Acknowledgments

I would like to dedicate this textbook to my late mother, an outstanding Obstetrician and Gynecologist who selflessly served her patients. The textbook is also incomplete without thanking many individuals without whom this venture would not have been possible. I would like to acknowledge the support of my wife Dr. Dulabh Kaur Monga and my children, Jappmann Kaur Monga and Jayvir Singh Monga for their incessant support and understanding throughout this undertaking. I would also like to acknowledge the patience of my laboratory members, including the graduate students, postdoctoral fellows, and technicians during the editing phase of the textbook. I would also like to thank my past assistant Ms. Candace Smigla and present assistant Ms. Lorrin Bowser for their incredible support and in keeping the materials organized and updated for efficient completion of this project. This book would not have been possible without the support of Ms. Barbara Lopez-Lucio, who very efficiently and patiently worked with me throughout the prepublication proceedings. Last but not by any means the least, I would like to acknowledge the time and effort of all the authors without whom this textbook would not have been possible at all. Despite their overwhelming commitments and tremendous responsibilities, my colleagues so graciously contributed an outstanding array of material that comprises the heart and soul of this textbook. With great humility I thank you all!

Satdarshan P.S. Monga, MD

Series Preface

The past two decades have seen an ever-accelerating growth in knowledge about molecular pathology of human diseases which received a large boost with the sequencing of the human genome in 2003. Molecular diagnostics, molecular-targeted therapy, and genetic therapy are now routine in many medical centers. The molecular field now impacts every field in medicine, whether clinical research or routine patient care. There is a great need for basic researchers to understand the potential clinical implications of their research whereas private practice clinicians of all types (general internal medicine and internal medicine specialists, medical oncologists, radiation oncologists, surgeons, pediatricians, family practitioners), clinical investigators, pathologists and medical laboratory directors, and radiologists require a basic understanding of the fundamentals of molecular pathogenesis, diagnosis, and treatment for their patients.

Traditional textbooks in molecular biology deal with basic science and are not readily applicable to the medical setting. Most medical textbooks that include a mention of molecular pathology in the clinical setting are limited in scope and assume that the reader already has a working knowledge of the basic science of molecular biology. Other texts emphasize technology and testing procedures without integrating the clinical perspective. There is an urgent need for a text that fills the gap between basic science books and clinical practice.

In the *Molecular Pathology Library* series, the basic science and the technology is integrated with the medical perspective and clinical application. Each book in the series is divided according to neoplastic and nonneoplastic diseases for each of the organ systems traditionally associated with medical subspecialties.

Each book in the series is organized to provide specific application of molecular pathology to the pathogenesis, diagnosis, and treatment of neoplastic and nonneoplastic diseases specific to each organ system. These broad section topics are broken down into succinct chapters to cover a very specific disease entity. The chapters are written by established authorities on the specific topic from academic centers around the world. In one book, diverse subjects are included that the reader would have to pursue from multiple sources in order to have a clear understanding of the molecular pathogenesis, diagnosis, and treatment of specific diseases. Attempting to hunt for the full information from basic concept to specific applications for a disease from varied sources is time-consuming and frustrating. By providing this quick and user-friendly reference, understanding and application of this rapidly growing field is made more accessible to both expert and generalist alike.

As books that bridge the gap between basic science and clinical understanding and practice, the *Molecular Pathology Series* serves the basic scientist, the clinical researcher, the practicing physician, or other health care provider who require more understanding of the application of basic research to patient care, from "bench to bedside." This series is unique and an invaluable resource to those who need to know about molecular pathology from a clinical, disease-oriented perspective. These books are indispensable to physicians and health care providers in multiple disciplines as noted above, to residents and fellows in these multiple disciplines as well as their teaching institutions and to researchers who increasingly must justify the clinical implications of their research.

Philip T. Cagle, MD
Series Editor

Preface

Molecular Pathology of Liver Diseases is the fifth volume in the *Molecular Pathology Library Series* by Springer. Owing to the improved understanding of the cellular and molecular mechanisms of diseases, academic medicine is undergoing an evolution. Novel molecular tests not only aid in a disease diagnosis, but also can be extrapolated for disease prognosis. Similarly, modulation of biological pathways for the treatment of a disease is becoming a reality. The molecular structure and function of a normal and abnormal gene product enables the determination of highly relevant diagnostic, therapeutic, and prognostic information. In essence, the physicians and scientists alike are inundated with basic and translational information on the mechanisms of health and disease. It is of great significance to generate resources capable of: (1) bridging molecular biology and pathology, and clinical medicine; (2) providing a unique educational resource to the academic physicians and researchers keeping abreast of the timely advances, evolving modalities, and shifting paradigms; and (3) providing fundamental concepts in organ-based molecular pathobiology. *Molecular Pathology of Liver Diseases* is a compilation of a broad range of topics in liver health and disease to serve as a unique, timely, and comprehensive resource for practicing physicians, researchers, and trainees in the ever-evolving field of hepatic pathobiology, as we move forward into an era of integrative and personalized medicine.

Molecular Pathology of Liver Diseases integrates the traditional knowledge of physiological and pathological processes in the liver with a balanced emphasis on fundamental concepts, timely advances in cellular and molecular mechanisms, and applied pathology. The textbook is organized into several sections, each of which includes an array of chapters that progressively and cohesively elaborate on pertinent liver biology and pathology. The first three sections discuss the cellular composition of the liver along with their specialized functions, and further dissect the molecular basis of the cellular processes that are so unique to the liver. The next section examines the mechanisms that are commonly implicated in the cellular and molecular basis of several hepatic pathologies, followed eventually by a section each on a multitude of nonneoplastic and neoplastic diseases of the liver. Thus, these sections provide an expansive understanding of hepatic physiology, whose aberrations have pathological consequences.

The textbook is written and presented as a one-stop and comprehensive reference on liver pathobiology for basic, translational and clinical researchers, and physicians. As is vividly reflected by the diversity of the contributing authors from various disciplines, I would also anticipate this textbook to be of value to pathologists, hepatologists, surgeons, oncologists, molecular biologists, physiologists, biochemists, and toxicologists with interest in the Liver. This textbook is also suitable for medical students, graduate students, residents, and fellows with an interest in liver biology. The format of the textbook is meant to serve as a ready reference to relevant topics in the liver, thus providing a practical disease-based integrative resource on the molecular pathology of liver disease.

Satdarshan P.S. Monga, MD
Director, Division of Experimental Pathology
Associate Professor of Pathology and Medicine
University of Pittsburgh, SOM

Contents

Part I Liver Cells and Functions 1

1 Gross and Cellular Anatomy of the Liver 3
Allan Tsung and David A. Geller

2 Liver Zonation 7
Sabine Colnot and Christine Perret

3 Hepatocytes 17
Alejandro Soto-Gutierrez, Nalu Navarro-Alvarez, and Naoya Kobayashi

4 Biliary Epithelial Cells 27
Yoshiaki Mizuguchi, Susan Specht, Kumiko Isse, John G. Lunz III, and Anthony J. Demetris

5 Stellate Cells 53
Chandrashekhar R. Gandhi

6 Kupffer Cells 81
Chandrashekhar R. Gandhi

7 Sinusoidal Endothelial Cells 97
Donna Beer Stolz

8 Hepatic Carbohydrate Metabolism 109
Dirk Raddatz and Giuliano Ramadori

9 Hepatic Protein Metabolism 125
Wouter H. Lamers, Theodorus B.M. Hakvoort, and Eleonore S. Köhler

10 Hepatic Lipid Metabolism 133
Jiansheng Huang, Jayme Borensztajn, and Janardan K. Reddy

11 Detoxification Functions of the Liver 147
Udayan Apte and Partha Krishnamurthy

12 Bile Acid Metabolism 165
John Y.L. Chiang

Part II Molecular Basis of Liver Development, Growth, and Senescence 181

13 Liver Development 183
Klaus H. Kaestner

14 Transcriptional Control of Hepatocyte Differentiation 193
Joseph Locker

15 Bile Duct Development and Biliary Differentiation 213
Frederic P. Lemaigre

16 Hepatic Progenitors in Development and Transplantation 225
David A. Shafritz, Michael Oertel, and Mariana D. Dabeva

17 Adult Liver Stem Cells 243
D. Hunter Best and William B. Coleman

18 Liver Regeneration 261
George K. Michalopoulos

19 Senescent Liver 279
Nikolai A. Timchenko

20 Signaling Pathways in the Liver 291
Abigale Lade and Satdarshan P.S. Monga

Part III Applied Liver Biology 307

21 Hepatocyte Transplantation 309
Mirela-Patricia Sirbu-Boeti, Kyle Soltys, Alejandro Soto-Gutierrez, and Ira J. Fox

22 Hepatic Tissue Engineering 321
Jing Shan, Kelly R. Stevens, Kartik Trehan, Gregory H. Underhill, Alice A. Chen, and Sangeeta N. Bhatia

23 Hepatic Gene Therapy 343
Hiroyuki Nakai

Part IV Basic Principles of Hepatobiliary Pathology 371

24 Liver Cell Death 373
Harmeet Malhi and Gregory J. Gores

25 Macroautophagy 389
Ying-Hong Shi, Jia Fan, Chih Wen Lin, Wen-Xing Ding, and Xiao-Ming Yin

26 Hepatic Ischemia/Reperfusion Injury 397
Callisia N. Clarke, Amit D. Tevar, and Alex B. Lentsch

27 Inflammation and Liver Injury 411
Pranoti Mandrekar and Gyongyi Szabo

28 Oxidative Stress and Liver Injury 427
Francisco Javier Cubero and Christian Trautwein

29 Fatty Liver 437
Jaideep Behari

30 Hepatic Fibrosis and Cirrhosis 449
Rebecca G. Wells

31 Biliary Cirrhosis 467
Jonathan A. Dranoff

32 Cholestasis 475
Michael H. Trauner

33 Portal Hypertension 485
Sumit K. Singla and Vijay H. Shah

Part V Molecular Pathobiology of Non-Neoplastic Hepatobiliary Disorders 497

34 Nonalcoholic Fatty Liver Disease 499
Onpan Cheung and Arun J. Sanyal

35 Alcoholic Liver Disease 511
Samuel W. French

36 Viral Hepatitis A 527
Shiv K. Sarin and Manoj Kumar

37 Viral Hepatitis B 553
Mark A. Feitelson, Alla Arzumanyan, Helena M.G.P.V. Reis, Marcia M. Clayton, Bill S. Sun, and Zhaorui Lian

38 Viral Hepatitis C 569
Jiaren Sun, Gaurav Chaturvedi, and Steven A. Weinman

39 Viral Hepatitis D 589
John M. Taylor

40 Viral Hepatitis E 597

Part I
Liver Cells and Functions

Chapter 1
Gross and Cellular Anatomy of the Liver

Allan Tsung and David A. Geller

Gross Anatomy of the Liver

The liver is the largest organ in the body and has an extraordinary spectrum of functions. Weighing approximately 1,500 g, it sits in the right upper abdominal cavity beneath the diaphragm, and is protected by the rib cage. It is reddish-brown in color and is surrounded by a thin connective tissue capsule known as Glisson's capsule. Traditionally, the liver is grossly separated into the right and left lobes by the external landmark of the falciform ligament, a ligament that runs along the umbilical fissure and anchors the liver to the anterior abdominal wall (Fig. 1.1). However, a more accurate description of lobar anatomy of the liver is based on its blood supply. The right and left lobes of the liver can be divided by a plane from the gallbladder fossa to the inferior vena cava, known as Cantlie's line [1]. The right lobe typically accounts for 60–70% of the liver mass, with the left lobe (and caudate lobe) making up the remainder. The caudate lobe lies to the left and anterior of the inferior vena cava. The right lobe can be further divided into anterior and posterior segments, while the left lobe can be divided by the falciform ligament into a medial segment (quadrate lobe), and a lateral segment.

A significant advance in our understanding of the liver anatomy came from the studies of the French surgeon and anatomist, Claude Couinaud, in the early 1950s. Couinaud enumerated the liver with eight segments to more accurately describe its functional anatomy (Fig. 1.2). Each segment is supplied by a single portal triad composed of a portal vein, hepatic artery, and bile duct. The caudate lobe is referred to as segment 1. Segments 2 and 3 comprise the left lateral segment, while segment 4 is the left medial segment. Thus, the left lobe is made up of the left lateral segment (Couinaud's segments 2 and 3) and the left medial segment (segment 4). Segment 4 can be sub-divided into segment 4A and segment 4B. Segment 4A is cephalad and just below the diaphragm, spanning from segment 8 to the falciform ligament adjacent to segment 2. Segment 4B is caudad and adjacent to the gallbladder fossa. The right lobe is comprised of segments 5–8, with segments 5 and 8 making up the right anterior lobe, and segments 6 and 7 the right posterior lobe [2, 3].

Additional functional anatomy can also be detailed based on the distribution of the hepatic veins. There are three hepatic veins (right, middle, and left) that pass obliquely through the liver to drain the blood to the suprahepatic inferior vena cava (IVC) and eventually to the right atrium. The three hepatic veins run in corresponding scissurae (fissures) and divide the liver into four sectors [4]. The right hepatic vein runs along the right scissura and separates the right posterolateral sector from the right anterolateral sector. The main scissura contains the middle hepatic vein and separates the right and left livers. The left scissura contains the course of the left hepatic vein, and separates the left posterior and left anterior sectors. The hepatic vein branches "bisect" the portal branches inside the liver parenchyma (e.g., the right hepatic vein runs between the right anterior and posterior portal veins; the middle hepatic vein passes between the right anterior and left portal vein; and the left hepatic vein crosses between the segment III and II branches of the left portal vein). These hepatic vein branches drain specific areas of the liver back to the IVC. The right hepatic vein drains segments 5–8; the middle hepatic vein drains segments 4 as well as segments 5 and 8; and the left hepatic vein drains segments 2 and 3. The caudate lobe is unique, as its venous drainage feeds directly into the IVC. In addition, the liver usually has a few, small, variable, and short hepatic veins that directly enter the IVC from the undersurface of the liver. The left and middle hepatic veins form a common trunk ~95% of the time before entering the IVC, while the right hepatic vein inserts separately (in an oblique orientation) into the IVC. There is a large, inferior, and accessory right hepatic vein (15–20% of cases) that runs in the hepatocaval ligament. Obstruction of the hepatic venous outflow has significant pathological relevance and is discussed in Chap. 48.

The liver is situated in the right upper abdominal cavity and is held in place by several ligaments: the round, falciform, triangular, and coronary ligaments (Fig. 1.1). The round ligament

is the remnant of the obliterated umbilical vein and enters the left liver hilum at the front edge of the falciform ligament. The falciform ligament separates the left lateral and left medial segments along the umbilical fissure. Deep in the plane between the caudate lobe and the left lateral segment is the fibrous ligamentum venosum, which is the obliterated ductus venosus and is covered by the plate of Arantius. The left and right triangular ligaments secure the two sides of the liver to the diaphragm. Extending from the triangular ligaments anteriorly on the liver are the coronary ligaments. The right coronary ligament also extends from the right undersurface of the liver to the peritoneum overlying the right kidney, thereby anchoring the liver to the right retroperitoneum. Centrally and just to the left of the gallbladder fossa, the liver attaches via the hepatoduodenal and the gastrohepatic ligaments. The hepatoduodenal ligament is known as the porta hepatis and contains the common bile duct, the hepatic artery, and the portal vein. From the right side and deep (dorsal) to the porta hepatis, is the foramen of Winslow, also known as the epiploic foramen.

The liver's interface with the digestive system allows for its crucial role in the processing of absorbed nutrients through the metabolism of glucose, lipids, and proteins.

The liver has a dual blood supply consisting of the hepatic artery and the portal vein. The hepatic artery delivers ~25% of the blood supply, and the portal vein ~75%. All nutrition absorbed by the intestinal system reaches the liver through the portal vein, except the complex lipids which are transported mainly by lymphatics. The portal vein is formed by the confluence of the splenic vein and the superior mesenteric vein. The inferior mesenteric vein usually drains into the splenic vein upstream from the confluence. The main portal vein traverses the porta hepatis before dividing into the left and right portal vein branches. The left portal vein typically branches from the main portal vein outside of the liver with a sharp bend to the left, and consists of the transverse portion, followed by a 90° turn at the base of the umbilical fissure to become the umbilical portion before entering the liver parenchyma. The left portal vein then divides to give off the segment 2, and segment 3 that branches to the left lateral segment, as well as the segment 4 feedback branches that supply the left medial segment. The left portal vein also provides the dominant inflow branch to the caudate lobe (although branches can arise from the main and right portal veins also) usually close to the bend between the transverse and umbilical portions. The division of the right portal vein is usually higher in the hilum and may be close to (or inside) the liver parenchyma at the hilar plate.

The hepatic artery arises from the celiac axis (trunk) which gives off the left gastric, splenic, and common hepatic arteries. The common hepatic artery then divides into the gastroduodenal artery and the hepatic artery proper. The right gastric artery typically originates off of the hepatic artery proper, but this is variable. The hepatic artery proper divides into the right and left hepatic arteries. This "classic" or standard arterial anatomy is only present in ~75% of cases, with the remaining 25% having variable anatomy. The most common hepatic arterial variant is a replaced or accessory right hepatic artery coming off the superior mesenteric artery 18–22% of the time. When there is a replaced or accessory right hepatic artery, it traverses posterior to the portal vein and then takes up a right lateral position before diving into the liver parenchyma. The left hepatic artery is replaced (or accessory) off of the left gastric artery in 12–15% of cases, and runs obliquely in the gastrohepatic ligament anterior to the caudate lobe before entering the hilar plate at the base of

the umbilical fissure. Other less common variants (~2% each) are an early bifurcation of the left and right hepatic arteries, as well as a completely replaced common hepatic artery coming off the superior mesenteric artery.

In addition to the portal vein and hepatic artery, the biliary system is the third component of the portal triad. Bile is a complex fluid containing organic and inorganic substances dissolved in an alkaline solution that flows from the liver, through the biliary system, and into the small intestine. The main components of bile are water, electrolytes, and a variety of organic molecules including bile pigments, bile salts, phospholipids (lecithin), and cholesterol. The two fundamental roles of bile are to aid in the digestion and absorption of lipids and lipid-soluble vitamins, and to eliminate waste products (bilirubin and cholesterol) through secretion into bile, and elimination in feces. In between meals, bile is stored in the gallbladder and concentrated through the absorption of water and electrolytes. Upon entry of food into the duodenum, bile is released from the gallbladder to aid in digestion. About one liter of bile can be produced by the human liver daily. However, more than 95% of the bile salts secreted in bile are reabsorbed in the intestine and then excreted again by the liver (enterohepatic circulation). Please see Chap. 12 for a detailed discussion on bile-acid metabolism.

Within the hepatoduodenal ligament, the common bile duct lies anteriorly to the right. It gives off the cystic duct to the gallbladder, and becomes the common hepatic duct before dividing into the right and left hepatic ducts. In general, the hepatic ducts follow the arterial branching pattern inside the liver. The bifurcation of the right anterior hepatic duct usually enters the liver above the hilar plate, while the right posterior duct dives behind the right portal vein and can be found on the surface of the caudate process before entering the liver. The left hepatic duct typically has a longer extra-hepatic course before giving off segmental branches behind the left portal vein at the base of the umbilical fissure. There is a considerable variation that occurs in 20–30% of cases for the hepatic duct confluence with accessory or aberrant ducts (Fig. 1.2).

Cellular Anatomy of the Liver

The liver consists of many different cell types. Broadly, they can be classified as parenchymal cells (hepatocytes) and non-parenchymal cells (NPC). The hepatocytes form the structural basis of the liver and make up the majority of the mass of the liver. The NPCs include other various cell types including Kupffer cells, sinusoidal endothelial cells, stellate cells, periportal fibroblasts, and hepatic dendritic cells. The characteristics and functions of these cell types will be covered in more detail in subsequent chapters.

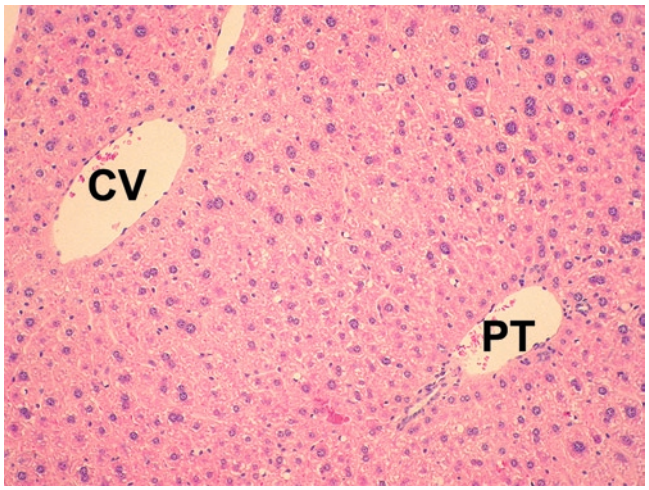

Fig. 1.3 Histology of normal mouse adult liver showing a central vein (CV) and a portal triad (PT)

The liver is made of functional units called liver lobules [5]. These polygonal masses of tissue consist of three to six portal triads at the periphery and a central vein in the center of the lobule. All portal triads of each lobule consist of a venule branch of the portal vein, an arteriole branch of the artery, and bile duct (Fig. 1.3). Originating from the porta hepatis outside the liver, the common bile duct, the hepatic artery, and the portal vein continue to travel together as they continue to branch, supplying the various segments, and ultimately culminate at the portal triad of a lobule. The portal-vein venules of each portal triad then branch into distributing veins that run around the periphery of each lobule, as well as branches than enter the lobules to form the sinusoids. The liver sinusoids are blood vessels with fenestrated, discontinuous endothelium that serve to provide oxygen and nutrients to the surrounding hepatocytes. The sinusoids are positioned radially in the liver lobule, and ultimately converge and form the central vein at the center of the lobule (Fig. 1.3). Similarly, as the hepatic artery continues to branch to form portal arterioles, these vessels also branch into the sinusoids to provide arterial blood to the cells. The central vein of each lobule is a thin walled vein consisting only of endothelial cells. As it is supplied by more sinusoids and exits each lobule, it forms larger veins, and ultimately these veins converge to form the three hepatic veins that drain into the IVC. The portal venous system is a valveless system. Thus, portal pressure in normal physiology is low (3–5 mmHg). However, in the setting of portal hypertension, the pressure can be quite high (20–30 mmHg). This results in decompression to the systemic circulation through portacaval anastomoses, and can produce symptoms of varices seen in settings of cirrhosis.

The direction of blood flow of each liver lobule is from the periphery to the center. The liver can be divided into three zones, based upon oxygen and nutrient supply [5]. Zone 1 is the periportal area where the blood from hepatic

arterioles and portal venules enters, zone 3 is the centrilobular area located around central veins, where oxygenation is poor, and zone 2 is located in between. With zonal arrangement, oxygen, and nutrients absorbed from the digestive system reach the hepatocytes located at the periphery of the lobule first, and then reach the cells located in the center. This lobular structure accounts for structural and functional differences between the periportal and centrolobular cells, as well as differences in their response to various stress or disease states. A greater discussion on liver zonation is presented in Chap. 2.

The hepatocytes are the building blocks of the liver lobule. They are arranged radially with sinusoids separating the plate of cells making up the lobule. The space of Disse is a subendothelial area that separates the endothelial cells from the hepatocytes. Every hepatocyte is in contact with the wall of the sinusoids through the space of Disse as well as with the surface of surrounding hepatocytes. This architecture of hepatocytes lined with the sinusoids consisting of a discontinuous layer of fenestrated endothelial cells allows for bi-directional permeability and exchange of materials from both the hepatocyte and blood. In addition, many nonparenchymal cells of the liver are located in the sinusoids and space of Disse, allowing for efficient immune surveillance and clearance, as well as other metabolic functions.

Bile is a complex fluid containing organic and inorganic substances dissolved in an alkaline solution that flows from the liver, through the biliary system, and into the small intestine. The main components of bile are water, electrolytes, and a variety of organic molecules including bile pigments, bile salts, phospholipids (lecithin), and cholesterol. The two fundamental roles of bile are to aid in the digestion and absorption of lipids and lipid-soluble vitamins, and to eliminate waste products (bilirubin and cholesterol) through secretion into bile and elimination in feces. Bile is produced by hepatocytes and secreted through the biliary system. Between each adjacent hepatocytes are tubular structures consisting of bile canaliculi. These canaliculi are the initial segments of the bile duct system. Similar to the portal vein and hepatic artery branches, except in the opposite direction, the bile canaliculi form networks and terminate in the portal triads at the periphery of the liver lobule. The canaliculi coalesce to from larger bile ductules and eventually make the right and left hepatic ducts, which drain into the intestine through the common bile duct [6].

Chapter 2
Liver Zonation

Sabine Colnot and Christine Perret

Introduction

Maintenance of liver homeostasis relies on the metabolic function of this organ. To carry out these metabolic functions at a maximal possible efficiency, hepatocytes are both quiescent and highly specialized. They specialize as a function based on their position along the porto-central axis of the liver lobule that determines their fate as either "periportal" (PP), or "perivenous" (PV) hepatocytes. This zonation of function mainly affects ammonia detoxification, glucose/energy metabolism, and xenobiotic metabolism. Over the last 30 years, since the initial discovery of liver zonation, the mechanisms by which this zonation is established and maintained have been widely investigated. The Wnt/β(beta)-catenin developmental pathway has been recently shown to play a key role in this functional heterogeneity of mouse hepatocytes. It is activated in perivenous hepatocytes, partly due to the absence, in the perivenous area, of adenomatous polyposis coli (APC), a tumor suppressor gene product. APC is a negative regulator of Wnt signaling, also described as the "zonation-keeper" of the liver lobule. The Wnt pathway induces the PV genetic program and represses the PP genetic program. The ras/mapk/erk pathway acts in a reciprocal manner to counterbalance Wnt signaling and favors a PP genetic program. More recently, a cross-talk between the transcription factor Hnf4α(alpha) and Wnt signaling has been proposed as a potential mechanism of liver zonation.

The Liver Lobule, the Zonated Unit of the Liver

The liver occupies a strategic position for efficient overall metabolic function in the body. As described in Chap. 1, it receives its supply of hydrophilic nutrients through the portal vein; these nutrients are absorbed by the intestine. It then delivers metabolized products to the other organs through the central vein. The hepatic artery located in the vicinity of the portal vein, within the portal triad (composed of the bile duct, portal vein, and hepatic artery), supplies the liver with blood enriched in oxygen. Blood flow within the liver determines the organization of the anatomical unit of the hepatic parenchyma, the liver cell plate, which is located within the liver lobule or acinus. Here, the blood flows from the portal vein and the hepatic artery (in a 75–25% ratio) to the centrilobular vein, while bile moves from the pericentral area to the periportal one. The liver cell plate consists of 15–25 hepatocytes that extend from the portal triad to the hepatic venule. This structure carries out metabolic functions mostly through specialized hepatocytes, which act in isolation, or together with non parenchymal cells (Fig. 2.1).

Thirty years ago, K. Jungermann demonstrated that hepatocytes, although being histologically indistinguishable, were specialized, and their function differed depending on their position along the porto-central axis of the liver cell plate [1]. Nearly six to eight PP hepatocytes (zone 1) surround the portal triad and are in close contact with the afferent blood. Nearly two to three PV hepatocytes (zone 3) are found close to the efferent centrilobular vein. A less well defined midlobular population of six to ten hepatocytes (zone 2) has also been described. Jungermann proposed the concept of "zonation." According to this concept, opposing or complementary metabolic pathways are carried out within distinct non-overlapping regions of the liver lobule to maintain optimal metabolic homeostasis [2].

Metabolic Zonal Functions

Not all hepatic processes are strictly zonal. The synthesis of large amounts of serum proteins, such as the transthyretin and transferrin transporters appears to occur in all hepatocytes. Albumin is also synthesized in all hepatocytes, with a higher concentration in the periportal area. The most studied zonated functions currently consist of glucose metabolism,

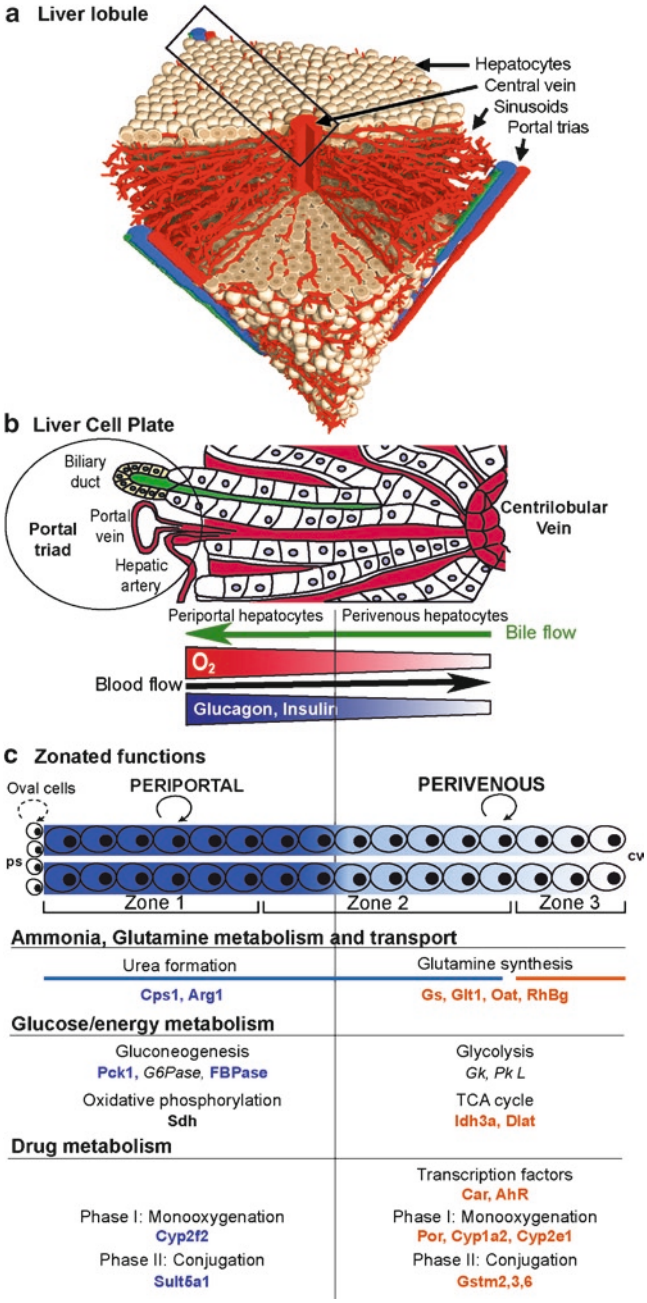

Fig. 2.1 Structure and functions of the zonated liver lobule. (**a**) Three-dimensional structure of the liver lobule. The liver lobule is centered around a branch of the centrilobular vein, limited at each end by the portal triad consisting of a branch of the portal vein, the hepatic artery, and a bile duct. The sinusoids and the vasculature are depicted in red (Hoehme et. al. [61]) (**b**) The liver cell plate, with blood circulation indicated in red. Bile is shown in green and circulates in the opposite direction to blood. The concentration of oxygen and hormones decreases along a continuous gradient from the PP area to the PV area. (**c**) Zonal functions. The proliferation of hepatocytes is achieved mostly by division of the mature hepatocytes themselves (*circled arrow*), which do not migrate along the portocentral axis, with proliferation from oval cells observed only rarely (*dotted circled arrow*). The zonated metabolic systems include the ammonia detoxification system, glucose and energy metabolism, and xenobiotic metabolism. The proteins involved in each type of zonal metabolism are indicated. The proteins displaying zonation regulated at the posttranscriptional level are shown in italics. The PV positive Wnt targets are shown in orange, and the PP negative targets are shown in blue. These targets were identified by microarray analysis on PV and PP hepatocytes [3], and on β(beta)-catenin-activated hepatocytes ([12] and unpublished data). *Gk* glucokinase; *PkL* liver-specific pyruvate kinase; *Sdh* succinate dehydrogenase; *Idh3a* isocitrate dehydrogenase 3a; *Dlat* dihydrolipoamide S-acetyltransferase; *Gstm* glutathione S-transferase mu; *Sult5a1* sulfotransferase family 5A, member 1

ammonia detoxification, and the metabolism of drugs and xenobiotics (Fig. 2.1). Other zonated processes include: lipid metabolism, with lipogenesis occurring perivenously and fatty-acid degradation periportally [2, 3]; Cyp7a1-mediated synthesis of bile acids derived from cholesterol, showing clear PV zonation [3, 4]; and the metabolism of several amino acids [3], the catabolism of histidine and serine being mostly periportal, and glutamine synthesis (associated with ammonia detoxification) being perivenous.

Glucose metabolism provides a historical example of compartmentalized metabolism. Jungermann showed that gluconeogenesis was mostly periportal, with gradual accumulation of phosphoenolpyruvate carboxykinase (Pepck1) in this region, whereas glycolysis was mostly perivenous (glucokinase and pyruvate kinase L, but not their respective RNAs, being perivenous) [1]. However, the concentration gradients of these enzymes differ depending on nutritional status, suggesting that nutrients and hormones play a role in the zonation of these components of glucose metabolism. Please see Chap. 8 for a more detailed review of carbohydrate metabolism in the liver.

Ammonia detoxification is subject to zonation and has been extensively studied by groups led by Gebhardt, Lamers, and Haussinger [5–7]. One of the major roles of the liver is the removal of harmful ammonia arriving from the intestine via the portal vein (Fig. 2.2). Ammonia is first metabolized by PP hepatocytes, through a high-capacity/low-affinity system, to generate urea. This involves the enzymes carbamoylphosphate synthetase (Cps1) and arginase 1 (Arg1). Residual ammonia is then converted to glutamine by perivenous hepatocytes, through a low-capacity/high-affinity system involving the perivenous enzyme glutamine synthetase (Gs). Chapter 9 discusses protein metabolism.

Metabolism of drugs and xenobiotics also displays well defined zonation, occurring mostly in the PV area. The cytochrome P450 system is responsible for the conversion of xenobiotics into excretable products. This involves monooxygenation followed by conjugation with either glucuronic or sulfuric acid. Monooxygenation mainly occurs in the PV zone, with glucuronidation as the major conjugation reaction in these cells, whereas sulfation is the predominant conjugation reaction in PP cells [2]. Chapter 11 discusses detoxification functions of the liver.

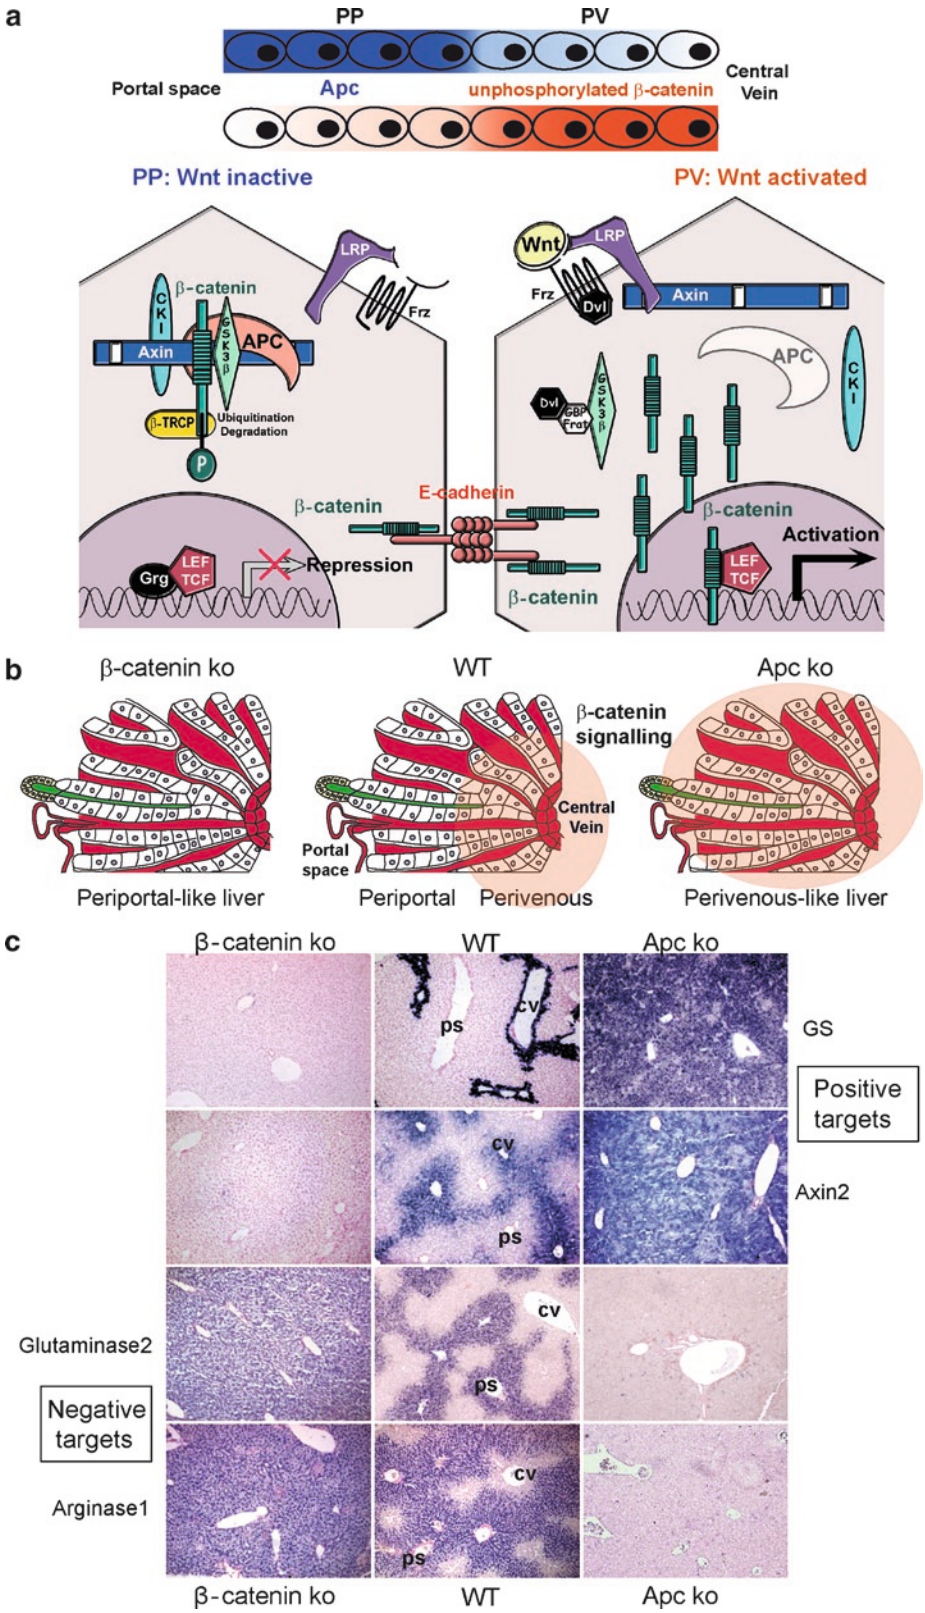

Fig. 2.2 Zonation of Wnt signaling in the liver. (**a**) Localization of Wnt partners. PP hepatocytes are enriched in APC, allowing the accumulation of active unphosphorylated β(beta)-catenin in PV hepatocytes. A schematic diagram of a PP hepatocyte in which Wnt is inactive is shown on the left, and the consequences of Wnt activation in a PV hepatocyte are shown on the right. (**b**) Mouse models of liver-specific β(beta)-catenin inactivation (β(beta)-catenin ko) or activation (Apc ko). (**c**) In situ hybridization showing the distribution of PV positive target gene expression and of PP negative target gene expression along the portocentral axis of the liver, in β(beta)-catenin-null, wild-type, and APC-null livers. The Axin2 gene is a universal target gene of β(beta)-catenin, and the signal generated for this gene on in situ hybridization is thought to correspond to the area of β(beta)-catenin activation

Possible Mechanisms for Zonation

Until recently, the mechanisms underlying zonation were poorly understood even if a number of hypotheses have been put forward.

The developmental hypothesis suggests that periportal and perivenous hepatocytes are derived from different embryonic origins, and distinct lineages. However, evidence for this is lacking; indeed, the perinatal liver is not zonated and coexpresses perivenous and periportal mRNAs, such as those encoding Gs, and Cps1 [8]. Zonation is only observed in the first week following birth in mice.

The streaming liver theory is based on the observation that periportal hepatocytes are more prone to proliferate (see section on proliferation). According to this model, hepatocytes are derived from the periportal area, where putative hepatic stem cells reside. Hepatocytes then migrate further along the portocentral axis to become perivenous, gaining a particular metabolic profile as they mature. However, cell-tracing studies have shown this not to be the case; instead, hepatocyte renewal seems to occur in both parts of the lobule [9].

The blood hypothesis offers a more feasible explanation, with aspects still to be explored. Blood entering the sinusoid is a mixture of blood from the hepatic artery and portal vein, and is rich in oxygen. The low oxygen tension in the hepatic venules [10] thus gives rise to a steep oxygen gradient across the sinusoid. Blood then perfuses hepatocytes in the plate sequentially. This means that the composition of blood changes as hepatocytes in the plate are perfused. Thus, hepatocytes located in different parts of the liver cell plate are exposed to different microenvironments. Accordingly, in this model, zonation may be determined by the concentrations of oxygen, hormones, drugs, or metabolites in the blood. However, changes in the hormone or oxygen content of afferent blood reverses the patterns of glycolysis and gluconeogenesis, and such changes do not affect ammonia detoxification [2]. This led to the definition of "dynamic zonal metabolism," which can be applied to the somewhat plastic processes of glucose and drug metabolism. By contrast, stable zonal metabolic systems, such as ammonia detoxification, cannot easily be reversed or lost.

Zonation is subjected to transcriptional control. Nevertheless, functional zonation is mainly controlled by differential expression of genes encoding the enzymes responsible for the functions concerned. This control may involve transcriptional or posttranscriptional regulation along the portocentral axis (Fig. 2.1). Transcriptional mechanisms seem to be crucial, as shown by microarray studies. These studies characterized mRNAs from the PP and PV hepatocytes, and confirmed that zonation of glucose, ammonia, and drug metabolism was mainly under the control of mRNA levels [3].

The identification of the PV glutamine synthetase gene as a direct target of β(beta)-catenin in liver suggested that β(beta)-catenin may be one of the *trans*-acting factors mediating liver zonation [11]. Studies of murine models with β(beta)-catenin signaling activated or inactivated in the liver have shown that the β(beta)-catenin pathway is one critical aspect involved in liver zonation [12–14].

The Wnt/β(Beta)-Catenin Pathway

The Wnt/β(beta)-catenin pathway, which has been strongly conserved through evolution, plays an important role in development and has been implicated in tumorigenesis in various tissues [15]. A detailed account on this pathway is available in Chap. 20. Wnt signaling is initiated by the binding of secreted ligands (Wnts) to frizzled receptors (fz), leading to the activation of canonical or non-canonical signaling. Canonical signaling activates β(beta)-catenin-mediated gene transcription [16] (Fig. 2.2). In the absence of Wnt signaling, β(beta)-catenin plays a role in cell adhesion, through interaction with cadherins. β(beta)-catenin is kept at low concentrations in the cytosol through its phosphorylation by CK1 and GSK3 kinases, within a degradation complex comprising two tumor suppressors, APC and axin. Phosphorylated β(beta)-catenin is ubiquitinylated by β(beta)-TrCP, resulting in it being targeted for degradation by the proteasome. Wnt binding to fz receptors together with LRP5/6 coreceptor activation, causes the dissociation of the β(beta)-catenin degradation complex; unphosphorylated β(beta)-catenin then accumulates and is translocated into the nucleus, where it associates with Lef/Tcf transcription factors to regulate the transcription of its target genes.

The Wnt pathway was initially described for its role in developmental processes, but has also been implicated in the maintenance of stem-cell compartments in adults [17]. These physiological, developmental, and oncogenic effects are mediated by the regulation of different genetic programs, depending on the temporal and spatial contexts.

β(Beta)-Catenin, A Master Signaling Molecule Orchestrating Metabolic Zonation in the Liver

The link between the Wnt pathway and the liver was initially established through the demonstration that β(beta)-catenin-activating mutations frequently occur during liver carcinogenesis [18]. These mutations define a particular carcinogenic route. Indeed, tumors in which β(beta)-catenin is activated display a specific transcriptome, which strongly favors PV

metabolism [13, 19–21]. More recent work has shown this signaling pathway to play a role in liver development and physiology, with a major role in determining the final patterning of the adult liver [12].

Initial observations suggesting a role for β(beta)-catenin in establishing liver zonation was based on the complementary distribution patterns of active β(beta)-catenin in PV hepatocytes and of the negative regulator APC in PP hepatocytes, in wild-type adult mice [12] (Fig. 2.2). Mice were then generated, in which APC was inactivated specifically in the liver. The subsequent activation of β(beta)-catenin signaling in these mice induced a PV genetic program throughout the entire lobule and repressed the PP genetic program. These findings were confirmed in mice producing Dkk1, a Wnt inhibitor, or with inactivation of β(beta)-catenin gene expression in the liver lobule. The PV genetic program was switched off in these mice, whereas the PP genetic program was active throughout the lobule [12, 14, 22] (Fig. 2.2).

The zonal metabolic pathways affected by changes in β(beta)-catenin signaling include those mediating ammonia metabolism potentially explaining the hyperammonemia observed in mice with aberrant hepatocytic β(beta)-catenin signaling. β(beta)-catenin exerts strict positive control over the PV genes encoding glutamine synthetase (Gs, or glul), Glt-1 (Eaat2 or slc1a2; a transporter of glutamate), and RhBg, a transporter of ammonia. It negatively regulates the glutaminase 2 (Gls2), arginase 1 (Arg1), and carbamoylphosphate synthase (Cps1) PP genes with Arg1 and Cps1 being key enzymes of the urea cycle [11, 12] (Figs. 2.1 and 2.2).

Drug metabolism is strongly controlled by the Wnt pathway. A study by Hebrok and colleagues demonstrated that mice with specific deletion of β(beta)-catenin in the liver were insensitive to intoxication with carbon tetrachloride (CCl_4), presumably due to the absence of CypP450-detoxifying enzymes in these mice [14]. Wnt signaling controls the expression of two major CypP450 enzymes, Cyp2e1 which metabolizes ethanol, and Cyp1a2 [13, 14, 23]. The aryl-hydrocarbon receptor (Ahr) and the constitutive androstane receptor (Car) are two PV proteins that act as both xenosensors and as transcription factors. They control the expression of drug-metabolizing enzymes induced by β(beta)-catenin in the liver [13, 14, 23]. Whether β(beta)-catenin signaling has a direct effect on the transcription of detoxifying enzymes or whether it acts indirectly involving Car and Ahr is yet unclear.

Mice with liver-targeted activation of the Wnt pathway have altered glucose metabolism and develop hypoglycemia [24]. This hypoglycemia may be caused by impaired gluconeogenesis, a PP process, through the negative regulation of the Pepck and FBPase genes in β(beta)-catenin-activated livers [12, 24]. β(beta)-catenin signaling may also modify the energetic profile of the hepatocyte. In APC null livers, ATP energy supply seems to be provided through glycolysis rather than through mitochondrial oxidative phosphorylation due to the upregulation of lactate dehydrogenase protein and activity, together with the downregulation of two mitochondrial subunits ATP5α(alpha)1 and ATP5β(beta) by β(beta)-catenin [24]. The potential zonation of these new β(beta)-catenin targets remains to be investigated.

These data clearly demonstrate that β(beta)-catenin signaling is a key pathway in the control of liver metabolism. APC appears to be the "zonation-keeper" of the liver, consistent with its specific distribution along the portocentral axis of the lobule and the major effects of its inactivation in mice.

The Consequences of Disrupting Zonation

The effects of activation of β(beta)-catenin signaling differ from the effects of loss of β(beta)-catenin signaling in mice. β(beta)-Catenin-null livers become periportal-like, but with no major effect on phenotype; however, APC-null livers, become perivenous-like, leading to death of the animals, mainly through lethal hyperammonemia arising from the lack of urea-cycle enzymes [12] (Fig. 2.2).

The fact that mice with loss of β(beta)-catenin signaling in the liver are viable implies that the perivenous functions of the hepatocytes are not essential for normal liver homeostasis. These mice are only more sensitive to nutritional dysfunction, with a protein overload leading to mild hyperammonemia, due to defects in perivenous enzymes and ammonia transporters, presumably including GS and RhBg [14]. This suggests that the perivenous genetic program is a scavenger system, which is not required for basal metabolism, but is activated in certain contexts. By contrast, mice with β(beta)-catenin activation in all the hepatocytes of the liver lobule rapidly die. Whether this is due to an essential role for periportal proteins in basal metabolism necessary for life, or to the disruption of liver homeostasis caused by aberrant expression of perivenous proteins throughout the lobule, remains unknown.

Establishment of Liver Zonation by β(Beta)-Catenin and Wnts

The role of β(beta)-catenin during liver development remains a matter of debate. β(beta)-catenin may play a limited role in hepatogenesis. Hepatogenesis occurs as a multistep process during embryonic development, beginning with the emergence of the liver bud from endodermal cells derived from the ventral foregut [25]. Liver bud formation requires

distinct signals emitted by different cell types. The role of β(beta)-catenin in this initial step is controversial, as this molecule seems to antagonize liver bud formation in *Xenopus,* but is required for this process in Zebrafish [26, 27]. At later stages of development, the Wnt pathway affects liver growth, probably in a restricted time-window, controlling the proliferation and differentiation of immature hepatoblasts into the biliary lineage [28, 29]. Wnt signaling also stimulates liver growth after birth [30]. Given that liver zonation appears in early postnatal development, Wnt signaling has to be correlated with the emergence of a compartmentalized liver.

Adenovirus-mediated liver transfer of Dickkhopf-1 (Dkk1), a molecule that blocks Wnt signal transduction, also blocks the physiological activation of β(beta)-catenin signaling in the PV area of the liver. Thus, β(beta)-catenin PV signaling requires Wnts [12]. Nineteen Wnt factors have been identified in mice, some of which are expressed in the liver [31]. However, the Wnt factors involved in zonal gene expression and the cells that produce them (presumably in contact with PV hepatocytes) are still unknown. The most likely sources of Wnt are endothelial cells, specifically those surrounding the centrilobular vein, or the PV hepatocytes themselves; this also remains to be resolved.

β(Beta)-Catenin and Hepatocyte Proliferation

The PV compartment was long thought to be resistant to proliferative signals and prone to hepatocellular necrosis or apoptosis [32]. Moreover, the oval "stem" cells recruited in very specific conditions for liver regeneration are located in the PP area [33]. The Wnt pathway has been implicated in the proliferation and self-renewal of stem cells; thus, the physiological activation of Wnt signaling in perivenous hepatocytes was unexpected.

This phenomenon must be considered in the context of liver homeostasis, a unique process, which differs, for example, from homeostasis in the intestine. In the intestine, a pool of β(beta)-catenin-activated crypt stem cells is responsible for the constant renewal of the epithelium. This renewal is essential, as enterocytes have a lifespan of 5–7 days. This essential role of the Wnt pathway has been demonstrated in mice showing major consequences of the loss of APC in the small intestine, in particular the enlargement of the crypt compartment [34, 35]. By contrast, the liver cells are quiescent and hepatocytes have a turnover rate estimated between 148 and 400 days. These cells very rarely divide during their lifespan. When such divisions do occur during a physiological process or following injury (as in the experimental model of 2/3 partial hepatectomy), it is the mature hepatocyte itself that enters the cell cycle. Hepatocytes are renewed independently of their location along the portocentral axis, even if the rate of replication is faster in the PP hepatocytes than in intermediate or PV hepatocytes (Fig. 2.1) [9]. The recruitment of oval "stem" cells for regeneration can be promoted using drugs to block the proliferation of mature hepatocytes [33]. Under such conditions, Wnt/β(beta)-catenin signaling may play an active role in the activation and proliferation of oval cells [36, 37].

Paradoxically, despite the fundamental metabolic role of physiological Wnt signaling in the quiescent liver, aberrant β(beta)-catenin activation throughout the liver leads to marked hepatocellular hyperproliferation [21, 38, 39], and the focal activation of β(beta)-catenin may induce liver cancer formation [21]. The Wnt pathway also plays an important role in liver regeneration, as deletion of the β(beta)-catenin gene in mice delays S-phase by one day after partial hepatectomy. This provides further evidence for the involvement of the Wnt pathway in controlling hepatocyte proliferation.

The set of genes involved in hepatocyte proliferation has yet to be elucidated. Target genes with a potential effect on hepatocyte proliferation, such as those encoding Reg1a and Reg3a/Hip/Pap, have been identified, but functional studies have not yet been performed [40]. In the intestine, the Wnt pathway controls cell proliferation through a cell-autonomous phenomenon, in which *c-myc* is a critical target gene [41]. By contrast, *c-myc* plays no role in liver cell proliferation [21, 38, 42, 43]. Cyclin-D1 has been shown to be a target of the pathway and is critical in G1 to S-phase transition. In many scenarios in liver biology, cyclin-D1 expression and subsequent proliferations are known to be regulated by β(beta)-catenin. Such examples include liver regeneration and development [29, 44]. Moreover, β(beta)-catenin-dependent hepatocyte proliferation is not cell autonomous, and only occurs when Wnt is activated above a critical threshold (activation in more than 70% of hepatocytes) [12, 21]. Future studies will now need to identify β(beta)-catenin target genes mediating this cell non-autonomous and threshold-dependent proliferation. This will provide a better understanding of both β(beta)-catenin-dependent liver carcinogenesis and the control of liver-cell renewal in a zonated-quiescent or regenerating liver.

Integration of β(Beta)-Catenin Signaling with Other Regulators of Zonal Liver Functions

Microarray studies comparing the Wnt targetome in various cell types show less than 5% of β(beta)-catenin targets to have a ubiquitous distribution [45]. This tissue-specificity of

β(beta)-catenin signaling responses suggest that the molecular mechanisms involved in this signaling are also dependent on cell type. In particular, the mechanisms underlying β(beta)-catenin-induced repression of the PP genetic program need to be elucidated.

Work by Schwarz and colleagues provided some initial insight into the mechanisms of β(beta)-catenin signaling in the liver. This group identified a Ras/Mapk/Erk signal in the periportal hepatocyte, which is activated by blood-borne molecules. This pathway favors the expression of a PP genetic program and blocks the PV program [46]. In this model, the Ras and β(beta)-catenin signaling pathways are antagonistic. However, in addition to this apparent physiological antagonism, cooperation between β(beta)-catenin and the Ras pathway appears to accelerate liver tumorigenesis [47]. Further characterization of the interaction between the β(beta)-catenin and Ras pathways could therefore help our understanding of liver physiopathology.

Hnf4 α(Alpha) Is a Liver-Enriched Factor Specializing β(Beta)-Catenin Transcriptome

Recent studies have suggested that Hnf4α(alpha) is a master player in establishing the molecular network that drives liver zonation. Hnf4α(alpha) had been previously described as a major transactivator of genes associated with liver differentiation and metabolism [48–52]. A pioneering genome-wide study revealed 12% of the promoters in liver bound Hnf4α(alpha), of which 80% were transcriptionally active [51]. However, Hnf4α(alpha) displays a relatively homogenous distribution throughout the liver lobule and controls transcription of both zonated and not zonated genes. Thus, despite its fundamental roles in the liver, Hnf4α(alpha) seemed an unlikely candidate for controlling liver zonation [53].

Two recent studies have demonstrated that Hnf4α(alpha) is a modulator of the zonal expression of genes [54, 55], acting through cross-talk with the Wnt pathway [54].

The first of these studies involved the analysis of zonal gene expression in Hnf4α(alpha)-null livers. Stanulovic et al. showed reexpression of some (but not all) of the PV genes, such as *Gs* and *Oat* in the PP hepatocytes of these mice [55]. This concept was further tested in fetal rodent hepatocytes, which can be differentiated in culture to display a hepatocyte phenotype [54]. In this model, only PP genes were transcribed, and the activation of Wnt pathway by the GSK3β(beta) inhibitor 6-bromoindirubin-3′-oxime (BIO) redirected the expression profile towards the PV program. The authors showed that one member of the Tcf/Lef family of transcription factors, Lef1, can interact with Hnf4α(alpha). They used chromatin immunoprecipitation assays to evaluate binding to regulatory elements in vivo and found that Hnf4α(alpha) and Lef1 interaction was required for *Gs* expression, whereas Hnf4α(alpha) binding alone seemed to repress the expression of this gene. Conversely, on three periportal promoters, the authors show that Hnf4α(alpha) alone activates these genes in the PP area, while the presence of β(beta)-catenin in the PV zone leads to the replacement of Hnf4α(alpha) by Lef1, silencing their expression (Fig. 2.3).

A genome-wide analysis of targets bound by Tcf4 in colon cancer cell lines identified several Hnf4α(alpha)-binding sites present at a high frequency in the vicinity of Tcf4-binding sites, and this reinforces the link between Hnf4α(alpha) and Wnt dependent transcriptions in epithelial tissues [56].

The cross-talk between Hnf4α(alpha) and Wnt signaling to ensure proper liver zonation should be extended on other hepato-specific genes. But, it opens up new perspectives in this domain, raising several new questions: What are the mechanisms determining whether Hnf4α(alpha) activates or silences target genes? Why is Hnf4α(alpha) not sufficient to activate the transcription of PV genes, such as the gene encoding glutamine synthetase, despite the recognition of its binding motif? How does β(beta)-catenin control the equilibrium between Lef1 and Hnf4α(alpha) binding to chromatin?

Conclusion

Studies over the last three years have provided considerable insight into the molecular mechanisms involved in liver zonation. In particular, these studies have established the involvement of β(beta)-catenin pathway and Hnf4α(alpha) transcription factor. The complex zonal organization of the liver is of particular interest in the study of hepatocarcinogenesis. The overall patient prognosis and disease course of HCC in β(beta)-catenin mutated versus non-mutated HCC remains unsettled. Two routes of hepatocarcinogenesis have been described, based on analyses of tumor transcriptome profiles [20, 57, 58]. The first of these is linked to a high level of genomic instability, with frequent LOH and loss of p53 [59]. The second carcinogenic pathway defines a different type of tumor progression, with maintenance of a stable chromosome profile during HCC development. Tumors undergoing this second route of progression are enriched in β(beta)-catenin mutations, and are well-differentiated tumors with a predominant activation of PV gene transcription. Immunostaining of these tumors with GS antibodies is now used as a marker of these β(beta)-catenin-mutated well-differentiated HCCs [19, 60]. The effect of this particular metabolic PV transcriptome on β(beta)-catenin-depen-

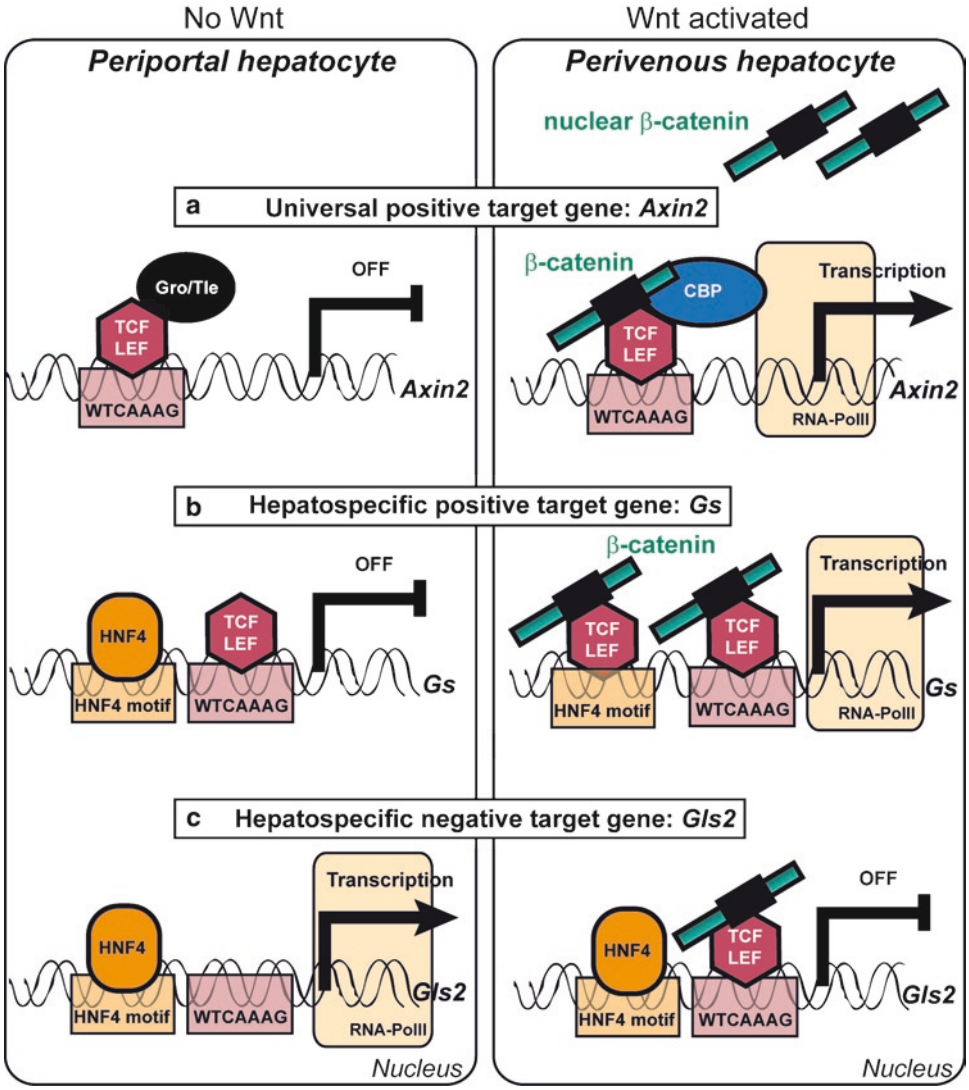

Fig. 2.3 *Trans*-acting partners of β(beta)-catenin and Lef/Tcf factors in the nuclei of PV versus PP hepatocytes. (**a**) Conventional interaction of β(beta)-catenin with Lef/Tcf factors on an example of universal target gene (Axin2). In the absence of β(beta)-catenin in PP nuclei, Lef/Tcf factors, bound to its recognition motif (WTCAAAG) recruit Groucho/Tle cofactors to repress the transcription of genes. In the presence of β(beta)-catenin, Lef/Tcf factors recruit CBP coactivator that establish a link to the preinitiation complex and the RNA Polymerase II to activate the transcription of genes. (**b**) For the transcription of the hepatospecific β(beta)-catenin target gene Gs, Lef1 factor is recruited to both Lef/Tcf and Hnf4 motifs in presence of β(beta)-catenin. In the absence of β(beta)-catenin, Hnf4 and Lef1 bind to their respective motif, and this has a repressive impact on transcription. (**c**) The transcription of the hepatospecific negative β(beta)-catenin target Gls2 is mediated by Hnf4 in the PP nuclei. The binding of Lef1 on its recognition motif in PV chromatin inhibits this Hnf4-dependent transcription

dent hepatocarcinogenesis is yet to be determined. This metabolic profile may offer new perspectives for targeted therapeutic strategies for the treatment of this subset of β(beta)-catenin-activated HCCs. This would represent a novel and unanticipated use of our current knowledge of liver zonation.

Acknowledgments We warmly thank Drs Jan Hengstler (IFADo, Dortmund, Germany), Stefan Hoehme and Dirk Drasdo (INRIA, France) for providing their three-dimensional reconstruction of the liver lobule (Fig. 2.1a) [61]. Chapter 3
Hepatocytes

Alejandro Soto-Gutierrez, Nalu Navarro-Alvarez, and Naoya Kobayashi

Introduction

The ability of the liver to regenerate was recognized by the Greeks in the ancient myth of Prometheus, the Titan god of forethought, who gave fire to the mortals and angered Zeus. Zeus then punished him for his crime by having him bound to a rock while a great eagle ate his liver every day only to have it grow back to be eaten again the next day [1]. In contrast to other solid organs, the human liver has the unique ability to regenerate after toxic injury, chronic inflammation, and surgical resection and is able to restore its original mass, cellular structure and functions [1–3].

The liver is responsible for the synthesis of serum proteins; intermediary metabolism of amino acids, lipids, and carbohydrates; and detoxification of xenobiotic compounds. Liver receives all exiting circulation from the small and most of the large intestine, as well as spleen and pancreas, through the portal vein. Its "strategic" location in relation to the food supply via the portal vein, and the unique gene-and protein-expression patterns of hepatocytes (the main functional cells of the liver) allow it to function as a master metabolic organ. These functions are performed primarily by its functional unit, hepatocytes. However, hepatocyte function (e.g., gene expression profile and biochemical activities) is not identical among all hepatocytes. Hepatocytes perform different roles depending on their physical location within the hepatic lobule [4] and it is discussed comprehensively in Chap. 2.

The liver of mammals receives the portal venous blood flow from the gastrointestinal tract and about 30% of the resting arterial circulation [5, 6]. Lymph flow from the liver is estimated to be 25–50% of the total thoracic duct flow, or approximately 0.5 ml/kg of liver/minute [5, 6].

The hepatocellular parenchyma accounts for 60% of the total cell population and 80% of the total volume of the organ, with the lobular parenchyma representing approximately 93%, the hepatic veins 4%, and the portal triads 3% of the hepatic parenchyma. Nonparenchymal cells comprise 30–35% of the total number of liver cells, but only 6% of the total liver volume. Almost half (40%) of the nonparenchymal cells are fenestrated endothelial cells. The remainder consists of phagocytic Kupffer cells (33%), extraluminal stellate cells (22%), biliary epithelial cells (4%), natural killer cells (1%), adrenergic or peptidergic nerve cells in primates and dogs, and mast cells in the dog [7].

The adult mammalian liver is composed of diverse cell types that arise from various embryologic origins. In this chapter, the discussion of the "hepatocytes" focuses on their physiology, functions, and regenerative capacities. Finally, we discuss briefly about the alternative sources of hepatocytes from stem cells.

Hepatocyte Structure

Polarity

The architecture of the liver parenchyma is unique when compared with other epithelia. In the adult liver, the hepatocyte is structurally and functionally polarized and has three distinct membrane domains: sinusoidal (basal), lateral, and canalicular (apical). Sinusoids carry the blood flow from the portal vein and hepatic artery to the central vein, and are lined with the endothelial cells, Kupffer cells (resident macrophages), and fat cells. Canalicular surfaces form the bile canalicular network that transports bile produced by hepatocytes to the bile ducts. Lateral plasma membranes fuse alongside bile canaliculi to form zonulae occludens (tight junctions) that occlude the apical domain from the basolateral surface, and thus from the blood-bile barrier. Intermediate junctions, desmosomes, and gap junctions, also on lateral domains provide cohesive strength and functional communication between hepatocytes [8].

Ultrastructive

An analysis of the fine structural features of hepatocytes and nonparenchymal cells has been undertaken using electron microscopic techniques. Hepatocytes normally show a typical large round-cell nucleus along with cytoplasmic organelles including both smooth (SER) and rough (RER), endoplasmic reticulum and many mitochondria (M) and dense glycogen granules appear to be distributed throughout the cytoplasm. The basal surface of the hepatocyte, neighboring the sinusoidal capillary space, displays a profuse elaboration of microvilli in the space of Disse (D). The space of Disse is situated just under the endothelial layer of the sinusoidal capillary. Adjacent hepatocytes are separated by an intercellular space with occasional intercellular junctional complexes.

Nonparenchymal cells have also been detected with electron microscopic methods. Kupffer cells can be encountered frequently, either situated upon underlying endothelial cells or as part of the lining of the sinusoidal capillaries. These cells display large numbers of lysosomes. Kupffer and endothelial cells display no specialized contacts. Stellate cells can be identified by the presence of prominent intracellular lipid droplets and filamentous material. These stellate cells are situated between endothelial cells and hepatocytes, or can be intercalated between hepatocytes as well. Endothelial cells can be identified by their elongated and flattened nuclei and by the presence of fenestrations in the cytoplasmic processes that form much of the lining of the sinusoidal capillaries. These fenestrations have diameters of approximately 125–175 nm. At sites where cell processes from apparent adjacent endothelial cells meet, specialized adhesive intercellular-junctional complexes can be identified [9].

Isolation and Culture of Hepatocytes

Hepatocytes are harvested using modifications of the two-step collagenase perfusion technique described by Berry, and Friend [10] and Strom et al. [11]. In general, the liver is perfused with a buffer containing ethylenediaminetetraacetic acid (EDTA), or ethylene glycol tetraacetic acid (EGTA), followed by a second, similarly constituted, buffer that contains collagenase. Each lot of collagenase must be assessed for its ability to release hepatocytes. Individual lots of collagenase that function well to isolate hepatocytes in mice may not function well in other species. Following perfusion with collagenase, the capsule of the liver is torn and the parenchymal cells are separated from the connective tissue using a nylon gauze filter. Hepatocytes are then washed several times and separated by centrifugation at $50 \times g$. The isolated cells after perfusion can be utilized for various applications such as storage, cell transplantation or primary culture.

For storage, isolated hepatocytes can be resuspended in ViaSpan or cryopreserved using dimethyl sulfoxide (DMSO). Viability is usually assessed based on the ability of cells to exclude trypan blue. Unfortunately, this measure is a poor guide to hepatocyte function and engraftment potential. In vitro characteristics of isolated hepatocytes have not been shown to correlate with engraftment, and the ability of the cells to adhere to tissue culture plates 24 h after seeding is a better in vitro assay of engraftment potential [12]. The number of cells needed to treat liver failure or cure inherited disorders of metabolism however, is variable for each condition, and has yet to be determined. In animal experiments, hepatocytes are transplanted fresh, but they can be used following cryopreservation. Additional details on preparation of cells for transplantation are provided in Chap. 21. The ability to preserve and bank hepatocytes, either by cryopreservation or tissue culture offers several theoretical advantages. These include: (1) donor/recipient tissue matching, (2) possible immunologic modulation of donor cells, (3) pooling of multiple donors, if needed, to increase cell numbers for transplantation, and (4) allowing the transplant procedure to be performed semi-electively. Unfortunately, human hepatocyte viability following cryopreservation is quite variable using present technology, and, despite recent advances which have made long-term maintenance of hepatocyte growth in culture possible, successful tissue culture often requires the use of biomatrices which may adversely affect hepatocyte use for transplantation [13, 14].

Ultrastructural studies in human isolated hepatocytes have demonstrated that hepatocytes are easily distinguishable from other contaminant cells because of their large number of mitochondria, microvillous borders, and bile canaliculus remnants. Microvilli surround the entire surface of the liver cell, indicating a complete loss of polarity, probably due to the loss of intercellular contact during isolation, whereas in undisrupted liver tissue they are confined to the bile canaliculus, sinusoidal surfaces, and perisinusoidal compartment.

With completely altered configuration and with total loss of cell polarity caused by the isolation procedure, scientists have attempted to reconstitute some basic aspects of their usual ultrastructure and polarity (bile canaliculi-like expansions, intercellular junctions, and polarized distribution of organelles, peribiliary bodies, and Golgi fields) by cell culture procedures. Cultured hepatocytes are used extensively as an experimental system to study liver functions and diseases, chemical toxicity, and xenobiotic metabolism. One major application of the system is to obtain data on species comparison of chemical toxicity, metabolism, and xenobiotic metabolism [15, 16]. Provided that a good scientific understanding of the correlation between in vitro cell culture and in vivo findings has been established, studies on chemical

toxicity and metabolism with primary cultures of human hepatocytes may yield information that would allow a more accurate extrapolation of data obtained from laboratory animals to humans.

The goal of hepatocyte culture is to create a culture system in which the cells can respond to various extracellular signals in a manner that is physiologically relevant to the in vivo circumstance. Therefore, researchers have investigated methods of hepatocyte culture aimed for maintenance, and improvement of hepatic function using extracellular matrix (ECM), growth factors, cytokines, and hormones [13, 17–19].

The establishment of long-term cultures of primary hepatocytes has long been desired and many efforts have been undertaken to achieve this goal. There is a strong need for robust long-term in vitro screening models, the use of which reduces the number of animals used in drug development. Today, cultures of primary human and animal hepatocytes have been adopted for a variety of pharmacological and toxicological experiments, allowing for the study of chronic effects in vitro. Although in vitro experimental models can never resemble the complexity of a whole organism, their simplicity provides the ability to specifically manipulate and analyze single parameters.

Culturing hepatocytes in a sandwich configuration between two layers of gelled ECM proteins, with collagen I and matrigel being the most commonly used, has dramatically prolonged the longevity of cultures displaying hepatocyte-specific functions [20, 21]. In addition, medium formulation (e.g., the addition/omission of serum, or specified hormone mixtures) has a significant influence on the morphological development and cell survival of hepatocytes in culture [18, 22–24].

Conventional monolayer hepatocytes quickly adopt their polygonal shape and establish extensive cell-cell contacts, whereas in sandwich culture, this takes markedly longer, being still mostly spherical and singular. In general, conventional monolayers appear more flattened than sandwich-cultured cells, a result of the lack of a three-dimensional ECM environment.

By overlaying monolayer cultures of primary hepatocytes with collagen gel, it is possible to obtain cultures displaying some features of the in vivo geometry. This configuration of hepatocytes in collagen sandwich cultures permits to maintain active expression of liver-specific features over extended periods of time (e.g., bile canaliculi-like structures). Cells cultured as a collagen sandwich in serum-free medium do not significantly spread out, and polygonal cell formats, clear plasma membrane boundaries, and stable bile canaliculi-like networks are still evident after 72 h of cultures. In contrast, hepatocytes incubated in serum-containing medium noticeably deteriorate, and lose cytoplasmic integrity and stability of their canaliculi-like structures. Thus, the use of collagen type I gel as ECM component for hepatocyte sandwich cultures is appropriate for long-term cultures. It is a fact that primary hepatocytes cultured in serum-free collagen sandwich cultures stay morphologically unchanged for a few weeks and offer the ability to investigate alterations in cellular structures induced by chemical treatment with the use of high content imaging [21]. In addition to the ECM application and media formulation, cell density also has some influence on the morphology of hepatocytes in culture [25, 26]. Since the polar differentiation of hepatocytes in culture is only visible in cell aggregates, cell density should always be close to confluency, about 90%.

