the 1940s and 1950s.¹ A prothrombin time (PT) ratio of 2.0 to 2.5 or 3.0, using a human brain thromboplastin reagent sensitive to a reduction in the vitamin K–dependent coagulation factors, was believed to represent this therapeutic range. However, less sensitive rabbit brain thromboplastin reagents came into use in the 1950s and 1960s, resulting in the need for a higher average warfarin dose to achieve the same prolongation of the prothrombin time (PT).²⁵ Hull and coworkers²⁶ demonstrated the consequences of this situation in a study of patients with deep venous thrombosis treated with warfarin by documenting a higher incidence of bleeding in those monitored with the less sensitive rabbit brain thromboplastin, yet no increase in recurrent thromboembolism in those monitored by the more sensitive reagent, when both groups were maintained in a similar therapeutic range.

To correct for differences in thromboplastin sensitivity, the World Health Organization recommended the use of an international standard PT.²⁷ All thromboplastins are equilibrated against a sensitive international reference thromboplastin, and the equilibration factor (the International Sensitivity Index [ISI]) is used to convert PT ratios (PT divided by the mean of the normal range) to an international ratio (the International Normalized Ratio [INR]). The INR is essentially the PT ratio one would obtain if the international reference thromboplastin had been used to measure the PT. Table 40-3 demonstrates how a local PT ratio is converted to an INR, which is now performed automatically by laboratory instrumentation. By converting all PT ratios to INRs one can interpret a patient's PT result

Table 40-3 Use of ISI to Calculate an INR

To convert a prothrombin time (PT) ratio to an INR equivalent:

INR = PT ratio^x (x = ISI)

Example:

PT = 17.9 sec

Mean of normal range = 12.2

ISI of thromboplastin = 2.3

Then:

$17.9 \div 12.2 = 1.47$ PT ratio

$1.47^{2.3} = 2.4$ INR

INR, International Normalized Ratio; a comparative rating of prothrombin time ratios for individuals with stable therapeutic anticoagulation; ISI, International Sensitivity Index; a comparative rating of different thromboplastins.

regardless of where it is performed and then follow the guidelines of international consensus groups for therapeutic effectiveness as outlined in Table 40-4.²⁸ Use of the INR does not eliminate all discrepancies in PT reporting,²⁹ but it significantly improves reporting PT results compared with using raw seconds or the PT ratio when monitoring patients on warfarin.

PRACTICAL ASPECTS OF ORAL ANTICOAGULATION MANAGEMENT

Initiation and Maintenance Dosing

The use of a loading dose of warfarin to initiate therapy is of historical interest only. It induces a rapid, but excessive, reduction in factor VII activity, predisposing patients to hemorrhage in the first few days of therapy, while it fails to achieve a more rapid decline of the other vitamin K₁–dependent coagulation factors (II, IX, and X).^{30,31} Therapy is properly initiated using an average maintenance dose (~5 mg) for the first 2 or 3 days.³¹ When an immediate effect is required, such as in the treatment of acute venous thrombosis, heparin should be given concurrently with warfarin for at least 5 days. Warfarin should overlap with heparin therapy for a period of 4 to 5 days because it takes that long to lower those vitamin K₁–dependent coagulation factors with longer half-lives. Heparin is usually discontinued when the INR has been in the therapeutic range on

Table 40-4 Indications for Oral Anticoagulation and Recommended Intensity of Treatment

Indication	Target INR (Range)
Prophylaxis of venous thrombosis	2.5 (2.0–3.0)
Treatment of venous thrombosis	2.5 (2.0–3.0)
Treatment of pulmonary embolism	2.5 (2.0–3.0)
Prevention of systemic embolism	
Atrial fibrillation	2.5 (2.0–3.0)
Recurrent systemic embolism	2.5 (2.0–3.0)
Postmyocardial infarction*	3.0 (2.5–3.5)
Bioprosthetic heart valves (M or Ao position) [†]	2.5 (2.0–3.0)
Mechanical prosthetic heart valves	
Bileaflet valve in Ao position	2.5 (2.0–3.0)
Bileaflet or tilting valve in M position	3.0 (2.5–3.5)
Mechanical valve + AF (any position)	3.0 (2.5–3.5)
Mechanical valve + additional risk factors	3.0 (2.5–3.5) + aspirin (81 mg/d)

*For prevention of recurrent MR, an INR of 3.0 (2.5–3.5) is recommended.

[†]For St. Jude or Carbomedics bileaflet or Medtronic-Hall tilting disc valve.

Ao, aortic valve; M, mitral valve.

From Hirsch J, Dalen JE, Anderson DR, et al: Oral anticoagulants: Mechanism of action, clinical effectiveness, and optimal therapeutic range. *Chest* 119 (Suppl):8S–21S, 220S–227S, 2001, with permission.

two measurements at least 24 hours apart. If treatment is not urgent (e.g., chronic stable atrial fibrillation), warfarin can be commenced out-of-hospital with an anticipated maintenance dose of ~5 mg/day, which usually achieves a therapeutic anticoagulant effect in about 5 days, although a stable INR may take longer to achieve. A recent study showed that using an initial 10 mg dose of warfarin in outpatients achieved a more rapid therapeutic INR compared with a 5-mg dose without producing a higher rate of excessive anticoagulation.³² The fear of creating a hypercoagulable state in patients with unrecognized protein C deficiency who are not simultaneously heparinized has not been substantiated. However, in patients with a known protein C deficiency or other thrombophilic state, it would be prudent to begin heparin before, or at the same time as, warfarin. Lower than a 5-mg starting dose might be appropriate in the elderly, in patients with impaired nutrition or liver disease, and in patients at high risk of bleeding. The physician should be aware of variables that influence the response to anticoagulation in the elderly. The dose required to maintain a therapeutic range for patients older than 60 years of age has been shown to decrease with increasing age,³³ and older patients are more likely to have other variables that might influence INR stability or might influence the risk of bleeding—such as a greater number of other medical conditions or concurrent drug use.³³ Consequently, it is advisable to monitor older patients more carefully to maximize their time in therapeutic range.³⁴

Estimation of the maintenance dose is often based on observations of the INR response following a fixed dose of warfarin over an interval of a few days. An individual who rapidly achieves a high therapeutic INR (above 2.0) after two doses of warfarin is likely to require a low maintenance dose. The opposite holds for those who show little

elevation of the INR (below 1.5) after two doses. It is now known that a major determinate influencing one's response to initial and maintenance dosing is one's genotype for the principal enzyme that metabolizes warfarin (CYP2C9) and the target enzyme through which warfarin mediates its effect (VKORC1).^{10–20} Polymorphisms in these genes account for almost 50% of the variability in dosing requirements. They are also associated with a higher rate of bleeding events. Whether it is cost effective to actually know one's genotype before initiating therapy is currently under scrutiny in randomized controlled trials.³⁵ Until such information is available, frequent monitoring of the INR response is the best means of predicting and establishing one's maintenance dose requirements.

PT monitoring is usually performed daily in the hospital (somewhat less frequently if initiated as an outpatient) until the therapeutic range has been achieved and maintained for at least 2 consecutive days—then 1 to 2 times weekly for 1 to 2 weeks—then less often, depending on the stability of PT results. Immediately after hospital discharge is often the most unstable and dangerous time for patients. Therefore, monitoring should be performed frequently for the first 1 to 2 weeks after discharge. If the PT response remains stable, the frequency of testing can be reduced to intervals as long as every 4 weeks, although there is growing evidence to suggest that more frequent testing will lead to a greater time in therapeutic range. If adjustments to the dose are required, then the cycle of more frequent monitoring is repeated until a stable dose response is again achieved.

Outpatient management of warfarin therapy should aim for simplicity and clarity to avoid patient confusion, poor compliance, and dosing errors that may result in complications.¹ It is recommended that a limited number of warfarin tablet strengths be used in clinical practice and that patients clearly understand the various dosing patterns that are used, such as alternate-day doses or dosing levels based on days of the week.¹ One must also be aware that there are several different warfarin products on the market that can lead to confusion for the patient. There are generic preparations sold as warfarin, brand preparations sold as Coumadin, and branded generics sold under a different name (e.g., Jantoven). Patients may be given different preparations and be taking both, not knowing that they are the same drug.

Management of Nontherapeutic International Normalized Ratios

Patients receiving long-term warfarin therapy often have unexpected fluctuations in dose response that require careful management. These may be due to inaccuracy in PT testing, changes in vitamin K₁ intake (increased or decreased vitamin K₁ in the diet), changes in vitamin K₁ or warfarin absorption (gastrointestinal factors or drug effects), changes in warfarin metabolism (liver disease or drug effects), changes in vitamin K₁-dependent coagulation factor synthesis or metabolism (liver disease, drug effects, worsening right sided heart failure with increasing hepatic congestion, other medical conditions), or patient compliance issues (surreptitious self-medication, missed doses, miscommunication about dose adjustment, and so on).

A nontherapeutic (e.g., elevated) INR can be managed by briefly discontinuing warfarin, administering vitamin K₁,

or infusing fresh frozen plasma (FFP) or a factor concentrate.³⁶ The choice is based largely on the severity of the clinical situation (e.g., the degree of elevation of the INR or the presence of severe bleeding). Assuming an ongoing normal food intake and reasonable hepatic function, when warfarin administration is interrupted, it takes about 4 to 5 days for the INR to return to the normal range in patients whose INR is between 2.0 and 3.0.³⁷ Those patients requiring a larger daily maintenance dose will return to normal more quickly than those requiring a lower daily maintenance dose. After treatment with oral vitamin K₁, the INR declines substantially within 24 hours. Because the absolute daily risk of bleeding is low even when the INR is excessively prolonged, many physicians manage patients with INR values of 4.0 to 9.0 by simply holding warfarin and monitoring more frequently,³⁸ unless the patient is at a higher risk of bleeding or bleeding has already developed. Vitamin K₁ can be administered by the intravenous, subcutaneous, or oral routes. Intravenous injection may rarely be associated with anaphylactic reactions, but it does lead to reversal of the INR more quickly than oral or subcutaneous vitamin K₁.³⁹ The response to subcutaneous vitamin K₁ may be unpredictable and sometimes delayed.⁴⁰ Recent studies confirm earlier reports that oral administration is predictably effective, more so than subcutaneous administration and has the advantages of safety and convenience over parenteral routes. Ideally, vitamin K₁ should be administered in a dose that will quickly lower the INR into a safe, but not subtherapeutic range, without causing resistance when warfarin is reinstated.^{41,42} High doses of vitamin K₁, although effective, may lower the INR more than is necessary and lead to warfarin resistance for up to one week.

In the presence of significant bleeding, the INR must be reversed immediately. This can be done by replacing the vitamin K–dependent factors using FFP. At least 15 to 30 mL/kg of FFP should be given to have a significant impact on factor replenishment.^{43,44} In the average 70-kg person, this equates to 4 to 8 units of FFP which may take up to 6 to 24 hours to order, thaw, and infuse, and in some patients may put an undue stress on the heart. Additionally, the half-lives of the individual vitamin K–dependent factors govern the durability of any response. More FFP might be required. In a patient with life-threatening bleeding, especially intracranial hemorrhage, maximal factor replacement must be achieved in the shortest interval possible. This can be achieved by using factor concentrates which have high factor concentrations in a small volume.⁴⁵ Prothrombin concentrates, containing the vitamin K dependent factors, have traditionally been used, but with the recent development of specific recombinant factors, PT concentrates are less available. Most recently, studies have shown that recombinant factor VIIa (NovoVII) can reverse the coagulopathy and associated bleeding induced by warfarin, as well as in other coagulopathies.^{46,47} Given the expense of these agents, one should use the lowest effective dose to control the bleeding. Prothrombin concentrates are often dosed in a range of 25 to 50 IU/kg, but the specific dose will depend on body weight, degree of INR prolongation, and desired level of correction. The same considerations are relevant for the dosing of recombinant rFVIIa, although the range of dosing reported empirically ranges from approximately 20 µg per kilogram body weight to more than 100 µg per kilogram body

weight. Both PT concentrates and rFVIIa have the potential to induce a prothrombotic state, and thromboembolism has occurred as a result of such therapy.^{48,49} Table 40-5 outlines the 2004 American College of Chest Physicians (ACCP) recommendations for managing patients on coumarin anticoagulants who need their INR lowered because of actual or potential bleeding.³⁶

The decision to cover a patient who presents to one's office with a subtherapeutic INR is similar to a bridging decision. If the thrombogenic risk is so high (such as within the first week or two of treating new DVTs and/or PEs) that even a few days at a subtherapeutic level places the patient at high risk, then treating the patient with LMWH for a few days until a therapeutic INR is achieved with higher doses of warfarin is appropriate. In most cases, this intervention is not needed, and simply raising the dose of warfarin is sufficient to reestablish a therapeutic range in a few days.

Management of Oral Anticoagulation During Invasive Procedures

Clinicians are often confronted with the challenge of managing anticoagulation in individuals requiring noncardiac surgery or other invasive procedures, especially in individuals with prosthetic heart valves who are currently taking warfarin (see Chapter 38). There is a paucity of critical studies examining the alternative choices for anticoagulation (called bridging therapy) in this setting. Physicians must assess the risk of bleeding from a procedure if anticoagulation is continued versus the risk of thrombosis if anticoagulation is discontinued, as well as the cost of alternative anticoagulation options. Recent reviews have addressed the management of these patients and the options available,⁵⁰ and the ACCP has made formal recommendations.³⁶ Historically, full-dose, intravenous unfractionated heparin had been the standard for patients who need full anticoagulant protection that is readily reversible before a procedure. Its major drawbacks are the complexity and cost associated with intravenous heparin therapy and hospitalization. Low molecular weight heparin (LMWH) offers another, less complex alternative in that it requires no monitoring and can be given at home.^{51–58} LMWH has been shown to achieve therapeutic anticoagulation more rapidly than UFH and a more consistent therapeutic level during the course of bridging.⁵⁸ LMWH is usually given at a therapeutic dose, but in situations where the thrombotic potential is lower, and bridging is still believed to be needed, a prophylactic dose may be suitable. Several recent prospective cohort studies or registries have clarified the risks of bleeding or thrombosis associated with the use of LMWH (Table 40-6).^{53–57} What is still unclear, however, is a better understanding of exactly who needs an alternative anticoagulant during the brief period that warfarin is held before and after a procedure.

When bridging therapy is implemented, warfarin is usually discontinued 4 or 5 days before the procedure and the INR is allowed to decline. LMWH is started 2 or 3 days before the procedure, usually at a full treatment dose (100 to 150 anti X_a U/kg subcutaneously) once or twice daily depending on the risk of thrombosis, with the last dose given the morning or night before the procedure (approximately 12 to 24 hours prior to the procedure).

Table 40-5 Recommendations for Managing Elevated INRs or Bleeding in Patients Receiving VKAs*

Condition	Description
INR above therapeutic range but <5.0; no significant bleeding	Lower dose or omit dose, monitor more frequently, and resume at lower dose when INR therapeutic; if only minimally above therapeutic range, no dose reduction may be required (Grade 2C)
INR $\geq$ 5.0 but <9.0; no significant bleeding	Omit next one or two doses, monitor more frequently and resume at lower dose when INR in therapeutic range. Alternatively, omit dose and give vitamin K ₁ ($\leq$ 5 mg orally), particularly if at increased risk of bleeding. If more rapid reversal is required because the patient requires urgent surgery, vitamin K ₁ (2 to 4 mg orally) can be given with the expectation that a reduction of the INR will occur in 24 h. If the INR is still high, additional vitamin K ₁ (1 to 2 mg orally) can be given (Grade 2C)
INR $\geq$ 9.0; no significant bleeding	Hold warfarin therapy and give higher dose of vitamin K ₁ (5–10 mg orally) with the expectation that the INR will be reduced substantially in 24–48 h. Monitor more frequently and use additional vitamin K ₁ if necessary. Resume therapy at lower dose when INR is therapeutic (Grade 2C)
Serious bleeding at any elevation of INR	Hold warfarin therapy and give vitamin K ₁ (10 mg by slow IV infusion), supplemented with fresh plasma or prothrombin complex concentrate, depending on the urgency of the situation; recombinant factor VIIa may be considered as alternative to prothrombin complex concentrate; vitamin K ₁ can be repeated every 12 h (Grade 1C)
Life-threatening bleeding	Hold warfarin therapy and give prothrombin complex concentrate supplemented with vitamin K ₁ (10 mg by slow IV infusion); recombinant factor VIIa may be considered as an alternative to prothrombin complex concentrate; repeat if necessary, depending on INR (Grade 1C)

*If continuing warfarin therapy is indicated after high doses of vitamin K₁, then heparin or LMWH can be given until the effects of vitamin K₁ have been reversed and the patient becomes responsive to warfarin therapy. It should be noted that INR values >4.5 are less reliable than values in or near the therapeutic range. Thus, these guidelines represent an approximate guide for high INRs.
INR, International Normalized Ratio; IV, intravenous.

Table 40-6 Recent Studies of LMWH Used as Alternative (Bridging) Therapy in Patients on Warfarin Requiring Invasive Procedures

Study	Patients	Bridging Regimen	Postoperative Follow-up (wks)	Major Bleeding (95% CI)	Thrombosis
Turpie ⁵⁶	174	Enoxaparin 1 mg/kg bid	4	2.3% (0.06–5.7)	0.6%
Kovacs ⁵³	224	Dalteparin 200 IU/kg qd	4	6.7% (4.1–108)	3.6% (1.8–6.9)
Dunn ⁵⁷	260	Enoxaparin 1.5 mg/kg qd	2	3.5% (1.6–6.5)	1.5%
Spyropoulos ⁵⁵	668	Enoxaparin/dalteparin 1 mg/kg 100 IU/kg bid	4	3.3% (2.0–5.1)	0.9%
Douketis ⁵⁴	650	Dalteparin 100 IU/kg bid	1	0.9% (0.4–2.0)	0.3%

bid, Twice daily; qd, every day.

It is then restarted about 12 hours after the procedure along with warfarin. If the risk of postoperative bleeding from the procedure is high, LMWH can be restarted in 24 to 48 hours, rather than 12 hours. When the INR becomes therapeutic, LMWH therapy is stopped. Studies suggest that LMWH is a simple and reasonably inexpensive alternative for full anticoagulation protection,⁵⁹ but randomized, controlled trials are still needed to identify the best means of alternative anticoagulation. Table 40-7 summarizes the 2004 ACCP Chest Consensus Conference recommendations for management of oral anticoagulation during invasive procedures.³⁶

Dental procedures represent a particularly common intervention for patients on anticoagulants. A recent comprehensive review of the subject indicated that, in most cases, no change in the intensity of anticoagulation is needed.⁶⁰ If there is need to control local bleeding, tranexamic

acid or ϵ -aminocaproic acid (EACA) mouthwash have been used successfully without interrupting anticoagulant therapy.^{61,62}

Diagnostic Evaluation of Bleeding

When bleeding occurs, especially from the gastrointestinal or urinary tract, it is important to consider the possibility of a serious, underlying occult lesion as the source of bleeding. A number of descriptive studies indicate the probability of finding such a lesion.^{63–66} Coon and Willis⁶⁴ identified occult lesions responsible for bleeding in 11% of 292 patients with hemorrhage. Jaffin and coworkers⁶⁵ found a 12% prevalence of positive stool occult blood tests in 175 patients on warfarin or heparin compared with 3% in 74 controls. There was no difference between the mean PT or PTT in patients with or without lesions. In

Table 40-7 Recommendations for Managing Anticoagulation Therapy in Patients Requiring Invasive Procedures (all Grade 2C)

Condition	Description
Low risk of thromboembolism*	Stop warfarin therapy approximately 4 d before surgery; allow the INR to return to near normal; briefly use postoperative prophylaxis (if the intervention itself creates a higher risk of thrombosis) with a low dose of UFH (5000 U BID SC) or a prophylactic dose of LMWH and simultaneously begin warfarin therapy; alternatively, a low dose of UFH or a prophylactic dose of LMWH can also be used preoperatively.
Intermediate risk of thromboembolism	Stop warfarin approximately 4 d before surgery; allow the INR to fall; cover the patient beginning 2 d preoperatively with a low dose of UFH (5000 U BID SC) or a prophylactic dose of LMWH and then commence therapy with low-dose UFH (or LMWH) and warfarin postoperatively; some individuals would recommend a higher dose of UFH or a full dose LMWH in this setting.
High risk of thromboembolism†	Stop warfarin approximately 4 d before surgery, allow the INR to return to normal; begin therapy with a full dose of UFH or a full dose of LMWH as the INR falls (approximately 2 d preoperatively); UFH can be given as an SC injection as an outpatient, and can then be given as a continuous IV infusion after hospital admission in preparation for surgery and discontinued approximately 5 h before surgery with the expectation that the anticoagulant effect will have worn off at the time of surgery; it is also possible to continue with SC UFH or LMWH and to stop therapy 12–24 h before surgery with the expectation that the anticoagulant effect will be very low or have worn off at the time of surgery.
Low risk of bleeding	Continue warfarin therapy at a lower dose and operate at an INR of 1.3–1.5, an intensity that has been shown to be safe in randomized trials of gynecologic and orthopedic surgical patients; the dose of warfarin can be lowered 4 or 5 d before surgery; warfarin therapy can then be restarted postoperatively, supplemented with a low dose of UFH (5000 U SC) or a prophylactic dose of LMWH, if necessary.

*Low risk of thromboembolism includes no recent (>3 mo) venous thromboembolism, atrial fibrillation without a history of stroke or other risk factors, and bileaflet mechanical cardiac valve in the aortic position.

†Examples of a high risk of thromboembolism include recent (<3 mo) history of venous thromboembolism, mechanical cardiac valve in the mitral position, and old model of cardiac valve (ball/cage).

INR, International Normalized Ratio; LMWH, low molecular weight heparin; SC, subcutaneous; UFH, unfractionated heparin.

16 patients evaluated, 15 had a lesion not previously suspected and 4 had neoplastic disease. Landefeld and coworkers⁶³ found 14 of 41 patients with gastrointestinal bleeding to have important remediable lesions of which two were malignant. This limited information supports the need for investigation because if occult blood is found in the stool, there may be a 5% to 25% chance of finding a malignant source.

In a randomized controlled study, Culclasure and coworkers⁶⁷ found microscopic hematuria at a prevalence of 3.2% in a warfarin-treated group compared with a prevalence of 4.8% in their non-anticoagulated control group. There was no difference in the rate of hematuria with therapeutic or high INRs. Following a second episode of hematuria, 43 patients (32 anticoagulated and 11 control) were investigated; 27 of 32 (84%) of the anticoagulated and 8 of 11 (73%) of the control patients were found to have significant underlying diseases with a total of 3 patients (from both groups) having cancers (7%). These findings are in contrast to results of other case series identifying a much higher likelihood of finding underlying lesions in patients who develop hematuria while receiving anticoagulant therapy.^{68–70}

PREDICTING AND MANAGING THE RISKS OF ORAL ANTICOAGULANT THERAPY

Over the last 20 years, several developments have improved the safety and efficacy of oral anticoagulation. These include defining the optimal intensity of therapy by well-designed randomized trials and standardizing the reporting

of PTs using the INR, leading to more appropriate and standardized therapy. Identifying the risk factors associated with bleeding has also advanced. Time in therapeutic range (TTR) is an important measure of the quality of anticoagulation care, and a strong relationship exists between TTR and either bleeding or thrombosis rates as demonstrated by Cannegieter and colleagues,⁷¹ Hylek and coworkers,^{72,73} and others.^{74,75} Besides TTR, a number of patient characteristics serve as risk factors for bleeding. These include age, a history of bleeding (especially gastrointestinal bleeding), a history of stroke, and the presence of a comorbid condition such as renal insufficiency, anemia, or hypertension.^{36,76}

Anticoagulation Management Services

A coordinated and focused approach to the management of therapy by specialized programs (anticoagulation clinics) significantly improves clinical outcomes by improving therapeutic control and TTR, lessening the frequency of hemorrhage or thrombosis, and decreasing the use of medical resources, leading to more cost-effective therapy. These programs are characterized by a knowledgeable provider whose primary responsibility is to manage therapy, an organized system of follow-up, rapid and reliable INR monitoring, and good patient communication and education.

Most patients receiving chronic oral anticoagulation today are managed by their personal physician (characterized as usual care) along with all other patients in their physician's practice without an organized program of management, education, or follow-up.^{36,77} Studies indicate a rate of major hemorrhage of at least 7% to 8% per

patient-year of therapy.^{36,78,79} There is a similar rate of recurrent or de novo thromboembolism for an overall serious adverse event rate of at least 15% per patient-year of therapy. These adverse events are generally a consequence of poor therapeutic control with hemorrhage or thrombosis occurring as a consequence of excessive or subtherapeutic anticoagulation. These outcomes can be contrasted to the rates identified in studies of care delivered by an anticoagulation management service (anticoagulation clinic),^{36,80–84} which indicate a more than 50% reduction in both major hemorrhage and thrombosis compared with usual care. A few studies also suggest a significant cost benefit to coordinated care compared with usual care by a reduction in adverse events and reduced use of hospital services.

PATIENT SELF-TESTING AND PATIENT SELF-MANAGEMENT

As a result of technological advances in PT measurement, there is potential for further simplifying and improving anticoagulation management by point-of-care (POC) testing.⁸⁵ POC testing allows for the determination of a PT from a finger stick sample of whole blood, and consequently, opens the possibility for patient self-testing. Portability of instrumentation means that INR measurements are no longer confined to the physician's office, a private laboratory, or a nearby hospital, but can be moved into the patient's home or even taken with the patient when traveling. Standardization of reagents and instruments, as well as reliance on the INR, further reduce the inaccuracies of multiple reagents and laboratories. In depth discussion of instrumentation for PT monitoring can be found in Chapter 41.

These POC instruments have been tested in a number of different clinical settings and their accuracy and precision are considered to be more than adequate for the monitoring of oral anticoagulant therapy in both adults and children^{86–93} and it is possible that this new model of care is significantly more reliable and consistent than the variable and haphazard PT monitoring often employed in the usual care of most patients on oral anticoagulants.⁹⁴ Use of these instruments is particularly rational for patients on prolonged or indefinite anticoagulant therapy.

A number of studies have demonstrated the ability of patients to perform self-testing and to obtain an accurate result. Patients can then call their physician and obtain instructions for warfarin dose adjustment, or select patients can manage their own warfarin dosing after proper training.^{95–109} Based on the foregoing, POC PT monitors offer the potential to improve the risk:benefit profile of anticoagulant therapy; to improve patient satisfaction, patient involvement, and possibly patient compliance; and by reducing the labor intensity of physician management, to encourage the more widespread use of warfarin. The cost effectiveness of such therapy needs to be studied.

Chapter 41

Point-of-Care Testing for Hemostatic Disorders

Kendra Kubiak, MD • B. Gail Macik, MD

With the consolidation of clinical laboratories to buildings often miles away from the patient, the “turn-around time” for a laboratory result is lengthening. For routine tests, consolidation improves cost effectiveness and is unlikely to be detrimental to patient care. However, if the patient is bleeding or is receiving a hemostatic drug, delayed testing cannot accurately monitor the rapidly changing clinical situation. Several coagulation testing systems are available that perform whole-blood prothrombin time (PT), partial thromboplastin time (PTT), heparin monitoring, platelet function studies, and other tests of hemostatic function near the site of patient care.¹ Some point-of-care (POC) technologies offer testing superior to that performed in the centralized laboratory or that is otherwise unavailable. Other technologies are not as precise as those available in the laboratory but provide clinically equivalent results that expedite care.

In 2005, a survey reported the availability of 13 analyzers manufactured by seven companies for measuring hemostasis at the point of patient care.¹ The use of these instruments has become an integral part of patient management. The POC market has grown in response to the demands of cardiologists, interventional radiologists, surgeons, and anesthesiologists whose increasingly complex interventions require a cadre of antiplatelet and anticoagulant drugs. Real-time monitoring of these drugs is a necessary component of care. In order to function as a consultant to the procedure-oriented specialties, the hematologist must be familiar with the technologies that are emerging to monitor hemostasis and drug effect for the best procedural outcome.

In addition to hospital use, POC monitoring of warfarin in the outpatient and home setting is a rapidly growing market. In 2002, Medicare began to cover the home use of POC INR (International Normalized Ratio) monitors for patients with mechanical heart valves on warfarin, a population of almost 600,000 in the United States.² The growth of home POC warfarin monitoring is a function of increased patient satisfaction with a technology that saves time and visits to the doctor’s office or laboratory. Patients gain a sense of competence in being able to contribute to their own management. In order to support this growing field of POC monitoring, the consultant hematologist must become familiar with the technology that is changing warfarin management.

The practicing hematologist must also be familiar with regulations governing the use of laboratory instruments. The Clinical Laboratories Improvement Act (CLIA) is a set of guidelines outlining the training and regulatory

requirements necessary to operate any laboratory instrument. Instruments are rated as low or high complexity depending on the level of expertise required to operate the instrument and interpret the results. A special “waived” category exists for very simplistic tests that require little expertise. Any individual or institution engaged in using laboratory instruments must register for CLIA approval unless the only instruments or tests performed are in the “waived” category.

When is a POC test indicated? The most obvious answer is when the test does not exist in the central laboratory. For example, most centralized laboratories offer no equivalent to the activated clotting time (ACT) for monitoring high-dose heparin during cardiac interventions and surgery. The need for time-sensitive information is another indication for POC testing. On the one hand, if a drug or clinical condition is of brief duration, waiting even 1 or 2 hours for a result from the central laboratory indicates only what *was* happening and not what *is* happening to the patient. On the other hand, obtaining a test result within minutes if no clinical decision will be made for hours is not appropriate use of POC testing. A POC instrument may improve care by enabling patient self-testing and management. For example, monitoring of warfarin by home PT instruments has the potential to improve anticoagulation control.

What are the cost implications and medical-legal implications of POC testing? POC tests usually cost more per test than similar automated batch testing performed in the central laboratory. Cost effectiveness, however, must take into account the effect on all aspects of care. Does rapid testing lead to improved outcome and fewer complications? Does the patient spend less time in the operating room or the hospital? Is the medical professional able to work more efficiently and cost effectively? Is the patient spared unnecessary blood transfusions or medical interventions? Currently, clinical trials are underway to answer the above questions and validate the perceived benefit of POC testing. Because all the POC tests discussed in this chapter have U.S. Food and Drug Administration (FDA) approval, medicolegal questions regarding the use of these instruments have not been an active concern.

OVERVIEW OF HEMOSTATIC POINT-OF-CARE TESTING

Evaluating the array of instruments for POC testing is a daunting experience. Knowing the characteristics and

limitations of the technology improves the chance of selecting an appropriate test system.³ The ideal POC test system is rapid, accurate, easy to use, durable, transportable, and of low cost. Additional desirable features include sample recognition software, continuous electronic monitoring of the system, electronic quality control, a program for transferring results to an information system, and a compact design to compete for space in the crowded workplace.^{1,4} Fresh fingerstick samples are popular because of the ease and rapidity of collection, but citrated samples allow repeat testing and addition of other tests to the same sample.

Choice of sample, adaptation of quality-control procedures, correlation to plasma-based assays, and determination of reference ranges are particular challenges for coagulation POC testing systems. New instruments have appeared, and older systems have been given new names as technology and distributors change. All systems in this review are cleared by the FDA for marketing. Other technologies are available for “research use only,” but they are “not for use in diagnostic procedures.” No specific endorsement or ranking of tests is implied. To expedite inquiries regarding a product, Table 41-1 lists the contact information

for manufacturers and distributors discussed in this chapter. To help follow the course of a technology, earlier generations of the same instruments that have different names than the current model are listed also.

OVERVIEW OF PLATELET FUNCTION ANALYZERS

The surgeon and internist alike dread the management of the patient with an undefined coagulopathy. Common causes of excessive bleeding or oozing at the site of surgical procedures are platelet dysfunction that may be drug induced or congenital or von Willebrand disease (VWD). Traditional laboratory assessment of platelet function is complicated, time consuming, and limited in scope. POC technologies are available that provide global assessment of primary hemostasis. The instruments are easy to use, provide results in less than one hour, and in some cases, provide information not available from larger laboratory instruments. As with most POC, monitoring of therapy (either blood product replacement or antiplatelet drugs) is the most common reason for requesting a platelet analyzer. Table 41-2 lists the platelet monitoring POC analyzers available. The instrument systems differ in the ease of use, parameters tested, and applicability of the test for detecting platelet and/or von Willebrand factor (VWF) abnormalities.⁵ Compared with the bleeding time and platelet aggregation studies, the results of POC may prove more clinically relevant than existing test methods.

VerifyNow (Ultegra) Instrument

The VerifyNow Instrument has replaced the Ultegra Rapid Platelet Function Assay (RPFA) (Accumetrics, San Diego, Calif., USA) in the assessment of platelet dysfunction induced by drugs such as inhibitors of the glycoprotein (GP)-IIb/IIIa receptor (i.e., abciximab and eptifibatide),

as well as by aspirin and clopidogrel. The VerifyNow IIb/IIIa instrument, which measures inhibition of the GP-IIb/IIIa receptor by both abciximab and eptifibatide, performs a semiquantitative, whole-blood platelet function assay.⁶⁻⁸ During testing, platelets are first activated to express GP-IIb/IIIa receptors that bind to the fibrinogen-coated beads and induce agglutination; however, agglutination is inhibited in the presence of abciximab and eptifibatide. The degree of agglutination is detected by a turbidimetric-based optical system, and the result is reported as a platelet aggregation unit (PAU). The assay, which requires 10 minutes to complete, can be used to determine the degree of platelet inhibition in a patient by comparing the PAU measured before and after infusion of the drug.

Similarly, the VerifyNow aspirin assay measures aspirin-induced platelet inhibition. A lyophilized preparation containing human fibrinogen-coated beads and a platelet agonist is added to the patient sample and platelet aggregation is detected as an increase in light transmittance. The Ultegra VerifyNow aspirin test has been demonstrated in the literature to reliably assess patient response to aspirin therapy and has received a CLIA waiver for this use.⁹

The newest assay, the VerifyNow P2Y₁₂, was cleared by the FDA in August, 2005 for the assessment of the inhibition of the P2Y₁₂ receptor on platelets. The assay does not require a baseline blood sample because the instrument has a second channel in which the platelet inhibition is overcome and a baseline value is calculated. It is the first assay cleared by the FDA to directly quantify platelet inhibition by clopidogrel. The assay is being marketed for the management of patients on chronic clopidogrel therapy; it is also used in the perioperative setting to determine if a patient who has discontinued clopidogrel prior to a procedure continues to exhibit ongoing significant platelet dysfunction.