Hepatocyte Functional Characterization

Hepatocytes, the functional unit of a liver, perform many important functions including detoxification, synthesis, and metabolism and these are discussed in-depth in forthcoming chapters. Here, we discuss some features that define hepatocytes both structurally and functionally. The availability of a homogeneous source of human hepatocytes is considered the most precious tool for toxicity screening. In addition to hepatotoxicity, hepatocytes provide a renewable, cell-based assay to examine other key factors of compound attrition such as the metabolism of xenobiotics by CYP450 enzymes, drug–drug interactions, and system for studying hepatic metabolism of xenobiotics, hepatotoxicity and the activity of drug transporters as well as regenerative medicine (Fig. 3.1).

The possibility of having a permanent source of human hepatocytes from stem cells opens exciting new possibilities for pharmacology and toxicology, as well as for cell therapy. However, the nature of the "hepatocyte-like cells" should be analyzed very carefully under several constrictions and a clear definition of the term *hepatocyte* has to be implemented. The expression of hepatocyte markers, such as alphafetoprotein, albumin, or cytokeratin 18, as well as induction of an epithelial phenotype and inducible cytochrome P450 has been reported in several works.

Properties such as epithelial morphology and expression of some hepatocyte markers are necessary, but not sufficient to consider a cell as a hepatocyte. Albumin expression and cytochrome (CYP) P450 are examples of this. In fact, hepatocytes are the only cell type that secretes albumin. However, the conclusion that any albumin-secreting or expressing cell necessarily represents a hepatocyte can be still be premature. For example, it is possible that stem-cell–derived cell types express albumin together with a limited number of hepatocyte markers, but this does not mean that they also express the necessary set of hundreds of genes that make up a true hepatocyte. Moreover, CYP enzymes are not exclusively limited to hepatocytes. Indeed, CYP induction has been reported for lung, colon, small intestine epithelial cells, white adipose tissue, and several other cell types [16, 27]. Therefore,

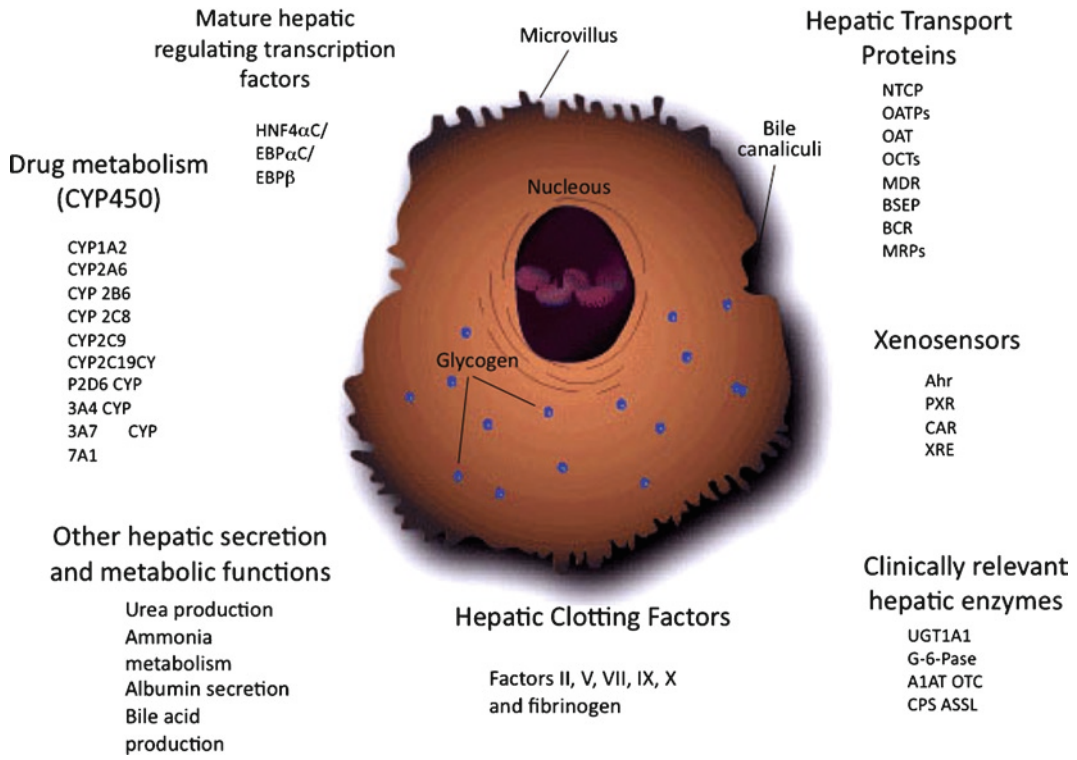

Fig. 3.1 Hepatocyte characterization

it is possible to unequivocally define whether a candidate cell is a hepatocyte or not. Thus, the definition of hepatocyte should include qualitative studies where the presence/absence of hepatocyte markers are demonstrated together with an enzymatic activity evaluation.

With the well known knowledge on the biology and usage of primary human hepatocytes [27], it seems reasonable to introduce additional criteria to define if a cell is a true hepatocyte or only shares several characteristics with a hepatocyte. In this perspective, it is also important to understand what properties a hepatocyte or the substitute hepatocyte-like cell should have. The resulting hepatocyte-like cells should be compared with human fetal and mature human liver, and we should define endpoints to measure in stem cell-derived hepatocytes, the level of hepatic maturation. Finally, we need fast and easy tests that provide relevant and robust information of the hepatic capacities of the produced stem cell-derived hepatocytes.

From a functional point of view, any candidate hepatocyte-like cell type should represent a minimal set of hepatic functions of a true hepatocyte. Here, we present a battery of relevant studies for the analysis of enzyme activities of stem cell-derived hepatocytes: (a) Analysis of expression of genes identified in mature livers, (b) metabolism of xenobiotics and endogenous substances (hormones and ammonia); (c) synthesis and secretion of albumin, clotting factors, complement, transporter proteins, bile, lipids, and lipoproteins; and (d) storage of glucose (glycogen), fat soluble vitamins A, D, E, and K, folate, vitamin B12, copper, and iron. Finally, a convincing in vivo experiment to prove hepatocellular differentiation is to restore liver function in animal models by means of repopulation assays. However, any repopulation experiment may only evaluate that a certain hepatic cell type has the capacity to generate hepatocytes in vivo. Thus, testing a defined battery of activities and comparing them with primary hepatocytes remains the only feasible option for evaluating the in vitro potential of stem cell-derived hepatocyte cultures as appropriate surrogates for primary human hepatocytes (Fig. 3.1).

The entire hepatic drug-metabolizing enzyme system in an integrated form provides an in vitro model that is a very useful tool for anticipating drug metabolism and drug hepatotoxicity in man. Cytochrome P450s (CYPs) are mixed function monooxygenases and the major enzymes in phase I metabolism of xenobiotics. Depending on the nature of the xenobiotic, this oxidative metabolism results in inactivation and facilitated elimination, activation of pro-drugs, or metabolic activation [28]. Evaluation of CYP for specific measurements in hepatocytes classified as phase 1 metabolism may include CYP1A2, CYP2A6, CYP 2B6, CYP 2C8, CYP2C9, CYP2C19, CYP2D6, CYP 3A4, CYP 3A7, and CYP 7A1. The major site of CYP expression is the liver and CYP 3A4 is the most abundant CYP isoenzyme in human adult liver. The enzymes of greatest importance for drug metabolism belong to the families 1–3, responsible for 70–80% of all phase I dependent

metabolism of clinically-used drugs [29]. Studies performed in primary human hepatocytes point to the CYP 3A4 as an important marker for hepatocytes, as this enzyme is the most abundant CYP enzyme in the human liver. CYP 3A4 activity can be measured using 6-beta hydroxytestosterone. It has been reported to be quantitative, sensitive, and specific test for 3A4 [16, 29].

CYP expression and activity present large interindividual variations due to polymorphisms [30]. Moreover, CYPs can be induced several fold or inhibited by specific drugs, resulting in additional, although transient, variability of metabolic activity. Inducibility of CYPs is a mature liver function that must also be observed in useful stem cell-derived hepatocytes. CYPs are inducible by exposure to phenobarbital, rifampicin, and to a lesser extent steroid hormones [16]. The CYP2C family also represents a significant proportion of total P450s (2C9, 2C8, 2C19, and 2C18), representing about 20% of the total P450 and metabolizes many drugs [31], thus making this enzyme subfamily important to monitor. CYP1A2 is a minor enzyme in the liver and only a small number of drugs (4%) are metabolized by this enzyme [16, 31]. However, it is involved in the bioactivation of pro-carcinogens and is therefore considered to be an important enzyme to test. CYP2B6 is emerging as an important enzyme in drug-drug interactions despite a previously reported low abundance in the liver (0.2% of total P450) [32]. However, once thought to be of minor importance and uninducible in humans, CYP2B6 may actually constitute at least 5% of the total P450, contribute to the metabolism of more than 25% of all pharmaceutical-drug metabolism and exhibit high inducibility [33]. CYP3A7 is mainly expressed in fetal liver even at mid-gestation, although in rare cases, CYP3A7 mRNA has been detected in adults. CYP3A7 activity can be induced by hydroxy progesterone caproate metabolism. The CYP3A forms have demonstrated an equal or reduced metabolic capability for CYP3A5 compared with CYP3A4, and a significantly lower capability for CYP3A7. Thus, active metabolism can be detected for both CYPs 3A7/3A4. CYP7A1, cholesterol 7a-hydroxylase, is found exclusively in the liver, where it catalyzes the first step in the major pathway responsible for the synthesis of bile acids [34]. The expression of this enzyme is subject to feedback regulation by sterols and is thought to be coordinately regulated with enzymes in the cholesterol supply pathways, including the low density lipoprotein receptor and 3-hydroxy-3-methylglutaryl-coenzyme A reductase, and synthase [34] (Fig. 3.1).

Hepatic transport proteins and mainly measurement of bile acids can serve as indicators of hepatic function. However, all hepatic functions do not mature at the same rate, and some hepatic transporters are expressed early in the development and may not be exclusive for liver. There is evidence that they are expressed in the intestine, kidney, brain, and other organs [35]. Some important hepatic transport proteins can be classified as follows: (a) the solute carrier (SLC) family, comprising among others such as Na+-taurocholate co-transporting polypeptides (NTCP), organic anion-transporting polypeptides (OATPs), organic anion transporters (OATs), organic cation transporters (OCTs); and (b) the ATP-binding cassette (ABC) transporter family, including the multi drug resistance proteins (MDR), bile salt export pump (BSEP) (both belong to the ABCB family), breast cancer resistance protein (BCRP, belonging to the ABCG or White family) and (c) the multi drug resistance associated proteins (MRPs), belonging to the ABCC family.

The basolateral NTCP transports bile acids from the space of Disse into hepatocytes. Human NTCP accepts most physiological bile acids while at the canalicular membrane the efflux of bile acids by the BSEP mediates concentrative excretion [36].

Sensors like the aryl hydrocarbon receptor (Ahr), pregnane X receptor (PXR), and the constitutive androstane receptor (CAR) are integral to the regulation and induction of the main P450s and their analysis may provide a strong evidence of the maturation state of stem cell-derived hepatocytes due to their up-regulation during liver development. These receptors control the expression of CYP1A (Ahr), CYP2, and CYP3A (PXR and CAR), families. Once activated, the receptors form heterodimers with other factors, such as Arnt (Ahr nuclear translocator) and retinoid X receptor (RXR for both PXR and CAR) and then bind to the target xenobiotic response elements (XRE) located in both the proximal and distal P450 gene promoters, resulting in the transcription of the respective CYP isoform [37].

The demonstration of expression of transcription factors regulating hepatic development and maturation is useful (HNF4α, C/EBPα, C/EBPβ), but not as useful as the CYPs for measuring maturation because they are expressed at near adult liver levels even at mid gestation.

Microarray data suggest that HNF1α binds to 222 target genes in human hepatocytes corresponding to 1.6% of the genes assayed. HNF6 bound to 227 (1.7%), and HNF4α bound to 1,575 (12%) of the genes, which means that HNF4α bound to nearly half of the active genes in hepatocytes [38] (Fig. 3.1).

The differentiated state of the hepatocytes is regulated by a coordinated interplay of hepatocyte-specific transcriptional factors, including HNF-4 and C/EBPα [38]. HNF-4 is involved in hepatocyte specific expression of serum proteins, such as albumin and transferrin, and of cytochrome P450 proteins. In primary cultures of rat hepatocytes, the expression of C/EBPα is rapidly reduced within a few days of culture, resulting in reduced hepatic functions. It has been demonstrated that the maintenance of C/EBPα, HNF-4, nuclear factor-kappa B (NFκB), and activator protein-1 (AP-1) contributed to the prolonged expression of liver-specific proteins in human hepatocyte cultures [39].

Additionally, analysis of some hepatic clotting factors (II, V, VII, IX, X, and fibrinogen), albumin production, urea production or ammonia metabolism and glycogen storage may provide additional robust evidence of an effective hepatic maturation in case the stem cell-derived hepatocytes are evaluated for their hepatic functional capacity (Fig. 3.1).

The presence of hepatic enzymes with clinical implications would be useful in the process of hepatic maturation categorization, for example UDP-glucuronosyltransferase (UGT1A1), an enzyme of the glucuronidation pathway that transforms small lipophilic molecules, such as steroids, bilirubin, hormones, and drugs, into water-soluble, excretable metabolites [40]. Another important enzyme that is present in mature hepatocytes is glucose-6-phosphatase (G-6-Pase)1, which catalyzes the hydrolysis of glucose 6-phosphate to glucose, which is the terminal step of both hepatic gluconeogenesis and glycogen breakdown [41]. In addition, alpha-1-antitrypsin (A1AT) is an example of a clinically relevant enzyme that is present in a mature stage of hepatocytes. As a member of the serpin superfamily of proteins, A1PI is a potent inhibitor of serine proteases, especially neutrophil elastase, which degrades connective tissue in the lung [42]. The A1AT gene is expressed in cells of several lineages, with expression being highest in hepatocytes.

Urea cell cycle related enzymes might be important when hepatic function of stem cell-derived hepatocytes is to be evaluated. Ornithine transcarbamylase (OTC) gene is expressed exclusively in liver and intestinal mucosa, and is located in the mitochondria and is part of the urea cycle as well as carbamyl-phosphate synthetase I (CPS) and argininosuccinate synthetase (ASSL) [43] (Fig. 3.1).

Epithelial to Mesenchymal Transitions of Hepatocytes

Successful liver repair results in replacement of damaged hepatocytes cells with healthy new epithelial cells; this process is recognized as liver regeneration. These responses differ depending on the severity and chronicity of liver injury. For example, residual mature hepatocytes and cholangiocytes proliferate to restore liver mass after acute partial hepatectomy, while liver progenitors are involved in the repair of chronically injured livers, or in special kind of injuries [44]. This repair of chronic liver injury also variably involves changes in mesenchymal cells and they may also lead to hepatic inflammation, vascular remodeling, and fibrosis, and result in hepatic architectural distortion and liver dysfunction and eventually culminate in cirrhosis [45].

By concept, epithelial cells (hepatocytes) are adherent cells that closely attach to each other, forming coherent layers in which cells exhibit apico-basal polarity as illustrated above in the hepatocyte structure section. On the other hand, mesenchymal cells are non-polarized cells, capable of moving as individual cells because they lack intercellular connections. Thus epithelial to mesenchymal transition (EMT) describes the process by which cells gradually lose typical epithelial characteristics and acquire mesenchymal traits. Moreover, mesenchymal to epithelial transition (MET) refers to the reverse process. It is important to emphasize that these transitions refer to changes in cell shape and adhesive properties.

Key epithelial features that are eventually lost during EMT include typical epithelial expression and distribution of proteins that mediate cell-cell and cell-matrix contacts, as well as the cytoskeletal organization that is responsible for normal epithelial polarity. In contrast, mesenchymal characteristics that are ultimately gained during EMT include the ability to migrate and invade the surrounding matrix. This migratory/invasive phenotype requires induction of mesenchymal filaments, cytoskeletal rearrangements, and increased production of factors that degrade ECM [46]. These alterations of EMT (or its reversal) require a carefully-orchestrated series of events that eventually lead to wide-spread changes in gene expression. This is regulated both at the level of gene transcription and via various post-transcriptional mechanisms [47].

Recent literatures have demonstrated that EMT/MET are involved in (a) embryogenesis/development, (b) wound healing/tissue regeneration/organ fibrosis, and (c) neoplasia.

The determination of whether or not EMT occurs in situ, and how significant this process might be to outcomes of liver injury (e.g., regeneration or fibrosis), is actually a very difficult task. Chronic epithelial degeneration is thought to provoke patchy epithelial-mesenchymal transitions that involve relatively small numbers of cells [48]. During culture, several resident adult liver cells appear capable of undergoing EMT and/or MET, raising the possibility that EMT/MET might be involved in liver regeneration. However, despite considerable effort to deploy state-of-the-art technology to determine if (and how) such phenotypic transitions influence the outcomes of liver injury, the issue remains controversial. The existing data that might be helpful in resolving the role of epithelial-mesenchymal transitions in adult liver repair has been derived so far from a few studies using transgenic mice, each of which likely marked distinct types of liver cells and their resultant progeny [49, 50]. Data interpretation is made further difficult by the fact that the published studies used different models of injury and examined outcomes at different time points. These studies (work in Alb-Cre/LacZ mice and GFAP-Cre/GFP mice) provide compelling in vivo evidence that EMT/MET do occur in certain types of adult liver injury, although the exact cell types that are capable of this response remain unclear. Also, when it occurs, EMT does appear to correlate with changes in hepatic matrix production/accumulation, although it has not yet been proven that the EMT-derived fibroblastic cells actually generate matrix.

There is also a growing immunohistochemical evidence for EMT/MET in various human liver diseases, including primary biliary cirrhosis, biliary atresia, alcoholic and nonalcoholic fatty liver disease [51, 52]. Further research is needed to evaluate this theory. The resulting knowledge may be important in designing novel diagnostic and therapeutic strategies to prevent, and treat chronic liver damage.

Alternative Production of Hepatocytes from Stem Cells

Liver regeneration capacity results mainly from mitotic division of mature hepatocytes, bile duct, and endothelial cells as mentioned above. But under special circumstances, hepatic progenitors called oval cells are activated to expand and take part in liver regeneration when the proliferative capacity of the mature native hepatocytes is impaired, and a stimulus of regeneration is present [14, 53]. Hepatic oval cells express markers associated with immature liver cells, such as alphafetoprotein; mature hepatocytes, such as albumin; hematopoietic stem cells such as c-kit, Thy-1, CD34, and Sca-1 [53]. These bi-potential progenitors, isolated from the liver, differentiate into mature hepatocytes after transplantation into the liver [14, 53, 54]. However, currently it is uncertain whether such cells can be maintained and expanded in vitro to be used in lieu of adult hepatocytes for clinical application; its contribution to carcinogenesis is not yet clear. Nonetheless, oval cells isolated from the adult liver represent a promising source for cell-based therapy.

Bone marrow cells are an attractive source for extrahepatic stem cells. Hepatocytes can, in fact, be generated from hematopoietic stem cells and the mechanism by which hematopoietic cells can directly affect hepatic regeneration includes both transdifferentiation and fusion of a cell of hematopoietic origin with defective hepatocytes [14, 55, 56]. Their capacity to integrate into injured livers of animals has been reported to be low and the clinical potential to correct liver disease remains to be determined from either bone marrow or adipose tissue mesenchymal stem cells (MSCs) [57]. Another mechanism reported to alleviate liver injury using MSCs is the secretion of soluble factors. Recent studies directed by our group have found that injection of conditioned-medium from MSCs or the use of a liver assist device can reduced hepatocytes death and increase hepatocytes replication [58]. However, the exact mechanism and the type of liver injury that can be treated by this strategy remains to be determined.

Another source of hepatocytes are fetal human liver progenitor cells, and these cells have shown enormous replication and differentiation potential, including the capacity to generate mature hepatocytes after transplantation in immunodeficient animals, [59] mainly due to the extended reconstitution of telomerase activity which maintains chromosomal integrity during cell division even after cryopreservation [60]. Oertel et al. have used fetal rat liver cells to show that at least three distinct subpopulations of hepatoblasts exist between embryonic days 12–14. Based on histochemical markers, one population appeared to be bipotential and the other two harbored either unipotent hepatocytes, or biliary epithelial cell phenotypes [61, 62]. The same group has reported that a phenomenon known as cell competition is responsible for the liver repopulation where the transplanted fetal liver cells are capable of repopulating the liver by inducing apoptosis in neighboring host hepatocytes that proliferate more slowly than the transplanted cells [61]. So that if the engrafted hepatocytes possess a greater proliferative capacity than the host hepatocytes, the engrafted cells would grow preferentially in response to mitotic stimuli, progressively competing out the host hepatocytes [61]. Nevertheless, the supply of fetal human tissues is also limited and the possibility of oncogenic perturbations needs further study. Moreover, it will be important to determine whether cells derived from fetal livers before 20 weeks of gestational age, when most elective abortions are performed, would express differentiated hepatocellular function after transplantation [63]. Clinical transplantation of fetal hepatocytes in patients with acute liver failure has been documented, but resulted in modest clinical decrease in serum bilirubin [64, 65]. Further studies need to be performed to corroborate clinical significance.

At this point, most published embryonic stem cells-differentiation protocols that generate hepatocyte-like cells have reported in general a limited functionality and not complete maturity. Major liver repopulation has been difficult to document. However, it has been reported that by selecting for cells expressing markers such as the asialoglycoprotein receptor, it is possible to isolate the most hepatocyte-like cells in the culture with repopulating capacity [66–68]. It appears likely that conditions and protocols will be developed for the practical production of embryonic stem cell-derived hepatocytes. Nevertheless, major advances have been difficult to achieve. The development of induced pluripotent stem (iPS) cells from adult somatic tissue [69] may provide major advantages on the development of hepatocyte-like cells. Confirmation that iPS cells have hepatocyte-lineage differentiation capacity comparable to that of existing differentiated embryonic stem cells needs to be studied. Nevertheless, iPS-derived hepatocytes are a very promising population for future therapeutic transplantation.

Hepatocyte Cell Lines

Whether originated from tumors or obtained by oncogenic immortalization, human hepatoma cell lines lack a substantial

set of liver-specific functions, especially many CYP-related enzyme activities. Most hepatocyte cell lines do not express the major metabolizing enzyme activities; they only exhibit some enzyme activities depending on the culture conditions and the source of the cells [16]. HepG2 and other cell lines stably integrated with specific P450 isoforms have been shown to be responsive to CYP inducers, but are of limited value for induction assays due to their lack of liver-specific functions [70]. Reexpression of CYPs has also been obtained by transfection of plasmid constructs expressing liver-specific transcription factors such as c/EBP-alpha, but similarly they do not mimic regulation of gene expression observed in normal hepatocytes [16].

Conclusions and Future Perspectives

Primary hepatocytes continue to be the most relevant in vitro model for advancing our knowledge of liver functions, the mechanisms underlying the regulation and drug induced changes of metabolic enzyme expression, hepatocellular integrity, liver cell-based therapy, and hepatic regeneration.

The value of hepatocytes has been enhanced further in recent years by technical improvements in cell handling conditions (cryo-preservation, cell culture and liver repopulation techniques), in the methods available to explore effects of xenobiotics on critical functions and in our understanding of the key role played by xenosensors and drug discovery.

The use of adenoviruses and transfected cell lines has increased our knowledge of cellular mechanisms, but these cannot yet replace primary hepatocytes for prediction of in vivo drug-drug interactions or hepatotoxicity. Likewise, hepatocyte-like cells are promising, but have a long way to go before they can be considered an alternative to primary hepatocytes. Although there is no complete consensus on the roles of hepatic stem cells in adult mammals, recent findings support a view in which mature-differentiated epithelial liver cells and facultative stem cells mediate liver maintenance and growth. Thus, processes such as normal liver turnover, regeneration after injury, or repopulation following transplantation are mediated by either cell type, depending on the precise circumstances. Oval cells are not a homogeneous well-defined cell population, but represent a complex mixture of different cell types, all of which are activated during progenitor-dependent regeneration. These cells are likely bipotential in that they can produce hepatocytes and bile duct epithelium. Multiple studies support the concept that liver stem cells reside within the biliary tree and are a subset of ductal cells. Extrahepatic cells (ES/iPS cells) also have the potential to become liver epithelium; although their role in liver physiology remains uncertain, they might be developed for use in therapeutic cell transplantation and important drug discovery studies.

For further progress, it will be important to clearly define activities that closely resemble those of primary hepatocytes and, even more importantly, others that are not hepatocyte-like. Recapitulating the above mentioned, gene and function of stem cell-derived hepatocytes must be compared to human fetal or adult liver; mature hepatic characteristics should be demonstrated using drug metabolism detoxification in a gene expression and functional level; additional characterization can be provided by analyzing hepatic transport proteins, mature hepatic transcription factors, and factors related to homeostasis, albumin secretion, production of bile acids, bilirubin conjugation assays, ammonia metabolism with the expression of related enzymes, and finally, the analysis of mature liver gene expression and function in animal models of liver failure after transplantation to the liver or ectopic sites. In addition, a clear definition of non-hepatocyte–like factors is important to identify mechanisms responsible for the lack of activity. Clarification of such mechanisms, for instance, loss of transcription factor expression or modification of signal transducers, is a requirement for further progress. It may be extremely difficult to differentiate stem cells to a cell type that resembles primary hepatocytes in all aspects of drug metabolism. However, promising results have been obtained with extra-hepatic stem cells since some previously silent hepatocyte markers become expressed during differentiation, and metabolic activities start appearing after new protocols have been reported.

Chapter 4
Biliary Epithelial Cells

Yoshiaki Mizuguchi, Susan Specht, Kumiko Isse, John G. Lunz III, and Anthony J. Demetris

Introduction

Biliary epithelial cells (BEC), or cholangiocytes, line a complex tree-like 3-dimensional network of conduits within the liver that form the biliary tract. The biliary tree can be divided into extrahepatic and intrahepatic components, and receives its blood supply exclusively from hepatic artery branches (Fig. 4.1) [1]. The extrahepatic biliary tract is composed of the gallbladder, common hepatic duct, common bile duct, and cystic duct [2]. The intrahepatic biliary tract contains the bile canaliculi, the canals of Hering (or intrahepatic bile ductules), interlobular bile ducts, intrahepatic bile ducts, and the left and right hepatic bile ducts [1].

BEC comprise only 3–5% of total liver cells (hepatocytes comprise 60% and account for 78% of the liver volume), but they are essential to the formation of bile components in the liver and effective transport of bile into the duodenum. Hepatocytes transport and secrete bile acids and other organic solutes (primary or hepatic bile) into the canalicular space between hepatocytes. The bile, in turn, is transported via the canalicular network to the smallest biliary radicals, or cholangioles, which are the first structures to be lined by typical BEC. After passing through a series of progressively larger BEC-lined channels, the bile is alkalinized and diluted by BEC via a series of secretory and absorptive processes [3]. Despite the comparatively small number of BEC, their secretions account for up to 40% of bile volume in humans [4].

BEC display functional heterogeneity along the biliary tree. For example, those lining large bile ducts participate in mucin secretion and hormone-regulated bile secretion, whereas BEC lining small bile ducts possess proliferative capabilities and a subpopulation display considerable plasticity, being able to assume a "reactive or reparative phenotype" in disease conditions [5, 6]. BEC are quiescent, or reside in the G_0 state of the cell cycle under normal conditions. However, they actively participate in reactive and reparative responses to various pathological stimuli during disease states [7, 8]. BEC lining the large bile ducts respond to direct injury, whereas BEC lining the smallest biliary radicals also participate in repair response involving hepatocytes and after vascular injury.

Cholangiopathies, or diseases that directly involve bile ducts, are categorized according to the underlying cause(s):

1. Immune disorders (discussed in Chap. 49)
   (a) primary biliary cirrhosis (PBC)/autoimmune cholangitis
   (b) primary sclerosing cholangitis (PSC) (discussed in Chap. 50)
   (c) acute and chronic allograft rejection
   (d) graft-versus-host disease (GVHD)
   (e) cholangiolytic adverse drug reactions (see below)
2. Bacterial, fungal, parasitic, and viral infections
3. Vascular/ischemic damage
   (a) intra-arterial chemo-ablative therapy
   (b) post-transplant hepatic artery stenosis/thrombosis
   (c) chronic liver transplant rejection
4. Adverse drug reactions or toxicity
5. Genetic disorders
   (a) Cystic fibrosis
   (b) Alagille syndrome
   (c) (Fibro)polycystic disease
6. Idiopathic diseases
   (a) biliary atresia
   (b) Sarcoidosis, idiopathic adulthood ductopenia
7. Neoplastic diseases: Benign and malignant (e.g. biliary cystadenoma, cholangiocarcinoma, and bile duct cancers [9] (discussed in Chap. 60)).

Cholangiopathies show a clear predilection for specialized regions of the biliary tree probably because of the heterogeneity of the BEC. For example, PBC mainly involves the small

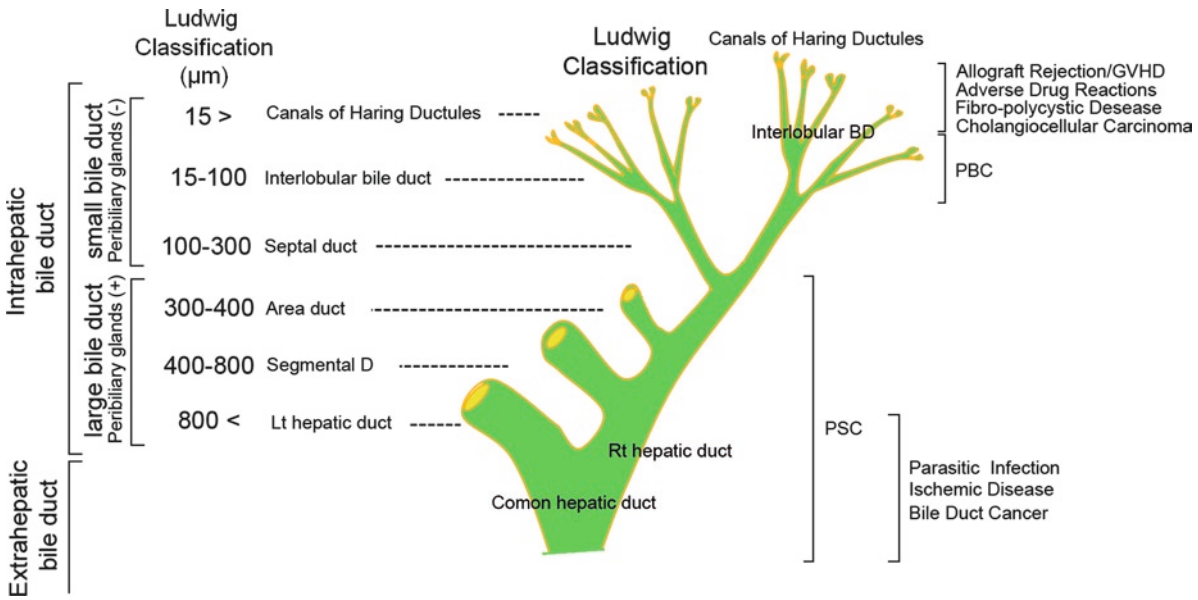

Fig. 4.1 Illustration of the biliary tree and nomenclature according to Ludwig classification, which is primarily based on the size of the bile ducts. The classification has practical utility because cholangiopathies show a clear predilection for specialized sections of the biliary tree

interlobular bile ducts, where secretin-stimulated secretion is more active. In comparison, drug-induced ductopenia is largely restricted to small cholangioles, indicating a difference between major ducts and cholangioles in terms of xenobiotic transport and metabolism [10]. Ischemic injury, parasitic infection, and choledocholithiasis primarily involve the larger bile ducts.

Despite disease heterogeneity, BEC in all cholangiopathies engage in pathophysiologic responses that are common to many studies of injury and repair. Included are the coexistence of BEC death (lytic or apoptotic), proliferation, inflammation and fibrosis, and qualitative/quantitative changes in bile production (cholestasis) [11]. During disease processes, BEC interact with various inflammatory mediators, cytokines and chemokines, products of cell death, and nearby parenchymal and stromal cells, and immune cells. Included are BEC apoptosis and proliferation [12], cell migration, fibrogenesis [13], damage to the peribiliary circulation, histocompatibility antigen expression [14], and alterations in biliary epithelium transport functions.

BEC lining the smallest cholangioles also participate in repair responses that primarily involve hepatocellular injury. This is probably related to the known plasticity of cells lining the smallest cholangioles and periportal hepatocytes: these BEC can trans-differentiate into hepatocytes and periportal hepatocytes can trans-differentiate into BEC [15–17]. In fact, BEC play a crucial role in the development of cirrhosis from most causes via: (1) their increased resistance to injury, compared to hepatocytes; (2) interactions with portal myofibroblasts and classical stellate cells; and (3) participation in "ductular reactions," which distort the hepatic architecture during the development of chronic necro-inflammatory liver disease (reviewed in [18]) (Fig.4.2). In addition, bi-potential progenitor cells or "liver stem cells" are thought to reside in the terminal cholangioles and/or periportal hepatocyte populations [19, 20] (Fig. 4.2). Although control mechanisms for hepatic progenitor cell activation and differentiation are only partially understood, Wnt/β(beta)-catenin [21, 22] and Notch/Jagged pathways [23], and a transcription factor – hepatocyte nuclear factor-6 (HNF-6) [24] have been implicated in hepatic stem/progenitor cell activation. Activation of these cells during disease states is thought to increase the risk of neoplastic transformation through initiation of progenitor cell populations [20, 25, 26] (Fig. 4.2).

There has been a rapid expansion of research aimed at elucidating key signaling pathways that regulate BEC development, differentiation, proliferation, survival, and function, as well as cellular and molecular mechanisms of cholangiocarcinogenesis and progression. This chapter addresses biliary epithelial cell (patho-) physiology by focusing on signaling pathways and mechanisms involved in BEC injury and response to injury.

Anion Transport and pHi Maintenance

Formation of bile and maintenanice of intracellular pH (pHi) are essential BEC functions that contribute to systemic homeostasis, including clearance of xenobiotics, enterohepatic circulation of bile salts, and intestinal absorption of lipids. These processes, in turn, significantly contribute to bile flow.

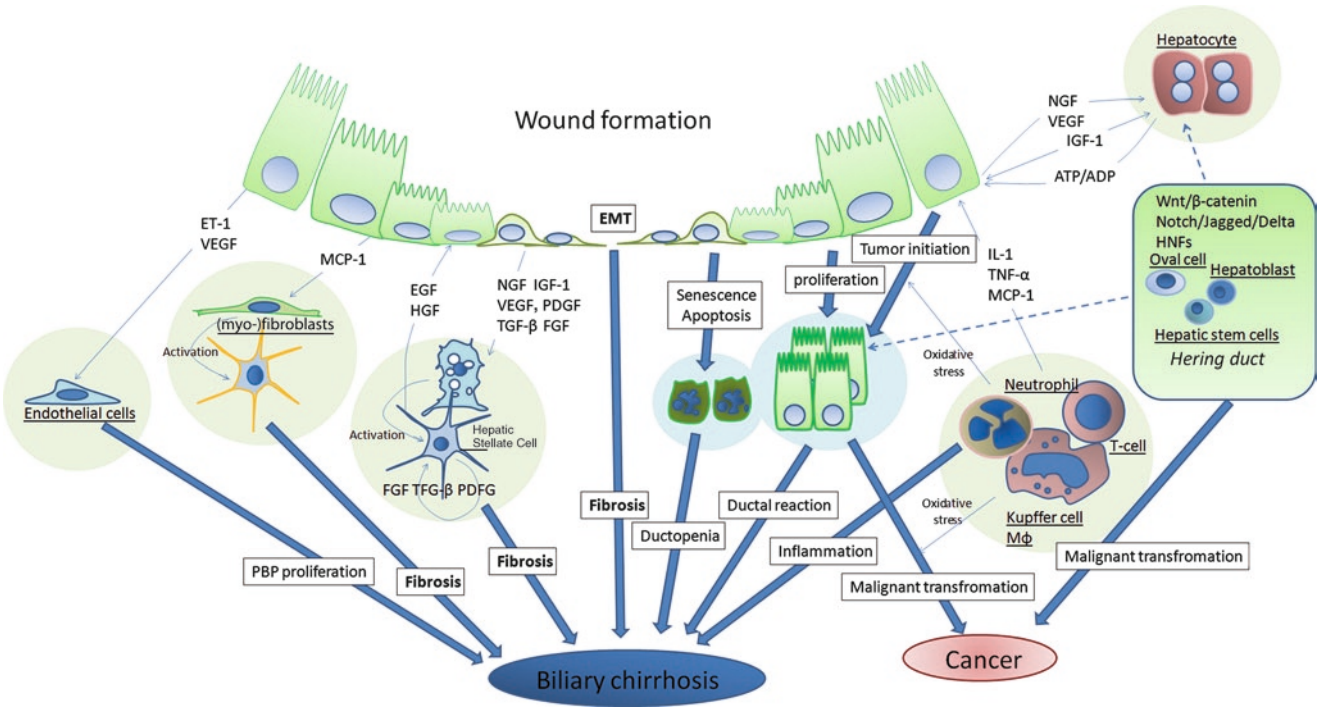

Fig. 4.2 BEC respond to injury by synthesizing and secreting a variety of mediators that enable BEC to interact with other nearby liver cells, such as hepatic stellate cells, portal (myo-) fibroblasts and inflammatory cells during cholangiopathies. Hepatic stem or progenitor cells that are thought to reside in or near terminal cholangioles can be activated during progression of cholangiopathies and differentiate into either hepatocyte or BEC; they also probably play a critical role in hepatic and biliary carcinogenesis

Regulation of pHi is mediated by specific acid/base carriers closely tied to a variety of cellular processes ranging from cell volume regulation to cell mitosis.

Mechanism Involved in Anion Transport and pHi Maintenance

Mechanisms involved in anion transport are depicted schematically in Fig. 4.3. In human BEC, HCO_3^- loading is accomplished by the Na^+/HCO_3^- co-transporter (NBCe2/NBC4/SLC4A5) [27] located on the apical BEC membrane, whereas the Na^+ dependent Cl^-/HCO_3^- exchanger (NDCBE/SLC4A8) [28] is found at the basolateral surface [29–32]. Bicarbonate influx occurs mainly through the exchanger, with the Na^+/HCO_3^- cotransporter being activated only at very low pHi conditions [32, 33]. HCO_3^- is also produced via carbonic anhydrase (CA), which is coupled to a carrier-mediated (NHE) H^+ extrusion [34, 35]. In mammalian liver, CA is mainly expressed in the BEC cytoplasm, but not hepatocytes, and catalyzes the hydration of carbon dioxide: $CO_2 + H_2O \leftrightarrow HCO_3^- + H^+$ [34]. Acid extrusion is mediated by the Na^+/H^+ exchanger (NHE) in both rat and human BEC (pig BEC have cAMP-activated H^+-ATPase [36]).

Both hepatocytes and BEC appear to have cAMP-responsive intracellular vesicles in which a Cl^-/HCO_3^- exchanger co-localizes with cell-specific Cl^- channels (cystic fibrosis transmembrane conductance regulator, CFTR) and aquaporin-1 [37–39]. cAMP-induced coordinated trafficking of these vesicles to either hepatocanalicular or BEC luminal membranes, and extracellular exocytosis results in increased osmotic forces and passive movement of water with net bicarbonate-rich hydrocholeresis. Bicarbonate secreted via the Cl^-/HCO_3^- exchanger is mediated by AE2/SLC4A2, the main contributor to biliary bicarbonate secretion [30, 40, 41]. This exchange is Na^+-independent and electroneutral. The exchange is facilitated by an outside to inside transmembrane gradient of Cl^- at relatively high intracellular concentrations of HCO_3^-, particularly upon secretin stimulation, and involves chloride efflux through activation of CFTR [30, 42–45].

Secretin, a hormone that interacts with specific G protein-coupled receptors, causes an increase in intracellular cAMP, which in turn, activates PKA and Cl^-/HCO_3^- BEC secretory mechanisms. Besides acid/base transporters, BEC also possess other ion carriers for Cl^-, Na^+ and K^+ that might ultimately lead to biliary excretion of bicarbonate via their exchange with luminal chloride. This exchange is facilitated by relatively low intracellular concentrations of chloride and

high concentrations of bicarbonate. In addition to CFTR, Cl^- also enters the lumen via a dense population of Ca^{2+}/calmodulin dependent Cl^- channels, which are activated through purinergic-2 (P2) receptors and nucleotide (ATP/UTP) binding [39, 46–49]. Cl^- might also enter through a high conductance, G-protein-regulated, Ca^{2+}/cAMP- independent Cl^- channel [50]. The role of these non-CFTR pathways still needs to be clarified, but they are more prominent in single BEC [50]. The basolateral $Na^+/K^+/2Cl^-$ co-transporter NKCC1/SLC12A2 participates in uptake of Cl^- to maintain high intracellular Cl^- concentrations that facilitate apical Cl^- excretion by the Cl^-/HCO_3^- exchanger [46, 51]. BEC possess a basolateral Na^+/K^+ ATPase [52–54] to maintain the cation gradient because NKCC1/ SLC12A2 influxes Cl^- together with Na^+ and K^+.

BEC also express a K^+ channel transporter, SK2/KCNN2, to prevent excess K^+ accumulation [50, 55]. The activity of SK2/KCNN2 is regulated by intracellular Ca^{2+} and cAMP. Activated basolateral K^+ conductance results in hyperpolarization of the BEC [56], facilitating the entrance of Cl^- into the cAMP- and/or Ca^{2+} activated Cl^- channel. This K^+ conductance seems likely to result from another not yet identified K^+ channel [50].

Aquaporins-1 and 4 (AQP1 and 4) are water channels that mediate a bidirectional passive movement of water molecules across BEC in response to osmotic gradients and contribute to ductal bile flow. As mentioned above, AQP-1 is located in intracellular vesicles, and co-localizes with both AE2/SLC4A2 and CFTR, which redistribute to the apical membrane upon secretin/cAMP/PKA stimulation [39].

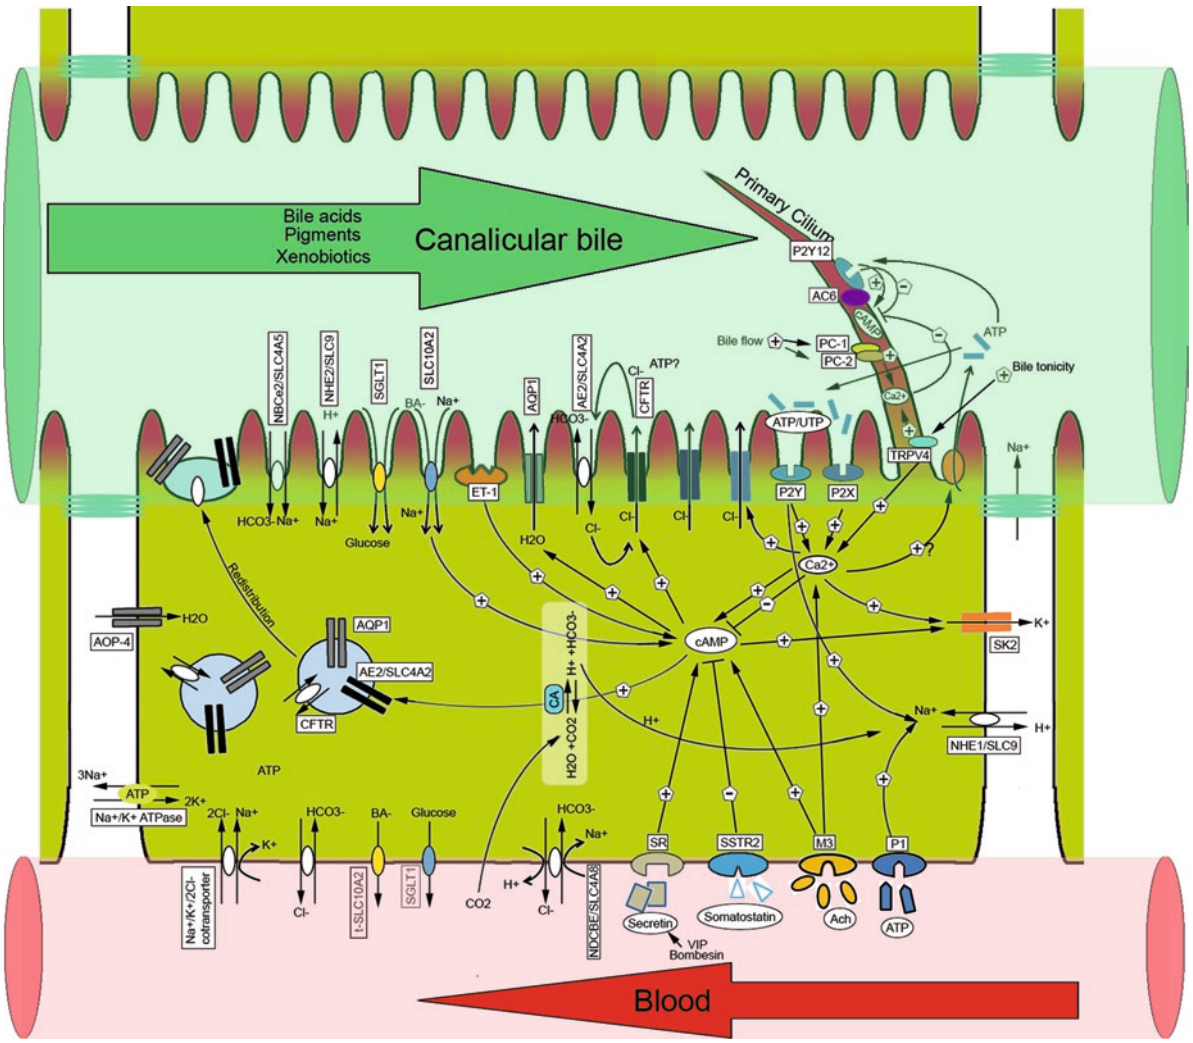

Fig. 4.3 Factors involved in regulation of ion transfer, pHi, and bicarbonate secretion are shown schematically in this figure and described in greater detail in the text.

AQP-4 is another water channel at the basolateral membrane of BEC [57, 58].

Conjugated bile acids [59, 60] are important constituents of bile produced by hepatocytes, but recycled by BEC. They are reabsorbed via an apical sodium-dependent bile acid transporter (SLC10A2, ASBT/ISBT) [59, 61, 62] and are exported through the basolateral membrane into the circulation via a truncated form of the transporter (t-SLC10A2) [63]. SLC10A2 is especially important during cholestasis. In rats, pretreatment of secretin activates SLC10A2 activity and is associated with the cholehepatic shunt pathway.

Regulatory Factors

Hormones

Gastrointestinal hormones and neuropeptides such as secretin, bombesin, vasoactive intestinal peptide (VIP), endothelin-1 (ET1), somatostatin, and gastrin, modulate ductular bile salt-independent flow [64]. These hormones interact with specific G protein-coupled receptors, causing increases in intracellular levels of cAMP and activation of cAMP-dependent Cl^- and HCO_3^- secretory mechanisms.

Secretin is produced mainly by S-cells of the duodenum and jejunum, released into the blood, and plays a pivotal role in the induction of bicarbonate-rich hydrocholeresis in many species [65]. Secretin exerts its physiological actions through its specific receptor SCTR, which is exclusively expressed at the basolateral membrane of BEC [66, 67]. Activation of SCTR stimulates AC/PKA [30, 42, 45, 68, 69] and canalicular 'bile salt-independent flow' [70–72]. Many other hormones contribute to secretin's effects. For example, vasoactive intestinal peptide (VIP), a member of the secretin family of proteins, is produced in neurons of the upper intestine and increases secretin-stimulated bile flow and bicarbonate excretion in humans [65, 73]. The neuropeptide bombesin can increase the release of secretin in dogs [74, 75]. Both these proteins also have pathways that are independent of secretin [76–78].

Somatostatin, produced in pancreatic islet D-cells, and in the stomach and duodenum, binds to its receptor SSTR2 and inhibits the formation of cAMP through AC [79, 80], which in turn, decreases secretin-induced secretion. Gastrin, originating from the stomach and G-cells of the upper intestine, inhibits the effects of secretin by reducing both SCTR expression and cAMP levels [81]. Binding of insulin-like growth factor 1 (IGF1) to its receptor (IGF1-R) was reported to inhibit secretin-induced secretion in bile duct ligated (BDL) rats through activation of PKC and inactivation of secretin-stimulated cAMP/PKA [30, 33].

Other Factors

Acetylcholine transmits parasympathetic signals and stimulates BEC secretion via the M3 muscarinic receptor, which increases cytosolic Ca^{2+} and stimulates cAMP formation via calcineurin [82, 83]. The D2 dopaminergic signal inhibits secretion by activation of PKC-γ(gamma) [84]. And α(alpha)1-adrenergic signals stimulate secretion by activation of AC [85]. There is accumulating evidence that release of ATP into the bile ducts is the final common pathway controlling ductal bile formation, and CFTR is involved in cAMP secretion [86, 87].

The P1 and P2 family receptors might also contribute to control of BEC secretion and anion export [88–93]. The P1 receptor is present on the basolateral membrane and stimulates basolateral NHE activity. The P2Y receptor on the apical membrane binds extracellular ATP found in the bile and activates apical Ca^{2+} dependent Cl^- channels and basolateral NHE that, in the presence of cAMP, stimulates apical AE2/SLC4A2 and bile secretion [91, 94].

BEC Primary Cilium

BEC are the only epithelial cells within the liver that contain primary cilia consisting of a 9+0 pattern microtubule-based axoneme [95]. The cilia extend from the apical plasma membrane into the bile duct lumen enabling detection of changes in bile flow, composition, and osmolality (Fig. 4.3). The physiological implications of BEC cilia are being elucidated.

Bending of BEC cilia by luminal fluid flow induces an influx of extracellular Ca^{2+}, through the functional complex of PC-1 and PC-2, which in turn suppresses cAMP by inhibiting adenylyl cyclase 6 (AC6) [96]. A recent study demonstrated that an osmosensor protein TRPV4 is expressed in rat BEC primary cilia, and is activated with hypotonic changes of bile osmolality [97]. Induction of TRPV4 increases intracellular Ca^{2+}, which in turn, affects ATP released into luminal fluid through unknown mechanisms.

Chemosensation by BEC cilia occurs with the involvement of $P2Y_{12}$, a receptor that is activated by biliary nucleotides (ATP/ADP) causing changes in intracellular cAMP levels [98]. Moreover, mutations in genes encoding ciliary associated proteins causes human congenital cholangiopathies including: (1) Autosomal Dominant Polycystic Kidney Disease (ADPKD) caused by mutations in either *PKD1* or *PKD2*, genes that encode PC-1 and PC-2, respectively [99] and (2) Autosomal Recessive PKD (ARPKD) caused by mutations in a single gene, *PKHD1*, that encodes fibrocystin [100]. This disease association suggests the importance of BEC primary cilia in bile formation and maintenance of BEC homeostasis.

Immune System and Cell Defenses

The immune system plays a critical role in maintaining biliary tract homeostasis and BEC participate in both innate and adaptive immune responses involving the biliary tree. For example, bile is actively involved in the transport of immunoglobulins to the intestine, and BEC's secretion of chemokines, cytokines, and expression of cell adhesion molecules serves to localize and help coordinate various immune responses occurring on, or in the vicinity of BEC. Evidence suggests that BECs may also function as professional antigen-presenting cells (APC) and, in the process, contribute to the modulation of inflammatory reactions. Finally, BECs are also targeted for injury and/or destruction by the immune system in several cholangiopathies (e.g., PBC).

Mechanism Involved in BEC Immune Regulation and Defense

Figure 4.4 shows some of the many possible interactions between BEC and immune cells in the liver. Under normal physiological conditions, the liver contains cells of immune origin and function including dendritic cells, mast cells, natural killer (NK) cells, stellate cells, and T and B lymphocytes, located primarily in the portal space [13]. Liver T lymphocytes contain conventional α(alpha)β(beta) T cell receptor (TCR)$^+$ subpopulations, as well as γ(gamma)δ(delta) TCR$^+$, NKT, and conventional NK lymphocytes (CD41, CD81, and double-negative cells); they altogether account for approximately 25% T cells and 40% NK cells of all hepatic lymphocytes, respectively [101]. Kupffer cells are predominantly distributed on the luminal surface of hepatic sinusoidal endothelial cells. They possess macrophage activities and play an essential role not only in host defense, but also in homeostatic responses [102].

BEC normally are in a quiescent state of the cell cycle [18] and lie on a basement membrane whose matrix is composed of laminin, collagen, and other glycoconjugates. Some basement membrane constituents (e.g. laminin) are produced by the BEC themselves, whereas others are produced by surrounding stromal cells. BEC normally express receptors for anchoring to basement membrane constituents [103]. Alterations of the BEC microenvironment leads to the release of inflammatory mediators, growth factors, and neurotransmitters. Lymphocyte trafficking is typically regulated by membrane glycoprotein adhesion molecules that mediate cell-cell or cell-matrix interactions.

Antigen Presenting Cell Capabilities

So-called "professional" antigen-presenting cells (APCs) present antigens via associations with class I or II major histocompatibility complex proteins (MHC) (or human leukocyte antigen [HLA]) in combination with a variety of co-stimulatory molecules to CD8$^+$ and CD4$^+$ T cells, respectively. In the liver, all cells, including BEC, express at least some level of MHC class I proteins. Class II antigens are found only on endothelial cells, capillary endothelium, and dendritic cells located in the portal, perivenular, and subcapsular areas. BEC under normal conditions are HLA class II negative [14, 104]. Studies on cultured BECs have shown that cytokines like IFN-γ(gamma) and IL-1 can induce the expression of HLA class II, which probably accounts for the upregulation observed in vivo during various cholangiopathies [14, 105, 106]. Intra-peritoneal injection of IL-2 in mice induces HLA class II expression on BEC and lymphocytic infiltration around bile ducts, which appears to be mediated through the induction of endogenous interferon-γ(gamma) [107]. During liver allograft rejection, HLA class II-specific lymphocytes infiltrate the allograft and play a role in the destruction of the biliary epithelium [108]. In addition, PBC patients express increased HLA class II on injured BEC [109].

The role of MHC class II-expressing BEC in inflammatory cholangiopathies is not entirely clear, but evidence suggests that it might enable BEC to function as APCs. However, for sufficient activation and proliferation of naïve T cells by APCs, co-stimulatory molecules such as B7–1(CD80) and B7–2 (CD86) are required along with MHC class II [110]. Leon et al. reported that cultured BEC lacked CD80 or CD86 molecules making them unable to induce effective responses in naïve T cells [111]. In contrast, other groups showed B7-2 expression in damaged BEC of PBC and primary sclerosing cholangitis (PSC) patients, in vivo [109, 112].

In vitro studies showed that cultured BEC expressing co-stimulatory molecules B7-1 and B7-2, were still incompetent at antigen presentation, and could not elicit effective T-cell activation [113]. These paradoxical observations might indicate that BEC present antigens in an inefficient manner to naïve T cells, resulting in specific T-cell anergy or deletion. Alternatively, the antigen presenting machinery of BEC might be effective only for eliciting recall responses in T cells already primed by conventional APC, such as dendritic cells [105, 114, 115].

Adhesion Molecules

BEC express a variety of cell surface adhesion molecules that localize and intensify immune responses (Fig. 4.4). Under in vitro basal conditions, BEC express low to moderate

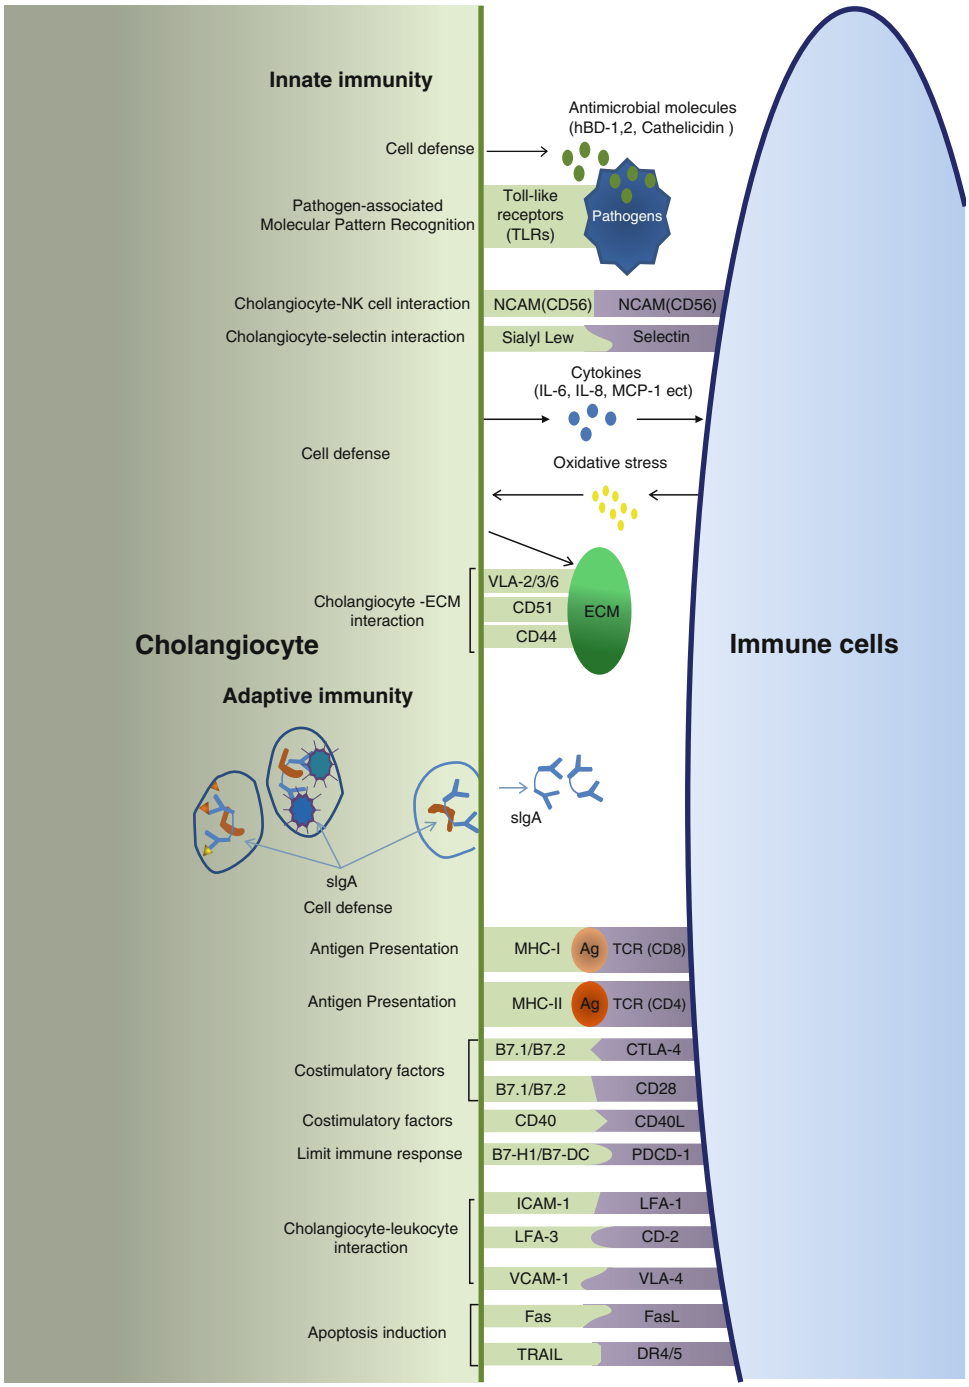

Fig. 4.4 Immune and cell defense of BEC: BEC express adhesion molecules that interact with CD4+ and CD8+ T cells. BEC express MHC class I and class II, and costimulatory factors on their surface, thus BEC can also be targets of cytotoxic injury and/or function as antigen-presenting cells (APCs). BEC also express Fas and TRAIL on their surface, making them susceptible to apoptosis. Moreover, BEC participate in innate immunity by expressing TLR that trigger intra-cellular signaling pathways when confronted with pathogens, and by producing antimicrobial molecules. BEC also produce chemokines and cytokines, which have either autocrine or paracrine effects and modulate immune reactions

levels of intercellular adhesion molecule 1 (ICAM-1), lymphocyte-associated antigen 3 (LFA-3), and MHC class I, but do not express NCAM (neural cell adhesion molecule, CD56), CD51, and MHC class II [14, 103, 116–118]. ICAM induction on endothelial cells is critical for cell-to-cell interactions and leukocyte extravasation at inflammatory sites; ICAM also binds to leukocyte function antigen 1 (LFA-1) present on T cells, neutrophils, and macrophages [119, 120]. On BECs, ICAM-1 expression facilitates binding of cytotoxic lymphocytes and facilitates cell-mediated cytotoxicity

[111]. LFA-3 on the surface of BEC also aids cell-mediated cytotoxicity through interactions with CD2 molecules expressed on cytotoxic T lymphocytes and NK cells [121]. BEC also actively participate in inflammatory reactions and upregulate NCAM (CD56) and CD51 expression in the presence of inflammatory cytokines. NCAM interacts with receptors on NK cells and CD51 assists in binding by recognizing the specific (RGD) sequences in the extracellular matrix (ECM) [103]. A significant increase of ICAM-1, HLA class 1, and HLA class II expression in BEC from normal and PBC liver becomes evident after stimulation with pro-inflammatory cytokines, such as TNF-α(alpha), IFN-γ(gamma), and IL-1 in vitro [14]. Conversely, transforming growth factor β(beta) markedly decreased ICAM expression, whereas it increased the LFA-3 expression [122].

T cells can also be activated by an alternative mechanism that involves CD40 expressed on BEC [122]. Moreover, the CD40/CD40L and the LFA-2/LFA-3 systems trigger production of IL-12, which plays an important role in the cytotoxic response of BEC. CD40 and CD40L expression in BEC are increased, respectively, by stimulation with IFN-γ(gamma) and activation of LFA-2 on T cells [122].

Secretion in Response to Cytokines and Chemokines

Innate immune defenses of the biliary tree are largely coordinated by BECs. By secreting chemokines and cytokines, BECs promote recruitment and activation of circulating leukocytes, resulting in their migration across the portal vein and portal capillary endothelium [12, 112]. Acute cholangitis, biliary obstruction, and other causes of pathological inflammation that target the biliary epithelium, trigger production of these mediators that regulate protective responses against pathogens present in the bile. For example, human BEC constitutively express IL-8 and monocyte chemotactic protein-1 (MCP-1) [123, 124], which are important chemotaxins for neutrophils, monocytes, and T cells. And IL-1 and TNF-α(alpha) increase IL-8 and MCP-1 expression, whereas IFN-γ(gamma) inhibits IL-8 production and upregulates MCP-1 [123]. MCP-1, but not IL-8, is also upregulated by lipopolysaccharide (LPS) stimulation of toll like receptor 4 (TLR-4) and subsequent NF-κ(kappa)B signaling in the absence of inflammatory cytokines [124].

Damaged BEC express TNFα(alpha) and IL-6 and their receptors (TNF-R and IL-6 α(alpha)-chain) [125], and IL-6 expression is upregulated by IL-1 or LPS stimulation [124, 126]. The IL-6 production induced during BEC damage aids in proliferation and biliary wound healing [126, 127]. BEC TNF-α(alpha) and IL-6 production is also involved in recruitment and stimulation of immune cells for the following reasons: IL-6 promotes terminal differentiation in certain T cell subsets and immunoglobulin secretion of B cells; TNF-α(alpha) increases cytotoxic activities of T cells; and TNF-α(alpha) induces the expression of adhesion molecules and HLA antigens on BEC. Thus BEC participate in innate responses as well as antigen specific adaptive immune responses. Furthermore, BEC IL-6 and TNF-α(alpha) production can also contribute to BEC apoptosis and nearby inflammation probably through autocrine mechanisms [128].

Stress, Apoptosis and Senescence-Related Changes

So-called, "vanishing bile duct syndromes" (a reduction in the number of bile ducts, or ductopenia) can be the end result of several immune-mediated liver diseases, such as chronic allograft rejection, cholangitic adverse drug reactions, PBC, PSC, and GVHD. In these disorders, BEC loss prevails over proliferation and apoptosis is the major process by which BEC die [129]. Although BEC are capable of antigen presentation useful for clearance of pathogens and preventing unwarranted infections, BEC are also targeted for injury or death/apoptosis by the immune responses.

Fas receptor/Fas ligand is the most thoroughly characterized BEC apoptotic pathway. BEC are sensitive to Fas-mediated apoptosis, and Fas expression is upregulated by IFN-γ(gamma), TNF-α(alpha), IL-4, and CD40 [122, 125, 130–133]. TNF-α(alpha) produced by inflammatory cells in the portal tract during inflammation can induce BEC apoptosis through TNF-R1 receptor followed by caspase 3 activation [134]. And BEC TNF-α(alpha) receptor expression is upregulated in PBC and PSC patients [125].

CD40 is a member of the TNF receptor superfamily, and CD40 ligand (CD40L) is upregulated on leukocytes from PBC patients [133]. Moreover, CD40 increases BEC expression of Fas/FasL and transcription of NF-κ(kappa)B and activator protein 1, which could result in autocrine and paracrine BEC apoptosis [133]. BEC might also be able to dampen immune responses by binding to PD-1 on leukocytes, which induces leukocyte apoptosis [135]. PD-1 ligands are B7 family members (programmed death-ligand 1 (PD-L1) (B7-H1) and PD-L2 (B7-DC)) normally expressed at low levels on BEC. Expression of B7-H1 is also induced in cultured human BEC following treatment with IFN-γ(gamma) [135]. TNF-related apoptosis-inducing ligand (TRAIL) is a ligand for death receptors 4 and 5 (DR4, DR5), which are expressed on BEC and upregulated by BDL. TRAIL binding and agonistic anti-DR5 antibodies can result in apoptosis of DR5-expressing BEC in certain mouse strains [136]. Although absent in normal conditions, the expression of

TRAIL on BEC is upregulated in patients with PBC and PSC [136]. Apoptosis is also regulated by bcl-2 family members, which are either pro-apoptotic (bcl-xs, bax, bad, or bak) or anti-apoptotic (bcl-2, bcl-xL, mcl-1, or bfl-1) [137]. The expression of bcl-2 in BEC is regulated by glutathione (GSH), a natural antioxidant [138].

Responses to Oxidative Stress and Senescence-Related Changes

Oxidative stress is characterized by the generation of reactive oxygen species (ROS), including the superoxide anion (O_2^-), H_2O_2, –OH, and singlet oxygen [139]. Oxidative stress is a common component of inflammation because of the generation of ROS by inflammatory cells and promotion of radical formation by cytokines [140–142]. ROS is also produced within BECs by nitric oxide synthetase induced by chronic inflammation [143], and is known to induce genotoxic damage [143, 144]. Almost one-half of GSH, the water soluble antioxidant, released by the adult liver, is secreted into bile and reabsorbed by BEC, raising the possibility that BEC GSH is an important BEC defense mechanism [138]. For example, in PBC, tissue GSH levels are markedly reduced. And oxidative stress in PBC BEC is accompanied by cellular GSH depletion [145], decreased Bcl-2 expression [138, 146], and active lipid peroxidation [147], which act together to promote BEC apoptosis. Recently, it has been shown that aberrant expression of genes associated with abnormal oxidative stress, or susceptibility to ROS such as Anion exchange protein 2 ($Ae2_{ab}$) [148], *GSTM1* [149], and *SPRR2A* [150] are upregulated during the progression of various cholangiopathies such as PBC, cystic fibrosis, and cancer.

Cellular senescence is defined as irreversible cell arrest that acts as a safeguard against tumorigenesis [151]. In BEC, cellular senescence results from the aberrant expression of cell cycle regulators like WAF1, p53, p16, and p21 followed by irreversible G1 cell cycle arrest and apoptosis, which deletes genetically damaged cells during carcinogenesis [152, 153]. In mouse BEC, H_2O_2 treatment to promote oxidative stress or exposure to pro-inflammatory cytokines such as INF-β(beta), INF-γ(gamma), and TNF-α(alpha) induce cellular senescence [154]. In PBC livers, cellular senescence progresses in response to genotoxic damage from oxidative stress, which in turn, results in upregulation of WAF1 and p53 in BEC [152]. And during the early phase of chronic liver allograft rejection, cellular senescence changes, including cell enlargement and multi-nucleation, occur in association with TGFβ(beta)1 and p21 expression and both decrease with successful treatment and recovery [153]. Moreover, telomere shortening and an accumulation of DNA damage coincide with markers of BEC senescence, such as increased expression of p16 and p21, which occurs in damaged BEC in PBC. Eventually, these senescent BEC are thought to contribute to progressive bile duct loss typical of this disorder. Recent studies from Nakanuma et al. showed that stemness genes *Bmi1* and *Ezh2* modulate BEC senescence in PBC [155], hepatolithiasis [156], and intrahepatic cholangiocarcinoma [157] through p16 expression.

SPRR2A

Small proline-rich proteins (SPRR) are encoded by a tandemly arranged four-member gene family of the Epidermal Differentiation Complex (EDC). *SPRR* (*SPRR1–4*) genes encode for a series of highly homologous proteins that function primarily as critical cross-linkers with other EDC genes [158–161]. Numerous gene array expression studies show *SPRR2A* to be among the most highly upregulated genes in many non-squamous, stressed and remodeling barrier epithelia (reviewed in [150]). In normal mouse liver, SPRR2A mRNA and protein are not expressed, but are non-coordinately upregulated in BEC after the stress of BDL [162]. Expression levels of SPRR2A after BDL are not related to squamous metaplasia and show strong dependence on IL6/gp130/STAT3 signaling. Deficient BEC *SPRR2A* expression in IL-$6^{-/-}$ mice following BDL is associated with impaired barrier function [162]. IL-6 replacement therapy restores *SPRR2A* expression to levels seen in wild type controls, and reverses the barrier defect in IL-$6^{-/-}$ mice. Moreover, a recent study demonstrated that forced expression of SPRR2A in a bile duct cancer cell line induces epithelial-mesenchymal transition (EMT), and promotes wound restitution by enhancing migration [150]

Other Defense Systems Against Pathogens

Immunoglobulin

Bile protein mainly consists of albumin and immunoglobulin [13]. IgG and IgM, whose origins are either intrahepatic or from plasma, are present in bile and provide immune defense against pathogens [163, 164]. However, secretory immunoglobulin A (sIgA) is the predominant immunoglobulin type of the mucosal immune system and participates in immunological protection at mucous membrane surfaces including the biliary tree. Bile contains approximately twice the concentration of sIgA compared to that found in the upper intestinal luminal fluid [165], and is composed of two IgA molecules, a peptide J chain, and a secretory component [166].

In humans, sIgA is synthesized by plasma cells in proximity to bile ducts, transported to the luminal surface, and secreted

into bile after binding to pIgR (also known as membrane secretory component [SC]) located on the BEC basolateral membrane [167, 168]. Proposed sIgA functions are: (1) binding to and neutralizing pathogens or bacterial toxins to prevent their adhesion to the BEC mucosal surface. Studies in rats demonstrated that bile contains natural IgAs directed against a variety of intestinal bacteria, and that inoculation of various antigens into the intestinal lumen or intestinal lymphoid tissues triggers a secretion of specific IgA antibodies [169]; (2) forming immune complexes with free antigens, facilitating their excretion. This reduces the systemic response caused by pathogens and prevents chronic inflammation derived from antigens [170, 171]; (3) binding to intracellular pathogens and their products during the transcytosis process [172].

The enzymes lactoferrin and lysozyme, which are produced by peribiliary glands, are also part of the defense against bacterial infections in the biliary tree [173].

Toll-Like Receptors

Epithelial immune detection and responses against microbial infection sometimes involve activation of pathogen pattern recognition receptors on BEC, and subsequent intracellular signaling. This signaling cascade triggers expression of a variety of proteins involved in immune responses, such as adhesion molecules, inflammatory mediators, and antimicrobial peptides. Toll-like receptors (TLRs) are the best characterized of these pattern recognition molecules, and BEC express all 10 of the known human TLRs [174]. TLR ligands include bacterial molecules, double or single stranded RNA, CpG, and LPS. The NF-κ(kappa)B and mitogen-activated protein kinase (MAPK) pathways are essential components of this immune defense in BEC [124, 175]. BEC TLR signaling can produce TNF-α(alpha), IL-6, IL-8, and IL-12, which could recruit and activate T-cells, macrophages, and NK cells to prevent or clear various biliary infections.

Antimicrobial Molecules

Defensins and cathelicidins are anti-microbial small cationic peptides belonging to the innate immune system [176]. They protect mucosal barriers by killing pathogens through membrane disruption. Defensins and cathelicidins also participate in adaptive immunity by recruiting $CD4^+$ T cells and immature dendritic cells [177]. Human β(beta)-defensin 1 (hBD-1) is constitutively expressed in the normal intrahepatic BEC, whereas hBD-2 is undetectable in normal bile ducts. However, hBD-2 is upregulated following *Cryptosporidium parvum* infection in a TLR–dependent manner, [174] and after IL-1β(beta) or TNF-α(alpha) treatment [178]. hBD-2 is expressed almost exclusively by BEC in large, diseased bile ducts. Cathelicidin is expressed by normal BEC, as well as hepatocytes. Bile salts and therapeutic bile salts, including chenodeoxycholic acid and ursodeoxycholic acid (UDCA), enhance cathelicidin expression through the farnesoid X and the vitamin D receptors [179].

Key components of anti-RNA viral immunity in the liver are Mx proteins, a class of dynamin-like large guanosine triphosphatases (GTPases), which are induced by IFNs [180]. Recent studies reveal that BEC express Mx proteins under pathological conditions, including chronic and fulminant hepatitis. And, significant increases of MxA proteins are found in patients with biliary atresia and in cultured BEC stimulated with a synthetic analog of viral dsRNA [181–183].