The VerifyNow assays require a citrated whole blood sample tested within 15 minutes of collection. The evacuated blood-draw tube attaches directly to the instrument. The analyzer automatically dispenses blood into the cartridge.

Table 41-2 Platelet Function Analyzers for Point-of-Care Testing

Company	Instrument	Test Method	Procedure
Accumetrics San Diego, CA 800-643-1641 www.accumetrics.com	VerifyNow Assays	Monitor platelet inhibition by ASA, clopidogrel, IIb/IIIa inhibitors Optical detection of fibrin-coated bead agglutination; drug decreases agglutination	Simple—no pipet sample or sample prep

Dade Behring Deerfield, IL 847-267-5300 www.dadebehring.com	PFA-100	Occlusion of an aperture in a collagen/ADP or collagen/epinephrine cartridge tests platelet adhesion (VWF), activation, aggregation, all in a flow system	Simple—pipet sample
Medtronic Cardiac Surgery Minneapolis, MN 800-328-3320 www.medtronic.com	HMS Plus: ACT, heparin dose response, heparin protamine titration	Indirect test of platelet function related to platelet activating factor (PAF)-induced shortening of the ACT	Simple—requires the HMS system

The result is available in 3 to 5 minutes. Concomitant medications that do not alter results include acetaminophen and other nonsteroidal anti-inflammatory drugs, β -adrenergic blockers, calcium channel blockers, "statins," and nitrates. Variable platelet counts between 100,000 and 350,000/ μ L, hematocrits between 25% and 45%, and fibrinogen levels between 200 and 600 mg/dL do not affect the assay results. Other GP-IIb/IIIa inhibitors affect the baseline PAU. Previous clinical trials report that the Ultegra RPFA is equivalent to a radiolabeled abciximab receptor blockade assay or platelet aggregometry for monitoring abciximab therapy.^{7,8} Data regarding the VerifyNow are currently being collected.

Whole Blood Aggregation

The Whole Blood Aggregometer (WBA) is a modified version of the larger platelet aggregometer manufactured by Chrono-log Corporation (Havertown, Penna., USA). Both systems use electrical impedance to study platelet aggregation in whole blood. An accurate platelet aggregation result can be obtained within 7 minutes of venipuncture. A citrated whole blood sample is diluted with an equivalent volume of isotonic saline and incubated at 37°C. Platelet aggregation is detected by passing a weak electrical current between two electrodes immersed in the sample and measuring the impedance between the electrodes. Platelet aggregation occurs at the electrodes, increasing the impedance. The increase in impedance is directly proportional to the platelet mass deposited on the electrode probe. The final increase in ohms is displayed as a numeric LED readout in a front panel digital display. Analog outputs provide the option to interface a chart recorder for a hard copy record of the aggregation curves.

Measuring 6 $\times$ 13 $\times$ 9 inches and weighing 10 pounds, the WBA was designed to be smaller, simpler, and more portable.¹⁰ One or two test channels are available. New disposable electrodes simplify testing by eliminating the need to sanitize the electrodes between tests. Automated calibration and readout functions and electronic quality control are provided. An optional printer and data management software are offered. Limitations include the lack of a positive identification system for the patient specimen and the lack of an onboard system for automatic error detection.

The WBA performs all the studies available with the larger instruments, but the smaller design makes it better suited for perioperative or antiplatelet drug monitoring. Like the parent model, the WBA may be used to detect platelet function abnormalities that increase bleeding risk during surgery.^{11,12} For drug monitoring, Mascelli and coworkers¹⁰ report that the WBA predicts the amount of GP-IIb/IIIa receptor blockade induced by the drug abciximab.

PFA-100 Platelet Function Analyzer

The PFA-100 Platelet Function Analyzer (Dade-Behring, Deerfield, Ill., USA) is an automated alternative to existing techniques for assessing platelet function.¹³⁻¹⁵ The PFA-100 measures platelet function under flow conditions that mimic the process of primary hemostasis in a damaged blood vessel. Whole blood passes through an aperture cut into a membrane coated with collagen and either epineph-

rine or ADP. The system measures the ability of platelets to occlude the aperture and reports the closure time. The biologic stimuli and the high shear rates generated by the standardized flow result in platelet attachment, activation, and aggregation; therefore, the system can detect defects at any stage of platelet function.

The analyzer measures 15.1 $\times$ 9 $\times$ 14.2 inches, weighs 24 pounds, and is best classified as a bench-top instrument. The disposable test cartridges contain all components for test performance. The collagen/epinephrine (CEPI) cartridge is used first to screen for platelet dysfunction induced by intrinsic platelet defects, VWF defects, or inhibitory drugs or substances. The collagen/ADP (CADP) cartridge is used only if the CEPI cartridge is abnormal. The CADP does not detect aspirin and, therefore, a prolonged CEPI with a normal CAPD suggests an aspirin-like side effect. Citrated whole blood, 800 μ L, is transferred into the sample reservoir of the cartridge by pipet. Results are reported as closure times in seconds. Platelet counts of less than 100,000/ μ L affect the closure time, as does a hematocrit of less than 15% to 20%. Heparin and oral anticoagulants do not affect the closure time, but antiplatelet drugs do.¹⁶⁻¹⁸ Neither electronic nor wet quality-control materials are available, so fresh control blood is required with each new lot of cartridges. Systems for automatic error detection and for identification of patient specimen and reagent are provided. Patient data can be transferred to an information system, but data management capability is lacking. Disadvantages include open sample handling, use of pipet, lack of defined quality controls, and negative effect of moderately decreased platelet counts.

Several studies support the usefulness of the PFA-100 in a variety of clinical settings.¹³⁻²³ The instrument can be used to help diagnose VWD,^{17,18} monitor antiplatelet drugs including abciximab,^{13,16,19} detect aspirin effects,^{13-16,20} and uncover congenital²¹ and acquired²² platelet function defects. The instrument has also been used to evaluate platelet-induced hemostasis in the pediatric population.²³ However, data do not support the routine use of the PFA-100 before surgery because the test does not predict surgical bleeding.

In a representative study by Ortel and coworkers,¹⁴ 305 patients from 12 different clinical settings were enrolled in a study to evaluate the PFA-100 in a population typical of a tertiary care practice. Of these patients, 29% reported a previous blood transfusion, 29% reported taking aspirin, and 19% were on oral anticoagulants. Of this population, 37% had a prolongation of the closure time. Isolated prolongation of the CEPI closing time for patients on aspirin was the most common abnormality (69%). Conversely, only 68% of patients who reported taking aspirin had a prolonged closure time. The study was not designed to correlate bleeding risk with closure times, and there was no correlation between results with hemorrhagic symptoms or a history of blood transfusions. In all, 93.5% of the patients with a prolonged closure time were found to have a specific quantitative or qualitative abnormality in platelet or VWF function. Other studies report 88% to 100% sensitivity for uncovering an underlying defect.¹³⁻²³ The PFA-100 advantages include its rapidity (results in 5 minutes), simplicity (three-step procedure), and global assessment of primary hemostatic function.

HemoSTATUS Platelet Activated Clotting Test

The HemoSTATUS assay is a family of cartridges used to measure platelet function using the Hepcon HMS analyzer (Medtronic Perfusion Systems, Minneapolis, Minn., USA). The Hepcon HMS platform is discussed subsequently. The system is used during cardiopulmonary bypass to determine pre-, intra-, and postoperative hemostasis. The test is a modified clotting time study that is designed to isolate and test platelet function. Platelet activating factor (PAF) is a potent, endogenous platelet activator that stimulates *in vitro* clot formation. Increasing concentrations of PAF are present in channels 3 to 6 of the cartridge, whereas channels 1 and 2 serve as controls. A kaolin-activated clotting time (k-ACT) is determined for each channel. Platelet procoagulant activity is determined by measuring the PAF-induced shortening of the k-ACT. A whole blood sample is collected in a 3-mL syringe that is then secured to the Hepcon HMS instrument. The instrument automatically distributes a 0.3 mL volume to each of the six channels in the self-contained test cartridge. Results are shown as a percentage of normal function. Based on these results, the HemoSTATUS test results are interpreted as low incidence of platelet-related bleeding (80% to 120%); moderate incidence of platelet-related bleeding (60% to 80%); and high incidence of platelet-related bleeding (0% to 60%).

The HemoSTATUS test has been reported to correlate with blood loss after cardiac bypass surgery,²⁴ but other investigators have found no correlation.²⁵ The test has been used to evaluate the effect of DDAVP during surgery,²⁶ to detect GP-IIb/IIIa blockade by abciximab,^{27,28} and to evaluate the need for platelet transfusion perioperatively.²⁹ ϵ -Aminocaproic acid (EACA) and aspirin do not affect the HemoSTATUS test.^{27,29} Platelet counts must be above 50,000 to 70,000/ μ L and the white blood count must be between 4000 and 9000/ μ L.²⁸ The controlled, reproducible test procedure is an advantage that is offset by the need for a large, expensive instrument.

OVERVIEW OF CLOT-DETECTION ANALYZERS

When is a second not a second? The answer is when the second is a result of a coagulation assay. Clotting time is determined by assay design, not clinical condition. For example, 200 seconds of actual time may indicate a high heparin concentration for a PTT assay or it may be a normal clotting time for a whole blood ACT system. Simply put, clotting times are “man-made” and there is nothing “physiologic” about a 300-second clotting time. The result of a PT, PTT, or ACT test must be interpreted using the normal and therapeutic ranges determined specifically for the assay method.^{30–34} Technology designed for POC testing must provide clinical information equal to that obtained with a standard laboratory method. Equality does not imply identical form or numerical result.³ However, most manufacturers of POC testing systems succumb to clinical pressure and convert their results to a “plasma equivalent time” to mimic laboratory ranges. Satisfying clinical demand masks the true differences between testing systems. Results differ because of the sample type, reagent,

or detection method used by an instrument.^{3,30–32} Freshness of the sample may also affect the result because clotting factors degrade and drug effects decay. Mathematical conversion of data cannot correct for all these variables. A new test method is compared with an existing technology to provide a frame of reference. Dissimilar numerical results may correlate better than results altered to give the illusion of being the same number. The take-home message is: look for correlation between methods, but do not expect identical results when comparing different testing systems.

For the PT, the INR improves comparability between results obtained using different reagents and assay systems. However, the INR fails to “normalize” whole blood results reliably, cannot overcome inherent differences in clot detection methods, and cannot completely offset the effect of reagents with markedly different sensitivities (ISI).^{30–32} Heparin monitoring with the PTT or ACT test has become an even greater challenge as new reagents and detection methods have entered the market. No INR-like system exists to even attempt to “normalize” differences in heparin response curves observed with different reagents and testing systems.^{33,34} Against these obstacles, the following POC instruments are striving to be accepted as accurate and reliable alternatives to standard laboratory testing.

Home PT Testing Systems

Self-testing and self-management of warfarin has emerged as a reliable alternative to traditional provider-based care. In 1999, at the 17th Congress of the International Society on Thrombosis and Hemostasis, several presentations reported that the experience in multiple countries with patient self-monitoring led to improved hemostatic control and increased patient satisfaction. More than 50,000 patients in Germany are currently managing their own anticoagulation using CoaguChek.³⁵ Several studies report that patients can test, adjust dosage, and achieve therapeutic goals as well as or better than healthcare providers or an anticoagulation clinic.^{36–41} Complications of warfarin therapy decrease by as much as 76% if values remain in the therapeutic range.⁴² A recent prospective, controlled trial reported by Menedez-Jandula⁴³ compared both clinical outcomes and the quality of anticoagulation based on self-testing versus management by a conventional anticoagulation clinic in 737 patients. The self-management group ($n = 368$) achieved a 58.6% success rate for keeping the PT in the target range compared with 55.6% for the conventional management group. Both major complications and minor bleeding episodes occurred less frequently in the self-management group (2.2% vs 7.3% and 14.9% vs 36.4 %, respectively). The improved testing outcome is likely due to the increased number of INR determinations and dose adjustments performed, but the impact of patient motivation cannot be ignored. Additionally, less time is spent out of therapeutic range because of the immediate feedback of results. A new trial, known as the INR Study, is currently ongoing through the Veteran's Affairs Hospital System; this trial compares outcomes in patients who are self-testing with those who are being monitored in anticoagulation clinics. The acceptance of home testing grows as studies support improvement in patient care. In the United States, approval by Medicare to fund home monitoring for one subset of patients, mechanical heart valve patients,

further opens the door to affordable home testing options. Table 41-3 lists the home PT testing systems. For home testing, the instrument must be extremely easy to use with no pipeting and a limited number of steps. Long-term studies to verify the clinical impact of home management are ongoing, but a new standard for anticoagulation control is on the horizon. Several POC PT/INR systems have been FDA-approved for home testing, but only the ProTime (International Technidyne Corp) and the INRatio (HemoSense) are actively marketed.

ProTime Microcoagulation System/ProTime 3 (ProTime Micro 1995; ProTime 3 2001)

The ProTime microcoagulation analyzer is a CLIA-waived home-testing system. (International Technidyne, Edison, NJ, USA). The analyzer is a table-top device measuring $2.5 \times 4.5 \times 9$ inches and weighing 3 pounds. The system uses a fingerstick sample and the sample cup must be completely filled or an error message is generated. There is no electronic control, but the test card has integrated quality-control reaction chambers that allow controls to be run with every patient sample. It takes less than 5 minutes to generate a test result. The instrument sends data to a printer, and automated transfer of data to an information system is available.

The ProTime uses an optical method to detect clot formation. Blood is added to a sample cup on the test cartridge. The sample is drawn into five parallel reaction channels and mixed with the appropriate reagents. A sensitive thromboplastin reagent with an ISI equal to 1.0 is used. When the blood clots, it no longer flows past the optical detector and a clotting time is generated. The result is reported as a plasma equivalent clotting time with calculated INR. The two outside channels serve as high and low controls with appropriate modifiers added to the channels to produce a clotting time within a predetermined value. The three middle reaction channels test the patient's blood in triplicate and a mean value is reported.

The ProTime has been evaluated at many clinical sites and compared in several studies with laboratory and other POC devices.^{32,41,44} A representative correlation coefficient compared with a laboratory standard is 0.93 and imprecision studies reveal coefficients of variation of 3% to 6%. As for other POC PT monitors, the INR result shows a positive bias (i.e., overestimation on the lower end of the therapeutic range) when compared with standard laboratory methods.^{32,45}

Biasiolo and coworkers⁴¹ studied 150 patients presenting to the anticoagulation clinic in a 15-day period. The average difference between the POC and the laboratory method was 0.2 INR. A difference of more than 1.0 INR was obtained in 5 of 150 (3%) patients. In four of five discordant patients, the difference was clinically relevant and in two of five the error was noted to be due to delay in filling the sample chamber. On a smaller number of patients ($n = 30$), Chapman and coworkers⁴⁴ reported far more variation between the ProTime and a standard laboratory value, with a mean INR difference of 0.56 and 50% discordance in clinical management prompted by the result. Other studies, however, find the ProTime equivalent to other methods for managing anticoagulation therapy.⁴⁶ The integrated high and low controls are a clear advantage for the ProTime.

INRatio

The INRatio is a portable home PT monitor (HemoSense Inc., San Jose, Calif., USA) approved for use in 2002. The hand-held device measures $6.5 \times 3 \times 2$ inches and weighs 10.5 ounces. A fingerstick sample of about 15 uL (an accurate volume is not needed) is applied to the testing strip which contains three channels. The sample is then drawn into three separate testing areas by capillary action where it combines with several reagents. The system uses human recombinant thromboplastin for actual clot detection. Two other areas contain various reagents to create low and high clotting times for normal and therapeutic clotting ranges, respectively. Clot formation is detected by a change in the impedance of the sample and results are available within 2 minutes. Quality control is built into the testing strip and automated high and low quality-control checks are performed with each analysis as mentioned. The testing strips can be stored at room temperature. The machine automatically performs both electronic and procedure self-testing to ensure accurate results and can detect sources of error including strip re-usage, unacceptable temperature ranges, and inadequate blood sample. The meter has memory storage of up to 60 test results which can be downloaded to a computer or a printer. One recent study found good correlation between the results of the INRatio and laboratory testing both in the normal and therapeutic INR ranges.⁴⁷

ACT: activated clotting time; HiTT: high thrombin time; HNTT: heparin neutralizing thrombin time; HRT: heparin response test; KHRT: kaolin-based heparin response test; KPDAO: kaolin-based protamine titration assay; LR-ACT: low-range activated clotting time; MAX-ACT: maximum factor XII activation ACT test; PDAO: celite based protamine titration assay; PRT: protamine response test; TT: thrombin time.

CoaguChek S and CoaguChek XS

The CoaguChek PT monitoring system (Roche Diagnostics Corporation, Indianapolis, Ind., USA) is commonly cited in the literature.^{37,44,45,48,49} The updated version of the instrument, the CoaguChek S, is approved only for use in a physician's office. Now there is a further update, CoaguChek XS, with more quality-control features. Older versions of different POC PT devices known as the CoaguChek DM, PPO, or Plus are no longer being manufactured. The CoaguChek S measures 1.8 × 4.9 × 6.8 inches and weighs 1.0 pounds. A fingerstick or venous sample is required. The system has onboard error control and an electronic and liquid quality control feature. The CoaguChek S provides a test result in about one minute. The system does not have data management or download capability. The CoaguChek S information is available in multiple languages and results are reported as an INR, Quick %, or ratio.

Blood (approximately 10 µL) is applied to the sample well on the test strip and drawn by capillary action into a reaction chamber, where it is mixed with a dry PT reagent. Paramagnetic iron particles are present in the reaction chamber and they move in response to a magnetic field. Reflectance photometry detects change in particle movement with clot formation and the time is converted into a plasma equivalent clotting time and INR.

The system is a proven POC device, widely used in clinical trials.^{44,45,48,49} Numerous studies have found the imprecision to be between 3% and 6% and the representative correlation coefficients range from 0.9 to 0.97. Chapman and coworkers⁴⁴ reported a 0.28 INR average difference between the CoaguChek and the laboratory value, with an 8.3% discordance rate in clinical management decisions. The instrument is reliable and is gaining acceptance in the home market outside the United States. The CoaguChek is not actively marketed but supplies are available.

Multitest Systems: PT, PTT, ACT

Table 41-4 lists the analyzers offering a broader testing menu. These instruments are used primarily for monitoring anticoagulation therapy or for guiding blood product replacement for the perioperative or bleeding patient. Heparin monitoring is a particular strong suit of several of these test systems. Despite the growing use of low molecular weight heparin, unfractionated heparin remains the standard of care for many clinical settings. For high-dose anticoagulation during cardiopulmonary bypass and invasive vascular procedures, heparin has no current rival. These instruments are rated as moderate CLIA complexity and are designed for use by healthcare professionals.

i-STAT and i-STAT 1

The i-STAT and the i-STAT-1 are both portable coagulation analyzers (Abbot Point of Care, East Windsor, NJ, USA). The i-STAT has been extensively documented in the literature to provide reliable results with regard to PT/INR assessment.^{50–52} The i-STAT is a bedside instrument that measures $8 \times 2.5 \times 2$ inches and weighs 18 ounces; the i-STAT-1 analyzer measures $9.25 \times 3 \times 3$ inches and also weighs 18 ounces. Both analyzers require either a whole blood or a fingerstick sample which must be added as a fixed volume marked on the cartridge (i-STAT) or cuvette (i-STAT-1). Clot formation is detected by the conversion of a thrombin substrate which is detected by an electrochemical sensor. The devices are FDA-approved to perform PT/INR, Celite, ACT, and Kaolin ACT as well as additional approval for the performance of electrolytes, chemistries, and blood gases. Results are available in two minutes for the PT and slightly longer for the ACT. Both systems will detect error from inadequate sample. Electronic, lyophilized, and liquid quality control are available. Quality control is integrated with each analysis and there is an automatic lockout for QC failure. Data management capability is optional and both machines can transfer the data to an information system.

Actalyke XL/Actalyke Mini II

The Actalyke XL (Helena Point of Care, Beaumont, TX, USA) is another portable coagulation analyzer measuring $5.6 \times 10.7 \times 10.3$ inches and weighing 15 pounds. It requires a whole blood sample of discrete volume entered into a cuvette. The machine uses dual test wells with a two point clot detection mechanism—one at 0 degrees and another at 90 degrees—to determine earliest clot formation. During clot formation, a magnet moves from detector one to detector two, triggering an endpoint when it reaches 46 degrees. It is approved for the evaluation of the ACT, MAX-ACT, celite, kaolin, glass, and maximum factor XII activation. Results are available in five minutes. Electronic, liquid, and lyophilized quality control is available; QC is not performed with each analysis but lockout does occur for QC failure. The system does not have data management capability. The instrument is used primarily during cardiac procedures such as CPB, catheterization, and angioplasty but is also in use for heparin monitoring with dialysis. There is some evidence that the Actalyke will yield shorter ACT values after heparin bolus and during hypothermia.⁵³

The Actalyke Mini II is a bench-top version of the XL measuring $6 \times 6 \times 5$ inches and weighing 5.3 pounds. Its mechanism of clot detection is the same as for the XL except that it employs a single testing well. It is approved for the measurement of ACT, MAX-ACT, C-ACT, K-ACT, and G-ACT. Quality-control methods are the same as those for the XL.

GEM Portable Coagulation Laboratory

The GEM Portable Coagulation Laboratory (PCL) is a small, whole blood analyzer that is available free-standing or as a component of the IL Synthesis or IL GEM Premier 3000 comprehensive, compact portable laboratory systems for POC (Instrumentation Laboratory (IL), Lexington, Mass., USA). International Technidyne (ITC) and IL have formed a partnership to co-develop the coagulation

component. The GEM PCL offers PT, PTT, ACT (heparin concentration 1.0 to 6.0 U/mL), and low-range ACT (LRACT) (heparin concentration below 2.5 U/mL) tests. The ACT and LRACT report results in “celite-equivalent” clotting times.

The instrument is a portable handheld device measuring $5.5 \times 2 \times 3.5$ inches and weighing 0.75 pounds. The GEM PCL accepts fingerstick or venous whole blood for all tests and citrated whole blood for the PT and PTT. The technology for clot detection is identical to the Hemochron Jr., discussed later, but the software for the clot detection algorithms differs. The analyzer reads the encoded cartridges to determine test type. One drop of blood (approximately 50 μ L) is applied to the sample well. The system will display a low sample error if the sample well is not adequately filled. The system is equipped with electronic quality control or wet quality-control material. Outboard error management is present. A comprehensive data management system, downloading, and printing capabilities are available as part of the larger workstation. Results are available in less than five minutes for PT but may require longer for PTT and ACT. Results are stored automatically with time and date. The advantages of the system include the connection to a comprehensive POC testing workstation, the expanded menu of coagulation tests, and a comprehensive onboard data management system. The instrument may be disconnected from the workstation and carried to the bedside.

Hemochron Jr. Signature/Signature+

The Hemochron Jr. Signature is the smallest of the line of multitask analyzers manufactured by International Technidyne Corporation (ITC) (Edison, NJ, USA). The system performs the same panel of tests described for the GEM PCL-PT, PTT, ACT (celite), and LRACT—but the reagents and test interpretation may differ. The PT and PTT are available using either citrated or noncitrated whole blood; the ACT and LRACT accept fresh whole blood.

The instrument is a portable, handheld device measuring $2 \times 7.5 \times 3.75$ inches and weighing 12 ounces. The test cartridge is composed of a waste channel and a test channel and is encoded with test type and other parameters. The PT and PTT assays are available in about two minutes, with slightly longer times for ACT. Electronic control and wet quality-control material are available. The Signature package provides a keypad and onboard data management, including the ability to identify, store, date, time stamp, and print patient and quality-control test results. Transfer of the data to an information system is available. No positive identification of patient specimens is available, but the system does have an onboard system for error control.

Blood (approximately 15 μ L) is placed in the sample well of the cartridge and a 15- μ L aliquot is drawn into the test channel that contains test-specific reagents. Excess blood from the sample well is directed to a waste channel. The test sample is pumped back and forth across a window, blocking light transmission between an LED and a light detector. Clot formation is signaled when the blood ceases to move. Clotting times are converted to test specific results.

The test system compares favorably with the ACT performed on the larger Hemochron instrument and to the laboratory PTT.⁵⁴ Correlation of the PT with several other POC instruments found the PT to be adequate, but it

had the lowest correlation coefficient with the routine laboratory method ($r = 0.89$) and tended to underestimate INRs above 3.0.³² This instrument is not approved for home use. The advantages include a variety of test options, and an onboard data management program.

Hemochron Response

A Hemochron analyzer (International Technidyne Corporation, Edison, NJ, USA), which has been used to monitor heparin therapy for the past 30 years, is one of the first portable, rapid, whole blood coagulation analyzers.⁵⁵ Several versions of the instrument, including single-well (401), double-well (801), and data management-equipped (8000) models, have been marketed. The newest version, the Hemochron Response, uses fresh or citrated whole blood, offers an expanded test menu, and provides additional software for warfarin, protamine, and heparin management.

The system offers a full package for heparin management. The ACT monitors high-dose heparin therapy (heparin concentration 1.0 to 6.0 U/mL). To supplement the ACT, other heparin tests are available, including a PTT, a thrombin time (TT), the heparin-neutralizing thrombin time (HNTT), the high thrombin time (HiTT), the heparin response test (HRT), and the protamine response test (PRT). The HNTT and HiTT determine circulating heparin effect. The HRT and PRT together with patient-specific determinants (age, weight, baseline ACT) are used by the onboard Rx Dx management program to determine heparin and protamine dosage.

The instruments vary in size and weight depending on the specific version. A 1.5-mL sample must be accurately pipetted into the sample test tube or an evacuated tube must be used. Test results are available in 1 to 5 minutes depending on the test. Electronic quality control, an onboard system for instrument error detection, and wet quality-control material are available on all instruments. The Hemochron Response offers several features, including quality-control lockout, identification for patient and operator, downloading capabilities, and a bar-code reader to identify reagent tubes.

The technology for clot detection is the same for all versions. Clot formation is detected by a sensitive electromagnetic method. A magnet is located in the sample test tube. The magnet aligns with a magnet detector within the instrument test well. The test well(s) slowly rotates and incubates the test tube during the coagulation test. The magnet and magnet detector remain aligned until the formation of a clot displaces the magnet, signifying test completion. The time to clot formation is converted into a plasma equivalent time for PT, PTT and TT.

A recent study demonstrated coefficients of variation on whole blood for the ACT of 0.6% to 11.2% (celite) and 2.4% to 7.0% (kaolin).⁵⁶ Varying results have been reported with the heparin management programs.⁵⁷ Many comparison studies are available.^{33,42,58–60} The PT and PTT are rarely mentioned in the literature, especially since the arrival of easier-to-use, smaller-volume analyzers. Advantages of the Hemochron include the rapid, easy-to-perform ACT, the heparin package, and the years of testing experience. The need for a measured, large-volume sample is the most important disadvantage as the newer, small-volume instruments gain popularity.

ACT Plus

The ACT Plus Automated Coagulation Timer (Medtronic Perfusion System, Minneapolis, Minn., USA) is another work horse in the operating room and catheterization laboratory. Several different cartridges are available to allow for specific testing scenarios: High Range Activated Clotting Time (HR-ACT) for use with fresh whole blood in cardiovascular or vascular surgery and PTCA; Low Range Activated Clotting Time (LR-ACT) for use with fresh whole blood in dialysis, ECMO and therapeutic heparin monitoring; Heparinase test Cartridge (HTC) for use with fresh whole blood to determine if heparin is present; Recalcified Activated Clotting Time (RACT) for use in citrated whole blood samples; and General Purpose Cartridge (GPC) for use with citrated whole blood or plasma to perform PT/PTT tests. The analyzer measures 11 × 8 × 13 inches, weighs 11.5 pounds, and has two reaction wells that allow for duplicate testing. The test requires at least 15 µL of whole blood, which is added to the cuvette; clot detection is mechanical through impedance of the blood flow. A result is available in up to 12 minutes, slightly longer for high ACT values. The instrument displays the celite-equivalent ACT value. Electronic quality-control and lyophilized quality-control material are available. The system offers data management and a data transfer system. The ACT II, precursor to the ACT Plus, has been compared in numerous studies with other POC heparin monitors.^{58,59}

Hepcon HMS Hemostasis Management System

The Hepcon HMS (Medtronic Perfusion System, Minneapolis, Minn., USA) uses the same clot detection method as the ACT Plus; however, the Hepcon is fully automated. The system offers complex testing programs including the HemoStatus platelet function assay (earlier) and a heparin management program. The heparin studies use four- to six-chambered cartridges that contain varying concentrations of heparin or protamine. Patient-specific information (sex, weight, height) and the concentration of heparin desired are entered into the management program and an initial heparin dose is suggested. ACT is followed to monitor the patient's response and to adjust the dose. For heparin reversal, the protamine dose is determined in a similar manner. A protamine assay to determine the concentration of heparin is also possible.

The Hepcon HMS is the largest analyzer in the category of POC instruments and is more transportable than portable. It measures 14.5 × 16.5 × 9.5 inches and weighs 30 pounds. A 3-mL syringe is used to collect a fresh venous sample. The syringe is attached to the instrument and the sample is automatically dispensed to each of the wells within a cartridge. The instrument has electronic quality control and uses a wet quality-control material. A minimum of 12 minutes is required for a test result. The analyzer does not have data management capability and it cannot transfer data to an information system. An onboard error detection system guides the automatic pipetting. The major disadvantages are the size, price, and length of time required for the test to complete. Evaluations of clinical studies have been mixed regarding the usefulness of several of the management programs.^{60,61}

GLOBAL ASSESSMENT OF CLOT FORMATION

Other POC instruments are significantly different from extant devices in that they do not mimic existing laboratory tests, but monitor the viscoelastic properties of clot formation. The Thromboelastogram (TEG) has experienced many face-lifts since its debut in the 1940s. The SonoClot Coagulation and Platelet Function Analyzer debuted in the late 1980s. Both of these instruments provide a “clot signature” that traces the progression of clot formation and clot resolution. By analyzing the tracing produced by the instruments, a global assessment can be made of the function of platelets, the soluble clotting proteins, anticoagulants present, and fibrinolysis. The major disadvantages of these systems are the skills required to perform and interpret the test, but newer computerized instruments are entering the market and gaining popularity.

Thromboelastogram (TEG)

The complexity of the Thromboelastogram (Haemoscope, Skokie, Ill., USA) was a major deterrent to routine use of this system for patient monitoring. In recent years, the technology has been automated and computerized to provide more reproducible and interpretable measurements and the instrument has been streamlined into a true POC test. The test is performed by placing a small amount of whole blood (approximately 360 μ L) into a cylindrical cup. A pin is suspended in the blood. The cup remains stationary and the pin is rotated through an angle of 4°–45°. As clot forms and viscosity increases, the rotary motion of the pin is progressively inhibited. Characteristic tracings are developed based on the motion of the pin (a tracing is shown in Chapter 39, Fig. 39-1). The components of the tracing have been ascribed to various counterparts of physiologic clot development and dissolution. The “R” value describes the time to clot formation and is prolonged in factor deficiencies or with anticoagulation. The maximal amplitude (MA) of the tracing represents platelet activity and fibrinogen concentration. The time to clot lysis is measured 30 minutes after clot formation. In non-activated blood, more than 30 minutes are required for the generation of the MA; however, an activator (e.g., kaolin) shortens the time to MA by inducing more rapid blood clotting. The major advantage of the TEG is the development of a full clot signature from initial platelet activation to eventual clot lysis. The major disadvantage has been the prolonged time required to see full development of the tracing and interpretation of the data, but computerization is now providing user-friendly clinically applicable results. There is growing literature regarding the clinical applications for the TEG. Perioperative transfusion algorithms based on data generated by the TEG is the most common clinical application.⁶² Transfusion, anticoagulant, and antifibrinolytic management for cardiac bypass^{63,64} is an active area of investigation and TEG information has long been used during liver transplantation to guide blood product replacement.^{65–67} Of interest, the two areas using these devices the most (cardiac surgery and liver transplantation) are also the two characteristically associated with late hyperfibrinolysis (see Chapter 37) underscoring the near monopoly TEG holds on prompt

evaluation of hyperfibrinolysis. Other specific surgical indications including pediatric surgery^{68,69} and noncardiac surgery⁷⁰ are being investigated.

SonoClot Coagulation and Platelet Function Analyzer

The SonoClot Coagulation Analyzer (Sienco Inc., Wheat Ridge, Colo., USA) differs in design from the TEG, but both systems measure the physical properties of the clot. Whole blood (approximately 400 μ L) is placed in a cylindrical cuvette in which a vertically vibrating probe is suspended. The change in mechanical impedance extended on the probe by the viscoelastic properties of the forming clot produces a characteristic clot tracing. Reduced platelet function causes a decreased slope from inflection to peak, a lower peak, and a reduced contraction rate. Several clinical trials have been reported using the SonoClot.^{71–74} The advantage of this test is the more rapid completion, usually within 15 minutes, and the global testing of the blood elements of primary hemostasis; however, despite being available for decades, the instrument has yet to make a major impact on the clinical market.

Chapter 42

Prevention and Treatment of Venous Thromboembolism in Neurologic and Neurosurgical Patients

David Green, MD, PhD

A patient is in a major vehicle accident, sustaining injuries to the brain and spinal cord, requiring immediate surgical intervention. What is the risk of venous thromboembolism (VTE) in the immediate postoperative period? What thromboprophylactic measures should be applied, and for how long? If the patient has a complete motor paralysis, should prophylaxis be continued for days, weeks, months, or indefinitely? Suppose the patient experiences a pulmonary embolism (PE) or deep vein thrombosis (DVT), what treatment would be appropriate, and for how long should it be continued? What is the risk of intracranial or spinal bleeding with anticoagulant therapy? These are some of the difficult questions that confront consultants regarding the care of patients with neurologic illness or injury.

STROKE

Acute Ischemic Stroke: Prophylaxis

Placebo-controlled trials indicate that the frequency of DVT in patients with ischemic stroke not receiving anticoagulant prophylaxis is 22%.¹ The majority of these trials were conducted using a heparinoid^{2,3} (danaparoid), which is no longer available in the United States; in only one study was a low molecular weight heparin (LMWH) used.⁴ A meta-analysis of all trials showed that the use of heparins achieved an almost twofold reduction in the number of VTEs (from 22% to 13%; $P = 0.002$), and with no increase in bleeding.¹ Based on this analysis, the Seventh American College of Chest Physicians (ACCP) Conference on Antithrombotic and Thrombolytic Therapy recommended that acute stroke patients with restricted mobility receive prophylaxis with low-dose unfractionated heparin (UFH) or LMWHs.⁵ They noted that these agents may be safely administered with aspirin, but that they should be withheld for the first 24 hours after thrombolytic therapy is given. Leg compression devices should be used in those patients with strong contraindications to anticoagulants.

Acute Hemorrhagic Stroke: Prophylaxis

Patients with ruptured aneurysms, subarachnoid bleeds, and intraventricular hemorrhage are also at high risk of VTE, but the use of anticoagulants is usually considered

to be contraindicated in such persons. Boer and colleagues⁶ observed that giving low dose UFH, 5000 U 3 times daily, lowered the frequency of PE compared with starting heparin 4 or more days later, without an increase in rebleeding in the brain. The ACCP Conference recommends the initial application of compression devices, followed by UFH on the second day after hemorrhage.⁵ As a further precaution, one might also repeat central nervous system imaging to confirm the absence of continued bleeding. Because the natural history of each of these three conditions is characterized by spontaneous rebleeding, anticoagulant use cannot be viewed as the sole cause in the event of a rebleed.

Stroke: Chronic Phase

Following recovery from acute stroke, patients are usually transferred to a rehabilitation facility. Studies have shown that the risk of venous thromboembolism persists into the post-stroke period.⁷ In a study that randomized post-stroke patients into groups who received either LMWH or compression boots, the frequency of objectively demonstrated DVT was 11.9% in the former and 5% of the latter ($P = \text{ns}$).⁸ Only two patients were symptomatic, and there were no PEs. One patient on LMWH had minor bleeding, and six patients assigned to compression boots left the trial early because the devices were too uncomfortable. The conclusion of the study was that use of either compression boots or LMWH is effective for the prevention of thromboembolism after stroke. The LMWH is better accepted, requires less nursing care, and is only marginally more expensive.

Treatment of Venous Thromboembolism in Stroke Patients

In general, the treatment of VTE in patients who have sustained an ischemic stroke is similar to that of most other individuals with PE or DVT, with the exception that there is a danger of converting an ischemic infarct into a hemorrhagic infarct if full doses of anticoagulants are given soon after a stroke. This observation is based on data from the International Stroke Trial,⁹ which showed that doses of 12,500 U of UFH twice daily increased the rate of hemorrhagic stroke threefold, and by a trial that administered LMWH (dalteparin, 100 U/kg twice daily) to patients with

acute embolic stroke.¹⁰ The frequency of recurrence, progression, death, or symptomatic cerebral hemorrhage within 14 days was significantly increased with LMWH as compared with aspirin. These reports led the ACCP Conference to suggest that patients with acute ischemic stroke not be exposed to full-dose anticoagulation.⁵ Unfortunately, there are few data regarding when it is safe to initiate therapeutic anticoagulation in such patients. In the two trials noted earlier, the anticoagulants were initiated within 48 hours of the ictus. Furthermore, large infarct size and elevated blood pressure predict a greater risk of hemorrhagic transformation.¹¹ Therefore, patients with these risk factors, or patients who sustain a VTE within 48 hours of an acute stroke, should be considered for a vena caval filter to prevent PE. Thought might be given to using a retrievable filter, inasmuch as after 1 to 2 weeks, full-dose anticoagulation would be acceptable and the filter could be removed. A special case pertains to patients with cerebral venous sinus thrombosis. On the basis of limited trial data, the ACCP recommended that heparins be given during the acute phase, even in the presence of hemorrhagic infarction. An alternative treatment in patients not responding to heparin is catheter-directed thrombolysis, which occasionally is successful but carries a greater risk of hemorrhage.¹²

SPINAL CORD INJURY

Prophylaxis

Spinal cord injury poses a great risk for VTE. A recent review of spinal cord injury admissions showed that 51 (21%) of 243 patients undergoing screening tests for VTE had objective evidence of thrombi, despite the use of various methods of thromboprophylaxis.¹³ A variety of potential risk factors were examined, including age, sex, weight, location of spinal cord injury, degree of paralysis, and surgical procedures such as spinal fusion. Hierarchical optimal classification tree analysis suggested that patients with concomitant cancer, men with flaccid paralysis, and women between the ages of 36 and 58 years had the highest likelihood of developing DVT or PE. In another study, age greater than 50 years, increased body mass index, and time from injury to initiation of thromboprophylaxis were noted to be weak risk factors for VTE.¹⁴ Because of the high frequency of VTE observed in all studies, the ACCP Conference recommends that all patients with acute spinal cord injury should receive prophylaxis, generally initiated within 24 to 72 hours of injury.¹⁵

A variety of methods for the prevention of thromboembolism in the spinal injury patient are available (Table 42-1). The use of compression boots alone has been shown to halve the frequency of DVT.^{16,17} There have been several theories as to why compression devices are effective. The rhythmic contractions may mechanically improve blood flow. Such a mechanism has been demonstrated for the foot pump, which empties the venous plexus on the sole of the foot, sending pulses of blood up the leg.¹⁸ In addition, stimulation of the vascular endothelium promotes the release of tissue factor pathway inhibitor (TFPI). This potent endogenous anticoagulant blocks the activation of coagulation by inhibiting factor Xa and the tissue factor:factor VIIa complex. A variety of com-

Table 42-1 Methods for the Prevention of Thromboembolism in Spinal Cord Injury

Mechanical Methods

- Compression boots, calf and thigh
- Foot pump
- Graduated compression stockings
- Vena caval filter

Pharmacologic Methods

- Unfractionated heparin
- Low molecular weight heparin
- Pentasaccharide (fondaparinux)
- Warfarin

Combined Modalities

- Compression device plus unfractionated heparin
- Graduated compression hose plus low molecular weight heparin
- Vena caval filter plus anticoagulants

pression devices have been shown to increase the levels of TFPI and reduce the concentrations of factor VIIa in normal subjects and patients with venous disease.¹⁹ During every nursing shift, the devices should be inspected to confirm that they are in proper position and that the underlying skin is free of abrasions or other damage.

The usefulness of UFH and LMWH has been examined in a number of clinical trials of patients with traumatic spinal cord injury.¹⁵ Several early studies showed that the use of compression boots or UFH alone was inferior to LMWH. Therefore, the Spinal Cord Injury Thromboprophylaxis Investigators¹⁴ randomized patients to receive either UFH (5000 U every 8 hours) plus compression boots or LMWH (enoxaparin, 30 mg every 12 hours). Proximal vein thrombosis or PE was noted in 16% of the former and 12% of the latter (not significant). Also, bleeding complications were similar in the two groups. Therefore, the ACCP Conference recommended either LMWH or UFH plus a compression device in patients with acute spinal injury.¹⁵ The use of compression devices alone is permissible if risk of bleeding contraindicates administration of an anticoagulant. Fondaparinux, a pentasaccharide anticoagulant, is safe and effective in preventing thrombosis in orthopedic and general medical patients,^{20,21} but trials in spinal cord injury have not been reported.

Thromboprophylaxis is generally continued during the rehabilitation phase of spinal cord injury. The Spinal Cord Injury Thromboprophylaxis Investigators²² continued their study of patients free of VTE after 2 weeks in an acute care facility; these patients were then transferred for rehabilitation. Those who had been previously randomized to enoxaparin continued on this agent, and those randomized to UFH and compression boots continued on UFH alone. After 6 weeks of follow-up, 13 of 60 patients on UFH, as compared with 5 of 59 on enoxaparin, developed a new VTE. This difference was of borderline statistical significance ($P = 0.052$). However, because patients were not randomized on admission to rehabilitation, the omission of compression boots from the heparin group could explain the difference in event rates. In a small study, 20 patients admitted to rehabilitation with negative ultrasound studies were randomized to UFH, 5000 U every 12 hours, or LMWH, 5000 U once daily, and a repeat ultrasound examination was performed at the time

of discharge (Do V, Green D, unpublished data). There were no symptomatic VTE and no new thrombi on ultrasound. Therefore, it is still unclear whether UFH or LMWH is to be preferred in the rehabilitation setting; only a very large, multicenter study could answer this question. At any rate, it is recommended that thromboprophylaxis be continued in all patients with spinal cord injury until discharge from a rehabilitation facility.

Data on the optimal duration of thromboprophylaxis is fragmentary and anecdotal. The Consensus Conference on Spinal Cord Injury^{23,24} reported that thromboembolism occurred 10 weeks or more after injury in an occasional patient whose prophylaxis was stopped at 8 weeks—suggesting that a longer duration of prophylaxis may be appropriate in some patients. One of these late thrombotic episodes was a fatal pulmonary embolism (PE). To examine the risk factors for fatal PE, we reviewed all autopsy-proved cases occurring in our center over a 5-year period.²⁵ Nine cases were encountered, eight men and one woman, whose ages ranged from 17 to 67 years. Cervical spine fracture with tetraplegia was present in 67%, obesity in 44%, and all had flaccid paralysis. These characteristics were significantly more common in the cases than in a concurrently selected control group. In addition, more of the control subjects than cases had received LMWH (60% vs 22%, $P = 0.07$). It was concluded that thromboprophylaxis needs to be especially aggressive in patients with cervical spine injuries, tetraplegia, and obesity.

Should any studies to detect the presence of thrombosis be performed prior to discontinuing anticoagulant prophylaxis? The experience with routine ultrasound has been disappointing. Ultrasound had a sensitivity of only 62% and a positive predictive value of 66% for detecting proximal thrombi when used to screen for DVT in patients after orthopedic surgery.²⁶ The D-dimer test may be more helpful in excluding the presence of thrombosis. In 67 patients with either paraplegia or tetraplegia, no patient with DVT had a negative D-dimer test, although 40 patients without thrombosis had positive tests.²⁷ The D-dimers were detected with either an ELISA test (Asserachrom D-Di) or a rapid automated turbidimetric test (STA-Liatest D-Di); the methods are important because some tests for D-dimer are more sensitive than others.

A reasonable strategy for deciding whether prophylactic anticoagulants should be discontinued is to measure D-dimer by a sensitive method. If the test is negative, prophylaxis is stopped. If the test is positive, prophylaxis should be continued—if clinical suspicion of thromboembolism is high, additional studies such as ultrasound of the legs, ventilation/perfusion lung scans, or other evaluations would be warranted. If a thrombus is detected, full therapeutic doses of anticoagulants should be administered.

Inferior Vena Caval Filters

Inferior vena caval (IVC) filters are devices that can be introduced into the IVC to block the passage of thrombi from the lower extremities and pelvis into the lungs. In recent years, retrievable devices have become available.²⁸ The largest experience has been with the Günther Tulip filter.²⁹ These have usually been inserted on admission to the trauma unit to prevent acute VTE in patients considered unsuitable for prophylactic anticoagulation. Such patients might have

intracranial or other active bleeding, coagulopathy, or lower limb fractures not amenable to the use of compression devices. Another potential indication for the use of an IVC filter is the patient with high cervical spinal cord injury who is ventilator dependent; even a small PE in such a patient could prove fatal. The data suggest that filters are effective in preventing PE, but because they do not prevent DVT, anticoagulant prophylaxis should be initiated as soon as feasible. Insertion of the filter requires technical expertise; in less experienced hands, complications such as guidewire entrapment, infection, failure of retrieval, and migration into the right atrium have been reported. Furthermore, the procedure is expensive; in patients receiving appropriate thromboprophylaxis, it is estimated that 100 filters would need to be placed to prevent two nonfatal PEs at a cost of \$500,000.³⁰ Therefore, the ACCP Conference recommended against the use of a filter as primary prophylaxis against PE.¹⁵ See Chapter 31 for a further review of these devices.

Treatment

To date, no studies have compared long-term therapy with warfarin versus LMWH in this patient population. Furthermore, there are no data with regard to the duration of treatment after a patient has experienced a thromboembolic event. Lim and coworkers³¹ examined the time to recanalization of thrombus in patients with tetraplegia, paraplegia, hemiplegia, and no paralysis. All patients received at least three months of anticoagulation prior to evaluation. Patients with tetraplegia and paraplegia took significantly longer for recanalization than nonparalyzed controls (54 days vs 33 days, $P = 0.04$); hemiplegic patients were intermediate. If persistent venous obstruction due to residual thrombus represents an ongoing risk factor for recurrent thrombosis,³² it would seem prudent to continue patients with paralysis on anticoagulant therapy until complete recanalization of veins has been documented by ultrasound or other techniques.

NEUROSURGERY

Prophylaxis

VTE is an important complication in patients undergoing major neurosurgery. Geerts and associates³³ observed that the rate of DVT in patients not receiving thromboprophylaxis was 22%, and the rate of proximal DVT 5%. Turpie and colleagues³⁴ reported that calf compression decreased the frequency of venous thrombosis from 20.8% in controls to 7.8% in patients given prophylaxis ($P = 0.01$). Subsequently, these investigators examined graduated compression stockings alone or with compression boots in another randomized trial of neurosurgical patients.³⁵ Again, the frequency of DVT was reduced from 19.8% in patients not receiving prophylaxis to 8.8% in those wearing stockings, and 9% in those with stockings and compression boots. Thus, graduated compression stockings alone or combined with compression devices have been favored by most neurosurgeons because they are efficacious and avoid the risk of inducing hemorrhage.³⁶

With the demonstration that LMWH administration was safe and effective thromboprophylaxis for patients

undergoing a variety of medical and surgical procedures, researchers became emboldened to evaluate these drugs in neurosurgery. Two clinical trials showed that the addition of LMWH to compression stockings enhanced the protection due to compression stockings alone. In 1996, Nurmohamed and coworkers,³⁷ using a venographic end point, noted thrombi in 26.3% of stocking-alone patients and 18.7% of stocking plus LMWH patients ($P = 0.065$). Furthermore, the rates for proximal DVT and PE were 10.2% for the stockings and 5.8% for LMWH ($P = 0.036$). Agnelli and colleagues³⁸ reported that LMWH reduced the frequency of DVT from 32% (stocking group) to 17% (LMWH group), $P = 0.004$. Proximal vein thrombosis was also decreased significantly: from 13% to 5%, $P = 0.04$. Two patients in the placebo group died of proved PE.

In these studies, the frequency of bleeding appeared to be related to the dose and the particular LMWH administered. Nurmohamed and associates³⁴ gave nadroparin in a dose of 7500 U and reported major bleeding in 6 LMWH versus two stockings-alone patients ($P = 0.87$), whereas Agnelli and coworkers³⁵ used enoxaparin in a dose of 40 mg daily and observed no difference in the frequency of bleeding (3% of both treated and control patients).

The studies just described, along with two earlier reports, were subjected to a meta-analysis.³⁹ A total of 187 thrombotic events were recorded in 827 patients (22.6%). Prophylaxis with heparins resulted in a 45% risk reduction for thrombosis. However, there was a twofold increase in overall bleeding rates (5.9% vs 2.9%, $P = 0.02$), but no significant difference in major bleeding events (2.3% vs 1.4%; $P = 0.24$). Thus, there was one major bleed for every seven thrombotic events prevented by heparins. However, it must be recognized that only good-risk patients were selected for these trials; exclusion criteria included patients with abnormal operative bleeding or coagulopathy, multiple cerebral aneurysms or unclipped aneurysm, or renal failure. Patients with these problems are at higher risk for bleeding and probably should not routinely receive anticoagulant prophylaxis. It is recommended that the initial dose of anticoagulant should be given no earlier than 24 hours postoperatively; the patient should be neurologically stable by physical examination and by an imaging study such as CT or MRI; and the surgical lesion should have been well-demarcated. There should have been no blunt dissection, necrotic tissue, or vascular metastasis.³³ In summary, all patients undergoing major neurosurgery should be fitted with compression boots or graduated compression stockings,¹⁵ and if they meet the criteria just indicated, they should receive daily prophylaxis with a LMWH.

Treatment

The management of documented venous thromboembolism in the neurosurgical patient hinges on one key issue: the likelihood of the patient having a hemorrhage when exposed to full therapeutic rather than prophylactic doses of anticoagulants. When does the risk of major intracranial bleeding subside in the patient who has had head trauma or surgery? The answer to this question hinges on several factors including the time and extent of injury, the type of trauma, and the anatomic lesion. For most kinds of

surgery, wounds are well sealed by 24 hours; exceptionally, a ligature will slip after this time and bleeding will recur. Crush injuries with large raw surfaces are more likely to ooze than cleanly severed tissue which has been re-approximated with sutures. Leaking aneurysms that cannot be fully embolized or ablated are another cause of potential bleeding.

The profile of the patient who can tolerate full-dose anticoagulant therapy is an individual who has sustained a well-demarcated wound more than 24 hours earlier and shows no signs of progressive neurologic deficit. A CT scan or MRI of the head should reveal a stable pattern, with no suggestion of continued bleeding. Subarachnoid or subdural hemorrhages should be contained, and multiple metastatic lesions or aneurysms should not be in evidence. If these conditions are met, systemic anticoagulation for newly recognized venous thromboembolism is indicated. LMWH is preferred to UFH for the following reasons:

1. LMWHs have more predictable pharmacokinetics and greater bioavailability than UFH.⁴⁰
2. A meta-analysis of 13 clinical trials has concluded that LMWH is more effective and is associated with less bleeding than UFH when used for the treatment of DVT.⁴¹
3. LMWH is easier to administer and generally does not require monitoring. However, under special circumstances, measurements of anti-factor Xa levels are suggested to ensure that the doses given are neither excessive nor subtherapeutic. Monitoring is recommended in persons weighing less than 50 kg or more the 120 kg, in children and pregnant women, and in patients with renal failure.⁴² Giving very high doses (for subjects weighing more than 110 kg), or treating patients with creatinine clearances of less than 30 mL/minute, may result in anti-factor Xa levels exceeding 1.0 U/mL, and require dose reductions. The half-life of LMWH is only 3 to 4 hours, so it is rarely necessary to try to reverse its action; however, if life-threatening bleeding or surgical intervention is required in a patient who has just received LMWH, efforts to combat its effects are justified. Protamine, in a dose of 50 to 100 mg depending on patient weight, may be given intravenously at a rate not to exceed 5 mg/minute, and with continuous monitoring of blood pressure.
4. An alternative anticoagulant is fondaparinux. This pentasaccharide enhances the activity of antithrombin III and has been effective in the treatment of patients with DVT and PE.^{43,44} It compares favorably with intravenous UFH and LMWH, and is given in doses of 7.5 mg subcutaneously daily. It is excreted entirely by the kidney, and is not neutralized by protamine, which are two potential drawbacks to its use.

When there is an absolute contraindication to the use of systemic anticoagulation, IVC filter placement, as previously described, is appropriate. However, anticoagulant therapy should be started as soon as the danger of bleeding has subsided because the filter alone is not an effective treatment of DVT.³⁷ The neurosurgical patient who has sustained either a DVT or PE is at high risk for a recurrence; long-term anticoagulation is usually necessary. Warfarin is a safe and

effective choice for patients who have a stable food intake and are cognitively intact; in such patients, the dose of warfarin can be adjusted to obtain an International Normalized Ratio (INR) in the accepted therapeutic range of 2 to 3. However, if the patient is not eating, having frequent seizures and falls, or cannot be relied on to take the prescribed dose of warfarin, use of the drug is potentially hazardous. Warfarin-induced bleeding is often observed in neurosurgical patients whose food intake is variable, and in those requiring antibiotics for infection control.

Warfarin resistance is found in patients receiving anticonvulsant medications. Therefore, finding a safe and effective dose of warfarin may be challenging in many neurosurgical patients. In these persons, LMWH therapy offers the advantages of safety and simplicity because its effectiveness is not affected by diet or other medications, and it is given once or twice daily subcutaneously without the need for monitoring in most instances. The doses given are based on body weight, either 1.5 mg or 175 to 200 U per kilogram body weight once daily or 1 mg or 100 U per kilogram body weight twice daily, depending on the agent selected.^{45,46} The newer long-acting, once-daily pentasaccharide anticoagulants would seem applicable also but have yet to be systematically studied in this situation. Treatment should be continued until the risk of recurrent thromboembolism is low; for patients without filters, this may be 3 to 6 months depending on neurologic recovery, but for those with filters, anticoagulation may be necessary for up to 2 years or more. When the patient is neurologically stable, cognitively intact persons may wish to switch from LMWH to an oral anticoagulant for reasons of convenience and cost.

Cost Containment Issues

Venous thromboembolism in the neurologic and neurosurgical patient is a very costly complication, economically as well as in terms of morbidity and mortality. Although UFH and warfarin are inexpensive medications, giving UFH by continuous intravenous infusion is expensive and prolongs hospitalization. Giving warfarin so that the INR remains within the therapeutic range requires frequent blood tests and dose adjustments; lapses may be penalized by episodes of either thrombosis or bleeding, leading to recurrent hospitalization. LMWH is more expensive but can be given at home and does not require monitoring. Cost-effectiveness analyses of DVT treatment have shown that the use of LMWH compares very favorably with that of UFH.⁴⁷

Medical-Legal Implications

Practicing thromboprophylaxis is good medicine. However, considerable judgment is required for the safe use of anticoagulants in neurologic and neurosurgical patients, and the medical literature is lacking in this regard. Placebo-controlled studies have shown that some patients with neurologic or neurosurgical disease have new intracranial bleeding in the absence of anticoagulants. Nevertheless, when new bleeding occurs, it is invariably attributed to these agents, and there may be litigation. The best defense is that most published reports stress that the benefit of antithrombotics outweighs the risks when the drugs are used in neurologically stable patients.

Role of the Consultant

With regard to the questions posed at the beginning of this chapter, the risk of venous thromboembolism in the immediate postoperative period is 22% and proximal DVT 5%. Graduated compression stockings and leggings should be applied on admission and continued during the perioperative period. The day after surgery, the patient should be evaluated for the use of pharmacologic prophylaxis. The following criteria should be met prior to starting anticoagulants:

- There should be no active bleeding, and the neurosurgeon should confirm that satisfactory hemostasis was achieved at the time of surgery.
- The patient's general condition should be stable; neurologic examination should show no progression of symptoms or signs.
- Laboratory studies should indicate adequate coagulation (platelet count >100,000/ μ L, prothrombin time <15 seconds, partial thromboplastin time <35 seconds).

If there is any question about neurologic stability, repeat imaging is recommended. LMWH in prophylactic doses is administered daily for at least 6 to 8 weeks. At some centers, patients considered at high risk for thromboembolism at the time of admission will have retrievable vena caval filters inserted and removed two weeks after surgery. Although this may reduce the frequency of PE, the patient is still at risk for DVT, and needs compression devices and anticoagulant prophylaxis. The latter are important not only for prevention of DVT in the lower extremities, but also for preventing thrombi from forming around or above the filter. From the neurosurgeon's point of view, it is certainly preferable to use the lower, prophylactic doses of anticoagulants than the higher doses that would be required if there were a venous thrombotic event.

Should a PE or DVT occur, full-dose anticoagulation should be promptly initiated, preferably with either a LMWH or fondaparinux. If anticoagulants are contraindicated, an IVC filter should be placed and anticoagulant therapy initiated as soon as feasible. Anticoagulants are usually continued for six months, but they may be stopped earlier if the patient becomes fully mobile. The risk of major bleeding with intravenous UFH is <3% in recent trials and between 1.1% and 1.3% in those receiving LMWH or fondaparinux.⁴⁸

Chapter 43

Hematologic Interventions for Acute Central Nervous System Disease

Fred Rincon, MD • Andres Fernandez, MD •
Stephan A. Mayer, MD

INTRODUCTION

Acute neurologic emergencies often involve bleeding into the central nervous system (CNS) or occlusion of vessels with resultant ischemia. Thus, the application of hemostatic or antifibrinolytic agents to minimize bleeding—and anticoagulants or fibrinolytic agents to reverse thrombosis and promote perfusion—has been a common clinical challenge that frequently requires hematology expertise. Clinical scenarios involving spontaneous intracerebral hemorrhage (ICH), aneurysmal subarachnoid hemorrhage (SAH), traumatic epidural and subdural hematoma, hemorrhagic infarction, cerebral sinus thrombosis, and brain tumor–related bleeding are among the most frequent issues for the consultant. In this chapter, we review the application of hematologic interventions for a wide variety of acute neurologic conditions.

STROKE

Spontaneous Intracerebral Hemorrhage

Spontaneous intracerebral hemorrhage (ICH) accounts for 10% to 30% of all stroke admissions,¹ leading to catastrophic disability, morbidity, and the highest mortality rates. Depending on the underlying cause of hemorrhage, ICH may be classified as *primary* when it originates from the spontaneous rupture of small vessels damaged by chronic hypertension or amyloid angiopathy, representing 85% of all cases, or *secondary* when bleeding is related to a tumor, vascular malformation, hemorrhagic conversion of an ischemic stroke, abnormal coagulation,^{2,3} sympathomimetic agent, trauma, or other cause.⁴

Primary ICH produces devastating neurologic disability and is by far the least treatable form of stroke. Apart from management in a specialized stroke or neurologic intensive care unit, until very recently, no specific therapies had been shown to improve outcome after ICH. ICH continues to be a health problem not only in the United States but also worldwide, with a prevalence of approximately 37,000 to 52,000 cases per year in the United States.^{5,6}

Differing from ischemic stroke, ICH is accompanied by a unique risk factor profile. Hypertension, particularly if untreated, is the most important risk factor for ICH,^{7–9} being present in 50% to 70% of cases.^{10,11} Other risk

factors include advanced age,¹² male sex, African and Japanese race/ethnicity,^{13,14} hypocholesterolemia,¹⁵ high alcohol intake,^{16–20} and cocaine use.^{21,22} Cerebral amyloid angiopathy (CAA) is an important risk factor for primary lobar ICH in the elderly. CAA is characterized by the deposition of β -amyloid protein in small- to medium-sized blood vessels of the brain and leptomeninges, which may undergo fibrinoid necrosis as seen in chronic hypertension.³

Physiopathology and Rationale for Ultra-Early Hemostatic Therapy

What was formerly considered to be a simple and rapid bleeding event is now understood to be a dynamic and complex process that involves several distinct phases. Initially, it was believed that the bleeding associated with ICH was completed within minutes of the ictus, and that the following neurologic derangement observed during the first day after the bleed was attributed to cerebral edema and mass effect around the hemorrhage.²³ However, more recent data from pathologic studies, computed tomography (CT) analysis, and clinical observations suggest that early hematoma growth occurs as a result of “ultra-early rebleeding” during the first 3 to 6 hours after onset (Fig. 43-1). Evidence from studies employing histopathology, CT analysis, single-photon emission computed tomography (SPECT), and both conventional CT and CT angiography (CTA) suggests that secondary multifocal bleeding into the tissue at the periphery of an existing clot as a possible mechanism of early hematoma enlargement. Brain tissue samples from ICH patients have confirmed the presence of microscopic bleeds in brain tissue surrounding the hematoma, representing congested and ruptured venules or arterioles.²⁴ Other studies employing simultaneous CT and SPECT analysis have shown that in some cases, early hematoma growth relates to secondary bleeding in the periphery of the existing clot into ischemic, congested, peri-lesional tissue.²⁵ The association between early hematoma growth and irregular clot morphology, which may reflect multifocal bleeding,²⁶ has been reported by several studies as well. In one study, the frequency of hematoma growth was greater in patients with irregularly shaped hematomas compared with those with round hematomas, and it was postulated that the irregular shape indicated bleeding from multiple arterioles.²⁶ In studies involving CTA immediately after ICH, active contrast extravasation into the hematoma was detected in more than 30% of

Figure 43-1 Early hematoma growth in a patient with a right putaminal intracerebral hemorrhage. The patient was subsequently declared brain dead. (Reproduced with permission from Mayer SA, Rincon F: Treatment of intracerebral haemorrhage. *Lancet Neurol* 4[10]:662–672, 2005.)

patients, and was associated with subsequent hematoma enlargement²⁷ and increased mortality.²⁸ Finally, simultaneous bleeding from multiple, lenticulostriate arteries has been demonstrated angiographically immediately after ICH.^{29,30} These data suggest that early hematoma growth occurs because of bleeding into a congested layer of tissue that forms acutely at the periphery of the hematoma.³¹

Frequency of Early Hematoma Growth

Retrospective studies in the late 1980s using CT scan analyses of small numbers of patients^{32,33} were the first to describe the phenomenon of early hematoma growth. More recent retrospective studies and a single prospective report involving larger patient populations ($n = 103$ to 627 patients) have provided further support for the occurrence of this early phenomena.^{26,34–36} In these studies, patients were scanned within 3 hours of onset of ICH with 18% to 38% of individuals having early hematoma growth as evidenced by subsequent CT scans. Interestingly, the highest rate of early hematoma growth (38%) was documented in the sole prospective study and the investigators concluded that the true frequency of hematoma growth must be higher than this rate, because clinical deterioration and immediate surgical intervention precluded the performance of the follow-up scans in some of the patients.³⁴

The only consistently identified predictor of early hematoma growth is the interval from the onset of symptoms to CT; the earlier the first scan is obtained, the more likely subsequent bleeding will be detected on a follow-up scan.^{26,36} As a corollary, hematoma growth occurs in only 5% of patients who are initially scanned beyond 6 hours of symptom onset.^{26,34,36,37} Early hematoma growth has been consistently associated with poor clinical outcomes^{26,34,36,37} and higher mortality rates.³⁶ Similarly, significantly greater deterioration in the Glasgow Coma Scale (GCS) and National Institute of Health Stroke Scales (NIHSS) has been reported among patients with documented hematoma growth on 1-hour follow-up CT scans, compared with those without growth.³⁴ Hence, limiting hematoma growth represents a prime target for therapeutic intervention.

Consultation Strategies

Ventilatory support, blood pressure reduction, intracranial pressure monitoring, osmotherapy, fever control, seizure prophylaxis, and nutritional supplementation are the cornerstones of supportive care for ICH in the ICU setting.³⁸

Ultra-early hemostatic therapy is a novel approach for treating ICH. When administered alone or in conjunction with surgical or neuroprotective intervention, ultra-early hemostatic therapy may have the potential to become the standard of care for ICH. Ideally, an ultra-early hemostatic medication that inhibits fibrinolysis and activates coagulation at the local level, allowing fast and effective hemostasis but without systemic adverse effects, would be the preferred agent.

Coagulation factor VII (FVII) is a naturally occurring initiator of hemostasis and its activated form (FVIIa) triggers the extrinsic coagulation pathway. Recombinant FVIIa (rFVIIa, NovoSeven; Novo Nordisk, Bagsvaerd, Denmark) is a genetically engineered human protein produced in cultured baby hamster kidney cells that is nearly identical to human plasma-derived FVIIa in structure and function. rFVIIa acts by binding to the surface of activated platelets where, in the presence of tissue factor (TF) generated at the site of the lesion, it accelerates local FXa and thrombin generation.³⁹ This agent was developed for the treatment of spontaneous and surgical bleeds in patients with hemophilia A or B with inhibitors to factors VIII and IX, respectively.⁴⁰ In 1999, a report of its successful use to stop what was deemed to be a lethal hemorrhage after an abdominal gunshot wound in a young soldier with no preexisting coagulopathy has prompted exploration of other uses of rFVIIa.⁴¹ Through its action of enhancing local hemostasis after binding to exposed TF, rFVIIa has been shown recently to be an effective initiator of hemostasis in patients with a normal coagulation system.^{42,43} rFVIIa has also been shown to effectively treat CNS bleeds in hemophilic patients. In one study of hemophilic patients with CNS hemorrhages, cessation of bleeding occurred in 84% of CNS bleeding episodes after administration of rFVIIa 80 to 100 μg per kilogram of body weight. Only one patient

Figure 43-2 Survival at 90 days in the recombinant activated factor VII (rFVIIa) ICH trial according to study group. Survival was significantly improved with treatment ($P = 0.02$, rFVIIa combined versus placebo). died, and there were no adverse events related to rFVIIa administration.⁴⁴

A recent phase IIB, randomized, placebo-controlled, dose-ranging study was conducted with rFVIIa in non-coagulopathic patients with ICH.⁴⁵ In that study, 399 patients with primary ICH, diagnosed by CT scan within 3 hours of onset of symptoms, were randomized to receive placebo or one of three doses of rFVIIa (40 µg per kilogram, 80 µg per kilogram, or 160 µg per kilogram body weight) within 1 hour of the baseline CT. The primary outcome of the study was change in hematoma volume at 24 hours. Secondary outcomes included clinical outcome at 3 months as measured by the Modified Rankin Scale, Barthel Index, Extended GCS, and NIHSS. The combined group of patients treated with rFVIIa had nearly 50% less hematoma growth relative to baseline than the placebo group and reduction of mortality by 38% at 3 months (Fig. 43-2). Importantly, there was also significant improvement of clinical outcomes at three months among survivors. This study posed ultra-early hemostatic therapy as a new and promising therapeutic option for ICH.⁴⁵ Currently, a phase III multicenter, multinational, randomized, placebo-controlled study, (FAST trial) is being conducted comparing placebo with doses of 20 µg per kilogram body weight and 80 µg per kilogram body weight of rFVIIa within 4 hours of ICH onset. The results of the FAST trial will be available by 2007.⁴⁶ Until these data are available, rFVIIa for spontaneous non-coagulopathic ICH should be considered investigational.