Trefoil Factor Family

The Trefoil factor family (TFF1, TFF2, and TFF3) contribute to biliary protection by increasing mucous viscosity [184–186], and are involved in biliary restitution following injury by promoting epithelial cell spreading and migration [187, 188]. Mouse and human BEC express predominately TFF3, mainly in the large bile ducts and peribiliary glands [189–192]. TFF expression is upregulated or induced in response to injury [192]. For example, expression of all TFFs is augmented markedly in BEC in hepatolithiasis and detected in the hepatic bile of hepatolithiasis patients [191]. BEC TFF3 expression is regulated through IL-6/gp130 signaling, with expression primarily dependent on STAT3 signaling and reciprocal negative regulation through the MAPK signaling pathway [193]. In addition, biliary TFF3 is also regulated by cytokines and growth factors (e.g. HGF and TGF-β(beta)) [189]. TFF3 expression is significantly higher in $IL\text{-}6^{+/+}$ than in $IL\text{-}6^{-/-}$ mouse livers, and in vitro $IL\text{-}6^{+/+}$ BEC show better migration and wound healing than $IL\text{-}6^{-/-}$BEC[189]. Following BDL, $IL\text{-}6^{-/-}$ mice have a chronic deficiency of biliary TFF3 expression and impaired biliary barrier function. Defective BEC migration in the $IL\text{-}6^{-/-}$ can be significantly reversed by treatment with recombinant TFF peptides. [189] In humans, p-STAT3 and TFF3 are co-expressed in BEC that are involved in florid duct lesions in PBC, and at other sites of BEC injury [189, 190]. This likely constitutes a primitive or innate mucosal defense system that guards against injury and stimulates repair.

BEC Proliferation and Wound Healing

The vast majority of BEC in the normal liver resides in G_0 of the cell cycle, but maintains the ability to divide throughout

adult life. BEC proliferation can restore defects and/or subsequently distort the biliary tree architecture in response to injury. An exuberant response of the smallest BEC to injury is thought to play a key role in the initiation and progression of liver fibrosis. Proliferating BEC can acquire mesenchymal, neuroendocrine [194], and progenitor cell characteristics and interact with other liver cells during repair responses (Fig. 4.2). The proliferative response of BEC is regulated through a complex integration of an array of microenvironmental cues, including interactions with matrix, cytokines, growth factors, gastrointestinal and neuroendocrine hormones via autocrine, juxtacrine, and paracrine signaling pathways (Table 4.1). In turn, several other liver cell types are activated by mediators secreted by proliferating BEC [18, 128].

Crosstalk Between Proliferating BEC and Other Liver Cells

Cellular cross talk among BEC and other liver cells exists and are active during development of the cholangiopathies (Fig. 4.2). In many cholangiopathies, small BEC upstream from the site of injury undergo proliferation, which in turn, usually provokes an extensive fibrotic response in the portal and periportal regions (Fig. 4.2). BEC do so by producing a variety of cytokines and growth factors that stimulate nearby stromal cells, such as platelet-derived growth factor (PDGF), transforming growth factor-β(beta) (TGF-β(beta)), endothelin-1 (ET-1), vascular endothelial growth factor (VEGF), insulin-like growth factor 1 (IGF-1), nerve growth factor (NGF), and nitric oxide (NO) [195–200]. BEC also synthesize basement membrane proteins such as laminin and collagen type IV [201, 202]. Many studies indicate that BEC are the major source of connective-tissue growth factors and consequently play an active role in stimulating the fibrogenic response, possibly by activating quiescent portal (myo-)fibroblasts and hepatic stellate cells (HSC). For example, portal (myo-)fibroblasts express NTPDase2 under normal conditions, which inhibits activation of basolateral P2Y receptors on BEC. When portal fibroblasts lose their NTPDase2 expression, BEC P2Y receptors are activated by nucleotides and downstream events lead to bile duct proliferation [203]. Proliferating BEC trigger portal fibroblast proliferation and myofibroblastic trans-differentiation in a paracrine fashion via release of the cytokine MCP-1 [204].

HSC have a central role in producing connective tissue in the liver, and their activation in cholangiopathies leads to a proliferative myofibroblast phenotype (Fig. 4.2). A recent study showed that during cholestasis, BEC participate in crosstalk with resident portal fibroblasts and injury-activated myofibroblastic HSC through Hedgehog (Hh)-mediated mesenchymal–epithelial interactions [205]. Mesenchymal cells produce Hh ligands that enhance the viability and proliferation of BEC, which in turn produce Hh ligands that promote the growth of myofibroblast cells.

Hepatocytes release purines into the bile that could potentially activate basolateral and apical P2Y receptors on BEC, resulting in Ca^{2+} signaling and activation of anion secretion. Hepatocytes also produce IGF-I and release insulin, which could activate apical receptors on BEC, and induce ERK1/2 and PI3K signaling [196, 206]. Conversely, proliferating BEC produce IGF-1, NGF, and VEGF and secrete them into the peri-biliary vascular plexus (PBP). These mediators subsequently reach the hepatic sinusoids, which in turn, aid hepatocyte survival during cholestasis [9, 207] (Fig. 4.2).

There is also crosstalk between proliferating BEC and endothelial cells of the peribiliary vascular plexus (Fig. 4.2), which is the sole source of their blood supply. BEC secrete the vasoactive substances VEGF-A and VEGF-C, which could stimulate angiogenesis resulting in remodeling of the bile duct vascular supply in response to the enhanced nutritional and functional demands of proliferating cells [197]. This relationship is supported by observations in a rat BDL model, where proliferation of intrahepatic bile ducts was associated with proliferation of the peribiliary plexus [208]. Moreover, VEGF secreted by proliferating BEC stimulate their self proliferation in an autocrine manner [197].

Epithelial-Mesenchymal Transition

Epithelial-Mesenchymal Transition (EMT) refers to the process in which mature epithelial cells lose the cell–cell contacts and protein expression patterns characteristic of epithelia, and acquire the phenotypic characteristics of mesenchymal cells (e.g., loss of E-cadherin). EMT is associated with decreased adhesion and enhanced motility, which have the potential to increase malignant behavior and an unfavorable clinical outcome in several human cancers [209]. Recently, the miR-200 family was shown to suppress EMT through down-regulation of transcription factors ZEB1 and ZEB2 [210]. And there is accumulating evidence that proliferating BEC have a role in the induction of fibrosis, either directly via epithelial-mesenchymal transition (EMT), or indirectly via activation of nearby portal myofibroblasts. For example, recent studies in biliary atresia [211], PBC [212], and chronic liver disease [213] suggested that proliferating BEC directly contribute to fibrogenesis directly via EMT. However, the extent to which this occurs needs to be studied further.

Table 4.1 Factors, receptors, pathways and effects on cholangiocytes proliferation

Hormone/factor	Receptor/ligand	Signal in cholangiocyte	Effect on proliferation	References
Somatostatin	SSTR2	cAMP	↓	[79, 80]
Gastrin	CCKB/gastrin receptor	IP3R/Ca^{2+}/PKC(α(alpha)/β(beta) I/β(beta)II)	↓	[228]

Common Intracellular Signaling Pathways Mediating BEC Proliferation

cAMP/PKA/ERK1/2

Mediators that modulate BEC proliferation (Table 4.1) are associated with changes in intracellular cAMP levels. In mammalian cells, cAMP activates the cAMP-dependent protein kinase PKA, which controls many cellular processes [214]. Acetylcholine, forskolin, dobutamine, and clenbuterol [215–217] increase intracellular cAMP levels, whereas gastrin [79], somatostatin [79], serotonin [218], 6-hydroxydopamine (6-OHDA) [217], and vagotomy [215] decrease intracelluar cAMP levels (Table 4.1).

Mitogen-activated protein kinases (MAPKs) are a widely conserved family of serine/threonine protein kinases involved in many cellular processes. One such MAPK, ERK1/2, can activate signaling in response to a diverse range of extracellular stimuli, including growth factors, and cytokines [219]. Forskolin, an adenylate cyclase (AC) stimulator, supports cAMP dependent BEC proliferation by activating PKA/ERK1/2 and SRC phosphorylation [220]. ERK1/2 is also involved in BEC proliferation through many other stimulators (Table 4.1). There are also multiple AC isoforms that have specific effects on BEC [221, 222]. Although mediators involved with these AC isoforms

are yet to be elucidated, stimulation of AC1 and AC8, and inhibition of AC5 and AC6 resulted in enhanced secretion and proliferation of BEC [221].

PI3K/AKT

Phosphoinositide 3-kinase (PI3K) catalyzes the production of phosphatidylinositol-3,4,5-triphosphate by phosphorylating phosphatidylinositol (PI), phosphatidylinositol-4-phosphate (PIP), and phosphatidylinositol-4,5- bisphosphate (PIP2). In BEC, growth factors and hormones trigger this phosphorylation event, which in turn, promotes cell growth and cell survival [221]. Activation of AKT, which is downstream of PI3K, increases in proliferating BEC of a rat BDL model [223]. In addition, many mediators, including bile acids [224] are involved in PI3K/AKT associated BEC proliferation (Table 4.1).

IP3R/Ca^{2+}/PKC

Inositol 1,4,5-triphosphate receptor (IP3R) is a member of the intracellular calcium release channel family and is located in the endoplasmic reticulum. There are three types of IP3R (IP3R 1, 2 and 3) [225, 226] that have the potential to stimulate the release of intracellular stores of Ca^{2+} [227], although the specific role of IP3R has not been established in BEC. IP3R plays a pivotal role in modulating the effects of different BEC mitogens or mito-inhibitors. For example, a recent study showed that dysregulation of IP3R/Ca^{2+} signaling is involved in cholestasis. The stimulatory or inhibitory effects on BEC proliferation and secretion depend on the PKC isoforms, which are downstream of this signal. PKCα(alpha), is activated by serotonin [218], ursodeoxycholate, and tauroursodeoxycholate [217], whereas gastrin activates PKCα(alpha), PKCβ(beta)I, and PKCβ(beta)II [228], and this results in inhibition of BEC proliferation and secretion. Furthermore, the activation of specific PKC isoforms is important in modulating cAMP dependent BEC proliferation and secretion [85].

Receptor Tyrosine Kinase (RTK)/Ras/MEK/ERK1/2 and STAT3

RTK/Ras GTPase/MAPK and STAT3 signaling pathways are used by BEC to control many different biological processes [18] and HGF, IL-6, and EGF trigger these signaling cascades. However, there are some differences in signal transduction among these cytokines. HGF activates the receptor tyrosine kinase met, resulting in phosphorylation of different intracellular transducers such as: SH2 motifs, such as the p85 subunit of PI3-kinase; Ras Gap; PLC-g; Src-related tyrosine kinases; the Grb-2 adaptor for SOS and Gab-1; and IRS-like multiadaptor protein [18]. Activation of the Ras/ERK1/2 pathway leads to cellular proliferation, whereas the PI3K pathway induces mitogenesis [229].

IL-6 binds to the ligand-specific IL-6 receptor α(alpha) (IL-6Rα(alpha)) or gp80, which leads to phosphorylation of gp130, the common transmembrane receptor that contains the signaling domain, and the associated Janus kinases (JAKs). Phosphorylation of specific tyrosine residues in both gp130 and JAKs induces at least three distinct signal transduction pathways; (1) JAKs; (2) SHP-2/RAS/MAPK; and (3) STAT3 [18]. In BEC, MAPK signaling induces mitogenesis [230], whereas STAT3 signaling is associated with wound healing and ductular reaction [127]. EGF binds to EGFR (ErbB1/Her1), which results in aggregation of EGFR, homo- and heterodimeric interaction within the ErbB family proteins, and trans-phosphorylation of multimeric complexes [231]. A number of intracellular substrates are activated by these trans-phosphorylations including PLC-γ(gamma), the GTPase-activating protein (GAP) of the Ras proto-oncogene and lipocortin I [18].

Factors Regulating BEC Proliferation

The various factors involved in regulating cholangiocyte proliferation are summarized in Table 4.1. Each is discussed in more detail below.

Extracellular Matrix

Growth, differentiation, and maintenance of cultured BECs are greatly affected by the substratum: (a) tissue culture plastic alone; (b) type I collagen in the form of (1) a collagen-coating, (2) a thicker collagen gel or (3) overlaid double collagen gel; (c) fibronectin and; (d) matrigel, which is composed of Type IV collagen and laminin [18]. Plastic alone and collagen coatings usually promote terminal senescence whereas thicker collagen gels trigger signaling pathways that promote extended passes [18]. CD44, a multifunctional adhesion molecule, is responsible for a number of cell–cell and cell–matrix interactions [232, 233] and has been implicated in BEC proliferation. CD44 and hyaluronic acid, the main component of the ECM, are among the pro-proliferative factors for BEC in cholestatic livers [234]. $CD44^+$ BEC are found closely associated with extracellular hyaluronic acid accumulated in the portal tracts of livers after BDL. Furthermore, in vitro BEC proliferation can be stimulated by hyaluronic acid treatment, and blocked by siRNA or antibody directed against CD44 [234]. And high expression levels of hepatic

CD44 have been observed in patients with PSC and cholangiocarcinoma [235, 236].

Bile Acids

The hydrophilic bile acid ursodeoxycholic acid (UDCA) and the UDCA conjugate tauroursodeoxycholic acid (TUDCA) inhibit BEC proliferation after BDL [237–239], whereas other bile salts, specifically the hydrophobic bile acids taurocholic acid (TA) and taurolithocholic acid (TCA), can stimulate BEC proliferation isolated from the larger bile ducts [240] in normal and BDL rats [241]. Other hydrophobic bile acids such as glycocholic acid (GC) and glycochenodeoxycholic acid (GCDC) decrease BEC proliferation at high concentrations [238]. The different effects of various bile acids on BEC proliferation are associated with changes in intracellular cAMP and PKCα(alpha) levels [238, 240], as discussed above.

Hormones

Both somatostatin and gastrin inhibit BEC proliferation [79, 228]. Somatostatin exerts its inhibitory effect through the SSTR2 receptor by decreasing intracellular cAMP levels [79, 80]. Somatostatin and its analog octreotide also decrease BEC proliferation after BDL, and in polycystic kidney diseased rats [85], it also inhibited cholangiocarcinoma growth, suggesting potential clinical usefulness [242–244]. Similar to somatostatin, gastrin inhibited BEC proliferation by decreasing cAMP in BDL rats and reduced cholangiocarcinoma growth through its receptor CCK-B [228, 245, 246]. Glucagon-like peptide 1 (GLP1), which maintains glucose homeostasis, and its receptor agonist extendin-4, both induced BEC proliferation via cAMP/PKA, PI3K, and Ca^{2+}/CAMKIIα(alpha) pathways in cholestatic rats [247].

Based on the female prevalence of PBC [205], and symptomatic autosomal dominant polycystic liver and kidney disease [248], estrogen has been considered for many years to play a role in the development of cholangiopathies. [249] In rats, BEC express both estrogen receptors (ER-α(alpha) and ER-β(beta)), and expression levels increase during cholestasis after BDL [250]. Modulation of BEC proliferation by estrogen was also confirmed by using 17β(beta)-estradiol on cultured BEC, using an anti-estrogen reagent (tamoxifen) or ER antagonist (ICI 182,780) on male BDL rats, and by studying BDL on ovariectomized female rats [250–252]. These experiments linked estrogen to activation of the cAMP/PKA and Src/ERK1/2 pathways.

Progesterone and its receptors (mRPα(alpha), PRGMC1, and PRGMC2) are also involved in proliferating BEC in both males and females. A study in rats showed that progesterone or supernatants from normal and BDL BEC cultures increased BEC proliferation, and this effect was prevented with anti-progesterone antibody or aminoglutethimide treatment [253]. Recently, other studies showed that pituitary hormones, such as follicle stimulating hormone (FSH) and prolactin, regulate BEC proliferation in rats [254, 255]. FSH uses the cAMP/ERK1/2 pathway, whereas prolactin uses the IP3R/Ca^{2}+/PKC pathway.

Thyroid hormone was also shown to influence proliferation. BEC from normal and BDL rats express alpha(1)-, alpha(2)-, beta(1)-, and beta(2)-thyroid hormone receptors (THRs). The thyroid hormone agonist 3,3′ 5 1-tri-iodothyronine (T3) decreased BEC proliferation in vivo in BDL rats through the IP3R/Ca^{2+}/ERK1/2 pathway. Reversal of the T3 effect was shown in vitro, through chemical inhibition of T3 with U-73122 and BAPTA/AM [256]. BEC also respond to growth hormone (GH) with production and release of IGF1 that modulates cell proliferation by transduction through IGF1-R involving both ERK and PI3K pathways. BEC, which normally express IGF1, IGF1-R, and GH-R, overexpress these molecules during BDL-induced BEC proliferation. Moreover, IGF1 and estrogen reciprocally potentiate their proliferative effects on BEC by interacting at both receptor and post-receptor levels [196].

Neuropeptides

Acetylcholine (Ach) normally transmits parasympathetic signals and stimulates secretion through the M3 muscarinic receptor in BEC, resulting in increased cytosolic Ca^{2+} and cAMP formation via calcineurin [82, 83]. The cholinergic effect of ACh on BEC proliferation has been confirmed in a BDL model where rats underwent total vagotomy [215], which downregulated the M3 receptor, decreased intracellular cAMP levels, and impaired BEC proliferation. Administration of forskolin to stimulate acetylcholine release, maintained cAMP levels and prevented the effects of vagotomy on BEC proliferation [215]. Proliferating BEC from BDL rats express the β(beta)1 and β(beta)2 adrenergic receptors [217]. Chemical adrenergic denervation of the liver via the administration of 6-OHDA also inhibited BEC proliferation, increased the number of apoptotic BEC, and decreased intracellular cAMP levels with concomitant impairment of the PKA/ERK1/2 and AKT signaling pathways. The effect of 6-OHDA on proliferation was partially reversed by concurrent treatment with clenbuterol (β(beta)2-adrenergic agonist), dobutamine (β(beta)1-adrenergic agonist), taurocholate, and forskolin [217, 257].

BEC express the serotonin 1A and 1B receptors. Their activation markedly inhibits the growth and choleretic activity of BEC lining the intrahepatic biliary tree during BDL, with downregulation of the IP3R/Ca^{2+}/PKC and cAMP/PKA/Src/ERK1/2 signaling pathways. BEC also secrete serotonin,

and blocking the secretion during the course of cholestasis enhances BEC proliferation. This illustrates the existence of a serotonin-based autocrine loop during the proliferative response of BEC during cholestasis.

Gigliozzi et al. demonstrated the existence of a nerve growth factor (NGF)-based autocrine signaling loop that modulates BEC proliferation via AKT- and ERK1/2-dependent pathways [258]. Inhibition of NGF during BDL in rats resulted in decreased biliary mass attributable to both reduced proliferation and enhanced BEC apoptosis. They proposed that regulation of BEC proliferation by stimulatory and inhibitory autocrine/paracrine loops (such as serotonin and NGF) during cholestasis plays an important role in the pathogenesis of cholestatic liver diseases [259].

Normal BEC after BDL express all of the histamine receptors (H1R-H4R) [260, 261] and the effect of histamine signaling on BEC proliferation is dependent on the specific receptor subtype involved. H3R is significantly increased in proliferating BEC after BDL in rats. Its activation through administration of histamine or the agonist (R)-(-)-α(alpha)-methylhistamine dihydrobromide (RAMH) decreased the growth of the biliary tree without increasing apoptosis and involved the cAMP/PKA/ERK1/2/Elk-1 pathway [260]. In contrast, activation of H1R in small BEC with the agonist histamine trifluoromethyl toluidide (HTMT dimaleate) resulted in increased BEC proliferation through the IP3R/Ca^{2+}/CaMK I/CREB pathway. Lastly, a recent study demonstrated that biliary expression of the α(alpha)-type calcitonin gene-related peptide 1 (α(alpha)-CGRP), which is a potent vasodilator, regulates BEC proliferation during cholestasis through PKA and CREB activation [262].

Cytokines and Growth Factors (Reviewed in [18, 259])

VEGF is a key regulator of biliary proliferation during cholestasis [197, 263]. And as mentioned above, BEC proliferation precedes the expansion of the peribiliary vascular plexus in the intrahepatic biliary tree after BDL [197]. VEGF regulates BEC proliferation during cholestasis in an autocrine manner through upregulation of VEGF secretion and VEGF2/VEGF3 receptor expression. And BEC proliferation can be induced in normal rats by treatment with recombinant VEGF-A and VEGF-C. VEGF-induced BEC proliferation involves the IP3R/Ca^{2+}/ PKCα(alpha) pathway and phosphorylation of Src and ERK1/2 [197].

In normal livers, IL-6 is produced at low levels by the BEC, [264] and secreted into the bile [125]. Virtually any bile duct insult, such as obstruction [265–267], infection [267, 268], or immunologic damage [125, 269, 270] triggers an increase in IL-6 production by BEC and peribiliary hematolymphoid cells [18]. Active IL-6/gp130/STAT3 signaling can be detected in normal IL-$6^{+/+}$, but not IL-$6^{-/-}$ mouse livers. Activated STAT3 (pSTAT3) in the normal biliary tree localizes to occasional BEC lining the large bile ducts and peribiliary glands [189]. pSTAT3 alerts BEC to environmental stimuli and leads to subsequent autocrine, paracrine, and juxtacrine gp130/STAT3 signaling at the site of injury [162, 189, 265, 266]. As in the gastrointestinal tract [193] and skin [271, 272], the absence of IL-6 in IL-$6^{-/-}$ mice leads to impaired wound healing [189] and poor biliary tree integrity [162, 189, 273].

HGF is one of the most well characterized mitogens for BEC [126, 274–276]. In the normal quiescent liver, low levels of HGF are produced primarily by hepatic stellate cells and neutrophils, but not hepatocytes or BEC. It exerts a paracrine effect on BEC, inducing mitogenesis, cell motility, and matrix invasion [265, 277, 278]. HGF/met signaling is likely to be of particular significance in proliferating BEC. Met is a receptor tyrosine kinase, which is expressed in vivo on normal human and mouse BEC, as well as cultured BEC [265, 274, 279]. HGF binding activates the Ras and PI3K pathways [229]. Periductal HGF production is increased after BDL and remains elevated during the BEC proliferative response [274, 280]. When BEC are injured, HGF/met signaling activates BEC proliferation, with eventual disruption of the limiting plate when BEC extend into the periportal hepatic parenchyma [281–283]. Also, adding HGF to BEC cultures containing three dimensional ductal structures causes the BEC to lose polarity, and promotes BEC invasion into the collagen gels, creating an anastomosing network of BEC [283]. In humans, proliferating BEC in hepatolithiasis and PSC have increased expression of met receptor [279, 283].

EGF is one of the EGF family members that binds specifically to EGFR (or Erb1/Her1) [231, 284]. Of all the non-neoplastic cells within the body, hepatocytes express the highest density of EGFR [284]. But EGFR is also expressed on normal BEC in vivo, as well as cultured BEC [285, 286], and BEC are capable of receptor-mediated endocytosis of EGF [286]. In addition to the BEC proliferative response, EGF signaling contributes to biliary ductal morphogenesis. Rat BECs cultured in the presence of EGF form structures that very closely resemble the polarized hyperplastic bile ductules/ducts seen in vivo [287].

There is also strong circumstantial evidence that EGF and its family members can contribute to ductular reactions, in vivo. BDL causes a significant increase in liver EGF [280, 288], which is coincident with BEC/hepatocyte proliferation, and the downregulation and translocation of EGFR to the nucleus [289]. Moreover, monkeys experience BEC hyperplasia following intravenous recombinant EGF infusion [290]. Studies also show that TGF-α(alpha) protein is produced by hepatocytes and released into the bile, where it has the potential to cause biliary proliferation and transformation through EGFR [285]. ErbB2/Her2, one of the EGF family member receptors, also has the potential to induce

BEC proliferation associated with MAPK and cyclooxygenase-2 (COX-2) [18].

The COX enzymes convert arachidonic acid (AA) to prostaglandins. Over-expression of COX-2 is associated with inflammation and neoplasia. COX-2 has been observed in non-neoplastic hyperplastic BEC in patients with hepatolithiasis and PSC [291], and in a variety of human and rat cancers [291, 292]. COX-2 expression has been mechanistically linked to ErbB2 signaling [293]. Consequently, over expression of ErbB2 in the biliary tree of transgenic mice induced COX-2 expression [294]. COX-2 inhibitors suppress the growth of cholangiocarcinoma cell lines, in vitro [291, 295]. In addition, both HGF and IL-6 induce production of arachidonic acid (AA), PGE2, and PGF2 (alpha) in a cholangiocarcinoma cell line [295]. Moreover, COX-2 inhibitors block HGF and IL-6-induced proliferation in these cholangiocarcinoma lines, suggesting that their growth stimulating effects may be at least partially dependent on prostaglandins [295].

Keratinocyte growth factor (KGF) is a member of the fibroblast growth factor (FGF) family, and plays an important role in embryonic development, angiogenesis, and tissue repair [296]. KGF is a potent mitogen in epithelial cells, but has no proliferative effect on mesenchymal cells. KGF stimulates proliferation of hepatocytes, as well as gastrointestinal and urothelial epithelium [296]. KGF binds to a transmembrane tyrosine kinase receptor (KGFR) [296], which initiates a phosphorylation cascade that leads to activation of phospholipase C-γ(gamma) and MAPK. KGF has not been tested on BEC, in vitro. However, the possibility that KGF can induce biliary proliferation is raised by studies in transgenic mice that express hepatic KGF/FGF-7 during late gestation. These transgenic embryos had enlarged livers with prominent biliary and pancreatic ductal epithelial hyperplasia [297].

Transforming growth factor β(beta) (TGFβ(beta)) and activin A inhibit BEC growth, in vitro, in humans [274] and rats [298]. The active form of TGFβ(beta) and Activin A bind to the TGFβ(beta) receptor II (Tβ(beta)R-II) and activin receptor II, respectively. Receptor/ligand binding results in receptor dimerization, and subsequent phosphorylation of TGFβ(beta) receptor I (Tβ(beta)R-I), and activin receptor I, respectively. TGFβ(beta)1 is produced primarily by stellate and inflammatory cells, but also by BEC in diseased livers [299, 300]. TGFβ(beta)2 is produced primarily by BEC in fibrotic livers [301]. Activin A is produced by hepatocytes in normal liver and in stellate cells of diseased livers, particularly at the edge of regenerative nodules [302]. After BDL, the BEC produce TGFβ(beta)1 [300], consistent with the down regulation of BEC proliferation at this time [265]. In addition, the mannose 6-phosphate/insulin-like growth factor II receptor, which activates TGFβ(beta)1, is also up-regulated in hyperplastic BDL BEC. TGFβ(beta)1 may also play a morphogenic role in the biliary tree [303]. TGFβ(beta)1 inhibits cell growth through upregulation of p21 [153, 304], a protein that also has a significant role in cellular senescence.

The immunosuppressive agent cyclosporine, which is excreted in the bile, can induce BEC TGFβ(beta)1 expression, which in turn, can cause upregulation of p21 in BEC cultures [153]. Patients treated with cyclosporine also have a greater frequency of chronic liver allograft rejection [305]. These findings suggest that after BEC injury, medications present in the blood and bile can influence biliary repair responses. BEC in normal livers do not express p21, whereas p27 is universally expressed in BEC. Up to 12 weeks after BDL in mice, BEC express both p21 and p27 [306]. Using the mouse BDL model, BEC p21 expression was induced immediately after BEC proliferation during the post-mitotic period [306], and under conditions of severe stress, where it is thought to have a mito-inhibitory function [306]. In cholangiocarcinomas, p21 expression is directly proportional to Ki67 staining [307], whereas in other non-neoplastic biliary tract diseases such as primary biliary cirrhosis, increased BEC expression of p21 [152] has been linked to BEC stress and apoptosis [152]. In contrast, the ubiquitous expression of p27 in BEC of normal, untreated mice decreases in direct proportion to increases in BEC proliferation.

Future Directions

It is now widely accepted that BEC actively participate in normal liver physiology and in disease pathophysiology; they are not simply the epithelial lining of a passive conduit for delivery of hepatic bile to the intestine. In the last decade, rapid progress has been made in unraveling molecular pathways that contribute to biliary tree and BEC structure, development, differentiation, proliferation, survival, and secretory and absorptive functions. This progress has been based on exploitation of novel experimental techniques, such as knock out and transgenic mice, which are often applied to classical models of biliary disease, such as BDL. The next step will be application of this knowledge to treatment of cholangiopathies, such as molecular targets, including microRNAs for cholangiocarcinoma therapy. And, continued interplay between basic and translational BEC research will provide a variety of choices in the treatment of biliary tract diseases.

Abbreviations

BDL	Bile duct ligation
CAMKII	Calcium/calmodulin-dependent protein kinase II
cAMP	Cyclic adenosine monophosphate
CCKB	Cholecystokinin B
CGRP	Calcitonin gene-related peptide

CLR	Calcitonin-receptor-like receptor
CREB	cAMP response element binding
ER	Estrogen receptor
ERK	Extracellular signal-regulated kinase
FSH	Follicle-stimulating hormone
GC	Glycocholic
GCDC	Glycochenodeoxycholic acid
GH	Growth hormone
GLP1	Glucagon-like peptide 1
HGF	Hepatocyte growth factor
IGF1	Insulin-like growth factor 1
IP3R	Inositol 1,4,5-triphosphate receptor
KGF	Keratinocyte growth factor
MAPK	Mitogen-activated protein kinase
PG	Prostaglandin
PI3K	Phosphoinositide 3-kinase
PKC	Protein kinase C
PPARγ(gamma)	Peroxisome proliferatoractivated receptor-γ(gamma)
PR	Progesterone receptor
PRLR	Prolactin receptor
RAMH	α(Alpha)-methyl histamine
RAMP1	Receptor activity-modifying protein 1
RCP	Receptor component protein
SSTR2	Somatostatin receptor subtype
TA	Taurocholic acid
TCA	Taurolithocholic acid
TGF-β(beta)1	Transforming growth factor-beta 1
TUDCA	UDCA conjugate tauroursodeoxycholic acid
Trk-A	Neurotrophic tyrosine kinase receptor type 1
UDCA	Ursodeoxycholic acid
VEGF	Vascular endothelial growth factor

Chapter 5
Stellate Cells

Chandrashekhar R. Gandhi

History, Location, and Morphological Characteristics of Stellate Cells

Stellate cells were identified by von Kupffer in 1876 [1] using gold chloride staining procedure, but based on their shape, he described them as phagocytes. In 1952, Ito reported cells containing lipid droplets in the perisinusoidal space and called them "fat-storing cells" [2]. Subsequently, Wake employed gold chloride staining, silver impregnation method, and vitamin A autofluorescence, and confirmed that von Kupffer and Ito had described the same cells [3]. The vitamin A- or fat-storing cells were named Ito cells and hepatic macrophages were named Kupffer cells in recognition of von Kupffer's contribution. In addition, stellate cells were also commonly known as lipocytes and perisinusoidal cells. A consensus was reached in 1996 that these cells be termed as hepatic stellate cells (HSCs) [4]. An excellent historical account of HSCs can be found in a review by Geerts [5].

Hepatic stellate cells constitute about 1.5% of the total liver volume and 5–8% of liver cell numbers [6, 7]. They are located in the space of Disse adjacent to hepatocytes, under the fenestrated sinusoidal endothelial layer. The perisinusoidal (also known as subendothelial) cytoplasmic processes of HSCs, which contain filaments and microtubules, can extend over two or three hepatocytes, and thus internucleus distance between two adjacent HSCs can be as much as 40 μm [8]. The cytoplasmic processes of HSCs are also seen to make physical contacts with sinusoidal cells, adjacent HSCs, and autonomous nerve endings. Some of the processes spread over the sinusoids whereas intersinusoidal (or interparenchymal) processes may extend into the adjacent sinusoids by penetrating hepatocyte plates [8] (Fig. 5.1).

Nearly 50–80% of the body's retinoids (retinol plus retinyl esters) are stored in the liver; HSCs accumulate 80–90% of these stores in numerous perinuclear fat droplets [9]. The smaller, type I lipid droplets (less than 2 μm diameter), but not the larger type II lipid droplets (about 2 μm diameter) are electron dense and surrounded by membrane [8, 10]. HSCs with large lipid droplets are found in the pericentral and midzonal areas, and those with smaller droplets in the periportal areas. The lipid droplets consist of retinyl esters (42%), cholesterol (13%), phospholipids (4%), and triglycerides (28%) [11]. Cellular retinol-binding protein-1 (CRBP-1), which mediates esterification of retinol to retinyl esters and its oxidation to retinal and retinoic acid, is highly expressed in the liver, particularly in HSCs. Expression of CRBP-1 in HSCs increases during activation and upon TGF-β(beta) treatment [12].

HSCs can be identified by quickly fading greenish fluorescence due to vitamin A (retinol) upon excitation at 320 nm [8], and by staining the lipid droplets with Sudan black, a neutral diazo dye that stains saturated neutral lipids in black [13]. Rodent HSCs are also identified immunohistochemically for cytoskeletal proteins desmin and vimentin. The number of desmin-positive cells is greater in the periportal area (about 13 cells/mm^2) as compared to the pericentral area (about 9 cells/mm^2) [14]. While rat HSCs express desmin uniformly, it is minimally expressed or even absent in human HSCs [15, 16]. About 70–80% of quiescent rodent HSCs express glial fibrillary acidic protein (GFAP) [17]; quiescent human HSCs do not express GFAP [18].

Physiologically, HSCs are quiescent, long-lived, and contain moderately developed rough endoplasmic reticulum and small number of mitochondria. Accumulation of cells containing fewer lipid droplets of smaller size and abundant endoplasmic reticulum (typical of fibroblasts) in fibrotic areas led to the hypothesis that these cells originate from HSCs [19, 20]. Subsequent work confirmed that HSCs lose retinoids and acquire a highly proliferative myofibroblast-like phenotype containing greater amounts of rough endoplasmic reticulum during liver injury. Similar phenotypical transformation or activation of HSCs also occurs in tissue culture on plastic. Activation of HSCs is associated with expression of platelet-derived growth factor (PDGF) receptors [21, 22], ferritin receptors [23], and decrease in the expression of peroxisome proliferator-activated receptor gamma (PPARγ(gamma)) [24–26]. In contrast to the rodent HSCs, which express α(alpha)-smooth muscle actin (α(alpha)-sma) upon activation, a significant number of human HSCs contain

α(alpha)-sma in physiology [16, 27]. The number of α(alpha)-sma positive cells increase in the cirrhotic human liver exhibiting significant correlation with the volume fraction of fibrosis [28]. Interestingly, activated rodent HSCs have reduced expression of GFAP [17] whereas its expression increases during activation of human HSCs [18]. Activated, but not quiescent, rat HSCs also express neural cell adhesion molecule [29] and nestin [30].

Origin of Stellate Cells

In mouse embryo, desmin-positive stellate-shaped cells appear in the perisinusoidal space from 11.5 days [31]. HSCs were suggested to originate from mesenchymal cells of septum transversum during early stages of organogenesis [32]. The conversion of the subendothelial cells expressing activated leukocyte cell adhesion molecule into myofibroblasts expressing α(alpha)-sma and their uptake of retinol when embedded in collagen gel affirm mesenchymal origin of HSCs [33]. The presence of desmin in HSCs indicates that they are of myogenic rather than fibrogenic lineage. Neural origin of HSCs has also been suggested due to expression by a large percentage of rodent cells of GFAP [17, 34], which is considered to be specific for astroglial cells, and expression of a class VI intermediate filament protein, nestin, by activated rat HSCs [30]. However, in transgenic mice expressing yellow fluorescence protein in neural crest cells, HSCs were found to be negative for this marker [31]. A subpopulation of human fetal liver-derived cytokeratin 7/8 (CK7/8)-expressing $CD34^+$ stem cells differentiate into HSCs in cell culture [35]. Bone marrow-derived stem cells are also shown to differentiate into HSCs; green fluorescence protein (GFP)-positive bone marrow cells injected into the mouse following whole body irradiation appear in the liver, accumulate lipid droplets, and are activated to myofibroblastic α(alpha)-sma-positive cells upon carbon tetrachloride (CCl_4) treatment [36].

Isolation and Culture of HSCs

The principle of isolation and purification of HSCs is based on their distinct density from other hepatic cell types due to the presence of large amounts of stored fat. To increase the

yield of cells, old rats (450–500 g) and mice (30–40 g) are preferred. The initial step in the isolation of HSCs is digestion of the liver with collagenase and pronase. DNase may be added to the digestion buffer. Both anterograde (in via the portal vein and out via the suprahepatic vena cava) and retrograde perfusions are equally effective without compromising the yield of HSCs. In case of inadequate digestion in situ, the liver may be minced and digested in a water bath at 37°C in presence of the enzymes. Nonparenchymal cells are separated from hepatocytes and cell debris by low speed centrifugation ($50 \times g$ x 2 min). The supernatant is centrifuged at $450 \times g$ for 10 min to pellet nonparenchymal cells, following which HSCs are purified by density gradient centrifugation using metrizamide, nycodenz, or percoll [37–42]. HSCs thus obtained are generally quite pure (90–95% purity) with Kupffer cells as major contamination. Kupffer cells can be depleted by magnetic antibody sorting using F4/80 and CD11b antibodies for further purification of mouse HSCs [43].

Purified HSCs are suspended in standard culture medium (e.g., Dulbecco modified Eagle's medium) containing 10–20% fetal bovine serum, or a mixture of 10% fetal bovine serum and 10% horse serum, and plated at a density of 0.05–$0.5 \times 10^6/cm^2$ on plastic culture plates. The cells generally attach within 3–6 h, after which the medium may be renewed to remove contaminating and unattached cells and cell debris. The cells can be easily identified by their classical morphology

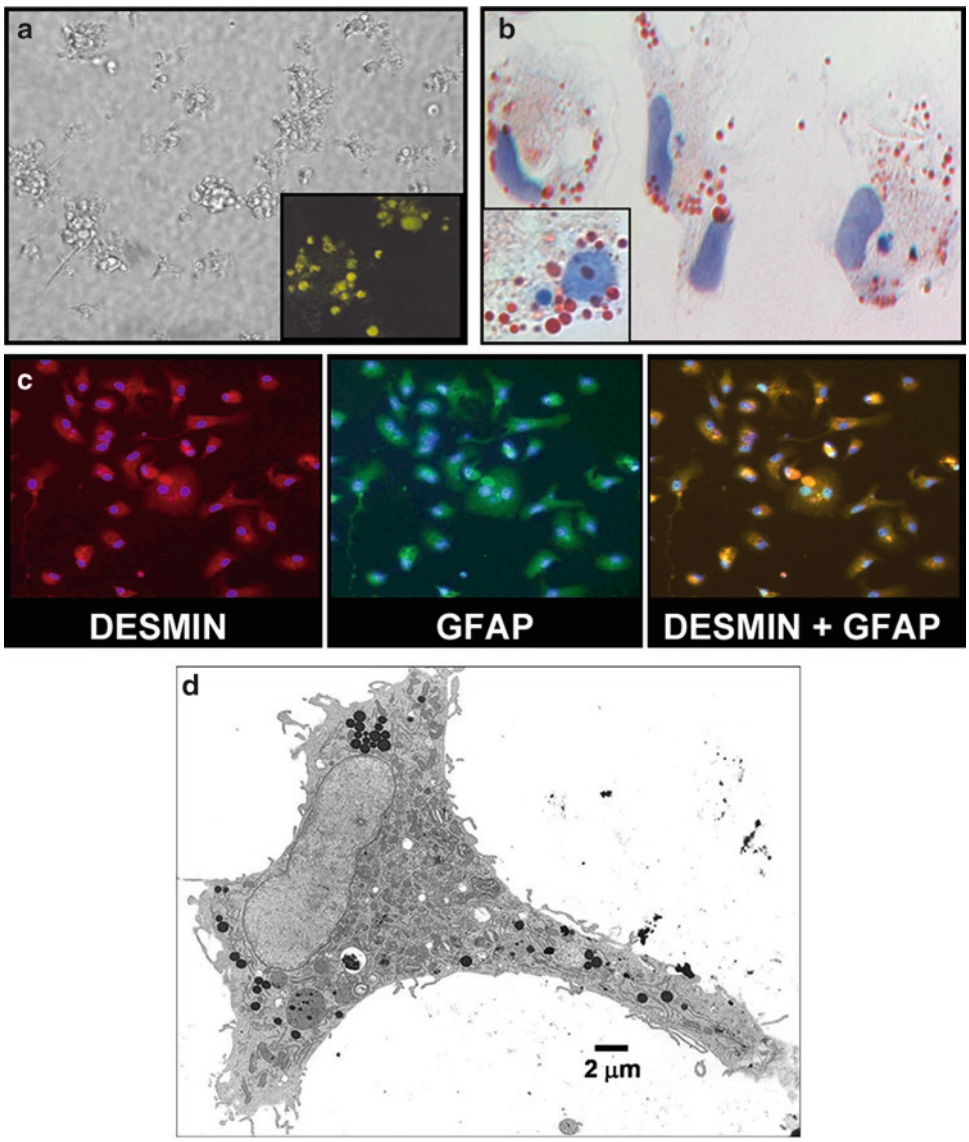

Fig. 5.2 (**a**) Rat HSCs in culture one day after isolation showing appearance of a bunch of grapes. Inset shows vitamin A autofluorescence. (**b**) Oil red staining of rat HSCs on day 3 showing lipid droplets (×60). Inset shows image of an HSC at ×120 magnification. (**d**) Transmission electron micrograph of a stellate cell on day 5. Several lipid vesicles are still present. Figure 5.2d was generated in collaboration with Dr. Donna Stolz, Center for Biologic Imaging, University of Pittsburgh

(appearance of clustered grapes) by phase contrast microscopy and vitamin A autofluorescence (Fig. 5.2a), and by staining the lipids with Oil Red (Fig. 5.2b) or Sudan Black [13]. It is a good practice to plate the cells on cover slips in parallel for immunohistochemical determination of specific markers (e.g., desmin, GFAP) to ascertain purity (Fig. 5.2c).

HSCs can be used a day after isolation (putatively quiescent state) [44–46]. However, it should be noted that the process of activation of HSCs begins rapidly after plating in culture media containing high concentration of serum, a rich source of soluble fibronectin and vitronectin, which bind to tissue culture plastic and provide an adhesive layer for the cells [47]. The closest system that can be employed to maintain quiescence of HSCs is culture over basement membrane-like matrix derived from Englebreth-Holm-Sarcoma or matrigel, which resembles the extracellular matrix (ECM) in the space of Disse [48, 49].

Between 7 and 14 days of culture, majority of HSCs express α(alpha)-sma and are considered activated, but they still contain smaller amounts of retinoids [50] (Fig. 5.3). HSCs in passage 3–5 lose their retinoid stores and are considered fully activated closely representing the cells in chronically injured liver. Activated HSCs can be isolated from the fibrotic liver by the same procedure described above, but higher concentrations of the enzymes and longer time of digestion are required. Also, the concentration of the gradient has to be adjusted as these cells are devoid of or contain relatively low levels of stored lipids [43, 51, 52].

The readers should note that discrepancies may exist between the results from various laboratories with regard to the responses of HSCs to specific stimuli. It is, therefore, important to carefully consider the phenotype of HSCs (early cultures between 2 and 10 days, early and late passages, and cells isolated from the fibrotic liver) in planning experiments to investigate mechanisms of the functions of HSCs and their relevance to hepatic physiology or pathology.

Activation and Proliferation of Stellate Cells

Activation of HSCs is a primary tissue repair response to hepatic injury of various types. The process of activation or transdifferentiation of HSCs into myofibroblast-like phenotype includes progressive loss of retinoids, proliferation, expression of α(alpha)-sma and increased contractility, and enhanced production of abnormal ECM. Activated HSCs are considered to be the major cell type to deposit ECM and cause fibrosis of the liver. A large body of evidence with regard to the mediators and mechanisms of activation and

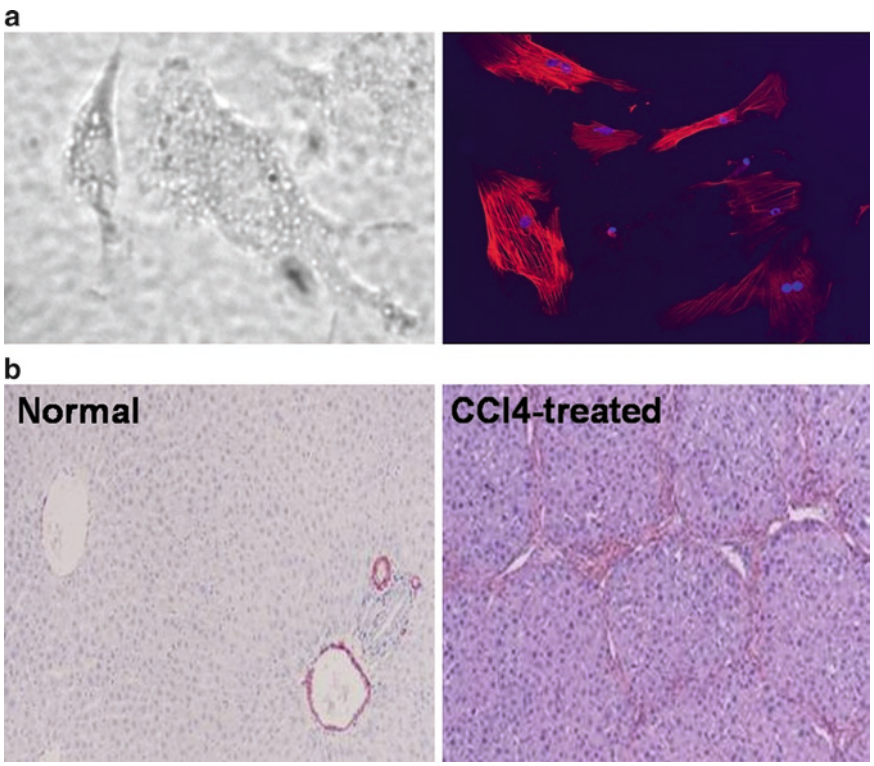

Fig. 5.3 (**a**) Rat HSCs on day 7 of culture show myofibroblast-like morphology, but still contain significant number of lipid droplets (*Left*). Staining with anti α(alpha)-sma antibody shows that most cells express this established marker of HSC activation (*Right*). (**b**) Sections of the liver from normal and CCl4-treated rats (6 weeks treatment) stained for α(alpha)-sma. While α(alpha)-sma is expressed only by smooth muscle cells of the blood vessels in normal liver, in the CCl4-treated liver cells, in the fibrotic area (activated HSCs) intensely staine for α(alpha)-sma

proliferation of HSCs is obtained from in vitro experiments exploiting their property to undergo phenotypical transformation in culture. However, differences might exist between the properties of cells activated in vitro and in vivo as indicated by significant difference in the gene expression pattern between HSCs activated in vivo (bile duct ligation or CCl_4 treatment) and in vitro [43].

Retinoids

Since activated HSCs found in chronic liver diseases are depleted of the retinoid stores [53–55], it is apparent that their proliferation is dependent upon the loss of retinoids. Active proliferation of cultured HSCs begins following an initial rapid and progressive loss of retinoids in the first 3 days followed by a lag period of 4–5 days [50, 56–58]. Uptake of retinoids by activated HSCs reduces their proliferation rate [50]. PDGF-induced proliferation of activated HSCs is also ameliorated upon treatment with retinoic acid without affecting the PDGF receptor density or ligand binding, cell morphology or viability, and collagen type I expression [59]. However, late passages of HSCs are impervious to the inhibitory effect of retinoids, which is attributed to the markedly reduced levels of cellular retinol-binding protein [57]. Transfer of activated HSCs onto matrigel leads to uptake of retinoids and deactivation as evidenced by reduced expression of α(alpha)-sma, procollagen I, tissue inhibitor of metalloproteinase-1 (TIMP-1), and reduced serum induced proliferation [60]. Furthermore, presence of retinoic acid during culture slows the activation process as characterized by morphology, and lower expression levels of α(alpha)-sma, and collagen type I than in cells incubated without retinoic acid [61].

Soluble Mediators

The accumulation of activated HSCs in the areas of necroinflammation indicates that mediators produced by inflammatory cells and macrophages as well as necrotic hepatocytes cause chemotaxis and activation/proliferation of HSCs. Experiments to identify soluble mediators responsible for activation of HSCs led to the finding that medium conditioned by rat Kupffer cells enhances activation and proliferation of HSCs. The process of activation is accelerated when Kupffer cells from CCl_4-injured rat liver [62], D-galactosamine- or thioacetamide-injured rat liver, or Kupffer cells stimulated with zymozan or phorbol esters [58] are used. Similarly, coculture with hepatocytes and rat hepatoma cells [63], as well as medium conditioned by tumoral rat hepatocytes [64] induce activation/proliferation of rat HSCs. A principal mediator released by hepatocytes that causes proliferation of HSCs was identified to be insulin-like growth factor I (IGF-I) [63]. IGF-I is also a potent chemoattractant for HSCs [65]. Additionally, oxidative stress, PDGF, epidermal growth factor (EGF), TGF-α(alpha), b-fibroblast growth factor (bFGF), and endothelin-1 (ET-1) are the mediators that can cause activation of HSCs [21, 63, 66–69]. Table 5.1 lists the mediators that affect activation, proliferation, survival, and other properties of HSCs.

Table 5.1 Various mediators that influence activation/proliferation of HSCs

Mediator	Source	Effect on HSCs
ROS	KCs, ECs, neutrophils, monocytes, hepatocytes	Activation/proliferation; fibrosis
TNF-α(alpha)	KCs, HSCs, lymphocytes	Promotes survival
PDGF	Platelets, monocytes, ECs	Survival; proliferation; chemotaxis
Thrombin	Platelets	Proliferation; contraction
TGF-α(alpha)	KCs, platelets, hepatocytes, HSCs	Proliferation
EGF	Brunner's gland, circulation	Proliferation
TGF-β(beta)	KCs, platelets, HSCs, ECs, monocytes	Survival; promotes proliferation
IGF-I	Platelets, ECs, hepatocytes	Proliferation; chemotaxis
ET-1(ETA receptor)	ECs, HSCs, hepatocytes,	Proliferation; contraction
Ang II	Circulation, HSCs	Proliferation; contraction
ROS	KCs, ECs, neutrophils, monocytes, hepatocytes	Apoptosis of activated HSCs
IFN-γ(gamma)	T-lymphocytes	Inhibits activation
TGF-β(beta)	KCs, platelets, HSCs, ECs, monocytes	Inhibits proliferation
Nitric oxide	HSCs, ECs, hepatocytes,	Inhibits proliferation; relaxation
ET-1 (ETB receptor)	ECs, HSCs, hepatocytes,	Inhibits proliferation; contraction
PGE2	HSCs, KCs, ECs	Inhibits proliferation; relaxation
Retinoic acid	HSCs, hepatocytes, circulation	Inhibits activation and proliferation

Ang angiotensin, *ECs* endothelial cells, *EGF* epidermal growth factor, *ET* endothelin, *IFN* interferon, *IGF* insulin-like growth factor, *KCs* Kupffer cells, *PDGF* platelet derived growth factor, *PG* prostaglandin, *ROS* reactive oxygen species, *TGF* transforming growth factor, *TNF* tumor necrosis factor

Reactive Oxygen Species

An early event during organ injury is the generation of reactive oxygen species (ROS) by infiltrating blood cells and resident macrophages (Kupffer cells), which persists with continued inflammation [70–75]. ROS are also produced intracellularly by cells exposed to certain types of stimulation (e.g., by inflammatory mediators). Generation of ROS exceeding the capacity of antioxidant defense results in peroxidation of lipids and LDL, and protein modification, which play an important role in hepatic fibrogenesis similar to fibrotic diseases of other organs [76–81]. Thus, oxidative stress represents a common link between chronic liver injury caused by toxins, iron overload, alcoholic hepatitis, and viral hepatitis [82–88], and involves ROS-induced activation of quiescent HSCs and fibrogenic activity of activated HSCs [89, 90]. The relationship between oxidative stress and activation/proliferation and fibrogenic activity of HSCs has been investigated in animal models. Oxidative stress and lipid peroxidation products are demonstrated to cause activation of HSCs during CCl_4-induced liver injury in rodents [91–94]. Following CCl_4 administration, the thymidine labeling index and the number of desmin-positive cells increase in the liver; the migration and increase in the number of HSCs occur at a much greater rate in the pericentral than in periportal areas [14, 95]. Amelioration of CCl_4-induced tissue damage, expression of TGF-β(beta), and collagen deposition by treatment with antioxidants such as vitamin E and butylated hydroxytoluene confirm the role of oxidative stress in activation of HSCs and fibrosis [92, 96, 97].

Activation of signaling via nuclear factor kappa B (NFκ(kappa)B)/Rel family of proteins is an important pathway that regulates an array of genes including those involved in inflammatory and immune modulating reactions [98]. TGF-α(alpha) and collagen type I both induce oxidative stress, nuclear translocation of NFκ(kappa)B, and activation of HSCs plated on matrigel to maintain quiescence [92]. However, unabated activation of HSCs expressing Iκ(kappa)B dominant negative protein, which blocks nuclear translocation of NFκ(kappa)B [99], suggests that NFκ(kappa)B might have a different function. Indeed, tumor necrosis factor (TNF)-α(alpha) induces nuclear translocation of NFκ(kappa)B in activated but not in quiescent HSCs [100–102], and activated HSCs expressing Iκ(kappa)B dominant negative protein undergo apoptosis upon stimulation with TNF-α(alpha) [99]. TGF-α(alpha) also stimulates activation of an oncogenic protein c-Myb in HSCs [92]. The Myb family of proteins are known to regulate cell growth and differentiation. Transfection of quiescent HSCs with c-Myb antisense oligonucleotide prevents their activation by TGF-α(alpha) [92] whereas transfection with c-Myb stimulates activation [103]. On the other hand, transfection with c-Myb antisense reduces α(alpha)-sma expression, a marker of activation, in activated HSCs that express c-Myb constitutively [103]. Thus, c-Myb causes activation of HSCs whereas NFκ(kappa)B is not essential for activation, but is required for the survival of activated HSCs. TGF-α(alpha) and oxidative stress-induced HSC activation are summarized in Fig. 5.4.

Platelet-Derived Growth Factor and Endothelin-1

PDGF is the most potent of all the growth factors for HSCs. The importance of the effects of PDGF on HSCs in hepatic injury is exemplified by expression of PDGF receptors by activated HSCs [21], positive correlation between increased PDGF/PDGF receptor levels, the severity of histologic lesions and collagen deposition [104, 105]. PDGF is produced by platelets, monocytes, and macrophages as a dimer of two polypeptide chains A and B in combinations as PDGF-AA, PDGF-BB, and PDGF-AB. While rat HSCs express only PDGF-β(beta) receptor, human HSCs express both PDGF-α(alpha) and PDGF-β(beta) receptors in abundance [106]. PDGF causes proliferation of activated HSCs via phosphatidylinositol-4,5-bisphosphate-3-kinase (PI3-kinase)/protein kinase B (c-Akt) [107], and phosphatidic acid mediated sustained activation (phosphorylation) of extracellular signal-regulated kinase (ERK) [108]. Blockade of PDGF-induced PI3-kinase partly inhibits ERK activity [107] and inhibition of PDGF-induced ERK phosphorylation inhibits c-fos activation, AP-1 binding activity and STAT-1 activation, but causes partial inhibition of cell proliferation [109]. These results suggest involvement of other signaling pathways in PDGF-induced proliferation of HSCs. In this regard, PDGF increases intracellular Ca^{2+} [110], stimulates Na^+/H^+ exchange and peroxisome proliferator-activated receptors [111–114], increases intracellular oxidative stress via NADPH oxidase and causes p38 MAPK activation [113, 115] all of which are coupled to proliferation of HSCs. PDGF-induced PI3-kinase activation is upstream of stimulation of NADPH oxidase activity, ROS production, and proliferation of HSCs [115]. PI3-kinase/c-Akt signaling also induces antiapoptotic pathway and promotes survival of activated HSCs [116]. Furthermore, association between stimulation of PI3-kinase, ERK-MAPK, Rac and Rho signaling pathways in activated HSCs and recruitment of nonactivated HSCs has been suggested to be a critical mechanism of perpetuation of fibrogenic activity in the injured liver [65, 117]. PDGF is also profibrogenic in conditions where inflammation is less evident, such as experimental cholestatic liver injury [118, 119]. Thus, PDGF clearly plays multifaceted roles in modulating HSC biology during liver injury.

Progressive increase in the number of activated HSCs during fibrogenesis is accompanied by their apoptosis [120–122].

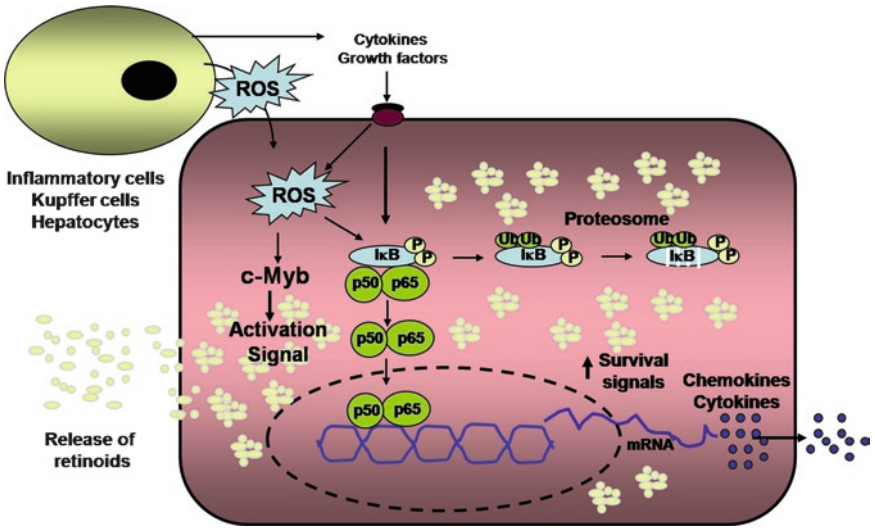

Fig. 5.4 Mediators (including reactive oxygen species, ROS) released by Kupffer cells, inflammatory cells and hepatocytes upon liver injury stimulate activation of cytosolic NFκ(kappa)B in HSCs. Cytokine-induced intracellular ROS also induce NFκ(kappa)B activation. NFκ(kappa)B is present as hetero- or homodimer of Rel family of proteins, the most common being p65:p50 heterodimer. The heterodimers are associated with inhibitory proteins Iκ(kappa)Bα(alpha) or Iκ(kappa)Bβ(beta). Its stimulation involves specific kinase-dependent phosphorylation of Iκ(kappa)B resulting in its dissociation from the NFκ(kappa)B complex, ubiquitination and degradation by proteosome. This reaction allows translocation of the NFκ(kappa)B homo- or heterodimers into nucleus, their binding to specific sites on the DNA and stimulation of transcription of genes involved in survival of HSCs (e.g., increased expression of antiapoptotic proteins such as Bcl2) and synthesis of cytokines and chemokines. Concomitant ROS-induced activation of c-Myb is responsible for transdifferentiation of HSCs into myofibroblastic phenotype

These observations suggest that while HSCs respond to the mitogenic effects of growth factors such as PDGF, simultaneous counter-regulatory signaling pathways limit their proliferation. A major mechanism of this effect involves increased levels of a second messenger cyclic adenosine monophosphate (cAMP), which is formed by the action of adenylate cyclase on adenosine triphophate (ATP). PDGF and another mitogen for activated HSCs ET-1 both stimulate synthesis of prostaglandin E2 (PGE2) and consequently cAMP, which inhibits proliferation of HSCs [123–125]. Interestingly, ET-1 exerts dual effect on HSCs; its binding to ETA and ETB receptors respectively stimulates pro- [69] and anti-proliferation [125] signaling pathways. The mechanisms of negative effect of cAMP on proliferation of HSCs appear to involve: (a) inhibition of Raf kinase, an upstream activator of ERK [126, 127], and/or (b) inhibition of STAT1 activation [128]. The PDGF- and ET-1-induced signaling pathways responsible for proliferation of HSCs are summarized in Fig. 5.5.

The other known mechanism of limiting HSC proliferation is contrasting effects of ROS. Although ROS induce activation of HSCs and stimulate synthesis of ECM in them, a subpopulation of culture-activated HSCs was found to undergo caspase-3-mediated apoptosis upon stimulation with exogenous ROS [122, 129]. Increased intracellular oxidative stress also induces death of activated HSCs [130, 131]. Resistance of quiescent HSCs to the proapoptotic effect of ROS suggests that retinoids, which possess potent antioxidant property, provide protection against the injury. ROS-induced apoptosis of activated HSCs is ameliorated upon pretreatment with retinoic acid [129]. Moreover, concentration of another antioxidant glutathione (GSH) is also lower in activated than in quiescent HSCs.

HSCs retain their proliferative activity through passages but become progressively less responsive to mitogenic effects of PDGF and EGF [50]. These results suggest that passaged HSCs either produce adequate amounts of autocrine growth factors or have fully functional constitutively activated signaling pathways responsible for proliferation. It also remains to be determined whether the reduced response of late passage HSCs to exogenous growth factors is due to decreased number of receptors or blunted post-receptor signaling.

Transforming Growth Factor-β(beta)

In addition to the mitogens that influence proliferation of HSCs, platelets as well as activated macrophages are also the source of a potent fibrogenic and cell growth-regulatory cytokine TGF-β(beta) during inflammation and tissue repair [132]. Among the peptides belonging to the TGF-β(beta) family, specifically the isoforms TGF-β(beta)1, TGF-β(beta)2, and TGF-β(beta)3, TGF-β(beta)1 is most abundant in both normal and fibrotic liver [133]. While TGF-β(beta)1 exerts growth-inhibitory and pro-apoptotic

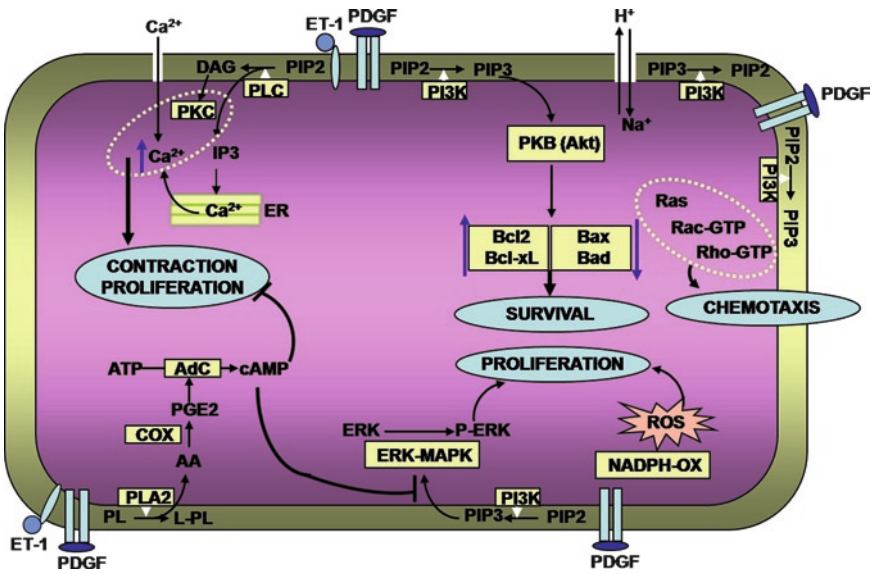

Fig. 5.5 Growth factors such as PDGF cause autophosphorylation of their receptors and recruit phosphatidylinositol-4,5-bisphosphate-3-kinase (PIP2–3-kinase or PI3-kinase) for intracellular signaling to elicit cellular responses. The recruitment PI3-kinase, which consists of an 85 kDa regulatory and a 110 kDa catalytic subunit, is achieved by binding of the Src-homology 2 (SH2) domain of the 85 kDa subunit to phosphotyrosine residue of the receptor (not shown). The binding relieves inhibition of the PI3-kinase catalytic subunit allowing the enzyme to catalyze phosphorylation of PIP2 to PIP3. PIP3 causes colocalization of downstream signaling proteins such as Akt leading to their survival. PIP3 also stimulates phosphorylation of ERK, Na^+/H^+ exchanger as well as reactive oxygen species (ROS) generation via NADPH oxidase (NADPH-OX), which then stimulates proliferation of HSCs. Another pathway of PDGF or endothelin-1 (ET-1)-induced proliferation is phospholipase C-dependent hydrolysis of PIP2 into two second messengers inositol-1,4,5-trisphosphate (IP3) and diacylglycerol (DAG), which release Ca^{2+} from intracellular stores and activate protein kinase C (PKC) respectively. This effect is followed by uptake of extracellular Ca^{2+} further raising its cytosolic concentration. This (PIP2 IP3 + DAG) pathway is also responsible for ET-1-induced contraction of HSCs. A negative feed-back regulation of contraction and proliferation is achieved via phospholipase A2 (PLA2)-induced release of arachidonic acid (AA) from phospholipids (PL) with formation of lysophospholipids (L-PL). AA is converted to prostaglandins (PGE2 in this case) by cyclooxygenase (COX). PGE2 stimulates synthesis of inhibitory second messenger cyclic AMP (cAMP) from ATP via adenylate cyclase (AdC). PDGF also stimulates Ras, Rac, and Rho pathways via PI3 kinase activation. This pathway then induces chemotaxis of HSCs and perpetuation of the overall responses during liver injury

effects on hepatocytes [134, 135], conflicting results are observed with regard to its role in activation and proliferation of HSCs. TGF-β(beta)1 was reported to accelerate transdifferentiation of quiescent HSCs to the activated phenotype in cell culture [136], to prevent spontaneous apoptosis of activated HSCs [45] and to potentiate their mitogenic response to PDGF and EGF [21]. However, another study observed that TGF-β(beta) inhibits the mitogenic effect of PDGF on HSCs by down-regulating its receptors [59]. Since activated HSCs express IGF-II/mannose-6-phosphate receptor that facilitates conversion of latent TGF-β(beta)1 into active form [137], HSCs appear to develop an interesting mechanism that regulates their own growth and fibrogenic response to TGF-β(beta)1. TGF-β(beta)1, per se, may not be required for the activation of HSCs as demonstrated by normal in vitro activation pattern of the cells isolated from TGF-β(beta)1 knockout mouse [138]. However, reduced synthesis of collagen type I that correlates with the extent of α(alpha)-sma expression in CCl_4-(single dose) treated TGF-β(beta)1 knockout mouse [138] indicates that TGF-β(beta)1 plays an indirect, but critical role in the activation of HSCs in vivo.

Hepatic Fibrosis and Stellate Cells

While the molecular basis of hepatic fibrosis is presented in Chap. 30, here we present a stellate cell perspective in this event. The postulate that HSCs may be the precursors of the cells responsible for excessive synthesis of ECM and hepatic fibrosis [139] was confirmed in a number of studies. An initial response to hepatic injury is infiltration of inflammatory cells (lymphocytes, granulocytes, and monocytes/macrophages), their attachment to the endothelial layer, and transmigration through the sinusoidal lining into the parenchyma [140–142]. These inflammatory cells participate in initiation and progression of liver fibrosis by releasing mediators that stimulate ECM synthesis in HSCs [143–146]. Although this chapter is devoted to HSCs, it is important to note that portal myofibroblasts are also a critical cell type contributing to hepatic fibrosis in chronic liver disease. Portal myofibroblasts are present in a large number in the fibrous tissue, and are differentiated from activated HSCs by their expression of fibulin-2, and absence of vimentin and an extracellular matrix protein reelin. These cells and their functions are reviewed in Chap. 31 and elsewhere [147, 148].

Recent evidence indicates that biliary epithelial cells can make transition into fibroblastic cells and contribute to hepatic fibrosis. The nature of this epithelial-mesenchymal transition could be reversible [Reviewed in 149, 150].

Extracellular Matrix

A fine balance between the synthesis and degradation of ECM components determines their steady state levels in physiology. The enzymes that regulate ECM levels are matrix metalloproteinases (MMPs) that degrade the ECM components, and tissue inhibitors of metalloproteinases (TIMPs), which inhibit activities of MMPs. An increase in the TIMP activity in association with decreased MMP activity is a primary mechanism of the pathogenesis of fibrosis. HSCs are at the center of fibrogneic activity, and in addition to synthesizing the components of ECM, they also produce MMPs and TIMPs [121, 151–153].

About 25 members of Ca^{2+}-dependent enzymes of the MMP family and 4 TIMPs (TIMP-1, -2, -3, and -4) have been identified. The MMPs are classified into five subclasses namely interstitial collagenases (MMP-1, MMP-8, and MMP-13), gelatinases (MMP-2 and MMP-9), stromolysins (MMP-3, MMP-7, MMP-10, and MMP-11), membrane type (MMP-14, MMP-15, MMP-16, MMP-17, MMP-24, and MMP-25), and metalloelastases (MMP-12). This classification is not rigid as MMPs belonging to different classes exhibit overlapping activities toward their substrates. MMPs are secreted as inactive proenzymes, which are activated by variable mechanisms. During activation of HSCs in vitro, the expression of MMPs is down-regulated, while that of TIMPs is up-regulated [154]. The expression of the MMPs and TIMPs is regulated by cytokines such as TGF-β(beta), and TNF-α(alpha) [154], as well as by retinoids [155, 156]. For a detailed review of hepatic MMPs and TIMPs, see Benyon and Arthur [153].

Disturbance in the balance between the expression and activities of MMPs and TIMPs during liver injury causes remodeling of the ECM. In addition, HSCs also increase deposition of abnormal ECM components. For example, Type I and type III collagens, levels of which are relatively low in the normal liver, are major constituents of the ECM deposited in fibrotic liver [157]. Extensive investigations have been performed to identify components of the ECM produced by HSCs, and mechanisms underlying their synthesis and degradation. While freshly isolated HSCs express mRNA for collagen type IV, followed by collagen type III, and very small amounts of collagen type I, activation of HSCs is associated with increased mRNA expression of collagen type I, type III, and type IV, appearance of fibronectin mRNA and decrease in the expression of chondroitin sulfate proteoglycan core protein [158]. Similarly, HSCs isolated from fibrotic livers have increased mRNA expression of procollagen type I, type III, and type IV compared to the cells from normal liver [159]. HSCs in primary culture are also found to synthesize laminin [37, 56], tenascin [160, 161], undulin [162], and glycosaminoglycan hyaluronic acid [163].

ECM is not only responsible for maintenance of the organ's architecture (in physiology) and its distortion (in pathology), but its components also exert profound influence on proliferation, survival and synthetic capabilities of the cells [164]. The pericellular ECM potentiates signals elicited by soluble growth and survival factors via receptors of α(alpha)/β(beta) integrin family [165, 166]. The ECM components also cause perpetuation of the transdifferentiation and proliferation of HSCs, and their fibrogenic activity by storing mediators such as TGF-β(beta)1, TNF-α(alpha), and PDGF.

Reactive Oxygen Species

In addition to causing activation of HSCs, ROS and lipid peroxidation products also act as pro-fibrogenic stimuli for HSCs [84, 86, 167]. Oxidative stress induced by ascorbate/$FeSO_4$ increases procollagen I mRNA expression in cultured human HSCs [96]. Reactive aldehydes such as 4-hydroxy-2,3-alkenals (HAK) exert direct profibrogenic effects on HSCs via activation and nuclear translocation of c-Jun NH2-terminal kinases (JNKs), upregulation of c-jun, and increased AP-1 binding [168]. However, 4-hydroxy-2,3-nonenal (HNE), an HAK, inhibits PDGF receptor tyrosine phosphorylation and attendant signaling associated with cell proliferation [169] indicating negative feed-back loop limiting the wound healing or fibrogenic response. During oxidation of LDL, oxidatively modified lipids such as PPARγ(gamma) ligands, aldehydes, and lipid hydroperoxides are formed that might be liberated from oxidized LDL [76, 170]. These substances induce activation of HSCs and elicit fibrogenic response [24, 81, 168, 171]. ROS scavengers and blockers of PPARs inhibit fibrogenic activity of HSCs due to oxidized LDL [172].

Transforming Growth Factor-β(beta)

TGF-β(beta)l is perhaps the most extensively studied molecule as a fibrogenic agent due to its stimulatory effect on the synthesis of ECM components including collagens type I and type III in activated HSCs [173–175]. Expression of TGF-β(beta)l is increased markedly in experimental models of hepatic fibrosis [98, 133, 174–179], as well as in human cirrhosis [136, 180], and there is strong correlation between the levels of hepatic

TGF-β(beta)l mRNA and collagen α(alpha)l(I) in experimental and human liver fibrosis. Further, transgenic mice overexpressing TGF-β(beta)1 develop hepatic fibrosis spontaneously [181, 182] and neutralizing antibodies against TGF-β(beta)1 ameliorate fibrosis in the animal models [183].

TGF-β(beta)1 is synthesized both by Kupffer cells [67] and activated HSCs [117], and as mentioned above, activated HSCs develop mechanism to convert latent TGF-β(beta)1 into the active form. Additionally, TGF-β(beta)1 increases its own mRNA expression in an autocrine manner in activated HSCs [158]. Targeted deletion of Bcl-xL (an anti-apoptotic molecule) from hepatocytes in hepatocyte-specific conditional Bcl-xL-knockout mice leads to intralobular fibrosis that follows persistent apoptosis of hepatocytes and increased synthesis of TGF-β(beta)1 [184]. These authors also reported that apoptotic hepatocytes induce TGF-β(beta)1 synthesis in cultured hepatocytes and macrophages. These observations provide a link between apoptotic loss of hepatocytes and development of fibrosis [185, 186]. Phagocytosis of apoptotic hepatocytes during liver injury is a function of Kupffer cells, which produce ROS and cytokines that promote activation and fibrogenic response of HSCs. However, HSCs can also engulf apoptotic bodies that results in fibrogenic response in association with further activation, and enhanced synthesis of TGF-β(beta)1 [187].

In activated HSCs, p38 MAPK-dependent Smad3 phosphorylation was found to cause TGF-β(beta)l-induced ECM production both in vitro and in vivo [188]. However, the magnitude of TGF-β(beta)l receptor binding and TGF-β(beta)l-induced Smad phosphorylation is greater in quiescent than in fully activated HSCs [189]. Further, while TGF-β(beta)l inhibits DNA synthesis and stimulates collagen α(alpha)2(I) mRNA expression in quiescent HSCs, the myofibroblastic HSC phenotype is impervious to these effects [189]. Since both HSC phenotypes express TGF-β(beta)1 receptors I and II, expressions of which are increased in activated HSCs [190], it is likely that the receptor density on the membrane of activated HSCs is reduced due to internalization. Interestingly, constitutively increased nuclear expression of Smad3 and Smad4 is observed in HSC cell line developed from cirrhotic liver, and exogenous treatment with TGF-β(beta)1 does not affect the increased collagen α(alpha)2(I) expression in them [191]. Since binding of TGF-β(beta)1 to its receptors on HSCs isolated from normal liver and CCl_4-treated rat livers at 48 or 72 h is similar [190], receptor down-regulation in fully activated HSCs might be an explanation for blunted response to exogenous TGF-β(beta)1.

Another mechanism by which TGF-β(beta)l promotes fibrosis may be by its influence on the expressions of MMPs and TIMPs. TGF-β(beta)l inhibits ECM degradation in fibroblasts by (a) inhibiting the production of MMPs such as collagenase and stromolysin and (b) by stimulating synthesis of plasminogen activator inhibitor (PAI-1) and TIMPs [192]. A similar mechanism might exist in HSCs. However, although TGF-β(beta)l causes an initial rapid decline in steady-state levels of MMP-13 mRNA at the time of induction of collagen α(alpha)1(I) mRNA expression in HSCs, expression of MMP-13 mRNA increases at later times [193]. Clearly, additional investigations are necessary to delineate precise mechanisms of TGF-β(beta)l-mediated fibrosis from the initiation of liver injury through the stages that lead to cirrhosis.

Endothelin

A vasoactive peptide endothelin-1 (ET-1) has also been shown to exert profibrogenic effect on HSCs. Progressive increase in hepatic ET-1 and its receptors during CCl_4-induced liver injury leading to cirrhosis in rats [194, 195], and increased hepatic ET-1 and its receptors in human cirrhosis [69, 196] suggested that endothelin system may have a critical role in the pathogenesis and complications of chronic liver disease. The increased levels of ET-1 in the cirrhotic liver is a combined effect of its enhanced synthesis and reduced metabolism [194, 196, 197]. The connection between ET-1 and tissue fibrosis was demonstrated by development of renal fibrosis in ET-1-overexpressing transgenic mice [198]. ET-1 was also shown to increase collagen synthesis in cardiac fibroblasts and vascular smooth muscle cells [199, 200], and up-regulate type I collagen gene expression in HSCs [51]. ET-1 and TGF-β(beta)1 demonstrate an interesting relationship in hepatic pathophysiology. TGF-β(beta)1 stimulates the synthesis of ET-1 in hepatic endothelial cells [201] as well as in quiescent and activated HSCs [52, 69, 202]. In contrast, ET-1 stimulates TGF-β(beta)1 and collagen synthesis in quiescent, but not in HSCs activated in vivo, probably because of the high level of basal synthesis of both substances [52], and TGF-β(beta)1-induced down-regulation of ET-1 receptors in activated HSCs [202].

Renin-Angiotensin System

The renin-angiotensin system expressed by the activated HSCs has been implicated in hepatic fibrosis with a major role of NADPH oxidase-derived ROS [203]. Isolated quiescent HSCs express components of renin-angiotensin system (angiotensinogen, renin, and angiotensin-converting enzyme) at barely detectable levels and do not secrete angiotensin II, but both in vivo- and culture-activated HSCs express high levels of active renin and angiotensin-converting enzyme, and secrete angiotensin II [204]. PDGF, EGF, ET-1 and thrombin, but not TGF-β(beta)1 and proinflammatory cytokines, stimulate synthesis of angiotensin II in HSCs [204].

Angiotensin II, TGF-β(beta), and PDGF-AB all stimulate synthesis of ET-1 in human activated HSCs [69]. Thus, autocrine loop of activation-dependent synthesis and actions of TGF-β(beta)1, ET-1 and angiotensin-II on contraction, proliferation and fibrogenic activity of HSCs contribute in a major way to the pathology of chronic liver disease.

Other Mediators

Other cytokines that are reported to modulate fibrogenic activity of HSCs are TNF-α(alpha) and IL-1β(beta). While both TNF-α(alpha) and IL-1β(beta) inhibit synthesis of collagen type I in passaged HSCs [176], TNF-α(alpha) does not elicit a similar response in primary culture of HSCs [158]. However, reduced hepatic collagen type I gene expression and collagen synthesis are observed in nude mice in which steady state level of TNF-α(alpha) is increased by gene transfection [205].

Adipocytokines

Higher incidence of cirrhosis in obese than in nonobese subjects [206], and accelerated progression of liver injury strongly correlating with visceral obesity due to steatosis in hepatitis virus C (HCV)-infected patients [207] indicate that obesity related factors positively influence hepatic fibrosis. Thus, the observations that serum levels of leptin are elevated in patients with alcoholic liver cirrhosis [208], and activated but not quiescent HSCs express leptin [209] stimulated interest in understanding the role of adipocytokines (leptin, adiponectin, resistin, and plasminogen activator inhibitor-1), produced in the adipose tissue, in hepatic fibrosis [recently reviewed in ref. 210]. Subsequent work showed that toxin-induced hepatic fibrosis in animals is augmented by recombinant leptin [211]. Very poor fibrogenic response of leptin-deficient *Ob/Ob* mice and leptin receptor-deficient Zucker rats to CCl_4, thioacetamide, or schistosoma infection [212–217] further strengthened the hypothesis that the effect of leptin on HSCs is an important mechanism of hepatic fibrosis. The mechanisms of leptin-induced fibrosis involve synthesis of TGF-β(beta)1 in hepatic endothelial and Kupffer cells [213], and leptin's direct promitogenic and profibrogenic effects on HSCs [215, 218, 219]. In contrast to leptin, adiponectin has been shown to exert antifibrogenic effect. Adiponectin knockout mice are more susceptible than wild type mice to CCl_4-induced fibrosis [220], and adiponectin is shown to reduce fibrogenic effect of leptin on activated HSCs [221]. Adiponectin inhibits AKT pathway through adenosine monophosphate-activated protein kinase and suppresses proliferation of activated HSCs [222, 223].

Hepatitis Virus C

Accelerated recurrence of fibrosis in a significant number of patients receiving transplantation for HCV-induced liver cirrhosis is a major clinical challenge. It is apparent that the subjects vulnerable to this life-threatening pathology that may necessitate retransplantation develop mechanisms of HSC activation. Cultured human HSCs have been found to express CCR7; activation of CCR7 with CCL21, levels of which are elevated in HCV-cirrhosis, induces signaling pathways associated with fibrogenic activity [224]. Human activated HSCs express mRNA for HCV receptors CD81, LDL receptor, and C1q receptor, and their incubation with HCV core and nonstructural proteins induce proliferative and fibrogenic response [225]. Moreover, the magnitude of HSC activation positively correlates with activation of peripheral $CD4^+$ and $CD8^+$ T cells, and is associated with enhanced IL-15 gene expression in HIV/HCV-coinfected and HCV-monoinfected subjects [226]. These results suggest a pathogenic role for IL-15-driven immuno-mediated hepatic fibrosis. Thus, it seems that $CD4^+$ and $CD8^+$ activation-dependent release of IL-15 (and perhaps other cytokines) induce activation of HSCs and their subsequent proliferation and fibrogenic activity is mediated by HCV core protein. Additional work is required to address this critically important issue for development of strategies to prevent HSC activation, fibrosis, and rejection of the graft.

Regulation of Sinusoidal Blood Flow by Stellate Cells

Although vascular smooth muscle cells (VSMC) of the pre- and post-sinusoidal vasculature play major role in hepatic blood flow regulation, substantial experimental evidence indicates an important contribution of sinusoids in this process. About 40–50% of hepatic vascular resistance has been attributed to sinusoids despite the lack of smooth muscle cells [227]. With their ability to contract and relax in response to vasoactive mediators, HSCs have emerged as an important cell type in sinusoidal blood flow regulation. Ultrastructural analysis has revealed the contact of HSCs with autonomous nerve endings [228], and presence of actin-like filaments in the cytosolic extensions [8] that spread over the hepatocytes and around the sinusoidal walls (see Fig. 5.1). Thus, the neurotransmitters released in the vicinity of HSCs might induce contraction or relaxation of HSCs [229].

Perhaps, two of the most important mediators that regulate sinusoidal blood flow are endothelin-1 (ET-1; a powerful vasoconstrictor) and nitric oxide (NO; a vasodilator). Vascular endothelial cells constitutively produce both ET-1 and NO; balance between their synthesis, actions, and

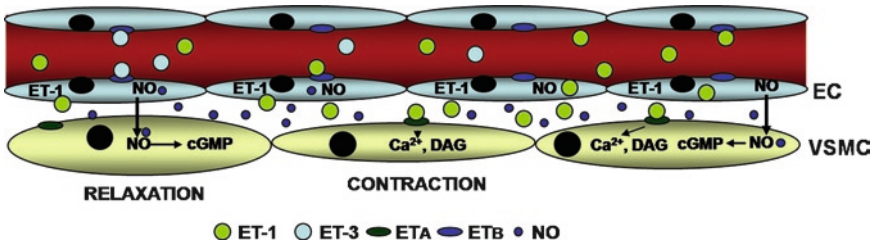

Fig. 5.6 ET-1 belongs to a family of small peptides, three mammalian isoforms (ET-1, ET-2 and ET-3) of which have been identified. ET-1 followed by ET-3, are the predominant forms found in mammalian systems. Originally, ET-1 was discovered to be produced by vascular endothelial cells, but various other cell types are now known to synthesize ET-1. ET-1 is produced as an inactive precursor protein named preproET-1 (about 200 amino acids) that is converted by two step hydrolysis, first to pro or big ET-1 (39 amino acids) and then to active ET-1 (21 amino acids) by endothelin-converting enzyme. Almost all mammalian cell types express ET-1 receptors, which belong to the 7-transmembrane G-protein-coupled superfamily of receptors. There are three subtypes of ET-1 receptors: ETA (ETA1 and ETA2), ETB, and ETC. Activation of ETA on vascular smooth muscle cells (VSMC) elicits vasoconstriction via Ca^{2+} and diacylglycerol (DAG; stimulates protein kinase C)-dependent mechanism. Physiologically, constitutive release of ET-1 and NO by EC, and their effects on VSMC maintain vascular tone. ET-1 exhibits equal affinity for ETA and ETB, whereas ET-3 has much higher affinity for ETB and thus has greater vasodilatory property. Function of ETC, the nonETA and nonETB receptor, are not defined. In addition to the vasoactive effects, ETs have been shown to elicit a variety of biological effects on vascular and nonvascular cell types. [Reviewed in refs. 230–233]

metabolism regulates vascular tone and blood flow (Fig. 5.6) [230–233]. In the liver, ET-1 is synthesized by vascular and sinusoidal endothelial cells [201], biliary epithelial cells [234], HSCs [202, 235, 236] and hepatocytes [197], and metabolized by hepatocytes [237]. ETA and ETB receptor subtypes constitute, respectively, 20% and 80% of ET-1 receptors in rat HSCs [202, 235, 236, 238]. The human HSCs, on the other hand, have predominance of ETA over ETB, but this pattern reverses upon activation with increasing predominance of ETB over ETA receptors during subcultures [69, 239].

Bolus portal introduction of both ET-1 and ET-3 at very low concentration induce powerful and long-lasting constriction of the hepatic vasculature [240]. Although vascular smooth muscle cells of the hepatic blood vessels may be responsible for a major part of this effect, intravital microscopic studies demonstrated ET-1-induced decrease in sinusoidal diameter due to contraction of HSCs [241]. Moreover, ET-1 was also shown to induce contraction of cultured quiescent and activated HSCs [235, 242–244]. Stimulation of both ETA and ETB receptors causes similar contraction of transitionally activated rat HSCs [245]. Since ETA is primarily responsible for contraction of VSMCs, ETB-mediated contraction of HSCs may have important pathophysiologic significance. In this regard, as mentioned above, density of ETB receptors is much greater than that of ETA receptors in rat HSCs and activated human HSCs [69, 202, 236]. Further, ET-3 and sarafotoxin S6c, which bind ETB receptor preferentially, cause potent contraction of hepatic vasculature [51, 241, 246]. In addition to several inflammatory mediators, fibronectin synthesized by activated HSCs may stimulate ET-1 synthesis in an autocrine manner [247]. These data and activation-dependent increased contraction of HSCs [248] indicate that up-regulation of ET-1 system in chronic liver disease [69, 196] has critical implications in the contractile component of portal hypertension. Amelioration of increased portal pressure in various experimental models of liver disease by ET-1 receptor blockade or inhibition of ET-1-induced signaling supports this notion [195, 249–252].

ET-1 stimulates phospholipase C-mediated hydrolysis of phosphatidylinositol-4,5-bisphosphate into two second messengers – inositol-1,4,5-trisphosphate and diacylglycerol [253]. The former causes release of Ca^{2+} from the intracellular (endoplasmic reticulum) stores while the latter stimulates activity of protein kinase C. Both Ca^{2+}-dependent and -independent pathways are responsible for the actomyosin-based contraction of HSCs [254] (see Fig. 5.5). Increase in intracellular Ca^{2+} [242], activation of protein kinase C [253], high conductance Ca^{2+}-activated K^+ channels [255], and stimulation of rho-associated kinase [249, 256] are mechanisms by which ET-1 mediates contraction of HSCs. Evidence indicates that increased Ca^{2+} causes the initial transient contraction while activation of protein kinase C is responsible for the sustained phase [257–259]. Thrombin, angiotensin-II, and norepinephrine are also found to induce contraction of human activated HSCs via increase in cytosolic Ca^{2+} [242, 260]. However, thrombin and angiotensin-II are unable to elicit contraction of rat HSCs [248] indicating species-specific differences in HSC biology.

Interestingly, superoxide causes increase in the functional ETB receptors and enhances the release of ET-1 from HSCs [236]. Constriction of the hepatic vasculature due to increased levels of endogenous ET-1 is a major mechanism of decreased hepatic blood flow during ischemia/reperfusion as indicated by amelioration of liver injury by ET-1 antagonists [261, 262]. ET-1-induced contraction of quiescent (nontransformed) HSCs in vivo [241] and in cell culture [244] suggests that sinusoidal narrowing due to the action of ET-1 on HSCs may contribute to ischemia/reperfusion injury.

The contractile effect of ET-1 on HSCs can be accompanied by parallel counter-regulatory relaxation. ETB receptor activation of human activated HSCs stimulates synthesis of

PGE_2 and PGI_2 [123], which cause their relaxation [243]. The liver endothelial cells express constitutive NO synthase (cNOS or eNOS), and Kupffer cells and HSCs express inducible NOS (iNOS) upon stimulation with inflammatory mediators and/or endotoxin. Inhibition of ET-1-induced contraction of HSCs by NO donors has been demonstrated [243]. While ET-1 stimulates NO synthesis in hepatic endothelial cells [263], gram-negative bacterial endotoxin (lipopolysaccharide, LPS) stimulates ET-1 [264] as well as NO synthesis in HSCs [264, 265]. Furthermore, soluble mediators released by endotoxin-challenged HSCs induce iNOS expression and stimulate NO synthesis in hepatocytes [266, 267]. However, NO synthesis in endothelial cells is reduced in cirrhotic rat liver [268], and LPS inhibits ET-1-induced NO synthesis in hepatic endothelial cells [263]. Thus, complex interactions between HSCs, ET-1 and NO regulate hepatic hemodynamics in physiology and pathology. In chronic liver disease and upon reperfusion following ischemic conditions, vasoconstrictor effect of ET-1 appears to predominate in contributing to portal hypertension and ischemia/reperfusion injury respectively.

Carbon monoxide (CO) is also investigated as a mediator of many important biological events including hemodynamic regulation in the liver [269–271]. Along with biliverdin, CO is generated as a by-product of the reaction catalyzed by heme-oxidizing enzymes heme oxygenase-1 (HO-1) and HO-2. Constitutive HO-2 is expressed by hepatocytes and to a smaller extent in Kupffer cells, while inducible HO-1 is expressed by Kupffer cells and HSCs upon appropriate stimulation [269, 270]. The role of CO in sinusoidal blood flow regulation via HSCs is indicated by (a) hepatic venous CO efflux; (b) elevation in vascular resistance concurrent with discrete patterns of constriction in sinusoids at the sites of HSCs and reduction of the sinusoidal perfusion velocity by heme oxygenase inhibitor zinc protoporphyrin IX; and (c) reversal of this effect by CO and cGMP [269].

Role in Hepatic Growth, Inflammation, and Immune Regulation

The liver receives nearly 75% of its blood from the abdominal organs, and thus is constantly exposed to gut-derived toxic substances, including endotoxin and antigens. Under pathological conditions, the liver receives greater amounts of microbial products, including LPS, as well as microbes, viruses, and viral-derived products. But the liver has the ability to process and clear these harmful substances with high efficiency. In addition to harboring the largest resident macrophage population (Kupffer cells) that plays a major role in clearance of toxins and microbes, the liver also contains immune competent cells, including dendritic cells (DCs), natural killer (NK), natural killer T (NKT), and extrathymic T cells [272, 273]. Moreover, the liver cells synthesize complement and acute phase proteins [274]. Thus, the liver provides the first line of host immune defense against antigens and aberrant cells by removing them from the portal circulation, and also contributes toward induction of peripheral immunotolerance and surveillance against circulating pathogens.

The blood cells move slowly through the liver's vasculature due to sluggish flow in the narrow sinusoids allowing lengthy interactions between the lymphocytes and liver-resident antigen-presenting cells (APCs). Such interactions are further lengthened when resistance to blood flow increases due to narrowing of the sinusoids (as during reperfusion following transplantation and resection). This causes extravasation of lymphocytes through endothelial fenestrations into the subendothelial space, allowing their direct contact with HSCs and hepatocytes. Professional APCs such as hepatic DCs and Kupffer cells express molecules required for antigen presentation (mainly HLA class II) and exhibit immune properties under basal conditions. The nonprofessional APCs such as sinusoidal endothelial cells gain this function primarily upon stimulation with cytokines [275–278]. Both types of cells express class I MHC and the B7 (CD80, CD86) co-stimulatory molecules, and can prime T cells in an antigen-specific and MHC-restricted manner [272, 278]. Nonprofessional APCs thus play a supporting role to the immune system in inflamed tissues.

Due to their central "privileged" location, ability to produce a number of cytokines, chemokines and growth mediators, and expression of antigen-presenting and co-stimulatory molecules, it was realized that HSCs could be a critical cell type to participate in hepatic inflammation and immunity. Table 5.2 shows the inflammatory and immune-regulatory molecules expressed and produced by HSCs. HSCs secrete chemokines such as monocyte chemoattractant protein-1 (MCP-1) [279–281], platelet-activating factor (PAF) [282], and IL-8 or its rat homolog cytokine-induced neutrophil chemoattractant [46, 283–285]. In quiescent HSCs, TNF-α(alpha) and not LPS induces MCP-1 expression, but LPS stimulates MCP-1 and macrophage inflammatory protein-2 (MIP-2) expression in activated HSCs independent of endogenous production of TNF-α(alpha) [286, 287]. Exogenous TNF-α(alpha) as well as other proinflammatory cytokines such as IL-1α(alpha) and IFN-γ(gamma) potently stimulate MCP-1 expression in activated HSCs [279, 287]. HSCs enhance neutrophil and monocyte transmigration from hepatic sinusoids into the parenchyma and induce their activation during hepatic injury, thus playing a major role in hepatic inflammation. These data have important clinical implications. For example, expression of MCP-1 in HSCs is elevated in patients with chronic viral hepatitis [279, 280], serum and hepatic levels of IL-8 correlate with severity of chronic viral hepatitis and cirrhosis [283], and marked neutrophil infiltration is associated with a rapid progression of alcohol-induced hepatitis to cirrhosis and poor prognosis [288].

Table 5.2 Inflammatory and immune-regulatory molecules expressed by HSCs, and their functions

Mediators	Functions
TNF-α(alpha)	Induction of surface ICAM-1 expression and chemokines
MCP-1	Chemotaxis of mononuclear leukocytes
MIP-2	Chemotaxis of neutrophils
PAF	Chemotaxis of neutrophils
CINC/IL-8	Chemotaxis of neutrophils
ICAM-1	Adhesion of inflammatory and immune regulatory cells
VCAM-1	Adhesion of inflammatory and immune regulatory cells
IL-10	Inhibition of macrophages and Th1 lymphocytes
TGF-β(beta)	Downregulation of Th1 lymphocytes; induction of Treg
Osteopontin	Chemotaxis for Kupffer cells and macrophages
IFN-β(beta)	Antiviral activity
Nitric oxide	Suppression of T cell activation
MHC I and MHC II	Antigen presentation
CD80, CD86, CD40	Costimulation of T cells
CD1d	Lipid antigen presentation to NKT cells

CINC cytokine-induced neutrophil chemoattractant, *ICAM-1* intracellular adhesion molecule 1, *IL* interleukin, *MCP-1* monocyte chemoattractant protein 1, *MIP-2* macrophage-inhibitory protein 2, *PAF* platelet-activating factor, *TGF* transforming growth factor, *TNF* tumor necrosis factor, *VCAM-1* vascular cell adhesion molecule 1

ICAM-1, expressed on the cell surface, contributes to cellular adhesion and transmigration of leukocytes through the vascular wall via interactions with β(beta)2 integrins, LFA-1 (CD11a/CD18) and myelin-associated glycoprotein-1 (CD11b/CD18) located on the leukocyte cell membrane [289, 290]. Although quiescent HSCs express mRNA transcript of ICAM-1 and also of VCAM-1, the protein expression is very low, mostly localized in the cytosol, activation of HSCs is associated with increased expression of these molecules at the cell surface [291, 292]. LPS and TNF-α(alpha) both upregulate the expression of ICAM-1 and VCAM-1 in activated HSCs and stimulate transmigration and attachment of lymphocytes [46, 291]. These properties of HSCs present an additional mechanism that contributes to hepatic inflammation.

The physiologic concentration of LPS in the portal blood is 1–10 ng/ml. LPS is endocytosed predominantly by Kupffer cells, which respond to its actions via specific receptors [293, 294]. Activation of LPS-responsive cells, such as monocytes and macrophages, occurs after binding of LPS to CD14 [295, 296]. The effects of LPS are enhanced in the presence of lipopolysaccharide binding protein (LBP) produced by hepatocytes and secreted in serum [294, 297]. TNF-α(alpha) is rapidly induced in cells of the mononuclear phagocyte system after stimulation with LPS [298, 299]. Production of TNF-α(alpha) by macrophages in response to microbial stimuli is critically dependent on activation of Toll-like receptor-4 (TLR-4) [300–302], which belongs to the family comprising of more than ten Toll-like receptors (TLRs). Mammalian TLRs are transmembrane proteins named after Toll, originally identified as a molecule essential for embryonic development of Drosophila. The cytoplasmic portion of mammalian TLRs exhibit similarity to IL-1 receptors, but the extracellular domains are quite different. TLRs function as pattern-recognition receptors and instigate cell's response by recognizing pathogen-associated molecular patterns. LPS acts as a ligand for TLR-4 whereas TLR-2 recognizes bacterial lipoproteins and glycolipids. For detailed review on basic characteristics of TLRs see Akira et al. [302].

Both quiescent and activated HSCs express CD14 [267, 303], and while the expression of TLR-4 is low in quiescent HSCs, it increases upon their activation [46, 267, 303]. TLR-4 elicits inflammatory signals such as synthesis of IL-8 and MCP-1, and expression of ICAM-1 and VCAM-1 in activated HSCs [46]. LPS stimulates synthesis of proinflammatory cytokines TNF-α(alpha) and IL-6, and of NO (induction of iNOS) via NFκ(kappa)B- and p38-MAPK-dependent signaling in HSCs [266, 267, 303]. LPS-induced synthesis of these molecules in quiescent rat HSCs that express very low levels of TLR-4, in the absence of lipopolysaccharide-binding protein [267], indicates an interesting possibility of non-TLR-4, non-CD14-mediated mechanism. Using ligands specific for various TLRs, antiviral cytokine (primarily IFN-β(beta)) production was found to occur upon stimulation of TLR-3 and -4 in murine HSCs and of TLR-3 in human HSCs [304].

Whereas TNF-α(alpha), IL-6 and NO produced by HSCs and other hepatic cell types are known to support hepatic regeneration, HSCs are a primary cell type to produce the most potent hepatocyte mitogen, hepatocyte growth factor, as well as another mitogen TGF-α(alpha) [134, 135]. HSCs can also support liver regeneration after fulminant liver failure by influencing oval cells. Oval cells are seen to proliferate and differentiate in close proximity to HSCs in both human and rodent livers [305–308]. In rats, HSCs penetrate continuous basement membrane surrounding the ductules formed by oval cells, and establish direct contact with them [306]. Further, activated HSCs express keratinocyte growth factor, which stimulates growth of hepatocytes via FGFR2-IIIb receptor exclusively expressed by the latter [308]. In contrast to the pro-mitogenic effects, HSCs can also prevent proliferation of hepatocytes. As yet, unidentified soluble mediators released by LPS-stimulated HSCs cause induction of iNOS, endoplasmic reticulum stress, inhibition of DNA synthesis, and promote apoptosis of hepatocytes [266, 267, 309]. Further, NO produced by LPS-stimulated HSCs and in turn by hepatocytes may be an important mechanism of the suppression of T cell activation [310]. Thus, multiple responses provoked by LPS in HSCs can contribute significantly to the pathophysiological changes associated with acute and chronic liver diseases, liver resection, and liver transplantation.

Recent work from several laboratories has shown that HSCs can act as antigen presenting cells by expressing MHC-I, MHC-II, CD80, CD86, CD40, and CD1d [311, 312]. Coculture of cytokine (IL-1β(beta)+IFN-γ(gamma))-stimulated

HSCs induce proliferation of allogeneic whole lymphocyte preparation in an HLA-II-dependent manner [311]. With this machinery and mechanism, HSCs can induce T cell activation and proliferation, and contribute to allogeneic graft rejection. However, activated mouse HSCs were found not to cause activation of $CD8^+$ T cells but to induce apoptosis of allogeneic activated $CD8^+$ T cells through the expression of inhibitory B7 molecule, B7H1 [312]. This apoptotic effect is partly inhibited by anti B7H1 antibody suggesting existence of additional mechanism. A major mechanism of T cells death in the liver involves Fas (expressed by T cells)/FasL interaction [273]. HSCs express and release FasL (Fig. 5.7), and can induce tolerance by promoting apoptosis of T cells. In this regard, apoptotic $CD4^+$ and $CD8^+$ T cells are observed close to HSCs in concanavalin A-treated fibrotic liver in vivo, and activated HSCs cause apoptosis of concanavalin A-activated T cells in vitro [313]. On the other hand, HSCs are also shown to present lipid antigens to CD1-restricted hepatic natural killer T (NKT) cells and promote their homeostatic proliferation through interleukin-15 [314]. Further, adaptive transfer of HSCs primed with bacterial peptides, mediate protection against bacterial infection by activation of T cells in antigen-specific manner [314]. Moreover, accumulation of $CD8^+$ T cells and NK cells in the proximity of HSCs in periportal area and along fibrous septa of CCl_4-treated rats suggests that this might be a mechanism of antigen presentation by the CD11c/MHC-II-expressing HSCs [315]. Thus, HSCs exhibit capacity to perform dual function of antigen-presentation and activation of T cells, and of eliciting apoptosis of activated T cells.

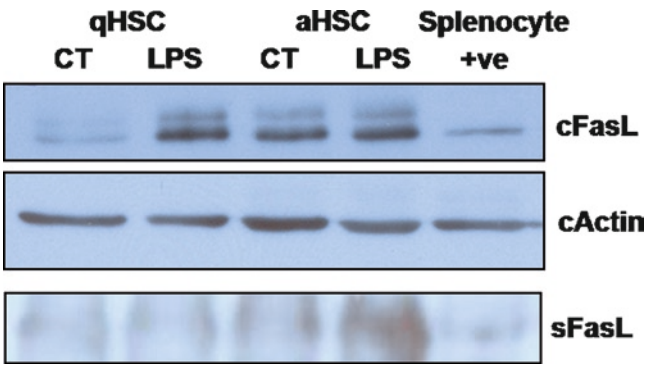

Fig. 5.7 Quiescent HSCs (day 2 of culture) or activated HSCs (day 8 of culture) were challenged with 100 ng/ml LPS and at 24 h, the medium was aspirated. FasL in the medium was immunoprecipitated. Western analysis was then performed to determine FasL expression in the cells and its release in the medium. Splenocytes were used as a positive control.

Recent investigations have provided strong evidence for the role of the transcription factor FoxP3-expressing $CD4^+$ regulatory T cells (Tregs) in immunological tolerance. The importance of retinoic acid in modulating immune cell responses was postulated over three decades ago [316], but only recently, mechanisms of immunoregulation by retinoic acid are being uncovered. An important mechanism of retinoic acid-induced suppression of immune responses involves induction of $FoxP3^+$ Treg. The generation of Treg from naive $CD4^+$ T cells is dependent on TGF-β(beta) and enhanced by retinoic acid [317, 318]. Retinoic acid also causes tropism of Treg [319–321]. As HSCs store large amounts of retinoic acid and also produce TGF-β(beta), they have the ability to promote graft tolerance via Treg induction and expansion. However, retinoic acid inhibits the generation of inflammatory IL-17 secreting $CD4^+$ T cells [318]. Thus, generation of Treg and Th17 cells follows reciprocal developmental pathways with TGF-β(beta) and retinoic acid inducing Treg, and TGF-β(beta) combined with IL-6 (both produced by HSCs [266, 267, 303]) inducing Th17 cells [322]. Co-transplanted activated-mouse HSCs were shown to protect islet allografts from rejection by reducing allograft immunocyte infiltration and enhancing their apoptosis [323]. The mechanisms of such protection involve expansion of $CD4^+CD25^+FoxP3^+$ Tregs, in addition to B7H1-mediated death of T cells [324, 325]. Figure 5.8 depicts possible mechanisms by which HSCs may provide protection, or contribute to rejection of the transplanted liver graft.

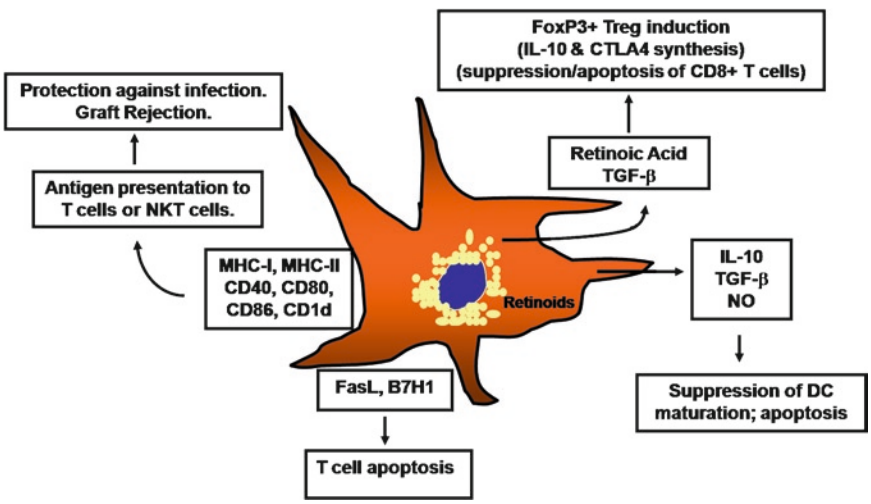

Fig. 5.8 Various currently known mechanisms by which HSCs can regulate hepatic immune responses. See text for description

Selective Elimination of HSCs as Therapeutic Strategy

The first clue that hepatic fibrosis can be reversed was presented nearly 30 years ago [326]. Subsequently, spontaneous recovery of fibrosis was demonstrated in rat models of bile duct ligation-induced [327] and CCl_4-induced [120] liver fibrosis upon termination of the causal factor. Several clinical trials have shown improved liver functions upon treating human cirrhosis of various etiologies with antiviral agents, steroids, immunosuppression, and surgical manipulations [328–335]. Treatment with antioxidant S-adenosine methionine (SAMe) improved liver functions in cholestatic liver diseases and alcoholic cirrhosis [336, 337], and some Chinese herbal medicines have demonstrated improvement in HBV-induced liver cirrhosis [338].

These findings demonstrate promising results in animal models and significant success in clinical trials in treating chronic liver diseases. It is beyond the scope of this chapter to describe the details of these investigations and all relevant publications (reviewed in 121, 339–341). Apart from anti-viral drugs and abstinence from alcohol or surgical correction for cholestatic liver injury, prevention of proliferation with induction of apoptosis of activated HSCs or their reversal to quiescent phenotype is a rational approach in treating hepatic fibrosis. Strategies employed to arrest and/or reverse cirrhosis by direct or indirect effects on HSCs are described below.

Inhibitors of Endogenously Produced Substances

Reducing the hepatic levels of TGF-β(beta) or antagonism of its actions is a logical approach in limiting fibrosis because of its multiple effects on HSCs. These effects include (a) potentiation of activation, survival and proliferation induced by agents such as PDGF and TNF-α(alpha), (b) stimulation of the synthesis of ECM components and TIMPs and inhibition of the synthesis of MMPs, and (c) stimulation of the synthesis of vasoconstrictor ET-1. Another advantage of anti-TGF-β(beta)1 treatment is that the cytokine has anti-growth and pro-apoptotic activities towards epithelial cells including hepatocytes [134, 135]. TGF-β(beta)1 neutralizing antibodies were found to reverse bile duct ligation-induced liver injury in rats [183].

As described above, ET-1 system is up-regulated in human cirrhosis of various etiologies [69, 196]. Because ET-1 is profibrogenic and mitogenic for HSCs [51, 69], and also a potent constrictor of vascular smooth muscle cells and activated HSCs, ET-1 antagonists can be promising therapy to reduce fibrosis and ameliorate contractile component of portal hypertension. The spontaneous resolution of CCl_4-induced liver cirrhosis is accelerated when rats received endothelin antagonist treatment [342], and arrest of fibrosis progression and reversal of the so called irreversible cirrhosis was demonstrated with ET-1 receptor antagonist treatment while continuing CCl_4 administration [343]. ET-1 antagonists were also found to be effective in reversing bile duct ligation-induced fibrosis [183, 344, 345]. It should, however, be noted that although ET-1 antagonists have shown benefits in treatment of chronic heart disease and pulmonary hypertension, in some of these trials there was evidence of mild liver damage [346–349]. On the other hand, one year treatment of Child A and Child B cirrhotic patients with angiotensin type 1 receptor blocker Candesartan cilexetil was found to cause mild reduction in portal pressure [350]. The effect was suggested to be due to reduced fibrogenic activity.

ECM stimulates focal adhesion kinase and in turn tyrosine phosphorylation in HSCs via integrins expressed on the cell surface [351]. Such interactions cause cell contraction, and potentiate PDGF-induced cell proliferation, cytoskeletal organization, and cell motility [352, 353]. Inhibition of the actions of integrins by specific neutralizing antibodies or antisense mRNAs was found to inhibit activation of HSCs and cause apoptosis of activated HSCs [351, 354].

Polyenylphosphatidylcholine, a mixture of polyunsaturated phosphatidylcholines, was also found to inhibit activation of HSCs and to ameliorate PDGF-induced proliferation of activated HSCs [355]. Polyenylphosphatidylcholine also prevents lipid peroxidation [356] and inhibits LPS-induced TNF-α(alpha) synthesis in Kupffer cells [357]. Moreover, treatment with polyenylphosphatidylcholine reduced the number of HSCs in patients with alcoholic liver disease [358]. SAMe, a precursor of glutathione, was found to inhibit HSC activation in both in vitro and in vivo models of liver fibrosis [359–361]. Similarly, vitamin E and agents such as silymarin, colchicine, and milotilate that stimulate antioxidant mechanisms have been shown to inhibit hepatic fibrosis in animal models [339, 362].

An endogenous cannabinoid anandamide (N-arachidonylethanolamine) causes necrotic death of both rat and human activated HSCs. However, anandamide also induced apoptosis of hepatocytes [363]. This observation, and inflammation and tissue damage associated with necrotic death of HSCs induced by anandamide as well as its vasodilatory property [364, 365] necessitate substantial work and development of its derivatives that target activated HSCs for therapeutic application. Another endogenously produced molecule that causes apoptosis of activated HSCs is nerve growth factor (NGF), receptor, which is expressed by activated but not quiescent HSCs [366]. Interestingly, NGF is expressed by hepatocytes during liver injury suggesting a paracrine action of the mediator on HSC apoptosis [367].

Inhibitors of Signaling Pathways Associated with Activation and Fibrogenic Activity of HSCs

An essential role of NFκ(kappa)B activation in survival and proliferation of HSCs generated the hypothesis that prevention of its activation will block proliferation and induce apoptosis of activated HSCs. Indeed, the compound sulfasalazine selectively blocked NFκ(kappa)B-dependent gene transcription and promoted apoptosis via activation of JNK [368]. Another substance pentoxifylline also inhibited NFκ(kappa)B activation and proliferation of activated HSCs in vitro and in vivo [369, 370].

Targeting signaling associated with PDGF-induced proliferation of HSCs (tyrosine phosphorylation of the receptor and PI3-kinase activation) is another strategy tested in cultured HSCs and in models of liver fibrosis in vivo. Treatment with tyrosine phosphorylation blocker SU-5874 led to significant decrease in CCl_4-induced hepatic fibrosis in rats; SU-5874 also markedly inhibited the proliferation of activated HSCs [339]. Transfection of HSCs with an adenovirus expressing a dominant negative form of PI3-kinase under control of α(alpha)-sma promoter was found not only to reduce proliferation, migration, and several profibrogenic genes, but also induced cell death [371]. Although this adenoviral transfection in vivo caused reduction in pro-fibrogenic mechanisms in a short-term bile duct ligation-induced injury in rats, it did not prevent liver cell damage [371]. It remains to be determined whether HSC-targeted PI3-kinase inhibition in animal models of advanced liver disease has any benefits.

Summary and Perspective

Since their discovery more than a century ago, and initial identification of their lipid-storing property over 50 years ago, the realization that HSCs could be the main cell type to cause liver fibrosis stimulated extensive research to elucidate the mechanisms of this function. Over the years, researchers unfolded many other interesting and important properties of HSCs ranging from storage and release of retinoids, to the synthesis of a number of cytokines/chemokines and growth mediators, contractility, and more recently hepatic inflammation and immune regulation. With their central privileged location, HSCs are uniquely versatile in their interactions with and influence the characteristics not only of the other hepatic cell types, but also of the blood cells that traffic through the liver. The Dr. Jekyll and Mr. Hyde personalities of HSCs have become a subject of intense interest for basic as well as clinical scientists, particularly to target specific elimination of these cells as a therapy for chronic liver diseases. Although considerable success has been achieved in inhibiting fibrogenesis by activated HSCs in animal models and human clinical trials, these cells have been successful in hiding the secret of that magic bullet that would remove them from the chronically injured liver. Undoubtedly, research in coming years will achieve this important goal. The ongoing and future work will also provide precise understanding of the role HSCs play in hepatic inflammation and immunity and its application to acute and chronic liver diseases, as well as liver transplantation.

Chapter 6
Kupffer Cells

Chandrashekhar R. Gandhi

Origin, Location, and Life Span of Kupffer Cells

Kupffer cells, the resident hepatic macrophages, form a major part of the reticuloendothelial or mononuclear phagocyte system. In 1876, German anatomist Karl Wilhelm von Kupffer observed cells that stained with gold chloride in the liver. He designated them as "sternzellen" based on their star shape and proposed that they were specialized endothelial cells that function as phagocytes. In 1898, a Polish pathologist Tadeusz Browicz proposed that the cells described by von Kupffer were macrophages [1]. In 1974, Wisse used electron microscopy and peroxidase staining, and correctly identified resident sinusoidal macrophages that are named Kupffer cells [2, 3]. Of the main nonparenchymal cell types (Kupffer cells, satellite cells, endothelial cells, and Pit cells or natural killer cells), Kupffer cells account for about 30–35% by volume and about 20% by number of the nonparenchymal cells [4, 5].

Bone marrow stem cells that circulate as monocytes differentiate and mature into Kupffer cells in the liver through the actions of mediators such as macrophage colony-stimulating factor, granulocyte/macrophage colony-stimulating factor, and interleukin-3 (IL-3) [6, 7]. Kupffer cells are irregular shaped and are located in the lumen of sinusoids (capillaries in the liver) adhering to the endothelial cells (Fig. 6.1). Their cytoplasmic processes (pseudopodia), which indicate phagocytic function, protrude into the sinusoidal lumen and may also penetrate into Disse's space through larger endothelial fenestrations.

Kupffer cells can be identified by immunostaining with antibodies against macrophage surface ED2 antigen CD163 (rat) (Fig. 6.2) [8, 9], a glycoprotein that binds low density lipoprotein CD68 (human) [10, 11], or a cell surface glycoprotein F4/80 (mice) related to the seven transmembrane-spanning family of hormone receptors [12, 13]. Kupffer cells in zone 1 (periportal), zone 2 (midzonal), and zone 3 (pericentral) of the liver acinus exhibit a ratio of 4:3:2 [14]. The size and phagocytic activity (lysosomal content and enzyme activity) of Kupffer cells are greatest in the periportal and least in the pericentral area [14, 15]. Functional differences in the periportal and pericentral Kupffer cells are also illustrated by relatively greater level of tumor necrosis factor-α (TNF-α), prostaglandin E2 (PGE2), and IL-1 synthesis by larger Kupffer cells, while reverse scenario is observed in regard to their nitric oxide (NO) synthetic capacity [16].

Based upon the distribution of the cells labeled with latex particles and [^{3}H]thymidine labeling index, the life span of rat Kupffer cells was estimated to be several months [15]. However, cells of donor origin repopulate the liver within 14–21 days after bone marrow transplantation in mice [17]. Depletion of Kupffer cells in rodents by liposome-encapsulated clodronate causes a robust proliferative response from the residual cells and recruitment of monocytes [18], resulting in complete repopulation between 14 to 16 days [8, 19]. In monocytopenic mice, Kupffer cells were found to be maintained for over 40 days with strong mitogenic activity [20]. While Kupffer cells of recipient origin completely replace the donor cells within 15–30 days after liver transplantation in rats, the cells of the donor liver persist for up to 1 year in humans [21].

Isolation and Culture of Kupffer Cells

Kupffer cells are isolated by collagenase and protease digestion of the liver via the portal vein. After separating the cells from the digested liver, the parenchymal cells are removed by low speed centrifugation, and the nonparenchymal cells are pelleted from the supernatant by centrifugation at higher speed. Kupffer cells can then be purified by isopycnic sedimentation in two-step Percoll gradient (25 and 50% Percoll) [22] with a yield of about $40–60 \times 10^6$ cells/rat liver. For additional purification, nonparenchymal cells are first obtained by density gradient centrifugation in 17.5% metrizamide; Kupffer cells and endothelial cells are then separated by centrifugal

elutriation [23, 24]. The cells can be plated in standard culture medium (e.g., William's medium E, or RPMI medium) supplemented with 10% fetal calf serum, and used after overnight culture or within 3 days following isolation. The primary contaminants in Kupffer cell preparation are hepatic endothelial cells (2–5%), but they do not attach to the plates under these culture conditions, and thus removed during renewal of the medium. The purity of the cells is determined by immunostaining with ED2 (Fig. 6.3) or F4/80 in conjunction with immunostaining for stellate cells (desmin or GFAP), endothelial cells (SE1 or factor VIII related antigen) and epithelial cells (clone AE1/AE3) [25, 26].

Mouse Kupffer cells can be purified via selection with CD11b or F4/80 antibodies. The nonparenchymal cells obtained as described above are treated with anti-CD11b or anti-F4/80 antibodies followed by purification of Kupffer cells by magnetic microbead cell sorting [27, 28].

Phagocytosis and Clearance Functions of Kupffer Cells

The liver provides the first line of the body's defense against noxious substances including gut- and environment-derived toxins, microbial and viral products, and xenobiotics to which it is constantly exposed via the portal blood. Kupffer cells play a major role in fulfilling this obligation, which is aided by sluggish blood flow through the sinusoids thus allowing their lengthy interactions with the components of the portal blood. Kupffer cells also remove microorganisms, senescent and damaged red blood cells, and circulating neoplastic cells. Phagocytosis of a variety of particulate matter including cell debris and bacteria or bacterial fragments is facilitated by their binding to plasma fibronectin, which is recognized by specific trypsin-sensitive receptors on Kupffer cells. The particulate material of size greater than 10 nm is phagocytosed by Kupffer cells, following binding to the surface receptors. Smaller particles are phagocytosed after aggregation to increase the size. The phagocytic activity of Kupffer cells can be measured by the ability to ingest latex particles [29]. Phagocytosis by Kupffer cells triggers synthesis of ROS, arachidonate metabolites (prostaglandins, thromboxanes, and leukotrienes), cytokines and chemokines, which play important role in defense as well as inflammatory responses [30].

In addition to the uptake of defective and senescent red blood cells [31, 32], Kupffer cells also remove efficiently vesicles containing hemoglobin shed by the red blood cells [33, 34] and hemoglobin–haptoglobin complexes [35]. Scavenger receptors class A type I and II, and CD163 mediate this clearance thus providing protection from free hemoglobin-mediated oxidative injury. Hemoglobin is degraded by heme oxygenase (HO)-1 (inducible isoform) and HO-2 (constitutive isoform) with the formation of iron, biliverdin, and carbon monoxide (CO). These three molecules play critically important protective roles against tissue

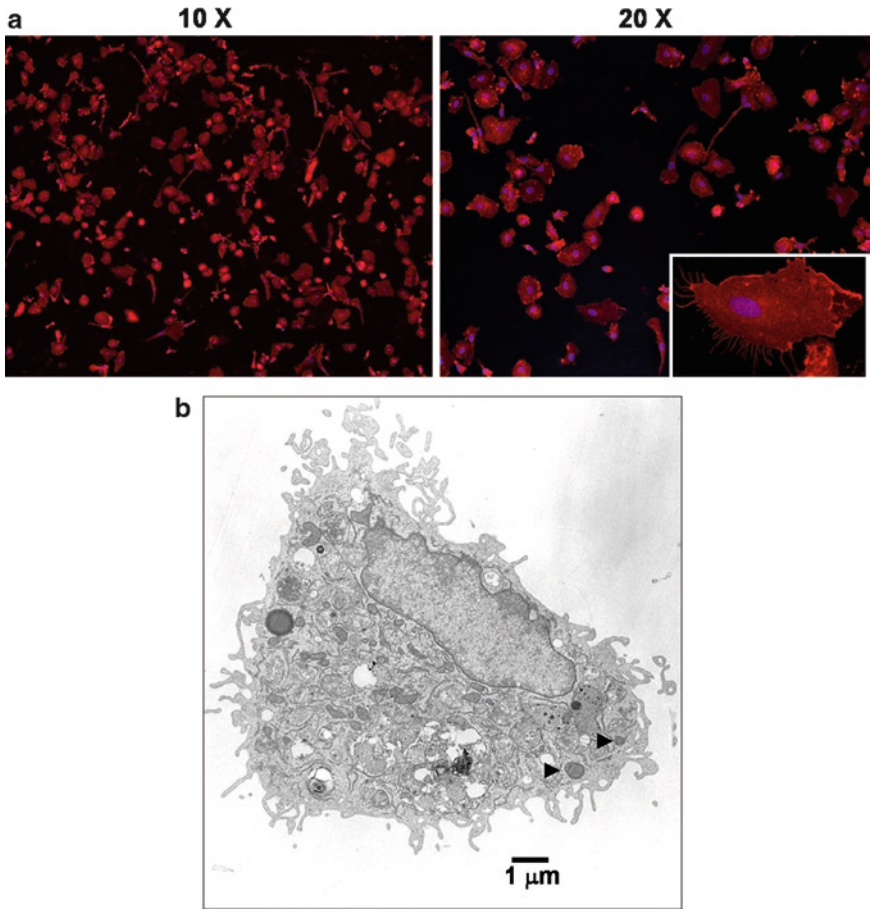

Fig. 6.3 (**a**) Kupffer cells in primary culture on day 2 stained with ED2. *Inset* shows a Kupffer cell with pseudopodia (×100). (**b**) A transmission electron micrograph of a cultured Kupffer cell on day 2. Pseudopodia are visible and lysozomes are indicated by *arrowheads*

injury: low levels of iron are cytoprotective and antiapoptotic [36]; bilirubin formed from biliverdin has antioxidant properties [37]; and CO imparts cytoprotection and prevents liver damage caused by stress conditions such as ischemia/reperfusion [38–40]. Apart from being a vasodilator, CO also exhibits antiapoptotic, anti-inflammatory, and antiproliferative properties [41]. Anti-inflammatory agents such as IL-10 and glucocorticoids increase expression of CD163 and HO-1 in Kupffer cells [39, 42].

As mentioned above, Kupffer cells phagocytose neoplastic cells, and therefore provide a critical mechanism of preventing hepatic metastasis of gastro-intestinal malignancies. The malignant cells detached from the primary tumor enter into the portal circulation [43], with Kupffer cells as the primary cell type to encounter them. The aggressive increase in the development of tumor in Kupffer cell-depleted liver exemplifies their importance in causing effective elimination of the metastatic cells [44–46]. The antitumor activity of Kupffer cells was shown to increase upon stimulation with IFNγ, granulocyte–macrophage colony stimulating factor, and muramyl dipeptides [47, 48].

Activation of Kupffer Cells

Kupffer cell responses are subject to alterations depending upon the concentrations and nature of substances present in the portal blood. Substances such as complement factors C3a and C5a [49], bacteria- and fungi-derived b-glucans [50], and gram-negative bacterial endotoxin (lipopolysaccharide, LPS) [19, 30, 51, 52] all cause activation of Kupffer cells. The effects of LPS on Kupffer cells have been studied extensively. LPS-induced activation of Kupffer cells occurs following its binding to CD14, a glycosylphosphatidylinositol-anchored membrane protein. The concentration of LPS required to cause activation of Kupffer cells is significantly reduced and the effects enhanced by its association with circulating LPS-binding protein (LBP) [53, 54], a 60-kDa acute-phase protein secreted by hepatocytes. The LPS-LBP interactions may have physiological importance considering chronic exposure of Kupffer cells to low levels of LPS. LPS-LBP complexes are shown to be more potent than LPS alone in stimulating synthesis of proinflammatory mediators such as TNF-α [55, 56]. However, the basal expression of CD14 in Kupffer cells is relatively much lower than in

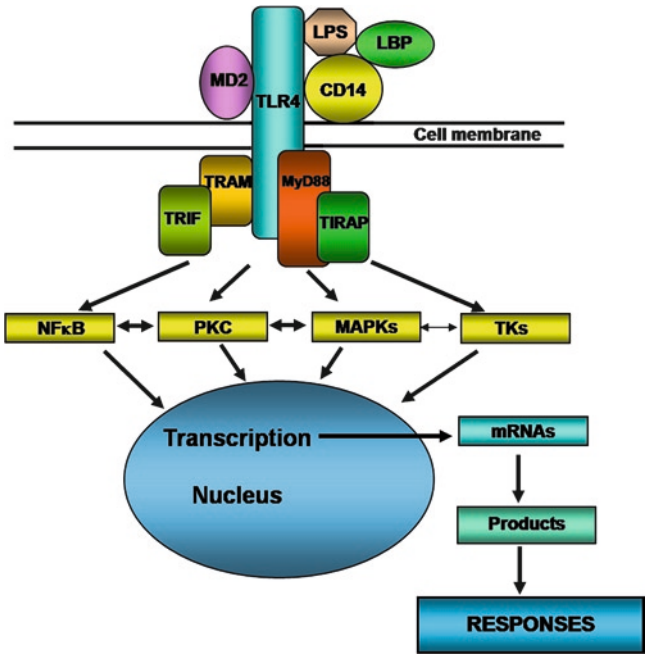

Fig. 6.4 The established TLR4/CD14 assembly of LPS receptor complex and transmembrane signaling molecules that mediate the intracellular effects of LPS. Please see text for detailed description

monocytes [57], and is up-regulated by a several mediators including LPS itself [58], and in liver diseases of various types [52]. The LPS/LBP/CD14 ternary complex stimulates multiple signaling pathways, including activation of nuclear factor κ-B (NFκ-B), nonreceptor tyrosine kinases (TK), protein kinase C (PKC), and mitogen-activated protein kinases (MAPKs) (Fig. 6.4) [59–65].

Since CD14 is a membrane anchored protein without transmembrane domain, it requires additional mechanisms to elicit cellular effects. These are provided by membrane-spanning Toll-like receptors (TLRs) [66], the most notable and extensively studied among them being TLR4 [67–69] (Fig. 6.4). MD-2, a secreted protein, closely associates with the extracellular domain of TLR4 imparting LPS responsiveness to the cells [68, 70]. TLR4 signals via four intracellular adaptor proteins, which operate in functional pairs: MyD88 (the myeloid differentiation factor 88)/TIRAP (toll-interleukin 1 receptor-containing adapter protein), and TRAM (TLR adapter molecule 2)/TRIF (TIR domain-containing adaptor-inducing IFN-β) [70–73]. Downstream of TLR4, signaling occurs via MyD88, which associates with IL-1 receptor associated kinase (IRAK) and TNF-activated factor-6 (TRAF-6). TRAF-6-mediated signaling pathways activate NFκ-B, which results in the production of proinflammatory cytokines [66].

TLR2 has also been suggested to cause LPS-mediated signaling by binding to LPS in the presence of LBP and CD14 [74, 75]. In Kupffer cells, TLR2 activation by zymosan was found to stimulate chemokine production that was mediated via activation of p38 and c-Jun N-terminal kinase (JNK) MAPK [76]. Further, upregulation of TLR2 in Kupffer cells during endotoxemia in mice suggests its role in hepatic innate immune responses via these macrophages [77].

LPS activates p38-, JNK-, and extracellular signal-regulated kinase 1/2 (ERK1/2)-MAPK in Kupffer cells. However, blockade of p38 activation was found to inhibit LPS-induced synthesis of both TNF-α and IL-10 [78]. These authors also reported that blockade of ERK1/2 activation reduced LPS-stimulated TNF-α production without having any effect on IL-10 synthesis. ERK1/2-dependent LPS-induced synthesis of TNF-α was also reported by other authors [79]. Interestingly, Kupffer cells isolated from ethanol-fed mice produce much greater amounts of TNFα upon LPS stimulation in the absence of NFκ-B activation indicating an alternate mechanism of the cytokine production [79]. Thus, LPS-induced TNF-α synthesis coupled to stimulation of early growth response protein-1 (Egr-1) was observed in Kupffer cells (Fig. 6.5). Greater nuclear binding of Egr-1 in LPS-stimulated Kupffer cells from ethanol-fed rats in comparison to cells from pair-fed rats was suggested to be a mechanism of increased TNF-α synthesis [79].

While NFκ-B activation has been implicated in the synthesis of inflammatory cytokines, receptor-mediated phopholipase C-induced phosphoinositide signaling pathway also plays an important role in Kupffer cell responses. Most G-protein coupled receptors, upon ligand binding, stimulate phospholipase C-induced hydrolysis of phosphatidylinositol-4,5-bisphosphate to diacylglycerol (DAG) and inositol-1,4,5-trisphophate (IP3). DAG stimulates PKC and IP3 causes release of calcium from intracellular stores (specifically endoplasmic reticulum), thus increasing concentration of cytosolic calcium (Fig. 6.5). In several instances, this initial reaction is followed by influx of extracellular calcium through specific membrane channels. Increased cytosolic calcium stimulates phospholipase A2 which catalyzes hydrolysis of membrane phospholipids with the release of arachidonic acid from sn-2 position. Arachidonic acid is then converted into eicosanoids including prostaglandins, thromboxanes, and leukotrienes by the enzymes cyclooxygenases (COX-I or COX-II), or lipoxygenase (Fig. 6.5). While PGE2 [80] and PGD2 [81, 82] stimulate glycogenolysis in hepatocytes [83], thromboxane A2 and leukotiene C4 cause hepatic vasoconstriction [84, 85]. Kupffer cell-derived PGE2 has also been implicated in hepatoprotection [86], putatively by inhibiting synthesis of TNF-α and prostaglandins [87, 88].

Kupffer cells are the primary hepatic site of the synthesis of a potent lipid mediator platelet-activating factor (PAF) in response to particulate matter [89] or LPS stimulation [83, 90, 91] (Fig. 6.5). Experimental findings that administration of PAF causes effects similar to those of LPS, such as hypotension, cardiac failure, vasoconstriction, and vascular leakage indicate that this lipid mediator plays a critical role

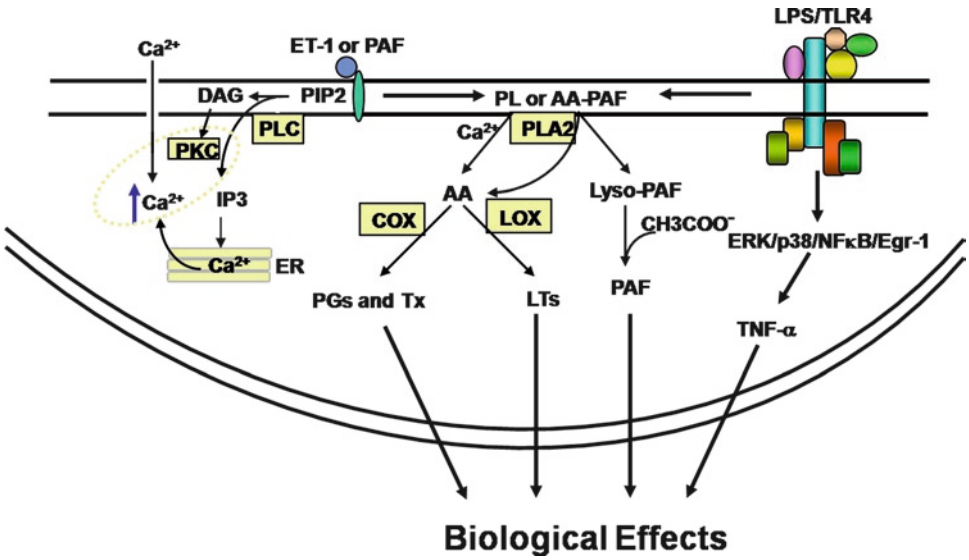

Fig. 6.5 Mechanisms of the effects of endothelin-1, PAF, and LPS on Kupffer cells. Endothelin-1 (ET-1) or platelet activating factor (PAF) bind to the G-protein coupled receptor and stimulate phospholipase C (PLC)-induced hydrolysis of phosphatidylinositol-4,5-bisphosphate (PIP2) into DAG and inositol-1,4,5-trisphosphate. IP3 causes release of calcium from intracellular stores (endoplasmic reticulum: ER), and DAG stimulates protein kinase C (PKC). The binding of ET-1 or PAF also facilitates entry of extracellular calcium. Increased cytosolic calcium stimulates phospholipase A2 that causes hydrolysis of phospholipids or 1-alkyl,2-arachidonyl-3-phosphocholine with the release of arachidonic acid, and formation of lysophospholipids or lyso-PAF. Lyso-PAF is converted to PAF with addition of acetyl moiety at sn2 position. Arachidonic acid is metabolized to prostaglandins (PGs) + thromboxanes (TXs) via the action of cyclooxygenase (COX), or to leukotrienes via the action of lipoxygenase. PAF and the arachidonic acid metabolites are released, and exert actions on the other cells of the liver. LPS also stimulates phospholipase A2 and subsequent reactions, in addition to stimulating the synthesis of inflammatory mediators via activation of ERK1/2 or p38 MAPK, NFκ-B or Egr-1

in LPS-induced biological responses *in vivo* [92]. PAF binds to a G-protein coupled receptor on Kupffer cells and stimulates synthesis of arachidonic acid metabolites [83, 93–95] (Fig. 6.5). LPS also stimulates synthesis of a potent vasoconstrictor endothelin-1 (ET-1) in rat liver [96], in hepatic stellate cells [97] and endothelial cells [98]. ET-1 instigates phospholipase C/phosphoinositide signaling cascade in Kupffer cells coupled to synthesis of prostaglandins and PAF [94, 95, 99] (Fig. 6.5). In isolated perfused rat liver, portal infusion of PAF as well as ET-1 causes vascular resistance and glucose output [100–102]. PAF administered via portal vein in situ causes hepatic vasoconstriction and systemic hypotension [103]. Such intrinsic mechanism of the synthesis of PAF, ET-1, and prostanoids, involving Kupffer cells, can be an integral part of metabolic changes and hemodynamic alterations acutely (ischemia/reperfusion) and in chronic liver diseases (portal hypertension). PAF has also been shown to be a mediator of LPS-induced liver injury in partially hepatectomized rats [104].

The binding of PAF to its receptor causes activation of NFκ-B [105, 106] and up-regulation of the TNF-α gene [107]. While PAF on its own was found to cause modest stimulation of TNF-α and superoxide generation, much greater level of synthesis of both TNF-α and superoxide induced by LPS (receptor-mediated), or zymosan (phagocytosis) are abrogated by PAF receptor antagonism [108]. The authors concluded that the PAF antagonists elicited such effect by interfering with LPS- and zymosan-induced signal transduction. On the other hand, LPS and PAF were reported to exert additive effect on the synthesis of nitric oxide in Kupffer cells [109].

At high concentrations, LPS can activate Kupffer cells indirectly by triggering complement activation either in the portal or in the systemic circulation [110]. The complement factors C3a and C5a stimulate phospholipase C cascade of signaling with the synthesis of ROS including superoxide (via NADPH oxidase), eicosanoids, and cytokines [111–113]. While ROS activate signaling pathways responsible for physiological processes and killing of the invading microorganisms [114], they are also implicated in the initiation and progression of liver pathologies [115, 116]. ROS and their lipid peroxidation products have been shown to damage macromolecules including DNA and to cause death of several cell types including hepatocytes [117–121]. Thus activated Kupffer cells, by producing an array of biologically active mediators, and by interacting with factors released in the hepatic microenvironment by other cell types, play critical roles in a variety of pathophysiological conditions. These conditions are described in the following sections.

Role in Liver Regeneration

Molecular basis of liver regeneration is discussed independently in Chap. 18.

The liver responds to many types of injuries (toxin-, chemical-, or virus-induced; partial resection to excise tumors; and transplantation) that cause cellular loss by initiating robust regenerative response. Most of the factors identified to influence regeneration process following injury are produced by the liver itself, but the contribution of humoral factors is also of significant importance. While powerful mitogens such as epidermal growth factor (EGF), transforming growth factor (TGF)-α, and hepatocyte growth factor (HGF); co-mitogens such as insulin, glucagon, insulin-like growth factor (IGF), and priming agents TNF-α and IL-6 appear to facilitate this process, the role of growth inhibitors, TGF-β and possibly IL-1β that are upregulated contemporaneously, is considered equally important. [122–124]. Many of these factors (HGF, TGF-α, TNF-α, IL-6, IL-1β, and TGF-β) are produced by Kupffer cells.

Substantial information has been obtained in regard to the role of Kupffer cells in hepatic regeneration and liver injury by inducing blockade of their functions by gadolinium chloride (GdCl3), or their elimination by liposome-encapsulated clodronate. Mice treated with clodronate show much lower level of HO-1 and eNOS expression and blunted regenerative response than control mice following resection [125]. Kupffer cells also promote liver regeneration by increased expression of ICAM-1 that facilitates recruitment of leukocytes. Liver regeneration after partial hepatectomy has been reported to be impaired in ICAM-1 knockout mice [126].

Stimulation of hepatic DNA synthesis by TNF-α administration [127, 128], increase in its concentration before activation of transcription factors STAT-1, c-jun, c-fos, AP-1, and NFκ-B [129–131], and its ability to cause fourfold increase in the mitogenic response of hepatocytes to HGF and TGF-α [132], indicate the importance of TNF-α in hepatic regeneration. Pretreatment of rats with neutralizing antibodies against TNF-α before partial hepatectomy was also found to inhibit hepatocyte proliferation for up to 72 h after the surgery [51, 133]. Because serum concentrations of TNF-α are not elevated after partial hepatectomy, it was suggested that liver injury probably results in local release of TNF-α [51]. Indeed, Kupffer cells are found to be a major source of intrahepatic TNF-α as indicated by lower levels of TNF-α and slow regeneration in Kupffer cell-depleted mice as compared to the control mice [126]. Comparison of early molecular responses to partial hepatectomy in anti-TNF-α-treated and control animals indicated that the trophic actions of TNF-α involve activation of JNK [134], several growth-related transcription factors (c-Jun [130], CCAAT enhancer binding protein-p (C/EBP+), and C/EBP-8 [135]) within minutes of liver injury. There is evidence that TNF-α elicits its actions in hepatic regeneration via IL-6 [136]. It has been shown that TNF-α stimulates IL-6 synthesis in Kupffer cells [137] and the defect in hepatic regeneration in animals lacking TNF receptors is restored by administration of IL-6 [138].

In contrast to the findings described above, rodents in which functions of Kupffer cells were blocked by pretreatment with GdCl3 still demonstrated increased TNF-α, IL-6 mRNA expression, and enhanced liver regeneration in association with enhanced signaling coupled to mitogenic responses [139]. The alternate or additional source of these cytokines remains to be determined. Although stellate cells produce both TNF-α and IL-6 in response to LPS [25, 140, 141], whether they synthesize these cytokines in partially hepatectomized animals is unclear. Kupffer cells were also found to exert detrimental effect on regeneration in mouse partial liver transplantation model, in which GdCl3 pretreatment improved portal blood flow and sinusoidal perfusion with superior survival outcome [142]. Similar outcome of partial liver transplantation in TNF receptor I knockout mouse led the authors to conclude that signaling events involving Kupffer cell-derived TNF-α is responsible for poorer results in control mice [142].

Role in Ischemia/Reperfusion Injury

The liver undergoes injury during procurement and cold preservation prior to transplantation, and during surgical resection when the blood supply is interrupted. The injury is escalated upon reperfusion of the graft, or of the residual post-resection liver due to accumulated, and newly formed ROS [120, 121]. The reperfusion injury is of even greater concern in case of marginal donor- and small-for-size (living-related donor) liver transplantation [143–145]. Amelioration of portal venous clamping-induced [146, 147] as well as transplantation-related [40] ischemia/reperfusion injury in rats by GdCl3 blockade of Kupffer cells, indicates their role in the pathological developments. Experimental evidence from several laboratories demonstrated that activation of Kupffer cells is an important multifactorial cause of ischemia/reperfusion injury. Kupffer cells have been found to be activated during cold preservation of the graft [86]. Furthermore, LPS, levels of which are generally high in patients with liver diseases and remain elevated for several days following liver transplantation [148, 149], can induce activation of Kupffer cells. Activation of Kupffer cells is associated with morphological alterations that cause reduction in sinusoidal blood flow [147, 150]. As described before, activated Kupffer cells also produce increased amounts of ROS, several proinflammatory cytokines such as TNF-α, IL-6, IL-1, arachidonic acid metabolites, PAF, and chemokines [30, 52, 151, 152]. In addition to causing damage to hepatocytes directly, Kupffer cell-derived

cytokines and chemokines also recruit inflammatory polymorphonuclear leukocytes and neutrophils, which escalate and perpetuate the liver injury [153–158].

The role of TNF-α and IL-6 in ischemia/reperfusion injury is of high significance. CO inhalation by recipient animals results in inhibition of hepatic TNF-α and IL-6 expression, and reduced ischemia/reperfusion injury to the transplanted graft [40]. Treatment with neutralizing TNF-α antibody also ameliorates ischemia/reperfusion injury [157, 158]. Reduced LPS-induced release of TNF-α and IL-6 by CO-treated, cultured Kupffer cells [40] not only supports the role of these macrophages in ischemia/reperfusion injury, but also suggests a therapeutic avenue. While there is overwhelming evidence for significant contribution of Kupffer cells to ischemia/reperfusion injury, activated Kupffer cells also produce anti-inflammatory mediators such as IL-10 and IL-13 [151, 152] suggesting an internal mechanism of limiting the injury caused by proinflammatory cytokines and ROS.

Another mechanism by which Kupffer cells cause and perpetuate ischemia/reperfusion injury is by producing PAF [83], or by releasing TNF-α, or TGF-β that stimulate synthesis of ET-1 in endothelial cells and stellate cells [159–163]. Both ET-1 and PAF are potent constrictors of the hepatic vasculature [102, 164]. Blockade of endothelin actions has been shown to ameliorate portal venous ligation-induced as well as transplantation-related ischemia/reperfusion injury [165–168]. Reduced endothelin secretion and improved liver function after warm ischemia/reperfusion in rats pretreated with GdCl3 [169], confirm the role of Kupffer cell in this pathology by stimulating ET-1 synthesis. PAF antagonism has also been shown to ameliorate ischemia/reperfusion injury induced by portal vein occlusion and liver transplantation [170–172].

Role in Alcohol-Induced Liver Injury

Alcohol consumption causes increased gut permeability and increase in the circulating levels of endotoxin (LPS) [173, 174]. Increased LPS elicits hepatic inflammatory response, which is primarily due to inflammatory cytokines produced by Kupffer cells. Work from several laboratories has shown that Kupffer cell activation and inflammatory mediators produced by them including TNF-α, IL-6, IL-1α, and IL-1β play a critical role in the onset and progression of ethanol-induced liver injury. While steatosis is the most common manifestation of alcohol-induced hepatic pathology in almost all of laboratory animals fed with alcohol, they do not develop hepatic fibrosis that is seen in advanced alcoholic liver disease in humans [131, 175]. Kupffer cell-derived inflammatory mediators and ROS have been proposed to play an important role in fibrosis development by inducing activation of hepatic stellate cells to the fibrogenic phenotype [176–178] (see also Chap. 5). The early events of the pathologic progression (fatty liver and inflammation) were found to be prevented upon depletion of Kupffer cells in rats fed with alcohol, intragastrically [179].

Kupffer cell-derived TNF-α plays an important role in alcohol-induced hepatic injury. Its concentration is found to increase in the blood of alcoholics [180, 181] and rats fed alcohol via gastric infusion [174]. Alcohol-induced liver injury is ameliorated in rats administered with anti-TNF-α antibodies [182] in TNF receptor 1-knockout mice [183], and in rats pretreated with antisense oligonucleotide targeted against TNF-α mRNA [184]. Since repeated exposure to LPS both in vivo and in vitro causes endotoxin tolerance, it is expected that Kupffer cell responses to LPS should be desensitized during ethanol feeding [185]. Interestingly, however, long-term ethanol consumption increases the susceptibility of rats to endotoxin-induced liver injury [186, 187]. Furthermore, alcohol feeding hypersensitizes Kupffer cells to LPS actions as illustrated by fourfold greater increase in TNF-α release by cells isolated from rats fed with alcohol in response to LPS compared to pair-fed rats [79]. This effect was attributed to enhanced activation of ERK1/2 and increased binding of early growth response-1 (Egr-1) to the TNF-α promoter upon LPS stimulation [79]. Prevention of LPS-induced NFκ-B and ERK1/2 activation, and TNF-α production in Kupffer cells from rats ingesting alcohol chronically by antioxidant dilinoleoylphosphatidylcholine [188] suggests that these effects are dependent upon generation of reactive oxygen species. In LPS-stimulated Kupffer cells, ROS are generated by membrane NADPH oxidase since its specific inhibitor diphenyliodonium abrogated ERK1/2 phosphorylation, and ROS, and TNF-α production [189, 190].

The above-mentioned intracellular signaling events coupled to LPS-induced increased TNF-α synthesis by Kupffer cells isolated from alcohol-fed animals may be explained by increased CD14 (receptors for LPS) expression in Kupffer cells, and elevated hepatic LBP concentration [191]. Up-regulation of CD14 in Kupffer cells by LPS [58], and reduced alcohol-induced liver injury in CD14-knockout mice [192], as well as LBP-knockout mice [193] strongly support LPS-Kupffer cell interactions in the pathology of alcoholic liver disease. Although unaltered [194] as well as increased [195] expressions of TLRs (particularly TLR4 and TLR2) have been reported in alcohol-fed animals, TLR4-knockout mice were shown to be resistant to alcohol-induced injury [196].

The other pathway by which Kupffer cell-derived TNF-α contributes to alcoholic liver disease is by increasing the generation of Th1 cytokines IL-6, IFN-γ, and IL-12 [197]. These authors also showed much greater levels of bioactive TNF-α and the Th1 cytokines by endotoxin treatment of mice on high fat, and alcohol diet relative to those on high fat diet alone.

Role in Non-alcoholic Fatty Liver Disease

Non-alcoholic fatty liver disease (NAFLD) is one of the most common causes of chronic liver disease in Western countries [198–200], with insulin resistance as the hallmark of its pathophysiologic progression [201]. NAFLD encompasses a wide range of pathologies, which include development of simple steatosis found in obese people that can progress to nonalcoholic steatohepatitis (NASH), decompensated cirrhosis and hepatocellular carcinoma. Many features of NAFLD are very similar to alcoholic liver disease with steatosis and inflammation driving each other's progression. TNF-α produced by activated Kupffer cells plays an important role in the development of steatohepatitis [202] and hepatic fibrosis associated with NASH [203]. The importance of TNF-α in NAFLD is supported by observations that its increased release is associated with development of insulin resistance and fibrosis [204, 205], and its deletion protects animals from high fat diet-induced insulin resistance [206]. TNF-α-induced JNK activation has been shown to inhibit tyrosine kinase activity of the insulin receptor and is suggested to be a critical mechanism of obesity-induced insulin resistance [207].

The low level subacute activation of NFκ-B in transgenic mice expressing IKK-β was found to mimic the inflammatory pathways leading to insulin resistance and fat deposition seen in mice fed high fat diet [208]. This effect, also observed systemically, was attributed to synthesis of proinflammatory cytokines including TNF-α, IL-6, and IL-1β in Kupffer cells, and could be alleviated by IL-6 neutralization [208]. Hepatic and circulating IL-6 levels have been shown to be increased in NAFLD and exhibit correlation with the severity of inflammation, fibrosis, and insulin resistance [209]. Based on the evidence that TNF-α-induced hepatic regeneration is mediated by IL-6 [136–138] and protection of high fat-induced insulin resistance by blockade of TNF-α [206], it is likely that IL-6 is a mediator of the effects of TNF-α in these conditions.