Thrombolysis for Intraventricular Hemorrhage. Intraventricular hemorrhage (IVH) commonly results from extension of ICH into the cerebral ventricular system, and is an independent predictor of mortality after ICH.⁴⁷ Commonly, hydrocephalus and IVH are managed with an external ventricular drain (EVD), but outcomes remain poor.³⁸ Intraventricular thrombolysis has recently been advocated for the management of IVH. Several studies have reported successful use of urokinase or tissue plasminogen activator (tPA) for the treatment of IVH, with the goal of accelerating the

clearance of IVH and improving clinical outcome.^{48,49} A large multicenter randomized control trial is currently investigating the optimal dose of intravenous tPA for accelerating IVH clot lysis.⁴⁹ When used off-label, a dose of 1 mg of tPA every 8 hours (followed by clamping of the EVD for 1 hour) is reasonable until clearance of blood from the third ventricle has been achieved. Doses of 3 mg or more of tPA for IVH thrombolysis have been associated with an unacceptably high bleeding rate (Daniel Hanley, MD, personal communication).

Coagulopathic Intracranial Hemorrhage

A growing source of ICH is vitamin-K inhibitor use, which accounts for approximately 10% to 15% of ICH.⁵⁰ Long-term anticoagulation may increase the risk of ICH by tenfold.⁵¹ Antiplatelet agent use has a risk of symptomatic bleeding complications but there is meager evidence implicating the use of single antiplatelet agent as a risk factor for ICH.^{52,53} However, a combination of antiplatelet agents such as ASA and ADP-receptor blockers such as clopidogrel, carries a higher incidence of ICH.⁵⁴ Other antiplatelet agents such as the glycoprotein receptor blocking agents (GPIIb/IIIa) produce hematologic abnormalities that may put the patient at risk of bleeding as well.⁵⁵ Similarly, patients exposed to recombinant tPA for stroke or myocardial infarction have a risk of ICH of 6% to 7%⁵⁶ and 0.2% to 1.4%, respectively.⁵⁷

Consultation Strategies

Reversal of Warfarin-Induced Coagulopathy. Warfarin (Coumadin; Bristol-Myers Squibb Co., Princeton, NJ, USA) inhibits vitamin K as a cofactor in the production of coagulation factors II, VII, IX, and X at the hepatic level. Among ICH patients, warfarin therapy doubles the risk of death and increases the risk of progressive bleeding and clinical deterioration.⁵⁸ Failure to rapidly normalize the International Normalized Ratio (INR) to below 1.4 further increases these risks.⁵⁹ ICH patients receiving warfarin should be reversed immediately with fresh frozen plasma (FFP) or prothrombin-complex concentrates (PCC), and vitamin K (Table 43-1).⁶⁰ Treatment should never be delayed in order to check coagulation tests. Unfortunately, normalization of the INR with this approach usually takes several hours, and clinical results are often poor. The associated volume load with FFP may also cause congestive heart failure in the setting of cardiac or renal disease.⁶¹ PCC, a concentrate of the vitamin K-dependent coagulation factors II, VII, IX, and X, normalizes the INR more rapidly than FFP; it can be given in smaller volumes,^{59,61} but carries the risk of triggering disseminated intravascular coagulation (DIC) in patients with severe brain injury.

Recent reports have described the off-label use of rFVIIa to speed the reversal of warfarin anticoagulation in ICH patients.^{62,63} A single intravenous injection of any dose of rFVIIa can normalize the INR within minutes, with larger doses producing a longer duration of effect (Fig. 43-3).⁶⁴ rFVIIa in doses ranging from 10 to 90 µg per kilogram of body weight has been used to reverse the effects of warfarin in acute ICH, primarily to expedite neurosurgical intervention, with good clinical results.^{62,64} When this approach is used, rFVIIa should be used as an adjunct to coagulation

Table 43-1 Emergency Management of the Coagulopathic ICH Patient

Scenario	Agent	Dose	Comments	Level of Evidence*
Warfarin	Fresh frozen plasma (FFP)	15 mL/kg	Usually 4 to 6 U (200 mL) each are given	II
	or Prothrombin complex concentrate	15–30 U/kg	Works faster than FFP, but carries risk of DIC	II
	and IV Vitamin K	10 mg	Can take up to 24 hours to normalize INR	II
Warfarin and emergency neurosurgical intervention	Above plus Recombinant factor VIIa	20–80 µg/kg	Contraindicated in acute thromboembolic disease	III
Unfractionated or low molecular weight heparin*	Protamine sulfate	1 mg per 100 U of heparin or 1 mg of enoxaparin	Can cause flushing, bradycardia, or hypotension	III
Platelet dysfunction or thrombocytopenia	Platelet transfusion	6 U	Range 4–8 U based on size; transfuse to >100,000/µL	III
	and/or Desmopressin (DDAVP)	0.3 µg/kg	Single dose required	III

*Class I, based on one or more high-quality randomized controlled trials; Class II, based on two or more high-quality prospective or retrospective cohort studies; Class III, Case reports and series, expert opinion.

*Protamine has minimal efficacy against danaparoid or fondaparinux. DIC, disseminated intravascular coagulation; ICH, intracranial hemorrhage; INR, International Normalized Ratio; IV, intravenous; U, units.

Figure 43-3 International normalized ratios before and as long as 348 hours after treatment with recombinant activated factor VII in anti-coagulated patients with intracranial hemorrhage. Time zero is defined as the time of treatment. Patients also received fresh frozen plasma, vitamin K, or both. (Reproduced with permission from Freeman WD, Brott TG, Barrett KM, et al: Recombinant factor VIIa for rapid reversal of warfarin anti-coagulation in acute intracranial hemorrhage. *Mayo Clin Proc* 79:1495–1500, 2004.)

factor replacement and vitamin K because the effect of rFVIIa will last only several hours.⁶¹

The safety of rFVIIa for warfarin-associated ICH in patients at high risk for thromboembolic complications, such as atrial fibrillation or a mechanical heart valve, has been a matter of intense debate. No definitive data exist on this topic, but several authors have reported the successful use of rFVIIa in this setting.^{62,65} The dosages of rFVIIa in these case reports have ranged from 20 to 80 µg per kilogram of body weight. The recently published data from the NovoSeven ICH trial⁴⁵ provides some reference data in a moderate-risk population. In this study, the frequency of

arterial thromboembolic serious adverse events (SAEs) was 5% in the 303 rFVIIa-treated patients compared with 0% in 96 placebo-treated patients ($P = 0.01$). These SAEs included seven myocardial ischemic events and nine cases of cerebral infarction that typically occurred within 4 days of dosing. However, fatal or disabling thromboembolic SAEs that were considered possibly or probably related to the treatment occurred in exactly 2% of the placebo and rFVIIa-treated patients. Secondary analyses of the trial data revealed that the risk of thromboembolic SAEs is higher when doses exceeding 120 µg per kilogram of body weight are used, but not when patients reported a history of

remote thromboembolic disease.⁶⁶ Based on these data, it is our opinion that when rFVIIa is used to reverse a coagulopathy in a patient with intracranial bleeding, smaller doses (40 to 80 µg per kilogram body weight) should be used, and a remote history of thromboembolic disease should not be considered an absolute contraindication to its use.

Timing of Reinstitution of Anticoagulation. Patients with ICH receiving long-term anticoagulant therapy for atrial fibrillation (AF) and mechanical valve replacement present a challenging therapeutic scenario because normalizing the INR increases the risk of embolic stroke.⁶⁷ Roughly, the incidence of major embolization in otherwise healthy patients with AF is 4% and 15% per patient-year for non-valvular and valvular AF, respectively.⁶⁸ It is higher in older or hypertensive patients and especially so in patients with prior embolic stroke. For patients with mechanical valves the incidence of major embolization (resulting in death or a persistent neurologic deficit) is 4% to 20% per patient-year in the absence of antithrombotic therapy. The risk of embolization is increased with mitral-valve prostheses, caged-ball valves, and multiple prosthetic valves.⁶⁹ In all of these patients, there is a compelling argument to resume anticoagulation fairly soon after stabilization of a CNS bleed.

Re-initiation of anticoagulation is best performed when clinical and radiologic stability has been achieved, but this approach poses a therapeutic dilemma. In order to clarify both the benefit of anticoagulation after ICH in high-risk patients, Eckman and colleagues developed a decision model to estimate the best clinical decision.⁷⁰ For patients with prior lobar ICH suggestive of amyloid angiopathy, withholding anticoagulation therapy indefinitely was the most beneficial strategy for improving quality-adjusted life expectancy. In sensitivity analyses for patients with deep ICH, anticoagulation could be considered if the risk of thromboembolic stroke is particularly high. They concluded that survivors of lobar ICH with AF should not be offered long-term anticoagulation and most patients with deep hemispheric ICH and AF should not receive anticoagulant therapy. However, patients with deep hemispheric ICH at particularly high risk for thromboembolic stroke or low risk of ICH recurrence (i.e., with excellent blood pressure control) might benefit from resuming long-term anticoagulation.⁷⁰

A recent retrospective review investigated the risk of thromboembolism after withholding or reversing the effect of warfarin therapy following a major hemorrhage in patients with prosthetic heart valves. In total, 27 patients were included, 2 patients suffered ICH. The mean time of warfarin withholding was 15 ± 4 days and none of these patients had thromboembolic events during this period.⁷¹ When warfarin is restarted after a major ICH, it can usually safely be started 7 to 14 days after onset.

Heparin-Induced Coagulopathy. Heparin produces an anticoagulant effect by attaching to and upregulating the activity of the plasma protein antithrombin III (ATIII). The ATIII-heparin complex rapidly interacts with circulating thrombin, inhibiting several other circulating coagulation proteases. There may be a slight antiplatelet effect induced by interaction with von Willebrand factor (VWF). Reversal of heparin effect depends on the administered dose.

Normally, the half-life of heparin is 2 hours and in cases of minor non-CNS hemorrhages, the infusion can simply be stopped. In the case of a neurologic or neurosurgical bleeding emergency, use of protamine sulfate is often indicated (see Table 43-1).

Low Molecular Weight Heparin-Induced Coagulopathy. Two commercial low molecular weight heparin (LMWH) preparations are available in the United States: enoxaparin (Lovenox; Rhone-Poulenc Rorer Pharmaceuticals, Collegeville, Pa., USA) and dalteparin (Fragmin; Pharmacia & Upjohn, Kalamazoo, Mich., USA). The mechanism of action of LMWH involves inhibition of activated factor X (Xa) during clot formation. This effect may last 4 to 12 hours after a single dose. Partial reversal of LMWH-induced coagulopathy can be achieved by administration of protamine sulfate at recommended doses (see Table 43-1).

Direct Thrombin Inhibitor-Induced Coagulopathy. Lepidurin (Refludan; Berlex Labs., Inc, Wayne, NJ, USA), argatroban, and bivalirudin (Angiomax; The Medicines Company, Cambridge, Mass., USA) may be used in some patients with allergies or contraindications to standard anticoagulation regimens such as those with heparin-induced thrombocytopenia (HIT). These agents directly inhibit plasma thrombin and, unfortunately, no direct antidote is available for their reversal. The use of rFVIIa to enhance local thrombin production may theoretically be of benefit, but it has not been reported to date.

Acetylsalicylic Acid- and Nonsteroidal Anti-inflammatory Drug-Induced Coagulopathy. Acetylsalicylic acid (ASA) and nonsteroidal anti-inflammatory drugs (NSAIDs) block platelet cyclo-oxygenase, inhibiting production of thromboxane A₂, resulting in inhibition of platelet aggregation for up to 10 days. Theoretically, reversal of the effects of ASA and other platelet antagonists requires stopping the medication and transfusing platelets (see Table 43-1). However, this is not often performed in clinical practice because of lack of evidence that antiplatelet therapy causes a substantially increased risk of uncontrolled intracranial bleeding. A single dose of intravenous desmopressin (DDAVP) might be of benefit by promoting platelet VWF expression, but this remains speculative.

ADP Receptor Blocker-Induced Coagulopathy. Clopidogrel (Plavix) and ticlopidine (Ticlid) alter platelet aggregability by irreversibly inhibiting the surface adenosine diphosphate (ADP) binding site and by reducing ADP release from activated platelets. Similar to the use of ASA, platelet function is permanently impaired and normal platelet production allows platelet function to normalize after 7 days of withholding therapy. As is the case with other antiplatelet agents, treatment of patients with neurologic bleeding emergencies who are taking these agents with platelet transfusion and DDAVP remains untested (see Table 43-1).

GIIb/IIIa-Induced Coagulopathy. Three agents are commercially available in the United States for the management of acute coronary syndromes: abciximab (ReoPro; Eli-Lilly and Co., Indianapolis, Ind., USA), eptifibatide (Integrilin; Cor Therapeutics, San Francisco, Calif., USA), and tirofiban (Aggrastat; Merck, West Point, Pa., USA). Usually, they are administered in combination with ASA, ADP receptor blockers, and LMWH or unfractionated heparin. These

agents reversibly bind to the GIIb/IIIa receptor, inhibiting platelet aggregation. Primary intervention GIIb/IIIa for CNS bleeding emergencies in patients treated with these agents include withholding the medication (which allows platelet function to recover after 48 hours for abciximab and 4 to 8 hours for eptifibatide and tirofiban), and possibly platelet transfusion and DDAVP, which again remains untested (see Table 43-1).

Thrombolytic-Induced Coagulopathy. Several available thrombolytic agents are used by cardiologists and neurologists throughout the world, including alteplase, streptokinase, urokinase, reteplase, and tenecteplase. All agents in this category produce the same anticoagulation effect by directly increasing fibrinolytic activity by the conversion of plasminogen to plasmin. These agents have a prolonged half-life and sometimes are used in association with heparin to extend its therapeutic effect. There are no demonstrated effective treatments available to reverse thrombolytic agents in the setting of CNS bleeding. Guidelines for the management of hemorrhagic complications of thrombolytic therapy published by the Stroke Council of the American Heart Association⁷² recommend immediate discontinuation of the agent, coagulation profile and complete blood count testing, and cross-matching for the possible administration of cryoprecipitate, packed red blood cells, FFP, or platelets as appropriate.

Ischemic Stroke with Hemorrhagic Transformation

ICH may occur shortly after ischemic stroke. Hemorrhage into an area of ischemic infarction occurs when vessel walls are damaged by ischemia and blood then extravasates into the brain parenchyma. The transformation requires sufficient time for an ischemic lesion to develop and then partial or total reperfusion with restoration of blood flow through the vessel or by collateralization.^{73,74} Large infarct size,⁷⁵ older age,^{73,74} hyperglycemia,⁷⁶ sustained hypertension,⁷⁴ thromboembolic mechanism (as opposed to penetrator occlusion),^{73–75} and preexisting micro-hemorrhages on magnetic resonance imaging (MRI)⁷⁷ have been identified as risk factors for hemorrhagic conversion of an infarct. Small asymptomatic petechiae are less important than frank hematomas, which may be associated with neurologic decline. Early administration of anticoagulants is also associated with an increase in the risk of clinically detectable hemorrhages.⁷⁸ In general, spontaneous hemorrhagic conversion after ischemic stroke occurs in 0.6% to 5% of patients admitted to the hospital.^{56,79,80} Management of spontaneous hemorrhagic transformations depends on the amount of blood extravasated and clinical symptoms.

Consultation Strategies

Hemorrhagic transformation may be asymptomatic and its management follows similar principles of those for ischemic stroke. Excessive hypertension and hyperglycemia should be avoided and surgical evacuation may be indicated for a life-threatening ICH. When diagnosed by CT or MRI, prompt discontinuation of antiplatelet agents or anticoagulation is indicated. Continuation of anticoagulation in these patients has been proved safe in small case

series when asymptomatic petechial hemorrhage is present,^{81,82} but to justify this approach, the indication to continue anticoagulation must be extremely compelling.

Ischemic Stroke after Spontaneous Arterial Dissection

Spontaneous cervicocerebral dissections account for approximately 2% of all ischemic strokes, but may account for more than 20% of strokes in children and young adults. Population-based studies have determined that the incidence of dissections is about 2.6 to 2.9 cases per 100,000 patients per year. The annual incidence of extracranial internal carotid (ICA) dissection is 3.5 cases per 100,000. Extracranial vertebral artery (VA) dissection is less common, accounting for up to 15% of reported cases, whereas intracranial VA dissection accounts for 5% of cases.⁸³ Observational studies indicate that the risk of recurrent thromboembolism during the first year after symptomatic cervicocranial arterial dissection is approximately 0.9% to 1.8%,⁸⁴ and that the greatest risk occurs in the first 30 days.

Consultation Strategies

The treatment of spontaneous extracranial cerebrovascular dissections is controversial and currently there is no controlled clinical trial evaluating the role of anticoagulation for preventing recurrent thromboembolism. In 2003, a Cochrane Review of the use of antithrombotic drugs for carotid artery dissection found no evidence to support routine use of anticoagulation or antiplatelet agents in this setting.⁸⁵ Therefore, treatment is based on clinical observations and expert opinions. Acute symptomatic extracranial dissections are commonly managed with full-dose heparin anticoagulant therapy (target PTT 2.0 to 2.5 times normal) and subsequent warfarin therapy (target INR 2.0 to 3.0) for 3 to 6 months. Therapy is monitored in stable patients every 3 months with noninvasive tests such as vascular ultrasound or magnetic resonance angiography (MRA). If at 3 months, noninvasive tests show resolution of dissection, then antiplatelet (usually ASA) therapy is instituted after discontinuation of warfarin. If noninvasive testing shows no reconstitution of the dissection, warfarin is continued for an additional 3 months.⁸³ At 6 months, new assessment of the involved vessel is performed, if in any circumstance there is persistent filling defect, then life-long antiplatelet therapy is indicated. Contraindications to the initial anticoagulation include intracranial arterial dissections associated with pseudoaneurysm formation and SAH and the presence of a large infarct with mass effect and/or hemorrhagic transformation. In these patients, a single antiplatelet agent can be used as an alternative.⁸³

Cerebral Sinus Venous Thrombosis

Cerebral sinus venous thrombosis (CSVT) is a rare and frequently misdiagnosed entity with an annual incidence of 0.5 cases per 100,000 patients.⁸⁶ Acute thrombosis of intracranial venous draining systems may manifest as venous infarcts that tend to become congested and hemorrhagic in about 40% of patients.⁸⁷ The clinical presentation depends generally on the venous anatomy, but the subacute onset of headache, abnormal mental status, seizures, and papilledema is suggestive of venous sinus thrombosis.

Superior sagittal sinus thrombosis (SST) is involved in about 70% of the cases. Acute venous sinus thrombosis may be seen in patients with predisposing factors such as dehydration, infection (sepsis), prothrombotic states (hormone related, cancer, and pregnancy), inherited hypercoagulable disorders (activated protein C resistance by factor V Leiden mutation, protein C or S deficiency), inflammatory states, mechanical causes such as cerebrovenous injury such as trauma, and medications (oral contraceptives and asparaginase) (see Chapter 16).⁸⁸

Consultation Strategies

Basic treatment includes rehydration with isotonic intravenous fluid administration, seizure prevention with antiepileptic medications, blood pressure control, and management of symptomatic mass effect and increased intracranial pressure (ICP)³⁸ with osmotic diuretics. In general, anticoagulation should be performed, even in the presence of hemorrhagic infarction. Small retrospective case series^{89,90} and randomized prospective controlled trials^{91,92} have demonstrated a nonsignificant beneficial trend toward anticoagulation in patients with CSVT. In the study by Einhaupl and colleagues a nonsignificant benefit of anticoagulation was seen in patients receiving full-dose unfractionated heparin versus placebo.⁹² In a prospective randomized controlled study by de Bruijn and Stam, the heparinoid nadroparin was compared with placebo in patients with CVT. This study showed a nonsignificant beneficial trend of anticoagulation with LMWH but, importantly, it demonstrated the safety of full anticoagulant therapy even in patients with ICH.⁹¹ A recent meta-analysis involving these studies showed a nonsignificant reduction in the risk of death or dependency.⁹⁰ On the basis of these results, we suggest intravenous anticoagulation with heparin with no initial bolus to achieve a minimal but therapeutic heparin level (0.3 to 0.6 U/mL), or standard dosing of low molecular weight heparin to attain full anticoagulation.

Almost all patients with CSVT require long-term oral anticoagulation for a period of at least 3 to 6 months. Duration of long-term anticoagulation depends mainly on whether or not a sustained hypercoagulable state is present. If this is not the case (such as with pregnancy-associated CSVT), then anticoagulation usually can be safely stopped at 6 months.

Endovascular options such as mechanical thrombectomy or thrombolysis are in experimental stages but its use seems attractive and reasonably safe.⁹³ No randomized prospective control trial has been achieved and its efficacy cannot be assessed based on the current published data. In our opinion, endovascular treatment for CVT should be attempted only at experienced centers when the patient is deteriorating clinically while on intravenous anticoagulant therapy.

Aneurysmal Subarachnoid Hemorrhage

Aneurysmal subarachnoid hemorrhage (SAH) is a complex entity requiring expertise for both recognition and management. Throughout the history of ruptured aneurysm treatment, rebleeding has been identified as a major cause of morbidity and mortality. In past decades, when delayed surgical aneurysm treatment was the norm, a 20% incidence

of rebleeding after 2 weeks and a 30% cumulative risk after 1 month was documented if the aneurysm was left unprotected.^{94,95} Currently, early aneurysm repair within 24 hours of diagnosis of SAH is practiced at most centers. However, even with aggressive strategies to clip or coil the aneurysm as soon as possible, rebleeding still occurs in nearly 7% of patients, with the majority of episodes occurring within 72 hours of the index hemorrhage.⁹⁶

Besides rebleeding, early complications of SAH include IVH and vasospasm.⁹⁷ IVH occurs in up to 20% of SAH patients and there is strong evidence of its association with increased morbidity, mortality, and poor outcomes.⁹⁷ Up to 30% of patients with SAH experienced symptomatic delayed cerebral ischemia, mainly between days 3 to 14 after the initial hemorrhage⁹⁷—a prominent cause of death and disability. The total amount of subarachnoid blood is a strong risk factor for vasospasm.⁹⁷ Treatment with hypervolemia, hemodilution, and induced hypertension (so called Triple-H therapy) aims to increase cerebral blood flow (CBF) and improve microcirculation by raising systolic blood pressure.

Consultation Strategies

Prevention of Rebleeding. Prevention of rebleeding is the goal before the aneurysm has been secured. This can be achieved by judicious blood pressure control and optimization of coagulopathy or platelet dysfunction if present. For coagulopathic patients, conventional use of FFP, vitamin K and/or platelet transfusions are used (see Table 43-1).

The use of synthetic lysine analogs with antifibrinolytic activity in humans⁹⁸ exerting their effect by blocking the lysine-binding site of the plasminogen molecule and displacing plasminogen from fibrin has been studied in SAH patients. In the 1970s and 1980s, before early surgical aneurysm repair was widely prevalent, many neurosurgeons treated SAH patients with antifibrinolytics for up to two weeks during the period of maximal vasospasm to prevent rebleeding prior to performing delayed surgery. Clinical trials and large observational studies indicate that these agents reduced the frequency of rebleeding, but they increased the frequency of delayed cerebral ischemia and other thrombotic complications, resulting in no overall benefit or outcome.^{99–101}

More recent evidence suggests that limiting antifibrinolytic therapy to the early period after bleeding onset may be more beneficial. In a large prospective controlled trial, a brief early course of tranexamic acid (1 g every 6 hours up to 72 hours after onset, or until a definitive aneurysm repair procedure was performed) reduced early rebleeding events by 80%.¹⁰² Based on our experience at the Neurological Intensive Care Unit of Columbia University, we give a single intravenous 4 g dose of ε-aminocaproic acid (EACA) (Amicar) followed by an infusion of 1 g per hour until the aneurysm is secured, for up to 72 hours after onset.

A single dose of rFVIIa given at the time of diagnosis of SAH to prevent rebleeding might be considered as well. However, it has not been studied as of yet in a large clinical controlled trial. Pickard and associates¹⁰³ performed a pilot study to evaluate the potential use of rFVIIa for the prevention of rebleeding in patients with good grade SAH who were not treated with early surgical repair. The study was suspended after the third rFVIIa-treated patient (who was

given an 80 µg per kilogram of body weight loading dose and a 7 µg/kg/hour infusion) developed a complete middle cerebral artery territory infarct after several days of therapy. Presumably the rFVIIa triggered thrombosis in the setting of delayed cerebral vasospasm. For this reason, the use of rFVIIa to prevent aneurysm rebleeding after SAH remains investigational.

Prevention of Symptomatic Vasospasm. Intracisternal fibrinolysis is an experimental approach that aims to decrease the incidence of symptomatic vasospasm by injecting tPA into the basal cisterns to promote the clearance of subarachnoid clot. Several studies have demonstrated that this therapy might decrease the incidence of vasospasm without any change in 3-month outcomes.^{104,105} Clinical experience with this technique has been relatively limited over the last decade. To date, no adequately powered randomized prospective controlled trial has evaluated the benefits of this technique over conventional management.

The use of antiplatelet agents or anticoagulants might theoretically reduce the risk of delayed ischemia from vasospasm. A small randomized trial investigating the use of aspirin after SAH has been reported, but definitive data for this approach are lacking.¹⁰⁶

The presence of large amounts of IVH is a well-established risk factor for poor outcome after SAH as well as ICH. If the third and fourth ventricles are completely filled with blood, the result is acute obstructive hydrocephalus, elevated ICP, and central herniation if a ventricular drain is not placed urgently. As described previously, intraventricular fibrinolysis is an experimental approach that aims to promote the clearance of IVH by injecting tPA via the ventricular drain. This technique is currently being tested on SAH and ICH patients.

BRAIN NEOPLASMS, ANTICOAGULATION, AND CENTRAL NERVOUS SYSTEM BLEEDING DISORDERS

Hemorrhage from a brain tumor comprises 2% to 10% of all cases of secondary ICH. Primary brain tumors with potential bleeding risk include glioblastomas, large schwannomas, and hemangioblastomas. Metastatic tumors can potentially bleed as well. Those that frequently do bleed include melanoma, renal cell carcinoma, choriocarcinomas, and thyroid carcinoma.¹⁰⁷ Nevertheless, bleeding disorders affecting the CNS are more common in patients with hematologic malignancies than those with solid tumors. Hemorrhage into the brain parenchyma, subdural, and subarachnoid spaces may result from DIC in patients with cancer.¹⁰⁸ A high index of suspicion for intracranial bleeding is needed when oncologic patients complain of headaches or sudden onset of neurologic dysfunction.

Venous thromboembolism (VTE) occurs commonly in patients with brain tumors. Symptomatic VTE develops in 19% to 29% of patients with gliomas, the most common type of primary brain tumor.^{109,110} Moreover, the incidence of asymptomatic VTE in the glioma population may be as high as 60%.¹¹¹ A recognized number of hemostatic and clinical factors contribute to this hypercoagulable state. Concern over the possibility of intracranial bleeding has limited the use of (low dose) prophylactic anticoagulant

therapy in this population yet the specter of requiring (high dose) therapeutic anticoagulant therapy when VTE arises (arguably one of the highest causes of morbidity and mortality in neurosurgical patients) must also be taken into calculating risk:benefit considerations. Probably more than one half of neurosurgeons will still use mechanical methods alone.¹¹² However, mechanical approaches such as vena caval filters have high complication and treatment failure rates in patients with intracranial malignancies (see Chapter 31). Available data suggest that anticoagulation can be used safely and effectively in most brain tumor patients. The use of LMWH or unfractionated heparin further decreases the rates of VTE as documented by a relative risk reduction of 38% reported in a recent meta-analysis (Figs. 43-4 and 43-5).¹¹³

For patients requiring craniotomy, the combination of LMWH at prophylactic doses plus mechanical compression devices have been proved superior in the prevention of VTE with nonsignificant risk of bleeding compared with placebo plus mechanical compression even if this approach is started within 24 hours of surgery.¹¹⁴

The PRODIGE study (Dalteparin Low Molecular Weight Heparin for Primary Prophylaxis of Venous Thromboembolism in Brain Tumour Patients), an international phase III clinical trial sponsored by the Ontario Clinical Oncology Group, is currently randomly assigning patients with high-grade gliomas to long-term LMWH (dalteparin) versus placebo to evaluate the benefits and risks of primary prophylaxis.

TRAUMA

Traumatic Brain Injury with Coagulopathy

ICH and contusional bleeding may occur after severe head trauma with coup and countercoup lesions seen in CT scan. Small areas of hemorrhage may occur acutely or delayed at the gray-white matter junction, reflecting axonal disruption due to differential mass density. Pathologic damage of the gray-white matter junction after trauma leads to diffuse axonal injury (DAI), a condition that carries an ominous prognosis. Sometimes, severe traumatic brain injury (TBI) can lead to a systemic coagulopathic state that has been linked to systemic release of TF, resulting in DIC and an enhanced fibrinolytic state.^{115,116}

Preinjury warfarin use is associated with an increased risk of morbidity and mortality in traumatized head-injury patients.¹¹⁷ In a study of 380 anticoagulated patients admitted to a level I trauma service, 37 patients (10%) had intracranial injuries, 12 of whom were receiving warfarin. Mortality in the warfarin group was 33% versus 8% in a matched control group.¹¹⁷

Consultation Strategies

FFP, cryoprecipitate, platelet and red blood cell transfusions in conjunction with vitamin K remain the mainstays of therapy for the traumatized patient with coagulopathy. Anecdotal reports of rFVIIa administration suggest that this agent can safely reverse TBI-related coagulopathy and especially serve as an antidote to warfarin-induced coagulopathy in patients with active, life-threatening hemorrhage and a survivable injury. This may facilitate the timely placement of an ICP monitor for management of cerebral edema.

Figure 43-4 Algorithm for the deep vein thrombosis (DVT) prophylaxis in hospitalized brain tumor patients. DIC, disseminated intravascular coagulation; ICH, intracerebral hemorrhage; IU, International Units; LMWH, low molecular weight heparin; SQ, subcutaneously; TID, three times daily; UFH, unfractionated heparin.

Figure 43-5 Algorithm for the treatment of acute deep vein thrombosis (DVT) or venous thromboembolism (VTE) in brain tumor patients. DIC, disseminated intravascular coagulation; ICH, intracerebral hemorrhage; LMWH, low molecular weight heparin; UFH, unfractionated heparin.

Dutton and coworkers¹¹⁸ reported a series of 81 traumatized patients who received rFVIIa to stabilize ongoing bleeding. Thirty-one patients had TBI and of this group 20 patients received rFVIIa (dose 41 to 178 µg per kilogram body weight) to control bleeding related to severe TBI or dilutional coagulopathy; eight for correction of warfarin-related coagulopathy; two for multiple organ system failure (MOSF)-related coagulopathy; and one for congenital FVIII deficiency. The majority of the patients with TBI-related coagulopathy also had severe extracranial injuries and were transfused a minimum of 10 U of packed red blood cells and 8 U of FFP prior to rFVIIa treatment. All of the patients in the series had immediate improvement of their PT/INR and 75% achieved clinical hemostasis after rFVIIa administration with an overall survival rate of 42%. In the TBI subgroup, cessation of intracranial hemorrhage occurred in 90% of the patients but long-term outcomes were poor with a mortality rate of 80%. Those authors proposed a possible role of rFVIIa in contributing to inappropriate microvascular thrombosis with subsequent worsening of perfusion, and chose to subsequently limit the use of rFVIIa in this population to patients with severe coagulopathy and early risk of death from exsanguination, or for the support of potential organ donors.¹¹⁸

REVERSAL OF COAGULOPATHY BEFORE NEUROSURGICAL INTERVENTIONS

The management of subdural, epidural (intracranial or spinal), and intracerebral hemorrhages requiring rapid surgical evacuation in warfarin-treated patients is a common scenario for the consultant hematologist. By convention, but without study-derived data, most neurosurgeons prefer a documented INR value below 1.4 before they consider proceeding with a craniotomy or placement of an intracranial bolt or ventricular catheter.

Consultation Strategies

The conventional approach of vitamin K and FFP administration is limited by the long time that it takes to order and infuse FFP, and then document normalization of the INR.

Warfarin-Induced Coagulopathy. Several authors have reported on the beneficial effect of rFVIIa for rapid correction of warfarin effect prior to neurosurgical interventions.^{62,119–121} rFVIIa has been used successfully in the management of anticoagulated patients with acute intracranial subdural hematomas,^{62,122} spinal SAH,⁶² and spinal epidural and subdural hematomas.^{119,123} All patients were characterized for having a high INR on admission and received intravenous rFVIIa at doses ranging from 10 to 120 µg per kilogram of body weight. In these case reports, rFVIIa was concomitantly used with FFP and vitamin K to achieve and maintain normalization of coagulation parameters.

Miscellaneous Coagulopathic States. Successful treatment of a wide variety of coagulopathies has been reported, including liver failure,¹²⁰ dilutional coagulopathy after multiple blood transfusions,¹²⁰ DIC,¹²⁴ TBI-related coagulopathy,¹²⁵ and congenital factor VII deficiency.¹²⁴ In these reports, all patients had an elevated INR on admission, received rFVIIa at doses ranging from 10 to 120 µg per

kilogram of body weight, and tolerated the procedure well. There were no thrombotic complications reported. These reports are promising, but because of the potential for publication bias, randomized controlled trials are needed to firmly demonstrate that rFVIIa given in addition to vitamin K and FFP is more effective and as safe as the traditional approach alone, and to identify the optimal dosing regimen for this indication.

In the largest series, Roitberg and colleagues¹²¹ administered rFVIIa to 29 patients as a second-line therapy after initial attempts at reversal with FFP had failed. Twenty-four patients treated with FFP and vitamin K alone before the introduction of rFVIIa were analyzed as control subjects. After initial FFP administration, INR tended to rebound in both groups. In the rFVIIa group, mean INR fell from 2.2 to 1.1 ($P < 0.05$) after an average of 1.4 mg of rFVIIa was given. INR in the rFVIIa group was documented as normalized within 7 hours after admission, compared with 47 hours ($P < 0.0005$) in the control group. The number of patients with good functional outcome was greater among patients treated with rFVIIa compared with those who received only vitamin K and FFP ($P = 0.04$). There were no thrombotic complications reported among the rFVIIa group.