In addition to their direct involvement, activated Kupffer cells also produce CXC (e.g., IL-8) and CC chemokines (e.g., MCP-1) that induce recruitment and activation of neutrophils and polymorphonuclear leukocytes, and subsequent fibrogenic activity via transdifferentiation of stellate cells [210]. Activation of Kupffer cells in NAFLD, similar to alcoholic liver disease, appears to involve LPS as indicated by a high frequency of small intestinal bacterial overgrowth, and endotoxemia in patients with NASH [211]. Although activation of Kupffer cells appears to be critical in the development of NAFLD, mice with increased constitutive activation of NFκ-B in myeloid cells due to lack of Iκ-B kinase also develop insulin resistance [212].

Recent work has indicated decreased negative regulation of NAFLD progression due to reduced anti-inflammatory cytokine production by Kupffer cells. Such negative regulation is provided by IL-10, the synthesis of which is stimulated by adiponectin, an anti-inflammatory adipokine [213]. Furthermore, adiponectin also inhibits LPS-stimulated TNF-α synthesis in Kupffer cells [214]. Circulating adiponectin levels were found to be reduced in alcoholic liver disease [214, 215] and NASH [216]. Interestingly, adiponectin receptors were found to be underexpressed in visceral fat, but overexpressed in the liver in NASH [216]. The importance of this adipokine as an anti-inflammatory agent and antisteatotic agent is underscored by the observations that hepatic triglycerides, inflammation, oxidative stress, and insulin resistance are increased upon deletion of adiponectin receptors, and steatosis is reduced in genetically obese mice overexpressing adiponectin [217].

Role in Regulation of Immune System

Being exposed continuously to a variety of noxious substances, including antigens and bacterial products, the liver has an obligation to respond to them rapidly and effectively. The liver eliminates circulating $CD8^+$ T cells specific for systemically disseminated antigens, and thus plays a critical role in preventing generalized inflammation [14, 218–220]. Hepatic natural killer cells, dendritic cells, and Kupffer cells form an integral and a major part of the hepatic innate immune system to provide such response and clear the potentially dangerous external attack [221]. Expression of a number of TLRs including TLR2, TLR4, and TLR9 by Kupffer cells and their response to stimulation of these receptors [76, 77, 195], attests to the seminal importance of Kupffer cells in hepatic innate immune system. Kupffer cells express scavenger receptors that recognize Fc component of the immunoglobulins and activated complement factor C3b, thus eliminating IgA- and IgM-coated particles and immune complexes [222–225]. Kupffer cells also phagocytose neutrophils and thereby contribute profoundly to the adaptive immune functions of the liver.

The liver is also naturally tolerant as evident from the persistent viral (hepatitis virus B and hepatitis virus C) and parasitic (malarial parasite) infections [226–228]. Such immunological privilege is also evident from the rare incidence of accelerated liver allograft rejection across the ABO barriers and is caused by the generation of antidonor antibodies seen frequently in kidney and heart transplantation [229–231]. Chronic rejection of the liver allograft is also infrequent as compared to the other organs [232, 233]. Kupffer cells can act as liver-specific professional antigen-presenting cells by expressing class I and class II MHC and co-stimulatory molecules (CD40, CD80, and CD86), and thus activate infiltrating and resident T cells, and NKT cells in an antigen-specific and MHC-restricted manner. However, in vitro experiments

demonstrated that despite the repertoire of antigen presentation machinery, the efficiency of Kupffer cells to present antigen and activate $CD4^+$ T cells is inferior to the macrophages derived from spleen, or bone marrow [234].

Abrogation of allograft survival induced by portal vein administration of allogeneic donor cells upon blockade of Kupffer cell functions [235] indicated their role in providing tolerance. Kupffer cells isolated from chronically accepted liver allografts were found to cause apoptosis of alloreactive T cells, and their infusion was found to prolong the survival of hepatic allografts in an acute rejection model [236]. A mechanism of such tolerance could be via generation of immunosuppressive cytokines IL-10 and TGF-β by Kupffer cells probably in response to LPS in the portal circulation [234]. Hepatic sinusoidal endothelial cell- as well as Kupffer cell-induced activation of CD4+ T cells was shown to be suppressed by IL-10 through down-regulation of receptor-mediated antigen uptake, and inhibition of cell surface expression of class II MHC and co-stimulatory molecules [237]. Moreover, IFNγ, and LPS [238], as well as phagocytosis [239] induce overexpression of FasL in Kupffer cells. Thus FasL-induced death of T cells [219, 221, 227, 239, 240] can be an additional important mechanism of liver tolerance.

Summary and Perspectives

The seminal role of Kupffer cells in protecting the liver and other organs from harmful substances and microorganisms is unquestionable. In addition to performing these functions by their phagocytic and endocytic activities, Kupffer cells also produce a variety of cytokines and ROS that destroy the microorganisms. By producing cytokines and growth factors, Kupffer cells also play an important role in hepatic regeneration when required. Furthermore, they have the ability to recruit white blood cells in performing these functions. However, Kupffer cells also contribute to pathological developments by persistently producing higher levels of the very same cytokines, chemokines, and growth mediators as well as ROS. These pathological conditions include, but are not limited to, reperfusion injury, alcoholic liver disease, NASH, and failure of transplanted liver graft. Depletion of Kupffer cells or blocking their functions to understand their role in physiology and pathology has provided critical information. However, evidence for both beneficial and detrimental roles of Kupffer cells in hepatic pathology has emerged from these studies. A more elaborate examination of Kupffer cell functions, as well as their interactions with other hepatic cell types, especially endothelial cells to which they are attached, stellate cells in the perisinusoidal space of Disse, and cells of the immune system (both resident and recruited via circulating blood) will be required to exploit Kupffer cells in liver health and disease.

Chapter 7
Sinusoidal Endothelial Cells

Donna Beer Stolz

The Liver Lobule, Microcirculation, and the Sinusoidal Endothelial Cell

In all organs in the body, the vasculature is lined by simple, squamous epithelium, properly termed endothelium. However, the endothelia represent an extremely heterogeneous population of cells, and those of each organ, or more appropriately, each specific functional part of an organ, maintain characteristic features that enable the vasculature to perform particular roles at the blood–tissue interface [1, 2]. Regardless of the organ in question, the endothelia in normal tissues maintain a nonthrombogenically lined conduit through which a variety of blood cells and vehicle (plasma) assist in delivering oxygen, nutrients, and maintenance factors to, while removing debris, waste, and breakdown products from the underlying tissue. While the liver sinusoidal endothelium undeniably perform these duties, they possess additional phenotypes with a wide variety of unique capabilities essential to maintaining liver function.

The capillaries of the liver are more properly called liver sinusoids since they are lined with discontinuous endothelium that do not possess a continuous basal lamina, similar in structure, but not function, to those of lymphoid tissue and some endocrine organs [3] (Fig. 7.1). This vasculature is distinctive among the endothelial population, in that, liver sinusoidal endothelial cells (LSEC) in normal, adult liver have fenestrations without semipermeable proteinaceous diaphragms (Fig. 7.2). Fenestrations (Latin fenestrae: "window") are transcellular pores with an average diameter of approximately 160 nm (in rats) that represent a porosity of about 6–10% along the hepatic microvascular surface [3]. First described in great detail by Dr. Eddie Wisse in the early 1970s [3, 4], these pores are concentrated in attenuated areas of the LSEC and arranged in groups of 20–50 fenestrations called sieve plates. There are reported differences in porosity, fenestration diameter, and basement membrane deposition among different mammalian and nonmammalian species, but the general architectural phenotype in the hepatic sinusoids is surprising well retained [5–8].

In contrast, the larger vessels of the liver lobule (i.e., portal and central veins and venules, and hepatic arteries and arterioles) are not fenestrated and possess the characteristic continuous basal lamina found in microvascular endothelium of other organs as well as larger vessels [9]. The endothelia of central venules are very smooth and often contain numerous attached leukocytes [9] (Fig. 7.3). However, the endothelia of the portal venules display a rippling of membrane at areas of cell–cell contact and rarely show attachment of leukocytes to the vessel wall under normal situations (Fig. 7.1c). Little is known about the function of this morphology, but it likely represents a potentially reactive surface by which circulating leukocytes may gain access to the underlying space of Mall, the fluid, and extracellular matrix rich area situated around the portal triad [10, 11]. There is a very abrupt morphological change in the endothelium when the portal venule transitions into the sinusoid. Here, the continuous endothelia of the portal venule become fenestrated immediately at the opening of the sinusoid (Fig. 7.1c). Likewise, the LSEC lose their fenestrations as the vessel merges with the central venules (Fig. 7.3a).

In a healthy individual at rest, hepatic blood volume represents approximately 25% of the total cardiac output and the liver itself is 25–30% blood by volume [10]. The total volume of blood circuits through the liver over 300 times in one 24-h period. Given this expansive reservoir of blood, it follows that the liver is a highly vascularized organ and a large percentage of the total body blood volume is in contact with the hepatic microvasculature at any given time. Approximately 75% of the hepatic blood enters the liver through the portal vein via the hepatic portal circulation directly from the intestines, spleen, and pancreas. This blood is nutrient rich, but oxygen poor. Additionally, under physiologic conditions, endotoxin concentrations in portal venous blood are usually between 100 pg/mL and 1 ng/mL [12]. The remaining 25% of the blood originates from the hepatic artery, a branch of the celiac artery, and brings oxygenated blood to the liver. These two sources of

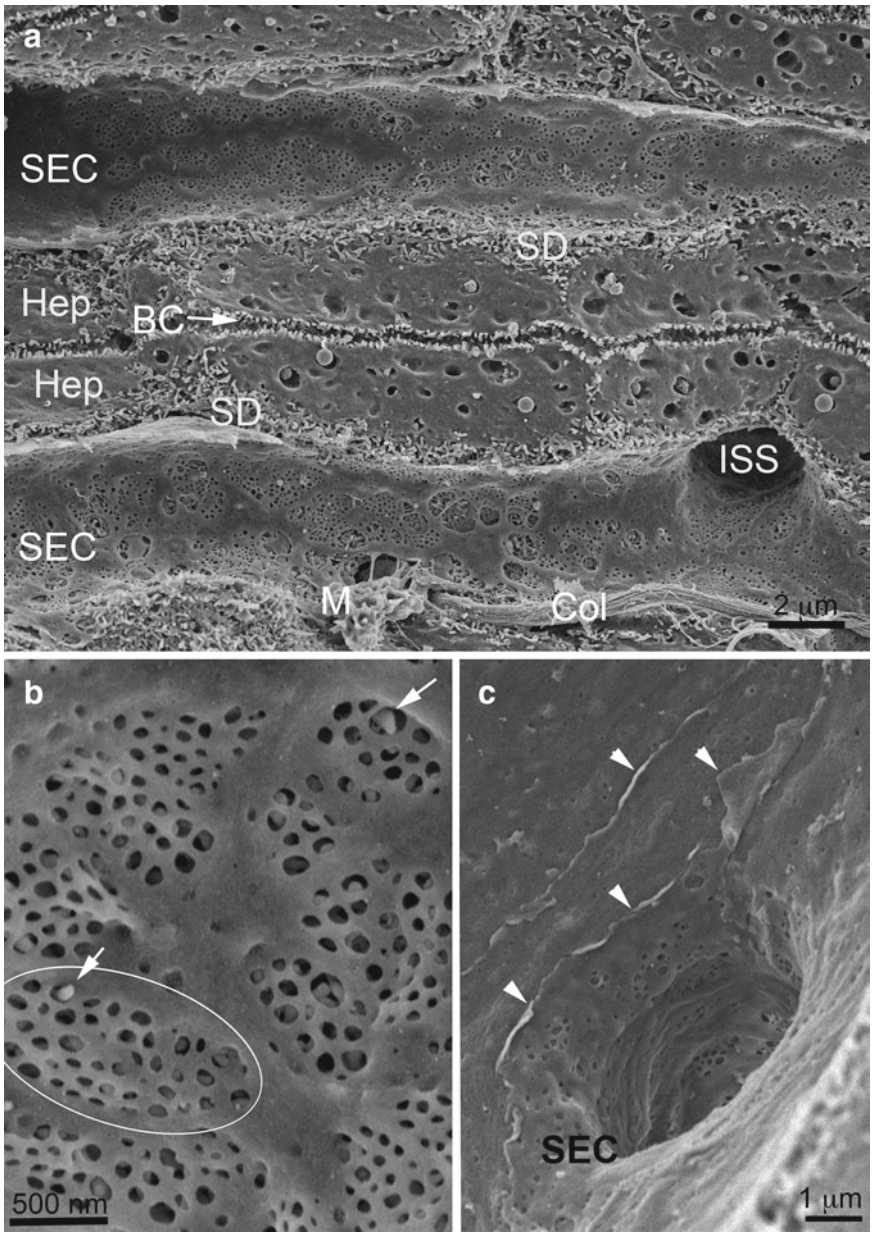

Fig. 7.1 Scanning electron micrographs of mouse liver sinusoidal endothelial cells. (**a**) A low magnification image accentuating the anatomy of the hepatic plate bounded by sinusoids. Fenestrated sinusoidal endothelial cells (SEC) line the sinusoids on either side of a hepatic plate comprised of two rows of hepatocytes (Hep) separated via their apical membrane by the bile canaliculus (BC). An intersinusoidal sinusoid (ISS) is observed entering one of the sinusoids. The ISS link parallel microvascular tracts in the liver. Also, a macrophage (M) is observed on the surface of a sinusoid, and a collagen bundle (Col) is observed emerging from a space of Disse (SD). (**b**) A high magnification micrograph of a sinusoid highlighting sieve plates (collections of fenestrations, *circled*) with the occasional hepatocyte basolateral microvillus poking through a fenestration into the sinusoid lumen (*arrows*). (**c**) Transition of the portal venule into the sinusoid (SEC). Endothelium in the portal venule have areas of raised membrane at cell–cell junctions (*arrowheads*). There is an abrupt change of nonfenestrated to fenestrated endothelium from the portal venule to the sinusoid

blood mix directly in the sinusoid as they exit the portal-triad area. The blood then continues through the length of the lobule via the sinusoids, to exit at a centrilobular hepatic venule where it empties into the hepatic vein to rejoin the systemic circulation via the inferior vena cava. This configuration results in metabolic zonation along the lobule that is driven primarily by an oxygen-tension gradient [13]. Blood entering periportal sinusoids have a pO_2 (partial pressure) of about 60–65 mmHg (~8% O_2), while for blood exiting the perivenous sinusoids, the pO_2 is only about 30–35 mmHg (~4% O_2). Heterogeneity in the LSEC along this gradient has been reported and reflects their

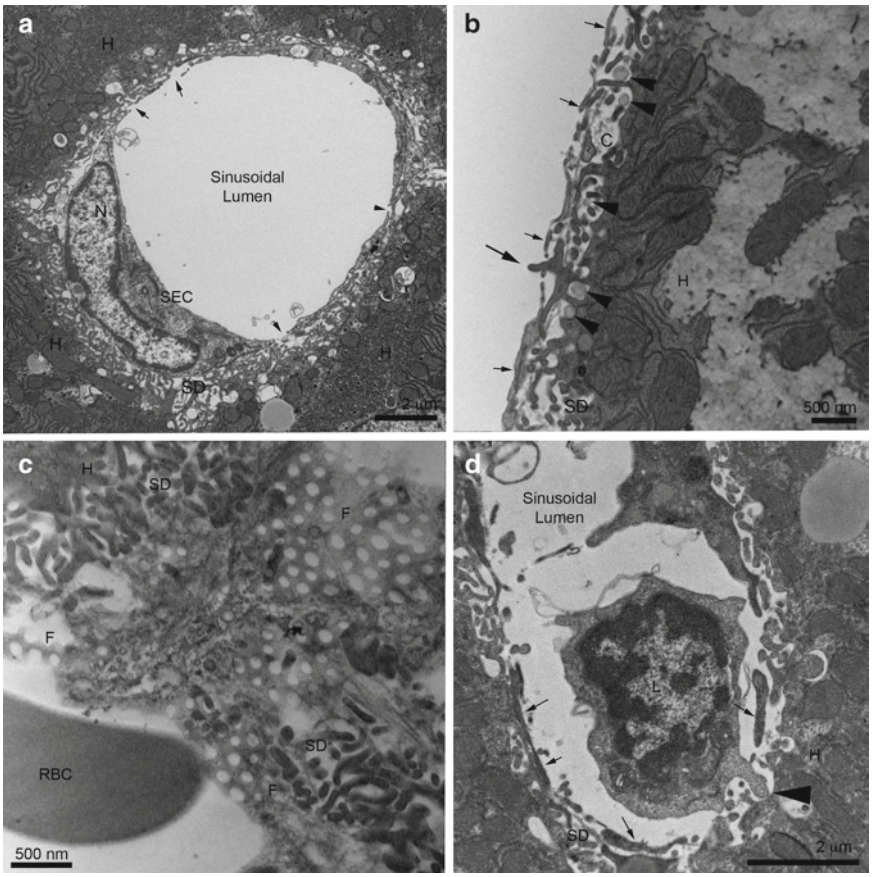

Fig. 7.2 Transmission electron micrographs of the hepatic sinusoid of a mouse. (**a**) Cross section through a typical sinusoid in the liver. The sinusoidal endothelial cell (SEC) outlines the sinusoidal lumen. Areas of fenestrations and/or gaps in the SEC are indicated by *arrows*. The SEC nucleus (N) is observed in this section. Separated by the space of Disse (SD), hepatocytes (H) surround the sinusoid. (**b**) High magnification of the space of Disse (SD) which is bounded by the SEC (*small arrows*) and the hepatocyte (H). A hepatocyte microvillus is observed penetrating through a fenestration in this field (*large arrow*). Chylomicron remnants are seen within the space of Disse (*arrowheads*). There is no basement membrane observed in the space of Disse. (**c**) Tangential section through a sinusoidal endothelial cell, accentuating the fenestrations (F) and the hepatocyte (H) microvilli within the space of Disse (SD). A red blood cell (RBC) is observed in the sinusoidal lumen. (**d**) A lymphocyte coursing through the sinusoid pokes a pseudopod through a larger fenestration of the sinusoidal endothelium (*arrows*) to make contact with the underlying hepatocyte (*arrowhead*)

(**a**) Fenestrated endothelium (SEC) abruptly lose their fenestrations when merging with the smooth surface of the central venule (CV). Attached to the central venule surface are two macrophages (M) as well as a red blood cell (RBC) at an area exiting the sinusoid. (**b**) A lower magnification view of the central venule showing many flattened macrophages (M) and attached leukocytes (L), as well as red blood cells (RBC), and platelet deposition (P) on the CV surface

function in the lobule including changes in porosity, specific lectin binding, and endocytic capability.

While the blood courses through the sinusoids, the role of the liver in metabolism, detoxification, endocrine, and immune function come into play. Given its peculiar confluence of blood supplies, it has become especially apparent that the liver is truly an immunological organ [14, 15]. Environment sensing is an important function in the liver since, the portal supply transporting blood primarily from the intestines can contain many food and bacterial antigens that have navigated through the intestinal barrier. Liver nonparenchymal cells, specifically Kupffer cells, a variety of leukocytes, and the sinusoidal endothelium, are all poised to react to changes, either in content or concentration, of these antigens. In cases of inflammation, the endothelia serve as a gatekeeper to the infiltration of inflammatory cells into tissue, by modifying their surface markers to allow for cell–cell interactions with circulating immune cells, assisting in their retention or homing to their correct destination.

Organization of Cells Relative to the Liver Sinusoidal Endothelial Cell

Hepatocytes are the parenchymal cells of the liver and constitute the largest number (60%) and volume (80%) of cells in the organ [14, 16]. Hepatocytes are arranged in anatomizing plates that are one cell thick and are bounded on either side by the sinusoids (Fig. 7.4). Lined by the sinusoidal endothelium, several other nonparenchymal cells are present and have specific roles within this environment. LSEC make up the second most abundant cell type in the liver, (about 50% of the nonparenchymal cells) and are positioned between the blood and the hepatocytes [14] (Figs. 7.1, 7.2, 7.4, and 7.5). As the lining of the specialized liver capillary, they occupy a unique niche where they directly interact with nearly all of the other cell types in the liver.

Along the luminal aspect of the sinusoid, LSEC interact quite intimately with Kupffer cells, the resident macrophages in the liver that account for about 20% of the nonparenchymal cells [17]. A more comprehensive account on this cell type is

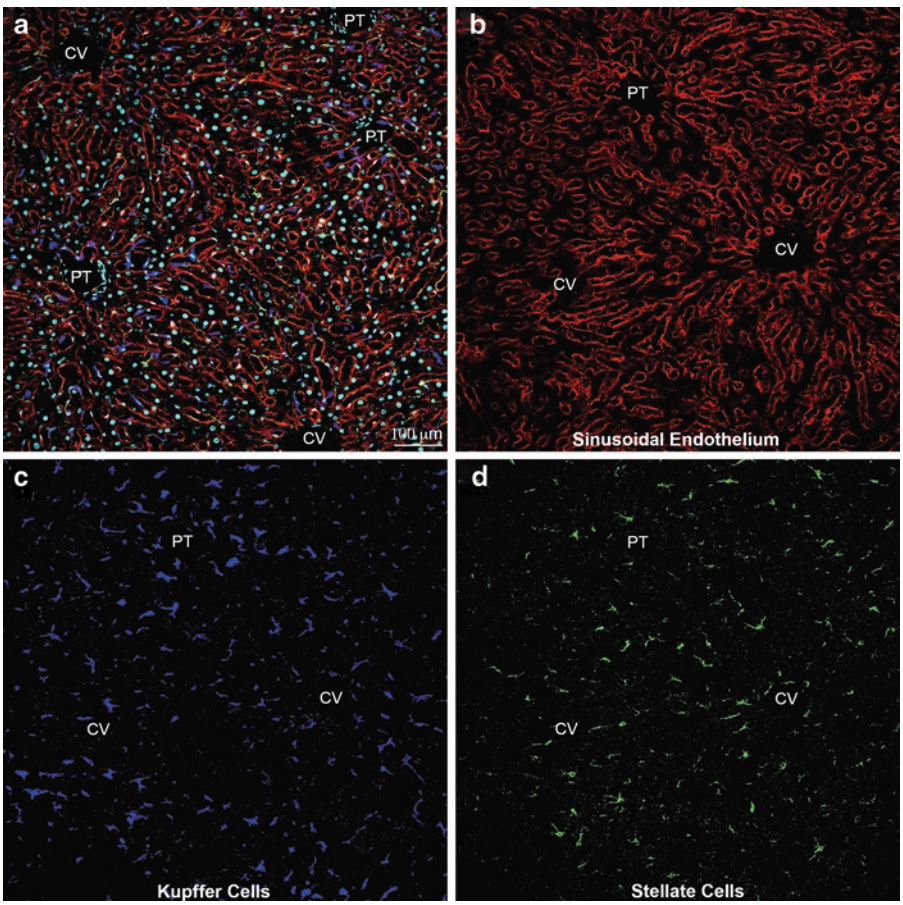

Fig. 7.4 Distribution of parenchymal and nonparenchymal cells in the liver. (**a**) Merged image from separate field with a Hoechst nuclear counterstain pseudocolored in cyan. Larger, round nuclei represent the hepatocytes. *CV* central venule; *PT* portal triad. (**b–d**) Low magnification confocal stack reconstruction image of a paraformaldhyde fixed, frozen rat liver section immunostained with antibodies specific for sinusoidal endothelial cells (goat anti-CD32b, *red* (**b**)), Kupffer cells (Mouse anti-ED2, *blue* (**c**)), and stellate cells (rabbit anti-GFAP, *green*(**d**))

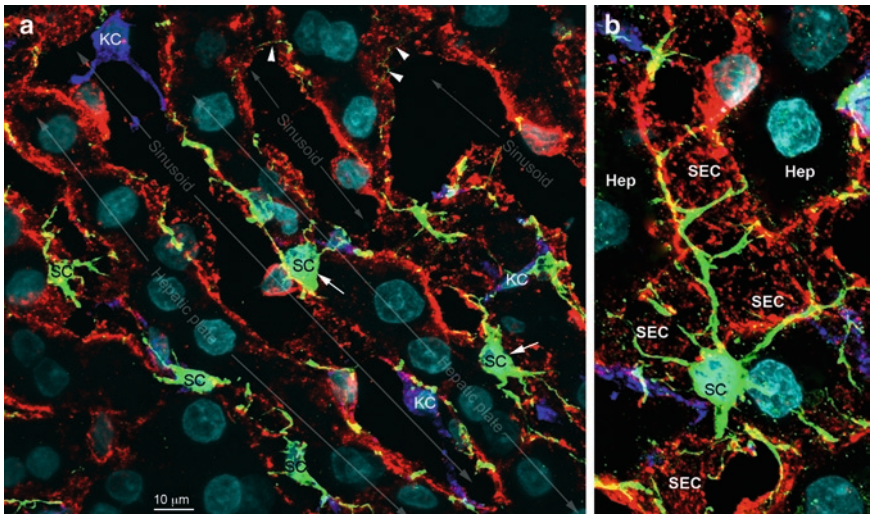

Fig. 7.5 High magnification reconstructed confocal stack from the same tissues as shown in Fig. 7.4. Sinusoidal endothelial cells are stained red, Kupffer cells are stained *blue*, and stellate cells are stained *green*. Nuclei are pseudocolored cyan. (**a**) Hepatic plates (with large, round nuclei) are bounded by the sinusoids lined by sinusoidal endothelium. Kupffer cells (KC) are found attached to the luminal side of the SEC. Stellate cells (SC) occupy spaces under the SEC and often extend processes through the hepatic plate to span between two sinusoids (*arrows*). Stellate cell processes, even very tiny projections, can be seen throughout the space of Disse (*arrowheads*). (**b**) Area of the liver lobule showing a stellate cell enveloping a large area surrounding a sinusoid

available in Chap. 6. Kupffer cells are an important first line of defense to eliminate and respond to particulate bacterial components that arrive from the gastrointestinal tract via the portal blood supply. Located throughout the lobule, they are more concentrated in portal areas, where they can act as sentinels and remove gut-derived products (Fig. 7.4). Kupffer cells migrate along the LSEC surface and often impede blood flow, facilitating interactions between the nonparenchymal cells and circulating leukocytes [18].

Pit cells, liver-associated natural killer cells, and part of the diverse hepatic leukocyte population, also occupy the sinusoidal lumen and interact with LSEC and Kupffer cells [19, 20]. Pit cells are about tenfold less abundant than Kupffer cells and possess the ability to kill tumor cells but are also thought to be involved in eliminating virally-infected cells [21–24]. Other leukocytes routinely found in the liver include dendritic cells, T cells, and B cells [14]. While dendritic cells are usually localized to spaces around the large vessels, B and T cells tend to circulate within the sinusoids, as well as collect in areas around the large vessels.

Abluminally, stellate cells (also called Ito cells, lipocytes, fat storing cells, or perisinusoidal cells) envelop the basolateral aspect of the LSEC between the vascular cells and the hepatocytes in the area called the space of Disse. Additional details on this cell type are provided in Chap. 5. Since they surround the LEC and are capable of contraction, they are often considered a sinusoidal pericyte [25, 26]. They comprise about 6–15% of the nonparenchymal cells and under quiescent conditions store retinoids, triglycerides, cholesterol as well as free fatty acids [16]. Stellate cells can also become activated under various inflammatory insults and transdifferentiate into a myofibroblastic phenotype [26]. Under activated conditions, the stellate cells lose their lipid stores, proliferate, and secrete a variety of cytokines and extracellular matrix proteins and as such are described as the main cell responsible for liver fibrosis and cirrhosis. Changes in extracellular matrix composition and increased matrix deposition within the space of Disse has profound effects on LSEC, causing loss of fenestrations (called capillarization or pseudocapillarization) and general LSEC dysfunction that likely contribute to disease progression [27, 28].

Also found in the space of Disse are splanchnic (sympathetic) and vagal (parasympathetic) nerves that emanate from the portal tracts and interact with LSEC, stellate cells, as well as the hepatocytes and regulate vascular tone [29]. However, there is a substantial variation of hepatic innervation with regard to species. Humans, cats, and guinea pigs show nerve endings throughout the lobule, while rats and mice show little intralobular innervation [30].

There is a complicated circuit of communication among the diverse nonparenchymal cell types that reside in the sinusoid [29]. Both Kupffer and pit cells, as well as any circulating leukocyte, like dendritic, B and T cells, can send pseudopodia through the LSEC fenestrations to interact with hepatocytes and stellate cells [19, 29, 31]. On the other hand, the basolateral microvilli of hepatocytes are often seen protruding through LSEC fenestrations [31]

(Figs. 7.1b and 7.2b) and can potentially interact with any passing cell in the lumen. The nature of these interactions are now being elucidated, and it is believed that they can affect the immune status of the liver if homeostasis is upset, in cases of sepsis, or other injuries. LSEC can directly modulate microvascular tone in the sinusoid by secreting factors such as endothelin-1 and PGF_{2a} that cause constriction of stellate cells, or relaxation by secreting PGE_2, PGI_2, nitric oxide, or adrenomedullin [16, 27].

Fenestrations: Function and Regulation of the Liver Sieve

Fenestrations are the undisputed hallmark of LSEC and it is well accepted that ultrastructural examination using electron microscopy techniques is still the only reliable imaging modality that allows for their critical evaluation [5]. Fenestrations permit the passive transport of solutes, and more importantly, regulate particulate traffic, between the blood supply and the underlying hepatocytes. Cholesterol metabolism by hepatocytes is critically regulated by LSEC fenestration diameter [32]. The sieving properties of the fenestrated LSEC allow for chylomicrons and their remnants that are smaller than fenestrations, access to the hepatocytes via the space of Disse (Fig. 7.2b). On the other hand, larger triglyceride-laden lipoprotein particles absorbed through the intestine and transported to the liver by way of the portal circulation are excluded until they are sufficiently reduced in size by lipases on systemic endothelium as well as LSEC and hepatocytes [16, 32]. In fact, there is belief among investigators that certain species, like rabbits or chickens, are more susceptible to atherosclerosis precisely because they possess smaller diameter fenestrations and lower sinusoidal porosity. These conditions allow for increased circulation times of cholesterol-rich chylomicrons, and animals challenged with high cholesterol diets suffer systemic circulatory complications over time resulting from this burden since small fenestrations do not permit access to the hepatocytes to metabolize the particles [8].

Wisse et al. postulated that the leukocytes and erythrocytes coursing through the sinusoids could massage the sinusoidal surface and assist in the "forced sieving" of fluid and particulates from the plasma into the space of Disse, facilitating their interaction with the underlying hepatocytes [9, 33]. Interestingly, there is a gradient of porosity and fenestration diameter along the hepatic lobule. Generally, the porosity increases from the portal triad to the centrilobular regions of the lobule, coincident with the increase in sinusoidal diameter along that axis [9, 34]. With this arrangement, forced sieving would be more marked in the narrower portal triad sinusoids (~4–5.9 μm) compared to the wider centilobular sinusoids (~5.6–7.1 μm) [8, 9].

Fenestrae are not rigid openings, but dynamic structures that are regulated by the actin cytoskeletal network. The proteins shown to regulate fenestration size include actin, myosin, small GTPases like Rho and Rac and the calcium-binding protein calmodulin [35–37]. Most studies that evaluate fenestration dynamics are performed on isolated cells in vitro as experimental conditions are more amenable to manipulation of conditions. The initial study that elucidated the mechanism for fenestral contraction was performed by Gatmaitan et al. Serotonin (5-hydroxytryptamine) rapidly (within 30–60 s) elicited fenestration contraction via the 5HT2 receptor on LSEC and this event is upstream of calcium signaling [38]. Following calcium influx, myosin light chains are phosphorylated resulting in increased actin-activated myosin ATPase activity in areas surrounding fenestrae, resulting in contraction. These events were further confirmed by using agents that modify intracellular calcium concentrations, and these similarly affected fenestration diameter. Calcium ionophore reduced fenestral diameter and this contraction could be inhibited by calcium chelation, or preincubating with calmodulin antagonists [8, 36, 38].

The fact that serotonin modulates LSEC fenestrations is intriguing. Serotonin is likely transported to the liver via the hepatic portal supply by platelets, which concentrate it intracellularly and release it by serotonin uptake receptors. Since 95% of the serotonin is synthesized in the gastrointestinal tract, rapid uptake and delivery to the hepatic microvasculature is readily achievable. Changes in serotonin secretion in the gut and its uptake by circulating platelets likely have downstream affects on LSEC fenestrae and corroborate the findings of cross talk between these two organ systems [39]. One case where this has been shown is liver regeneration following partial hepatectomy. Regeneration of the liver, as measured by hepatocyte proliferation, is known to be directly affected by serotonin [40]. Following partial hepatectomy, we [34] and others [41] have shown that there are fenestration diameter and porosity changes in the LSEC at various times following liver resection. It is tempting to suggest that serotonin levels might be regulating these LSEC changes, but further study is needed.

Many other substances are known to affect fenestration diameter and LSEC porosity both in vivo and in vitro [8, 38]. In general, drugs, toxins, or other agents that induce irreversible defenestration also induce atherosclerosis and hyperlipidemia since capillarized sinusoids do not allow for removal of lipoproteins from the blood. Defenestration is also usually accompanied by deposition of collagen, and basement membrane components such as laminin, as well as significant thickening of the LSEC. Recent reports also point to toxins and situations that increase reactive oxygen species (ROS) as major effectors of defenestration. For example, low levels (50–250 ppb) of trivalent arsenic, a major environmental contaminant in drinking water, reduced LSEC porosity

within 2 weeks in mouse models [42]. This capillarization was found to be the result of NADPH oxidase (NOX) generated superoxide and animals deficient in NOX activity were protected from fenestration loss [37]. Oxidative stress also contributes to the defenestration of liver that is coincident with aging [43, 44] and is likely exasperated by concurrent reduction in the levels of natural antioxidants like glutathione as tissue age. On the other hand, fenestrations can be induced or their number increased by various microfilament-inhibiting drugs, such as cytochalasin B, latrunculin A, and misakinolide [8].

Concurrent with capillarization is the upregulation of PECAM (platelet endothelial cell adhesion molecule or CD31) expression on the LSEC surface, especially at areas of cell–cell adhesion [37, 45]. DeLeve et al. had reported previously that upregulation of PECAM on rat LSEC is inversely correlated with porosity [45] and therefore constitutes a reliable marker for dedifferentiation-related defenestration. It is interesting that PECAM expression on LSEC is much lower than in other vascular endothelium, and anti-CD31 immunomagnetic isolation of rat liver endothelium resulted in the enrichment of endothelium that lacked fenestrations [45, 46]. Vascular endothelial cell growth factor (VEGF) is also critically important in the maintenance of LSEC porosity. VEGF, which is produced constitutively by neighboring hepatocytes and stellate cells, stimulates autocrine production of nitric oxide by LSEC, which then maintains the fenestrations in these cells [45]. In pathologies like liver cirrhosis where either VEGF or NO is reduced, capillarization of the sinusoid is also observed.

Reports in the literature had suggested that fenestrations were structurally related to caveolae (Latin *caveolae*: little caves), the 50–100 nm flask-shaped membranous invaginations found on a variety of cells, especially endothelial and smooth muscle cells, and involved in endocytosis and transcytosis [47]. Recent evidence now suggests the contrary as caveolin knock-out mice exhibit the same LSEC fenestration diameter and porosity as wild-type mice [48].

Other Novel Functions of LSEC

Besides providing a permeable barrier between the blood and the parenchyma, LSEC have substantial endocytic and scavenger capabilities. Unlike Kupffer cells that typically phagocytose large particles and insoluble material, LSEC rapidly and selectively clear soluble components and colloidal particles that are less that 0.23 μm from the blood by receptor-mediated endocytosis [49, 50]. At least five distinct types of scavenger receptors have been identified on LSEC surfaces that remove a variety of physiologic waste products of all types of biomacromolecules including proteins, polysaccharides, lipids, and nucleic acids [51]. Large volumes of waste products can be removed within minutes of injection, indicating their remarkable ability to clear blood of soluble debris and colloidal material.

Due to their ability to interact with leukocytes, their position downstream from the hepatic portal blood supply and their incredible scavenger activity, LSEC are now categorized as an antigen presenting cell and a major contributor to the innate immunity in the liver. The liver is an organ that appears to prefer practicing immunotolerence over promoting immunity under most circumstances [52]. In this environment, keeping the immune response in check, the presence of circulating endotoxins and variable antigen flux is critical to maintaining hepatic homeostasis. Unlike vascular endothelium, LSEC express the costimulatory MHC class I molecule required for cross-presentation of antigen to T cells. LSEC can cross-present antigens that can tolerize CD8+ T cells to a variety of signals like endotoxin [53], tumor cells [54], oral antigens [55], and allogenic antigens [56]. MHC class II presentation of antigen by LSEC to CD4+ T cells has been shown to induce differentiation of those cells toward a tolerogenic regulatory T cell phenotype [52]. It has also been shown that LSEC can suppress the activity of neighboring antigen presenting cells such as dentritic cells that could potentially induce T cell immunity [57].

Repopulation and Derivation of LSEC and their Role in Diseases

Injury to liver sinusoidal endothelium occurs under a variety of conditions [58, 59]. For the most part, diseases that directly involve liver vasculature are uncommon. Those involving the hepatic microvasculature encompass a discreet set of circumstances that affect the LSEC mostly as the result of toxic insult or ischemic conditions. Capillarization, is the loss of fenestrations, which was discussed above, is a common phenomenon that results from a variety insults, including loss of VEGF, and/or NO signaling observed in cirrhosis [27, 28], oxygen radical induced damage associated with aging [43], toxicants such as arsenic [42], or autoimmune antibodies directed toward LSEC [60].

Sinusoidal obstruction syndrome (SOS, also called hepatic veno-occlusive disease) has two known causes: consumption of pyrrolizidine alkaloids and injury resulting from chemotherapy and irradiation protocols often used in preparation for bone marrow transplantation. This pathology is independently described in Chap. 48. In both cases, obstruction of the sinusoid is caused by LSEC detachment and death coupled with blood cell invasion between LSEC and hepatocytes. As a result, the hepatic microvasculatures are blocked and the areas experience loss of perfusion, local necrosis,

and tissue death. In vivo models of SOS are induced by gavage of monocrotaline, a pyrrolizidine alkaloid plant toxin. DeLeve and coworkers has shown that sinusoidal repopulation following monocrotaline-induced LSEC death in rats is at least partially regulated by bone marrow-derived endothelial cell progenitors [61]. Infusing male bone marrow into female recipients on day 5 after treatment, the time of peak denudation of LSEC, indicated that ~27% of the LSEC were bone marrow derived when examined using Y-chromosome fluorescence in situ hybridization on the isolated LSEC on day 12.

Cold ischemia/reperfusion injury associated with liver transplantation represents another injury model to study endothelial cell repopulation. It is well known that cold storage of livers prior to transplantation results in significant LSEC denudation and death prior to, and is potentiated upon reperfusion [62–64]. Repopulation events were evaluated using syngeneic wild-type to GFP-transgenic rat liver transplantation. Under these conditions, ~5% of the LSEC that lined the sinusoids were double-positive for LSEC markers and GFP, indicating vasculogenic events occurred following orthotopic liver transplantation [65].

Others have shown in mouse models that partial hepatectomy of engrafted GFP bone marrow radiation chimeras results in the repopulation of ~70% of the LSEC by bone marrow derived progenitors [66].

Study In Vitro: Isolation and Culture of Liver LSEC

Isolation of liver LSEC is an important technique to study functional aspects of these cells. Since the LSEC comprise only ~3% of the liver volume, detecting changes in these cells apart from the hepatocytes that comprise 80% of the liver volume is challenging unless in situ techniques like immunohistochemistry or immunofluorescence are performed on intact tissue. Various techniques have been implemented that enrich LSEC for cell culture, biochemical analysis, and other functional studies. The protocols described below are general and can be applied to a variety of species with minimal modification. However, when isolating LSEC from human sources, only liver resections and not livers that have been previously stored for transplantation can be used if substantial numbers of LSEC are required. This is because cold-stored livers are known to have compromised LSEC, resulting in extremely low yields [62–64].

In all cases for cell culture techniques, the liver is digested to single-cell suspension with various proteolytic enzymes, such as collagenase, pronase, or commercial mixtures of collagenases and neutral proteases such as Blendzyme (Roche) based on the two-step protocol described by Seglen [67]. Once the tissue is dissociated, hepatocytes are easily removed from the suspension by low speed centrifugation, typically at $50 \times g$. The cells in the supernatant will contain a mixture of nonparenchymal cells (LSEC, Kupffer cells, leukocytes, and stellate cells) that require additional separation. At this point, various protocols can be applied to the suspensions.

The method of Braet et al. [68] involves differential centrifugation of the nonparenchymal component through Percoll step gradients, followed by differential plating technique, also called panning. Panning removes contaminating Kupffer cells in the preparation since they rapidly adhere to plastic in the absence of serum. This technique does not require any special equipment other than a preparative tissue culture centrifuge and is accessible for most laboratories and is popular for this reason (Fig. 7.6a).

Another popular technique involves centrifugal elutriation that takes the nonparenchymal component and separates the various cell populations by relative density using continuous flow centrifugation [69, 70]. Typically, this will give a high yield of relatively pure LSEC with minimal Kupffer cell contamination. The disadvantage is that elutriators are usually not readily available and are expensive to purchase. Set up of elutriation rotors on preparative centrifuges often dedicates them to this one particular purpose.

Recently, immunomagnetic isolation of LSEC has streamlined the isolation process. There are currently two major formats of immunomagnetic isolation and the main difference is the size of the beads to which antibodies are covalently attached. Larger beads, like those supplied by Dynal are approximately 2–3 μm in diameter (Fig. 7.6b). Smaller beads, like those from Miltenyi are only about 20–50 nm in diameter, allowing for the separation of cells by flowing them through a magnetized column (Fig. 7.6c). Only a few surface markers are known to be specific for positive selection of liver LSEC. For isolation of rat LSEC, the antibody SE-1, prepared and described by the Enomoto laboratory, was shown to specifically isolate LSEC [71, 72]. SE-1 antigen was recently found to be identical to the CD32b protein [73]. As mentioned above, CD31 (PECAM) is not a desirable marker to isolate fenestrated LSEC in the rat, since CD31 isolated only nonfenestrated endothelium that are likely derived from the large vessels [46]. Regardless of how viable LSEC are isolated, the cells maintain their fenestrations while in suspension and in early culture (Fig. 7.6d). Other surface markers used for LSEC immuno-isolation include CD105 (endoglin) [74], stabilin-2 [75], and a lymphatic hyaluronen receptor – LYVE-1 [76].

Other techniques have been successfully used to isolate LSEC, magnetically, without the use of antibodies. One technique is a modification of the cationic colloidal-silica protocol that takes advantage of the availability of the LSEC surface via vascular perfusion, and the negative charge normally found on cell membranes [77]. The cationic colloidal silica membrane isolation technique has been used by our

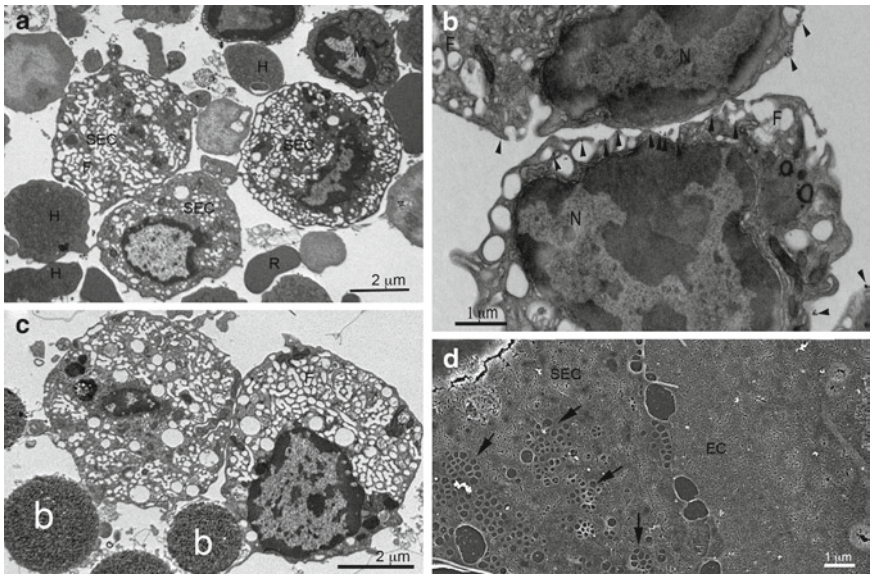

Fig. 7.6 Morphology of isolated rat sinusoidal endothelial cells. (**a**) SEC isolated using the Percoll differential centrifugation technique, showing SEC with fenestrations that are retained even though isolated and in suspension. Also observed are macrophages (M) as well as red blood cells (R) and hepatocyte remnants (H) in the suspension. This image shows the material collected from the SEC-enriched area of the 25–50% Percoll interface. (**b**) Isolation of SEC using Dynal magnetic beads (b) covalently linked to SE-1. Preparation is clear of debris and shows little contamination from other cell types. Fenestrations are observed in these suspended cells (F). (**c**) SEC isolated using SE-1 linked magnetic microbeads (Miltenyi), showing the difference in size (*arrowheads*) between the two immuno-magnetic isolation techniques. (N) SEC nucleus, (F) SEC fenestrations. (**d**) Cells isolated using the Percoll differential centrifugation technique and processed for SEM 24 h after plating onto collagen coated glass coverslips. A fenestrated SEC is observed next to an unfenestrated (large vessel) endothelium. Fenestrations are observed arranged in sieve plates (*arrows*)

laboratory to highly enrich sinusoidal cell-associated membrane proteins relative to nonsinusoidal tissue proteins [42, 78]. Similarly, cationic colloidal magnetite, which utilizes positively-charged beads about 20–50 nm in diameter, binds to cells with access to the vasculature and coats the surface with positively charged magnetite beads. Tissue is then dissociated using collagenase, hepatocytes are removed, and LSEC are then isolated from the nonparenchymal component using Miltenyi column. Using this technique, we successfully isolated LSEC from both rat [65] and mouse (unpublished results). Because other cells types are present in this isolate, such as Kupffer cells and other leukocytes that populate the sinusoid, selective panning to remove them is necessary if relatively pure cultures are needed. These isolates are amenable to evaluate the population of cells residing in the sinusoid using flow cytometry.

Once cells are isolated, a variety of media bases, serum concentrations, growth factors, and matrices have been used to culture LSEC. Regardless, LSEC start to lose their fenestrations and scavenger characteristics in culture almost immediately, [49] so caution should be exercised when employing cultured LSEC with regard to the specific question being addressed. Culture condition manipulation has resulted in increased maintenance of specific characteristics [45, 49], with VEGF and NO being one of the most important components required to maintain porosity.

Acknowledgments The author acknowledges the amazing technical assistance of the entire staff of the Center for Biologic Imaging, at the University of Pittsburgh Medical School, but especially Mark Ross for his dedication to all aspects of liver processing and imaging. Chapter 8
Hepatic Carbohydrate Metabolism

Dirk Raddatz and Giuliano Ramadori

Introduction

The liver plays a unique role in controlling carbohydrate metabolism by maintaining glucose concentrations in a normal range. This is achieved by a tightly regulated system of enzymes and kinases regulating either glucose breakdown, storage as glycogen, or synthesis in hepatocytes. This process is under the control of glucoregulatory mediators among which insulin plays a key role. The fact that insulin is secreted into the portal system, takes the same route as absorbed glucose, and that the liver eliminates a large portion of the portal insulin at the first pass highlights the role of the liver not only as glucose supply, but as a site of glucose uptake and storage.

When the hepatic function is impaired by either diminished hepatocellular function (e.g., fatty liver) by reduced number of hepatocytes (liver cirrhosis), alterations in hepatic glucose metabolism – mainly consisting of diminished glucose and insulin uptake following carbohydrate ingestion – occur, leading to peripheral "insulin resistance" (elevated glucose and insulin levels).

Knowledge of the processes involved in maintaining glucose homeostasis as well as insulin mechanisms of action in the liver alone and in concert with other hormones (e.g., glucagon, cortisol, catecholamines, IGF-1, GLP-1) is a prerequisite to develop new therapeutic approaches in diabetes type 2.

Hepatic Glucose Uptake, Glycogen and Lipid Synthesis

The liver displays the capacity to remove 30–40% of the glucose presented to it following glucose ingestion and therefore must be considered a significant site of postprandial glucose removal [1].

e-mail: draddat@gwdg.de

It appears that the contribution to hepatic-glycogen synthesis following a meal will depend on the preexisting metabolic state [2, 3].

The liver as a sensory organ detects a glucose concentration gradient between the hepatic artery and the portal vein [4] by intrahepatic sensory-effector nerves, generating a cholinergic signal for an insulin-dependent net hepatic glucose uptake [5]. Interestingly, portal insulin may also stimulate intestinal glucose absorption via cholinergic hepatoenteral nerves [6]. The fact that insulin is released into the portal blood and reaches the liver together with glucose, and the observation that 70% of the insulin from the portal blood is taken up in the liver after the first passage [7] imply that in the postprandial state the most important function of insulin is to influence the utilization of glucose into the hepatocytes and to stimulate glycogen and lipid synthesis.

Due to the high capacity of the glucose transporter (Glut-2) in the liver intra- and extracellular glucose levels are in a tight equilibrium in hepatocytes. It has been shown that glucokinase (GK) is the rate limiting enzyme for further glucose utilization [8]. GK expression is enhanced by insulin [9]. In transgenic mice overexpressing hepatic GK, glycolysis and glycogen synthesis are increased and these animals have lower glycemia than controls after a glucose tolerance test, indicating that GK overexpression in liver increases glucose uptake, confirming the rate limiting role of GK in vivo [10]. Similar results were obtained with transgenic mice carrying additional or more extra copies of the entire GK gene. Moreover, it was shown that overexpression of GK may reverse diabetes in a mouse model of streptozotocin-treated mice [11], suggesting that influencing hepatic GK activity may be a valuable therapeutic strategy in treating diabetes mellitus. In fact, recent approaches with allosteric activators of GK are on the way [12].

With 10% of its weight (≈150 g), the liver has the highest specific glycogen content of any tissue (muscle approx. 1%, ≈300 g). Hepatic glycogen metabolism is controlled by coordinate action of the enzymes glycogen synthase (GS) and glycogen phosphorylase (GP), both regulated by phosphorylation. Insulin regulates glycogen metabolism by promoting the dephosphorylation and activation of GS [13]. A major function of glycolysis in the liver is to provide acetyl-CoA from

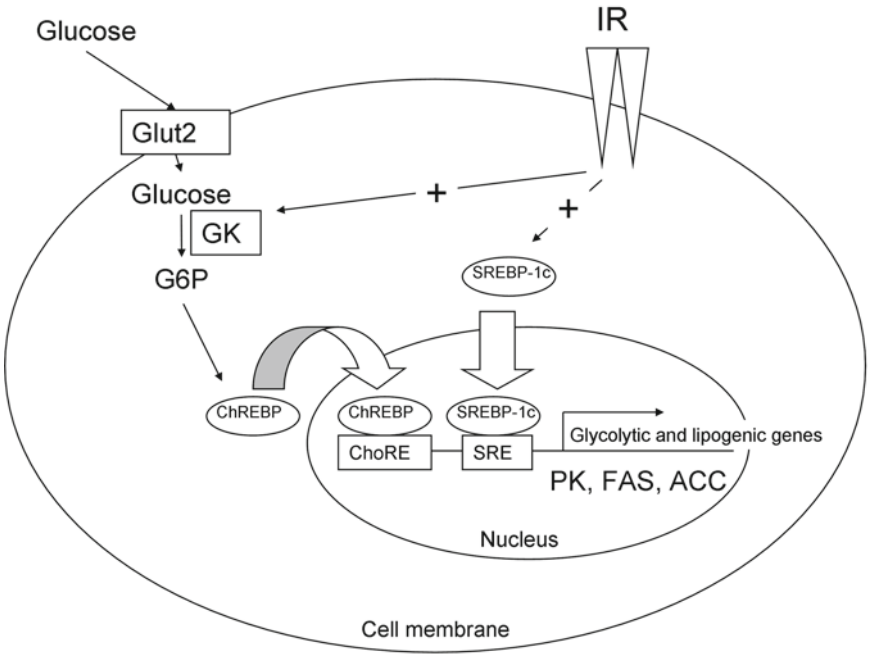

Fig. 8.1 Synergy of glucose and insulin in regulating glycolytic and lipogenic gene expression. On the intracellular level, this synergism is mediated by coordinate action of the transcription factors SREBP-1c (sterol responsive element binding protein) and ChREPB (carbohydrate responsive element binding protein). Except for GK (glukokinase) which is only induced by insulin, genes of the glycolytic and lipogenic pathways are also regulated by glucose (*FAS* Fatty Acid Synthase; *ACC* acetyl-CoA carboxylase; *PK* pyruvate kinase)

glucose for de novo lipid synthesis. The synthesis of fatty acids depends on two signals, glucose and insulin, to promote expression of lipogenic genes like acetyl-CoA carboxylase (ACC) and fatty acid synthase (FAS). The transcription SCREP-1c has emerged as a major mediator of insulin action on hepatic GK and lipogenic gene expression. Remarkably, SCREP-1c controls not only the rate of triglyceride synthesis in the liver but also the amount of storage in the liver [14].

With the exception of GK which is exclusively regulated by insulin, other genes of the lipogenic pathway are also regulated by glucose. Glucose- or carbohydrate-response elements (ChoRE) have been identified in the promoters of these genes and recently a glucose-responsive transcription factor named ChREBP (carbohydrate responsive element binding protein) has been identified. ChREBP is an important link of hepatic carbohydrate and lipid metabolism. Silencing ChREBP gene expression with a siRNA approach in hepatocytes and experiments with knockout mice revealed that ChREBP mediates the glucose effect on both glycolytic and lipogenic gene expression and that this transcription factor is a key determinant of lipid synthesis in liver [14, 15] (Fig. 8.1).

Regulation of Hepatic Glucose Production

The liver produces glucose by breaking down glycogen (glycogenolysis) and by de novo synthesis of glucose (gluconeogenesis) from non-carbohydrate precursors such as lactate, amino acids and glycerol. Both pathways are tightly regulated. The relative contribution in maintaining glucose homeostasis varies with time. While glycogenolysis occurs within 2–6 h after a meal, gluconeogenesis has a greater importance with prolonged fasting.

The rate of gluconeogenesis is controlled mainly by the activities of the unidirectional enzymes phosphoenolpyruvate carboxykinase (PEPCK), fructose-1, 6-bisphosphatase (FP2ase), and glucose-6-phosphatase (G6Pase). The gene transcription of these gluconeogenic enzymes is controlled by hormones, mainly insulin, glucagon, and glucocorticoids. While insulin inhibits gluconeogenesis by suppressing the expression of PEPCK and G6Pase, glucagon and glucocorticoids stimulate hepatic glucose production by inducing those genes. In diabetes, both type 1 and 2, an increased hepatic glucose production is a main contributor to fasting hyperglycemia.

Direct and Indirect Effects of Insulin on the Liver

The contribution of hepatic insulin receptor signaling to normal glucose homeostasis and pathogenesis of diabetes type 2 is a matter of ongoing debate. Systemic administration of insulin lowers blood glucose levels and inhibits HGP within minutes. Insulin exerts its effects on hepatic glucose fluxes via direct and indirect mechanisms [16, 17]. The direct effects can be further divided into *acute* insulin actions leading to rapid decrease in HGP [18] and *chronic* insulin actions inhibiting the gene expression of key enzymes of gluconeogenesis [19–21].

The indirect effects of insulin on hepatic glucose output include the suppression of lipolysis, the inhibition of glucagon secretion [22], and the activation of hypothalamic descending pathways [23]. There is a controversial discussion over which mode of insulin action is most important under physiological conditions Fig. 8.2.

In overnight fasted dogs, changes in the portal insulin concentration in the absence of changes in plasma glucagon, free fatty acids (FFA), or precursors of gluconeogenesis effectively inhibit HGP [24, 25]. Confirming these results, it has been recently shown that in addition, a rise in head insulin levels does not enhance insulin-suppressive effect on HGP [26], suggesting that insulin exerts its effect on HGP mainly directly. The importance of hepatic insulin receptors for a direct insulin action was also supported by the observation that in liver specific insulin receptor knockout (LIRKO) mice insulin is unable to suppress HGP sufficiently [27]. However, restoration of insulin receptor in LIRKO mice did not improve insulin's ability to suppress HGP [28], questioning the dominance of direct insulin effect in that certain mouse model. In fact, LIRKO mice display a certain hepatic phenotype with a liver approximately half the size of wildtype mice and changes in the expression of insulin regulated genes [29], which might have been responsible for the severe hepatic resistance in this model. To avoid changes in the liver phenotype, Buettner et al. [30] used an antisense oligonucleotide technique to acutely silence hepatic insulin receptors in mice. Despite a severe deterioration of hepatic insulin signaling, insulin was able to suppress HGP indicating that at least in mice insulin's indirect effects play the main role in inhibiting HGP.

Interestingly, ablation of insulin receptor in arcuate and paraventricular nuclei of the hypothalamus led to the inability of insulin to inhibit HGP in mice with intact liver insulin signaling [28], suggesting that inhibition of HGP by insulin involves central regulation. In summary, aforementioned studies from dogs clearly point to the dominance of direct insulin effects, while data from studies of mice suggest that insulin's indirect effects dominate. How to reconcile these apparent contradictory findings?

Apart from a number of methodological considerations which might at least explain in part these divergent findings as discussed by Cherrington [31], different physiology of dogs and mice have to be taken under consideration as recently discussed by Girard [32]. For instance, basal HGP per kilogram bodyweight in mice is 10–15 times greater than in dogs, plasma glucagon being similar. Removal of hepatic insulin receptor in mice could have led to an increased neural control of HGP as a protective response. Moreover, in fasted dogs gluconeogenesis contributes to less than 50% of HGP, while in rodents it contributes to 80–90%. Since hepatic gluconeogenesis is less sensitive to insulin than glycogenolysis, it is possible that inhibition of gluconeogenesis requires central nervous inputs. In fact, it has been shown previously that

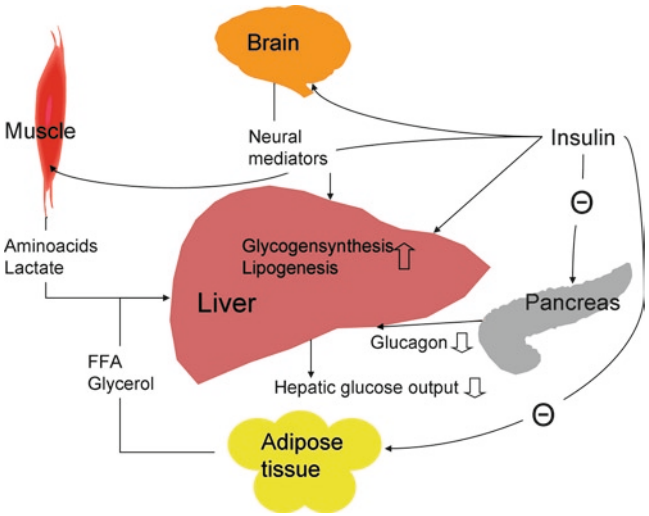

Fig. 8.2 Insulin actions on the liver. Insulin may influence hepatic glucose metabolism either directly in the liver or indirectly by influencing several humoral or nerval factors which might in turn act on the liver

an autonomic nervous input can modulate liver carbohydrate metabolism [33, 34].

As interesting as the above-mentioned data from mice and dogs may be, the crucial question is about the situation in men and especially in human disease. In men under physiological conditions, both insulin's direct and indirect effects play a role [24]. A summary of mechanisms by which insulin can act directly or indirectly is provided in Fig. 8.2. However, the relative contribution of insulin's direct and indirect effects however, may be crucial in the treatment of diabetes. The enhanced HGP in patients with type 2 diabetes is mostly attributable to an increase of hepatic gluconeogenesis [35]. Therefore, future therapeutic strategies should aim to suppress gluconeogenesis. Since gluconeogenesis is less sensitive to insulin than glycogenolysis, the use of insulin in this setting is questionable. In this context it is noteworthy that glucagon, which is increased in diabetes mellitus type 2 [36], stimulates hepatic gluconeogenic enzymes [37], so that inhibition of glucagon would be a desirable goal. GLP-1 analogs, recently established in the treatment of type 2 diabetes are known to inhibit glucagon secretion, so that those agents might provide a causal therapy for treating type 2 diabetes and possibly other conditions with an assumed "hepatic" insulin resistance.

Transcriptional Regulation of Gluconeogenic Enzymes

Transcriptional regulation of PEPCK and G6Pase, two key enzymes of gluconeogenesis, involves a "cross-talk" between a network of transcription factors. The PEPCK promoter is

known to be induced by various stimuli such as glucagon and adrenaline via cAMP, glucocorticoids, thyroid hormone [38], and transcription factors like CREB, HNF-3, HNF-4α and PPARα. The transcription factors, hepatocyte nuclear factor-4α (HNF-4α), and the peroxisome proliferative activated receptor (PPAR)-γ co-activator-1α (PGC-1α) are of particular interest in the transcriptional regulation of PEPCK and G6Pase genes. PGC-1α affects gluconeogenic gene regulation by directly binding to HNF-4α and to other transcription factors such as Foxo1 (Fig. 8.3) and is induced by cAMP and glucocorticoids in isolated hepatocytes and in liver in vivo [39]. In vitro studies have shown that the transcription factor Foxo1, which directly interacts with PGC-1α, regulates both PEPCK and G6Pase genes through an interaction with their consensus insulin response elements (IRE) [20]. Insulin signaling through the serine/threonine protein kinase Akt can attenuate the effects of increased levels of PGC-1α in fasting and other conditions by promoting the dissociation of PGC-1α from Foxo1 [40] (Fig. 8.3).

The transcription factor STAT-3, an important signal transducer used by the IL-6 family, also contributes to the transcriptional regulation of hepatic gluconeogenic genes. IL-6 reduces PEPCK- [41] and G6Pase- [42] gene-expression in isolated hepatocytes and in mice respectively. In a recent mouse model of liver-specific inactivation of STAT-3, genetically manipulated (L-ST3KO) mice show insulin resistance associated with increased PGC-1α expression, associated with a parallel increase in gluconeogenic gene expression [43].

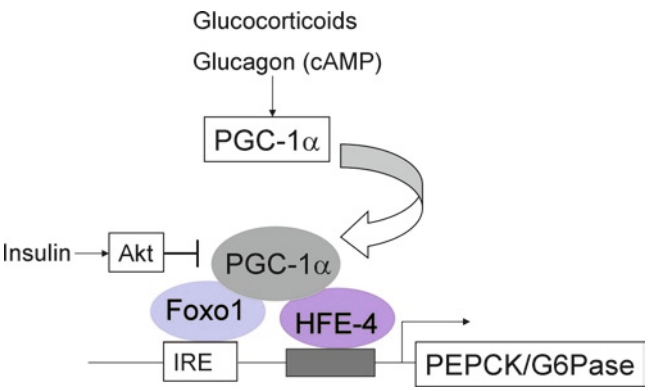

Fig. 8.3 Transcriptional control of gluconeogenic genes. PGC-1α and Foxo-1 play important roles in the suppression of hepatic gluconeogenesis by insulin. Foxo1 regulates PEPCK and G6Pase through insulin responsive elements (IRE). PGC-1α affects gluconeogenic gene regulation by binding to transcription factors like Foxo1 or HNF-4α. PGC-1α is induced by cAMP and glucocorticoids and by fasting and insulin deficient states in liver. Insulin signaling through Akt can attenuate the effects of increased levels of PGC-1α in fasting conditions by promoting the dissociation of PGC-1α from Foxo1

Overexpressing either G6Pase or PEPCK in vivo using transgenic mouse models results in impaired glucose tolerance, pointing at the significance of the deregulation of hepatic gluconeogenic genes in diabetes pathophysiology [44, 45]. In hepatocytes, G6P concentrations are determined by the balance between G6Pase and glucokinase (GK) activities, leading to the suggestion that the ratio of GK to G6Pase is crucial for the metabolic fate of glucose in liver [46]. In fact, G6Pase is increased in animal models of diabetes [47].

Overexpression of G6Pase in hepatocytes results in a reduction of glycogen synthesis and an increase in glucose production. Overexpression of G6Pase in rat liver in vivo results in glucose intolerance, hyperinsulinemia, decreased hepatic glycogen content, and triglyceride accumulation in skeletal muscle, all typical features in diabetes type 2 [45]. However, overexpression of G6Pase does not increase fasting blood glucose consistent with the notion that the main function of G6Pase is to buffer G6P concentrations in the post-absorptive state.

Transgenic mice overexpressing PEPCK in liver show increased basal hepatic glucose production, but normal whole-body glucose disposal during a hyperinsulinemic-euglycemic clamp study compared to wild type controls [44], suggesting a severe hepatic insulin resistance. Accordingly, insulin signaling in the liver of these mice was diminished. In another transgenic mouse model with even higher overexpression of PEPCK in the liver, animals also displayed fasting hyperglycemia and peripheral insulin resistance [48]. Altogether, these models demonstrated that increased flux through gluconeogenesis, either via PEPCK or G6Pase overexpression is suitable to generate metabolic disturbances observed in diabetes mellitus type 2. However, recently Samuel et al. could show that PEPCK and G6P mRNA was not increased the liver of patients with DM undergoing bariatric surgery and in two mouse models of diabetes challenging this dogma [49].

The Role of Growth Hormone and Insulin-Like Growth Factor in Carbohydrate Metabolism

Although under physiological conditions insulin is the principal regulator of glucose metabolism, there is evidence that the growth hormone (GH)-insulin-like growth factor (IGF)-axis contributes to the carbohydrate homeostasis. GH has well known diabetogenic potency. In healthy subjects and subjects with diabetes type 1, GH increases hepatic glucose output (HGP) by increasing gluconeogenesis and glycogenolysis. Furthermore, GH decreases peripheral glucose utilization in the muscle. Stimulation of lipolysis with release of FFA

provides an additional mechanism for the diabetogenic properties of GH.

IGF-1, which is synthesized in hepatocytes upon GH stimulation is a 5,807 kDa single chain polypeptide, which has structural homology with pro-insulin. Ninety percent of IGF-1 is bound in a ternary complex comprising of IFG-1, IGF binding protein (IGFBP)-3 and an acid labile subunit (ALS). A schematic diagram of GH and IGF-1 action is provided in Fig. 8.4.

By acting through the type 1 IGF-receptor, IGF-1 can directly activate the insulin receptor substrate (IRS)-1 and phosphatidylinositol-3-kinase cascade, resulting in GLUT4 translocation to the plasma membrane and thus stimulating glucose uptake in the muscle. Historically, the role of the GH/IGF-1 axis has been analyzed in human and rodent hormone deficiency models. One problem in interpreting most studies on the role of IGF-1 has been that in addition to enhancing insulin effects, it also suppresses GH secretion. Therefore, it has been difficult to determine if the observed effects were due to a direct effect or have been mediated by a suppression of GH.

However, the development of tissue selective knockout mice has brought new insights in understanding the relative roles of those hormones in carbohydrate homeostasis.

A liver-specific gene-deletion knockout of the IGF-I gene resulted in a mouse model with reduced circulating IGF-I levels, that led to insulin resistance due to the secondary elevation of circulating GH levels [50]. Using the transgenic approach, IGF-I and insulin receptor function was inhibited by the overexpression of a dominant-negative IGF-I receptor in skeletal muscle. The result was a severe insulin resistance in muscle, followed by insulin resistance in fat and liver, and eventually beta-cell dysfunction and development of type 2 diabetes [51]. The interpretation of the authors was that IGF-1 might be necessary to sensitize the muscle to insulin.

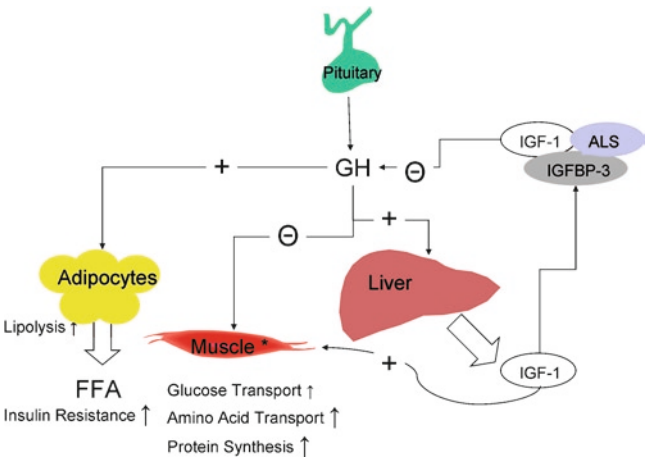

Fig. 8.4 Scheme of the GH/Igf-1 axis. IGF-1 is produced in the liver under the control of GH. In the serum it is bound in a ternary complex consisting of IGF-1, the acid labile subunit (ALS) and IGF binding protein (IGFBP)-3, suppressing pituitary production of GH in a negative feedback loop. GH opposes insulin action in adipose tissue by promoting lipolysis and generation of free fatty acids (FFA) which in turn induce insulin resistance. Although GH alone inhibits glucose utilization in muscle, the net effect of GH and IGF-1 working together in physiological conditions is synergistically with insulin

Crossing liver specific IGF-1 (LID) knockout mice with animals that do not express the acid-labile subunit (ALS), a protein which stabilizes the half-life of IGF-1, showed enhanced insulin sensitivity in muscle and fat tissue despite high GH levels, but no change in the liver [52]. These data suggest a dominating effect of IGF-1 in muscle and fat, while the major site at which GH blocks insulin action is the liver. To clarify this point, a fourth study was performed in which GH action was blocked in LID mice by crossing them with GH antagonist (GHa) transgenic mice [53]. The ability of insulin to inhibit hepatic glucose production was impaired in the LID mice. When GH action was blocked in LID + GHa mice, hepatic glucose production was suppressed to the levels observed in control mice. These results show that despite low levels of circulating IGF-1, hepatic insulin sensitivity in LID mice could be improved by inactivating GH action, suggesting that chronic elevation of GH levels plays a major role in insulin resistance mainly in the liver. In a recent study by O'Connell and Clemmons [54], a GH receptor antagonist was given to acromegalic patients for 6 months to block GH action. This study clearly demonstrated that GH receptor antagonist treatment significantly improved insulin sensitivity. Addition of IGF-1 in combination with the GH-receptor antagonist resulted in substantially greater improvement in the insulin sensitivity, suggesting that IGF-1 exerts additional effects on insulin sensitivity that are not mediated through suppression of GH action.

In summary, aforementioned data suggest that influencing the GH/IGF-1 axis may offer an alternative strategy in treating diabetes. However, future work will have to confirm the efficacy and safety of IGF-1 containing compounds.

Glucocorticoids and Hepatic Carbohydrate Metabolism

Glucocorticoid hormones play essential roles in the regulation of carbohydrate metabolism. Their effects primarily depend on their binding to intracellular receptors leading to altered target gene transcription, as well as on cell-type specific biotransformation between cortisol and its inactive 11-oxo-metabolite cortisone. The latter effect is accomplished by two different 11-alpha-hydroxysteroid dehydrogenase

isoenzymes (HSD). Whereas the type-1-enzyme transforms, in most instances, in vivo cortisone to active cortisol, the type-2-enzyme is a dehydrogenase of glucocorticoids, thus "protecting" the mineralocorticoid receptor against occupation by cortisol.

Alterations in HSD-activity are linked to metabolic disturbances in the cause of the metabolic syndrome [55, 56]. Knockout of 11β-HSD-1 in mice improves hepatic insulin action and protects against obesity and hyperglycemia [57, 58]. Conversely, selective overexpression of 11β-HSD-1 in adipose tissue in mice results in development of visceral obesity, hyperglycemia, hyperlipidemia, and hypertension [59].

In obese, nondiabetic humans, the liver accounts for all splanchnic cortisol production [60].

Interestingly, hepatic HSD-1-activity is under the control of growth hormone [61], a mechanism which might explain the positive effect of GH on body composition in GH-deficiency.

Pharmacological inhibition of HSD in animal models leads to lowered hepatic glucose production and increased insulin sensitivity [62] and may be a promising target in the treatment of the metabolic syndrome [63].

Glucose Homeostasis in Liver Disease

Insulin Resistance, the Common Link in Metabolic Syndrome, Nonalcoholic Fatty Liver Disease, and Hepatogenous Diabetes

Role of IRS1/2

Insulin mediates its action via binding its receptor on the surface of insulin-responsive cells. The stimulated receptor phosphorylates tyrosine sites of itself and several substrates including members of the IRS class, thereby promoting downstream signaling events [64, 65]. A reduction in expression and tyrosine phosphorylation of IRS1 in adipocytes has been reported in diabetic patients. Moreover, several polymorphisms of IRS1 have been linked to insulin resistance in men [66]. In contrast, polymorphisms of IRS2 were seldom found associated with IR, arguing against a major role of IRS2 polymorphisms in the pathogenesis of type 2 diabetes [67].

While IRS1 is the major substrate leading to glucose uptake in adipose tissue and muscle, earlier IRS2 knockout models suggested a dominant role of IRS2 in hepatic metabolism [68]. However, later studies on liver specific IRS2 knockout mice challenged this view of being the most important IRS in the liver, since affected animals displayed only a mild insulin resistance and a slight reduction of hepatic insulin signaling [69], or even no insulin resistance [70], but no diabetes, suggesting that IRS1 alone is sufficient to allow almost normal hepatic insulin signaling.

IRS are unique docking molecules whose actions are tightly regulated by phosphorylation at several sites. Control over insulin signaling can be achieved by autoregulation, where downstream events inhibit upstream components via feedback control.

Alternatively, unrelated pathways such as inflammatory signals may inhibit this pathway downstream of the IR, thus inducing insulin resistance. TNFα and high levels of FFA stimulate inhibitory phosphorylation of serine instead of tyrosine residues of IRS-1, thereby inhibiting downstream signaling and insulin action [71–73].

In recent times, it became apparent that inflammatory pathways may become activated by metabolic stress from inside the cell as well as from extracellular mediators (Fig. 8.5).

Intracellular Activators of Inflammatory Pathways

Reactive oxygen species (ROS), produced by mitochondria in case of hyperglycemia are important intracellular activators of inflammatory pathways [74, 75]. In addition, intracellular stress may arise from the endoplasmic reticulum (ER), faced with the requirements of adipocytes to cope with increased substrate fluxes and altered tissue architecture in case of obesity [76, 77]. As recently shown, experimental lowering of ROS levels ameliorates IR in different models of IR, suggesting ROS to be a common mechanism in different settings of IR [78]. Interestingly, during viral infection, intracellular stress pathways are activated by an excess of viral proteins in the ER, which might be of importance in the development of IR in chronic viral diseases as chronic hepatitis C.

Inflammatory Pathways Involved in Insulin Resistance

JNK-1, -2, and -3, three serine/threonine kinases belonging to the MAPK family, play a major role in the development of IR in obesity [79]. In response to ER-stress, cytokines and FFA JNK is activated, and phosphorylates IRS-1 on Ser307, thereby impairing insulin action [80].

JNK activity is increased in obesity. Modulation of JNK-1 activity in the liver affects systemic glucose metabolism, underscoring the importance of this particular pathway in the liver [79]. The two kinases PKC and IKK play a role in counteracting insulin action especially in response to lipid metabolites. Lipid infusions lead to a rise in intracellular metabolites like diacylglycerol and fatty acyl CoA. This rise is accompanied by an activation of PKC and an increase in Ser307 phosphorylation of IRS-1 [81].

IKKb directly serine phosphorylates IRS-1 and secondly phosphorylates inhibitor of NFκB (IκB), thereby activating

the NFκB pathway, which in turn stimulates a battery of proinflammatory mediators including TNFα [82] (Fig. 8.5). Support for the relevance of this pathway comes from mice heterozygous for IKKb, being partially protected against IR triggered by lipid infusions.

Of note, the IKK pathway seems to play a particular role in the liver. Cai et al. showed that mice with a hepatic overexpression of IKK develop a diabetes-type-2-phenotype, characterized by hyperglycemia, profound hepatic insulin resistance, moderate systemic insulin resistance, and increased hepatic production of proinflammatory cytokines, providing evidence that lipid accumulation in the liver promotes hepatic and to a lesser extend systemic IR [83].

The mTOR complex 1 and its downstream kinase S6K1, integrators of nutrient and insulin signaling are also critically involved in mediating nutrient effects on IR (Fig. 8.5). Recently, Ser1101 was identified as another S6K1 site in IRS-1. Phosphorylation of Ser1101 was increased in liver of obese (db/db) or WT, but not of S6K1−/− mice, implicating S6K1 as the kinase involved [84]. In accordance with these findings, rapamycin, an mTOR inhibitor, improved insulin actions in a short-term in vivo study [85]. In contrast, long-term treatment with rapamycin increased rather than decreasing the insulin resistance [86], which might be explained by an increased activity of stress-response kinases in muscle and islets.

Adipokines

Recently, it became clear that adipose tissue communicates with the rest of the body by synthesizing and releasing a number of secreted cytokine-like molecules, collectively designated as "adipokines," which along with FFA, significantly effect total body glucose metabolism and insulin sensitivity. Steatosis and steatohepatitis could be attributable to the combined effects of insulin resistance, and a relative failure of adipokine mediators to combat the effect of hyperinsulinemia and fasting hyperglycemia on hepatic lipid turnover.

Adiponectin

Adiponectin, also known as ACRP30, is a 30 kDa protein abundantly and selectively expressed in white adipose tissue. Its role in insulin resistance and atherosclerosis has been well established. Two adiponectin receptors have been cloned in mouse and humans, and both are expressed in liver [87]. In the liver, adiponectin increases insulin sensitivity and regulates FFA metabolism by suppressing lipogenesis and activation of FFA oxidation [74].

Adiponectin/ACRP30-knockout (KO) mice showed delayed clearance of FFA in plasma, high levels of tumor necrosis factor-alpha (TNFα) mRNA in adipose tissue, and high

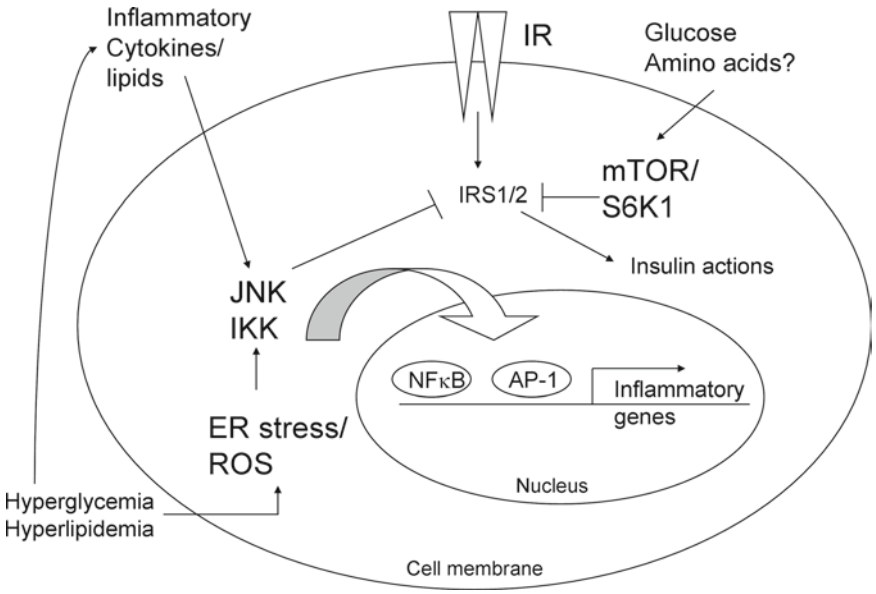

Fig. 8.5 Molecular mechanism of insulin resistance. Inflammatory pathways can be initiated by extracellular mediators such as cytokines, hyperglycemia, and lipids or by intracellular stresses such as ER stress or excess ROS production by mitochondria. Signals from all of these mediators converge on inflammatory signaling pathways, including the kinases JNK and IKK. These pathways lead to the production of additional inflammatory mediators through transcriptional regulation via the transcription factors AP-1 and NFκB as well as to the direct inhibition of insulin signaling. In addition the kinase mTOR and its downstream kinase S6K1 are candidates for negative regulation of IRS, mediating signals of nutrient overload (glucose and amino acids). *Arrows* represent activation, *bars* represent inhibition

plasma TNFα concentrations. Moreover, KO mice exhibited severe diet-induced insulin resistance with reduced IRS-1-associated PI3-kinase activity in muscle [88].

Adiponectin levels correlate negatively with liver fat and hepatic IR in NAFLD [89], suggesting that hypoadiponectinemia is part of a metabolic disturbance characterized by central fat accumulation. Moreover, low adiponectin levels are associated with a more extensive inflammation in NAFLD patients [90], suggesting an anti-inflammatory role of adiponectin in controlling hepatic inflammation. This is highlighted by the fact that adiponectin administered in ob/ob mice alleviates liver steatosis and attenuates inflammation in NAFLD mouse models [91]. However, adiponectin levels in the liver and plasma are not always correlated. In NASH adiponectin-receptor, (AdipoRII)-mRNA is negatively correlated with the histological grade of fibrosis, but not with serum or hepatic adiponectin. No correlation was observed between adiponectin-levels and liver adiponectin-expression [92]. In advanced liver fibrosis adiponectin-levels are even higher than normal [93], a phenomenon which might be explained by a reduced hepatic extraction.

Leptin

Leptin plays a pivotal role in regulating food intake, energy expenditure, and neuroendocrine function. Leptin stimulates the oxidation of fatty acids and the uptake of glucose, and prevents the accumulation of lipids in nonadipose tissues, which can lead to functional impairments known as lipotoxicity. Moreover, it exerts a proinflammatory influence regulating T-cell response [94]. Long term leptin-treatment improves hepatic and peripheral glucose metabolism in insulin resistant lipodystrophic patients and improves liver histology [95]. Leptin-receptors are expressed on hepatic stellate cells and leptin is believed to be involved in liver fibrosis [96].

Leptin-deficient mice develop obesity; however, they fail to develop liver fibrosis during steatohepatitis or in response to chronic toxic liver injury. Restoration of physiological levels of circulating leptin, but not correction of the obese phenotype by dietary manipulation, restored fibrosis indicating an essential role in developing liver fibrosis [97]. Elevated serum-leptin levels have been detected in patients with liver cirrhosis, a disease frequently associated with hypermetabolism and altered body weight [98]. However, implantation of a transjugular intrahepatic portosystemic shunt (TIPS) improved nutritional status in patients with cirrhosis while leptin levels increased (most probably via decreasing hepatic degradation), suggesting that increased leptin levels are not a major reason for poorer body composition in liver cirrhosis [99].

The significance of leptin in human NAFLD has been questioned recently [100]. A more comprehensive overview about the role of leptin in liver disease is published elsewhere [101].

Resistin

Resistin is a 10 kDa adipose tissue-specific hormone that was identified when screened for genes selectively upregulated during adipogenesis, but decreased by PPARγ agonist treatment. Injection of resistin into wild-type mice resulted in reduced glucose tolerance and insulin action, whereas injection of neutralizing antibodies into diabetic obese mice improved insulin action [102]. A significant role for resistin in regulating insulin sensitivity was further confirmed in resistin knockout mice which display low glucose levels after fasting, suggesting an impact on hepatic glucose production [103].

Transgenic mice that have high circulating levels of resistin in the setting of normal weight display higher fasted blood glucose and an impaired glucose tolerance than their non-transgenic littermates. Metabolic studies revealed that chronically hyperresistinemic mice have elevated glucose production and this increase in glucose production may be partly explained by an increased expression of hepatic PEPCK [104].

Insulin resistance caused by resistin infusion was attributed to an increase in the rate of glucose production and not to an increase in glucose uptake, indicating that resistin has effect on hepatic, but not peripheral insulin sensitivity in rat [105] and mouse [106] models of insulin resistance. However, other groups have shown resistin-mRNA in most mouse models of insulin resistance to be down-regulated [107]. In addition, resistin expression in human adipocytes was very low [108]. In fact, human resistin expression was higher in monocytes [109]. Furthermore, some studies have failed to show a link between resistin levels and BMI or insulin sensitivity [108, 110], whereas others argue for such a connection [111, 112].

In a cirrhotic rat model using bile duct ligation (BDL), the BDL-induced cirrhotic rats showed significantly higher resistin mRNA and protein levels were evident as compared to sham animals [113]. Resistinlevels are also increased in human liver cirrhosis. However, as in case of obesity, the link between resistin and insulin sensitivity is not clear.

While in one study serum resistin correlated with insulin secretion and inversely with insulin-sensitivity [114], another study failed to show such a correlation. Moreover, after liver transplantation resistin levels remained unchanged while insulin sensitivity improved [115], challenging the concept of resistin directly influencing insulin sensitivity in humans. Another study in NAFLD-patients failed to show a correlation between resistin and BMI, HOMA-IR, insulin and glucose, but could show a positive correlation between resistin and histological inflammation, supporting a link between histological severities of the disease but not between resistin and insulin resistance in NAFLD [116].

Taken together, most of these studies shed doubt on the role of resistin in insulin resistance associated with obesity and/or liver disease. However, there is probably a role for resistin in regulating body composition both in obesity and in liver disease. Further studies in humans and the identification of a receptor will be necessary to determine the clinical relevance of resistin in humans.

Tumor Necrosis Factor-α

TNFα plays a central role in IR. TNFα impairs insulin signaling by inhibiting the function of IRS-1 through serine phosphorylation [117]. Both in vivo and in vitro experiments have demonstrated that adiponectin and TNFα suppress each other's production and also antagonize each other's action [88]. TNFα knockout mice demonstrate less IR with high-fed feeding [118]. Overproduction of TNFα in liver tissue has been proposed to play a key role in the pathogenesis of fatty liver. Fatty liver disease in ob/ob mice is significantly improved by inhibition of hepatic TNFα production or infusion of anti-TNFα neutralizing antibodies [119].

IL-6

IL-6 is expressed at high levels in omental adipose tissue and is released following a meal [120]. IL-6 is elevated in subjects with hyperinsulinemia and obesity [121, 122]. On the other hand, muscular IL-6 release in an autocrine fashion has a beneficial effect on glucose disposal [123] and insulin signaling in muscle during exercise [124] designating IL-6 as a "myokine" [125]. Although fat-fed IL-6 knockout mice demonstrate a higher plasma glucose following glucose tolerance testing, these mice were characterized by a lack in overt diabetes and obesity when compared to wild-type mice [126]. Somehow confusing, a previous study with another IL-6 knockout strain showed that IL-6 KO mice developed maturity onset diabetes and insulin resistance [127]. The reason for this discrepancy is not clear. A possible explanation might be the use of a different background strain or the introduction of subtle genetic differences into the IL-6 knockout lines.

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis

A detailed account on NAFLD and NASH is provided in Chap. 34. A summarized account is mandated in this section on carbohydrate metabolism. IR is a key feature of NAFLD [128], a condition which ranges from fatty liver to nonalcoholic steatohepatitis (NASH). It has been shown that glucose disposal is reduced to approximately 50% in nondiabetic NAFLD patients compared to normal subjects, and a similar extent in patients with diabetes mellitus type 2 [129]. If IR causes NALFD or vice versa, or if both conditions occur in parallel are still not completely understood. Also, the matter of whether hepatic or peripheral IR has the primacy in NALFD is still a matter of debate.

The recurrence of NALFD after liver transplantation is one argument against a primary hepatic defect. Recent data indicate that most probably the primary site of IR in NAFLD is the periphery, where lipolysis in adipose tissue is suppressed insufficiently, followed by a reactive hyperinsulinemia. As a consequence, there is an increase of FFA into the liver, followed by hepatic TG deposition and finally a hepatic-insulin resistance as summarized by Bugianesi et al. [130] in a recent review.

However, in a dog fat-fed model, subcutaneous and visceral adiposity was accompanied by hyperinsulinemia, modest peripheral IR, but a complete inability of insulin to suppress hepatic glucose production, suggesting that IR of the liver may be the primary defect in the development of insulin resistance associated with obesity [131].

The etiopathogenic sequence of hepatic IR being a consequence of liver steatosis has been shown in rats fed with a high-fat diet or [132] in lipoprotein lipase transgenic mice [133]. Moreover, a correction of steatosis reverses hepatic IR in leptin deficient (ob/ob) mice [134].

In humans, mitochondrial defects on a genetic basis eventually worsened by environmental factors have been suggested to be a cause of impaired β-oxidation in the liver. In fact, mitochondrial abnormalities have been described in NASH livers [135], favoring the liver as primary site of insulin resistance. Hepatic TG-deposition is a process, which is normally linked to increased insulin sensitivity. It has been suggested that hepatic lipid accumulation results from a selective intracellular sensitivity, such that while signaling to glycogen storage and HGP is impaired, signaling to lipid synthesis is preserved. This apparent contradiction might be dissolved by a recent animal model in which the hepatic transcription factor Foxo1 was shown to have dual properties, since in a state of impaired insulin signaling, Foxo1 activity increases, leading to excessive glucose production while at the same time TG synthesis and fatty acid oxidation decreases [136]. However, further studies will be required to establish the role of Foxo1 in human disease.

Insulin-resistance is a target for specific treatment of NAFLD, and insulin-sensitizing agents (metformin or thiazolidinediones) as well as lifestyle changes to reduce visceral adiposity are the most promising therapeutic options. Future trials need to be performed in order to test the long-term effectiveness of these treatments on the basis of clinically relevant histological outcomes.

Hepatitis C and Diabetes

A detailed account of hepatic phenotype in hepatitis C infection is provided in Chap. 38. Here, the evidence of the role of hepatitis C in contributing to metabolic disease is provided. Since the discovery of the hepatitis C virus (HCV) in 1989, it has been noticed that HCV does not solely affect the liver. In fact, a number of diseases like cryoglobulinemia and glomerulonephritis occur in patients with HCV infection. A role of hepatic steatosis in the pathogenesis of chronic hepatitis C has also been known, implying hepatitis C as a metabolic disease. Furthermore, epidemiological studies have suggested a linkage between type 2 diabetes and chronic HCV infection [137, 138]. For hepatitis B, the situation is less clear. However, the majority of epidemiologic studies found a higher prevalence of diabetes in patients with HCV as compared to HBV infection [138, 139].

Earlier studies have been criticized because HCV might have been transmitted due to frequent measurement of blood sugar, and additional factors influencing glucose tolerance such as advanced cirrhosis or obesity and aging were difficult to rule out in epidemiologic studies. However, in a recent epidemiologic study, HCV was shown to be independently associated with an impaired glucose tolerance [140]. IR can be found in patients with HCV infection even in the absence of hepatic fibrosis [141]. In addition, the presence of diabetes in patients with HCV infection, but without cirrhosis was shown to be independently linked to the risk of developing hepatocellular carcinoma [142].

Moreover, basic studies performed in experimental systems were able to prove the association of HCV infection and diabetes. Transgenic mice expressing HCV core protein have elevated serum levels of insulin, although they do not develop diabetes. In insulin tolerance test, glucose levels were significantly higher in transgenic than in normal mice, signalizing insulin resistance. In addition, hyperinsulinemic-euglycemic clamp experiments and measurements of muscle glucose uptake revealed that this insulin resistance was a central, hepatic one [143].

A closer analysis of the insulin-signal pathway in these animals revealed a disturbed tyrosine phosphorylation in transgenic animals, which was sensitive to an inhibition of TNFα by applying anti-TNFα antibodies [144]. Although a direct impact on insulin signaling cannot be excluded, these data suggest a crucial role for TNFα in HCV-associated insulin resistance. Disturbed insulin signaling with impaired tyrosine phosphorylation of IRS-1 was also detected in ex vivo insulin stimulated liver biopsies explanted from patients with HCV infection [145].

IRS-1 and 2 have been found to be down-regulated in patients with HCV, and HCV core downregulated the expression of IRS-1 and -2 in human hepatoma lines and in transgenic mice. HCV has been shown to induce suppressor of cytokine signaling 3 (SOCS3), which is capable of ubiquitinating and thereby inactivating IRS [146], thus providing an additional mechanism of IR in HCV.

IR in HCV infection may have significant clinical implications, since IR and hyperinsulinemia have been shown to be independent predictors of progression of liver fibrosis [141], suggesting a causal role of insulin in liver fibrosis.

Strategies which improve insulin sensitivity thereby preventing hyperinsulinemia should therefore be of use in those patients in whom an antiviral therapy was not successful. Therefore, weight control should be an advice to patients with persistent HCV infection. If the use of drugs like thiazolidinediones or GLP-1 analogs will be beneficial in this situation is an intriguing question and clinical studies are urgently required.

Hepatogenous Diabetes

The changes in carbohydrate metabolism occurring in liver cirrhosis, a condition of loss of hepatic function and capacity, highlight the notion that the liver is the main regulator of glucose metabolism and important site of insulin resistance. The term “hepatogenous diabetes” was coined by Naunyn in 1898, who discovered the coincidence of diabetes and liver cirrhosis [147]. In the 1970s, observation was confirmed by larger epidemiologic studies. The prevalence of diabetes and impaired glucose tolerance among patients with liver cirrhosis are by far higher than in subjects without liver diseases. Sixty to eighty percent of cirrhotic patients are reported to be glucose intolerant and up to 20% develop overt diabetes [148–151]. Moreover, the development of diabetes is an established risk factor for long-term survival in cirrhosis [152].

Glucose clamp studies have shown that insulin-induced glucose metabolism is reduced in cirrhosis [153]. Insulin resistance occurs early in the natural history of cirrhosis and is not associated with degree or etiology of liver damage [154]. Insulin resistance is associated with reduced skeletal muscle glucose disposal [155], whereas whole body glycolysis and carbohydrate-induced lipogenesis remain unaffected [156]. Although chronic hyperinsulinemia has been undoubtedly linked to insulin resistance in cirrhosis, the underlying mechanisms and the resulting sequence of endocrine and molecular alterations are only partially resolved.

Several factors, including hyperinsulinemia, elevated contrainsulinary hormones like growth hormone, glucagon, and catecholamines, an increase in FFA, or decreased insulin-like growth factor have been proposed to contribute to cirrhosis-associated abnormalities in carbohydrate metabolism as discussed in detail elsewhere [157]. Moreover, disease

related putative liver factors, like HCV (discussed above) may be involved in developing insulin resistance and/or diabetes in liver disease.

Diabetes type 2 is characterized by an impaired augmentation of postprandial insulin secretion by gastrointestinal hormones like GLP-1 ("incretin" effect). If this is also the case in hepatogenous diabetes remains to be elucidated. However, if this should be the case, it is not due to diminished GLP-1 secretion, since GLP-1 response in the portal blood is not different between cirrhotic patients with and without diabetes [158].

Experimental data from animal models revealed that hyperinsulinemia in cirrhosis is not due to an increase of insulin-secretion from islets, but could be explained by a decreased hepatic clearance of insulin [159]. It is known that about 70% of the portovenous insulin is extracted during the first pass through the liver [7]. In fact, in human liver cirrhosis, hepatic insulin clearance is diminished [156, 160]. Both, portosystemic shunting and an impaired liver function are suggested to play a role in hyperinsulinism observed in liver disease. Furthermore, portosystemic shunting is involved in hyperglucagonemia, a phenomenon frequently observed in liver cirrhosis [161].

Data from liver transplanted patients support the view that a disturbed hepatic insulin clearance is of major importance in developing hyperinsulinism, since insulin suppression of hepatic glucose production could be restored after transplantation. However, in about one third of the patients, diabetes did not disappear because of persistence of a reduced beta-cell function [162].

Summary

Although an important role of the liver in carbohydrate metabolism has been known for decades, the recent years taught us important details about the liver's communication with other organs, the lipid metabolism and about the intracellular mechanisms regulating glucose homeostasis. Moreover, it became apparent that there is a close interrelationship between liver disease and alterations of the carbohydrate metabolism, which is characterized by insulin resistance, culminating in the suggestion to include NAFLD in the catalog of the metabolic syndrome, a disease of pandemic dimension. Transgenic and gene knockout mice proved to be valuable tools to identify factors and pathways involved in regulating glucose homeostasis. Dissection of insulin signaling taught us that the direct effect of insulin on the liver is probably more important in maintaining glucose homeostasis than previously believed. Moreover, a deepened insight into the regulation of intracellular glucose fluxes may give us an idea about how therapy of insulin resistance and associated diseases could look like in the future.

Chapter 9
Hepatic Protein Metabolism

Wouter H. Lamers, Theodorus B. M. Hakvoort, and Eleonore S. Köhler

Introduction

The body cannot store protein to any extent under steady state conditions. The equivalent of all amino groups of the protein component of the food has, therefore, to be deaminated. The resulting ammonia has to be detoxified and excreted (largely as urea), whereas the carbohydrate component has to be burned, or stored as glycogen, or fat. Hyperammonemia is frequently associated with, or is even ascribed to failing liver function, but few studies have summarized the available data on substrate load and functional capacity of the liver to metabolize ammonia. This chapter discusses the quantitative aspects of protein metabolism in the body with significant emphasis on the role of liver in this phenomenon and highlights the role of periportal vs. pericentral hepatocytes.

Protein Ingestion and Metabolism to Urea

A 25g mouse consumes ~3.5 grams of chow a day [1]. The minimum maintenance content of protein in mouse food is 12% [2], but regular mouse chow typically contains ~20% protein, while a high-protein diet contains >40% protein. As a result, the mice cited have to produce ~2, ~3, and ~6 mmol urea per day, or ~75, ~115, and ~250 mmol urea.kg^{-1}.day^{-1}. For a "typical" 70 kg human consuming 0.3, 1.0, or 2.5 g protein/kg^{-1}.day^{-1} [3], these numbers are ~100, ~300, and ~800 mmol urea per day, or ~1.4, ~4.5, and ~11 mmol urea.kg^{-1}.day^{-1}. These numbers correspond well with the urea synthesis rates as determined with isotopes in mice [4, 5] and in humans [3, 6–9], and with the observed daily urea excretion rates (for a review, see [10]). The species difference arises from the fact that metabolic rates scale to approximately three fourth power of the animal's body mass [11, 12].

Urinary Excretion of Urea Accounts for 70–80% of its Production

Studies on urea synthesis rates in humans in vivo have consistently shown that urea excretion via the urine accounts for only 70–80% of urea synthesized over a wide range of protein intakes [3, 6, 8, 13–15], with some studies reporting a value as low as ~60% [9] (Fig. 9.1). This apparent "leak" is generally ascribed to urea excretion to the gut [9, 16]. Microbial urease can make this urea available for the resynthesis of amino acids. However, measured as the contribution of labeled lysine, fecal microbial amino-acid synthesis from $^{15}NH_4^+$ or $[^{15}N]_2$-urea contributes only 5–10% to the appearance rate of essential amino acids in plasma in man [17–19]. In agreement, fecal nitrogen loss, and reabsorption of ammonia and reentry into the urea cycle are quantitatively more important fates of intestinal urea than the rescue of nitrogen for amino-acid synthesis [3, 14, 20, 21]. Urea hydrolysis in the intestine is most prominent in the fasting period [21]. The finding that oral $^{15}NH_4^+$ is a ~65% better precursor for intestinal amino-acid synthesis than $[^{15}N]_2$-urea [22] indicates that microbial urease expression is a determining factor, which varies with the feeding cycle [23].

Although as much as 50% of urea that is excreted to the intestine during fasting may be hydrolyzed [21], Young and co-workers [3, 21] argue that the resulting ammonia is recycled to urea in the liver, whereas Jackson c.s [9, 24]. claim that as much as 80% is reincorporated into amino acids (the disagreement centers about the degree to which the ^{15}N tracer is exchanged). The numbers from both sets of studies [9, 21] nevertheless, indicate that, in the postprandial period in man, ~30–90 μmol intestinal ammonia.kg^{-1}.h^{-1} from endogenously synthesized urea returns again to the liver. This corresponds to ~10% of the protein intake.

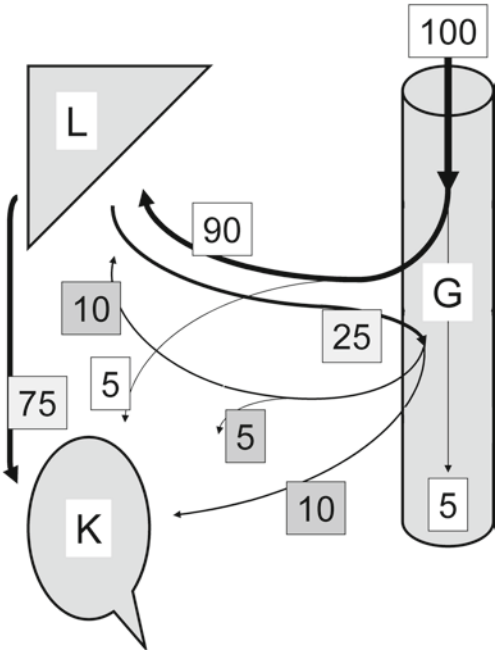

Fig. 9.1 Fate of the amino groups of dietary proteins. The scheme demonstrates the extensive recycling of urea. The numbers refer to rodents and humans fed an average protein-containing diet, and are expressed as a fraction of the dietary intake. Numbers on a white background: of all ingested dietary proteins, ~5% remains undigested and will eventually be catabolized by the colonic flora. If no acidosis or alkalosis exists, the amino groups of another ~5% is excreted as ammonia by the kidney. The amino groups of the remaining ~90% will eventually be metabolized to urea by the liver. Numbers on a light gray background: of all urea synthesized by the liver, ~75% is excreted by the kidney, while the remaining ~25% is excreted to the gut. Numbers on a dark gray background: ~60% of the urea excreted to the intestine (equivalent to ~15% of the ingested amino groups) will be hydrolyzed by the intestinal microbial flora and used for amino-acid synthesis (~5%) or returned to the blood (~10%). The remaining urea (~10% of the ingested amino groups) is reabsorbed into the blood. For more details, see main text. *L* liver; *G* gut; *K* kidney

Intestinal Microbial Urea Recycling in Ruminants

The recycling of urea for microbial amino-acid resynthesis in the human intestine is a quantitatively weak reflection of a similar process in ruminants. In ruminants, urea excretion to the gut occurs almost exclusively in the stomach and small intestine [25]. In cows, the fraction of endogenous urea production that is excreted to the gut decreases from ~100% in animals on a low-protein diet to ~30% in animals on a high-protein diet, and appears to reflect the fact that the gut entry rate of urea depends on the plasma urea concentration rather than protein intake [26]. A nearly fixed fraction (30–35%) of the urea that enters the gut returns to the ornithine cycle, whereas the remainder is used for amino-acid synthesis in enteral bacteria [26]. As a result, the recycling of urea through the digestive tract functions as a buffered source of amino acids when protein in the food becomes limiting, but does not enhance amino-acid utilization at higher, growth-promoting protein supplies in the food.

In contrast to the findings in ruminants, studies in pigs [25, 27] and the only comparable study available in humans [3] indicate that urea excretion to the gut increases with increasing protein intake and endogenous urea production. Apparently, the circulating urea concentration does not directly determine the rate of urea excretion into the gut in pigs and humans, as it does in ruminants (see previous paragraph).

Ammonia Excretion

Most of the ammonium excreted by the kidney is produced in the kidney itself from amino acids, chiefly glutamine. In normal control humans, only ~5% of the daily production of ammonia is excreted into the urine, but if acidosis develops, this number can rise to almost 30% [28]. Under alkalotic conditions, ammonia excretion into the urine virtually ceases (~1%).

Digestibility of Dietary Proteins

The true oro-ileal digestibility of proteins in simple-stomached animals is 90–95% [29–31]. Most of the remaining protein is metabolized by bacteria in the colon. In agreement, luminal colonic ammonia levels were found to increase with the protein content of the diet. In rats on a low-protein diet (8 en%), the ammonia concentration was 20–25 mM in the proximal colon and 30–40 mM in the distal colon, irrespective of whether the diets contained 12 or 48 en% fat [32]. In rats on a high-protein diet (32 en%), the ammonia concentration in the proximal colon was ~50% higher than in rats on a low-protein diet (30–40 mM) and ~2-fold higher in the distal colon [32]. In another rat study, a 60 en%-protein diet resulted in ~2-fold higher ammonia levels in the proximal colon than a 20 en%-protein diet (~20 vs. ~10 mM, respectively), without differences in the distal colon (10–15 mM). The differences in colonic ammonia content were reflected in the ammonia concentration of the colonic vein (~100 vs. ~175 μM) [33]. In agreement, experimental introduction of ammonia into the pig colon showed a direct relation between colonic ammonia content and the appearance of ammonia in the portal vein [34].

Intestinal Ammonia Production from Glutamine

The now classical studies of Windmueller and Spaeth [35–37] revealed that glutamine rather than glucose is the major metabolic fuel of the enterocytes of the small intestine, that the amount

of glutamine utilized is similar in germ-free and conventional animals, and in the fed and the fasted state, and finally, that both luminal and vascular glutamine can be utilized by the enterocytes to meet requirements in both the fed and the fasted state. First-pass catabolism of glutamine, glutamate, and aspartate is near complete, while that of most other amino acids amounts to 30–50%. Only alanine, arginine, and tyrosine are produced [38, 39]. The limited role of intestinal bacteria in ammonia production can be deduced from the findings that ammonia levels in germ-free and conventional anhepatic rats rose equally fast [40], and that circulating ammonia levels decline only moderately upon antibiotic treatment (for a review, see [41]).

In rats in vivo, intestinal glutamine utilization was reported to be 200–900 μmol.kg^{-1}.h^{-1} [38, 42, 43], while glutamine utilization of the intestine was ~500 μmol.kg^{-1}.h^{-1} in postabsorptive mice [44] and 20–30 μmol.kg^{-1}.h^{-1} in fasting humans [45]. Glutaminolysis in enterocytes accounts for ~65% of total small-intestinal ammonia production in the fed condition and for ~95% in the fasted condition [38]. These numbers are based on arterial-portal-vein concentration differences and, therefore, do not reveal the glutamine contributed by the food. When glutamine was provided both enterally and vascularly, glutaminolysis was ~1.5-fold higher than when glutamine was provided from either side alone [46]. Irrespective of these considerations, the numbers indicate that intestinal glutaminolysis accounts for ~10% of the daily ammonia supply for urea synthesis in both rodents and humans.

Role of Intestine in Ammonia Production

We have discussed three sources of intestinal ammonia production. Glutamine deamination contributes ~10% of the total daily ammonia production, urea recycling ~10%, and colonic bacterial catabolism due to incomplete small-intestinal protein digestion ~5% (Fig. 9.1). These numbers are similar in the fed and postabsorptive periods [38], and imply that ~75% of ammonia that is converted into urea is carried to the liver as amino acid (Fig. 9.2).

Hepatic Ammonia Detoxification

The maximal activity of urea synthesis in human liver amounts to 1–3 mmol urea.kg^{-1}BW.h^{-1} [47–49]. The capacity to synthesize urea in cirrhotics is ~80% of that in controls [48]. In rat liver, this number amounts to 3.5–5.5 mmol urea.kg^{-1}BW.h^{-1} [50–53]. We recently determined the capacity to synthesize urea from ammonia in perfused mouse liver in situ and found it to be 4–5 mmol urea.kg^{-1}BW.h^{-1} in animals fed with 18% protein diet (He et al. unpublished). Assuming a protein consumption of 70–140 g (human), 2.7 g (rat), and 0.6 g (mouse;

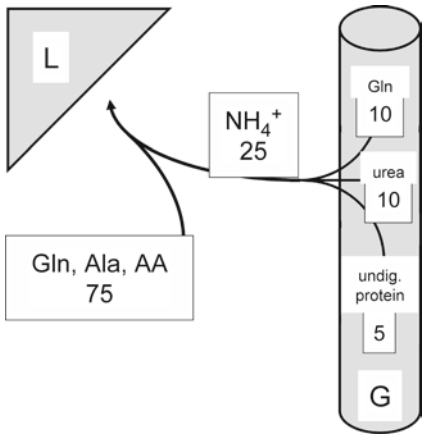

Fig. 9.2 Sources of substrate for urea synthesis. The portal vein carries intestinal ammonia derived from glutaminolysis (equivalent to ~10% of the ingested amino groups), microbial intestinal urea hydrolysis (~10%), and colonic microbial catabolism of undigested protein (~5%) to the liver. The remaining amino groups for urea synthesis (equivalent to ~75% of the ingested amino groups) are carried by glutamine, alanine, and other amino acids. For more details, see main text

the latter two numbers are based on a daily consumption of 15 and 3.5 g pellets, containing 20% protein, per "typical" 300 g rat or 25 g mouse, respectively [1]), ~1,300, ~25, and ~6 mmol ammonia per day needs to be detoxified (see Sect. "Protein Ingestion"). Since ammonia detoxification proceeds relatively independent of feeding (~85 and ~60% in the postabsorptive state relative to the fed state in humans and rats, respectively [21, 38]), these numbers amount to 0.2–0.4, ~1.7, and ~5 mmol.kg^{-1}BW.h^{-1} urea synthesis for humans, rats, and mice, respectively. This comparison reveals that human liver has a ~5-fold overcapacity to detoxify ammonia, whereas this number is only ~2-fold in rats and barely exceeds one in mice. The ~4-fold increase in ammonia detoxifying activity per gram of liver after an 80% partial hepatectomy in humans due to substrate accumulation [49] is in agreement with this conclusion. In further agreement, the liver remnant of rats that have undergone a 65% partial hepatectomy 24 h earlier can indeed double its urea output in response to substrate accumulation [54, 55]. For mice, no data are available. The limited reserve capacity of the liver to detoxify ammonia explains why the capacity to synthesize urea corresponds directly with the protein content of the food in both man [56] and in rats [51, 57], and suggests that mammals limit their capacity to synthesize urea to avoid loss of amino acids at low protein intake.

Sources of Hepatic Urea Synthesis

The main sources of the liver for urea synthesis are ammonia and amino acids, especially alanine and glutamine (Fig. 9.3). The liver can, however, also become a producer of glutamine,

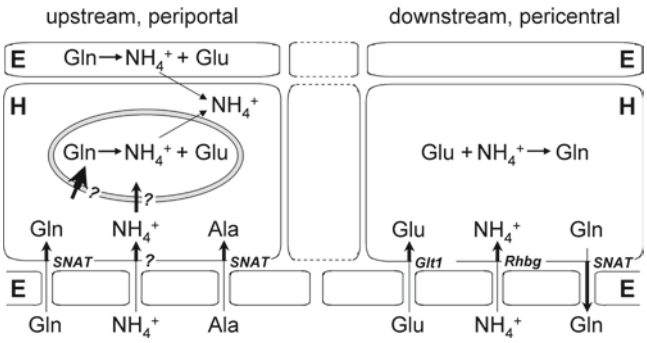

Fig. 9.3 Amino-acid and ammonia transport into the liver. An upstream, periportal and a downstream, pericentral hepatocyte (H) and sinusoidal endothelial cell (E) are shown. Glutamine and alanine are transported mainly by SNAT transporters. Ammonia is transported into pericentral hepatocytes by the Rhbg transporter and glutamate by the Glt1 transporter. The carrier for concentrative transport of glutamine across the mitochondrial membrane (?) is not yet identified. Furthermore, it is unknown whether ammonia accumulates inside periportal hepatocytes by a concentrative transporter (?) or results from spill over of mitochondrial glutaminase-2 or endothelial glutaminase-1. For more details, see main text

particularly in the fasted state [38]. Ammonia reaching the liver has a threefold higher chance of being metabolized to citrulline than to aspartate, whereas the reverse is true for alanine [58, 59]. Glutamine has a twofold smaller chance of ending up in citrulline than ammonia [60]. The more contentious issues pertain to the relative contributions of ammonia and glutamine to hepatic urea and glutamine synthesis. Due to the extensive glutamine utilization by the enterocytes, postabsorptive portal glutamine levels amount to 50–70% of arterial glutamine levels. Under these conditions, portal ammonia levels were ~4-fold higher and portal alanine levels almost twofold higher than the corresponding arterial levels in mice (He et al. unpublished data).

Zonation of Ammonia-Metabolizing Enzymes and Transporters

The expression of the enzymes involved in hepatic ammonia and glutamine metabolism is highly heterogeneous. Urea-cycle enzymes are found in the upstream, periportal hepatocytes [61–63], whereas glutamine synthesis is confined to the downstream, pericentral hepatocytes [64]. Periportal hepatocytes also express the liver-type glutaminase (glutaminase-2) [65], which may play a crucial role in citrulline synthesis by producing high amounts of ammonia intramitochondrially. Mitochondrial carbonic anhydrase (type V), also a crucial enzyme in mitochondrial citrulline synthesis, is nearly hepatocyte-specific in its organ distribution [66, 67], but its zonal distribution has not been established definitively [67]. In a typical mouse liver, the porto-central axis is ten hepatocytes long [68]. Of these, the upstream 7–8 cells express the urea cycle enzymes and the most upstream 3–4 cells glutaminase-2. The presence of glutaminase-2 in the upstream hepatocytes and of glutamine synthetase in the downstream hepatocytes implies that the liver can both consume and produce glutamine. Glutamate dehydrogenase is present in the mitochondria of periportal and pericentral hepatocytes [69, 70]. The putative role of the aquaporin AQP9 in urea export from the hepatocytes [71] also remains questionable, since this transporter is predominantly expressed in the sinusoidal membrane of the pericentral rather than the periportal hepatocytes [72, 73], and its systemic deficiency does not cause a perturbation in urea production or transport [73].

The hepatocytes in the downstream comprise 2–3 cell layers, and are well equipped to take up ammonia and glutamate from the blood by strongly and exclusively expressing the plasma membrane glutamate transporter Glt1 (SLC1A2) [74, 75] and the ammonia transporter Rhbg (SLC42A2) [76]. Glutamate accumulates in pericentral hepatocytes [70] via import from the circulation [74] and the selective expression of the glutamate-supplying enzyme ornithine aminotransferase [77]. The role of pericentral glutamine synthesis in ammonia detoxification appears, nevertheless, limited. Circulating ammonia levels were not increased in Rhbg-deficient mice [78], while only a twofold increase in systemic ammonia levels was found in hepatocyte-specific β(beta)-catenin-deficient mice that were fed a high-protein diet [79]. These mice lack expression of all pericentral ammonia-transporting and metabolizing proteins in their pericentral hepatocytes.

The major transporters of glutamine and alanine in liver appear to be the sodium-coupled neutral amino-acid transporters (SNATs) 3–5 (SLC38A3, -4, -5) [80–83] (for review, see [84]). SNAT1 is expressed in fetal liver, but disappears neonatally [85], whereas SNAT2 is not expressed in normal adult liver, but is strongly upregulated with a periportal distribution in diabetic liver [83]. SNAT3 mRNA [83, 86, 87] and protein [81] are present in a shallow centro-portal gradient. SNAT4 mRNA, in contrast, has a pronounced pericentral localization [83]. SNAT5 mRNA has, like SNAT3, no clear zonal distribution [87]. The SNAT3 [88] and SNAT5 transporters [82] appear to prefer alanine over glutamine, whereas SNAT4 prefers glutamine over alanine [80]. However, it should be kept in mind that alanine can also be transported via several other transporters that are expressed in the liver [89].

Amino-Acid Transport into the Liver

The upstream, periportal hepatocytes are committed to urea synthesis, mainly from ammonia, glutamine, and alanine (Fig. 9.3). The conversion of precursors to urea nitrogen is

very fast [90, 91]. Although this finding points to an important role for transporters, none of them is, as far as known, specifically expressed in the upstream region of the liver (see previous paragraph). The ammonia concentration in rat liver is 0.2–0.5 mmol/kg [92], whereas that of glutamine is 3–4 mmol/kg [93–95] and that of alanine is ~2 mmol/kg [95]. In mice, we found the hepatic concentration of glutamine to be 1–1.5 mmol/kg and that of alanine ~3 mmol/kg (He et al. unpublished data). These findings show a two to fourfold increase in concentration of ammonia, alanine, and glutamine in the hepatic tissue compared to the surrounding blood.

The electrogenic properties of the SNATs imply that these transporters both facilitate a Na^+-dependent uptake of glutamine or alanine and increase the cytosolic pH of the hepatocytes by the simultaneous export of H^+ ions, whereas export of glutamine or alanine has the reverse effect. Since all enzymes involved in urea synthesis have their activity optimum at pH ~8 (for a review, see [92]), the SNAT-dependent import of glutamine and alanine facilitates urea synthesis. The concentration of glutamine is increased a further three to fivefold in a pH-dependent manner across the mitochondrial inner membrane by a yet unidentified transporter [93, 94]. This stepwise increase in glutamine concentration brings about a mitochondrial glutamine concentration that is in the range of the K_m of glutaminase-2 for glutamine (~25 mM).

Ammonia Transport into the Liver

The (human) liver effectively detoxifies intestinal ammonia up to at least 6 $mmol.h^{-1}$ [96]. Although portal ammonia levels rise to ~0.5 mM in these cases, the high K_m value of carbamoylphosphate synthetase for ammonia (1–2 mM) [97] implies that this rate-limiting enzyme of the urea cycle functions at <25% of maximum activity under these conditions unless there is a concentrating mechanism for ammonia in the upstream hepatocytes. However, no measurable levels of transporters of the Rh glycoprotein family of ammonia transporters were found in periportal hepatocytes [76]. Alternatively, the increase in intracellular ammonia levels may depend on glutaminase activity. Ammonia may escape as product of mitochondrial glutaminase-2 before it is captured by carbamoylphosphate synthetase (Fig. 9.3) [98]. This mechanism assumes that metabolite channeling between the mitochondrial enzymes glutaminase-2, carbamoylphosphate synthetase, and ornithine transcarbamoylase to form citrulline from glutamine is not very efficient, if at all existing [60, 90, 99]. Alternatively, ammonia may originate from the recently described glutaminase-1 activity in (porcine) sinusoidal endothelium (Fig. 9.3) [100]. The latter two options would imply that glutamine rather than ammonia is the real substrate for citrulline (and urea) synthesis.

pH and Ammonia Detoxification

A normal liver is able to effectively correct to systemic levels the substantial changes in portal ammonia and amino-acid concentrations that result from feeding and metabolism [95, 96]. As an example, circulating ammonia levels are ~10-fold lower than portal ammonia levels up to at least 2 mM portal ammonia in guinea pigs [101]. Similarly, increasing glutamine concentrations (0–2.3 mM) in the perfusate induced an almost linear response in liver glutamine metabolism with glutamine production decreasing between 0 and 0.5–0.6 mM glutamine, and switching to increasing glutamine consumption at higher glutamine concentrations [87]. In this latter study, the relation between the afferent glutamine concentration and hepatic glutamine metabolism could be entirely ascribed to glutamine transport via the SNAT transporters. In agreement with the electrogenic properties of these receptors, ammonia detoxification is very sensitive to changes in the acid-base balance. Most importantly, acidosis decreases liver ammonia detoxification [102], because the reduced amino-acid transport into the liver [103] and the reduced glutamine transport into the mitochondria [94] decrease substrate availability. The inhibitory effects of acidosis on substrate transport are magnified by the alkaline pH, optimum of the activity of most enzymes involved in urea synthesis [92]. At the same time, ammonia excretion, a vehicle of H^+, into the urine increases up to ~6-fold in acidosis [28]. This ammonia is almost exclusively derived from glutamine. The net effect of a developing acidosis is, therefore, a shift in glutamine catabolism from the liver to the kidney. The capacity of the kidney to eliminate ammonia is, however, limited to ~30% of the daily production of ammonia [28]. Perhaps equally important is that the pH dependence of ammonia detoxification reduces the already small margin (two to fourfold excess capacity) between the hepatic capacity to metabolize ammonia and the supply of this toxic substrate if acidosis develops.

Ammonia Detoxification in the Compromised Liver

In addition to inborn errors of metabolism, liver cirrhosis is arguably the best studied cause of hyperammonemia. Hyperammonemia due to liver failure increases ammonia detoxification as glutamine in peripheral organs, such as muscle, and increases ammonia elimination in the kidney via

glutaminolysis in rodents and man [104–106]. In anhepatic animals, plasma glutamine levels can increase to ~4 mM [104]. In addition, the intestine switches from glutaminolysis to glycolysis as source of energy [107, 108], even though there are no signs of hypoxia [107]. Instead, this change in metabolism is attributed to the hypermetabolic state [109], a condition that frequently develops after significant injury to the body. These findings demonstrate that ammonia detoxification is a distributed property, with many organs that express the enzyme glutamine synthetase [110] able to contribute. The decreased glutamine consumption by the splanchnic region [107, 108] also supports ammonia detoxification by reducing its production. The capacity of the kidney to eliminate ammonia produced from glutamine appears to be limited [104], even if acidosis is invoked [28] (see Sect. "Ammonia Excretion").

Conclusions

Thus, it is relevant to emphasize that there is extensive recycling of urea through the gut, even in simple-stomached mammals. It is also important to emphasize that about 25% of the amino groups that have to be detoxified by the liver are supplied as ammonia, even though the periportal hepatocytes apparently do not have ammonia-concentrating transporters. Finally, the ammonia detoxification by the liver is highly pH-sensitive, so that a developing acidosis can quickly eliminate the small surplus ammonia-detoxifying capacity of the liver.

Chapter 10
Hepatic Lipid Metabolism

Jiansheng Huang, Jayme Borensztajn, and Janardan K. Reddy

Introduction

The liver is a major regulator of lipid metabolism in the body. It plays a central role in the synthesis and degradation (oxidation) of fatty acids. Fatty acids serve as an important source of energy as well as energy storage for many organisms and are also pivotal for a variety of biological processes, including the synthesis of cellular membrane lipids and generation of lipid-containing messengers involved in signal transduction [1]. Fatty acids can generally be stored efficiently as non-toxic triglycerides (triacylglycerols/fat), which generate more than twice as much energy, for the same mass, as do carbohydrates or proteins. Accordingly, liver is a key player in energy homeostasis: first, as it converts excess dietary glucose into fatty acids that are then exported to other tissues for storage as triglycerides as lipid droplets [2]; second, under conditions of increase in synthesis and decreased oxidation of fatty acids the liver contributes to the progressive accumulation of excess unspent energy in the form of energy-dense triglycerides in adipocytes of adipose tissue, which provide virtually limitless capacity to store energy and finally, under chronic energy over-load situations the liver may serve as a surrogate reservoir for storing considerable quantities of excess fat, leading to the development of hepatic steatosis and steatohepatitis [3]. For molecular pathogenesis of fatty liver, please see Chap. 29. Independent chapters are also included on non-alcoholic fatty liver disease (NAFLD) (Chap. 34) and alcoholic liver disease (Chap. 35). This ability of the liver to store lipids is viewed as a protective mechanism, neutralizing the potential toxicity of long-chain fatty acids [4].

In addition to synthesis, oxidation, and secretion of fatty acids for transport and storage in extrahepatic tissues, the liver also functions in the maintenance of plasma lipid levels, a) through its ability to assemble and secrete lipoproteins into the circulation and b) through its central role in the removal of lipoproteins from circulation [5]. Accordingly, an understanding of fat metabolism in liver is important for delineating the pathophysiological implications of altered energy balance and in developing pharmacological strategies for preventive and therapeutic approaches. The emphasis of this chapter is on the sources and synthesis of fatty acids, very low density lipoprotein assembly and secretion, and fatty acid oxidation.

Sources and Synthesis of Fatty Acids

Fatty acids utilized by the liver for energy generation, for storage as triglycerides, and incorporation into lipoproteins, are generally derived from: (a) hepatic uptake of plasma non-esterified fatty acids (NEFAs) transported in the circulation after release by adipose tissue, as well as after hydrolysis of circulating triglyceride-rich lipoproteins; (b) breakdown of triglycerides of chylomicron remnants taken up by hepatocytes; (c) hepatic cytoplasmic triglyceride stores that manifest as lipid droplets, big or small, in all cell types; and (d) synthesis in situ (lipogenesis).

Hepatic Uptake of Plasma NEFAs Released by Adipose Tissue and Hydrolysis of Circulating Triglyceride-Rich Lipoproteins

Fatty acids deposited as triglycerides in white adipose tissue represent the primary energy store in animals. Under conditions of caloric deficit (e.g., starvation) or increased energy demand, triglycerides are hydrolyzed and free fatty acids are released into the circulation. Thus, in these situations, most of the circulating fatty acids taken up by the liver are mobilized from adipose tissue triglycerides. The hydrolysis of triglyceride is catalyzed by adipose tissue lipases in sequential steps leading to the formation of NEFAs and glycerol. Adipose triglyceride lipase (ATGL) and hormone-sensitive

S.P.S. Monga (ed.), *Molecular Pathology of Liver Diseases*, Molecular Pathology Library 5,
DOI 10.1007/978-1-4419-7107-4_10, © Springer Science+Business Media, LLC 2011

lipase (HSL) are the major triglyceride lipases involved in this process (Fig. 10.1). ATGL specifically performs the first step in lipolysis generating diacylglycerol and fatty acid [6], and subsequent action of HSL most efficiently hydrolyses diacylglycerol, further releasing fatty acids. Together, ATGL and HSL are responsible for more than 95% of the triglyceride hydrolase activity present in white adipose tissue [7]. Also involved in the mobilization of fatty acids from stored sites are members of perilipin family [8]. The initial hydrolysis of triglyceride to diacylglycerol is known to be the rate-limiting step, since hydrolysis of diacylglycerol is tenfold faster. The released free fatty acids become bound to circulating albumin and are carried to the liver, as well as other tissues, for uptake and utilization. Fatty acid mobilization from fat is tightly controlled by hormones such as insulin, glucagon, epinephrine, and adrenocorticotropic hormone. Mice deficient in HSL secrete less insulin and are glucose intolerant and reveal adipocyte size increase and decrease plasma free fatty acids, mostly due to the attenuation of lipolysis [9, 10]. Of interest is that the surface of the lipid storage droplet coated with a variety of proteins has emerged as a central site of regulation of lipolysis (see below). The mechanism by which HSL attacks the lipid droplets is not yet firmly established, but may be involved in the activation of a lipid binding domain on HSL and translocation from the cytosol by a carrier protein [11].

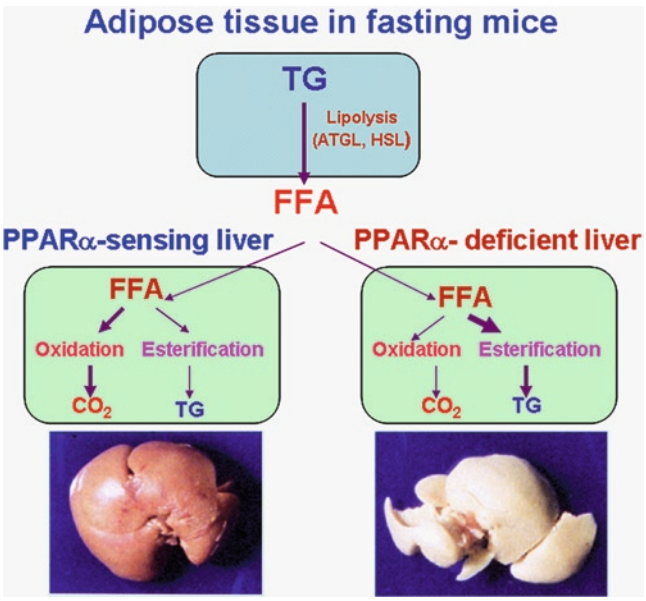

Fig. 10.1 Adipose tissue lipolysis during fasting, fatty acid influx into liver and PPARα sensing. Under conditions of caloric deficit such as fasting, or increased energy demand, trigylcerides (TG) in adipose tissue stores are hydrolyzed and free fatty acids (FFAs) are released into the circulation. The hydrolysis of TG is catalyzed by adipose triglyceride lipase (ATGL) and hormone sensitive lipase (HSL). Nuclear receptor PPARα in liver, senses the influx of FFAs and upregulates all three fatty acid oxidation systems, reduces fatty acid esterification to TGs and minimizes hepatic steatosis (*see* wild type mouse liver on the *left*). If PPARα sensing is deficient as in PPARα/ACOX1 double knockout mouse liver (*right*), fatty acid oxidation systems are not upregulated to burn the influxed FFAs. This results in increased TG synthesis contributing to the development of hepatic steatosis. Modified from Yu et al. [91] with permission

Although circulating fatty acids derived from adipose tissue stores are important during starvation as well as during increased energy demand states, plasma fatty acids taken up by the liver in the postprandial state are derived mainly from the catalytic action of lipoprotein lipase (LPL). This enzyme is present on the endothelial surface of capillaries of skeletal and cardiac muscles and in adipose tissue and is responsible for the hydrolysis of circulating triglyceride-rich lipoproteins synthesized and secreted by the intestine (chylomicrons) or liver (very low density lipoproteins/VLDL) [12]. The action of LPL-mediated lipolysis of chylomicrons requires apoC-II as a cofactor acquired from plasma high density lipoproteins (HDLs) [12]. Most of the fatty acids generated from the LPL-mediated hydrolysis of chylomicrons and VLDL triglycerides are taken up by the tissues where the enzyme is located to be either oxidized (muscles) or stored (adipose tissue) [13]. However, a considerable fraction of the generated unesterified fatty acids become bound to plasma albumin and, in this form, are transported to the liver where they are taken up [13, 14]. It has been estimated that >50% of long chain fatty acids bound to albumin can dissociate and bind to liver cells in single pass through the liver [15]. The six-member family of fatty acid transport proteins (FATP-1 through FATP-6) present as integral transmembrane proteins facilitates the uptake of long chain and very long chain fatty acids into cells [14, 16]. These proteins exhibit fatty acid synthetase activity implying that fatty acids are rapidly converted to acyl-CoAs in the cell after translocation across the plasma membrane. The mechanism whereby the fatty acids enter the hepatocytes has not yet been fully elucidated, but it appears that FATP5 plays a major role in hepatocellular uptake of fatty acids [17]. Furthermore, hepatocytes contain cytoplasmic fatty acid binding protein (FABP1) and fatty acid translocase (FAT/CD36) are also known to be involved in the cellular uptake of fatty acids [18]. Whether fatty acids enter into hepatocytes by passive diffusion through the plasma membrane or the entry is facilitated exclusively by fatty acid membrane protein transporters remains unclear [19].

Chylomicron Remnants

As indicated above, a major source of fatty acids for the liver in the postprandial state are triglycerides associated with chylomicrons. These lipoproteins are synthesized in the intestine and are responsible for the transport of most of the

absorbed dietary fatty acids and cholesterol. However, the chylomicrons themselves do not contribute to the hepatic fatty acid pool because they are not cleared from circulation by the liver. Instead, chylomicrons, as well the triglyceride-rich VLDL, are acted upon by LPL in the peripheral vascular bed, which hydrolyzes the triglycerides in the core of the particles generating unesterified fatty acids, some of which bind to plasma albumin for transport to the liver [12]. As a result of LPL action, chylomicrons are converted into remnant particles, which are smaller than their parent chylomicrons but retain most of their original cholesterol content as well as a considerable amount of triglycerides. Unlike the chylomicrons, remnants are readily cleared from circulation by the liver where they are disassembled, thus providing fatty acids to hepatocytes. The efficient uptake of chylomicron remnants – but not intact chylomicrons – by the liver is the result of a complex and as yet not a fully elucidated process that involves the interaction of apoprotein E on the surface of the particle first with glycosaminoglycans in the space of Disse, followed by its binding to the low density lipoprotein receptor (LDLR) on the surface of hepatocytes and finally endocytosis of the particle [20].

Hepatic Cytoplasmic Lipid Droplet Stores

All eukaryotes, from yeast to humans, synthesize triglycerides and store this excess energy in the form of cytoplasmic lipid droplets for use when needed [21, 22]. Lipid droplets, once considered inert or static, are emerging as metabolically dynamic structures. During times of energy scarcity, this stored energy from lipid droplets is retrieved by the action of lipases [23]. Although the lipid droplet-rich adipocytes of adipose tissue are the principal sites of energy storage and retrieval, all other cell types in animals, including hepatocytes, can accommodate under normal physiological conditions, limited quantities of energy in the form of smaller, less conspicuous, lipid droplets. These smaller lipid droplets provide immediate energy source for hepatocytes and other non-adipocyte cells, and serve as fatty acid source for utilization in intracellular signaling cascades [24]. However, in steatotic states, hepatocytes can accumulate massive amounts of energy-rich macro- or micro-vesicular lipid droplets and lead to the development of fatty liver disease [25].

The entry and sequestration of lipid in lipid droplets as well as lipolysis to release the packaged fatty acids are physiological processes regulated by evolutionarily conserved families of lipid-droplet surface proteins, including the members of the perilipin (perilipin amino-terminal/PAT proteins) and Cide (cell-death-inducing DFFA-like effector) families [26]. The perilipin family includes five members: Perilpin-1 (perilipin), perilpin-2 (adipocyte differentiation-related protein/ADRP/adipophilin), perilipin-3 (tail-interacting protein of 47 kDa/TIP47), perilpin-4 (S3–12), and perilipin-5 (oxidative tissue-enriched/OXPAT) [27]. These five members share sequence similarity and are differentially expressed in different cell types [28]. These proteins are amphiphilic proteins that are associated with the phospholipid monolayer surrounding lipid droplets and participate in lipid droplet maturation and metabolism [29]. Perilipin-2 and -3 are expressed in most cell types. Although perilipin-4 (S3–12) is expressed mostly in adipocytes and to a lesser extent in heart and skeletal muscles, it can be induced in liver cells in response to PPARγ overexpression reflecting its function in hepatic adiposis [30]. Perilipin-5 is expressed in tissues with high fatty acid oxidation capability including the liver [31]. Fasting and PPARα activation are known to induce perilipin-5 expression in liver, consistent with its role in fatty acid oxidation [32–35] (Fig. 10.1). It appears that perilipin-4 and perilipin-5 are reciprocal in function, in that the former is associated with lipid storage and the latter with fatty acid oxidation [31, 36]. Perilipins decorate lipid droplets either constitutively (perilipins 1 and 2), or in response to lipolytic challenge (perilipins 3–5) [37]. Because of this differential presence, lipid droplets may be heterogeneous in a given cell with reference to perilipin composition [38]. Evidence suggests that perilipin-1 and perilpin-2 serve as physical barriers to lipolytic enzymes under basal conditions, but in response to lipolytic stimulation, these two proteins can also facilitate interactions with lipases [39]. Perilipin-1 is more effective at attenuating lipid droplet lipolysis than perilipin-2 [40]. Therefore, absence of perilipin-1 or perilipin-2 reduces the amount of triglyceride in adipose tissue and liver, possibly due to increased lipolysis resulting from the removal of barrier to lipase action [41]. The relative contributions of various members of perilipin family in lipid droplet composition, assembly, and hydrolysis of triglycerides in the progression of fatty liver disease remain to be clarified [42].

In recent years, the importance of the three members of the Cide family of lipid droplet proteins CideA, CideB, and CideC (also known as Fsp27), in lipid droplet metabolism is being increasingly recognized [43]. Similar to perilipins, Cide proteins are also associated physically with lipid droplets and appear to modulate droplet size and lipid metabolism in liver during lipid overload conditions [44]. The expression of perilipin-1, CideA, and CideC is markedly elevated in liver with severe steatosis [31, 45]. CideC expression is elevated in the liver following PPARγ overexpression [46]. Mice deficient in perilipin-2, CideB, or CideC do not develop fatty liver disease implying that these proteins normally function to facilitate lipid storage in the cell [47]. Although the lipid droplet biology is gaining enhanced attention, the state of knowledge is rudimentary since very little

is known about the ~100 lipid droplet associated proteins [48]. It is noteworthy that the storage of lipid in the liver may also protect the cells against lipotoxicity [49–51]. The packaged lipids in droplets may also be important in transportation of lipid to specific cellular destinations or for specific functions. Moreover, the lipid droplets may provide a shelter for some special proteins when they are at a higher level in the cells [22, 52].

De Novo Lipogenesis

Lipogenesis encompasses fatty acid synthesis and their utilization for phospholipid and triglyceride generation. The human body is able to synthesize all fatty acids with the possible exception of two polyunsaturated fatty acids, namely linoleic acid (C18:2) and α-linolenic acid (C18:3). Liver and adipose tissue are the major sites of fatty acid synthesis and mammary glands also generate fatty acids during lactation. Lipogenesis requires acetyl-CoA precursors that are generated during certain metabolic processes as these precursors provide all the carbon atoms necessary for fatty acid synthesis [53]. Liver is the principal organ responsible for the conversion of excess carbohydrate (glucose), beyond organism's energy needs, to fatty acids via a series of metabolic steps that are regulated by several factors, including nutritional, hormonal, and genetic elements [54]. Glucose is first converted to pyruvate, which enters the Krebs cycle in the mitochondria to yield citrate [55]. Citrate is then transported into the cytosol and broken down by ATP citrate lyase to yield acetyl-CoA and oxaloacetate. Acetyl-CoA is converted to malonyl-CoA, the rate-limiting step in the lipogenesis pathway catalyzed mainly by acetyl-CoA carboxylases (ACC1 and ACC2) [56]. Successive molecules of malonyl-CoA, which serves as a two carbon donor, are added to the acetyl-CoA primer by a multifunctional enzyme complex, the fatty acid synthase (FAS) [57]. Palmitic acid (C16:0) is the predominant fatty acid generated by FAS [58]. FAS is expressed in the liver and adipose tissue, but in the humans, the liver appears to be the major site for de novo lipogenesis [59]. Palmitic acid is desaturated by stearoyl-CoA desaturase-1 (SCD-1) to palmitoleic acid or elongated to yield stearic acid (C18:0). SCD-1 catalyzes the conversion of stearoyl-CoA to oleoyl-CoA, which is a major substrate for triglyceride synthesis [60]. Oleic acid (C18:1) is formed as a result of desaturation of stearic acid and is regarded as the end product of de novo fatty acid synthesis. However, the saturated C16 fatty acid, first synthesized during *de novo* lipogenesis, is the essential precursor for almost all the newly synthesized fatty acids including the formation of very long chain fatty acids [61].

Very long chain ($>C_{22}$) saturated, monounsaturated, and PUFAs are synthesized by elongation and desaturation reactions performed by enzymes located in the endoplasmic reticulum [62]. Palmitoyl-CoA is elongated by type III fatty acid synthetases, now known as elongases (elongation of very long chain fatty acids; ELOVLs) [63, 64]. Seven ELOVL enzymes (ELOVL1–7) are known in mammals, and they reveal different fatty acid substrate preferences for catalyzing the elongation reaction [64]. ELOVL1 and ELOVL3 exhibit high activity toward all of the saturated C20- to C26-CoAs, while ELOVL2 elongates C20 and C22 PUFAs [65]. Fatty acids with chain lengths longer than C26 are elongated by ELOVL4 [65]. ELOVL5 has been shown to be responsible for the elongation of C18 substrates and ELOVL6 participates in the elongation of C_{12}–C_{16} fatty acids [65]. ELOVL7 exhibits significant activities to C18-CoAs and less to C16:0-CoA. ELOVL1 and ELOVL7 are expressed in many tissues, suggesting that ELOVL7 elongates C18:0-CoA to C20:0-CoA, which is then transferred to ELOVL1 [63, 64].

Very Low Density Lipoprotein Assembly and Secretion

Fatty acids taken up by the liver and which do not undergo oxidation, are mainly esterified and collected in a common cytosolic triglyceride pool [66]. Conditions in which the delivery of fatty acids to the liver is increased may be associated with increased hepatic triglyceride content. However, under normal conditions, triglycerides do not accumulate in the cytoplasm of hepatocytes but are mobilized and, together with cholesterol and phospholipids, are assembled into VLDL particles for secretion into the circulation. The secretion of VLDL into the blood is crucial in preventing the accumulation of triglycerides by liver cells that may lead to steatosis and its resulting pathologic consequences.

The synthesis of VLDL requires the availability of apolipoprotein B (apoB), a complex protein that serves as the scaffolding upon which the VLDL is assembled. ApoB occurs in two forms, apoB-100 and apoB-48 [67]. ApoB-100 is essential for the assembly of VLDL in the liver, and apoB-48 is essential for the assembly of chylomicrons in the intestine. Both apoBs are the products of a single gene. ApoB-100 is synthesized as a 4536-amino acid polypeptide and apoB-48 – a truncated form containing 48% of the protein from the N-terminus – is synthesized as a result of apoB mRNA editing, a process that requires a multi-component enzyme complex containing an RNA-specific cytidine deaminase, apobec-1, and an RNA-binding subunit, apobec-1 complementation factor (ACF) [68]. In humans, the RNA editing occurs in the intestine but not in the liver. In rodents, apoB-48 is also synthesized in the liver and secreted into the circulation

associated with VLDL. Thus, human VLDLs carry only apoB-100 whereas rodent VLDL particles carry either apo B-100 or apoB-48 [67].

The synthesis of apoB in the liver for the assembly of VLDL apparently occurs at a constant rate. However, only a fraction of newly-synthesized apoB protein serves as the scaffold for VLDL assembly [69]. The assembly of VLDL has been proposed to occur in two sequential steps [70]. In the first step, apoB, during its co-translational translocation through a protein channel in the membrane of the rough endoplasmic reticulum, acquires a small quantity of triglycerides, phospholipids and cholesterol ester, forming a small, dense, VLDL precursor. At this stage, the apoB, if not properly folded or if it acquires an insufficient amount of lipids, is rapidly degraded and this process appears to be the principal determinant of the amount of apoB that is secreted into the circulation associated with the VLDL [71]. The acquisition of triglycerides by apoB is mediated by microsomal triglyceride transfer protein (MTP), which functions in the endoplasmic reticulum lumen as a chaperone shuttling triglycerides and phospholipids to the newly synthesized apoB [72]. In a second step, the small, dense VLDL precursor undergoes maturation by the further acquisition of triglycerides, a process that is still poorly understood, but which is thought to occur primarily by fusion between the newly lipidated particle with triglyceride droplets in the smooth endoplasmic reticulum [73]. This process does not appear to require the mediation of MTP [74, 75]. Under physiological conditions, the production of VLDL depends, primarily, on the availability of fatty acids that are taken up by the liver. However, overproduction of VLDL can occur resulting in hypertriglyceridemia. The mechanisms underlying VLDL overproduction are poorly understood although insulin appears to play an important role. High levels of this hormone increase levels of MTP expression; increase apoB availability, and induce the transcriptional regulation of hepatic lipogenic enzymes, all of which can lead to increased VLDL production and secretion [76].

Fatty Acid Oxidation

Breakdown of the major energy fuels namely, carbohydrates, amino acids, and fats, generates ATP, which is the universal cellular energy source. For ATP to be synthesized from these complex fuels, they first need to be broken down into their basic components. In general, carbohydrates are hydrolyzed into simple sugars, such as glucose and fructose, proteins to amino acids and fats (triglycerides) to fatty acids. Mitochondria use these energy-generating fuels and play a dominant role in ATP generation. The extent to which these fuels contribute to ATP production within an organism varies, but fatty acids are considered the major source of energy for many cell types except the brain, which uses glucose and also ketone bodies for ATP generation [4, 77].

Liver plays a central role in the fatty acid oxidation for energy generation and for the production of substrates for the synthesis of ketone bodies for use by extrahepatic tissues under fasting conditions for energy. In liver cells, fatty acids are oxidized in three cellular organelles, with β-oxidation confined to mitochondria and peroxisomes, and the CYP4A catalyzed ω-oxidation taking place in the endoplasmic reticulum [4, 78]. The major pathway for the catabolism of fatty acids is mitochondrial fatty acid β-oxidation [4, 79]. The following is a brief overview of the fatty acid oxidation processes in the liver.

Mitochondrial β-Oxidation

Mitochondrial β-oxidation is responsible for the degradation of the major portion of the short- ($<C_8$), medium- (C_8–C_{12}), and long- (C_{14}–C_{20}) chain fatty acids [74]. Although long-chain fatty acids (LCFAs) are β-oxidized predominantly in mitochondria, the peroxisomal β-oxidation system does indeed contribute to the oxidation of LCFAs as an overflow contingency. On the other hand, very long-chain fatty acids (VLCFAs) ($>C_{20}$) are almost exclusively, but incompletely β-oxidized (chain-shortened) in peroxisomes and the resulting chain-shortened acyl-CoAs are shuttled to mitochondria for the completion of the oxidation (see below). Since LCFAs constitute the bulk of dietary fat, their mere abundance makes them the predominant source of energy production by ATP generating mitochondrial oxidative phosphorylation. Importantly, mitochondrial β-oxidation conserves double the energy compared with peroxisomal β-oxidation, because the energy generated during the first step of peroxisomal β-oxidation dissipates as heat [79, 80].

Mitochondrial fatty acid β-oxidation is a complex process which is regulated at several levels, but mainly by carnitine palmitoyltransferase 1 (CPT1), the carnitine concentration, and malonyl-CoA, which inhibits CPT1. It should be noted that, after entry into the cell, the fatty acids are activated to acyl-CoA esters by acyl-CoA synthetases and targeted into the mitochondrial β-oxidation spiral [4]. Because the mitochondrial inner membrane is impermeable to long-chain acyl-CoAs, they are transported across to the mitochondrial matrix by the so-called carnitine shuttle. This rate-controlling shuttle utilizes three proteins: CPT1, carnitine acylcarnitine translocase (CACT), and CPT2 [81]. CPT1 exchanges the CoA group of long-chain acyl-CoA for carnitine to form long-chain acylcarnitines, which are transported across the mitochondrial inner membrane by carnitine acylcarnitine translocase [82]. CPT2 located at the mitochondrial inner

membrane releases the carnitine group from acylcarnitines in exchange for a CoA group and delivers the CoA esters to mitochondrial matrix for oxidation. The released carnitine shuttles back to the cytosol for reuse [81, 82].

In the mitochondria, fatty acyl-CoAs ($<C_{22}$) are completely β-oxidized to acetyl-CoA subunits and this process occurs in a sequence of four reactions and each reaction may be catalyzed by more than one enzyme [4, 79, 83]. The β-oxidation is a repetitive process in which acyl-CoAs are progressively shortened by releasing two carboxy-terminal carbon atoms as acetyl-CoA subunits, which either condense into ketone bodies (acetoacetate, acetone, and β-hydroxybutyrate) in liver to serve as oxidizable fuels for extrahepatic tissues, or enter into the tricarboxylic acid cycle for further oxidation into water and carbon dioxide [84].

The mitochondrial β-oxidation has two distinct components. The first, which is mitochondrial inner membrane bound, is active with long-chain fatty acyl-CoAs (C_{12}–C_{20}) and after 2–3 cycles, generates medium-chain acyl-CoAs for further oxidation in the mitochondrial matrix. The inner membrane-bound mitochondrial β-oxidation system involves four enzymatic reactions performed by two membrane bound proteins. The first protein, a very long-chain acyl-CoA-dehydrogenase (VLCAD), catalyzes the α-β-dehydrogenation of the acyl-CoA ester, the initial, rate-limiting first step of mitochondrial fatty acid β-oxidation, to generate trans-2,3-enoyl-CoA [77]. The second membrane bound protein involved in long-chain acyl-CoA oxidation is a mitochondrial trifunctional protein (MFP, L-PBE), with long-chain enoyl-CoA hydratase/long-chain 3-hydroxy acyl-CoA dehydrogenase/long-chain 3-ketoacyl-CoA thiolase activities responsible for performing steps 2–4 of β-oxidation. In the second step, enoyl-CoAs are hydrated by 2-enoyl-CoA hydratases to generate L-3-hydroxyacyl-CoAs, which in the third step are catalyzed by short chain L-3-hydroxyacyl-CoA dehydrogenase to produce 3-ketoacyl-CoAs. The final step is catalyzed by 3-ketoacyl-CoA thiolases [77, 85]. After 2–3 cycles using these membrane bound enzymes, the resulting medium acyl-CoAs ($<C_{14}$) are metabolized by mitochondrial matrix based second β-oxidation system. This matrix based chain-length specific system consists of LCAD (C_8 to C_{20}), MCAD (C_4–C_{12}), and SCAD (C_4–C_6) that catalyze the first step to yield enoyl-CoA [77, 86]. The second, third and fourth steps of this matrix based system are carried out by the 2-enoyl-CoA hydratase, L-3-hydroxyacyl-CoA dehydrogenase, and 3-ketoacyl-CoA thiolase, all which are present in the mitochondrial matrix as individual enzymes (not as trifunctional protein) encoded by separate genes [77, 87]. Each mitochondrial β-oxidation cycle results in the production acyl-CoA shortened by two carbon atoms and an acetyl-CoA. The resulting shortened acyl-CoA reenters the fatty acid oxidation cycle and the acetyl-CoA is used for ketone body generation for export to organs such as heart, or it can enter the citric acid cycle for ATP generation.