Park and coworkers¹²⁰ performed a retrospective review of nine patients with diverse non-hemophilic coagulopathies in which rFVIIa was used in the preoperative period of urgent neurosurgical interventions. The coagulopathies consisted of three patients in anticoagulant therapy for AF, four patients with liver dysfunction, and two patients with dilutional coagulopathy after resuscitation for extensive traumatic hemorrhage. Neurosurgical indications included two patients requiring craniotomy for ICH or epidural hematoma, one patient requiring ventriculostomy for intraventricular hemorrhage, and three patients requiring an ICP monitor for diffuse cerebral edema. All patients, except two, were initially treated with FFP with no effective correction of their coagulopathy. Doses of rFVIIa ranged from 40 to 90 µg per kilogram of body weight; there were no procedure complications or thrombotic events identified. Pre-dose INRs ranged from 1.5 to 3.8, and normalization of the INR was reached in all patients as early as 20 minutes after the infusion of rFVIIa, which allowed for prompt surgical intervention.

Huang and associates¹²⁴ report three cases of patients with factor VII deficiency and associated hemorrhages of the CNS. One patient presented with multiple injuries including traumatic SAH and subdural hematoma. He initially received multiple doses of vitamin K and FFP with persistence of coagulopathy and his factor VII level was found to be 21% (reported normal level 50% to 150%). Because of concern about increase in the hematoma and worsening mental status, he was given rFVIIa at an initial dose of 95 µg per kilogram of body weight, and then at lower doses ranging from 10 to 38 µg per kilogram of body weight throughout the next several days. The patient was alert and following commands and discharged at 2 months. The second patient also presented with multiple injuries including contusions, traumatic SAH, and subdural hematoma. On admission, the patient had findings consistent with DIC and received multiple doses of FFP, red blood cells, and platelets, along with antibiotics. After 6 days, the level of factor VII was found to be 40% of normal and rFVIIa therapy was instituted at doses ranging from 45 to 60 µg per kilogram of body weight for the next 12 days.

The patient was discharged after 1 month with slight improvement in neurologic status, but not following commands. The third patient presented 2 weeks after a lumbar laminectomy with a large epidural hematoma which was surgically evacuated. On the second postoperative day from the evacuation, the factor VII level was found to be 27%. Because of continuous bleeding from the incision, rFVIIa therapy was started at 24 µg per kilogram of body weight for the following 3 days. At day 5 after surgery, the mass effect had lessened, but the hematoma persisted.

Liver Disease-Related Coagulopathy. End stage liver disease results in a complex and variably severe failure of hemostasis that predisposes to abnormal bleeding (see Chapter 39). The diverse spectrum of hemostatic defects includes impaired synthesis of clotting factors, excessive fibrinolysis, DIC (and situations mimicking DIC), thrombocytopenia, and platelet dysfunction. Attempts to correct these deficits are required, as much as can be accomplished, in the setting of CNS bleeding emergencies. FFP, cryoprecipitate, and platelet transfusions remain the mainstays of therapy. Anecdotal reports of rFVIIa administration suggest that this agent may safely reverse liver failure-related coagulopathy and facilitate the timely placement of an ICP monitor for management of cerebral edema. Larger trials testing the efficacy and safety of rFVIIa for this indication are ongoing.

Atrial Septal Abnormalities and Cryptogenic Stroke

Peter C. Block, MD

BACKGROUND

Atrial septal abnormalities (patent foramen ovale [PFO] and/or atrial septal aneurysm [ASA]) occur in up to 20% of the general population, and the link of PFO to patients with cryptogenic stroke may be twice that number. Whether this association has pathophysiologic significance is debated, but most theories suggest a central role for thrombosis and embolization. Thus, aspirin and warfarin are the first line of medical therapy, and a variety of secondary prevention studies have assessed their impact on stroke recurrence. The evaluation of any patient with cryptogenic stroke must rule out other established factors that may cause stroke (carotid stenosis, atrial fibrillation) or contribute to the chance of thromboembolism (hypercoagulable states).

There is no doubt that patients with isolated PFO or atrial septal aneurysm and a first ischemic stroke respond well to either aspirin or warfarin therapy. Aspirin or oral anticoagulation with warfarin is the U.S. Federal Drug Administration (FDA) current recommendation for therapy. PFO closure is FDA indicated only if a second event occurs during adequate anticoagulation or antiplatelet therapy. Despite these guidelines, many patients with a first cryptogenic stroke undergo percutaneous PFO closure. All of these therapies are effective in reducing stroke recurrence, yet all are also associated with some risk. Thus, the correct choice of therapy for individual patients is controversial. In the absence of randomized controlled trials comparing medical therapy and percutaneous closure, the decision for a therapeutic strategy should be done in conjunction with the patient, while considering the individual patient's clinical presentation, risk profile, occupation, choices, and lifestyle.

INTRODUCTION

More than 700,000 new or recurrent stroke cases are diagnosed annually in the United States.¹ Most are ischemic in origin and occur in older patients in association with atrial fibrillation, hypertension, smoking, hyperlipidemia, and diabetes. However, approximately 40% of ischemic strokes are cryptogenic² and occur in patients younger than 55 years of age. In such patients, there is frequently an association with atrial septal abnormalities, leading to speculation that there is a causal relationship.

In utero, the cranial remnant of the septum primum covers the foramen ovale and acts as a one-way valve

allowing placental, oxygenated blood to flow from the right to left atrium.^{3,4} At birth, the lungs expand and pressure in the pulmonary circuit falls. As a consequence, the higher pressure in the left atrium pushes the septum primum against the septum secundum, closing the foramen ovale. The septum primum and the caudal part of the septum secundum then fuse. However, if fusion does not occur or is incomplete, patency of the foramen ovale may persist into adulthood. Transient right-to-left blood flow in such individuals can be induced by a variety of maneuvers and pathologic changes, the most common being a simple Valsalva maneuver. In addition, the cranial portion of the septum primum can be thin and have redundancy and hypermobility. Such an atrial septal aneurysm is identified if septal excursion is >10 mm with a base diameter of more than 15 mm.^{5,6} Thrombi might potentially form in the redundant areas of the atrial septal aneurysm or the aneurysm may promote right-to-left blood flow by producing a current effect through the foramen ovale. If the foramen is not overlapped completely or if the septum secundum is incomplete, there is a persistent opening in the atrial septum. Because left atrial pressure normally exceeds right atrial pressure, blood flow is left-to-right through such an atrial septal defect, but may also transiently or permanently become right-to-left if changes in the atrial pressure relationships occur.

STROKE RISK

The potential role of atrial septal abnormalities in the pathogenesis of stroke is supported by an increased prevalence of PFO in patients with cryptogenic stroke compared with controls. In the general population, PFO is present in 9% to 27%.⁷⁻¹⁰ In patients with cryptogenic stroke, PFO was found in 42% to 54%, with the strongest association noted in patients ≤ 55 years of age.^{11,12} A meta-analysis of nine case-control studies showed a fivefold increase in the risk of stroke in patients with atrial septal aneurysm, and the strongest correlation was noted with the combination of both PFO and atrial septal aneurysm in patients ≤ 55 years of age.⁵ Mas and colleagues¹³ reported an association between interatrial septal abnormalities and stroke recurrence rates in patients (mean age 40 years) with cryptogenic stroke on aspirin, but the risk of recurrent events was only significantly increased in patients with both PFO and atrial septal aneurysm. There is speculation, therefore,

that the motion of the aneurysm could favor the movement into the systemic arterial circulation of thrombi formed locally in the PFO or traveling from more distant sites in the venous circulation. The mechanisms remain speculative and appear contradicted in some clinical studies. Homma and colleagues failed to demonstrate an increased risk of recurrence in patients with combined PFO/atrial septal aneurysm compared with those with either abnormality alone.¹⁴ Other studies have shown no association between stroke recurrence and degree of shunting.¹⁵

Thus, causation of stroke in patients with atrial septal abnormalities remains debatable.¹⁶ Nevertheless, support for the theory of paradoxical embolization of thrombus, air, or fat from the venous system through a PFO, and into the arterial circulation comes from a number of observations (Fig. 44-1).

Right-to-left shunting across a PFO can be induced by transient increases in right atrial pressure. Either deep coughing or the Valsalva maneuver characteristically is used clinically to demonstrate right-to-left shunting by transthoracic or transesophageal echocardiography (TEE) (positive “bubble” study) or transcranial Doppler. Presence of a large remnant eustachian valve can also preferentially direct blood from the inferior vena cava across the PFO and into the left atrium. Strokes may be more common in patients at risk for deep venous thrombosis (cancer, post-immobilization, long travel) or following diving (air accumulation from decompression), although many patients with cryptogenic stroke do not have such predisposing factors. The simultaneous occurrence of right- and left-sided embolic events in the same patient further support this proposed mechanism. The association between PFO and prothrombotic states (mutations in the factor V or prothrombin genes), which result in venous hypercoagulability,¹⁷ may support paradoxical embolization. Alternatively, stroke may occur due to local thrombosis in the cerebral circulation, especially in patients with increased levels of the anticardiolipin antibody, which results in either venous or arterial hypercoagulability. The incidence of deep venous thrombosis (DVT) in patients with cryptogenic stroke and interatrial shunting ranges between 9% and 57%^{18,19} making the association

unclear. Further support for the role of paradoxical embolism comes from reports of atrial septal abnormalities associated with PFO.^{20–24}

DIAGNOSTIC TESTING

The most sensitive tests for the diagnosis of PFO are a transcranial Doppler of the middle cerebral artery or a transesophageal echocardiography with a “bubble” study^{3,4,6} using an intravenous injection of agitated saline. The appearance of bubbles in the left atrium or cerebral circulation within 3 to 5 cardiac cycles of a venous injection of agitated saline identifies PFO with right-to-left shunting. Use of a Valsalva maneuver or cough with injection of the saline into the femoral vein increases the sensitivity of this test.^{4,6,25–28} Despite the demonstration of a PFO it is critical to rule out other potential causes of stroke or factors that might contribute to thromboembolism.

Venous hypercoagulable states that may affect therapeutic strategies for care of patients with stroke include positive testing for the factor V Leiden mutation, prothrombin 20210 mutation, antiphospholipid antibodies, hyperhomocysteinemia, protein S deficiency, protein C deficiency, elevated lipoprotein(a), and antithrombin III deficiency. In any patient with cryptogenic stroke, identification of a hypercoagulable state is important because a venous hypercoagulable state may directly impact a decision for or against closure of a PFO and may also affect procedural and periprocedural therapy. Heparin, for example, is usually given during percutaneous closure, but a venous hypercoagulable state increases the risk of venous thrombosis at the femoral vein catheter insertion site, implying prolonged periprocedural heparin use. In such a case should lifelong warfarin be prescribed, and if so, is closure warranted in the first place? If closure is successful, must these patients be treated with lifelong warfarin, or will aspirin be adequate (Table 44-1).

It is also important to screen for arterial hypercoagulable states. Patients with arterial hypercoagulable states and a history of stroke may warrant lifelong oral anticoagulation with warfarin regardless of closure of a PFO. If closure is undertaken, these patients may also require periprocedural heparin therapy. Arterial prothrombotic states that may require indefinite oral anticoagulation with history of stroke are the presence of antiphospholipid antibodies, dysfibrinogenemia, and perhaps protein S and protein C deficiencies.

Thus, the presence or absence of hypercoagulable states should directly affect the decision to either close or not

Figure 44-1 Transesophageal echocardiogram showing a long thrombus straddling a patent foramen ovale (arrows = thrombus).

Table 44-1 Implications of Results of Screening Tests for Hypercoagulable State

Periprocedural heparin?
Increased risk of DVT at insertion site?
Postprocedural warfarin?
Better than aspirin to prevent device thrombosis?
Need for lifelong warfarin anyway?
Perhaps not, if closed PFO?
With a history of stroke, the patient may need lifelong anticoagulation regardless of PFO closure

DVT, deep venous thrombosis; PFO, patent foramen ovale.

close a PFO associated with stroke. If a venous hypercoagulable state is present and closure is done, heparin should be used during the procedure and perhaps continued for 12 hours after the venous sheath is removed. Warfarin should probably be used instead of aspirin for at least the first 3 months after closure to minimize thrombus formation on the device. If an arterial hypercoagulable state is present and closure is done, heparin should be used during the procedure, and lifelong warfarin should be prescribed regardless of closure (Table 44-2).

TREATMENT

The best strategy for secondary prevention in patients with cryptogenic stroke is yet to be determined. Randomized trials of medical (antithrombotic) therapy versus anatomic closure have been hampered by slow patient recruitment. Reports of individual site registries are all we have. Medical therapy has centered around the use of antiplatelet agents and warfarin. Aspirin and warfarin have mostly been studied in patients after a first cryptogenic stroke. Here too, the results of retrospective and prospective studies are inconsistent. Daily aspirin use (300 mg/day) was associated with a yearly rate of recurrent stroke/transient ischemic attack (TIA) of 1% in patients with either PFO or atrial septal aneurysm,¹³ but recurrence events were 4.7% in patients with coexisting PFO and atrial septal aneurysm.

In the warfarin-aspirin recurrent stroke study (WARSS), comparing warfarin (mean target International Normalized Ratio [INR] 2.1) with aspirin (325 mg/day) in patients with ischemic stroke,²⁹ recurrent stroke or death occurred in 17.8% of patients assigned to warfarin and in 16% of patients assigned to aspirin ($P = 0.25$) at 2 years. This study may be inadequate owing to the low target INR.

The PFO in cryptogenic stroke study (PICCS) studied 630 WARSS patients who underwent a TEE.¹⁴ Forty percent of the patients had sustained a cryptogenic stroke. The study population was equally divided between aspirin and warfarin therapy. In this substudy, the end point of recurrent stroke or death was similar in patients with ischemic stroke regardless of the presence or absence of a PFO. The size of the foramen (degree of shunting) and the presence of an atrial septal aneurysm did not identify increased risk of events. Whereas data from these studies suggest equal efficacy of aspirin and warfarin in patients with isolated PFO or atrial septal aneurysm manifesting with a first cryptogenic stroke, the best medical therapy for

patients with the combination of PFO and atrial septal aneurysm remains unclear. The results of the study by Mas¹⁵ showing the inadequacy of aspirin in reducing the risk of stroke in this group of patients are contradicted by the conclusions derived from the PICCS cohort. Some of the discrepancy could be accounted for by the different populations studied. It is possible that in older patients with both PFO and atrial septal aneurysm (mean age 59 years in PICCS) either therapy is effective for secondary prevention, but that younger patients (≤ 55 years) with similar presentation constitute a particularly high-risk group that would benefit most from adequate oral anticoagulation (INR 2 to 3) with warfarin or PFO closure. Strategies for primary prevention still need to be defined. Moreover, the next therapeutic step in patients who fail aspirin, warfarin, or both, has not been established—although PFO closure is currently recommended. Target INRs and especially achieved INRs must be closely considered prior to assigning a patient as a warfarin failure.

Percutaneous PFO closure for patients with cryptogenic stroke is an alternate strategy. Reports of the safety profile and the effect on recurrent stroke rate of percutaneous PFO closure are mostly retrospective. Technical success is excellent with successful closure in more than 90% of patients.³⁰ At 5-year follow-up,³¹ the annual recurrence risk was 3.4% for the combined end point of TIA, stroke, and peripheral embolism. The presence of a postprocedural shunt was the best predictor of recurrent events with a relative risk increase of 4.2 ($P = 0.03$). Hung and colleagues reported their experience using the Clamshell, CardioSEAL, or Sideris buttoned devices.³² Eighty-six percent of patients had effective closure of the PFO. Stroke recurrences were attributed to suboptimal device performance, including the presence of residual postprocedural shunting. Hong and coworkers reported the experience with the Amplatzer device.³³ Although patients were few, PFO closure was complete in 67% at the end of procedure and 100% at 2 years of follow-up. No recurrent embolic neurologic events were reported.

A larger study using the PFO-STAR device in 276 patients³⁴ reported implantation success in all patients but periprocedural complications included transient ST-segment elevation (1.8%), and TIA (0.8%). At 15-month follow-up, TIA had occurred in 1.7%. No recurrent stroke or peripheral emboli occurred. Windecker and colleagues³¹ provided insight into a potential benefit of endovascular PFO closure over medical therapy in select patients with prior stroke. The study identified 308 patients having had a cryptogenic stroke associated with an atrial septal aneurysm. Of these, 150 patients had percutaneous PFO closure and 158 were treated medically. Patients with residual shunts (17%) or other indication for aspirin continued this therapy indefinitely. In the group receiving medical therapy, one half were prescribed warfarin (target INR 2 to 3), whereas the rest received antiplatelet therapy—mostly in the form of aspirin. PFO closure showed a nonsignificant trend toward a lower risk in the combined end point of death, stroke, or TIA when compared with medical therapy at 4-years follow-up. In a subgroup analysis, percutaneous PFO closure was found to be superior to aspirin but not to warfarin therapy. Importantly, in patients with complete occlusion of their PFO and more than one stroke at baseline had a significantly lower risk of recurrent stroke or TIA after

Table 44-2 PFO Closure and Hypercoagulability

No hypercoagulable states: Close
Venous hypercoagulable state: Close, but...
Periprocedural heparin?
Warfarin and aspirin for 3 months, then aspirin?
Probably lifelong warfarin if prior recurrent DVT/PE?
Arterial hypercoagulable state: Close, but...
Periprocedural heparin?
Warfarin indefinitely?

DVT/PE, deep venous thrombosis/pulmonary embolism; PFO, patent foramen ovale.

closure compared with medical therapy (7.3% vs 33.2% and 6.5% vs 22.2%, respectively). These results are certainly not conclusive. Medical noncompliance, the long-term use of aspirin in more than one third of patients after closure, and the nonblinded follow-up could have produced bias.

A review of seven reports since 2000 of percutaneous PFO closure^{31,32,34,35–38} in a total of 1221 patients with a mean age of 48 years shows a 2.4% weighted recurrence rate of stroke (Table 44-3). It is not statistically valid to compare these results with the recurrence rates of warfarin or aspirin therapy in the Mas¹³ and PICCS¹⁴ reports (3.7% and 7.2%, respectively), but it is all that we have.

The lack of randomized studies comparing medical therapy with percutaneous PFO closure thus limits evidence-based recommendations for treatment of patients with cryptogenic stroke and atrial septal abnormalities. Thus, any decision for therapy in patients with cryptogenic stroke must be made on an individual basis using best judgment. Device deployment is not without risks (e.g., bleeding, cardiac tamponade, air embolization, TIA, and stroke) nor is medical treatment (e.g., bleeding, noncompliance with medication). Antiplatelet therapy is a conservative, reasonable first choice in young patients with cryptogenic stroke who have an isolated PFO or atrial septal aneurysm (but **not** the combination). Patients with coexisting PFO and atrial septal aneurysm seem to be better protected from embolic recurrence by warfarin. Warfarin alone or in combination with aspirin could also be considered in patients who failed aspirin therapy alone, although no clear data support such a recommendation. At present, there are no data to support the additional use of clopidogrel or other antiplatelet agents. Importantly, there is little doubt that atrial septal aneurysm with PFO is associated with cryptogenic stroke in patients younger than 55 years of age. Such high-risk patients, those with contraindications for antiplatelet or anticoagulant use, or others at risk (e.g., divers with PFO) should be strongly considered for percutaneous PFO closure.

What should well-informed patients with cryptogenic strokes be told? They should know the following:

1. Young patients with cryptogenic stroke and PFO with atrial septal aneurysm, or others at high risk, should strongly consider percutaneous closure.
2. Patients younger than 55 years of age with cryptogenic stroke and PFO should be told that recurrent risks of CNS events on warfarin or aspirin therapy

range from 3.7%¹³ to 7.2%¹⁴ per year and that registry results of PFO closure show slightly lower recurrence rates.

3. For patients older than 55 years of age, the decision is yet to be determined.
4. For patients with associated venous or arterial hypercoagulable states, closure can be performed, but ongoing antithrombotic therapy or antiplatelet therapy will be needed.

Pulmonary Hypertension: Thrombotic and Nonthrombotic in Origin

Lewis J. Rubin, MD

INTRODUCTION

Pulmonary arterial hypertension (PAH), defined as a mean pulmonary arterial pressure greater than 25 mm Hg at rest or 30 mm Hg with exercise with a normal left heart filling pressure (<15 mm Hg), is increasingly recognized as a source of major morbidity and mortality. A revised classification system for pulmonary hypertension has recently been proposed that highlights the heterogeneous nature of this condition.¹ Pulmonary hypertension can be classified into the following four broad categories (Table 45-1): (1) pulmonary arterial hypertension (PAH); (2) pulmonary venous hypertension (e.g., left ventricular dysfunction, mitral valve disease); (3) pulmonary hypertension due to chronic thrombotic or embolic disease; and (4) pulmonary hypertension associated with disorders of the respiratory system, usually with hypoxemia (e.g., chronic obstructive or restrictive lung disease).

Although therapy for PAH has evolved dramatically over the past decade, including the development of new potent pulmonary vasodilator and antiproliferative agents,² the optimal implementation of treatment strategies is contingent on establishing the diagnosis and defining its etiology. When medical therapy fails, lung transplantation provides a surgical option, with pulmonary hypertension from all causes accounting for approximately one third of all lung transplants performed. However, this surgical therapy carries a significant operative risk, and its effectiveness is limited in the long term by the side effects of immunosuppressive therapy and allograft rejection.³

As awareness of pulmonary hypertension has increased, it has become apparent that chronic thromboembolic pulmonary hypertension (CTEPH) as a cause of chronic pulmonary hypertension is a more prevalent condition than had been previously considered.⁴ With the development and acceptance of pulmonary endarterectomy as a definitive surgical therapy for these patients, recognition and identification of CTEPH as the cause of unexplained dyspnea or pulmonary hypertension is critical.

PATHOGENESIS

The pathogenesis of PAH is complex and our understanding of the interplay between a variety of pathogenic mechanisms is evolving.⁵ Simply put, pulmonary hypertension can be caused by narrowing of the precapillary vessels,

loss of vascular surface area, or passive back pressure from the postcapillary vessels.

Precapillary pulmonary hypertension can be produced by several mechanisms. Embolic material, such as venous thrombi, can lodge in the pulmonary artery, producing acute obstruction or, if unresolved and organized into the vessel wall, chronic obstruction. In situ thrombosis can also occur. Chronically increased blood flow, as seen in large left-to-right intracardiac shunts, is associated with remodeling of the pulmonary arterial walls into vessels that resemble systemic arteries. Remodeling of the pulmonary arterial and arteriolar walls as a result of inflammation or endothelial dysfunction can also occur, for example, in idiopathic pulmonary artery hypertension (IPAH) or PAH due to connective tissue diseases. Loss of the pulmonary vascular bed as a result of destructive processes such as emphysema or interstitial fibrotic disease will increase resistance to blood flow and produce pulmonary hypertension. Hypoxia-induced pulmonary vasoconstriction and vascular remodeling further augment the degree of pulmonary hypertension in this setting. Processes that increase left atrial or left ventricular end-diastolic pressures will also increase pulmonary arterial pressure, with less dramatic increases in intrinsic pulmonary vascular resistance.

Regardless of the etiology, when pulmonary hypertension occurs, the vasculature responds by undergoing changes that further increase its resistance. The patterns of histopathologic change seen in pulmonary hypertension, including medial hypertrophy, intimal thickening, plexogenic pulmonary arteriopathy, and thrombotic pulmonary arteriopathy likely represent a final common pathway of response to pulmonary vascular injury and persistent pulmonary hypertension.

ENDOTHELIAL INJURY

The lungs contain the largest expanse of endothelium in the body. In addition to its role as a semipermeable barrier between blood and interstitium, the endothelium serves a wide array of biologically important functions. Among these functions are the synthesis, uptake, storage, release, and metabolism of vasoactive substances; transduction of blood-borne signals; modulation of coagulation and thrombolysis; regulation of cell proliferation; engagement in the local inflammatory and proliferative reactions to injury; involvement in immune reactions; and angiogenesis.

Table 45-1 Nomenclature and Classification of Pulmonary Hypertension**Pulmonary Arterial Hypertension (PAH)**

Sporadic (intermittent) (IPAH)

Familial (FPAH)

Related to

Collagen vascular disease

Congenital systemic to pulmonary shunts (large, small, repaired, or nonrepaired)

Portal hypertension

HIV infection

Drugs and toxins

Other (glycogen storage disease, Gaucher disease, hereditary hemorrhagic telangiectasia, hemoglobinopathies, myeloproliferative disorders, splenectomy).

Associated with significant venous or capillary involvement

Pulmonary veno-occlusive disease

Pulmonary capillary hemangiomatosis

Pulmonary Venous Hypertension

Left-sided atrial or ventricular heart disease

Left-sided valvular heart disease

Pulmonary Hypertension Associated with Hypoxemia

Chronic obstructive pulmonary disease

Interstitial lung disease

Sleep disordered breathing

Alveolar hypoventilation disorders

Chronic exposure to high altitude

Pulmonary Hypertension due to Chronic Thrombotic and/or Embolic Disease

Thromboembolic obstruction of proximal pulmonary arteries

Thromboembolic obstruction of distal pulmonary arteries

Pulmonary embolism (tumor, parasites, foreign material)

Miscellaneous

Sarcoidosis, histiocytosis X, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

The cells that compose the monolayered endothelial lining communicate not only with each other by anatomic junctions and bridges but also with the underlying smooth muscle by way of biologically active substances. This interaction participates in regulating normal vasomotor tone as well as in response to the administration of vasoactive substances. It is not difficult to imagine that damage to the lining cells, proliferation of the intima, or hypertrophy of the smooth muscle will upset the normal interplay. Endothelial injury is a central process in the pathogenesis or progression of the pulmonary vasculopathy that characterizes many forms of PAH. This injury results in impaired production of vasodilator, antiproliferative and antithrombotic substances such as prostacyclin and nitric oxide, as well as excessive production of vasoconstrictive and angiogenic substances such as endothelin. Furthermore, the injured endothelium is more susceptible to thrombotic influences, predisposing to in situ thrombosis as a contributory factor in the pathogenesis of pulmonary vascular disease.

THROMBOSIS

Although most patients who experience an acute pulmonary embolism manifest resolution of the emboli with no physiologic or functional sequelae, both acute and chronic

thromboembolism can result in pulmonary hypertension. Patients with sufficient clot burden to result in acute pulmonary hypertension usually experience prompt and dramatic hemodynamic improvement or resolution of cardiopulmonary compromise with thrombolytic therapy; rarely is acute surgical embolectomy indicated in the modern era. Although a clinical history of acute pulmonary embolism is absent in half or more of all patients who develop chronic thromboembolic pulmonary hypertension (CTEPH), it is likely that most of these patients have experienced one or more clinically silent episodes of acute venous thromboembolism in the past.⁶ Thrombotic material will proceed along large vessels until it reaches a bifurcation where the luminal diameter is less than the diameter of the material resulting in occlusion. At this point, the blood in the distal vessel will demonstrate stasis, with in situ thrombosis leading to the development of propagated thrombus, as originally described by Virchow.⁷ In addition, the proximal blood flow becomes turbulent with associated development of laminar thrombus. The original occlusive material may now change in one of two ways: First, the organized thrombus may recanalize, producing a variable number of endothelialized channels, which may also demonstrate internal elastic laminae. These channels remain separated by fibrous septa. Second, the clot may undergo complete fibrous organization without canalization, which in turn becomes continuous with the propagated thrombus, forming dense plugs that completely occlude the arterial lumen. In these patients, failure to resolve these thromboemboli is the presumed cause of the disease, although the exact mechanism responsible for failure of the normal fibrinolytic pathway is unclear.

Although the prevalence of CTEPH is unknown, a recent report of patients followed after an initial episode of pulmonary embolism found an incidence of 3.8% at 2 years.⁴ However, this may be an underestimation of the true prevalence because many patients with CTEPH have not experienced a clinically recognized prior episode of venous thromboembolism.

Approximately 20% of patients with CTEPH have an identifiable prothrombotic predisposition, including antithrombin III, protein C or S deficiencies, lupus anticoagulant, or antiphospholipid antibodies.⁶ Recent evidence suggests that some patients with CTEPH have elevations in factor VIII that may also be responsible.⁸

Patients with predisposing factors to the development of pulmonary hypertension may also develop in situ thrombosis;^{5,9} in these cases, differentiation between thrombosis as the primary, and, therefore, potential reversible, process from a secondary complication can be challenging. Other conditions mimicking CTEPH include patients with embolizing myxomas, tumor emboli, and emboli from indwelling prostheses such as ventriculoatrial shunts or pacing systems. In addition, pulmonary artery sarcomas may also manifest with the features of CTEPH.¹⁰

Although loss of up to one half of the pulmonary vascular bed (for example, with a surgical pneumonectomy) does not result in the development of PH, pulmonary hypertension is present in many cases of CTEPH in which less than one half of the pulmonary vascular bed is obstructed. It has been suggested that the nonobstructed pulmonary capillary beds develop a vasculopathy similar to that seen in other forms of pulmonary hypertension.

These changes may persist even after surgical clearance of occlusive material and result in persistent PH.

The factors responsible for this small-vessel arteriopathy remain unknown, although it has been suggested that a variety of locally produced mitogens or vasoactive mediators may be responsible.⁹ These findings support early intervention—before the vascular changes in other parts of the lung have become established.

DIAGNOSIS

The diagnosis of pulmonary vascular disease may be difficult to establish because its clinical presentation is often insidious and it is often confused with other conditions.¹¹ Pulmonary arterial hypertension occurs at all ages, but it is most common between the ages of 30 and 50 years; overall, there is no substantial difference in distribution between the sexes.

The most frequent early symptom is progressive exertional dyspnea, which will be present before the development of pulmonary hypertension at rest. Dyspnea is often initially attributed to other conditions such as airway disease, cardiac disease, or physical deconditioning. Indeed, the average delay from the onset of cardiopulmonary symptoms to the establishment of the correct diagnosis is typically several years.⁸ More advanced symptoms include exertional chest pain, a chronic nonproductive cough, hemoptysis, palpitations, and exertional dizziness or syncope.

Signs

As with the symptoms, the physical signs seen in patients with PH are often relatively nonspecific and may become apparent only as right-sided heart failure ensues. Peripheral cyanosis may occur with severe reduction in cardiac output, and central cyanosis may be present if there is a significant intracardiac right-to-left shunt, for example, through a patent foramen ovale. Examination of the legs may reveal signs of chronic venous stasis and skin discoloration, gross varicose veins or even varicose ulceration. Peripheral edema is usually present as right heart failure develops.

Auscultation of the chest is often unremarkable, although in later stages of the disease the murmur of tricuspid regurgitation may be audible. Auscultation may also reveal the presence of intrapulmonary systolic bruits in patients with CTEPH.⁶ These bruits resemble those encountered in congenital pulmonary branch stenosis and are assumed to result from turbulent blood flow past a segmental narrowing. These bruits have not been described in patients with other forms of pulmonary arterial hypertension.

Investigations

Complete blood count and biochemical studies are standard but are rarely disordered. Hematologic abnormalities that may predispose to pulmonary hypertension, such as sickle cell disease or previous splenectomy, may be identified. Secondary erythrocytosis may develop in cases of longstanding low cardiac output and hypoxemia. Liver function tests may be disordered as a result of hepatic congestion or intrinsic liver disease with portal-pulmonary hypertension. Additionally, low cardiac output states may produce prerenal

Figure 45-1 Ventilation/perfusion lung scan ($\dot{V}/\dot{Q}$) from a patient with chronic thromboembolic pulmonary hypertension (CTEPH) demonstrating multiple mismatched perfusion defects.

impairment with elevation of serum creatinine levels. Chest radiograph, electrocardiogram, and pulmonary function tests are useful investigations to exclude other conditions, but they have little value in differentiating thromboembolic pulmonary hypertension from other forms of pulmonary hypertension.

Two-dimensional transthoracic echocardiography is a useful investigation because this helps to define the presence of pulmonary hypertension and excludes underlying cardiac conditions. The typical findings are of right-sided dilatation and right ventricular hypertrophy. The main pulmonary trunk is also enlarged. Interventricular septal motion is paradoxical and the septum may appear flattened, with encroachment of the right ventricle into the left ventricular cavity. Tricuspid regurgitation is usually present to varying degrees. It is unusual to identify pulmonary arterial obstructive material echocardiographically.

Radioisotope perfusion scanning is a critical screening investigation. In chronic thromboembolic disease, discrete lower or segmental defects are normally seen (Fig. 45-1)—in contrast to the appearance of primary pulmonary hypertension in which the scan is either normal or has a patchy and mottled appearance.^{12,13} The presence of an equivocal scan in patients with other features suggestive of chronic thromboembolic disease should always prompt additional investigation.¹³

CT scanning has also proved very useful in helping to identify patients with parenchymal lung disease or CTEPH (Fig. 45-2).¹⁴ The imaging can confirm occlusion in the main and lobar pulmonary arteries and, on occasion, it may be possible to follow thrombotic material into segmental vessels. Occlusion of the main pulmonary arteries is relatively uncommon and its presence suggests a pulmonary artery tumor. When viewed on lung settings, a mosaic pattern of lung attenuation on the CT scan represents regional perfusion inhomogeneities that may be suggestive of chronic pulmonary thromboembolism. The standard for the diagnosis and planning of surgery, however, remains the standard pulmonary angiogram.¹⁵ The combination of right heart catheterization and selective pulmonary artery angiography allows accurate assessment of

Figure 45-2 Helical CT scan from a patient with chronic thromboembolic pulmonary hypertension (CTEPH) demonstrating organized thrombotic material in the proximal vasculature (arrows).

the level of pulmonary hypertension, permits an assessment of surgical accessibility, and excludes other diagnoses.^{15,16} When the pulmonary vascular resistance appears to be higher than expected based on the degree of vascular occlusion, the presence of underlying small vessel arteriopathic changes should be considered. These patients will carry a higher perioperative risk and their long-term benefit is unlikely to be as great.¹⁶

Pulmonary angiography has been reported as being a high-risk procedure for patients with pulmonary hypertension, but in our experience this investigation can be performed safely and is performed on an almost daily basis at our centers. We have performed more than 3000 angiograms in CTEPH patients without a death and with minimal morbidity using selective injections with nonionic contrast agents.