Peroxisomal β-Oxidation

In the liver, both mitochondria and peroxisomes participate in the β-oxidization of fatty acids. While short- and medium-chain fatty acids are β-oxidized rather exclusively in mitochondria, LCFAs can be oxidized in both mitochondria and peroxisomes. However, VLCFAs ($>C_{20}$), such as C24:0 and C:26:0 are β-oxidized exclusively by the peroxisomal β-oxidation system as mitochondria lack very long-chain fatty acyl-CoA synthetase to convert these VLCFAs into acyl-CoA esters for entry into the mitochondria. Some pertinent differences between the mitochondrial and peroxisomal β-oxidation systems are listed below.

- Mitochondria lack very long-chain fatty acyl-CoA synthetase, hence VLCFAs ($>C_{20}$) cannot enter these organelles. Peroxisomal membrane on the other hand has at least two acyl-CoA synthetases: a long chain acyl-CoA synthetase and a very long-chain acyl-CoA synthetase capable of activating LCFAs and VLCFAs, respectively [88]. While LCFAs can be oxidized both in the mitochondria and peroxisomes, the presence of very long-chain fatty acyl-CoA synthetase on peroxisomal membrane accounts for the exclusively streamlined β-oxidation of VLCFA within the peroxisomes.
- The first oxidation step in the peroxisomal β-oxidation of fatty acids is catalyzed by fatty acyl-CoA oxidase 1 (ACOX1) in the classic inducible pathway, but unlike in mitochondria, the β-oxidation in peroxisomes is not coupled to ATP synthesis. Instead, the high-potential electrons are transferred to O_2 to yield H_2O_2, which is further converted into H_2O and O_2 by peroxisomal catalase. The energy released during peroxisomal fatty acid oxidation is dissipated as heat.
- Unlike the mitochondrial system, peroxisomal β-oxidation does not go to completion, as the appropriately chain-shortened acyl-CoAs are exported to the mitochondria for the completion of β-oxidation.
- Peroxisomal β-oxidation generated chain-shortened acyl-CoAs are shuttled to mitochondria, either as carnitine esters and/or as free fatty acid for the completion oxidation. Peroxisomes contain carnitine acetyltransferase and carnitine octanoyltransferase for conjugation and transport of short- and medium-chain acyl-CoAs respectively. Mitochondria on the other hand use carnitine shuttle with carnitine palmitoyl transferase-1 (CPT1) and CPT2 as major players.

It is noteworthy that the peroxisomal β-oxidation is uniquely geared toward the metabolism of less abundant and relatively more toxic and biologically active VLCFAs ($>C_{20}$), 2-methyl-branched fatty acids, dicarboxylic acids, prostanoids, and C_{27} bile acid intermediates, among others [89]. VLCFAs are not completely β-oxidized in peroxisomes, but

this system serves to shorten the chain length for further completion of oxidation in mitochondria [77, 90]. Although this system normally functions in the shortening of VLCFA-CoA, it also breaks down LCFA-CoA when the mitochondrial β-oxidation is decreased or overwhelmed. Long-chain dicarboxylic acids produced by the microsomal ω-oxidation of LCFAs and VLCFAs (see below) are also metabolized by the peroxisomal β-oxidation system [91]. Dicarboxylic acids are generally considered more toxic than VLCFAs and are known to inhibit mitochondrial fatty acid oxidation system and thus may contribute to the development of hepatic steatosis. Peroxisomal β-oxidation also acts in the synthesis and metabolism of docosahexanoic acid (DHA) and retroconversion of DHA to eicosapentaenoic acid.

Similar to the mitochondrial β-oxidation system, the peroxisomal β-oxidation spiral consists of four sequential steps with each metabolic conversion carried out by at least two different enzymes [90, 92]. These enzymes are separated into two pathways, inducible and non-inducible, with each pathway consisting of three separate enzymes. The first step of the peroxisomal β-oxidation in each pathway is catalyzed by a different ACOX, with an inducible classic ACOX1 exhibiting specificity for straight-chain VLCFA-CoA esters, dicarboxylic acids, and eicosanoids the non-inducible ACOX2 acting on CoA esters for 2-methyl branched-chain fatty acids [77, 93]. This first step converts acyl-CoA into enoyl-CoA. The second and third reactions, hydration and dehydrogenation of enoyl-CoA esters to 3-ketoacyl-CoA are catalyzed by one of two bi/multi-functional enzymes (PBE/MFP) with enoyl-CoA hydratase/L-3-hydroxyacyl-CoA dehydrogenase (L-PBE/MFP1) in the inducible pathway, or D-3-hydroxyacyl-CoA dehydratase/D-3-hydroxyacyl-CoA dehydrogenase (D-PBE/MFP2) in the non-inducible pathway. D-PBE/MFP2 of this pathway can substitute for the L-PBE/MFP1 function in the inducible [4, 90, 94]. The fourth step in the peroxisomal β-oxidation converts 3-ketoacyl-CoAs to acyl-CoA that is two carbon atoms shorter than the original molecule and acetyl-CoA. This function in the inducible pathway is performed by straight-chain 3-oxoacyl-CoA thiolase and in the noninducible pathway by the sterol carrier protein x (SCPx), which possesses thiolase activity [94, 95]. The functional significance of peroxisomal β-oxidation system is to metabolize potentially toxic substrates such as VLCFAs and shuttle the chain-shortened metabolites to mitochondrial β-oxidation system for further degradation and to prevent hepatic steatosis.

Microsomal ω-Oxidation

Liver also utilizes the microsomal ω-oxidation system to metabolize fatty acids (C_{10}–C_{26}) as an alternative pathway to β-oxidation, especially when β-oxidation is defective. In the ω-oxidation pathway, the first step involves the conversion within the endoplasmic reticulum of the ω-methyl group of the fatty acid into a ω-hydroxyl group by P450 enzymes belonging to the CYP4A/F subfamilies. In the human CYP4A11 of CYP4A family and CYP4F11 of the CYP4F family appear to be the predominant catalysts for fatty acid ω-oxidation [96, 97]. The resulting ω-hydroxy fatty acid is then dehydrogenated to a dicarboxylic acid in the cytosol. The dicarboxylic fatty acids generated by ω-oxidation require β-oxidation in mitochondria and or peroxisomes to shorter chain dicarboxylic acids for excretion into the urine [98]. Prior to entering β-oxidation spiral, dicarboxylic acids are converted into dicarboxylyl-CoAs by acyl-CoA synthase present in endoplasmic reticulum. Medium-chain dicarboxylyl-CoAs are oxidized in mitochondria, whereas long- and very long-chain dicarboxylyl-CoAs are metabolized exclusively by the classic inducible peroxisomal β-oxidation system in humans. Although ω-oxidation is a minor catabolic pathway accounting for <10% of total fatty acid oxidation in the liver, this system constitutes a critical route in the elimination of potentially toxic levels of free fatty acids. First, ω-oxidation is upregulated when β-oxidation is defective, and this poses a problem as the dicarboxylic acids so generated cannot be adequately metabolized to avert accumulation of toxic levels of dicarboxylic acids. A defect in β-oxidation leads to dicarboxylic acid toxicity [77, 99]. Significant quantities of dicarboxylic acids are also generated under conditions of fatty acid overload in the liver, for example, in obesity and diabetes, and in conditions where mitochondrial oxidation is inadequate to oxidize fatty acids.

Fatty Acid α-Oxidation

Plants synthesize fatty acids such as phytanic acid with odd numbers of carbon and these 3-methyl branched fatty acids cannot be β-oxidized, but use an alternate α-oxidation pathway present in peroxisomes [100]. Oxidation of phytanic acid proceeds as follows: phytanic acid is activated to phytanoyl-CoA by long-chain acyl-CoA synthetase, which is then hydroxylated to 2-hydroxyphytanoyl-CoA by phytanoyl-CoA 2-hydroxylase. Subsequently, 2-hydroxyphytanoyl-CoA is cleaved to yield formyl-CoA and pristanal. Pristanal is oxidized to pristanic acid and upon activation to pristanoyl-CoA, it enters peroxisomal β-oxidation spiral, eventually generating propionyl-CoA and acetyl-CoA. In essence, 3-methyl branched fatty acids in mammalian liver are subjected to α-oxidation in the initial steps and to β-oxidation process subsequently to generate acetyl-CoA and 2-methyl propionyl-CoA [100].

Ketogenesis

Under conditions contributing to increased fatty acid uptake and oxidation in the liver, large amounts of acetyl-CoA are generated. When acetyl-CoA concentrations exceed the capacity of tricarboxylic acid cycle to metabolize, acetyl-CoAs are utilized to generate ketone bodies called acetoacetate, β-hydroxybutyrate, and acetone. These products of ketogenesis, can be used as energy source by tissues such as brain, heart, skeletal muscle, liver, and kidneys [84, 101]. Accordingly, ketogenesis depends on the capacity of liver to fully oxidize fatty acids. It should be noted that the release of glucose by the liver is essential to meet the energy needs of many cell types. During fasting conditions, after the hepatic glycogen reserves are exhausted, the organism relies on ketone bodies which become the main alternative fuel source. Ketone bodies released from liver provide up to 80% of the total energy needed. This glucose sparing effect of ketone bodies is extremely important in cerebral tissue in infants due to the high proportional glucose utilization [101].

Regulation of Hepatic Lipid Metabolism: Clues from Knockout Mouse Models

Over the years, the importance of lipid metabolism in liver in the development of alcoholic steatohepatitis and chronic fatty liver disease is well recognized. Currently, lipid metabolic dysfunctions in liver, in particular steatosis and steatohepatitis, related to obesity and metabolic syndrome are receiving considerable attention. Accordingly, an understanding of the regulatory factors influencing overall energy balance and attempts at pharmacological intervention are of paramount importance.

Several genetic disorders affecting the mitochondrial and peroxisomal fatty acid oxidation system genes at different levels of the catabolic spiral have been discovered in humans [4, 80, 91]. These defects have provided fascinating insights into the role of fatty acid catabolism in maintaining energy homeostasis and causing dysfunction. In addition, during the past 25 years, several gene knockout mouse models have been generated to investigate the functional roles of many genes involved in various aspects of lipid metabolism.

The following provides a brief overview of the regulatory molecules that influence lipogenesis, and fatty acid oxidation [102]. Abnormalities in lipogenesis, fatty acid oxidation, and in fatty acid intake and export, contribute to the development of hepatic steatosis and these functions in liver are influenced by many factors [103]. In this regard, attention is focused on two key transcription factors, the sterol regulatory element-binding protein 1-c (SREBP1-c) that controls the expression of genes involved in lipogenesis, and peroxisome proliferator-activated receptor-α (PPARα), which controls the expression of genes of the fatty acid oxidation systems in liver [104–106]. Two other members of PPAR subfamily, namely, PPARβ/δ and PPARγ, also play key roles in overall lipid metabolism of the organism [106]. Fatty acids and their metabolites control the expression of these factors. Retinoid X receptor α (RXRα), a heterodimerization partner of PPARs and several other nuclear receptors [105, 107], are also involved in lipid homeostasis. Evidence is also emerging about the role of microRNAs in the regulation of genes that participate in liver lipid metabolism [108].

Regulation of Hepatic Lipogenesis

As de novo synthesis of fatty acids in liver is regulated by insulin and glucose, it is essential to understand their role in activating the membrane-bound lipogenic transcription factor SREBP-1c, an important member of SREBP family of transcription factors [109]. Insulin is a key regulator of SREBP-1c, one of the three SREBP isoforms in humans and rodents [110]. SREBP-1c and SREBP-2 are the predominant forms in the liver. SREBP-1a and SREBP-1c activate hepatic fatty acid synthesis through regulation of lipogenic genes, such as ACC2, FAS, SCD-1 and glycerol phosphate acyltransferase [111]. ACC2-generated malonyl-CoA inhibits fatty acid entry and oxidation in mitochondria, because malonyl-CoA inhibits CPT1 activity. As noted above, mutation of ACC2 results in increased fatty acid oxidation due to reduced malonyl-CoA production [112]. SREBP-1c induces lipogenic genes by binding to sterol response element (SRE) sites in their promoters, which is impaired in SREBP-1c–/– mice. SREBP-1c gene contains two response elements for lipogenic transcription factor liver X receptor (LXR), and the activation of LXR by oxysterol ligands induces the transcription of SREBP-1c [102]. Disruption of SREBP-1c gene expression in ob/ob mice improves hepatic steatosis, while overexpression of SREBP-1c in the liver leads to increases in hepatic glycogen and triglyceride contents [113]. Glucose regulates lipogenesis as glucose is converted to fatty acids. Glucose-mediated stimulation of lipogenesis is controlled by transcription factor carbohydrate response element-binding protein (ChREBP) [114]. ChREBP activates the expression of genes involved in the synthesis and uptake of fatty acids, including those encoding ACC, FAS, SCD-1, and ATP citrate lyase [102, 115]. Glucose exerts the ChREBP activation by regulating the entry of ChREBP from the cytosol into the nucleus thus influencing the DNA binding and transcriptional activity of this transcription factor [116].

The transcriptional activities of ACC1, ACC2, and FAS in liver are regulated by both glucose and insulin [102, 117].

Deficiency of ACC1 is embryonically lethal in mice, whereas ACC2 null mice are viable but exhibit enhanced metabolic rate, manifesting as continuously elevated fatty acid oxidation and reduced adiposity [118, 119]. In ACC2 null mice, CPT1 activity increases resulting in an increased rate of fatty acid oxidation [120]. It would appear that malonyl-CoA, generated by ACC1 and ACC2, work independently and that there is minimal, if any, overlap of their functions. FAS, which catalyzes the first committed step in fatty acid biosynthesis to generate mostly the saturated fatty acid palmitate, also plays an important role in fatty acid oxidation (see below). When FAS gene is conditionally inactivated in mouse liver, it causes decreased fatty acid oxidation suggesting that this enzyme is involved in generating ligands that activate the lipid sensing transcription factor, PPARα, a critical regulator of fatty acid oxidation [90, 121]. SCD-1 is also modulated by a number of dietary, physiological and hormonal factors including insulin and glucose, and is critical in maintaining intracellular lipid flux. SCD-1 has also been suggested in representing a key step in the partitioning of lipids between storage and oxidation [122]. Mice with global deletion of SCD-1 are resistant to high-fat diet induced obesity and SCD-1 deficiency also prevents the development of hepatic steatosis [123]. Significant increase of SCD-1 expression and reduced energy expenditure in ob/ob mice result in marked hepatic steatosis, hyperlipidemia and increase of lipid secretion.

Regulation of Fatty Acid Oxidation

Oxidation of fatty acids in liver involves the participation of several enzymes that are affected by a multiplicity of factors including more prominently the nuclear receptor PPARα [90, 91]. Enzymes such as CPT1 and CPT2, and substrates (fatty acid metabolism intermediates), such as malonyl-CoA are known to influence mitochondrial fatty acid β-oxidation [82]. Likewise, several structurally diverse compounds called peroxisome proliferators [4, 90, 91], and certain metabolic pathways that generate or degrade biological (endogenous) PPARα ligands, also affect fatty acid catabolism, especially by activating PPARα, which is referred to as lipid and peroxisome proliferator-sensor in liver [77]. PPARα transcriptionally regulates all key enzymes of peroxisomal and mitochondrial β-oxidation pathways, as well as microsomal ω-oxidation system [4, 90, 91, 124–127]. Several genetic disorders in humans involving the enzymes of the mitochondrial and peroxisomal fatty acid β-oxidation pathways have been identified that have provided considerable insights into the regulatory aspects of energy homeostasis and in particular implications of disturbances in fatty acid metabolism. Genetic defects affecting mitochondrial β-oxidation in humans include: deficiencies of CPT1, CPT2, CACT, VLCAD, MTP, MCAD, M/SCHAD, and among others [4, 77, 91]. Mouse models of gene disruption affecting mitochondrial β-oxidation include: CPT1a, CPT1b, LCHAD/MTP, VLCAD, LCAD, MCAD, and SCAD among others [90, 91]. Most of these gene knockout mouse models exhibit severe or lethal phenotype and, in most part, mimic human disease with some exceptions [90, 128, 129].

In both humans, and mouse models, peroxisomal β-oxidation pathway disruptions have been studied in considerable detail [4, 50, 89, 91, 125, 127–129]. Three genetic disorders affecting peroxisomal β-oxidation spiral, namely ACOX1 deficiency, DPBE/MFP1 deficiency and SCPx deficiency have been identified and studied in detail in humans [4, 91, 127]. Gene knockouts in the mouse include disruptions of genes encoding ACOX1, L-PBE/MFP1, D-PBE/MFP2, and SCPx [4, 89, 91, 128, 129].

The following focuses, first, on the role of the transcription factor PPARα in regulating the fatty acid oxidation system genes, and second, as to how disruption of these genes contributes to high levels of unmetabolized substrates that function as PPARα ligands [128]. It is also worth noting that some of these substrates/ligands may be generated by a proximal enzyme in the oxidation pathway. It is becoming increasingly clear that some of the enzymes in fatty acid oxidation systems contribute to the formation or degradation of biological ligands of PPARα [4, 90, 92, 128].

First, all three members of the PPAR subfamily are known to function as sensors for fatty acids and fatty acid derivatives and thus control important metabolic pathways involved in lipid and energy metabolism [90, 91, 126]. Of these, PPARα is a key regulator of mitochondrial, peroxisomal, and microsomal fatty acid oxidation enzyme systems in liver [4, 90, 130–133]. Exposure to peroxisome proliferators, which are synthetic PPARα ligands, results in massive induction of these fatty acid oxidation systems in liver culminating in increased energy combustion [4, 77]. This receptor is also activated by both saturated and poly-unsaturated fatty acids and their derivatives. PPARα also plays an important role in lipoprotein synthesis and inflammatory responses and in the development of liver cancer [90]. PPARα knockout mice have demonstrated unequivocally that this receptor is indeed the bona fide receptor for transcriptionally activating the fatty acid oxidation genes and inducing the peroxisome proliferator-mediated pleiotropic responses including liver tumors [130, 134]. PPARα null mice display normal basal levels of the inducible peroxisomal β-oxidation enzymes in liver but possess generally lower levels of mitochondrial β-oxidation enzyme activities [131]. Under fasting conditions, PPARα senses the fatty acid influx into the liver and up-regulates all three fatty acid oxidation systems to combust the energy and minimize hepatic steatosis [33–35]. Mice deficient in PPARα fail to upregulate fatty acid burning

enzymes in liver and become grossly steatotic when fasted [33–35] (Fig. 10.1). When maintained on a diet deficient in methionine and choline, PPARα null mice develop severe steatohepatitis [135].

Second, increasing evidence suggests that PPARα senses certain endogenous lipid metabolic intermediates as ligands and participates in their metabolic breakdown by inducing downstream lipid metabolism genes [90, 128]. Studies with ACOX1 null mice revealed that disruption of this gene encoding the first and rate-limiting enzyme of the fatty acid β-oxidation system results in profound activation of PPARα in liver [94, 128] (Fig. 10.2). Animals with ACOX1 deficiency have high levels of VLCFAs and since VLCFA-CoAs are incapable of entering the fatty acid oxidation pathway due to ACOX1 deficiency, these unmetabolized substrates act as ligands to hyper activate PPARα in liver [4, 90, 128]. Recent studies with gene knockout mouse models suggest that enzymes such as ACOX1, L-PBE/MFP1, D-PBE/MFP2, and SCPx of peroxisomal β-oxidation spiral are necessary for the degradation of endogenously generated PPARα ligands [50, 78, 80, 89–91, 102, 104, 128, 129]. It is also becoming clear that other enzymes such as FAS, FACS, and certain lipoxygenases are required for PPARα ligand generation in vivo [90, 104, 121]. For example, FAS deficient mice reveal a phenotype resembling PPARα deficiency. FAS generated 1-palmitoyl-2-oleoyl-sn-glycerol-3-phosphocholine (16:0/18:1-GPC), functions as a physiologically relevant PPARα ligand [104] (Fig. 10.2). Thus, absence of an enzyme such as FAS fails to generate a ligand, where as absence of an enzyme such as ACOX1 fails to degrade endogenous PPARα ligand(s). These observations establish that fatty acid metabolism in liver is intricately regulated to prevent to harmful accumulation of products that may lead to hepatic steatosis and steatohepatitis, or that fail to upregulate PPARα under conditions of stress such as that induced by excess fatty acid influx into liver during fasting or excess energy overload.

MicroRNAs in the Regulation of Lipid Metabolism

Recent studies suggest that microRNAs play a role in regulating lipid metabolism [136–139]. For example, ectopic expression of let-7 blocks 3T3 L1 cell growth and completely inhibits terminal differentiation [136]. miR-103(1), miR-103(2), and miR-107 within introns of the pantothenate

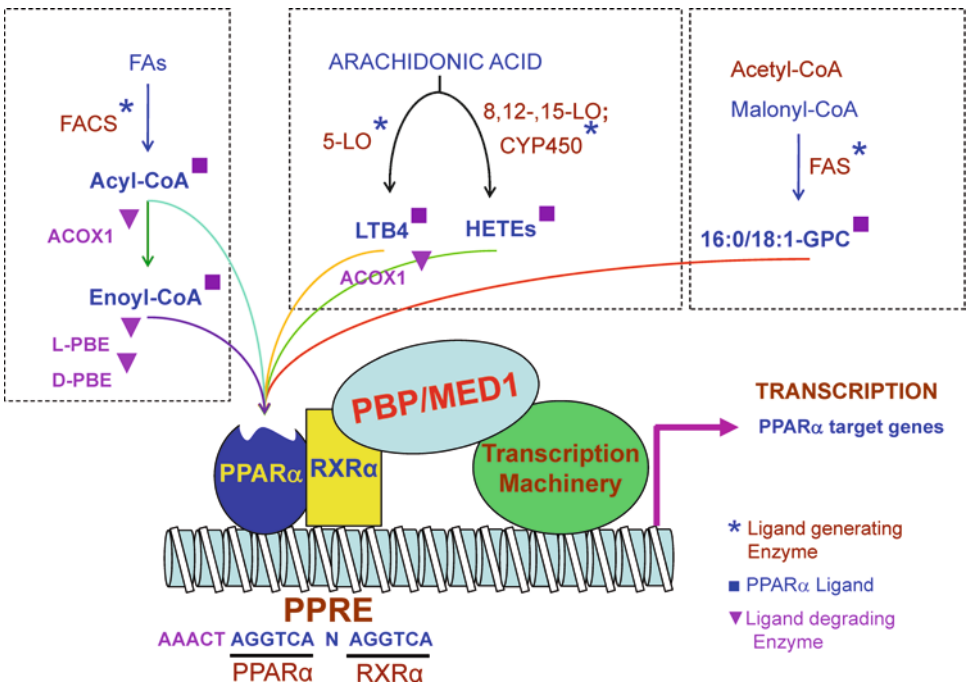

Fig. 10.2 Biological ligands of PPARα. Lipid metabolism generates intermediary metabolites and if some of these, for example acyl-CoAs generated by fatty acyl-CoA synthetase (FACS) remain unmetabolized as in the absence of ACOX1, they can act as biological (endogenous) PPARα ligands in liver. Gene knockout mouse models have provided valuable insights regarding PPARα ligand degrading and ligand generating enzymes in liver. The model also shows peroxisome proliferator response element (PPRE) hexanucleotide direct repeat separated by one nucleotide (DR1) and the putative PPAR and RXR heteridimer binding half-sites. Also shown are the basal transcription machinery and the transcription coactivator PBP/MED1 as they appear critical for PPAR regulated transcriptional activity. From Pyper et al. [90] with permission

kinase gene appear to be important in the regulation of cellular acetyl-CoA synthesis [137]. miR-122 is a liver specific microRNA, expressed in rodents and appears to regulate cholesterol and hepatic lipid metabolism [138]. Inhibition of miR-122 in mice results in a significant improvement in liver steatosis, which may result from a reduction of several lipogenic genes and stimulation of hepatic fatty-acid oxidation. Recent studies showed that PPARδ and PPARα coactivator Smarcd1/Baf60a are the target genes of miR-122 [138].

Several microRNAs have been proposed to be associated with obesity. The expression of miR-335 in liver is elevated in obese mouse models, including ob/ob, db/db, and KKAy mice and its expression accounts for increase of body, liver size, and white adipose tissue stores [139]. miR-335 levels are closely correlated to the expression of PPARγ, aP2, and FAS expression, the markers for adipocyte differentiation. Thus, the induction of miR-335 may contribute to the pathophysiology of obesity and to the development of hepatic steatosis [139]. Recent microarray data showed that miR-151, -192, -34a, -24, -10b, -132 are upregulated in hepatic steatosis [140]. The identification of target genes for these micro-RNAs and authentication of changes in their expression require further attention to appreciate the regulatory implications of these pivotal molecules in hepatic lipid metabolism. Manipulating microRNA levels may be an another layer of gene regulation, and may present a potential for therapeutic targets.

Summary

Lipids constitute an important source of energy. Liver plays a central role in lipid metabolism as it is critical for lipogenesis and fatty acid catabolism. Several enzymes participating in these energy balancing processes are affected by a variety of pathophysiological conditions and regulated by certain transcription factors. Evidence indicates that SREBPs and PPARα play prominent roles in controlling the hepatic expression of genes responsible for fatty acid synthesis and oxidation, respectively. Elucidation of the role of enzymes and of transcription factors that regulate the expression of these enzymes is critical for understanding the intricacies involved in the pathogenesis of hepatic steatosis and for the development of therapies. Several genetic disorders affecting the mitochondrial and peroxisomal fatty acid oxidation systems have been identified, and in recent years, gene knockout-mouse models have also been generated to investigate in detail the role of a given gene in modulating the metabolic pathways when their function is disrupted. These genetically altered mouse models are also providing considerable insights into the role of enzymes in generating and degrading endogenous ligands for transcription factors. The substrates and/or products generated by specific enzymatic processes appear to function as biological ligands for the transcription factors that control the expression of genes responsible for lipid metabolism in liver.

Chapter 11
Detoxification Functions of the Liver

Udayan Apte and Partha Krishnamurthy

Introduction

The body is exposed to a variety of chemicals everyday in the form of pharmaceutical agents, household chemicals, dietary supplements, and environmental contaminants, many of which are extremely toxic. The primary defense mechanisms against xenobiotics in the body are the drug metabolizing enzymes (DMEs) involved in metabolism and excretion of xenobiotics [1]. Liver is the primary organ involved in the metabolism of xenobiotics including chemicals and pharmaceutical agents. Other organs including kidney and intestine have minor drug metabolism capabilities but liver is the site of metabolism for a vast majority of drugs and chemicals [2]. The chemical reactions involved in drug metabolism generally convert chemicals into more water-soluble metabolites rendering them easier for eventual excretion in the urine. Whereas many reactions catalyzed by the DMEs result in more water-soluble products, which are relatively less harmful, a number of the DME-mediated reactions result in the production of metabolic intermediates, which are highly reactive and induce tissue damage [3]. Therefore, the detoxification function of the liver is not homogenous and metabolism of each chemical in the liver should be investigated on a case-by-case basis. Nevertheless, there are some general principles that apply to the entire drug metabolism process.

The chemical reactions that are involved in drug metabolism process can be divided into four broad categories as hydrolysis, reduction, oxidation and conjugation reactions [3]. Traditionally, drug metabolism process is divided into Phase I and Phase II, where enzymes involved in hydrolysis, reduction and oxidation are considered as Phase I enzymes and the enzymes involved in conjugation reactions are considered as Phase II enzymes. The so-called Phase I enzymes include cytochrome P450 (CYP450), flavin containing monooxygenase (FMO) and aldehyde and alcohol dehydrogenase enzymes, which mainly conduct hydrolysis, oxidation, and reduction reactions [2]. The Phase II enzymes generally conduct conjugation reactions such as glucuronidation, glutathione conjugation, sulfation, methylation, acetylation, and amino acid conjugation. Generally, the chemical first undergoes Phase I biotransformation and the product of Phase I metabolism becomes a substrate for the Phase II conjugation reactions. This traditional classification of DME has been challenged in recent years mainly because of new evidence suggesting that many chemicals can be first conjugated and later become substrates for CYP450 enzymes. Similarly, many drugs are directly conjugated and do not undergo CYP450 mediated metabolism unless in case of an overdose. For example, acetaminophen, which is known to induce liver injury and acute liver failure, undergoes conjugation to glucuronic acid and sulfonic acid and only in the case of an overdose, it is metabolized by CYP2E1 [4]. Furthermore, the original idea behind considering conjugation reactions as Phase II was that the conjugated product was thought to be less toxic. However, substantial evidence in recent years has shown that many conjugation processes can result in generation of toxic intermediates. A classic example is trichloroethylene (TCE) a known hepatotoxicant and chemical carcinogen, which undergoes Phase I metabolism and Phase II glutathione conjugation to produce a highly nephrotoxic intermediate called *S*-(1,2-dichlorovinyl)-L-cysteine [5].

Majority of the DMEs in the liver are present in hepatocytes thus making hepatocytes, the center of the detoxification process not only in the liver, but also in the entire body [2]. There are a large number of enzymes known to be involved in drug metabolism in the liver and the list is growing. The most important enzymes in terms of drug metabolism and toxicity include the classic CYP450, FMO, aldehyde dehydrogenase, alcohol dehydrogenase, monoamine oxidases, epoxide hydrolases, glutathione transferases, glucuronosyltransferases, sulfotransferases, methyltransferases, and *N*-acetyl transferases. Whereas majority of DMEs are present in smooth endoplasmic reticulum, (also called microsomal, since upon isolation

using differential centrifugation, ER forms lipid micelles called as microsomes) many are present in the cytoplasm (cytosolic). Because of this spatial variation within the cell, DMEs are sometimes also referred to by their location along with the reaction they catalyze (For e.g., microsomal epoxide hydrolase). Certain enzymes such as glutathione transferase are also present in the mitochondria.

In recent years, a third dimension of drug metabolism process, which has received much attention, is the drug transport [6]. Both hepatocytes and biliary epithelial cells in the liver express a variety of influx and efflux transporter proteins, which are critical in determining the cellular levels of xenobitics. Studies have highlighted the importance of drug transporters in the bioavailability of various chemicals and drugs, and transporters are now considered as the Phase III of the drug metabolism process.

Major DMEs in the Liver

Whereas there are many enzymes involved in catalyzing specific reactions in drug metabolism and detoxification in the liver, few have a much higher impact on liver biology and human health in general than others. These include CYP450s and FMO in the so-called Phase I metabolic reactions and the glutathione transferases, glucuronosyltransferases, and sulfotransferases in the Phase II reactions [2]. The following section describes the general mechanism of action of these enzymes with details on some of the more important isoforms of these enzymes.

Cytochrome P450

CYP450 form the largest group of DMEs with 57 known human isoforms [2]. CYP450 are versatile enzymes and can catalyze oxidation of a wide range of the substrates including drugs, chemicals, and endogenous substrates [7]. CYP450 are heme-containing proteins and the heme (iron) is generally present in the ferric (Fe^{3+}) state. Upon reduction to ferrous state (Fe^{2+}), the CYP450 enzymes form a complex with substrates such as oxygen and carbon monoxide (CO). The CYP450-CO complex was found to absorb light at 450 nm, which gave these enzymes their name. However, depending on the isoforms, these enzymes can absorb light at various wavelengths between 447 and 452 nm following binding to CO. This peculiar absorbance at 450 nm is because of a formation of thiolate bond between a highly conserved cysteine residue next to the heme moiety and the ligand. Upon dissociation of this thiol bond, CYP450 becomes catalytically inactive and shows maximum absorbance at 420 nm.

The basic CYP450 reaction is a mono-oxygenation reaction in which the substrate (RH) is oxidized by the incorporation of one oxygen atom to generate the product (ROH) (Fig. 11.1a). The second atom of oxygen is used to produce water by using reducing equivalents donated by NADPH [7]. Most CYP450 enzymes function in collaboration with another protein called NADPH oxidoreductase, a flavin containing enzyme. NADPH oxidoreductase is critical for CYP450 activity because CYP450 enzymes bind to the substrates directly, but not to NADPH. The FMN and FAD, which are parts of NADPH oxidoreductase, aid in transfer of electrons from NADPH to CYP450. This is mainly true for CYP450 present in endoplasmic reticulum, whereas for CYP450 present in mitochondria, two other proteins called ferrodoxin and ferrodoxin reductase are involved in electron transfer from NADPH to CYP450. In addition to NADPH oxidoreductase, another protein called cytochrome b_5 is also involved in the electron donation in CYP450 enzymes. Cytochrome b_5 increases the rate of CYP450 reaction and also increases the substrate-binding affinity of CYP450 enzymes. Whereas several CYP450 isoforms have been identified, both NADPH oxidoreductase and cytochrome b_5 do not have any isoforms.

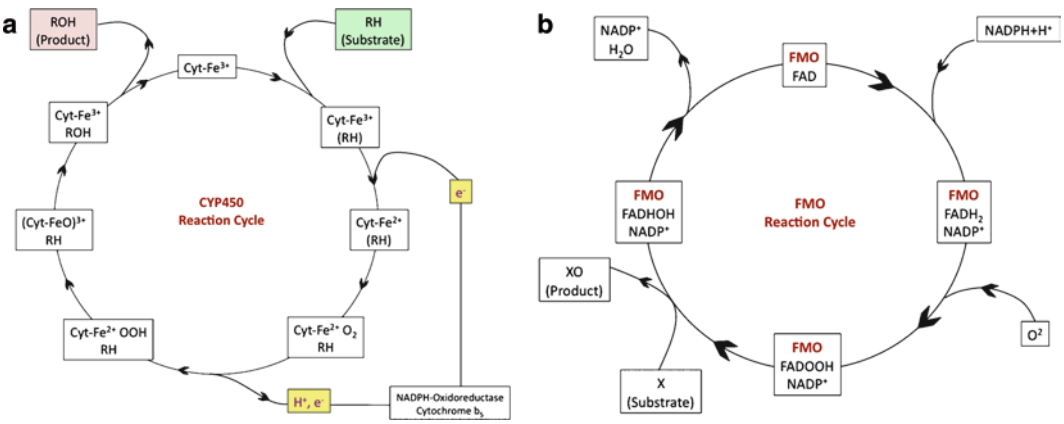

Fig. 11.1 Reaction cycles of (**a**) CYP450 and (**b**) FMO enzymes. See text for details

CYP450 Isoforms

There are 57 known isoforms of CYP450 in humans (Table 11.1). The classification of CYP450 isoforms is based on amino acid sequences of individual enzymes [8]. The enzymes are divided into families (CYP1, CYP2, CYP3, etc.), subfamilies (CYP1A, CYP2E, CYP3A, etc.), and individual genes (CYP1A1, CYP2E1, CYP3A4, etc.). The CYP450 enzymes grouped into each family and subfamily share common characteristics including substrates, type of reactions catalyzed, chemical inducers and inhibitors. Whereas each of the 57 CYP450 enzymes are unique and have specific functions, enzymes from some CYP450 enzymes have deeper impact on liver, and overall physiology and pathobiology than others [9]. These CYP450 enzymes important for liver biology are further discussed here.

CYP1A2

The most well-characterized and physiologically relevant enzymes in CYP1A family include CYP1A1 and CYP1A2 [10]. In humans, the main hepatic CYP1A family member is CYP1A2. However, the CYP1A1 is not expressed in the human liver,but it is present in many extrahepatic tissues. The expression of CYP1A family members is regulated mainly

Table 11.1 CYP450 isoforms expressed in humans

CYP450 family	Specific isoform	Function
CYP1A	CYP1A1, 1A2	Xenobiotic metabolism
CYP1B	CYP1B1	Xenobiotic metabolism
CYP2A	CYP2A6, 2A7, 2A13	Xenobiotic metabolism
CYP2B	CYP2B6,	Xenobiotic metabolism
CYP2C	CYP2C8, 2C9, 2C18,2C19	Xenobiotic metabolism, fatty acid and ecosinoid metabolism
CYP2D	CYP2D6	Xenobiotic metabolism
CYP2E	CYP2E1	Xenobiotic metabolism
CYP2F	CYP2F1	Xenobiotic metabolism,
CYP2J	CYP2J2	Xenobiotic metabolism, fatty acid and ecosinoid metabolism
CYP2R	CYP2R1	Vitamin D metabolism
CYPS, U, W	CYP2S1, 2U1, 2W1	Unknown
CYP3A	CYP3A4, 3A5, 3A7, 3A43	Xenobiotic metabolism, bile acid synthesis
CYP4A	CYP4A11, 4A22	Fatty acid and ecosinoid metabolism
CYP4B	CYP4B1	Fatty acid and ecosinoid metabolism
CYP4F	CYP4F2, 4F3, 4F8, 4F11, 4F12, 4F22	Xenobiotic metabolism, fatty acid and ecosinoid metabolism
CYP4V, 4X, 4Z	CYP4V2, 4X1, 4Z1	Unknown
CYP5A	CYP5A1	Fatty acid and ecosinoid metabolism, thromboxane A synthesis
CYP7A	CYP7A1	Bile acid synthesis
CYP7B	CYP7B1	Bile acid synthesis
CYP8A	CYP8A1	Fatty acid and ecosinoid metabolism, prostaglandin synthesis
CYP8B	CYP8B1	Bile acid metabolism
CYP11A	CYP11A1	Steroid synthesis
CYP11B	CYP11B1, 11B2	Steroid synthesis
CYP17A	CYP17A1	Steroid synthesis
CYP19A	CYP19A1	Steroid synthesis
CYP20A	CYP20A1	Unknown
CYP21A	CYP21A2	Steroid synthesis
CYP24A	CYP24A1	Vitamin D metabolism
CYP26	CYP26A1	Retinoic acid metabolism
CYP26B	CYP26B1	Retinoic acid metabolism
CYP26C	CYP26C1	Vitamin D metabolism, retinoid acid metabolism
CYP27A	CYP27A1	Bile acid synthesis
CYP27B	CYP27B1	Vitamin D metabolism
CYP27C	CYP27C1	Unknown
CYP39A	CYP39A1	Bile acid metabolism
CYP46A	CYP46A1	Bile acid metabolism
CYP51A	CYP51A1	Bile acid metabolism, cholesterol biosynthesis

via aryl hydrocarbon receptor (AhR)-mediated mechanism. The chemicals that are known to induce CYP1A enzymes include AhR agonists such as 3-methylcholanthrene, TCDD, and other polyaromatic hydrocarbons. CYP1A2 catalyzes O-dealkylation, epoxidation, and N-hydroxylation reactions that are commonly associated with metabolic activation of many chemical carcinogens. Numerous chemicals are known to inhibit CYP1A2 including drugs such as acyclovir, ciprofloxacin, and Verapamil [2].

CYP2B Family

The CYP2B family is represented by CYP2B6 in the human liver, an isoform that is regulated by nuclear receptors CAR and PXR [11]. The inducers of CYP2B family members are agonists of CAR and PXR including phenobarbital, antitubercular drugs such as rifampicin, and herbal preparations such as St. John's wort. CYP2B6 catalyzes N-demethylation of substrates, which include various pharmacological compounds such as bupropion, propofol, ketamine, and tamoxifen. The inhibitors of CYP2B6 include pharmaceutical agents such as clopidogrel.

CYP2C Family

There are four isoforms from the CYP2C family expressed in the humans including CYP2C8, 2C9, 2C18, and 2C19 [12]. Together, these enzymes play a critical role in metabolism of endobiotics as well as xenobiotics. The CYP2C enzymes are regulated by CAR/PXR and the agonists of these nuclear receptors induce CYP2C enzymes. The substrates of CYP2C enzymes are varied and include paclitaxel, rosiglitazone (CYP2C8), various NSAIDs including diclofenac, ibuprofen, naproxen (CYP2C9), omeprazol and lansoprazol (CYP2C19). CYP2C8 is of particular importance as it can metabolize glucoronide conjugates of various drugs leading to significant toxicity. Some of the substrates of CYP2C enzymes including pioglitazone and rosiglitazone are also CYP2C inhibitors.

CYP2D6

CYP2D6 is involved in metabolism of a large number of pharmaceutical agents of various chemical structures and chemical classes. Therefore, CYP2D6 has a deep impact on human health in general and drug metabolism in specific [13]. Some of the substrates of CYP2D6 include dexamethorphan, codeine, chlorpromazine, imipramine, propanolol and tamoxifen [2]. CYP2D6 exhibits extensive genetic polymorphism in the human population and humans can be divided into four distinct groups depending upon their CYP2D6 levels including, poor metabolizers, intermediate metabolizers, extensive metabolizers, and ultra-rapid metabolizers. CYP2D6 polymorphism is associated with toxicity of many drugs including debrisoquine, codeine, and perhexiline.

CYP2E1

No other CYP450 isozyme has caught more attention of liver biologists than CYP2E1, which is involved in metabolic activation of a number of hepatotoxic chemicals including alcohol, acetaminophen, carbon tetrachloride, halothane, benzene, chloroform, trichloroethylene, and diethylnitrosamine [14]. CYP2E1 is expressed primarily by the centrilobular hepatocytes and converts its substrates into highly reactive metabolites causing extensive hepatic necrosis. Metabolic activation of acetaminophen, the active ingredient of Tylenol® and many other antipyretic-analgesic formulations, to a reactive metabolite *N*-acetylbenzoquinoneimine (NAPQI) is the mandatory initial step involved in acetaminophen hepatotoxicity and subsequent acute liver failure [4]. The inducers of CYP2E1 include chemicals such as alcohol, isoniazid, and physiological conditions such as diabetes. The inhibitors of CYP2E1 include diallyl sulfide and disulfiram. CYP2E1 has been studied extensively for its role in alcoholic liver disease, acetaminophen hepatotoxicity, as well as non-alcoholic steatohepatitis and remains at the center of research focused at liver injury.

CYP3A4 Family

The isozymes that belong to CYP3A family including CYP3A4, 3A5, 3A7, and 3A43 are the most abundant CYP450 enzymes in human liver [15, 16]. The substrates of CYP3A family of enzymes include a wide variety of chemicals, drugs and, herbal preparations. CYP3A4 is estimated to metabolize approximately 70% of all drugs and thus is critical for human health. CYP3A enzymes are regulated by the nuclear orphan receptor CAR and CAR agonists are potent inducers of CYP3A. A wide variety of chemicals inhibit CYP3A4 activity including verapamil, clotrimazole, and ketoconazole.

CYP4A11

This member of CYP4A family, which includes 12 isozymes in humans, is of particular interest to liver biologists as it is regulated by PPAR-α, especially in rodents [17]. PPAR-α agonists such as clofibrate are potent inducers of CYP4A11 and levels of CYP4A11 have been used as markers of PPAR-α activation. CYP4A enzymes are involved in metabolism of endobiotics including fatty acids and eicosanoids, and are involved in prostaglandin metabolism.

Regulation of DME Expression

The DMEs, especially CYP450 enzymes are inducible and their expression can be induced by a large number of CYP450-family specific inducers. In most cases (with the exception of CYP2E1), CYP450 inducers are ligands for nuclear receptors and induce their expression via nuclear receptor based mechanism [18]. The four nuclear receptors that play a major role in regulation of CYP450 are constitutive androstane receptor (CAR), pregnane X receptor (PXR), aromatic hydrocarbon receptor (AhR), and peroxisome proliferator activated receptor-alpha (PPAR-α). Apart from these classic nuclear receptors, NF-E2-related factor 2 (Nrf-2) is also involved in regulation of CYP450 enzymes in response to oxidative stress. Some nuclear receptors such as HNF4α are master regulators of hepatic differentiation and regulate expression of CAR and PXR, and thus, also regulate CYP450 enzymes.

AhR regulates CYP1A1, 1A2, 1B1, and 2S1 expression. AhR functions in conjunction with aryl hydrocarbon receptor nuclear transporter (ARNT). CAR and PXR regulate a large number of CYP isoforms from CYP2A, 2B, 2C, and 3A families and PPAR-α regulates members of CYP4A family. CAR, PXR, and PPAR-α all require retinoid X receptor (RXR) as a binding partner for their function.

CYP2E1 is a unique enzyme not regulated by the commonly involved nuclear factors. However, substantial evidence indicates that CYP2E1 levels are negatively regulated by insulin. Similarly, recent data obtained from tissue specific knockout mice implicates β-catenin in stimulation of CYP2E1 expression.

Zone Specific Expression of CYP450

Metabolic zonation of hepatocytes is a hallmark of liver biology. It is known that the CYP450 expression is relatively higher in the centrilobular region (zone 3) of the liver lobule [19]. The zonal expression of DME is regulated by various factors including oxygen tension in the circulation, blood pressure and zonal expression of several transcription factors that regulate DME gene expression. Recent studies indicate that transcriptional coactivator β-catenin may be involved in zone specific expression of various CYP450 enzymes including CYP2E1 and CYP1A2 [20, 21]. Data from hepatocyte specific knockout mice indicates that β-catenin regulates the expression of CYP2E1 and 1A2 in the centrilobular hepatocytes. The zone specific expression of DME in the liver is the main reasons behind zone specific injury of many hepatotoxic chemicals such as acetaminophen (APAP). For example, in case of APAP, an overdose of APAP will result in specifically centrilobular (zone 3) necrosis because, CYP2E1, the main enzyme involved in metabolic conversion of APAP into NAPQI is expressed mainly by the centrilobular hepatocytes.

Flavin Monooxygenase

Apart from CYP450 enzyme, the other significant DMEs in the liver are the members of FMO family. FMO enzymes play important roles in detoxification function of the liver and are involved in the metabolism of a large variety of nitrogen, phosphorous, and sulfur containing chemicals [2, 22]. There are five FMO isoforms known designated as FMO1 to FMO5. FMO6 has also been identified, but it is a nonfunctional enzyme produced by mRNA from a pseudogene. The tertiary structure of FMO is not known and many aspects of FMO biology remain undiscovered partly due to their heat labile property (FMO can be destroyed at 50°C for 1 min) and lack of specific chemical inducers and inhibitors.

FMO uses FAD as an electron donor and is involved in metabolizing nucleophilic targets including tertiary and secondary amines, thiols, thioethers, thiocarbamates, and phosphines. It has been postualted that in vivo, the FMO enzymes bind a peroxyflavin moiety produced from binding of $FADH_2$ to oxygen (Fig. 11.1b). In the initial step, NADPH reduces FAD to produce $FADH_2$. The resultant free $NADP^+$ remains bound to the FMO enzyme. When a substrate (X) binds to FMO, it is oxidized (XO) followed by the removal of $NADP^+$ from the FMO enzyme complex to return FAD to its oxidized state.

The substrates of FMO are varied and include pharmaceutical agents such as cimetidine, and chemicals such as nicotine, 2-acetylaminofluorene, hydrazines, thiols and thioamides such as thioacetamide, and thiobenzamide, and phosphines such as diphenymethylphosphine [22].

DMES Involved in Conjugation Reactions

The conjugation reactions, which were previously grouped as Phase II drug metabolism reactions, form an important part of the detoxification function of the liver. The conjugation reactions involved in drug metabolism include glucuronidation, sulfation (or sulfonation), acetylation, methylation, amino acid conjugation, and glutathione conjugation (Table 11.2). With a few important exceptions, the conjugation reactions convert the substrates into a more water-soluble and less toxic product [2]. The conjugation enzymes catalyze reactions where various molecules such as glucose, glucuronic acid, amino acids, and glutathione are conjugated

Table 11.2 Overview of conjugation reaction involved in the liver

Type of conjugation reaction	Conjugating enzyme	Cofactor	Number of human isoforms
Glucuronidation	UDP glucoronosyl transferase (UGT)	UDP-glucuronic acid UDP-glucose UDP-xylose UDP-galactose	22 Isoforms classified into 8 families
Sulfation	Sulfotransferase (SULT)	3′-Phosphoadenosine-5′-phsphosulfate	13 Total, 6 expressed in the liver
Glutathione conjugation	Glutathione transferase (GST)	Glutathione	17 Isoforms divided into 8 different classes
Acetylation	*N*-acetyl transferase (NAT)	Acetyl Co-A	2 Distinct isoforms with several genetic polymorphisms
Methylation	Methyl transferase	*S*-adenosyl methionine	10 Distinct enzymes classified according to substrates used
Amino acid conjugation	ATP dependent acid:CoA ligase and Acyl:CoA amino acid *N*-acyltransferase	Glycine, glutamine, taurine, serine and proline	2 Known enzymes but more enzymes have been postulated

with the substrate to give rise to more hydrophilic products. The conjugation reactions are classified into two types of reactions. Glucuronidation, sulfation, acetylation, and methylation involve conjugation of substrates with an activated or "high energy" cofactor. Amino acid conjugation and glutathione conjugation involves conjugation of an activated and highly reactive xenobiotic intermediate to either amino acids, or glutathione.

Glucuronidation

Except animals from the cat family, glucuronidation is the prominent conjugation reaction observed in mammals. Glucuronidation is catalyzed by enzymes called UDP-glucuronosyltransferases (UGTs), which use several forms of modified sugar molecules as cofactors and conjugate a wide variety of pharmaceutical agents, chemicals, and endogenous substrates [23]. Whereas UDP-glucuronic acid is the most common cofactor used by UGTs, other cofactors including UDP-glucose, UDP-xylose, and UDP-galactose are also used. UGTs are expressed in a number of tissues but the levels of UGTs are highest in the liver smooth endoplasmic reticulum.

In humans, a total of 22 UGT isoforms are known and majority of them are expressed in the liver. The human UGTs are classified into four families including UGT1, UGT2, UGT3, and UGT8. Out of these, UGT1 and UGT2 are the best-characterized enzymes and pertinent to the detoxification function of the liver. UGT1A family of UGTs is transcribed from a single UGT1A gene locus. Due to alternative exon usage and splicing, 13 different transcripts are produced from UGT1A gene locus (UGT1A1 – UGT1A13) but only nine functional enzymes can be identified in vivo (UGT1A2, 1A11, 1A12, and 1A13 are pseudogenes). Ten different UGT2 enzymes, which belong to UGT2A and UGT2B subfamilies, are known. Studies have shown that out of all the UGTs expressed in the liver UGT1A1, 1A3, 1A4, 1A6, 1A9, 2B7, and 2B15 are the most important for the drug metabolism function of the liver.

The substrates of glucuronidation reaction are varied and include a large number of drugs, chemical and endobiotic. These include commonly used antipyretics such as acetaminophen and ibuprofen, other drugs such as naproxane, diclofenac, propofol, oxazepam, zedovudin etc. The endogenous compounds conjugated by UGTs include mainly include bilirubin, thyroid hormones, and steroids including 17-β-estradiol and testosterone. Because UGTs are involved in conjugation of endobiotics such as bilirubin, they play a critical role in liver and physiological homeostasis and genetic polymorphism in some UGTs such as UGT1A1 are associated with Crigler–Najjar syndrome and Gilberts syndrome. A large number of genetic polymorphisms have been identified in various UGT isoforms including in UGT1A1 and several UGT2B family members including UGT2B4, 2B7, 2B15 and 2B28.

There is substantial evidence that UGT expression is regulated by nuclear receptors. In fact, in the rat, UGTs can be categorized into four groups depending upon their time of expression and type of inducers. Group 1 UGTs are expressed embryonically and are induced by AhR-agonists such as 3-methylcholantherene. Group 2 UGTs are expressed perinatally (day 5 after birth) and are induced by CAR agonists such as phenobarbital. Group 3 and 4 UGTs are expressed around puberty and are regulated by PXR agonists such as PCN, and PPAR-α agonists such as clofibrate, respectively.

Sulfation

Sulfation or sulfonation is a conjugation reaction catalyzed by enzymes called sulfotransferases (SULTs) [2]. Sulfation involves conjugation of the substrates with sulfonate moiety donated by a cofactor called 3′-phosphoadenoside-5′-phosphosulfate (PAPS) [24]. Many substrates that undergo glucuronidation also undergo sulfation. However, sulfation is a high-affinity low-capacity process mainly because of the relatively lower concentration of PAPS (4–80 μM as compared to 200–350 μM of UDP-glucuronic acid). Whereas many organs including kidneys, lungs and intestine express SULTs, these enzymes are primarily present in the liver.

There are two types of SULT enzymes known depending upon their cellular location and function. The membrane-bound SULTs are present in the Golgi apparatus, are involved in sulfation of endobiotics such as cholecystokinin and play minimal role in detoxification of xenobiotics. The soluble SULTs present in cytosol are critical for xenobiotic metabolism and conjugate a large variety of substrates to produce hydrophilic sulfuric acid esters excreted in the urine. In humans 11 distinct genes encode for 13 distinct SULT isoforms that have been classified into SULT1, SULT2, and SULT4 gene families. Out of the 13 known SULTs, six are expressed in the liver. Studies have shown that both rodent and human SULTs can be regulated by nuclear receptors such as CAR and PXR. In humans, compelling evidence suggests that agonists of PXR including rifampin are potent inducers of SULTs and such drug-mediated induction of SULT is of critical clinical importance as it can change the bioavailability and elimination of many pharmaceutical agents.

The SULTs can conjugate a variety of endobiotics and xenobiotics including dopamine, 17-β-estradiol, tamoxifen, 2-acetylaminofluorene, and acetaminophen.

Glutathione Conjugation

One of the most important conjugation reactions pertaining to detoxification function of the liver is the glutathione conjugation because it is directly involved in conjugating a number of hepatotoxic chemicals and serves as a defense mechanism against oxidative stress [25]. Glutathione (GSH) is a tripeptide made of three amino acids including glycine, cysteine and glutamic acid. GSH conjugation is catalyzed by an enzyme called glutathione transferase (GST) expressed in all tissues, but is in especially higher quantities in the liver. GSTs can be found in the cytosol, mitochondria, endoplasmic reticulum, peroxisomes, and nucleus and are also involved in cellular functions distinct from drug metabolism.

Whereas the substrates of GSH conjugation are structurally varied, they all have three common chemical properties. These include presence of an electrophilic atom, ability to react with GSH in nonenzymatic fashion up to certain extent, and relatively high hydrophobicity. Depending upon the chemistry, GSH conjugation reactions are classified into "displacement" reaction where GSH displaces the electron-withdrawing group of the substrate, and "addition" reaction where GSH is added to an activated double bond or ring structure in the substrate. GSH conjugation subsequently results in mercapturic acid synthesis via a multistep process. The first step is catalyzed by GST, and results in the formation of GSH conjugate followed by formation of cysteinyl-glycine conjugate catalyzed by γ-glutamyltranspeptidase. The cysteinyl-glycine conjugate is converted to premercapturic acid by cysteinyl glycine dipeptidase. In the last step, premercapturic acid is converted to mercapturic acid by acetylation catalyzed by *N*-acetyltransferase.

GSTs are dimeric proteins formed from two similar or different subunits [23]. The cytosolic GSTs are divided in to seven classes designated as alpha (GST A), mu (GST M), pi (GST P), sigma (GST S), theta (GST T), zeta (GST Z) and omega (GST O). Each family of GSTs has several isoforms and they are designed depending upon the dimers, which form the active enzyme (for e.g., GSTA1-1, GSTA2-2 etc.). Apart from the cytosolic GSTs, a distinct form of mitochondrial GST, which seems to have evolved separately, is classified as the kappa class (GST K).

Because it is one of the primary cellular defenses in the cell against oxidative stress, GSH conjugation plays a critical role in cellular homeostasis. Depletion of GSH or inhibition of GSTs is associated with acute hepatotoxicity of many compounds including acetaminophen and also with chemical-induced tumorigenesis including chemicals like aflatoxin B1. GSH conjugation plays a critical role in pathogenesis of acetaminophen-induced acute liver failure because GSH conjugation of NAPQI, the reactive metabolite of acetaminophen, is the primary cellular defense mechanism against acetaminophen overdose. The current therapeutic use of *N*-acetyl cysteine (NAC) to treat acute liver failure is based on the evidence that NAC provides essential cysteine moieties necessary for biosynthesis and replenishment of GSH.

Acetylation

Many chemicals especially those containing aromatic amine or hydrazine groups are substrates for N-acetylation [26], a conjugation reaction catalyzed by a cytosolic enzyme called *N*-acetyl transferase (NAT). The cofactor used for acetylation reaction is acetyl Co-A, which is conjugated to the substrates by NATs via a two-step mechanism dubbed as "Ping Pong Bi Bi" mechanism.

In humans, two, highly polymorphic genes produce two, distinct isoforms of NATs designated as NAT1 and NAT2. Depending on genetic polymorphism humans can be distributed into "slow acetylators" (mainly in Middle-Eastern populations), and "fast acetylators" (mainly Asian populations).

The substrates that undergo N-acetylation generally first undergo CYP450-mediated metabolism. The substrates include metabolites of caffeine, nitrozepam, and isoniazid.

Methylation

Methylation, a relatively minor, but unique form of conjugation reaction, results in decreased water solubility of the substrates. Methylation is catalyzed by a large group of enzymes called methyl transferases using a cofactor called *S*-adenosylmethionine (SAM or SAMe) [2]. Depending on the heteroatom of the substrate involved, methylation reactions are categorized into O-, N-, and S-methylation. Methylation is much more important and common with endobiotic substrates than xenobiotic substrates and plays a critical role in cellular homeostasis. The classic example of methyl transferase enzyme is catechol-*O*-methyl transferase (COMT), an enzyme present in both cytosol and endoplasmic reticulum. The substrates of COMT include neurotrasmitters such as dopamine, epinephrine, and norepinephrine, and various catechol drugs such as L-dopa. Other examples of methyl transferase enzymes include histamine *N*-methyl transferase (HNMT), phenylethanolamine *N*-methyl transferase (PNMT), thiopurine methyl transferase (TPMT), and thiol methyl transferase (TPT).

Amino Acid Conjugation

Amino acid conjugation reactions can be divided into two groups depending upon the chemistry of the substrate and the amino acids used in conjugation [2]. The conjugation reactions in the first group involve xenobiotics containing carboxylic acid groups and are conjugated with amino acids such as glycine, glutamine, and taurine. In the second group, xenobiotics containing a hydroxylamine group are conjugated with amino acids such as serine and proline. Amino acid conjugation is of immense importance in bile acid biology where bile acids are conjugated with glycine and taurine, increasing their ability to be secreted in the bile. It also plays a critical role in the metabolism of NSAIDs such as ibuprofen.

Several enzymes are involved in amino acid conjugation, and it has been postulated that a separate enzyme specific to each amino acid catalyzes their conjugation. In general, amino acid conjugation is a two step process where the initial step is formation of an acyl Co-A thioester and is catalyzed by an enzyme called ATP dependent acid:CoA ligase. The second step involves transferring the acyl moiety of the xenobiotic to the amino group of the accepting amino acid and is catalyzed by an enzyme called acyl:CoA amino acid *N*-acyltransferase.

Role of Transporters as a Detoxification System in the Liver

Unbound compounds in the sinusoidal blood are taken up by the hepatocytes typically by a transporter-mediated mechanism or by diffusion across the basolateral membrane. Further, Phase II conjugates formed inside the hepatocytes are typically too hydrophilic to passively diffuse across the canalicular membrane into bile or across the hepatic basolateral membrane into the sinusoidal blood. Therefore carrier-mediated transport is required to cross this diffusional barrier. Thus, the extent of drug movement across the hepatocyte membranes is generally affected by the membrane transporters, which have a significant role in facilitating or preventing drug movement. Although, numerous transport proteins are present on the hepatic sinusoidal and canalicular membrane, only a few of these play a major role in the hepatic sinusoidal uptake as well as biliary and basolateral excretion. Therefore, this chapter will focus on reported interactions between the major detoxification transport proteins (Fig. 11.2). Other transport proteins, which play a minor role in hepatic excretion of Phase II metabolites, will be mentioned only briefly.

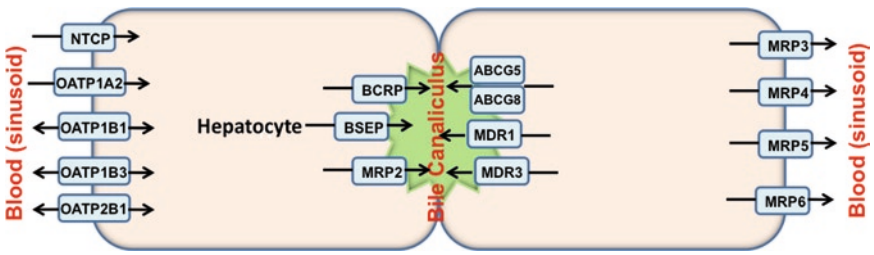

Fig. 11.2 Expression and localization of detoxification transporters in the liver. See text for details

Basolateral (Sinusoidal) Excretion

Excretion of drugs and/or metabolites from the hepatocyte across the basolateral membrane is primarily mediated by members of the ATP-driven multidrug-related protein (MRP) family. In the liver, ABCC3 (MRP3), ABCC4 (MRP4), ABCC5 (MRP5), and ABCC6 (MRP6) reside on the basolateral membrane and pump organic anions and bile acids from the hepatocyte into sinusoidal blood [27]. Of these four hepatic basolateral efflux transporters, only MRP3 and MRP4 appear to play a major role in the basolateral excretion of sulfate, glucuronide, and glutathione metabolites.

ABCC3 (MRP3)

MRP3 is a 1,527 amino acid protein that localizes to the basolateral membrane of hepatocytes [28–31]. MRP3 is a typical organic anion transporter able to transport organic compounds and bile acids into sinusoidal blood. MRP3 is responsible for the transport of conjugated (sulfate, or glucuronate) bile acids including bilirubin-glucuronides [28, 32–37]. Although MRP3 can efficiently transport sulfated bile acids, transport of sulfated xenobiotics and steroids appear to be weak. Transport of glutathione-conjugated xenobiotics (such as dinitrophenyl-*S*-glutathione and acetaminophen glutathione) by MRP3 appears to be controversial [38]. A list of substrates for human MRP3 is presented in Table 11.3.

MRP3 in the liver is highly inducible and is upregulated during cholestasis and in the absence of functional MRP2, as seen in patients with Dubin–Johnson syndrome (DJS) [39]. This is thought to be a compensatory response to enhance excretion of potentially toxic anions into sinusoidal blood for clearance. Further, MRP3 expression has been shown to be regulated by nuclear receptors (RXRα, PXR, PPARα, and Nrf2) [40, 41].

ABCC4 (MRP4)

MRP4 encodes a 1,325 amino acid protein [42]. In the liver, MRP4 localizes to the basolateral membrane of the hepatocytes [42, 43]. MRP4 has high affinity to the sulfated bile

Table 11.3 Human MRP substrates

Human MRP2 substrates		
Sulfate conjugates	*Glucuronide conjugates*	*Glutathione conjugates*
Benzo[a]pyrene-1 [121]	Acetaminophen [122]	Hydroxynonenal [123]

Estradiol-3,17-di [45]		Dinitrophenol-mercapturate [139]

acids and steroids [44, 45]. Although, glucuronide metabolites can interact with MRP4, they appear to have a low affinity. MRP4 can transport and be inhibited by glutathione conjugates, and thus might play a role in hepatic basolateral efflux of the glutathione conjugates [43, 46]. A class of endogenous substrates of MRP4 that is structurally related to the bile salts is represented by the conjugated steroids such as E2-17-β glucuronide and dehydroepiandrosterone-3 sulfate (DHEAS), prostaglandin E1, and prostaglandin E2, and other prostanoids [45, 47]. A list of MRP4 substrates is presented in Table 11.3.

Although MRP4 protein levels are relatively low in the liver, they increase under hepatic stress. MRP4 expression is induced with reduced levels of the major canalicular bile salt pump, BSEP and also in the absence of functional MRP2 [44, 45, 48]. Similar increase in MRP4 expression is seen during obstructive jaundice [49, 50]. As with MRP3, this increase appears to be a compensatory response to enhance detoxification of potential toxins into the sinusoidal blood for clearance. MRP4 expression has been shown to be induced by nuclear receptors (CAR and PPARα) [44, 51].

ABCC5 (MRP5) and ABCC6 (MRP6)

MRP5 encodes a 1,437 amino acid protein with an estimated molecular weight of 160 kDa that is expressed at low levels in healthy liver, but is upregulated under cholestatic conditions, suggesting that MRP5 protein levels may be increased as a part of hepatic response to cholestatic conditions [52]. MRP5 has similar substrate specificity as MRP4, including glutathione conjugates, and could play a role in the hepatic basolateral excretion of anionic conjugates [30, 53].

MRP6 gene encodes for a 1,503 amino acid protein with a molecular weight of 165 kDa. MRP6 has been shown to localize to the basolateral/lateral surface of hepatocytes [54, 55]. It transports glutathione conjugates [55, 56]. Relatively little is known about the contribution of MRP5 and MRP6 to the hepatic basolateral excretion of conjugated organic anions, and further studies are needed to evaluate their potential contribution.

Canalicular (Biliary) Excretion

ABCB1 (MDR1 or *P*-Glycoprotein or Pgp)

The multidrug resistance protein 1 (MDR1) is probably the most studied ATP binding cassette transporter due to its notorious role in limiting the oral bioavailability of bulky lipophilic and organic cations [57, 58]. MDR1 is highly expressed at the canalicular membrane of the hepatocytes. As an export transporter capable of efflux against concentration gradient, the predicted function for MDR1 is the extrusion of its substrates from the hepatocyte into the bile. MDR1 transports an extremely wide variety of chemically and structurally diverse compounds including a large number of cytotoxic drugs and their metabolites. MDR1 substrates are usually organic molecules ranging in size from about 200 Da to over 1,000 Da. The list of substrates and inhibitors for MDR1 is growing and the reader is directed to the various reviews for further information [59–64].

In the liver, Pgp contributes to the first-pass elimination of drugs after oral administration, and/or forms an essential pathway for drug biliary excretion after parenteral administration [59]. Nevertheless, the hepatic expression and function of this transporter are highly interindividually and intraindividually variable, which can produce unpredictable changes in drug plasma concentrations and therapeutic effects.

ABCB4/MDR3

ABCB4 codes for a 140 kDa membrane protein that is localized to the canalicular membrane of hepatocytes. MDR3 functions as a flippase, capable of flipping phosphatidyl choline molecules from the inner leaflet of a bilayer to the outer leaflet [65]. ABCB4 appears to play very little role in the direct transport of Phase II conjugates.

Defect in ABCB4 function causes the production of bile with low phospholipid content, increased lithogenicity and high detergent properties leading to cholestasis, referred to as progressive intrahepatic cholestasis type 3 (PFIC III) [66, 67].

ABCB11 (BSEP)

BSEP is a 1,321 amino acid glycol-protein with an apparent molecular mass of 160 kDa [68]. BSEP is expressed at the canalicular plasma membrane of hepatocytes and is responsible for the biliary excretion of unconjugated and conjugated bile acids [68, 69]. While BSEP has not been shown to transport Phase II conjugated drugs, several xenobiotics are known to inhibit BSEP function leading to drug-induced cholestasis and hepatotoxicity [70–72].

Absence of BSEP or nonfunctional mutations in the BSEP gene leads to severe forms of intrahepatic cholestasis [68, 73, 74]. Clinically, cyclosporine A as well as glibenclamide, rifampicin, and rifamycin are competitive inhibitors of BSEP [70, 72, 75, 76]. Other drugs that have been shown to inhibit

BSEP are bosentan, troglitazone, and fluvastatin [70]. Such drugs may precipitate cholestasis in susceptible population, which rapidly resolves after the withdrawal of the drug. Progesterone-sulfate, a key metabolite that increases during pregnancy can result in BSEP dependent cholestasis [76].

BSEP mRNA levels are reduced in individuals with poor drainage as compared to controls (in patients undergoing biliary drainage) [77]. Similarly, in primary biliary cirrhosis, BSEP expression is reduced [68, 78]. In experimental septic models, BSEP mRNA and protein levels were reduced, suggesting that sepsis in patients with gram-negative infections may be associated with BSEP mediated cholestasis [79]. Ursodeoxycholic acid, which is frequently used to treat cholestatic liver disease, was recently demonstrated to stimulate BSEP expression. BSEP expression is also regulated by nuclear receptors; AhR and PXR down regulate BSEP expression while CAR and FXR upregulate BSEP expression [80].

ABCC2 (MRP2)

Human MRP2 is a 190 kDa transmembrane glycoprotein (1,545 amino acid residues) and localizes to the bile canalicular membrane of hepatocytes [81, 82]. MRP2 transports glucuronide, sulfated and glutathione conjugates of both endobiotics and xenobiotics [27, 82–87]. A detailed list of well characterized MRP2 substrates is presented in Table 11.3.

Loss of function mutations in MRP2 is the cause of DJS in humans, a condition which is characterized by conjugated hyperbilirubinemia [88, 89]. This syndrome is an autosomal, recessively inherited disorder characterized by increased concentrations of bilirubin glucuronosides in blood (hyperbilirubinemia) and deposition of a dark pigment in hepatocytes [90, 91]. Many sequence variants in the MRP2 gene have been identified in the human population, but only some of them cause DJS. Among these are sequence variants that result in the absence of a functionally active MRP2 protein. It should be noted, however, that this loss of MRP2 function is usually well tolerated and compensated by the upregulation of other membrane transporters.

In MRP2-deficient rats, the bile flow rate is reduced approximately 50% to that of normal rats, due to the complete absence of bile acid independent bile flow [77]. Accordingly, it is possible that inhibition of MRP2 function results in reduced bile flow rate, which might be clinically significant in diseases such as sclerosing cholangitis, hepatitis C infection, and cholestasis, where MRP2 expression has been demonstrated to be reduced [92].

MRP2 is also expressed in hepatocellular carcinoma. Although the significance of this overexpression is not clear, based on cell culture models, this has been attributed to the acquisition of drug resistance against antitumor drugs [93].

The mechanism of induction of MRP2 has been studied in vitro in cell culture models using cultured human, mouse and rat hepatocytes and in vivo in animal models. In these studies, MRP2 was shown to be regulated by cytokines (IL-1β, TNF-α, and IL-6) and nuclear receptors (AhR, CAR, PXR and FXR) [40, 51, 79, 94]. These results suggest that SNPs in the promoter/enhancer region of MRP2 should also be taken into consideration in accounting for inter-individual differences in MRP2 inter-individual expression levels.

ABCG2/BCRP

BCRP is a 75 kDa protein that localizes to the canalicular membrane of hepatocytes [95]. BCRP transports a wide variety of chemically and structurally diverse compounds including a large number of cytotoxic drugs and their metabolites (Table 11.4). At the canalicular membrane, BCRP is capable of transporting sulfated conjugates of steroids and xenobiotics [95]. The importance of BCRP in biliary excretion is exemplified by the fact that in MRP2 loss of function phenotypes, BCRP inhibitors can significantly alter the biliary excretion of sulfated conjugates [95–99].

The normal function of BCRP is probably to prevent the accumulation of both intracellular and extracellular toxins in cells. Overexpression of this transporter in carcinomas gives rise to the phenomenon of multidrug resistance.

Multiple SNPs have been identified in BCRP, which result in the loss of function phenotypes. Although the role of this

Table 11.4 Human BCRP substrates

Sulfate conjugates	Glucuronide conjugates	Glutathione conjugates
Aminomethylphenylimidazopy-ridine [144]	Estradiol-17β [98, 128, 145]	Leukotriene C4 [98]
Estrone [145, 146]	Estrone-3 [145]	Dinitrophenol [98]
Estradiol [98, 145]	Estradiol-3 [145]	
Dehydroeipandrosterone [98, 145]	4-Methylumbelliferone [98]	
Taurolithocholate [98]	SN-38 [97, 147]	
4-Methylumbelliferone [98]	Aminomethylphenylimidazopyridine [144]	
p-Nitrophenol [98]		

loss of function mutants has been well characterized in multidrug resistance, little has been done with reference to their role in biliary excretion of endogenous conjugates.

ABCG5 and ABCG8

ABCG5 and ABCG8 encode for proteins of 75 and 62 kDa molecular weights, respectively. These proteins function as a single unit [100], as they dimerize to function in transport [100, 101]. They are localized to the canalicular membrane of the liver, and are involved in the transport of cholesterol and other sterols from the liver into bile [101]. Cholesterol and nuclear receptors such as LXR have a significant effect on the regulation of these transporters while deoxycholic acid represses their expression [102, 103]. Mutation in both these genes leads to a disorder characterized by defective transport of plant and fish sterols, and cholesterol (sitosterolemia) [104].

Drug Uptake Transporters in Detoxification

Although drug uptake transporters such as OATs and OATPs can mediate transport across the basolateral membrane into sinusoidal blood, because of their bidirectional nature and their dependence on ion exchange as the driving force for transport, they most likely function as uptake transporters under physiological conditions.

Most of these uptake transporters belong to the solute carrier family (SLC), which currently includes 43 families and 298 transporter genes. Among the SLC family members, only the major liver detoxification related members will be discussed in this chapter. A detailed description of transporters of other organs is beyond the scope of this chapter.

SLC10A1; Na+/Taurocholate Co-Transporting Polypeptide

The human NTCP is a 349-amino acid polytopic membrane glycoprotein with an apparent molecular mass of approximately 56 kDa [105]. NTCP is expressed at the basolateral (sinusoidal) plasma membrane of human hepatocytes, and transports conjugated (taurocholate and taurochenodeoxycholate) and unconjugated bile salts from the portal blood into the hepatocytes [105]. Thus NTCP promotes efficient extraction of bile salts from portal blood to keep plasma concentrations at a minimum and plays an important role in enterohepatic circulation. The driving force for NTCP-mediated transport is provided by the inwardly directed Na^+ gradient maintained by the basolateral Na^+, K^+-ATPase, as well as the negative intracellular potential [105].

An inherited defect in NTCP has not yet been reported. However, NTCP mRNA and protein expression is decreased in various animal models of cholestasis and liver disease [106, 107]. In addition, recent studies have also shown similar decreased NTCP expression levels in percutaneous liver biopsies of patients with cholestatic liver disease [78].

Pharmacologically, NTCP is ideally suited to target drugs to the liver, because its expression is restricted to hepatocytes. Thus, any kind of liver-specific disease is a potential target for treatment with drugs that are conjugated to bile salts, but which, in an unconjugated form, do not home efficiently to the liver. The feasibility of such an approach has been shown for several compounds such as antisense oligonucleotides, amino acids and peptides as well as for cytostatic drugs, which keep their potency even after conjugation to bile salts [108, 109].

Among the nuclear receptors, AhR, CAR, and PXR all downregulate the expression of NTCP [80, 94].