The classic signs visible on pulmonary angiography are dilated proximal and main pulmonary arteries with irregular lumens, indicating the attachment of thrombus to the

vessel wall.⁶ Bands or webs may be seen crossing the vascular lumen, sometimes with a post-stenotic dilatation, and with failure of filling of branch vessels to the periphery. In addition, there may be abrupt termination of pulmonary vessels with a pouch-like appearance (Fig. 45-3).

MEDICAL THERAPY

Several detailed discussions of medical therapy have been recently published.^{11,17} Most of the newer treatments have been shown to produce benefit in a broad array of conditions causing pulmonary hypertension, largely through their antiproliferative effects. Among the most potent therapies used for PAH, the prostacyclins also exert antiplatelet effects that may account for part of their potency in these conditions.

Although not supported by results from randomized, controlled clinical trials, chronic anticoagulant therapy has become a mainstay of medical management for many forms of PAH, as well as CTEPH. The rationale for anticoagulation in PAH is based on the increased risk of thromboembolic events due to physical inactivity, venous stasis, dilated right heart chambers, and sluggish pulmonary blood flow. Additionally, sudden death occurs in approximately 10% of PAH patients and may be due to venous thromboembolism, in addition to other potential causes such as arrhythmia. The pathologic demonstration of organized thrombus in the small vessels of patients with PAH suggests a contributing role in its pathogenesis. Several uncontrolled studies have suggested improved survival in PAH patients treated with oral anticoagulants. Accordingly, consensus has been that patients with PAH should be treated indefinitely with warfarin to achieve an International Normalized Ratio (INR) between 2.0 and 2.5.¹⁷ Patients with CTEPH are similarly treated unless specific thrombotic predispositions, such as the antiphospholipid antibody syndrome, warrant a more intense degree of anticoagulation.

Pulmonary Thromboendarterectomy for CTEPH

Patients suspected of having CTEPH should be referred to a center experienced with this condition to determine candidacy for pulmonary thromboendarterectomy (PTE). A detailed discussion is beyond the scope of this chapter, and the reader is referred to descriptions of the procedure published elsewhere.^{6,18,19} It should be emphasized, however, that this procedure is a true endarterectomy, not embolectomy: the organized, fibrothrombotic material is adherent to the vessel wall and must be dissected off the wall, much like removing an orange from the peel without destroying the orange or the peel.

The majority of patients undergoing PTE will experience near normalization of their pulmonary hemodynamic derangement.^{6,18,19} Even patients with severe right heart failure exhibit normalization of right heart function once right ventricular afterload is reduced. Further improvement is often observed over the first year after surgery. For the majority of patients, surgery results in effective and complete treatment of their pulmonary hypertension, although some patients require medical therapy for persistent pulmonary hypertension.²⁰ These patients, who are

Figure 45-3 Helical CT scan from a patient with chronic thromboembolic pulmonary hypertension (CTEPH) showing a mosaic-like perfusion pattern.

both high-risk candidates for surgery and are the least likely to benefit from PTE, may now be identifiable preoperatively using novel techniques to differentiate those with proximal (and operable) vascular obstruction from those with distal (inoperable) disease.¹⁶ Because more than one third of perioperative deaths and nearly one half of long-term deaths are attributed to persistent pulmonary hypertension,²⁰ implementation of these novel diagnostic techniques will hopefully lead to improved patient selection and reduced operative morbidity and mortality.

Special Circumstances for the Consulting Hematologist

Patients with severe pulmonary hypertension may develop thrombocytopenia, which has been attributed to increased intrapulmonary platelet destruction due to shear stress. Epoprostenol therapy has also been suggested as a cause of thrombocytopenia, although it is unclear whether it is the cause, because this therapy is reserved for patients with the most advanced disease. Patients with portal pulmonary hypertension may develop thrombocytopenia due to hypersplenism.

Bosentan may cause a mild anemia that is believed to be due to hemodilution. Patients with hereditary hemorrhagic telangiectasia who carry the *Alk-1* gene mutation are at risk for developing pulmonary artery hypertension.²¹ As with any patient with impaired cardiopulmonary function, anemia can compromise tissue oxygen delivery in PAH and its cause should be sought and treated aggressively.

CONCLUSIONS

Pulmonary hypertension remains an underdiagnosed condition. Many patients receive inappropriate therapy in the belief that they have some other underlying condition such as asthma or heart failure of unclear origin. Until recently, the only effective therapy was lung or heart-lung transplantation, but with the associated perioperative mortality and the long-term complications of immunosuppressive therapy, this is now unnecessary for the majority of patients.

With the advent of effective medical and surgical treatment options, the responsibility must lie with physicians to recognize this condition. There are now options for patients that will allow their return to normal levels of activity, with improved life expectancy. The hematologist may play a critical role in assisting in the diagnostic approach of patients with unexplained pulmonary hypertension and with the management of these patients once a diagnosis has been established.

Chapter 46

Hemorrhage Control and Thrombosis Following Severe Injury

Ann B. Zimrin, MD • John B. Holcomb, MD •
John R. Hess, MD

INTRODUCTION

Injury is common. Small hospitals have emergency rooms, which deal with a spectrum of injuries, but intensive care of the most severely injured is a highly centralized endeavor, taking place chiefly in regional trauma centers. It has been estimated that in the United States, 36 million people (one in every seven members of the population) are significantly injured each year. Three quarters of the injured seek medical care, leading to 27 million doctor or hospital visits annually.¹ About 1 in 10 of the injured who are medically evaluated is hospitalized, leading to 2.7 million admissions each year. About 1 million of the more severely injured are directly admitted or transferred to one of the nation's 1200 Level I, II, or III trauma centers. Altogether, about 93,000 individuals die each year as a result of their injuries, with fully one half dying before they reach the hospital. Of those who will die, but reach the hospital alive, the great majority die of brain injury or uncontrolled hemorrhage within the first 24 hours of hospitalization.² Of those admitted to a hospital, about 250,000 receive blood products. From these numbers, it can be further estimated that perhaps 20,000 times each year, an injured patient will be admitted to a trauma center with massive uncontrolled hemorrhage and will be transfused acutely with more than 10 units of red blood cells (RBCs) in the first 24 hours of care. Such patients stand an approximately 40% chance of dying and an equivalent chance of developing thrombotic complications if they survive the first day.³ They are cared for by trauma and critical care surgeons, trauma anesthesiologists, intensivists, trauma orthopedists, and neurosurgeons. The hematologic questions that lead to consultation in this environment can be as broad as the background population that sustains injury and/or as restricted as the blood products available for their treatment. The common element is urgency.

Appropriate disaster preparedness suggests that hematologists who work in acute care hospitals should be able to address the basic issues that are likely to arise after massive injury. Determining the extent of injury is facilitated now with 13-second whole body CT scans and focused abdominal sonography for trauma (FAST). At the extreme end of the survivable injury spectrum are the patients with devastating injuries for whom immediate hemorrhage control is not always possible. These patients require large amounts of blood while surgeons work to limit

hemorrhage, control gut contamination of body cavities, and shunt blood, bypassing disruptions of the largest vessels, in a process called "damage control" that emphasizes reestablishing normal physiology at the expense of normal anatomy.^{3a} This chapter deals with the hematologic issues that arise during this process, as well as later in the course of care of the severely injured trauma patient.

As the consulting hematologist arrives on the trauma floor, operating room, or section of the emergency department, a sense of culture shock might be the prevailing emotion. In short supply are thoughtful, deliberative internists, replaced by fast-moving figures in scrubs who must make life-changing decisions with insufficient data and expect quick answers from consultants for problems involving patients who are unresponsive, have "too many" IVs, and injuries which threaten to become lethal in the immediate future. A familiarity with the pathophysiology of the hematologic abnormalities involved, preplanned approaches, and the presence of a well-prepared blood bank will stand the hematologist in good stead.

MASSIVE TRANSFUSION AND THE COAGULOPATHY OF TRAUMA

Pathogenesis

Exsanguinating hemorrhage is second only to head trauma as the most common cause of death among injured patients who reach the hospital alive.² Although disruption of the integrity of the vasculature is the proximate cause of the bleeding, the primary injury, the body's response, and therapeutic interventions can combine to produce a secondary coagulopathy that complicates efforts to both evaluate and control bleeding. This coagulopathy of trauma is a combination of the effects of blood loss, physiologic and therapeutic hemodilution, coagulation factor and platelet consumption, acidosis, hypothermia, and inappropriate fibrinolysis.

Loss of clotting activity occurs early in massive hemorrhage. The entire store of clotting activity for a healthy 70 kg man is 10 grams of fibrinogen and 15 mL of platelets. One half of that fibrinogen and one third of those platelets can be lost in massive hemorrhage or hematomas even before the treatment of injury begins. Therapies aimed at increasing vascular volume also increase blood pressure and drive more blood loss.

Dilution of remaining blood by physiologic vascular refill and from the administration of asanguinous fluid or plasma-poor RBCs further reduces coagulation factor activity and platelet concentration. This therapeutic dilution is considered standard of care. Emergency medical technicians and paramedics administer intravenous (IV) fluids in the field. Larger IV lines are placed on arrival at the trauma center and vascular access is tested with fluid boluses. Hypotension that threatens tissue perfusion is treated aggressively with volume. In the early phases of trauma care, before a blood type is available, volume is provided with crystalloid fluids and uncross-matched blood group O packed red blood cells (pRBC). Because blood volume is reduced, the combination of ongoing loss and dilute replacement leads to accelerated whole-body washout of clotting activity.

Consumption of plasma coagulation factors and especially platelets leads to significant decreases in their concentrations in the circulating blood, especially after blunt trauma, ballistic wounds, or high-energy-transfer injuries. These injuries typically cause millions of endothelial microtears, each exposing subendothelial tissue factor and collagen, which then serve as sites for local activation of coagulation factors and platelet adhesion. Moderate injury can largely deplete the platelet pool, which in aggregate can cover only a very small fraction of the total endothelial surface. The lung capillary bed, as an example, has a surface area similar in size to a football field, whereas the circulating blood contains enough platelets to cover 5 square meters. Moreover, certain injuries, such as head injury with brain tissue embolization, large bone fractures with fat embolization, or amniotic fluid embolization can cause acute disseminated intravascular coagulation (DIC) with defibrination.

Hypothermia occurs when the injured suffer exposure in the prehospital and assessment phases, are resuscitated with cold fluids, or sustain evaporative and conductive heat loss in the operating room.⁴ Hypothermia slows the rates of all the enzymatic plasma coagulation reactions,^{5,6} but has its greatest effect on the activation of platelets. Platelet activation from torsion on the GP-Ib-IX-V complex by von Willebrand factor is largely abolished at 30° C.⁷ This acquired Bernard-Soulier-like platelet dysfunction results in platelets in the wound that do not secrete, aggregate, or provide active surfaces for coagulation factor complex assembly. At core temperatures between 32° C and 34° C, platelet activities are present but reduced.

Acidosis occurs when hypotension leads to loss of critical oxygen delivery to tissues. Acidosis interferes with plasma coagulation by reducing the activity of the vitamin K-dependent factor complexes on negatively charged cell surfaces.⁸ These complexes are held together by the γ -carboxyglutamic diacids complexing calcium ions against negatively charged phospholipid rafts on activated platelet surfaces. Increased proton concentrations partially destabilize and markedly reduce the activity of these coagulation factor complexes.

Thrombolysis is activated at the same time as the coagulation cascade, but is normally inhibited by the thrombin-activated fibrinolysis inhibitor (TAFI). However, when thrombin activity is reduced by low concentrations of prothrombin and low activity of the activating complexes, TAFI is not released.⁹ Fibrin strands, normally thick when

Table 46-1 Probability of Life-Threatening Coagulopathy Increases with Shock, Acidosis, and Hypothermia*

Clinical Status	Conditional Probability of Developing Coagulopathy (%)
No risk factor	1
ISS > 25	10
ISS > 25 + SBP < 70 mm Hg	39
ISS > 25 + pH < 7.1	58
ISS > 25 + temperature < 34° C	49
ISS > 25 + SBP < 70 mm Hg + temperature < 34° C	85
ISS > 25 + SBP < 70 mm Hg + temperature < 34° C + pH < 7.1	98

*The risk factors for developing coagulopathy in the early phases of trauma care include severe injury, shock, and hypothermia. When patients have all of the risk factors, they are almost universally coagulopathic.

ISS, Injury Severity Score; SBP, systolic blood pressure.

From Cosgriff N, Moore EE, Sauaia A, et al: Predicting life-threatening coagulopathy in the massively transfused trauma patient: Hypothermia and acidosis revisited. *J Trauma* 42:857–862, 1997.

produced by high local activities of thrombin acting on normal concentrations of fibrinogen, are thin with high surface-to-volume ratios when laid down in the presence of reduced thrombin activity or low concentrations of fibrinogen. The high surface-to-volume ratio makes the fibrin strands more susceptible than usual to enzymatic lysis.

The interactions of these pathophysiologic mechanisms are at least additive and in many cases multiplicative (Table 46-1).¹⁰ Loss, dilution, and consumption all contribute to reduce the concentrations of plasma coagulation factors and platelets. Hypothermia and acidosis reduce the activities of those factors and platelets that remain. Uninhibited thrombolysis reduces the effect of the limited clotting activity available and contributes fibrin breakdown products, which interfere with further coagulation. The ongoing result of all of these mechanisms is the coagulopathy of trauma.

The coagulopathy of trauma bears a strong resemblance to, and is sometimes indistinguishable from, DIC.¹¹ As noted earlier, in the presence of brain, fat, or amniotic fluid embolization, coagulation with marked consumption of coagulation factors and platelets can occur in the intravascular space at sites remote from initial injury. This is classic DIC. However, in the usual situation in severe trauma, consumption of coagulation factors and platelets is largely restricted to sites of injury, but is made ineffective because of concurrent loss, dilution, hypothermia, acidosis, and thrombolysis (Fig. 46-1).

Clinical Presentation

The disturbance in the coagulation system caused by the initial physiologic response, and the subsequent complications of hypothermia and acidosis, are demonstrated in clinical studies of patients arriving in emergency departments, in whom abnormal coagulation parameters were common and unrelated to dilution. The presence of an abnormal coagulation test on arrival in the emergency

Figure 46-1 The causes of coagulopathy in severely injured patients are multifactorial. DIC, disseminated intravascular coagulation.

department increased with the severity of the injury, and predicted an increased mortality rate.^{12,13} An elevation in the prothrombin time was a particularly ominous sign, correlating with a 326% increase in all-cause mortality.¹³

The initial treatment of the severely injured, hypotensive patient results in an exacerbation of the coagulopathy in several different ways. Infusion of crystalloid or colloid solutions dilutes the clotting factors and platelets remaining within the vasculature.^{14–18} Although it is not intuitively obvious, massive transfusion of rapidly hemorrhaging patients, using a unit-for-unit ratio of RBCs, plasma, and platelets, will inevitably result in a coagulation defect. Because the processing of 500 mL of donated red cells involves the addition of 180 mL of anticoagulant and additive solutions and results in the loss of some of the cellular components as the blood is processed, when recombined the resulting product has a hematocrit of 29%, coagulation factor levels of approximately 60% of their normal levels, and a platelet count of 90,000/ μ L.¹⁹ Any increase in the relative amount of plasma or platelets transfused to correct the coagulopathy will decrease the effective hematocrit of the material infused. In addition, transfusion of RBCs, which are stored at 4° C, worsens hypothermia if blood is not warmed; older RBC units have a decreased pH, which exacerbates the acidosis that may already be present.

Although considerable individual variability is seen, dilutional coagulopathy generally becomes a problem when approximately one blood volume has been transfused (10 to 12 U in the average patient). The clinical manifestations of this dilutional coagulopathy are a diffuse bleeding diathesis, with oozing from surgical incisions, mucous membranes, and venipuncture sites, as well as difficulty controlling the bleeding in the traumatized region.

Patients with injury to the brain are at particularly high risk for the development of bleeding problems. The brain is rich in tissue thromboplastin which, when exposed to circulating blood, activates the extrinsic arm of the clotting cascade. Traumatic brain injury is commonly associated with thrombocytopenia and coagulopathy, with the incidence increasing with the severity of the insult. DIC can be seen, although its incidence is variably reported. The incidence of abnormal coagulation tests increases in the population of patients with moderate or severe traumatic brain injury over the 3 days following the insult, so repeat laboratory evaluation is warranted.²⁰

Treatment of Post-injury Coagulopathy

The treatment of the coagulopathy seen after major trauma is multifaceted—only a small portion of which is within

the purview of the consulting hematologist. A resuscitation effort with a blood pressure target that is appropriately low will minimize the crystalloid dilution of the patient's blood and decrease the rebleeding risk.^{21,22} Aggressive rewarming efforts will reverse the coagulopathy and platelet dysfunction associated with hypothermia.^{8,23} Damage control surgery, an approach to intra-abdominal trauma that involves surgical control of the hemorrhage and intra-abdominal packing, with definitive repair of the injuries deferred until the patient has been stabilized, has been shown in retrospective studies to result in a decreased mortality rate in the most severely injured patients.²⁴

In patients who are bleeding steadily but not to a degree to cause hemodynamic instability, replacement should be guided by frequent CBCs and coagulation testing, addressing prothrombin or partial thromboplastin times greater than 1.5 times normal with thawed plasma, platelets less than 50,000/ μ L with platelet concentrates, and fibrinogen levels less than 0.8 mg/dL with cryoprecipitate.²⁵ These end points are somewhat arbitrary—not derived from prospective studies—but do reflect consensus.

In patients who are exsanguinating, resuscitation should be started with uncross-matched group O red blood cell transfusions. Patients in this group usually are bleeding fast enough that it is impossible and inappropriate to rely on laboratory values as a guide to transfusion. If bleeding persists beyond 6 U of RBC and the stability of the patient and speed of the clinical laboratory do not allow decisions regarding the use of plasma and platelets to be based on test results, empiric plasma transfusions (2 to 6 U for each 6 U of red cells), although not proved useful in prospective clinical trials, will provide fluid, colloid, and coagulation factor support and is a rational choice for the patient in extremis. In these patients, it is deemed appropriate to stay out of trouble, rather than get out of trouble. By the time 12 U of RBC in additive solution have been given without plasma support, frank coagulopathy will have developed. Higher ratios of numbers of units of plasma to units of RBC, up to 1:1, appear desirable in mathematical models, in retrospective series, and from the practical standpoint of ease of administration.²⁶ A recent international consensus conference on massive transfusion for trauma has recommended this ratio.²⁷ Platelet concentrates should also be added empirically before 20 U of RBC have been given, and again mathematical considerations and retrospective series suggest that massively transfused patients who receive more platelets fare better.²⁸ Maintaining thawed plasma in the blood bank allows the issue of plasma as soon as an ABO type is known.

Use of Factor VIIa for Post-injury Coagulopathy

Since the first report of the successful use of recombinant factor VIIa (rFVIIa) in a patient with life-threatening bleeding after a gunshot wound lacerated his inferior vena cava, there have been many reports of its use in post-injury coagulopathy. Case reports and series of patients have shown that rFVIIa is often effective in stopping the hemorrhage.²⁹ A single randomized trial comparing three doses of rFVIIa with placebo showed that when early deaths were excluded, there was a decrease in the number of RBC transfusions in

patients with blunt trauma in patients treated with rFVIIa, but no survival advantage.³⁰ rFVIIa appears to be less effective at very low pH (<7.10)^{31,32} which may account for the rare clinical failures. For rFVIIa to work, platelets and fibrinogen must be present in quantities sufficient to form a viable clot. The optimal dose has not been determined; doses of 70 to 100 µg per kilogram of body weight have been recommended, based on the available empiric evidence.^{27,33} Controlled clinical trials are necessary to definitively determine the role of rFVIIa in the care of trauma patients.

Patients with Congenital Bleeding Diatheses

Patients with preexisting bleeding diatheses are particularly problematic. Because the physiologic response to trauma can cause abnormalities in the coagulation profile,¹² the diagnosis of a preexisting coagulopathy can be difficult in a patient with severe trauma who is unable to give a history. In patients with a known preexisting coagulopathy and severe trauma, treatment should be aimed at providing 100% correction using standard guidelines for 3 days or until clinical stability is achieved. In patients with hemophilia A, a bolus dose of factor VIII of 25 to 50 u per kilogram of body weight followed by a continuous infusion at 4u/kilogram/hour has been shown to be effective in maintaining hemostasis,^{34,35} and could be considered an alternative to the more standard bolus dosing. If signs of head trauma are present or its presence is suspected by the history, 100% replacement should be sought and maintained while confirmatory scans are being performed. With lesser injuries, infusions at a rate of 2u/kilogram/hour or bolus doses of factor VIII to maintain 50% levels may be adequate. In patients with known inhibitors to factor VIII, rFVIIa should be administered at doses ranging from 90 to 200 µg per kilogram of body weight, depending on the severity of the injury.

Patients with Acquired Bleeding Diatheses and Comorbid Conditions

As the population of the industrialized countries ages, the elderly are increasingly represented in the population presenting to trauma centers. Patients in this age group are more likely to have comorbid conditions, and are more likely to be on anticoagulant and platelet-inhibiting drugs. Preinjury warfarin use has been shown to be associated with more severe brain bleeding and a higher likelihood of death.^{36,37} In patients with minor head injury and normal neurologic examination on presentation, neurologic deterioration occurred within 6 hours of the injury in those patients who developed significant intracranial hemorrhage.³⁸ However, several studies suggest that when patients with head injury are excluded, patients taking warfarin are not at higher risk for in-hospital complications and have similar mortality rates to case-matched controls.^{39,40}

In anticoagulated patients with prolonged prothrombin times who have severe injuries, the warfarin effect may need to be reversed quickly with rFVIIa followed by infusions of fresh frozen plasma and intravenous vitamin K, 5 to 10 mg. rFVIIa at doses of 15 to 90 µg per kilogram of body weight, have been shown to be effective in antico-

agulated patients with intracranial hemorrhage or in need of invasive procedures,⁴¹ but it should be kept in mind that the duration of action of rFVIIa is short (2 to 3 hours), and further therapeutic intervention with repeat dosing or plasma may be necessary. The immediate post-injury state is often characterized by a hypercoagulability (discussed in more detail subsequently), and anticoagulation should be re-instituted as soon as the stability of the patient permits.

The data regarding aspirin use and risk of intracranial bleeding is conflicting, with studies showing an increase in mortality⁴² and no increase in bleeding.⁴³ In patients without head trauma, there is no conclusive evidence for an increased bleeding risk, although patients taking aspirin were more likely to be anemic on presentation.^{44,45}

Other comorbid conditions can affect the patient's bleeding risk. Renal dysfunction can cause a platelet function disorder,⁴⁶ which is difficult to quantitate. Patients with end-stage renal disease on chronic hemodialysis have an increased rate of complications and an increased mortality rate following major trauma,^{47,48} but this seems to be secondary to ongoing metabolic disturbances and an increased incidence of coexisting medical problems, such as diabetes, hypertension, and cardiac disease.

Hepatic cirrhosis, with its myriad of concomitant hemostatic alterations (discussed in Chapter 39), poses a more formidable challenge. In a retrospective analysis of the effect of preexisting medical conditions on mortality, cirrhosis was most strongly associated with a higher mortality rate.⁴⁹ Specific factors that appear to play a role in the pathophysiology of the poor outcome include the increased risk of bleeding, decreased hepatic blood flow in conditions of low perfusion pressure secondary to the increased dependence on the arterial blood supply, and increased risk of other organ failure, such as renal failure and acute respiratory distress syndrome. Mortality in cirrhotic trauma patients undergoing laparotomy approaches 50%^{50,51} and is high even in patients with minor or moderate injuries.⁵⁰ Close monitoring and aggressive intervention to correct coagulopathy is suggested to improve the outcome in this very high risk group. rFVIIa has been shown to control bleeding in patients with upper gastrointestinal hemorrhage and Child B-C cirrhosis, but was not successful in decreasing transfusion requirements in a trial of patients undergoing liver transplantation.⁵² Its use in patients with liver disease and trauma has not been investigated.

Thrombocytopenia

Thrombocytopenia is common in victims of severe trauma, more so even than in the population of critically ill patients as a whole.^{46,53} The fall in the platelet counts seen in the first 3 to 4 days appears to be secondary to dilution and consumption (see earlier). Causes of thrombocytopenia occurring later in the patient's course include the usual etiologic factors found in critically ill patients: sepsis/infection causing increased consumption and/or bone marrow suppression; medication-induced thrombocytopenia, including heparin-induced thrombocytopenia, more rarely EDTA-dependent pseud thrombocytopenia,⁵⁴ and post-transfusion purpura. This subject is discussed in more detail in Chapters 9, 10, 12, and 25.

THROMBOSIS IN TRAUMA PATIENTS

Although excessive bleeding is often the first manifest challenge to confront the consulting hematologist, hypercoagulability soon supersedes coagulopathy as a source of morbidity and mortality. Tissue factor is released after major trauma and the concentration of fibrinogen increases as an acute phase reactant causing a hypercoagulable state; this combines with the other two components of the Virchow triad, stasis and vascular injury, to cause a thrombotic diathesis. In a study of untreated trauma patients who underwent serial impedance plethysmography and lower-extremity contrast venography, 58% were found to have deep venous thrombosis, with the vast majority of those being unsuspected on clinical grounds.⁵⁵ Risk factors can be identified to delineate the patients at highest risk—age, lower extremity fractures, spinal cord injury, head injury, high injury severity score, more than 3 ventilator days, venous injury, and the need for a major operative procedure.^{56,57} However, there is no group of patients who have sustained major trauma whose risk is low enough that thromboprophylaxis is not necessary.

Given the obvious risk of anticoagulation in patients who have recently had the integrity of their vasculature interrupted, thromboprophylaxis in trauma patients presents a challenging problem. Lower extremity compression devices can be applied very early in the hospital course, although they are not feasible in many patients with lower extremity injuries—a group at high risk for thrombotic disease. Although the notion of heparin prophylaxis in the acute trauma patient seems initially uncomfortable, it must be recalled that prophylactic doses are considerably lower than therapeutic doses, especially considering the very high rate of thromboses in trauma patients surviving the first few days. Because prophylaxis is effective, fewer patients will need the higher therapeutic doses of anticoagulants if prophylaxis is generally employed. Although the data from prospective randomized clinical trials are limited, the available information suggests that low molecular weight heparin is the most efficacious method of reducing the risk of thromboembolic events.^{52,57,58} The timing of the initiation of therapy needs to be carefully judged, given the risk of bleeding, particularly at sites that are difficult to detect. More information about thrombosis and thromboprophylaxis is available in Chapters 14 and 15 of this text. Briefly, many critical care providers wait 72 hours before starting DVT prophylaxis in the head and spine injured patient and wait until the prothrombin time is approaching normal before starting anticoagulation in the massively transfused.

Thrombocytosis in Trauma Patients

Although a fall in the platelet count during the first week following the injury is common in trauma patients, the second week is often accompanied by a rise in platelet counts to supra-normal levels, with one quarter of trauma patients in the ICU developing levels above the normal range.^{53,59} This increase is caused by increased production of thrombopoietin in response to inflammatory factors, such as IL-6, and is not associated with an increased risk of thromboembolic events or increased mortality.⁶⁰ The inflammatory stimuli that provoke the thrombocytosis can include the injury

itself, particularly in the case of crush injuries with massive tissue damage, infection, and acute respiratory distress syndrome. Thrombocytosis can also be seen in the postsplenectomy state, beginning 2 to 10 days after the surgery and continuing for 2 weeks to several months. There does not appear to be a need for treatment in this situation, even when platelet counts exceed 1,000,000/ μ L.

Hemostatic Aspects of Sickle Cell Disease

Kenneth Ataga, MD • Richard Lottenberg, MD

HISTORICAL PERSPECTIVE

The seminal work of Pauling and colleagues on the properties of hemoglobin S provided the basis for a hypothesis that heralded the concept of “molecular medicine.”¹ Indeed, sickle cell anemia (SCA*) is touted to be the prototypic example of a single gene disorder. Although a single gene mutation is responsible for the sickle hemoglobin abnormality, inter-individual variability is observed in clinical manifestations and laboratory findings that cannot be accounted for simply by the hemoglobin genotype (e.g., Hb SS, S/β thalassemia, or Hb SC). It is now appreciated that there are multiple genetic determinants interacting with environmental factors contributing to the occurrence of painful crises and other complications of sickle cell disease (SCD).^{2,2a}

Remarkable improvement in the survival of patients with SCD has occurred over the past 25 years. The use of prophylactic penicillin therapy and administration of effective vaccines in infancy have resulted in a dramatic reduction in life-threatening pneumococcal infections.³ Additional preventive measures, as well as ongoing care provided by comprehensive pediatric sickle cell disease programs, have provided the opportunity for the majority of such patients to reach the age of 18.⁴ A prospective 10-year cohort study initiated in the late 1970s revealed a median survival of 42 to 48 years for patients with Hb SS and 60 to 68 years for patients with Hb SC.⁵ It can be anticipated that continuing improvement in survival for patients with SCD will be observed as hydroxyurea therapy for symptomatic patients becomes more widely adopted and more effective strategies to prevent end-organ complications become available.

PATHOGENESIS

Red Blood Cell and Hemoglobin S Polymerization

Sickle hemoglobin (HbS) results when the normal β⁶ glutamic acid residue is replaced by valine (GAG to GTG mutation at codon β⁶). The polymerization that occurs when homozygous HbS (α₂β₂^S) is deoxygenated is the primary event in the pathophysiology of SCD and results in damage

to erythrocytes, tissues, and organs.⁶ Notwithstanding this straightforward molecular basis, the pathophysiology of clinical disease is exceedingly complicated. The rate and extent of HbS polymer formation is dependent on the intraerythrocytic HbS concentration, the degree of hemoglobin deoxygenation, and the intracellular concentration of fetal hemoglobin (HbF).⁶ The HbS polymer is a twisted, rope-like structure composed of 14 strands⁶ that distorts the red blood cell into the classic sickle shape. The Hb tetramer is oriented such that in one of the two β subunits, β⁶ valine forms a hydrophobic contact with a complementary site on a β subunit of the partner strand. There is evidence that the polymerization of HbS is extremely cooperative and can be regarded as a simple crystal-solution equilibrium.⁷ The lag period required for the concerted formation of polymer is referred to as the delay time. Because the range of transit times in the microcirculation is short relative to the range of delay times of sickle red blood cells (sRBCs), polymers do not form in most of the cells.⁸ If, however, the sRBCs are subjected to prolonged transit times, then HbS polymer would form in almost all the cells as a result of equilibration at the lower oxygen tension. Hb F inhibits the polymerization of HbS, primarily owing to the glutamine residue at codon γ87,⁹ which prevents a critical lateral contact in the double strand of the sickle fiber.

The density distribution of sRBC is unusually broad, due mainly to the high number of reticulocytes with a relatively low intracellular hemoglobin concentration, and the presence of a high number of very dense cells. These dense cells occur due to enhanced cellular dehydration following polymerization-induced damage to the cell membrane.⁶ Because the rate of HbS polymerization is strongly dependent on the intracellular hemoglobin concentration,⁷ dense sRBC are more likely to polymerize and contribute to the hemolytic and vaso-occlusive aspects of SCD than less dehydrated cells.

Leukocytes

The important contribution of leukocytes to the pathogenesis of the sickle hemoglobinopathies is illustrated by the clinical findings that elevation of the leukocyte count is now recognized as a risk for early death,⁵ acute chest syndrome,¹⁰ and hemorrhagic stroke¹¹ in patients with SCA. Episodes of severe vaso-occlusive crisis and acute chest syndrome have occurred following administration of granulocyte colony-stimulating factor (G-CSF) to patients with SCD in their steady state.^{12,13} Leukocytes interact with sickle cells and vascular endothelium and are stimulated to release injurious cytokines.^{14,15} The

*SCA refers to a specific disease, namely, homozygosity for hemoglobin S (i.e., Hb SS); SCD is the more generic term referring to any sickling syndrome that is composed, at least in part, of Hb S and includes Hb SS as well as double heterozygous genotypes (e.g., Hb S/β+ thalassemia, Hb SC).

adhesion of leukocytes to vascular endothelium is mediated by several adhesion molecules.¹⁶ In addition to the adhesion to vascular endothelium, leukocytes interact with platelets and erythrocytes to form cell aggregates, stabilized via CD36-TSP, CD31-CD31, and CD62L-CD162 bonds.¹⁶ In patients with SCD, these cell aggregates could more effectively occlude the microvasculature than single cells. Activated neutrophils also contribute to endothelial damage. During episodes of infection, increased numbers of activated neutrophils secrete inflammatory cytokines that activate the vascular endothelium.¹⁶ In addition, these activated leukocytes express increased levels of adhesion molecules and attach more readily to activated endothelium.

Monocytes may enhance vaso-occlusion in SCD by contributing to endothelial activation. Monocytes from patients with SCA are activated and can enhance vaso-occlusion through an endothelial inflammatory response promoted by the nuclear factor-kappa B-mediated upregulation of adhesion molecules and tissue factor.¹⁷ The activation of endothelial cells by monocytes from patients with SSD appears to be mediated by tumor necrosis factor- α and interleukin-1 β , both markers of monocyte activation. The activated endothelial cells increase their expression of ligands for adhesion molecules on leukocytes (WBCs) and RBCs, thereby promoting vaso-occlusion.

Platelets

Older children and adults with SCD typically exhibit moderate degrees of thrombocytosis.¹⁸ These patients also exhibit increased numbers of young, metabolically active platelets (megathrombocytes), a finding that is attributed to a loss of splenic sequestration following the functional asplenia observed in SCA patients. Although there are conflicting reports regarding platelet survival in SCD,^{19,20} platelet aggregation does appear to be enhanced in adult patients in the non-crisis, steady state possibly due to an increase in the number of megathrombocytes in the peripheral circulation.^{18,21,22} The enhanced platelet aggregation could also reflect increases in the circulating levels of such platelet agonists as thrombin, ADP, or epinephrine. In children however, platelet aggregation is normal or reduced, a finding attributed to preservation of some of their splenic function and/or to fewer circulating megathrombocytes.^{23–25} The reduced platelet responsiveness to aggregating agents observed in children with SCD may be a result of ongoing, platelet activation and secretion in vivo, changes that could, in turn, cause depletion of platelet granule stores.

There is evidence of increased platelet activation in the non-crisis, steady state.^{26–33} Patients with SCD have decreased platelet thrombospondin-1 (TSP-1) content when compared with normal controls,²⁷ suggesting a state of ongoing release and depletion of TSP-1 from activated platelets in these SCD patients. Platelet expression of CD62, CD63, and PAC-1 antigen in SCD patients are significantly increased compared with ethnically-matched and nonmatched controls.³³ The expression of both P-selectin (CD62P) and CD40 ligand (CD40L) is substantially higher in children with SCD than in healthy control subjects.²⁹ Plasma from patients with SCD in the non-crisis, steady state exhibits significantly higher levels of platelet factor 4 and β thromboglobulin.²⁶ In addition,

platelet procoagulant activity demonstrated by binding of annexin V to phosphatidylserine(PS)-rich membrane domains, is increased when compared with platelets from normal control individuals.²⁶

Endothelium

Because the potential for sRBCs to initiate a vaso-occlusive event is dependent on whether the rate of polymer formation is within the range of the capillary transit time,³⁴ any event that slows the transit of sRBCs through the microcirculation could be expected to have an effect on the pathogenesis of vaso-occlusion. The degree of adherence of sRBCs to vascular endothelium strongly correlates with the severity of disease.³⁵ Multiple studies in static and dynamic conditions demonstrate that sRBCs attach more readily to cultured endothelial cells than do normal RBCs.^{35–38}

These adhesion reactions are mediated mainly by interactions between receptors on sRBCs and endothelial cells or subendothelial matrix proteins (Fig. 47-1). The plasma ligand thrombospondin (TSP) provides a bridge between the RBC receptor CD36 and several constitutively expressed endothelial receptors.^{39,40} As TSP is composed of a number of heterogeneously distinct domains, vascular adhesion to TSP depends on several endothelial sites, including the vitronectin receptor ($\alpha_v\beta_3$), the transmembrane glycoprotein CD36, and endothelial cell surface heparan sulfate proteoglycans. Sick RBCs also interact with immobilized TSP via the integrin-associated protein, CD47, a molecule that is associated with the Rhesus membrane complex.⁴¹ Interactions occur between the integrin complex, $\alpha_4\beta_1$ (VLA-4), expressed on reticulocytes, and both endothelial vascular-cell adhesion molecule 1 (VCAM-1),^{42–45} a molecule expressed on the surface of endothelial cells (especially following activation by inflammatory cytokines and hypoxia) and fibronectin.⁴⁶ High molecular weight multimers of von Willebrand factor (VWF)^{47,48} promote red cell adhesion to endothelial vitronectin receptor $\alpha_v\beta_3$ and the GP-Ib-IX-V complex. Interactions also occur between sRBCs and subendothelial immobilized matrix proteins, including laminin, TSP, VWF, and fibronectin, proteins also present in plasma in a soluble form.⁴⁹ Laminin binds avidly to sRBCs via the erythrocyte basal cell adhesion molecule-Lutheran protein receptor (B-CAM/LU), the protein that carries Lutheran blood-group antigens.⁵⁰ Non-receptor-mediated adhesive mechanisms include a role for RBC sulfated glycolipids and PS.^{51–53}

Inflammation

SCD is often referred to as a chronic inflammatory state owing to the presence of a chronic elevation in leukocyte counts, shortened leukocyte half-life, and abnormal activation of neutrophils and monocytes.^{54,55} The circulating endothelial cells in patients with SCD are activated, with pro-adhesive and procoagulant properties, and exhibit evidence of oxidative stress.⁵⁴ In addition, there is activation of the coagulation system,⁵⁶ increased circulating platelets, and increased number of microparticles (MPs) derived from monocytes and endothelial cells.

In addition to these observations, SCD patients, even in the non-crisis, steady state exhibit elevated levels of inflammatory mediators (such as interleukin-6, tumor necrosis

Figure 47-1 Adhesive interactions between sickle RBCs and endothelium or plasma proteins. $\alpha_4\beta_1$, integrin receptor VLA-4; $\alpha_v\beta_3$, integrin vitronectin receptor; B-CAM/LU, basal cell adhesion molecule/Lutheran protein; FN, fibronectin; GP-1b, glycoprotein 1b; HSPG, heparan sulfate proteoglycan; LM, laminin; PS, phosphatidylserine; SE matrix, subendothelial matrix; SO_4 glycolipid, sulfated glycolipid; TSP, thrombospondin; VCAM-1, vascular cell adhesion molecule-1; VWF, von Willebrand factor. CD47 is also known as the integrin-associated protein or IAP. (From Setty BNY, Kulkarni S, Stuart MJ: Role of erythrocyte phosphatidylserine in sickle red cell-endothelial adhesion. *Blood* 99:1564–1571, 2002.)

factor α , and interleukin-1), acute phase reactants (such as C-reactive protein, secretory phospholipase A2, and G-CSF), and markers of endothelial cell injury (such as soluble VCAM).⁵⁴ The inflammatory biology in patients with SCD appears to result from infection, as well as iron replete (or overloaded) states, sRBC adhesion to endothelium, and the reperfusion-injury physiology observed in these patients.⁵⁴

Hemostatic Changes

Multiple studies show that SCD patients exhibit increased thrombin generation, abnormal activation of fibrinolysis, decreased levels of anticoagulant proteins, activation of platelets, as well as increased circulating levels of soluble tissue factor (TF)⁵⁶ in the non-crisis, steady state (Table 47-1). As a result of these findings, SCD has been referred to as a “hypercoagulable state.” There, however, remain conflicting data as to whether further activation of coagulation and platelets occur coincident with the development of vaso-occlusive crises.

TF, a transmembrane protein that provides for calcium-dependent binding of coagulation factor VII and its activated form, factor VIIa^{57,58} is abnormally expressed on circulating

endothelial cells in patients with SCD and its expression is increased further during pain crises.⁵⁹ In addition, TF levels, as well as TF procoagulant activity are elevated in the plasma of patients with SCD when compared with normal controls,^{60,61} although no difference in TF procoagulant activity was observed when patients with SCD in steady state were compared with those patients with a pain crisis.⁶⁰

MPs, which are small, membrane-derived vesicles released by cells on activation or during apoptosis, are TF positive. MPs in circulating blood are derived from RBCs and platelets as well as endothelial cells and monocytes.⁶² Both total MPs, as well as TF-positive MPs are significantly elevated in SCD patients in steady state compared with normal controls and are further increased during pain crises.⁶² The TF-positive MPs appear to be derived from endothelial cells and monocytes, but not from RBCs or platelets.

Patients with SCD have elevated levels of prothrombin fragment 1.2 (F1.2) and thrombin:antithrombin III complexes (TAT), both markers of thrombin generation.^{63–66} Along with this, they have reduced plasma levels of factors V and XIII in the steady state, findings that are consistent with ongoing generation of thrombin

activity.⁶⁷ Plasmin-antiplasmin complexes (PAP), D-dimers, fibrinopeptide A, and fibrin-fibrinogen fragment E are elevated when plasma samples from SCD patients in the steady state are compared with those of normal individuals,^{63,64,66–69} suggesting enhanced thrombin formation, fibrinogen proteolysis, and subsequent fibrin degradation. There is a significant correlation between markers of coagulation activation (D-dimer, F1.2, and TAT) and total MPs, total TF-positive MPs, monocyte-derived TF-positive MPs, and RBC-derived MPs.⁶² In addition, a significant correlation exists between the frequency of pain episodes and the extent of plasma fibrinolytic activity, assessed by D-dimer levels, when SCD patients are in the non-crisis, steady state.⁶⁸

In addition to the increased thrombin generation and abnormal fibrinolysis, both protein C activity and protein S antigen and activity levels are decreased in plasma from patients with SCD.^{63,70} Decreased protein C and S activity levels are also observed in plasma from SCA patients who have experienced thrombotic strokes when compared with SCA patients who have not experienced similar events.^{71,72} Investigators disagree on the activity of antithrombin III (ATIII) in SCD patients both in the non-crisis, steady state and during vaso-occlusive crises.^{73–75}

Pathogenesis

The pathogenesis of the hemostatic changes in SCD is likely secondary to multiple factors. In the steady state, the choline-containing phospholipids, phosphatidylcholine and sphingomyelin are located in the outer monolayer of the RBC plasma membrane, whereas phosphatidylserine (PS) is exclusively and phosphatidylethanolamine (PE) is primarily found in the inner monolayer.⁷⁶ In normal erythrocytes, maintenance of membrane phospholipid asymmetry is provided by the action of an ATP-dependent aminophospholipid translocase (or flippase), that transports PS and PE from the outer to the inner membrane surface,^{77,78} and a nonspecific floppase that transports phospholipids from the inner to the outer monolayer.⁷⁹ In addition, scramblase, when activated, results in the movement of all phospholipids in both directions to achieve

rapid PS exposure.⁷⁶ Loss of normal phospholipid asymmetry is present in SCD, occurring in mature erythrocytes, RNA-containing reticulocytes, and transferrin receptor-positive “stress” erythrocytes.^{80–85} The abnormal PS exposure is believed to occur due to sickling-induced membrane damage,⁸⁶ inactivation of the ATP-dependent translocase and premature activation of apoptosis in bone marrow cells. The abnormal phospholipid asymmetry and the resulting adherence of sRBCs to the vascular endothelium both appear to be involved in the hemostatic changes observed in SCD.^{35,87,88} Several factors provide evidence for a relationship between the sRBC membrane abnormalities and the hypercoagulable state in patients with SCD. Plasma prothrombin F1.2 levels are significantly associated with the quantity of PS-positive RBCs.⁸⁵ Furthermore, there is a significant correlation between PS-positive sRBCs and F1.2, D-dimer, and PAP complexes.⁸⁹ However, no correlation was found between PS-positive platelets and any hemostatic markers,⁸⁹ suggesting that sRBC, and not platelets, are responsible for the hypercoagulable state observed in SCD. Finally, sRBCs containing high amounts of HbF are associated with decreases in MP formation, PS exposure, and thrombin generation,⁸⁵ suggesting a protective effect of HbF on membrane bilayer flip-flop and PS exposure.

Circulating endothelial cells are identified in patients with SCD.^{90–92} The surface expression of endothelial adhesion molecules^{90,91} plays a significant role in the recruitment of leukocytes^{93,94} and the promotion of thrombosis⁹⁵ at sites of vascular inflammation. The expression of adhesion molecules (VCAM-1, intercellular adhesion molecule [ICAM-1], E-selectin, and P-selectin), elevated plasma levels of inflammatory mediators (interleukin-6, monocyte chemotactic protein-1, platelet activating factor), and the increased procoagulant phenotype (decreased thrombomodulin and increased VWF and TF phenotype) are characteristic of endothelial activation or injury and have been implicated in the vascular biology of SCD.³⁶

The inflammatory state present in SCD may also contribute to its hypercoagulability. Studies in transgenic mouse models show that exposure of NY1DD mice (a mild sickle cell phenotype) to hypoxia-reoxygenation (H/R) results

in increased TF expression in the pulmonary veins of the mice following placement in a hypoxic environment for 3 hours followed by a return to ambient air for 18 hours, suggesting a role for ischemia-reperfusion injury.⁹⁶

CLINICAL CONSIDERATIONS

The Role of Hemostatic Abnormalities in Vaso-occlusion

Despite the plethora of evidence supporting activation of coagulation and platelets in the non-crisis, steady state in patients with SCD, there are conflicting data as to whether further increases occur during vaso-occlusive crises.^{90,97–106} This apparent conflict may be a result of the somewhat artificial distinction between steady state and pain crisis.

The supporting evidence for a role of activation of the coagulation system in the pathophysiology of SCD remains weak. Activation of the coagulation system and/or platelets may be secondary to, rather than causative of, the ongoing vascular occlusion and/or end-organ damage that characterizes this clinical disorder. Furthermore, the published clinical studies of either anticoagulants or antiplatelet agents in SCD have been small, poorly controlled, and of relatively low quality (Table 47-2).^{103,107–115} However, the majority of these studies, which have focused on pain crisis as a clinical outcome, report that treatment with antiplatelet agents or anticoagulants results in only modest clinical benefit at best.

A demonstration of the etiologic relationship between activated platelet and blood coagulation and SCD will come only from well-designed, adequately-powered studies employing anticoagulant and/or antiplatelet therapy, employing both clinical end points of vaso-occlusion and suitable laboratory markers.

By reducing TF activity at sites of mechanical vascular injury, dietary n-3 fatty acids appear to abolish vascular thrombosis in experimental animals without significantly impairing their hemostatic function.¹¹⁶ A controlled study of dietary n-3 fatty acids in SCD patients demonstrated a significant reduction in the frequency of pain episodes along with decreased markers of thrombin generation and fibrinolysis.¹¹⁶ Whether the observed reduction in pain episodes was a consequence of this reduction in prothrombotic activity still needs confirmation.

Although the majority of studies have failed to assess the in vivo effect of antiplatelet agents on platelet activation, it remains possible that newer antiplatelet agents such as glycoprotein-IIb/IIIa inhibitors, some of which may have anti-adhesion effects,¹¹⁷ when administered at doses sufficient to inhibit platelet activation, could have important therapeutic benefits in SCD.

Thrombophilic DNA Mutations

With the evidence of clinical thrombosis and increased thrombin generation in SCD, multiple studies have evaluated the roles of various inherited thrombophilic mutations.

Table 47-2 Published Reports of Anticoagulants and Antiplatelet Agents in Patients with Sickle Cell Disease

Study (First Author)	Genotype	No. of Subjects	Therapy	Randomized	Duration	Efficacy Outcome Measure
Salvaggio ¹⁰⁷	Hb SS	12	Warfarin	No	12–34 Months	Frequency and severity of VOs

	Hb Sβ Thal	4				

2,3 BPG, 2,3 bisphosphoglycerate; ASA, aspirin; CBC, complete blood count; Hb F, fetal hemoglobin; Hb, hemoglobin; ISC, irreversible sickle cell; O₂ Sat, oxygen saturation; pO₂, partial pressure of oxygen; VOE, vaso-occlusive episode.

Although SCD patients are resistant to activated protein C (APC) when they were compared with normal control subjects,¹¹⁸ there have, to date, been no reported relationships between either the factor V Leiden (i.e., G1691A) or the prothrombin gene (i.e., G20210A) mutation and the subsequent development of complications in patients with SCD.^{119,120}

Plasma homocysteine levels obtained from children with SCD are similar to those obtained from healthy children,¹²¹ although higher homocysteine levels were reported in SCD patients who have experienced one or more ischemic strokes compared with SCD patients who have not had ischemic strokes.¹²² Finally, although the methylenetetrahydrofolate reductase (MTHFR) mutation was identified as a risk factor for the development of avascular necrosis among SCD patients,¹²³ multiple other studies do not show a significant association between the MTHFR mutation and a variety of thrombotic complications in patients with SCD.^{119,124–126}

RED BLOOD CELL TRANSFUSION

Transfusion remains a mainstay in the treatment of SCD. Patients experiencing symptomatic anemia benefit from the simple transfusion of packed RBCs. Alternatively, blood transfusion is used to dilute the concentration of red cells containing Hb S to ameliorate or prevent vaso-occlusive events. Although beyond the scope of this chapter, specific indications for transfusion have been addressed and the reader is referred to the monograph by Rosse and colleagues¹²⁷ and the NIH publication on the Management of Sickle Cell Disease for a comprehensive review.¹²⁸

In direct contrast to transfusion therapy for patients without SCD, strict attention to avoiding hyperviscosity is necessary to minimize complications. In the acute setting, the posttransfusion total Hb levels should not exceed the 10 to 11 g/dL range. Depending on the baseline Hb level or the posttransfusion Hb S target, it is often necessary to use exchange transfusion to accomplish this goal. Manual or automated techniques can be used depending on the urgency of transfusion and/or availability of erythrocytapheresis equipment (see Chapter 30). Patients with SCD are at a particular high risk of alloimmunization, which can be reduced by leukodepletion and selecting units that are phenotypically matched for the C, E, and Kell in addition to ABO and D antigens.¹²⁹

HYDROXYUREA THERAPY

Hydroxyurea (HU) is currently the only drug approved by the U.S. Food and Drug Administration to treat SCD. Hydroxyurea inhibits DNA synthesis by targeting ribonucleotide reductase, the enzyme responsible for the conversion of ribonucleotide diphosphates to the corresponding deoxyribose forms.¹³⁰ Its exact mechanism of action in SCD is unknown. Although it is generally assumed that the benefit of HU is due to an increase in Hb F levels, a multivariable analysis of data from the Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH) showed that the percentage of F cells was inversely correlated with the rate of painful crises only during the first three months of therapy.¹³¹ However, there was a strong correlation

between the neutrophil count and the rate of pain crises throughout the treatment period. As a result, the observed neutropenia may not only contribute to, but also be necessary for the effectiveness of the drug. HU has also been reported to decrease the expression of PS on the surface of RBCs and platelets in patients with SCD, an effect that may contribute to its therapeutic benefit.¹³² The RBCs from those patients receiving HU adhere less avidly to thrombospondin,¹³³ and in preliminary studies, treatment with HU resulted in a decrease in the level of D-dimer in the peripheral circulation.¹³⁴ Finally, the ability of HU to decrease vaso-occlusive phenomena may, in part, be attributed to vasodilation and/or decreased platelet activation induced by HU-derived nitric oxide.^{135,136}

Treatment with HU results in a significant decrease in the frequency and severity of painful crises, a reduction in the incidence of acute chest syndrome, and a reduction in the need for blood transfusions.¹³¹ HU treatment also results in substantial reduction in clinical events requiring hospitalization.¹³⁷ Furthermore, HU has been reported to result in reduced mortality in adults with severe SCA.¹³⁸

ACUTE CHEST SYNDROME

Acute chest syndrome (ACS) is the second most common cause of hospitalization and a leading cause of death in patients with SCD.^{5,10} It is defined by the presence on a chest radiograph of a new pulmonary infiltrate and respiratory symptoms that include cough, tachypnea, and chest pain.^{139–141} The symptoms at presentation are age-dependent, with fever, wheezing, and cough being predominant in children younger than 10 years.¹⁴² Adults, on the other hand, typically present with shortness of breath, chills, and severe pain, with multilobe and lower lobe involvement on chest radiograph.¹⁴² Nearly one half of the patients are admitted with a diagnosis other than ACS (usually pain), with the syndrome being defined after about 2.5 days of hospitalization.¹⁴³

The incidence of ACS is higher in patients with Hb SS [12.8/100 patient-years] and in patients with Hb S β^0 thalassemia (9.4/100 patient-years), and lower in patients with Hb SC (5.2/100 patient-years) and patients with Hb S β^+ thalassemia (3.9/100 patient-years). ACS occurs more commonly in young children, patients with low levels of Hb F, and patients with higher steady state WBC counts and hemoglobin levels.¹⁰

Etiology and Pathophysiology

In a study using rigorous methods, including bronchoscopy, deep sputum cultures, and extensive serologic evaluations, a specific etiology (pulmonary fat embolism or an infectious agent) was identified in 70% of cases of ACS with complete data.¹⁴³ Pulmonary infarction was presumed to be the cause in 16% of episodes in those subjects with complete data for whom no etiology was identified. Of the multiple isolated pathogens, *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* were the most frequently identified. Patients with pulmonary fat embolism as the cause of ACS were older, had lower oxygen saturation, and were more likely to have upper lobe infiltrates compared with those patients with infection or infarction as the cause.¹⁴³

However, the overall complication rates, with the exception of incidence of pain events, were similar in all three groups.

The pathogenesis of ACS appears to be due to hypoxia-enhanced in vivo sRBC adhesion to pulmonary microvasculature.¹⁴⁴ Hypoxia has been shown to enhance the adhesion of RBCs to endothelial cells, an interaction mediated by the binding of VCAM-1, expressed on endothelial cells, to $\alpha_4\beta_1$ on red cells.⁴⁵ Plasma concentrations of soluble VCAM-1 are elevated in patients with ACS, and this increase is inversely related to plasma concentrations of nitric oxide (NO) metabolites.¹⁴⁴ In accompanying in vitro experiments, exposure to both hypoxia and oleic acid increased the expression of VCAM-1 in pulmonary endothelial cells and resulted in increased adherence of sRBCs to these endothelial cells. However, exposure to NO donors resulted in reduced adhesion of sRBCs to endothelial cells following exposure to hypoxia and oleic acid.¹⁴⁴ These findings suggest that increased expression of adhesion molecules as a result of hypoxia, fat embolization, and cytokines in the setting of decreased NO production observed in sickle cell pain crises and ACS contributes to systemic and pulmonary RBC sequestration.¹⁴⁵

Clinical Management

The routine use of invasive procedures, such as bronchoscopy, is not required in the evaluation of patients with ACS (Table 47-3). However, routine serologic tests for *Chlamydia*, *Mycoplasma*, and *Legionella* may be incorporated (when available) with routine cultures in the overall management

Table 47-3 Management of Acute Chest Syndrome

Prophylaxis

Close monitoring of oxygen saturation during hospitalization
Aggressive incentive spirometry and ambulation as tolerated
Judicious use of opioid analgesics to avoid oversedation
Avoidance of overhydration—encourage oral hydration if patient is able to drink adequately
Adequate immunization—pneumococcal, influenza, and possibly parvovirus B19
Hydroxyurea in patients with frequent pain episodes or history of severe/recurrent acute chest syndrome

Diagnostic Testing

Blood cultures and serologies for *Chlamydia*, *Mycoplasma* (if available)
Deep sputum for bacterial culture
Chest radiograph
Arterial blood gas for changes in oxygen saturation

Treatment

Supplemental oxygen for hypoxia (oxygen saturation <92%)
Judicious fluid management
Optimal pain control
Incentive spirometry and chest physical therapy (unless chest pain is present)
Empiric antibiotics to cover community-acquired pneumonia (levofloxacin or azithromycin + cephalosporin)
Bronchodilator therapy (even in the absence of obvious wheezing)
Blood transfusion therapy (simple or exchange) with leukocyte-reduced phenotypically compatible red cells keeping total hemoglobin ≤ 10 –11 g/dL
Mechanical ventilation or extracorporeal membrane oxygenation, if necessary

strategy. Prophylactic measures such as incentive spirometry for SCD patients hospitalized for vaso-occlusive episodes¹⁴⁶ and judicious use of analgesics to avoid excessive sedation are especially important.¹⁴⁷ Once patients develop ACS, the use of antibiotics, such as newer fluoroquinolones or macrolide and a cephalosporin, with coverage against *Chlamydia* and *Mycoplasma* are recommended. Oxygen therapy is indicated for hypoxia, and strict attention to fluid balance to avoid overhydration is necessary.

Blood transfusion improves oxygenation, as well as the clinical status of patients with ACS.^{143,148} Its use may be especially important in those patients with radiographic evidence of extensive lobar involvement, thrombocytopenia, and a history of cardiac disease (all predictors of respiratory failure),¹⁴³ as well as neurologic abnormalities. Either simple or exchange transfusion appears to result in similar improvements in oxygenation.¹⁴³ There are no strict criteria for choosing between the techniques, but exchange transfusion to reduce the Hb S level below 30% should be considered if there is respiratory failure. However, during transfusion of these patients, it is important not to exceed a hemoglobin concentration of 10 to 11 g/dL. In those instances when patients develop respiratory failure, mechanical ventilation, as well other modalities such as extracorporeal membrane oxygenation (ECMO), may be helpful.¹⁴⁹

There are several reports of the pharmacologic use of NO in mechanically ventilated patients with respiratory failure.^{150,151} A short course of steroid therapy was shown to reduce the length of hospital stay in children with ACS, although a rebound effect with increased patient readmission was observed.¹⁵² Additional rigorous studies of both steroid and NO administration in ACS are required before they are recommended for routine use.

PULMONARY HYPERTENSION IN SICKLE CELL DISEASE

Pulmonary hypertension (PHT) (see Chapter 45), usually defined as a sustained elevation of the mean pulmonary arterial pressure to more than 25 mm Hg at rest or to more than 30 mm Hg with exercise,¹⁵³ is recognized as a common complication in patients with SCD. Multiple reports suggest a high occurrence of PHT in these patients, with recent cross-sectional studies reporting a prevalence of 20% to 35%.^{154–157} Furthermore, SCD patients with PHT have a significantly increased mortality rate compared with those SCD patients without PHT.^{154,156,158–160} In the study by Castro and coworkers, SCD patients with PHT confirmed by right heart catheterization had a 50% 2-year mortality rate compared with a survival greater than 70% at the end of a 119-month observation period in SCD patients without PHT.¹⁶⁰

Pathophysiology

The pathogenesis of PHT in SCD is likely multifactorial. Chronic intravascular hemolysis, with resultant scavenging of NO and development of NO resistance, appears to play a prominent role in the development of PHT.^{156,161–166} As a result of this NO resistance, vascular smooth muscle guanylyl cyclase is not activated and vasodilation is

inhibited. Hemolysis also results in the release of arginase, which converts L-arginine (the substrate for NO synthesis) to ornithine.¹⁶⁷ Elevated arginase activity, with resultant decrease in arginine/ornithine ratio is associated with elevated pulmonary pressures.^{156,168} Furthermore, lower arginine/ornithine ratio is independently associated with increased mortality in patients with SCD.¹⁶⁸

PHT may also result from recurrent vaso-occlusion and ACS leading to parenchymal lung injury,^{169,170} although recent studies^{156,157} did not find any association between PHT and a previous history of ACS. Pulmonary thromboembolism^{171–174} and progressive endothelial damage with concentric pulmonary vascular intimal hyperplasia and in situ thrombosis^{174,175} may contribute to the pathogenesis of PHT in SCD. Other mechanisms that may contribute to the development of PHT in SCD include chronic and recurrent acute hypoxemia, possibly exacerbated by hypoventilation during sleep;¹⁷⁶ elevated pulmonary capillary wedge pressure due, in large part, to left ventricular diastolic dysfunction¹⁶⁰; and functional asplenia, present in most adult patients with SCA.¹⁷⁷

Clinical Management

The symptoms of PHT in patients with SCD are nonspecific in the early stages.¹⁶⁹ Patients may present with increasing shortness of breath after physical exertion, chest pain, near-syncope or syncope, and peripheral edema in more advanced stages. With the nonspecific nature of symptoms at the early stages and recognition of increased mortality, many experts now advocate periodic screening of SCD patients with transthoracic echocardiography, at least every 2 to 3 years.^{178,179}

Despite the increased recognition of PHT in patients with SCD, there is no consensus in the management of these patients. There are conflicting reports on the effect of HU in PHT.^{156,157} However, a recent report suggests a lower prevalence of PHT in those SCD patients on HU therapy.¹⁵⁷ The role of transfusion therapy in the treatment of patients in this setting remains controversial. Although some preliminary studies suggest that PHT may be ameliorated or even partially reversible with transfusion therapy,¹⁸⁰ others have reported no benefit with RBC transfusion.¹⁵⁹ Hypoxia is known to result in vasoconstriction of the pulmonary vessels¹⁸¹ and as a result, supplemental oxygen would be expected to be of benefit in hypoxic patients with PHT. Those with disorders of breathing during sleep should be assessed for response to nocturnal oxygen or continuous positive airway pressure (CPAP).

A short course of oral arginine given to 10 SCD patients with PHT led to a significant decline in the pulmonary artery systolic pressure (PASP) (63.9 ± 13 to 54.2 ± 12 mm Hg, $P = 0.002$).¹⁸² However, adequately powered, controlled studies are required to confirm the efficacy of arginine in these patients. With the possibility that thrombosis contributes to the pathogenesis of PHT in SCD, clinical trials evaluating the effect of anticoagulant therapy are needed. This is especially in view of reports that anticoagulation provides a survival benefit for patients with idiopathic pulmonary arterial hypertension.¹⁸³ The prostacyclin analog, epoprostenol, known to prolong survival in patients with primary PHT,¹⁸⁴ and other prostacyclin analogs have been used in SCD patients with PHT,¹⁶⁰ although their usefulness has

yet to be confirmed in controlled trials. Treatment with sildenafil, a phosphodiesterase type 5 inhibitor, for at least 3 months results in improved PASP and functional capacity, as assessed by a 6-minute walk test.¹⁸⁵ Most of the patients in this preliminary study were women (of the three male subjects, two were receiving chronic RBC transfusion and one had erectile dysfunction); there remains concern regarding the risk of priapism in male SCD patients on sildenafil therapy.

With the increased mortality associated with PHT in patients with SCD, it is imperative that patients are aggressively evaluated and treated. They should be evaluated in their non-crisis, steady state, as increases in the PASP are known to occur during vaso-occlusive episodes¹⁸⁶ and during ACS. In the absence of proved therapies from adequately controlled studies, newly diagnosed patients should be enrolled in clinical trials evaluating the effects of different treatments on PHT in SCD.

STROKE

The overall reported prevalence of overt stroke in children with SCA is approximately 10%. These events are predominantly ischemic in etiology. In addition to the clinically identified events, MRI scans of the brain of apparently unaffected children reveal a 15% to 20% incidence of silent infarction.^{187,188} The pathogenesis of cerebral infarction in children with SCD is not simply sickling of RBCs in the microcirculation. Endothelial injury as described earlier for vaso-occlusive events is likely a major contributor to the pathophysiology.¹⁸⁹ Prior transient ischemic attack, anemia, recent or frequent ACS episodes, and hypertension have been identified as risk factors.¹⁹⁰ The majority of children presenting with stroke symptoms corresponding to a specific arterial distribution demonstrate stenosis or occlusion of major intracranial arteries. In a subset of patients with such abnormalities of the internal carotid arteries, a network of collateral vessels develop (moyamoya syndrome) which appears to confer an increased risk for recurrent cerebrovascular events.¹⁹¹

The Stroke Prevention Trial in Sickle Cell Anemia (STOP) addressed the use of prophylactic RBC transfusion in children 2 to 16 years of age with SCA who were at high risk for an initial stroke based on transcranial Doppler ultrasonography (TCD).¹⁹² There was a significant reduction in the incidence of strokes in patients randomized to receive prophylactic transfusions to reduce the hemoglobin S level to below 30% (1 of 63) compared with patients receiving standard care (11 of 67). The optimum duration of chronic transfusion necessary to provide protection from a cerebrovascular event is not known. However, the results of the Optimizing Primary Stroke Prevention in Sickle Cell Anemia (STOP 2) trial addressing this issue have recently been reported.¹⁹³ Seventy-nine patients with abnormal TCD before transfusion and who had received at least 30 months of RBC transfusion were randomized to stop or continue transfusions. Of the 41 patients randomized to discontinue transfusion, 16 reached the primary end point events (14 patients with reversion to high-risk TCD and 2 patients with ischemic strokes) compared with neither of these events in the 38 patients continuing to receive transfusions. These results indicate that discontinuation of chronic transfusion

after 30 months cannot be recommended. Primary prevention of cerebrovascular events in patients older than 16 years of age has not been addressed in clinical trials and TCD screening for adults cannot be recommended for routine use at this time.

The differential diagnosis of a child with SCD presenting with new neurologic deficits includes infection, ischemic stroke, and intracranial hemorrhage. The initial evaluation should include a non-contrast CT scan. For the patient with apparent evolving or completed ischemic stroke, emergent transfusion is indicated. Although simple transfusion can be considered if the Hb level is below 10 g/dL, exchange transfusion is recommended to more promptly reduce the Hb S level to below 30%. MR imaging including MRA will assist in providing essential information concerning the presence of arterial vasculopathy. Hemorrhagic stroke occurs more commonly in young adults.¹⁹⁰ Subarachnoid hemorrhage may be due to rupture of a cerebral aneurysm (which may be multiple in SCD) or the moyamoya collaterals. Conventional angiography may be necessary to identify arteriovenous malformations or aneurysms.

The recurrence rate of stroke in children with ischemic events not receiving subsequent treatment was found to be 66%.¹⁹⁴ Two case series demonstrated that long-term blood transfusion substantially reduced the risk of recurrence.^{195,196} Current clinical practice is to begin a chronic transfusion program to maintain the Hb S level below 30%. After 3 to 4 years, a decrease in frequency of transfusion to allow the target value to rise to 50% may be considered.¹⁹⁷ Randomized clinical trials addressing the duration of transfusion for secondary stroke prevention have not been conducted. Children stopping transfusion after 5 to 12 years experienced a 50% recurrence rate.¹⁹⁸ The current standard of care is to continue a chronic transfusion program indefinitely. Recurrent events are observed for patients continuing on a chronic transfusion program. The largest published experience is a retrospective multicenter study of 137 children with stroke maintained on chronic transfusion for at least 5 years revealing a recurrence rate of 2.2 per 100 patient-years.¹⁹⁹

HU therapy combined with phlebotomy has been evaluated in 35 children as an alternative to chronic transfusion.²⁰⁰ Patients received transfusions for approximately 4 years prior to being switched to HU, which was titrated to maximally tolerated doses. The recurrence rate was 5.7 events per 100 patient-years with a mean duration of 3.5 years follow-up. The protocol was modified to overlap HU rather than to abruptly discontinue transfusions and resulted in a reduced recurrence rate of 3.6 events per 100 patient-years. A multicenter randomized controlled trial examining HU therapy as an alternative to transfusion is planned. HU therapy should be considered for patients who wish to discontinue transfusion or have such problems as extensive alloimmunization preventing maintenance transfusions.

For adolescents and adults, the evaluation of acute stroke should also address etiologies relevant to patients without SCD (e.g., hypertension, embolism, arterial dissection, atrial fibrillation, and infection). There are no clinical trials addressing the use of recombinant tissue plasminogen activator or the role of antiplatelet agents in SCD patients with acute ischemic events. The role of

chronic transfusion for the patient with the initial event as an adult has not been defined.

Anticoagulation for Atrial Fibrillation and Prosthetic Cardiac Valves

Thomas G. DeLoughery, MD

OVERVIEW

The most common indications for chronic anticoagulation therapy are stroke prevention for patients with atrial fibrillation and embolism prevention for those with prosthetic cardiac valves. However, many patients have risk factors for bleeding or other comorbid conditions that can make anticoagulation challenging. This chapter will review the data supporting antithrombotic therapy. Most attention will be spent on discussing challenging patients—older patients, those with risk factors for bleeding, those difficult to anticoagulate, and pregnant patients—the very patients most likely to generate consultation.

Atrial Fibrillation

Atrial fibrillation is the most common cardiac condition leading to embolism. The risk of stroke due to embolism in patients with atrial fibrillation is 3% to 7% per year. It is estimated that 15% of all strokes can be attributed to atrial fibrillation. The incidence of atrial fibrillation is age dependent and ranges from 0.5% for people younger than age 55 to 9% for people older than age 80.¹

In the past 15 years, well-designed studies have clarified the role of antithrombotic therapy for stroke prevention in patients with nonvalvular atrial fibrillation.² Robust data support the effectiveness of warfarin. Five randomized clinical trials have shown that warfarin anticoagulation reduces the risk of first stroke from 5% per year down to 1% per year.^{3–5} Warfarin is the only effective therapy that prevents disabling and fatal strokes.^{6–8} There is evidence that results of these trials can be replicated in clinical practice.^{9,10} In addition, the EAFT study demonstrated the effectiveness of warfarin in secondary prevention of stroke with a reduction from 16.5 to 8.5 strokes per year.¹¹

An International Normalized Ratio (INR) range of 2 to 3 is most effective for stroke prevention. Stroke risk rises with INRs of less than 1.9 and is no different than no therapy at INRs below 1.5.^{9,12,13} Conversely, the risk of excessive bleeding does not fall to baseline risk until INRs are 1.5 and below. These data refute the common practice of using a lower INR target in patients at high risk for bleeding (1.5 to 1.9); such practice does not reduce the risk of bleeding yet will increase the risk of stroke. The INR range of 2 to 3 has been supported by studies showing that, even when patients have strokes, those in the therapeutic range have smaller strokes and better outcomes.^{14,15,15a}

The issue of antiplatelet therapy for stroke prevention in atrial fibrillation remains contentious.² The AFASAK trial showed 75 mg of aspirin (ASA) to be of no benefit in the prevention of embolism. SPAF showed 325 mg of aspirin was effective but only in patients younger than 75 years of age.^{3,4,16} SPAF III demonstrated that in patients believed to be at low risk of stroke, aspirin was effective in preventing embolism.¹⁷ However, the effect of aspirin is modest, with meta-analysis showing only a 22% risk reduction.^{18–20} Head-to-head studies of aspirin versus warfarin *strongly* favor warfarin.⁸ Finally, aspirin has no effect on preventing disabling or fatal strokes. It may be that in patients who have no other risk factors for stroke, the presence of atrial fibrillation acts as a marker for cerebrovascular disease for which aspirin might offer protection.^{21,22}

It seemed intuitive to think that converting patients' cardiac rhythm from atrial fibrillation to sinus rhythm would reduce the risk of stroke, but two randomized trials have shown that rhythm control without anticoagulant therapy offers no advantage in reducing strokes over rate control.^{23–26} These findings support the notion that having or having had atrial fibrillation serves as a marker, more than a cause, for cardiovascular disease sufficient to be associated with cardioembolism.

Prediction rules now exist to risk-stratify patients and help the clinician choose between warfarin and aspirin therapy. Data have been pooled from multiple clinical trials to make a variety of these prediction rules. Clinically the most useful appears to be the CHADS2 rule (Table 48-1).^{27,28,160} In the CHADS2 system, one point is assessed for presence of Congestive heart failure, Hypertension, Age greater than 75 years, and Diabetes, respectively, and two points for history of Stroke. For the average patient, a CHADS2 score of 0 to 2 would suggest low risk of stroke and aspirin therapy, whereas a higher score would support the use of warfarin.

Given the practical difficulties in using warfarin, the appeal is great for new antithrombotic agents that would be easier to use. The oral direct thrombin inhibitor ximelagatran appeared in two randomized trials to offer the same antithrombotic protection as warfarin without need for dose adjustment or interactions with other medications.²⁹ Unfortunately, the rates of liver toxicity were deemed unacceptable and at the time of this writing, no new agents have advanced into the late clinical testing phase.

Table 48-1 CHADS2 Scoring System*

CHADS2 Score	Yearly Risk of Stroke	Therapy
0	1.9	Aspirin
1	2.8	Aspirin
2	4.0	Warfarin
3	5.9	Warfarin
4	8.5	Warfarin
5	12.5	Warfarin
6	18.2	Warfarin

*One point each for recent heart failure, hypertension, age >75 years, and diabetes. Two points assigned for history of stroke. CHADS2: Congestive heart failure, Hypertension, Age >75 years, Diabetes, history of Strokes (two).
Data from Gage BF, Waterman AD, Shannon W, et al: Validation of clinical classification schemes for predicting stroke: Results from the National Registry of Atrial Fibrillation. JAMA 285(22):2864–2870, 2001.

Risk of Bleeding with Warfarin

The use of warfarin is increasing markedly due to data indicating that warfarin is the most effective agent for stroke prevention in atrial fibrillation. Accompanying the increased use is a higher rate of patients bleeding due to warfarin.³⁰ The annual risk of fatal bleeding is 0.6% to 1% and the risk of major bleeding is 3%.^{31,32}

Risk factors for bleeding on warfarin therapy have been studied many times, but most reports agree on several basic factors. The first is supratherapeutic INRs.^{33–37} The two-week bleeding risk for an INR greater than 6 is 4.4%.³⁸ The risk of bleeding and of intracranial hemorrhage (ICH) rises dramatically with increasing INRs.^{34,39} The odds ratio for ICH with an INR greater than 4.5 is from 8 to 11.^{36,40} Duration of therapy is also a reproducible risk factor with patients just starting therapy being at highest risk of bleeding.^{31,32,36} Concomitant use of antiplatelet agents increases the risk of bleeding by 20% to 100%.^{41–44} History of gastrointestinal bleeding, poor compliance, stroke, low vitamin K intake, and alcohol abuse are also risk factors for bleeding.^{31,35,41,45–49}

Recent research has focused on variations in cytochrome 2C9 (CYP2C9) and the VKORC1 gene affecting warfarin metabolism.^{50,50–56} Patients with polymorphisms that predict a lower maintenance dose of warfarin have a higher risk of bleeding. However, until rapid assays are available for these polymorphisms, the usefulness of prospectively knowing these genotypes to predict bleeding in an individual patient will remain limited.

There is increasing evidence that assessing a limited set of pretreatment variables can help predict the risk of bleeding. The best studied is the outpatient bleeding index (Table 48-2).^{28,57,58} In several studies, the risk of bleeding has ranged from 0% to 2% per year for low-risk patients to 10% per year for high-risk patients. Although further validation is needed for a broad range of patients, the outpatient bleeding index can be helpful for anticoagulation decision making.

Atrial Fibrillation—Special Situations

Patients with atrial fibrillation undergoing cardioversion have up to a 5% incidence of embolism at or near the time of cardioversion. Consequently, patients with atrial fibrillation for more than 2 days typically receive warfarin to achieve a documented INR of 2.0 to 3.0 for a duration of 3 weeks

Table 48-2 Outpatient Bleeding Index

Assign one point for:

- Age ≥65
- History of stroke
- History of gastrointestinal bleeding
- Recent myocardial infarction, hematocrit <30%, creatinine >1.5 mg/dL, or diabetes (one point maximum)

Score	Risk Group	Yearly Risk of Major Bleeding
0	Low	0%–1.1%
1–2	Intermediate	2.5%–4.9%
3–4	High	8.8%–10.6%

Data from references 28, 57, and 58.

prior to cardioversion. This should allow any thrombus present to organize. Because mechanical activity of the atria may not fully resume until some time after resumption of normal sinus rhythm, patients should remain anticoagulated for at least 4 weeks if not indefinitely after cardioversion. The same procedure should be followed for patients undergoing chemical cardioversion for atrial fibrillation. Atrial fibrillation in thyrotoxic heart disease is associated with a high rate of embolic phenomena. Therefore, these patients should receive warfarin to maintain an INR of 2.0 to 3.0 until 4 weeks after the resumption of normal sinus rhythm.

CARDIAC VALVES

Mechanical Prosthetic Heart Valves

Patients with mechanical heart valves have an extremely high risk for embolization, and continuous anticoagulation is strongly recommended.^{59–61} It is estimated that the risk of thrombosis without anticoagulant ranges from 12% to 30% per year. It does appear that the newer generation of mechanical valves is less thrombogenic than the older ball-cage valves. Even with anticoagulation, the yearly rate of thrombosis ranges from 2.5% with ball-cage to 0.5% with bileaflet valves.⁵⁹ Patients with mechanical aortic valves are at lesser risk of thrombosis than those with mechanical mitral valves. However, the rates of embolism and valve thrombosis are still substantial with newer valves, and anticoagulation is still recommended.

For all valve types and positions, the addition of antiplatelet therapy is useful for additional protection.⁶² The effect of antiplatelet therapy is most important for “high-risk” situations—older valves in the mitral position. The risk of bleeding is increased but is outweighed by the benefit of therapy. The addition of proton-pump inhibitor therapy to aspirin therapy will reduce the risk of gastrointestinal bleeding.

Patients with mechanical prosthetic valves can be stratified by assessing (1) type of valve; (2) valve position; (3) history of stroke; and (4) presence of atrial fibrillation. Using these four clinical factors to risk stratify patients^{62–64} one can select an antithrombotic strategy as follows:

- Bi-leaflet valve in aortic position: INR 2 to 3
- Ball-cage valve: INR 2.5 to 3.5 with 80 to 100 mg/day aspirin

- Others: INR 2.5 to 3.5, or INR 2 to 3 with 80 to 100 mg/day aspirin
- Patients with risk factors such as atrial fibrillation, previous embolism, or coronary artery disease should be considered for combined therapy.

Bioprosthetic Heart Valves

Although the risk is lower, bioprosthetic heart valves still have a definite risk of associated embolization. This is highest immediately after surgery and in patients with bioprosthetic valves who have other risk factors such as atrial fibrillation. In the past, it was recommended that patients with a newly placed bioprosthetic valve should be anticoagulated with warfarin for 3 months after surgery to an INR of 2.0 to 3.0. Recent data and clinical trials do not support this recommendation; for most patients, aspirin suffices for antithrombotic therapy.⁶⁵ Patients with atrial fibrillation, history of embolism, or those with left atrial thrombi should be anticoagulated indefinitely with warfarin.

WHO SHOULD NOT RECEIVE ANTICOAGULANT THERAPY

Although there is much discussion in the literature regarding who should be administered oral anticoagulants, there are some patients for whom the risk of therapy is so substantial that they are judged to be safer with no therapy; if such is determined, that decision should be documented in the patient's chart. Patients with severe underlying bleeding diathesis are not candidates for antithrombotic therapy. An example of this would be a patient with classic hemophilia A or B. In patients with type 1 von Willebrand disease, decision making is harder. One strategy is to approach the risk of warfarin therapy in these patients in a manner similar to the risk of combined warfarin-antiplatelet therapy because, in effect, von Willebrand disease results in platelet function similar to the platelet defect from aspirin administration. When risk of thrombosis is high, use of warfarin would be justified. Severe thrombocytopenia is also a contraindication to warfarin. Based on the data showing that hemophiliacs encounter a higher rate of intracranial bleeding with platelet counts below 50,000/ μ L, this count might be a reasonable cutoff for use of warfarin.

Dialysis patients are especially challenging to anticoagulate. The rate of bleeding in the dialysis patient even without anticoagulation is substantial—as high as 11% per year in one study.⁶⁶ This complication rate doubles with use of warfarin. Uremia slows the metabolism of warfarin and the bleeding defects of uremia are well known. However, dialysis patients are also at much higher risk for thrombotic complications. In one study, atrial fibrillation was a predictor of both stroke (35%) and increased risk of death.^{67,68} Dialysis patients with mechanical valves or atrial fibrillation with high CHADS2 scores (≥ 4) should be strongly considered for warfarin therapy.

If warfarin is used, scrupulous attention must be paid to control of the INR. Erratic drug metabolism can result in unstable INRs. Despite its renal clearance, we have had good outcomes with using renal dose-adjusted low

molecular weight heparin in dialysis patients who had complications stemming from erratic INRs.

Management of High INRs and Bleeding

The risk of bleeding with an elevated INR depends on the degree of elevation of the INR and on the reason for anticoagulation therapy. An older patient being anticoagulated for an arterial reason (stroke, valve, and so on) is at higher risk for bleeding than a younger patient being anticoagulated for a venous indication. The rate and route of therapeutic intervention to address the INR correction depend on whether the patient is bleeding.

For modest INR elevations (4.5 to 10) in a nonbleeding patient, the goal is to return the INR to the 2 to 3 range. The choice is between oral vitamin K versus holding the warfarin for one or more doses. One study clearly shows faster INR correction and a lesser incidence of long-term bleeding with 1 mg of oral vitamin K. For patients at increased risk for bleeding, oral vitamin K is recommended. For higher INRs (>10), 2.5 to 5 mg of oral vitamin K is needed.

In the bleeding patient, use of vitamin K is mandatory. Oral vitamin K acts within 12 hours. For faster onset, intravenous vitamin K will take effect in 4 to 6 hours. If given slowly over 1 hour, the risk of anaphylaxis with vitamin K is 1 in 3300.^{69–73} In multiple studies, subcutaneous vitamin K administration has been shown to be less reliable than oral vitamin K and should not be used for this indication.^{73–77} Fresh frozen plasma can be used to supplement the vitamin K effect, but large amounts are needed—15 mL per kilogram of body weight—which is 4 to 5 units for the average patient. It is important to supplement the plasma with vitamin K because the effect of plasma is brief; the patient may have a rebound rise in the INR within several hours if vitamin K is not given owing to the short half-lives of some transfused factors.

In the patient with intracranial or other life-threatening hemorrhage, correction of the INR with vitamin K and plasma is too slow; faster modalities are needed. The use of prothrombin concentrates (which contain all the vitamin K–dependent clotting factors) results in a more rapid correction of coagulation than does plasma.^{78–80} Patients suffering life-threatening hemorrhage should be considered to receive prothrombin concentrates such as Konyne or Profilnine at a dose of 50 U per kilogram of body weight.^{79,81–83} Unfortunately, these products are not often readily available. There are some recent data showing that the use of recombinant factor VIIa (rFVIIa) can reverse warfarin-induced bleeding.^{84,85} The exact dose of rFVIIa is uncertain; given a need for prompt and complete reversal, our approach has been to err on the side of using a larger dose of 40 μ g per kilogram of body weight.

When is it Appropriate to Restart Anticoagulation after Serious Bleeding?

A common dilemma concerns the timing of resumption of anticoagulation after a serious bleeding episode. Although people are more fearful about resuming anticoagulation after a cerebral bleeding event, data show that gastrointestinal bleeding has the higher rate of recurrence. Rebleeding after intracranial hemorrhage is low—perhaps 1% to 2%

over the next few years. For most patients this risk is outweighed by the benefits of anticoagulation. The exception to this is the patient with evidence of cerebral amyloid angiopathy who should probably never be re-anticoagulated given their very high (>30%) risk of rebleeding even independent of warfarin resumption. The timing of resumption of anticoagulation is also not settled. Studies do indicate that with intracranial hemorrhage, only a short period off anticoagulation is needed. There are even two reports of patients continuing to receive heparin at therapeutic doses despite the presence of an intracranial hemorrhage. There are enough data to suggest that once the INR is normal, a period of only 24 to 48 hours without anticoagulant therapy is necessary before resumption of warfarin therapy.

In summary, when a patient presents with bleeding, one should rapidly normalize the INR. For intracranial hemorrhage, heparin can be started within 1 to 2 days if the patient's INR is corrected. For life-threatening gastrointestinal or genitourinary bleeding, the patient should have a vigorous evaluation for any underlying lesions.

Temporary Cessation of Warfarin for Procedures

As more and more patients are receiving chronic anticoagulant therapy, management around the time of medical procedures or operations has become more of an issue.^{86,87} The risk of thrombosis or embolism needs to be balanced by the risk of surgical bleeding. The approach needs to take into account the reason the patient is being anticoagulated (extremely variable risks) and the risk of bleeding (nearly always overestimated) with a given procedure.

In theory, the risk of thrombosis with holding anticoagulation should be low. For example, if the 1-year risk of thrombosis/embolism with a mitral ball-cage valve is 30%, then simple math yields a daily risk of 0.08% and a 2-week risk of 1.15%. For less thrombogenic valves, presumably the risk would be lower. However, this calculation does not take into account the considerable enhancement of hypercoagulability induced by the surgery, which itself appears to significantly increase the risk of thrombosis. Retrospective data suggest an overall risk as high as 1% to 2% of thrombotic arterial events in patients if their anticoagulation is held before surgery.⁸⁷

One can approach perioperative anticoagulation in several ways. The simplest is to continue the warfarin and perform the procedure with the patient anticoagulated. This is the standard approach for dental procedures, cataract surgery, and endoscopy. A recent pilot study also showed this method to be a safe and effective approach even for complex surgeries.⁸⁸ This approach is associated with the lowest risk of strokes (0.4%) but does carry the risk of increased bleeding.⁸⁷

The next simplest approach would be to stop the warfarin 4 to 5 days before surgery, allow the INR to drift back to normal, and then restart oral anticoagulation after surgery. This would expose the patient to a thrombotic risk for up to 4 to 8 days.

In recent years the concept of "bridging" therapy has been proposed with the idea of using low molecular weight heparin (LMWH) to "bridge" the patient when the warfarin effect is gone.⁸⁹⁻⁹¹ This presumably would have the lowest risk of thrombosis but may expose the patient to

Table 48-3 Bridging Therapy

Consider bridging for patients with mechanical cardiac valves, bioprosthetic valve with history of thrombosis, and patients with atrial fibrillation who have suffered a stroke or have a high CHADS2 score.

Method

Day-5: Stop warfarin 5 days before procedure.

Day-3: Start therapeutic LMWH every 12-24 hours

Day-1: If on q day LMWH therapy, give last dose in AM. If on q12-hour therapy, give last dose evening before surgery unless patient is to receive an epidural; then only the AM dose is given.

Day-0: Check PT/INR/PTT morning of surgery. For most procedures restart warfarin the night of surgery. If very minor procedure, restart therapeutic LMWH; otherwise start prophylactic dose and change to therapeutic dose when risk-to-benefit ratio is favorable.

PT/INR/PTT, prothrombin/International Normalized Ratio/prothrombin time; LMWH, low molecular weight heparin.

bleeding, especially postoperatively. Previous fears about reduced effectiveness of LMWH with prosthetic valves have proved unfounded with the risk of embolism estimated at 0.4% when used as bridging therapy.^{90,92} The newer pentasaccharide anticoagulant agent may have a yet-to-be confirmed role in this area.

Analysis of published studies suggests the following approach: for low bleeding risk procedures (and modest risk ones—if the surgeon agrees) warfarin is continued with an INR goal in the 2 to 2.5 range. For patients with low risk of thrombosis—that is, primary stroke prevention in atrial fibrillation—the warfarin can be held before surgery and restarted afterward. For patients at higher risk of bleeding, bridging therapy such as suggested in Table 48-3 can be used.

Epidural Hematomas

The increasing use of LMWHs for both therapy and prophylaxis has lead to concerns about the risk of epidural hematomas. With unfractionated heparin prophylaxis (most often starting 2 hours before surgery), epidural hematomas were rare. Large case series have reported that patients who received epidural anesthesia during full anticoagulation with unfractionated heparin suffered a low incidence of complications (1:22,000). Early European use of LMWH was associated with rare bleeding complications in case series involving more than 23,000 cases.^{93,94} However, with the introduction in the United States of LMWH, multiple case reports of epidural hematomas were reported. The exact reason for the disparity between Europe and the United States is unknown. One major factor that has been cited is differences in dosing. European dosing practice is a single daily dose of the agent (most often enoxaparin 40 mg every day) versus 30 mg twice daily in the United States. The twice a day dose is associated with high trough levels of LMWH which may predispose to bleeding. However, European patients also received a dose of LMWH 2 hours before surgery, which intuitively would seem to have increased the risk of bleeding. Another major factor is that all patients reported to the FDA had additional risk factors for bleeding—such as concomitant use of antiplatelet agents, early administration of LMWH, and difficulty with the epidural procedure.⁹⁵

The absolute magnitude of risk of epidural hematoma with spinal anesthesia is unknown, with estimates ranging from 1:10,000 to 1:3000 for patients receiving LMWH.⁹⁵ Risk of hematoma with standard heparin ranges from 0% to 0.2%.⁹³ This risk must be balanced by the fact that without prophylaxis, up to 1 in 250 patients receiving lower-extremity orthopedic procedures will die of pulmonary embolism.

Current guidelines suggest that, if LMWH is used for prophylaxis, the first dose should be given 10 to 12 hours after placement of the epidural catheter and LMWH should be held 12 hours before removal of the catheter. Given the longer half-life of fondaparinux, epidural catheters are contraindicated in patients receiving this agent unless the drug is held for 48 hours before catheter insertion.

The Patient with an Erratic INR

Rarely the clinician is faced with the patient who requires massive doses of warfarin for adequate anticoagulation or the patient who seems to be resistant to even large doses of warfarin. In these patients, a careful evaluation is needed to determine the cause of the warfarin resistance. True genetic warfarin resistance is extremely rare, with only four kindreds reported.⁹⁶ The patients are always difficult to anticoagulate and may respond to only very large doses (i.e., 150 milligrams) of warfarin. More common is acquired resistance to warfarin. The three major causes of acquired resistance are medications, concurrent ingestion of vitamin K, and noncompliance.⁹⁷

It is less common for medicines to inhibit rather than to potentiate the action of warfarin. Common drugs that inhibit warfarin action are barbiturates, rifampin, and nafcillin.⁹⁸ Patients on these medications may require 20 mg of warfarin per day to maintain a therapeutic INR. Because most drug-warfarin interactions are mediated through induction of liver enzymes, it may take several days for the warfarin resistance to be noticed after starting the drug. Cholestyramine uniquely interferes with warfarin absorption.

Vitamin K is found in several nutritional supplements and use of these products can result in warfarin resistance (see Chapter 33). For example, Ensure contains 80 µg of vitamin K per 1000 kcal and Sustacal 230 µg per 1000 kcal.⁹⁶ In patients who depend solely on these products for nutrition, large doses of warfarin or anticoagulation with heparin may be required. If the patient changes supplements or starts ingesting regular food, warfarin requirements often change dramatically. Even 1 or 2 days of high intake of vitamin K-rich food can dramatically lower INRs.⁹⁷

Some patients who present with warfarin resistance are simply not compliant. These patients initially require the usual doses of warfarin therapy but then present with normal INRs despite increasing warfarin dosage. Measuring serum warfarin levels is useful in patients suspected of noncompliance.⁹⁹ Patients with undetectable warfarin levels, despite allegedly being on large doses of warfarin are most likely not taking the drug. In the patient who has nondetectable warfarin, a level should be repeated after the patient is witnessed taking the drug to ensure that the patient is not suffering from rare malabsorption of warfarin. One case has been described of a patient who could not absorb

warfarin but could absorb phenindione, a non-coumarin vitamin K inhibitor.¹⁰⁰ Curiously, this malabsorption occurred after 2 years of stable warfarin therapy.

Anticoagulation in the Elderly Patient

Age alone remains controversial as a risk for bleeding.^{40,101,102} Older patients are more sensitive to warfarin, tend to be on more medications that may interact with warfarin, and have more comorbid illnesses.^{103,104} Patients who are older require less warfarin, with patients older than age 65 requiring one half to one third of the warfarin doses of younger patients.^{105,106} Another difficulty in older patients is poor nutrition. Low or irregular intake of vitamin K can lead to unstable INRs.^{47,107} Older patients are more likely to be suffering from cerebral amyloid angiopathy, which is a potent risk factor for bleeding.^{108,109} Unfortunately, older patients are also at higher risk for embolic events and should not be denied warfarin unless other major bleeding risk factors are present.^{102,110}

Despite years of robust trials demonstrating that warfarin is effective in atrial fibrillation, only 50% of patients eligible for therapy receive warfarin, with older patients being less likely to be anticoagulated.^{111,112} More disturbing are data showing that known risk factors for stroke do not seem to play a role in physician decision making about antiplatelet or warfarin therapy for stroke. Physicians tend to overestimate the risk of bleeding with warfarin and underestimate the benefits.¹¹³ Patients, in contrast, fear stroke more than death and are more willing than physicians to accept the risk of serious or fatal bleeding to prevent strokes.¹¹⁴

One common but unsubstantiated reason for denying older patients warfarin therapy is the fear of bleeds with falls. The incidence of intracerebral hemorrhage (ICH) with falling is very low; it has been estimated that there will be one ICH for every 254 ground level falls.¹¹⁵ In addition, the patient who falls is also the patient at risk for stroke. Instead of denying a beneficial therapy, the patient who falls and also needs warfarin should receive it along with efforts made to address risk factors for falling.

Pregnancy and Valves

A growing number of pregnant women need anticoagulant therapy (see Chapter 36). Once rare, increasing experience is being gained in the management of anticoagulants during pregnancy. However, the lack of clinical trials in this population has made this area contentious. The use of warfarin is now considered contraindicated during pregnancy by the manufacturer.¹¹⁶ Warfarin use significantly increases the rate of fetal loss.¹¹⁷ Warfarin crosses the placenta, rendering the fetus unable to synthesize vitamin K-dependent proteins. From gestational week 6 to 12, synthesis of proteins crucial for bone and cartilage formation is impaired by warfarin and its ingestion results in a condition known as warfarin embryopathy.¹¹⁸ Babies affected with this condition will have nasal and limb hypoplasia and stippling of the cartilage. The incidence of children with warfarin embryopathy born from mothers exposed to warfarin is estimated in large series to be 5% to 10%.¹¹⁹ The incidence of the embryopathy appears to be dose dependent with low rates reported with average daily

doses under 5 mg.^{120,121} Later in pregnancy, the fetus itself becomes anticoagulated, resulting in a higher incidence of intracranial hemorrhage and fetal loss. In addition, a variety of central nervous system abnormalities involving midline structures have been reported.¹¹⁹

Because of these concerns about warfarin, heparin has become the anticoagulant of choice for pregnant women, despite concerns about its effectiveness in women with mechanical heart valves. Advantages of heparin are that it does not cross the placenta and has not been associated with teratogenic effects.^{119,122} However, standard heparin has several disadvantages for its use in pregnancy. One is that the partial thromboplastin time (PTT) can be unreliable for monitoring, especially as the pregnancy progresses; therefore, specific heparin assays should be used.^{119,123} Second, at the time of delivery there may be a sudden prolongation of the half-life of heparin leading to persistent anticoagulation of the mother.¹²⁴

The major concern with the long-term use of standard heparin is the development of osteoporosis.¹²⁵ The risk of osteoporosis varies with different studies but evidence of bone loss can be seen in up to 20% of women on therapeutic standard heparin for more than 6 weeks with 2% of women having fractures.^{119,125} In two prospective cohort studies, 28% to 36% of pregnant women experienced a significant decline in bone density while receiving heparin.^{125,126} Surprisingly, neither of these studies demonstrated greater osteoporosis with increasing heparin dosage. Pregnant women on standard heparin should receive calcium and vitamin D, although there is no evidence this will prevent bone loss.¹²⁷ Bone loss is greatest during the time of breastfeeding.¹²⁸ Warfarin is secreted in an inactive form in the breast milk, so there is no contraindication to initiation of warfarin therapy after birth to lessen time of heparin exposure.¹¹⁶

For these reasons, LMWH is now considered the antithrombotic therapy of choice in pregnant women.^{119,129,130} Multiple studies have demonstrated that LMWHs do not cross the placenta. LMWHs have multiple pharmacokinetic advantages over standard heparin and display consistently more reliable dosages.^{131,132} Dosing of LMWH appears to remain stable throughout the duration of the pregnancy.^{119,133} LMWHs are associated with a lower incidence of osteoporosis than standard heparin—with several trials showing no difference in bone density compared with a control group of pregnant women.^{127,129,134,135}

Although poor results have been reported with the use of standard heparin in women with mechanical heart valves,¹³⁶ many of these patients receive only 5000 to 10,000 U of heparin twice a day or, if higher doses were used, a target PTT ratio of 1.5 to 2.0 was selected.¹¹⁸ This dose would be subtherapeutic in most patients—predisposing them to thrombosis. A review of reports concerning valve thrombosis in pregnant woman receiving LMWH also demonstrates that most women were not receiving adequate doses of LMWH.¹³⁷ In these studies, the thrombosis rate appears higher with heparin than with warfarin. This is in contrast to other situations where heparin is superior to warfarin and can “salvage” warfarin failures.^{138,139} In reviewing these early studies, none appeared to use heparin levels or PTT calibrated against heparin levels. In a recent study of 54 women (37 with prosthetic valves), heparin dosage was guided by heparin levels.¹⁴⁰ Only one valve thrombosis was

reported in a woman who was initially treated at another center with low dose heparin (15,000 U per day).

In the patient with a mechanical prosthetic valve, one should use either standard heparin or LMWH.^{116,119,140} It is uncertain but highly likely that the new pentasaccharide agent will also be useful in this situation. Some articles recommend using heparin only during weeks 6 to 12 and then after week 32,¹⁴¹ but it is unclear whether this approach entirely eliminates the risk of fetal malformation and still places the fetus at risk of warfarin-induced intracranial hemorrhage. Standard heparin should be started at a dose of 17,500 to 20,000 U every 12 hours to achieve a goal PTT that corresponds to an anti-Xa level of 0.3 to 0.7 U/mL.^{118,142,143} If LMWH is used, one should start with a dose of enoxaparin 1 mg per kilogram of body weight every 12 hours and monitor anti-Xa levels. A level should be performed every 2 to 4 weeks, 4 to 6 hours after the injection—aiming for an enoxaparin level between 0.9 and 1.1 anti-Xa units.^{131,137,144}

When the patient goes into labor, further doses of heparin should be held. If the labor is prolonged, one might start a lower dose of heparin (400 U/hour) to provide prophylaxis or 40 mg of enoxaparin can be used.¹³⁰

Women of childbearing age who require prosthetic cardiac valves might consider having a bioprosthesis placed to minimize the concerns about pregnancy and anticoagulation.^{145–147} Reported thromboembolism rates of bioprosthetic valves range from 0.5% to 3% per year without the use of anticoagulants.^{148,149} This thromboembolism rate is comparable with that of anticoagulated patients with mechanical valves. However, the life span of bioprosthetic valves in young women is considerably shorter than in older patients.¹⁵⁰ In a recent study by Salazar and colleagues the failure rate was 3.5% per year.¹⁵¹ Also disturbing is the mortality rate of reoperation that ranged from 5% to 11%.^{136,151,152} Given the improved results seen with appropriate monitoring of women with mechanical valves, it is not clear that placement of a bioprosthesis with the need for eventual reoperations is safer than a mechanical valve.¹¹⁹

The Patient on Warfarin Who Desires to Become Pregnant

There are several treatment options for the patient on warfarin who is seeking pregnancy.¹¹⁶ One is simply to stop the anticoagulation. This is obviously the least desirable option, but this may be a useful time to review the indications for the patient being on anticoagulant therapy.

Another option is to change the patient to heparin while the couple is trying to conceive. This is the most “desirable” as far as risk to the child but carries the highest risk of osteoporosis. Using LMWH instead of standard heparin simplifies monitoring and lessens the risk of osteoporosis, but this option could result in very long-term heparin exposure if there is difficulty conceiving. Patients will need heparin monitored periodically to ensure that heparin levels are in the therapeutic range.

The final option would be frequent pregnancy tests and immediate conversion to heparin when the test becomes positive. This reduces the risk during the most dangerous time of warfarin therapy for the 6- to 12-week-old fetus. Couples who pursue this option need to be facile and compliant with pregnancy testing.

Endocarditis and Anticoagulation

Emboic events are frequent complications of endocarditis.^{153,154} Despite the fact that infectious vegetations are rich in fibrin and platelets, the use of anticoagulants in native valve endocarditis is associated with an increased rate of hemorrhage.^{155,156} Therefore, anticoagulation should be limited to patients with clear indications such as venous thrombosis or severe heart failure with emboli. However, for most prosthetic valve endocarditis the continuation of anticoagulation is indicated to prevent embolic events, although clearance of the infection is crucial.¹⁵⁷ Exceptions to this are patients with left-side prosthetic valves who are bacteremic with *Staphylococcus aureus* endocarditis. These patients have a high rate (>50%) of fatal central nervous system hemorrhage and should have anticoagulants held until the bacteremia has resolved.^{59,158} Kupferwasser and coworkers reported that patients with endocarditis who have antiphospholipid antibodies have a dramatically higher rate of embolism (61.5% vs 23.1%).¹⁵⁹ If these findings are confirmed, this may lead to trials of “targeted” anticoagulation therapy. For patients with intracranial hemorrhage, anticoagulation should be held for 1 week before restarting.

- Abciximab
as adjunct to thrombolytic therapy, 493
in cardiopulmonary bypass surgery, 618
in cardiovascular disease, 343t, 350–351
hemorrhagic complications of, 365t
intracranial hemorrhage with, 695–696
specific characteristics of, 352–353, 352t, 353f
- Abdominal aortic aneurysm, disseminated
intravascular coagulation and, 187
- Abdominal pain, in mesenteric vein
thrombosis, 260
- ABO-incompatible bone marrow
transplantation, plasmapheresis in, 515
- Abscess, drainage of, in disseminated
intravascular coagulation, 194
- Acetylsalicylic acid, intracranial hemorrhage
with, 695
- Acidosis
recombinant factor VIIa therapy and, 467
after trauma, 718
- Acquired immunodeficiency syndrome. *See*
Human immunodeficiency virus (HIV)
infection.
- ACT Plus Automated Coagulation Timer, 681
- Actalyke XL/Actalyke Mini II, 680
- Actinic purpura, 173
- Activated protein C
formation of, 225
infusion of, in disseminated intravascular
coagulation, 195, 205–206
resistance to, 232. *See also* Factor V Leiden
mutation.
- Activation assays, in heparin-induced
thrombocytopenia, 429–430
- Acute chest syndrome, in sickle cell disease,
728–729, 729t
- Acute coronary syndromes. *See also*