Organic Anion Transporting Polypeptides (SLC21/SLCO/OATP)

The family of organic anion transporting polypeptides contains over 52 members that mediate the sodium independent transport of a wide range of amphipathic organic compounds including bile salts, organic dyes, steroid conjugates, thyroid hormones, anionic oligopeptides, numerous drugs, and other xenobiotic substances. Among the members of this family OATP1A2, OATP1B1, OATP1B3, and OATP2B1 are expressed in the liver and thus appear to play an important role in liver detoxification.

The human Organic anion transporting polypeptide 1A2 is a glycoprotein of 670 amino acids [110]. In the liver, OATP1A2 is expressed at the basolateral (sinusoidal) plasma membrane of human hepatocytes. OATP1A2 transports a wide range of amphipathic organic compounds including bile salts and BSP, steroid conjugates and thyroid hormones [111]. OATP1A2 mediated transport is Na+-independent and the driving force for transport appears to be coupled to cellular efflux of bicarbonate, glutathione, and/or glutathione conjugates [111].

The human OATP1B1 encodes a 691-amino acid glycoprotein with an apparent molecular mass of 84 kDa [111–113]. OATP1B1 expression appears to be restricted to the basolateral (sinusoidal) plasma membrane of hepatocytes and transports a spectrum of compounds including bile salts, conjugated and unconjugated bilirubin, BSP, steroid conjugates, and thyroid hormone [112–116]. Thus, OATP1B1 exhibits a similar wide-substrate spectra as the OATP1A-subfamily members. The apparent exclusive expression of OATP1B1 in human liver suggests that it plays a crucial role in the hepatic clearance of amphipathic organic compounds.

Transcriptional expression of OATP1B1 in primary sclerosing cholangitis patients is about 50% lower than the healthy control livers [92]. In addition, basal expression of human OATP1B1 is dependent on the liver-enriched transcription factor HNF-1α [117].

OATP1B3 encodes a glycoprotein of 702 amino acids with an apparent molecular mass of 120 kDa [118, 119]. OATP1B3 shares 80% amino acid identity to OATP1B1. Like OATP1B1, OATP1B3 is predominantly, if not exclusively, expressed at the basolateral plasma membrane of hepatocytes. The spectrum of transport substrates of OATP1B3 is similar to OATP1B1 and includes bile salts, monoglucuronosyl bilirubin, BSP, steroid conjugates, and thyroid hormone [111]. OATP1B3 has been shown to be expressed in various human cancer tissues as well as in different tumor cell lines derived from gastric, colon, pancreas, gallbladder, lung, and brain cancers [118]. The pathobiological significance of this expression remains to be investigated. Hepatic expression of OATP1B3 appears to depend on the nuclear transcription factors HNF-1α, as well as on the bile acid nuclear receptor FXR [117]. These findings indicate that induction of OATP1B3 gene expression by bile acids could serve to maintain hepatic extraction of xenobiotics and peptides under cholestatic conditions.

OATP2B1 is a 709 amino acid protein that localizes to the basolateral membrane of hepatocytes [120]. OATP2B1 substrates include BSP, estron-3-sulfate and dehydroepiandrosterone sulfate [111, 112, 114]. At low pH, OTAB2B1 is also known to transport taurocholate, fexofenadine, statins, glibenclamide, and the loop diuretic M17055 [111].

Conclusion

Detoxification function of the liver is highly complex involving hundreds of different enzymes with unique substrate specificity, regulation, and activity. The drug metabolism function of the liver is also extremely intertwined with metabolism of endobiotics, which provides insights into evolutionary mechanisms involved in fine-tuning the detoxification functions of the liver.

Chapter 12
Bile Acid Metabolism

John Y.L. Chiang

Introduction

Bile acids are physiological agents that facilitate biliary secretion of lipids and metabolites, and intestinal absorption of fat and nutrients. Bile acids are also signaling molecules that activate nuclear receptors and cell signaling pathways to regulate hepatic lipid metabolism and homeostasis. Bile acids are synthesized from cholesterol in the liver, stored in the gallbladder, secreted to the intestine and reabsorbed in the ileum, and transported back to the liver. This physiological process of enterohepatic circulation of bile acids is regulated by a complex network of membrane transport systems in the hepatocytes, cholangiocytes, and enterocytes. Bile acid-activated nuclear receptors, farnesoid X receptor (FXR), pregnane X receptor (PXR), and vitamin D receptor (VDR), play critical roles in regulation of key regulatory genes involved in bile acid metabolism in the liver and intestine. The bile acid receptors also regulate lipid, glucose, drugs, and energy metabolism. Inborn errors of bile acid synthesis cause neonatal liver diseases. Disruption of bile flow causes cholestatic liver diseases. Bile acids are therapeutic agents that have great potential for treating cholestasis, gallstone, fatty liver, cardiovascular diseases, obesity, and diabetes in humans.

Bile acids are the end products of cholesterol catabolism [1–3]. Please see Chap. 10 for an independent discussion on fat metabolism in the liver. Conversion of cholesterol to bile acids accounts for daily turnover of more than 90% cholesterol. Bile acid synthesis generates bile flow and provides the driving force for biliary excretion of bile acids, phospholipids, cholesterol, and other metabolites. Cholic acid (CA) and chenodeoxycholic acid (CDCA) are the major primary bile acids synthesized in human livers. These bile acids are conjugated with taurine and glycine, and secreted into bile. Highly complex and sophisticated membrane transport systems located in the polarized membranes of hepatocytes and enterocytes, control the rate of bile acid synthesis and absorption, distribution of nutrients, and disposal of toxic metabolites and xenobiotics [4].

Recent discovery of bile acid-activated receptors has revealed the molecular mechanisms of bile acid feedback regulation and metabolic control in the enterohepatic system (review in [5–7]). Bile acids are endocrine hormones that activate FXR to regulate bile acids, lipoprotein, and triglyceride metabolisms [8–10]. Recent studies have also uncovered an important role for FXR in regulation of glucose and energy metabolism [9, 10]. Bile acids also have nongenomic function of activating cell-signaling pathways in the liver and other tissues [11–13]. These cell-signaling pathways crosstalk with nuclear receptor signaling to regulate bile acid synthesis [11], lipid and glucose metabolism [12, 14], and apoptosis [15]. An important autocrine function of bile acids is activation of a G protein-coupled receptor TGR5 in brown adipose tissues to stimulate energy metabolism [9]. This chapter will cover bile acid metabolism, its regulation by nuclear receptor and cell signaling; the role of bile acids in regulation of lipid, glucose, and energy metabolism; the molecular pathology of the enterohepatic system; and bile acids as therapeutic agents for human liver diseases.

Bile Acid Metabolism

Bile Acid Structures

Bile acids (or bile salts) are derived from cholesterol. Figure 12.1 shows the structures of cholesterol and CA. Cholesterol is a C_{27}-sterol consisting of the steroid nucleus with four fused carbon rings; three six-carbon rings (A, B, and C) and a five carbon ring (D); and an eight-carbon side-chain (Fig. 12.1). The A ring has a 3β-hydroxyl group and the B ring has a double bond between carbon 5 and 6. The 8-carbon side chain is attached to the D ring. All "modern" bile acids have 24 carbon atoms. C_{27} bile alcohols and C_{27} bile acids exist in the lower vertebrates [16]. Conversion of cholesterol to bile

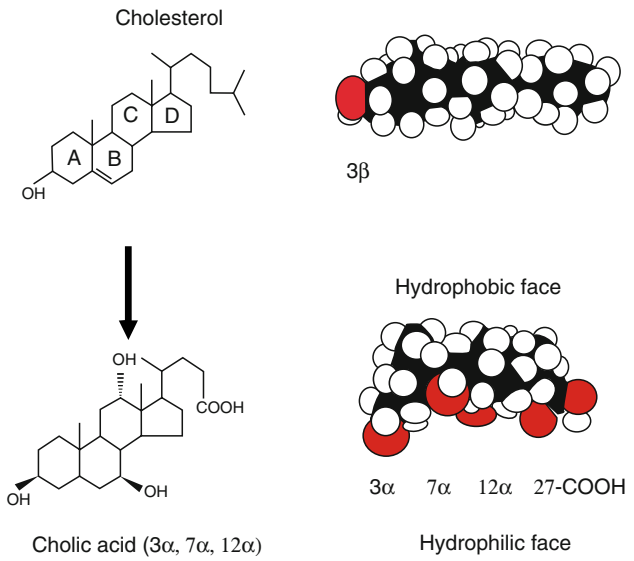

Fig. 12.1 Cholesterol and bile acid structure. The chemical structures of cholesterol and cholic acids are illustrated on the *left*, and the space filling models of cholesterol and cholic acid on the *right*. Oxygen atoms in hydroxyl groups are colored in *red*. The 5β-hydrogen is in a cis-configuration at the A/B junction, and introduces a kink in the planar steroid nucleus in cholesterol to a concaved bile acid structure that has all hydroxyl groups facing in one direction to form a highly hydrophilic face opposing the highly hydrophobic face consisting of carbon skeleton

acids involves hydroxylation reactions, saturation of the double bond, epimerization of the 3-hydroxyl group, and oxidative cleavage of a 3-carbon unit from the side chain. The 3-hydroxyl group in all bile acids has a α-configuration. Most bile acids have a 5β-hydrogen group and a kink along the A and B junction (cis-configuration) in the steroid nucleus (Fig. 12.1). All hydroxyl groups and the carboxyl group in bile acids are faced to one side of the molecule forming a hydrophilic face opposing the highly hydrophobic face consisting of the carbon skeleton. Thus bile acids are amphipathic molecules with detergent properties.

Bile Acid Synthesis in the Liver

An average 70 kg man synthesizes about 600–900 mg cholesterol per day and uptakes about 300–500 mg cholesterol from the diet [17]. This input of about 1–1.5 g cholesterol contributes to a total cholesterol pool of about 100 g. About 500–600 mg of cholesterol is converted to bile acids and another 600 mg of cholesterol is excreted into bile daily. Only about 85 mg cholesterol is incorporated into cell membranes and 50 mg cholesterol is converted to steroid hormones. A constant cholesterol pool is maintained by these input and output mechanisms. Thus bile acid synthesis is the predominant pathway for cholesterol catabolism and plays a critical role in maintaining cholesterol homeostasis in our body. The liver is the only organ that has all enzymes needed for the synthesis of bile acids. There are two major bile acid biosynthetic pathways [1]. The neutral bile acid pathway (or classic pathway) is initiated by cholesterol 7α-hydroxylase (CYP7A1), a cytochrome P450 enzyme located in the endoplasmic reticulum of the liver. The acidic pathway (or alternative pathway) is initiated by sterol 27-hydroxylase (CYP27A1), a cytochrome P450 enzyme located in the mitochondria of most tissues. The neutral pathway is the major pathway that synthesizes two primary bile acids, CA and CDCA in human livers (Fig. 12.2). The acidic pathway contributes up to 9% of total bile acid synthesis in human livers [18], but may be quantitatively important in liver diseases and the neonates. Cholesterol can be hydroxylated to form oxysterols in liver and other tissues. Three hydroxylases may be involved in oxysterol synthesis. In macrophages and other tissues and organs, mitochondrial CYP27A1 converts cholesterol to 27-hydroxycholesterol and 3β-hydroxy-5-cholestenoic acid. In the liver, a microsomal sterol 25-hydroxylase converts cholesterol to 25-hydroxycholesterol. In the brain, a specific microsomal sterol 24-hydroxylase (CYP46A1) converts cholesterol to 24-hydroxycholesterol, an abundant cerebral-sterol in the brain. A nonspecific oxysterol, 7α-hydroxylase (CYP7B1) then converts 27-hydroxycholesterol and 3β-hydroxy-5-cholestenoic acid to 3β, 7α-dihydroxy-5-cholestenoic acid, and 25-hydroxycholesterol to 5-cholesten-3β, 7α, 25-triol. A brain-specific sterol 7α-hydroxylase (CYP39A1) converts 24-hydroxycholesterol to 5-cholesten-3β, 7α, 24(S)-triol. These oxysterols may be transferred to the liver and converted to CDCA. It has been suggested that transfer of oxysterols from macrophages to the liver to convert to bile acids may be a reverse cholesterol transfer system to protect against atherosclerosis in humans.

The microsomal 3β-Δ^5-C_{27} steroid oxidoreductase (HSD3B7) then catalyzes isomerization of the Δ5, 6 double bond to Δ4, 5 double bond, and dehydrogenation of a 3α-hydroxyl group to a keto group, to form 7α-hydroxy-4-cholesten-3-one (C4), a common precursor for CA and CDCA. The serum C4 levels parallel the CYP7A1 activity in the liver and have been used as a marker for bile acid synthesis [19]. C4 undergoes isomerization and saturation by two reductases. First Δ^4-oxysteroid-5β reductase (aldos-keto reductase 1D1, AKR1D1) reduces the Δ^{4-5} double bond by insertion of a hydrogen at 5β-position, which change the trans- to cis-confirmation at the A/B junction of the steroid nucleus in C4. Then AKR1C4 (3α-hydroxyl steroid dehydrogenase) reduces the 3-keto group to a 3α-hydroxyl group to form 5β-cholestan-3α, 7α-diol. CYP27A1 then oxidizes the C27-carbon of the steroid side chain to a carboxyl group to form 3α, 7α-dihydroxy-5β-cholestanoic acid (DHCA), a precursor of CDCA. A microsomal cytochrome P450 enzyme, sterol 12α-hydroxylase (CYP8B1) hydroxylates C4

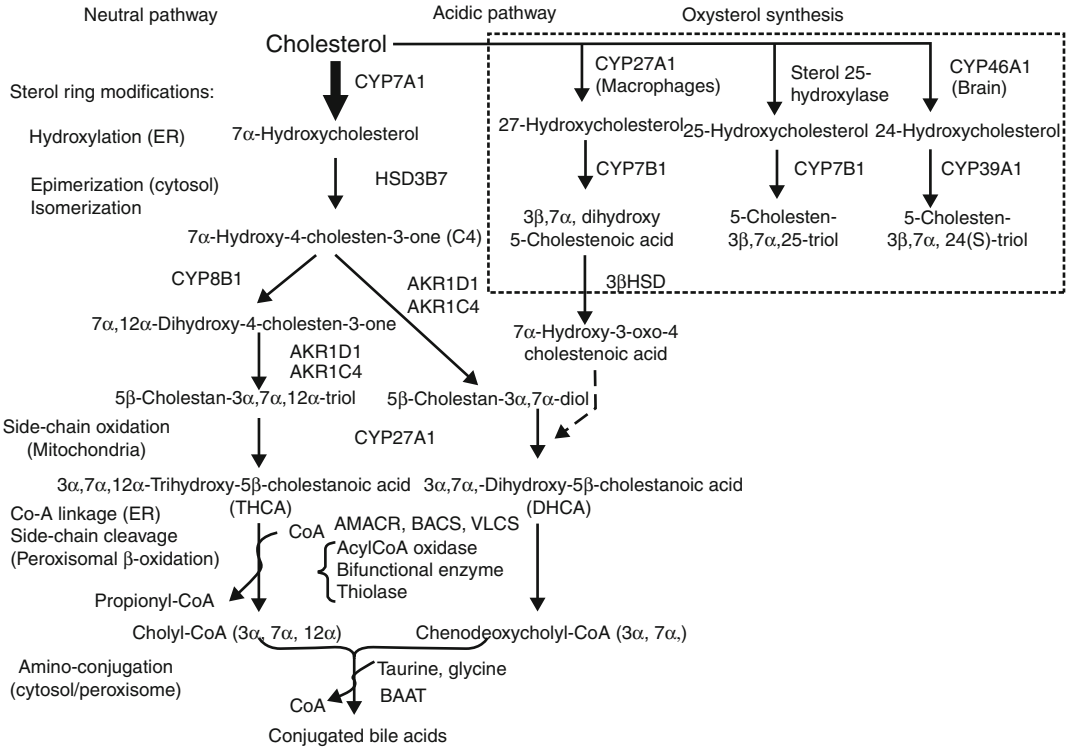

Fig. 12.2 Bile acid biosynthetic pathways. Two bile acid biosynthetic pathways are shown. The neutral (or classic) pathway is initiated by cholesterol 7α-hydroxylase (CYP7A1) located in the endoplasmic reticulum of the liver, whereas the acidic (or alternative) pathway is initiated by mitochondrial sterol 27-hydroxylase (CYP27A1). There are three hydroxylases that convert cholesterol to oxysterols. In macrophages and other tissues and organ, CYP27A converts cholesterol to 27-hydroxycholesterol. In the liver, microsomal sterol 25-hydroxylase converts cholesterol to 25-hydroxycholesterol. In the brain, sterol 24-hydroxylase (CYP24) converts cholesterol to 24-hydroxycholesterol. A non-specific oxysterol 7α-hydroxylase (CYP7B1), in most tissues hydroxylate 27 and 25-hydroxycholesterol, and a brain-specific oxysterol 7α-hydroxylase (CYP39A1) hydroxylate 24-hydroxycholesterol. These oxysterols could be converted to CDCA if transported to the liver. In the liver, sterol 12α-hydroxylase (CYP8B1) is involved in the synthesis of cholic acid (CA). 3β-hydoxysteroid dehydrogenase (3βHSD), aldos-keto reductase 1D1 (AKR1D1), and AKR1C1 catalyze isomerization and saturation of the steroid ring. Then CYP27A1 catalyzes steroid side-chain oxidation to form cholestanoic acids, THCA and DHCA. Bile acid-Co-A synthase (BACS) in ER, or very long-chain Co-A synthase (VLCS) in ER, or peroxisomes, ligate Coenzyme A to the carboxyl groups. Bile acid thioesters are transported into peroxisomes, where α-methylacyl-CoA racemase (AMACR) converts the methyl group from 25 (R) to 25(S) conformation, and three peroxisomal β-oxidation enzymes, branched-chain acyl-CoA oxidase, D-bifunctional enzyme, and thiolase (or sterol carrier protein x) catalyze oxidative cleavage of a propionyl group from the steroid side-chain to form cholyl-CoA and chenodeoxycholyl-CoA. Cytosolic or peroxisomal bile acid: amino-acid transferase (BAAT) catalyzes conjugation of amino acids, glycine or taurine to the carboxyl group of Cholyl-CoA and chenodeoxycholyl-CoA to form conjugated bile acids and release a propionyl-CoA

to 7α, 12α-dihydroxy-4-cholesten-3-one, leading to the synthesis of 3α, 7α, 12α-trihydroxy-5β-cholestanoic acid (THCA), a precursor of CA. A microsomal bile acid, Coenzyme-A synthase (BACS) or peroxisomal (or ER) very long-chain CoA synthase (VLCS) ligates a Co-A group to THCA and DHCA. These two CoA thioesters enter the peroxisomes, where a α-methylacyl-CoA racemase (AMACR) converts the methyl group from 25 (R) to 25(S) conformation, and three peroxisomal β-oxidation enzymes, branched-chain acyl-CoA oxidase, D-bifunctional enzyme, and thiolase (or sterol carrier protein x) catalyze oxidative cleavage of a propionyl group from the steroid side-chain to form cholyl-CoA and chenodeoxycholyl-CoA. Cytosolic or peroxisomal bile acid: Amino-acid transferase (BAAT) catalyzes conjugation of amino acids, glycine or taurine to the carboxyl group of Cholyl-CoA and chenodeoxycholyl-CoA to form conjugated bile acids, and release a propionyl-CoA.

Bile Acid Biotransformation

In humans, most bile acids are amino-conjugated at the carboxyl group (amidation) with the ratio of glycine- to taurine-conjugates of about 3:1. Conjugation of bile acids increases ionization and solubility at acidic pH, prevents Ca^{+} precipitation, minimizes passive absorption, and prevents cleavage by pancreatic enzymes in the intestine. Bile acids are sulfated at the 3α-position by sulfotransferase 2A1 (SULT2A1), amidated at the carboxyl group by BACS and

BAAT, and glucuronidated at 3α, 6- and/or 24-positions by UDP-glucuronosyl *N* -transferases, (UGT1A1, 2B4 and 2B7). In the intestine, conjugated-CA and CDCA are first deconjugated. Then, bacterial 7α-dehydroxylase converts CA and CDCA to deoxycholic acid (DCA) and lithocholic acid (LCA), respectively. DCA and LCA are the secondary bile acids (damaged bile acids) generated in the intestine. LCA is highly toxic. Small amounts (1%) of LCA circulated to the liver are rapidly conjugated by sulfation and amidation to form di-conjugated-LCA, which is rapidly excreted into bile. Sulfation is the major pathway for detoxification of hydrophobic bile acids in humans [20]. Mice, but not humans, are able to re-hydroxylate LCA at 7α-position to form CDCA, and hydroxylate at 6α-position to form hyodeoxycholic acid (HDCA, 3α, 6α). CDCA can be metabolized to other soluble bile acids in different species. CDCA is hydroxylated at 6-carbon position by Cyp3a11 to form hyocholic acid (3α, 6α, and 7α) in humans and pigs. CDCA also can be epimerized to UDCA (3α, 7β) in humans and bears. Cyp3a11 and epimerase converts CDCA to 6α- and 6β-muricholic acids (3α, 6α/β, 7β), the predominant hydrophilic bile acids in mice. Hydroxylation at the 6α/β or 7β-position renders bile acid highly soluble and nontoxic.

Enterohepatic Circulation of Bile Acids

Bile acids synthesized in the liver are immediately secreted into bile, reabsorbed in the intestine and transported back to the liver. The enterohepatic circulation of bile acids not only plays an important role in absorption and transport of nutrients and disposal of toxic metabolites and xenobiotics, but also serves as a feedback control of bile acid synthesis. Biliary secretion of bile acids generates bile flow to secrete conjugated-bilirubin and other metabolites. Small amounts of bile acids may spill over into sinusoidal blood, reabsorbed when passing through the renal tubules in the kidney, and are circulated back to the liver through systemic circulation. Some bile acids secreted in the bile duct are reabsorbed in the cholangiocytes (bile duct epithelial cells) and recycled back to hepatoytes (the cholangiohepatic shunt). Bile acids are stored in the gallbladder. After each meal, cholecystokinin secreted from the intestine stimulates gallbladder contraction to empty bile acids into the intestinal tract. When passing down the intestinal tract, small amounts of unconjugated bile acids are reabsorbed in the upper intestine by passive diffusion. Most bile acids (95%) are reabsorbed in the brush border membrane of the terminal ileum, trans-diffused across the enterocyte to the basolateral membrane, secreted into portal blood circulation to liver sinusoid, and taken up into hepatocytes. In the colon, DCA is reabsorbed and recycled with CA and CDCA to the liver. A bile acid pool of ~3 g consisting of ~ 40% CA, 40% CDCA, 20% DCA, and trace amount of LCA (1–4%), is recycled 4–12 times a day. Bile acids lost in the feces (~0.5 g/day) are replenished by *de novo* synthesis in the liver to maintain a constant bile acid pool. Interruption of the enterohepatic circulation of bile acids causes malnutrition and cholestatic liver diseases in humans.

Regulation of Bile Acid Metabolism

Bile acid synthesis is inhibited by bile acids returning to the liver via enterohepatic circulation by inhibiting CYP7A1, the first and the only rate-limiting enzyme of the classic pathway. Bile acids inhibit CYP7A1 gene transcription and mRNA stability [1]. Bile acids also inhibit CYP8B1, which determines the ratio of CA to CDCA, and thus the hydrophobicity index of bile acids in human bile. The promoters of CYP7A1 and CYP8B1 genes consist of several AGGTCA-like repeating sequences that are recognized by nuclear receptors [1, 6]. Nuclear receptors are ligand-activated transcription factors that play important roles in embryogenesis, development, and metabolic regulation. These highly conserved sequences confer bile acid inhibition, and are referred as the bile acid response elements (BARE) in the CYP7A1 and CYP8B1 gene promoters [11]. The mouse BARE-I sequence (-73 to -55) contains a direct repeat separated by four nucleotides (DR4), which binds a nuclear receptor liver X receptor (LXR) to induce *Cyp7a1* gene transcription [21]. Feeding a high cholesterol diet to wild type mice stimulates bile acid synthesis to excrete excess dietary cholesterol, but causes massive accumulation of cholesterol in the liver of *Lxr* knockout mice [22]. However, the DR4 sequence is altered in the human *CYP7A1* promoter and LXRα does not bind to the human *CYP7A1* gene [23]. Thus mice and rats are able to convert excess dietary cholesterol to bile acids, whereas humans cannot. The BARE-II (-149 to -118) has an 18-nucleotide sequence that is completely conserved in different species. The BARE-II contains a DR1 sequence, which binds an orphan nuclear receptor, hepatocyte nuclear factors 4α (HNF4 α, NR2A1). HNF4α interacts with a nuclear receptor coactivator, peroxisome proliferator-activated receptor (PPAR) γ coactivator-1α (PGC-1α), and trans-activates the *CYP7A1* gene.

Bile acids activate three nuclear receptors, FXR (NR1H4) [24], PXR (NR1I2), and VDR (NR1I1) [25]. FXR is activated by free and conjugated-bile acids; the hydrophobic bile acid CDCA is the most efficacious bile acid ligand of FXR (EC50 = ~10 μM), followed by LCA, DCA, and CA, while UDCA and MCA do not activate FXR. LCA and its metabolite 3-keto-LCA are the most efficacious bile acid ligands for both VDR and PXR (EC50 = ~100 nM). Bile acids also indirectly activate the constitutive androstane receptor (CAR). These nuclear receptors coordinately regulate bile

acids, lipoproteins, drugs, glucose, and energy metabolism [7, 9]. Bile acids also have been shown to activate several cell-signaling pathways, which regulate bile acid synthesis, glucose, and energy metabolism [12]. Thus, bile acid activation of nuclear receptors and cell signaling pathways converge to coordinately regulate a complex network of cellular metabolisms (see recent reviews in [8–10, 26]).

Regulation by Bile Acid Receptors

FXR is a master regulator of bile acid metabolism: Bile acid-activated FXR plays a critical role in regulation of bile acid synthesis in the liver, biliary bile acid secretion, intestinal bile acid absorption, and hepatic uptake of bile acids (Fig. 12.3). Thus FXR regulates bile acid metabolism and the enterohepatic circulation of bile acids. FXR activates target gene transcription mainly by binding to an inverted repeat with one-base spacing (IR1) in the gene promoter. *Fxr* knockout mice have increased bile acid synthesis and Cyp7a1 expression suggesting FXR mediating bile acid inhibition of Cyp7a1 [27]. FXR does not bind to the CYP7A1 and CYP8B1 gene promoter. The negative effect of FXR is through an indirect mechanism to be described below. FXR induces BACS and BAAT gene transcription by binding to the FXR response elements in the genes. FXR induces a bile salt export pump (BSEP, an ATP binding cassette transporter, ABCB11) located in the canalicular membrane of hepatocytes. BSEP is the principal bile acid efflux pump, which utilizes ATP hydrolysis to excrete conjugated-bile acids against a biliary bile acid concentration about 1,000-fold higher than in hepatocytes. FXR also induces a multidrug resistant protein 3 (MDR3), which effluxes phosphatidylcholine

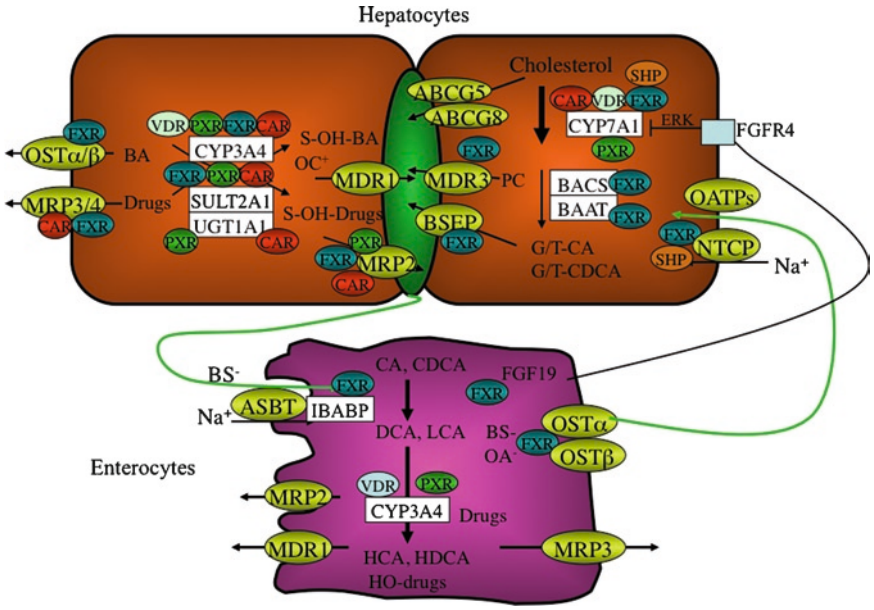

Fig. 12.3 Bile acid-activated nuclear receptors regulate enterohepatic circulation of bile acids. Major bile acid transporters in human hepatocytes and enterocytes are shown. Enzymes and transporters regulated by FXR, SHP, PXR, VDR, and CAR are indicated. In hepatocytes, bile acid activates FXR, VDR, PXR, and CAR to inhibit *CYP7A1* gene transcription. FXR induces SHP to inhibit CYP7A1. In enterocytes, FXR induces intestinal hormone FGF19, which is circulated to hepatocytes to activate FGFR4 signaling to inhibit CYP7A1 via activation of the ERK1/2 pathway. FXR induces bile acid-Co-A synthase (BACS), which links a Co-A to cholestanoic acid for peroxisomal oxidative cleavage of a three carbon-unit to form C24 bile acids. FXR induces bile acid: amino acid transferase (BAAT) to conjugate glycine or taurine to form conjugated bile acids. Conjugated CA and CDCA are excreted into the bile via BSEP. FXR coordinately induces bile salt expert pump (BSEP) to efflux bile acids and MDR3 to efflux phosphatidylcholine to bile. Bile acids also facilitate cholesterol efflux by ABCG5/ABCG8. FXR, PXR, CAR, and VDR induce phase I drug oxidation enzyme CYP3A4, the major drug-metabolizing enzyme in liver and intestine. These receptors also induce phase II drug conjugation enzymes, UDP-glucuronosyl transferase 1A1 (UGT1A1) and sulfotransferase 2A1 (SUL2A1). This drug-metabolizing system detoxifies bile acids and metabolites in the liver and intestine. FXR, PXR, and CAR also induce phase III drug transporter multidrug resistant protein 2 (MRP2), which effluxes glucuronidated- and sulfated-bile acids, organic anions, and drugs into bile. In the sinusoidal membrane, FXR, PXR, and CAR induce MRP3/4 to efflux bile acids and metabolites as an adaptive response to cholestasis. FXR also induces organic solute transporter α/β dimmer (OSTα/β) to efflux bile acids into sinusoidal blood. In enterocytes, bile acids are reabsorbed by apical sodium-dependent bile salt transporter (ASBT) in the apical membrane. FXR induces IBABP, which binds bile acids. In the basolateral membrane, OSTα/β effluxes bile acids into portal circulation. MRP3 may be induced by FXR as an adaptive response to cholestasis. Bile acids returned to hepatic sinusoid are taken up mainly by Na+-taurocholate cotransport peptide (NTCP), and also by Na+-independent organic anion transport proteins (OATPs). FXR inhibits NTCP via SHP to protect hepatocytes as a feedback control of bile acid influx. Many of these membrane transporters (ASBT, OSTα/β, MRP2/3) also are present in cholengiocytes for reabsorption of bile acids, and in renal proximal tubule cells for reabsorption of bile acids from blood circulation and excretion of hydrophilic bile acids

(Fig. 12.3). FXR also induces multidrug resistance related protein 2 (MRP2, ABCC2), which effluxes glucuronidated and sulfated bile acids, organic anions and drugs [28]. ABC-half transporters, ABCG5 and ABCG8 heterodimer may be responsible for biliary excretion of cholesterol. In the gallbladder, bile acids form mixed micelles with phosphatidylcholine and cholesterol. This allows storage of bile acids in high concentrations (mM) and prevents cholesterol from precipitation in the gallbladder. In the terminal ileum, conjugated bile acids are reabsorbed by apical sodium-dependent bile salt transporter (ASBT) located in the brush border membrane of the enterocytes (Fig. 12.3). Once inside the enterocytes, bile acids bind to the ileum bile acid binding protein (IBABP), which is highly induced by FXR [29]. Bile acids are excreted into portal circulation by the organic solute transporter α and β dimer (OSTα/β) located in the basolateral membrane [30, 31]. OSTα/β appears to be the major bile acid efflux transporter in the intestine [32]. FXR induces OSTα/β gene transcription [33]. Bile acids are circulated via portal blood to hepatocytes, where a sinusoidal Na^+-dependent taurocholate cotransport peptide (NTCP) uptakes bile acids into hepatocytes. FXR inhibits NTCP gene transcription [34]. Thus, FXR plays a critical role in coordinated regulation of bile acid synthesis, biliary bile acid secretion, intestinal bile acid reabsorption and secretion, and bile acid uptake into hepatocytes. Defective regulation of these FXR target genes impairs enterohepatic circulation of bile acids, and causes cholestatic liver diseases (see Sect. "Molecular Pathology of the Enterohepatic System", below) [35–38].

The liver initiated-FXR/SHP/LRH-1 pathway. FXR inhibits *CYP7A1* gene transcription by indirect mechanisms. It is thought that bile acid-activated FXR inducts the small heterodimer partner (SHP) to inhibit *CYP7A1* and *CYP8B1* gene transcription [39, 40]. SHP is a negative nuclear repressor that has no DNA-binding domain. SHP inhibits the transactivating activity of liver related homologue-1 (LRH-1, also known as α-fetoprotein transcription factor, NR5A2), and results in inhibiting CYP7A1 gene transcription [39, 40]. SHP also interacts with HNF4α to block HNF4α interaction with PGC-1α and results in inhibiting *CYP7A1* and *CYP8B1* transcription [41, 42]. The FXR/SHP mechanism is supported by the finding that SHP and CYP7A1 mRNA expression levels show an inverse relationship, and CYP7A1 expression and bile acid synthesis is induced in *Shp* knockout mice. Paradoxically, bile acid feeding to *Shp* knockout mice inhibits CYP7A1 expression and bile acid synthesis [43, 44]. More recent studies of conditional liver- or intestine- *Lrh-1* knockout mice shows that CYP7A1 expression is not affected and a FXR agonist GW4064 inhibits CYP7A1 mRNA expression in *Lrh-1* knockout mice [45, 46]. These surprising results suggest that LRH-1 is not required for FXR inhibition of *Cyp7a1* gene transcription. In contrast, *Cyp8b1* gene expression and CA synthesis is abolished in *Lrh-1* knockout mice indicating that the FXR/SHP/LRH-1 mechanism is involved in bile acid inhibition of CYP8B1 and CA synthesis.

The intestine initiated FXR/FGF19/FGFR4 pathway. Another FXR-dependent mechanism is based on the observation that GW4064 induces an intestine hormone, fibroblast growth factor 19 (FGF19), which activates a hepatic FGF receptor 4 (FGFR4) signaling to inhibit CYP7A1 mRNA expression in hepatocytes [47]. A subsequent study shows that FXR induces FGF15, a mouse orthologue of human FGF19 in mouse intestine, and the expression of FGF15 mRNA is inversely correlated to the CYP7A1 mRNA expression levels in mouse livers [48]. Both *Fgfr4−/−* and *Fgf15−/−* mice have increased bile acid pool, fecal bile acid secretion, and CYP7A1 expression [49]. Overexpressing of a constitutively active FGFR4 represses CYP7A1 expression and decreases bile acid pool size in wild type mice [50]. These results are consistent with the role of FGF15/FGFR4 in mediating bile acid inhibition of bile acid synthesis. It appears that FGF15 functions as an enterohepatic signal to activate FGFR4 signaling to inhibit CYP7A1 [48]. Furthermore, GW4064 represses CYP7A1 expression in liver *Fxr* knockout mice, but not in intestine *Fxr* knockout mice [51]. Interestingly, FXR-mediated repression of CYP8B1 expression is more dependent on liver FXR than intestine FXR, and FGF15 represses CYP7A1, but not CYP8B1 expression. These results provide convincing evidence that the intestine FXR, but not liver FXR is required for bile acid inhibition of *CYP7A1* gene transcription. FGF19 activation of FGFR4 signaling requires a membrane-bound glycosidase β-Klotho [52]. In *β-Klotho* knockout mice, bile acid synthesis and secretion and CYP7A1 expression was increased, but CYP8B1 expression was not altered [53]. All these studies support the differential regulation of CYP7A1 by the FXR/FGF19/FGFR4 pathway and CYP8B1 by the FXR/SHP pathway.

Serum FGF19 levels exhibit a diurnal rhythm with two major peaks at 3 and 9 PM, which are ~90–120 min following the peaks of serum bile acids and C4 [54]. These observations are consistent with the concept that FGF19 is secreted from the intestine to blood circulation in response to postprandial efflux of bile acids to inhibit bile acid synthesis in the liver. However, GW4064 and bile acids also are able to induce FGF19 synthesis and secretion in human hepatocytes [55]. The FGF19/FGFR4 signal mainly activates the MAPK/ERK1/2 pathway to inhibit *CYP7A1* gene transcription.

Regulation by Cell Signaling Pathways

Bile acids are signaling molecules that have been shown to activate several cell signaling pathways to regulate bile acid synthesis, lipoprotein, and glucose metabolism in the liver, and energy metabolism in brown adipose tissue and skeletal muscle [11, 12, 14].

PKC

It has been reported that bile acids mimic phorbol esters to activate several protein kinase C isoforms (PKCα, PKCβ, PKCδ, PKCε, PKCξ) in different tissues and cells, and either stimulate or inhibit cAMP production via activation of GPCR, G protein, and adenylyl cyclase (review in [14]). Bile acids may play a role in regulation of glucagon receptor via PKC. Some bile acids induce translocation of phospholipase C (PLC)δ, PKCα and PKCβ1 to cell membranes, and PKCδ to the nucleus to activate cell signaling. Earlier studies show that bile acid (TCA) activated-PKCα activates the MAPK/JNK pathway to inhibit *CYP7A1* gene transcription in rat hepatocytes [56, 57]. Recent studies have shown that the JNK pathway activates and phosphorylates cJun, which phosphorylates HNF4α to inhibit HNF4α trans-activation of the *CYP7A1* and *CYP8B1* genes [6].

Proinflammatory Cytokines

Bile acids are known to activate proinflammatory cytokine (TNFα and IL-1β) release from Kupffer cells [58]. These cytokines may cross sinusoid to hepatocyte to activate cytokine receptors, Toll-like receptors signaling to activate the Rac/MEK4/7/JNK1/2 signal cascade, which phosphorylates HNF4α and reduces its binding to the BAREs, and results in inhibiting *CYP7A1* and *CYP8B1* gene transcription [59, 60].

Growth Factor and Insulin Signaling

It has been reported that conjugated-bile acids activate both AKT and the MAPK/ERK1/2 pathway. Taurocholic acid activation of tyrosine phosphorylation of epidermal growth factor receptors (EGFRs) is blocked by pertussis toxin suggesting that Gαi protein-coupled receptors mediate these bile acid effects [61]. However, there is no direct evidence that TCA binds and activate these GPCRs. Unconjugated bile acids may also activate the AKT pathway through mitochondrial reactive oxidizing species (ROS), which activate EGFRs [62]. AKT phosphorylates and inhibits glycogen synthase kinase 3, and activates glycogen synthesis in rat primary hepatocytes [63]. This implies that bile acids may mimic the insulin action in regulating glucose metabolism by stimulating glycogen synthesis and inhibiting gluconeogenesis. AKT is known to phosphorylate forkhead box transcription factor O1 (FoxO1), which is excluded from the nucleus and results in inhibiting phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G-6-Pase).

TGFβ1 secreted from Kupffer cells activates the Toll-like receptor 4 in hepatic stellate cells (HSC), which also secrets TGFβ1 to activate the TGFβ1 receptor and the Smad signaling pathway in hepatocytes. Bile acids stimulate TGFβ1 expression in hepatocytes and activate the latent TGFβ1 in HSC, and activate HSC. Smad3 recruits histone deacetylase (HDAC) and a repressor mSin3A to inhibit HNF4α activation of CYP7A1 gene transcription [64]. TGFβ1 and bile acids activate the Ras/MAPK/JNK pathway to interact and phosphorylate a tumor suppressor p53 [65, 66], which is known to interact with HNF4α [67] and inhibit HNF4α transactivation of CYP7A1. Another cytokine, hepatocyte growth factor (HGF) has been shown to inhibit bile acid synthesis in primary human hepatocytes [68]. HGF secreted from HSCs activates a tyrosine receptor kinase cMet and rapidly inhibited CYP7A1 expression. HGF induces cJun and SHP, and the ERK/1/2 and JNK pathways. This leads to recruitment of cJun and SHP, but inhibits coactivators PGC-1α and CBP binding to CYP7A1 chromatin, and results in inhibiting CYP7A1 gene transcription.

Role of Bile Acids in Metabolic Regulation

Bile Acids Regulate Lipid Metabolism

It has been known for long time that bile acid sequestrants or interruption of enterohepatic bile acid circulation increases serum triglyceride and VLDP levels, and bile acid treatment reduces serum triglycerides in hyperlipoproteinemic patients [69]. The finding that FXR null mice have increases hepatic bile acids, cholesterol, triglycerides, and pro-atherogenic serum lipoprotein profiles provides the first evidence that bile acid-activated FXR plays a role in regulation of lipid metabolism [27]. It has been shown that FXR induces human apolipoprotein C-II expression [70]. ApoC-II activates lipoprotein lipase involved in lipolysis in adipocytes and muscles. FXR also regulates several other genes involved in lipoprotein and triglyceride metabolism, including ApoA-V, ApoC-III, apoE, PPARα, syndecan-1 [8, 26]. It has been reported that FXR mRNA expression is induced by PPARγ and HNF4α during fasting to reduce serum triglyceride levels by improving triglyceride clearance [71]. The role of FXR in triglyceride metabolism is also supported by the finding that overexpression of FXR by adenovirus-mediated transduction or treatment with GW4064 reduces serum triglyceride levels in wild type and diabetic mice [72]. Another study shows that the FXR/SHP pathway inhibits steroid response element binding protein-1c (SREBP-1c) and other lipogenic genes, and results in reducing serum triglycerides and VLDL production in mice [73].

Bile Acids Regulate Glucose Metabolism

It has been reported that bile acids inhibit PEPCK suggesting that bile acid synthesis and gluconeogenesis are coordinately regulated and linked to the fasting-to-refeeding cycle in mice [74]. This study shows that during starvation CYP7A1 expression is stimulated in parallel to PEPCK, and bile acids inhibit both CYP7A1 and PEPCK gene expression. Another study shows that FXR inhibits PEPCK by SHP-dependent inhibition of HNF4α and FoxO1 [75]. Several recent studies of wild type, FXR null mice and diabetic mice have consistently shown that FXR regulates glucose metabolism and insulin resistance. FXR expression is reduced in diabetic mice and overexpression of FXR or treatment with GW4064 reduces serum glucose and improves insulin sensitivity in wild type and diabetic mice [72]. This is consistent with elevated serum glucose and impaired glucose and insulin tolerance in *Fxr* null mice [76]. Furthermore, activation of FXR increases glycogen levels and induces L-pyruvate kinase, ACC and spot 14 involved in glucose metabolism during fasting-refeeding transition [77]. It should be mentioned that the reported effects of bile acids and FXR on glucose homeostasis in mice are small, and may be limited to the fasting-refeeding cycle [8]. It has been observed that CYP7A1 expression is increased in starvation and parallels the increase of PGC-1α, suggesting that PGC-1α is responsible for fasting and diabetes dependent induction of CYP7A1 in mouse livers [78]. This is in contrast to reduction of bile acid synthesis in fasting and increase of bile acid synthesis during the postprandial period in humans [79]. Also, mice and humans have different diurnal rhythm in bile acid synthesis. In mice, diurnal rhythm of bile acid synthesis shows a peak at midnight and reduces to minimal in mid-day. In contrast, human bile acid synthesis increases in the morning and exhibits two peaks at 1 PM and 9 PM, and decreases at night, regardless of feeding. Glucagon and cAMP induce CYP7A1 in mice, but inhibit CYP7A1 in human hepatocytes [80].

Bile Acids Regulate Energy Metabolism

Fatty acids and glucose are two major fuel molecules in the body. By controlling lipid and glucose metabolism, bile acids play a central role in energy metabolism. However, the mechanism of bile acid regulation of energy metabolism is not clear. The role of FXR in energy metabolism is implicated by the finding that FGF19 increases metabolic rate and reduces adipocity, and reverses diet-induce and leptin-deficient diabetic mice [81, 82]. FGF19 induces hepatic leptin receptor, reduces acetyl-CoA carboxylase 2 expression, and increases fatty acid oxidation. FXR deficiency in mice increases susceptibility to torpor supporting the role that FXR plays in energy metabolism [83]. It has been reported recently that FGF19 suppress insulin-induced fatty acid synthesis in hepatocytes by inhibiting lipogenetic genes and PGC-1α, and inducing SHP [84]. It has been reported that *Shp* null mice show increased energy expenditure, PGC-1α expression, and diet-induced obesity suggesting that SHP is involved in energy production in brown adipocyte tissue by inhibiting PGC-1α expression [85].

Recently, TGR5 has been identified as a bile acid-activated Gαs protein coupled receptor [86, 87]. Conjugated and free bile acids bind and activate TGR5 in the order of TLCA>LCA>DCA>CDCA>CA. TGR5 is expressed in many tissues including gallbladder, spleen, liver, intestine, kidney, skeletal muscle, pancreas, and adipocytes. TGR5 is not expressed in hepatocytes, but has been detected in liver sinusoidal endothelial cells and gallbladder epithelial cells [88, 89]. TGR5 signaling stimulates cAMP, which activates PKA and target gene expression. It has been reported recently that bile acids increases energy expenditure in brown adipose tissue and TGR5-dependent cAMP activation of a type 2 iodothyronine deiodinase (D2) is required for bile acid effect on energy metabolism. D2 converts thyroxine T_4 to the biologically active hormone T_3, which is known to regulate oxygen consumption in mice [90]. In *D2 −/−* mice, bile acids are unable to increase energy production. Knockout of the *Tgr5* gene reduced bile acid pool size by 25%, and female *Tgr5* null mice showed significant weight gain and fat accumulation when fed a high fat diet [91]. These phenotypes are consistent with the role of TGR5 in energy metabolism. However, adult humans have very little brown adipose tissues and the role of TGR5 in energy metabolism in men is not clear. TGR5 regulates energy metabolism in human muscle cells. However, TGR5 levels in human skeletal muscle, adipose tissues, and intestine are very low [87]. The role of TGR5 in energy metabolism in humans remains unclear.

It has been reported that bile acids and TGR5 stimulate glucagon like peptide-1 (GLP-1) secretion in an enteroendocrine cell line STC-1. Knockdown of TGR5 mRNA expression by siRNA reduced GLP-1 secretion suggesting that bile acid induces GLP-1 secretion by TGR5-dependent cAMP production [92]. GLP-1 plays a critical role in regulating glucose homeostasis, appetite, insulin and glucagon secretion in pancreas, and diabetes. Interestingly, *Tgr5* null mice did not develop gallstones when fed a lithogenic diet [93]. These mice have impaired bile acid feedback, and upregulation of CYP7A1 may prevent gallstone formation in *Tgr5* null mice. A study of human gallstone patients reports that TGR5 mRNA and protein are expressed in all patients, and TGR5 mRNA but not protein expression levels are increased in gallstone patients [89]. This study shows localization of TGR5 in the apical membrane and recycling of endosome in gallbladder epithelial cells. TGR5 is colocalized with cystic fibrosis transducer regulator

(CFTR) and ASBT suggesting the coupling of TGR5 in bile acid uptake and chloride secretion.

Molecular Pathology of the Enterohepatic System

Bile acids increase cell proliferation and apoptosis in the liver and intestine [13, 15]. Accumulation of toxic endobiotics and xenobiotics causes damage to cells and organs in the digestive tract. Inborn errors in bile acid metabolism have been identified by analysis of abnormal bile acid metabolites in human patients [94]. Disruption of the enterohepatic circulation of bile acids by obstruction of bile duct causes cholestatic liver diseases [95].

Metabolic Defects in Bile Acid Metabolism

Decrease of bile acid synthesis can be caused by a primary defect in the enzymes involved in the bile acid biosynthetic pathways or secondary to the diseases of the digestive system. Five enzyme defects in bile acid synthesis have been identified.

Defects in Bile Acid Synthesis

A decrease in bile acid synthesis and reduced CYP7A1 activity has been reported in patients with gallstone diseases (review in [96]). Recently, a family of patients with a mutation in the *CYP7A1* gene has been reported [97]. These patients have marked reduction of fecal bile acids (94% lower), hypercholesterolemia, premature atherosclerosis, and gallstone disease supporting the critical role of CYP7A1 in regulating lipid homeostasis. Deletion of double T (1302–1302delTT) in exon 6 causes a frame shift and early termination. The mutant CYP7A1 expressed in 293 cells has no enzymatic activity due to truncation of the C-terminal heme-binding region. Analysis of liver biopsy of one patient showed 70% decrease of CYP7A1 activity and twofold increase of CYP27A1 activity. Analysis of the bile acid composition revealed reduced cholic acid plus deoxycholic acid to CDCA plus LCA ratio. These data are consistent with upregulation of the alternative bile acid biosynthetic pathway as compensation to CYP7A1 deficiency. It is possible that other 7α-hydroxylase activities may be involved in bile acid synthesis in these patients.

An infant patient with a mutation in the *CYP7B1* gene has been reported [98]. This infant has severe neonatal cholestasis, cirrhosis, and liver failure. Analysis of bile acids showed increased urinary sulfate and glycosulfate conjugates of mono-hydroxy-bile acids, 3β-hydroxy-5-cholenoic, and 3β-hydroxy-5-cholestenoic acids indicating a defect in 7α-hydroxylation. Hepatic CYP7B1 activity was undetectable. Sequence analysis revealed a C to T transition resulting in the conversion of R388 in exon 5 to a stop codon. The truncated enzyme was inactive when expressed in 293 cells. The cholestasis caused by CYP7B1 deficiency in this infant suggests that the acidic pathway is quantitatively important in synthesis of bile acid in neonate, and accumulation of hepatotoxic mono-hydroxy bile acids causes cholestatic liver diseases.

The defect in 3β-Δ^5-C_{27} steroid oxidoreductase (HSD3B7) activity is the most common inborn error in bile acid synthesis [99]. Infant patients have hepatitis, cholestatic jaundice, and accumulation of monosulfate and glycine conjugates of 3β, 7 α-dihydroxy-and 3β, 7α, 12α-trihydroxy-5-cholenoic acids (DHCA and THCA). A two-base mutation (Δ1057–1058) in exon 6 of the HSD3B7 gene was identified in an infant with progressive intrahepatic cholestasis [100]. Additional patients with HSD3B7 mutations have been identified more recently [101].

Defects in Δ^4–3-oxysteroid 5β-reductase (AKR) activity have been identified in infants with neonatal hepatitis, cholestasis, and hemochromatosis [102, 103]. Predominant bile acids in these patients are 7α – hydroxy-3-oxo-4-cholenoic and 7α, 12α-dihydroxy-3-oxo-4- cholenoic acids, consistent with a defect in AKR. More recent case studies have identified several patients with AKR1D1 mutations [104, 105].

Mutations of the *CYP27A1* gene cause cerebrotendinous xanthomatosis (CTX), a sterol storage disease [106, 107]. Patients have progressive neurologic dysfunction, xanthoma, and accumulation of cholesterol in the tissues, premature coronary heart disease, and cholesterol gallstones. CTX patients have decreased bile acids, particularly CDCA. The defect in CYP27A1 leads to excessive accumulation of 7α-hydroxycholesterol, 7α-hydroxy-4-cholesten-3-one (C4), 5β-cholestane, 3α, 7α, 12α-triol, cholesterol and C27 bile alcohol, cholestanol, which is derived from C4. The reduced bile acid synthesis in CTX patients may upregulate CYP7A1 activity and leads to the accumulation of these intermediates. Since bile acid feedback also inhibits HMG-CoA reductase, lacking bile acids in CTX patients' increases de novo cholesterol synthesis and causes accumulation of cholesterol in serum. CDCA and UDCA have been used to replace bile acids, and inhibit CYP7A1 to reduce bile acid intermediates in CTX patients. Surprisingly, *Cyp27a1* null mice do not develop CTX phenotypes. This is because mouse liver CYP3a11 is able to metabolize 5β-cholestane-3α, 7α, 12α-triol by 25-hydoxylation to form 5β-cholestane-3α, 7α, 12α, 25-tetrol is, which a potent mouse PXR ligand and induces Cyp3a11 expression in mice, but not in humans [108].

Defects in Bile Acid Conjugation

Oxidative cleavage of the steroid side chain by β-oxidation occurs in peroxisomes. A general defect in peroxisome biogenesis impairs bile acid synthesis and accumulation of C27-bile acid intermediates, DHCA and THCA [109]. Zellweger syndrome and related peroxisomal diseases are characterized by neurological disorder, and defective bile acid synthesis [110, 111]. C27-bile acid intermediates are cytotoxic and cause mitochondria dysfunction by inhibiting oxidative phosphorylation, and the respiratory chain [112]. Bile acid therapy has been used to treat peroxisomal diseases [113].

Cholestatic Liver Diseases

Cholestasis is caused by a disruption of bile flow, which results in a lack of bile in the intestine, accumulation of toxic bile acids and other metabolites in the liver, and increased bile acids in the systemic circulation [36]. A detailed account on the molecular basis of this pathology is available in Chap. 32. Obstruction of the bile ducts by tumors or stones, genetic mutations of bile acid transporter genes, and acquired dysregulation of bile transport system by drugs, pregnancy and pathophysiological conditions causes intra- and extrahepatic cholestasis. A detailed review of the molecular mechanisms of cholestasis has been published recently [95].

Hereditary Cholestatic Diseases

The hereditary defects of ABC transporters in the hepatobiliary system in the neonates and children have been identified. The progressive familial intrahepatic cholestasis (PFIC) and benign recurrent intrahepatic cholestasis (BRIC) are autosomal recessive diseases linked to mutations in ATP8B1 (Type 1, PFIC1), BSEP (Type 2, PFIC2), and MDR3 (Type 3, PFIC3). PFIC1 (also known as Byler disease) is linked to mutations in ATP8B1, which codes an aminophospholipid flippase that maintains membrane asymmetry by inward flipping of phosphatidylserine. The mechanism of ATP8B1 in pathogenesis of PFIC1 is unknown. Several studies have shown reduced hepatic FXR expression levels in PFIC1 patients [114, 115]. It has been suggested that a membrane signaling involving PKCξ may regulate FXR activity by phosphorylation and nuclear translocation [116]. In contrast, another recent study reports that hepatic FXR mRNA expression is not altered and ATP8B1 deficiency may disrupt the bile canalicular membrane structure and cause cholestasis [117].

PFIC2 is linked to BSEP mutations [118]. Bile acids are accumulated in the liver and leaked into systemic circulation. This causes hepatitis and liver damage requiring liver transplant in pediatric patients. BSEP mutations and polymorphisms have been linked to intrahepatic cholestasis of pregnancy (ICP) [119–121] and drug-induced liver injury [122].

PFIC3 is linked to mutation of MDR3, a phospholipid flippase in the canalicular membrane [119, 123]. PFIC3 patients have high levels of γ-glutamyl transpeptidase activity (GGT), progressive cholestasis, bile duct damage, and may require liver transplant. Patients have low phospholipids in bile, which are required for mixed micelles formation with bile acids and cholesterol. Without forming mixed micelles, bile acids damage canalicular membrane and cholangiocytes. Mutations of MDR3 may cause cholesterol gallstone diseases and has been linked to ICP [123, 124].

Mutations in MRP2 has been linked to Dubin-Johnson syndrome, a disease characterized by chronic hyperbilirubinemia [125]. MRP2 excretes conjugated bile acids, bilirubin, and other organic anions. Patients have elevated bile acids and cholestasis. MRP2 mutations have been associated with ICP.

Acquired Cholestasis

Genetic polymorphisms and heterozygote mutations of the PFIC1, PFIC2, and PFIC3 genes may increase susceptibility to the acquired cholestasis in adults including ICP, drug-induced liver injury, primary biliary cirrhosis (PBC), and primary sclerosing cholangitis (PSC).

Obstructive Cholestasis

In obstructive cholestasis, bile flow is decreased due to blockage of bile duct by gallstones or tumors, and bile acids are accumulated in the liver and are absent in the intestine. A study of obstructive cholestasis in human patients shows that bile acid synthesis is suppressed, but CYP7A1 expression is not altered [126]. Based on the FXR/SHP mechanism, accumulation of bile acids in the liver in cholestatic patients should activate FXR to inhibit CYP7A1 expression. However, based on the FXR/FGF19/FGFR4 pathway, reduced intestinal bile acids should reduce FGF19 in obstructive cholestasis and result in increasing CYP7A1 expression and bile acid synthesis. A recent study reports that CYP7A1 mRNA expression is repressed in human patients with obstructive extrahepatic cholestasis [127]. These investigators found that plasma FGF19 levels were increased, instead of decreased, and FGF19 mRNA are detected in human livers [127]. These observations suggest that bile acids may induce FGF19 in hepatocytes to inhibit CYP7A1 by an autocrine pathway [55].

Activation of FXR protects cholestatic injury by bile acids, drugs, and other xenobiotics. Bile acids induce FXR to

inhibit CYP7A1 and reduce bile acid synthesis. FXR inhibits NTCP and OATPs to inhibit sinusoidal uptake of bile acids. FXR also may upregulate MRP3, MRP4, and OSTα/β in the sinusoidal membrane as an adaptive response to efflux bile acids into systemic circulation in obstructive cholestasis in mice. It remains to be verified that this adaptive response to cholestasis exists in cholestasis patients. Bile acids also play a protective role in controlling bacterial overgrowth in the intestine [128]. Obstruction of bile flow or knockout of the *Fxr* gene in mice increases bacterial growth and mucosal injury in the intestine, and bile acid administration reduces bacterial growth in obstructive cholestasis.

Bile Acids as Therapeutic Agents

The therapeutic potential of bile acids and derivatives for treating liver diseases and metabolic diseases are now well recognized [9, 28, 129].

Bile Acid Displacement and Replacement

CDCA and UDCA have been used for effective gallstone dissolution for many years. However, CDCA and CA have toxic effect in humans, and are difficult to manage. CDCA has been used to treat bile acid deficient patients as a replacement of bile acids in the bile acid pool. CA is less toxic than CDCA, but is converted to DCA, which is more toxic than CA and a colon cancer promoter. CA is more efficient in intestinal absorption of cholesterol than other bile acids, and may cause gallstone formation and hypercholesterolemia in human patients [130]. UDCA is a highly soluble, nontoxic bile acid, and has been approved for gallstone dissolution and PBC. UDCA has been used in traditional Chinese medicine for treating digestive disease for several centuries. UDCA reduces the cytotoxicity of circulating bile acid pool, protects cholangiocytes, stimulates hepatobiliary secretion, and inhibits liver cell apoptosis [15]. UDCA may also activate PXR and induce PXR target genes, CYP3A4, SULTs, UGTs, BSEP, MDR3, and MRP4. Bile acid sequestrants, cholestyramine, and cholestipol have been used for gallstone dissolution and lipid lowering in humans. These drugs bind bile acids in the intestine and interrupt enterohepatic circulation of bile acids, and result in stimulating bile acid synthesis, increasing LDL receptors, and in reducing serum cholesterol levels. Cholestyramine and colesevelam also have glucose-lowering effect [131]. Colesevelam has been approved for improving glycemic control for type 2 diabetes [132].

FXR Agonists for Cholestasis, Gallstone, Fatty Liver and Cardiovascular Disease

The therapeutic potential of FXR agonists for metabolic diseases has been recognized. A specific FXR agonist GW4064 has been widely used to study the function of FXR and to identify FXR target genes. GW4064 reduces serum triglycerides and cholestasis in mice. However, this FXR agonist has poor bioavailability and is not a suitable therapeutic drug. A potent synthetic bile acid derivative, 6-ethyl-CDCA (INT-747) is effective in protection against estrogen-induced cholesterol in mice [133]. INT-747 is in the second phase of clinical trials for primary biliary cholestasis. Another bile acid derivative 6α-ethyl-23(S)-methyl-CDCA is a selective TGR5 agonist [134], which is in the first phase clinical trials for diabetes and obesity. Fatty acid: Bile acid conjugates have potential for treating nonalcoholic fatty liver disease [135, 136], gallstone disease, [137–139] and cardiovascular diseases [140, 141].

Part II
Molecular Basis of Liver Development, Growth, and Senescence

Chapter 13
Liver Development

Klaus H. Kaestner

Introduction

About 5% of the body mass of mammals is made up by the liver, our largest internal organ. Absence of the liver is not compatible with life, due to the multiple essential metabolic functions of the organ. In addition, multiple diseases are caused wholly or in part by impaired liver function. Examples of the impressive functional diversity of the liver, which are discussed in detail elsewhere in this volume, are the secretion of serum components and clotting factors, the regulation of glucose, protein and lipid metabolism, and the detoxification of xenobiotics, drugs, and other chemicals.

The development of the vertebrate liver has served as a paradigm for understanding fundamental mechanisms of organogenesis in general. Multiple approaches have been employed over the years to address this important problem: from embryonic explant cultures to inducible and tissue-specific gene ablation, from gene expression profiling to lineage tracing. While, like all developmental processes, liver development represents a continuum, for didactic purposes it is useful to divide this into several stages, from the formation of the earliest hepatic bud, or "Anlage" from the embryonic endoderm, to the final functional maturation of hepatocytes and cholangiocytes that are the epithelial cells that constitute the bulk of the liver. In this chapter, I will focus on the earliest events of liver formation, those which take place in the first 48 h of hepatogenesis in the mouse embryo, and that span the induction of the first hepatogenic progenitors, the delineation of the hepatic domain from neighboring organ systems, and the migration of the first hepatoblasts out of the liver diverticulum.

Inducing the Hepatic Domain in Foregut Endoderm

Fate Mapping of Liver Precursors: Where to Hepatoblasts Come from?

During gastrulation of the early vertebrate embryo, three germ layers are established: the ectoderm, mesoderm, and endoderm. During subsequent organogenesis, the ectoderm gives rise to the nervous system and skin; the mesoderm to heart, kidneys, and blood; and the endoderm to the alimentary tract with its associated organs including salivary glands, thyroid, lungs, pancreas, and liver.

Initially, the endoderm is comprised of a single-cell layer epithelial sheet lining the ventral surface of the embryo. Shortly after the definitive endoderm emerges from the embryonic node, the important organizing center of gastrulation, this epithelium invaginates anteriorly to form the foregut tube, which will later fuse with the oral cavity. The ventral foregut gives rise to liver, lung, thyroid, and ventral pancreas, while the dorsal endoderm develops into the intestine and the dorsal pancreatic bud [1–3]. Central questions in the field of organogenesis are: How is the positional information established that differentiates anterior structures such as salivary glands from posterior structures such as the colon? How do certain cells in the endoderm, which begins as a simple epithelial sheet, know that they will become hepatoblasts, the precursors of hepatocytes and cholangiocytes?

Fate mapping studies have recently established which cells in the endoderm become liver progenitors. For these studies, very early mouse embryos, at a stage when there are neither morphological nor molecular markers of the liver primordium evident, where injected in individual or clusters of cells of the endoderm with a nondiffusible dye. The embryos were then cultured to allow for further development, and assessed for whether dye-injected cells had become part of the liver primordium [4]. Surprisingly, it was found that there is not a single domain of hepatic precursors, but rather three spatially separated areas. As shown in Fig. 13.1, there are two paired lateral domains at the one to three somite

stage, which migrate anteriorly and medially to fuse with a third, medial endoderm domain when hepatoblasts are eventually specified.

From Endoderm to Hepatoblasts: Inductive Signals

These fate-mapping studies raise an important question: Are these liver-fated cells already specified irreversibly in the endoderm at the early foregut stage, or do they need instructive signals to activate a hepatogenic gene expression program? Multiple studies, beginning as long as 45 years ago, have addressed this question and strongly favor the latter model. In the 1960s and 1970s, LeDourain used tissue explant studies with chicken embryos to demonstrate that isolated endoderm by itself will not develop into a hepatic primordium [5–8]. Rather, only when foregut endoderm was cultured together with cardiogenic mesoderm was the early liver fate induced. Thus, it is clear that signaling from the early heart field to the adjacent foregut endoderm is instructive for liver development.

So what is the nature of the signaling molecules(s) that are derived from the cardiogenic mesoderm? It was only 10 years ago that some of these inducers were discovered. Again using cultured endoderm explants, though this time from the mouse, Zaret et al. showed that blocking fibroblast growth factor (Fgf) signaling from the cardiac mesoderm to the co-cultured foregut endoderm prevented induction of early liver-specific gene expression [9]. Conversely, when endoderm was cultured without cardiogenic mesoderm, but in the presence of Fgf, the hepatic program was activated. Thus, Fgf signaling is one of the important inducers of hepatic fate.

These initial studies have since been confirmed and extended in multiple systems and species [10–16]. Fgfs can signal both via mitogen-activated protein kinase (MAPK) and the phosphatidyl inositol 3 kinase (PI3 kinase) pathway. Using specific inhibitors, Calmont et al. established that the MAPK pathway is essential for hepatic induction. Interestingly, Fgf signaling simultaneously suppresses the ventral pancreatic program, thus taking part in the differentiation of closely related fates that will be discussed in detail below [10, 15, 16].

Fibroblast growth factors are not the only signaling molecules that have been shown to be involved in early liver development. Adjacent to the heart is the septum transversum mesenchyme, which will later develop into the diaphragm and ventral mesentery. Bone morphogenetic proteins (Bmps), secreted from the septum transversum mesenchyme, have been shown to act coordinately as inductive signals mediating both the hepatic and ventral pancreatic fates [15–17]. Interestingly, suppression of other signaling events is also required for the early stages of endoderm specification. Wnt signaling, for instance, must initially be inhibited to allow proper hepatic specification, although its re-activation is required at later stages to support expansion of the liver bud and liver organogenesis [18–22].

From Endoderm to Hepatoblasts: Intrinsic Factors

It is now believed that the signaling pathways described above impact cell-autonomous factors such as transcriptional regulators to initiate highly-specific gene expression programs. However, it has also been suggested that these inductive signals alone are not sufficient to elicit the desired impact on their target cells in the developing endoderm. Rather, specific molecular events within the receiving cells must first occur before the tissue can become competent to respond to the instruction of the signal [23]. This model is based on the observation that dorsal endoderm, which does not normally

differentiate into liver cells, can be induced to express the liver marker albumin if dissected between E8.5 and E11.5 and cultured in the presence of Fgf [24]. This competence is lost, however, if the dorsal endoderm is isolated at E13.5 or later, suggesting that factors required for competence are no longer present at this stage or have ceased to disseminate the directive of the signal. Interestingly, there is a direct correlation between the ability of Fgf to induce hepatic gene expression in the dorsal endoderm, and the binding activity of Foxa and Gata proteins to an albumin gene enhancer region. Thus, the loss of competence was accompanied by the loss of Foxa and Gata binding in the more mature dorsal endoderm [24]. In support of this model, earlier studies from the Zaret lab had demonstrated selective binding of Foxa and Gata transcription factors to this enhancer in the endoderm, even prior to activation of the albumin gene, further implicating Foxa and Gata proteins as important factors involved in the establishment of developmental competence [25, 26].

The intrinsic or cell-autonomous transcription factors important in hepatogenesis were first identified from the analysis of the regulatory elements that govern the expression of the earliest liver-specific transcripts, among them albumin, alpha-fetoprotein, and transthyretin. In addition, expression studies of early mouse embryos established that these transcriptional regulators are expressed in the right place and at the right time, that is, in the endoderm before liver induction. The first Foxa gene to be activated in vertebrate embryos is Foxa2, whose mRNA and protein gene expression are first detectable in the mouse at embryonic day 6.5 (E6.5) in the "node" and the anterior primitive streak [27–30]. The node of the mammalian embryo is critical to gastrulation, the process that first establishes the three germ layers mentioned above. Indeed, embryos deficient for Foxa2 lack anterior and medial endoderm, and thus all derivate structures [31]. However, because of the failure to develop foregut endoderm, the Foxa2-null embryos were not informative with regard to the question of whether Foxa factors are required for liver induction; the answer to this question required the application of cell-type-specific gene ablation, which is discussed in detail below. The Foxa2 gene is not only active in the early embryo, but also in adults, including the endoderm derivatives such as liver, pancreas, lung, thyroid, and prostate [30, 32–35].

Foxa1, a close relative of Foxa2, is expressed in a very similar pattern in the early embryo and into adulthood; however, Foxa1 is activated about 12 h later than Foxa2 [27–30]. While genetic experiments (see below) have shown Foxa1 and Foxa2 to have overlapping functions in many developmental processes, there is a time when the only Foxa gene expressed in the embryo is Foxa2. This explains why Foxa2-null embryos have a severe early embryonic phenotype, while Foxa1- or Foxa3-null embryos develop almost normally until birth [36–42]. The third gene in this subclass of Foxa transcription factors is Foxa3, expression of which does not initiate in the endoderm until E8.5, and which is not present in the primitive streak or axial mesoderm [28]. For this reason, the Foxa3 regulatory elements have been used successfully to drive the expression of specific transgenes into the endoderm, including a Cre recombinase used to delete loxP-flanked target genes in the early gut tube (see below [43, 44]).

The Foxa factors have been shown through in vitro studies to differ in important functional properties from other sequence-specific DNA binding proteins and transcriptional regulators. Most transcription factors are thought to promote gene activation via the recruitment of cofactors that interact with the basal transcriptional machinery or that covalently modify certain histone residues, thereby altering the chromatin structure. The Foxa proteins are different in that they appear to be able to directly modify chromatin structure. Such a mechanism of action was first suggested when the crystal structure for the Foxa DNA-binding domain complexed with DNA was solved. Strikingly, the Foxa DNA-binding domain is similar to that of the linker histone H5, where both are configured in a so-called winged helix motif [45, 46]. Linker histones play a role in the compaction of chromatin, which renders the DNA inaccessible to most sequence-specific DNA binding proteins. The structural similarity of the Foxa proteins and linker histones raised the possibility that the Foxa factors could directly disrupt nucleosome assembly by displacement of linker histones. Elegant in vitro studies from the Zaret lab showed that Foxa proteins could indeed bind their target sequences in DNA templates that are fully covered by nucleosomes, and even alter local nucleosome occupancy [47–49]. A nucleosome-covered template containing the part of the albumin enhancer could not be bound by transcription factors such as NF-1 and C/EBP unless Foxa protein was added first [48, 50]. In combination with its capacity to bind target sequences in advance of gene activation, it is this unique ability to engage target sites compacted in nucleosomal DNA and to enable the subsequent binding of additional regulators that has led to the designation of Foxa proteins as "pioneer" factors [23]. Interestingly, members of the GATA family of transcription factors, which are also expressed in the foregut endoderm, have similar properties in vitro, although their binding to nucleosome compacted targets in the albumin enhancer is weaker than binding by Foxa proteins [48].

In addition to sites in the albumin enhancer, the Foxa proteins bind to and/or regulate numerous genes in the liver [51–54]. In fact, the Foxa proteins were initially purified as "Hepatocyte nuclear factor 3" because of their ability to bind to regulatory regions of the liver-expressed transthyretin (Ttr) and alpha-1-antitrypsin genes [55]. Their many target genes in the liver, the aforementioned properties as pioneer factors that can bind to compacted chromatin targets, and the

activation in the hepatogenic region of the foregut endoderm have made the Foxa proteins as prime candidates to be essential intrinsic regulators of the hepatic fate. However, the genetic analysis of their contribution to liver development was complicated by: (a) partial functional redundancy between closely related proteins, and (b) important roles of Foxa2 in gastrulation. Specifically, the early lethality of Foxa2$^{-/-}$ embryos, owing mostly to node and notochord defects [36, 42], prevented the analysis of liver development in these mice. To overcome these limitations, conditional ablation using the Cre/loxP system was employed.

The Cre/loxP system is an elegant technology that allows for the derivation of "designer mosaic mice," that is, animals that contain wild type amounts of the gene product of interest in most cells of the body, but are deleted in the cell type(s) of interest. The system was first employed in mice about 15 years ago by Rajewsky et al. and has revolutionized mouse genetics, not only in how it applies to liver development, but all aspects of biology and biomedicine [56]. The system consists of a site-specific DNA recombinase enzyme termed Cre (for "causes recombination") that recognizes only one specific DNA target, the 34-bp loxP (for "locus of crossing over") sequence. Thus, when loxP sites are placed strategically surrounding an essential exon of a gene of interest, but without interrupting gene function, then the gene can be deleted in all cell types that express the Cre recombinase enzyme – in the liver, for instance, under the control of the albumin promoter.

Using this approach, mice homozygous for a "floxed" (surrounded by loxP sites) Foxa2 allele were derived [57]. As expected, these mice were phenotypically wild type, as they expressed normal levels of Foxa2 protein in all cells. Surprisingly at first, when these mice were crossed to mice carrying a Foxa3-driven Cre recombinase, effecting deletion in the endoderm and its derivatives beginning at day 8.5 of gestation, the resulting *Foxa2*$^{loxP/loxP}$; *Foxa3*-Cre mice were viable, and showed a histologically normal liver, even though they lacked Foxa2 protein in all hepatocytes [43]. As mentioned above, Foxa1$^{-/-}$and Foxa3$^{-/-}$mice also have normal liver histology [39, 40]. So are the Foxa proteins not required for hepatogenesis? The answer came when mice lacking both Foxa1 and Foxa2 in foregut endoderm were obtained. In a complex mating scheme, Foxa1$^{-/-}$; Foxa2$^{loxP/loxP}$; Foxa3-Cre embryos were produced, and were found to lack all histological and molecular markers of hepatogenesis [58]. Thus, mice deficient for Foxa1 and Foxa2 are "liverless" [59]. Furthermore, when foregut endoderm from these embryos was placed in culture and incubated with the hepatogenic inducer Fgf2 mentioned above, none of the early liver genes were activated [58]. What these data also imply, incidentally, is that the third member of the Foxa class, Foxa3, is not able to compensate for the absence of its two relatives in liver formation. This observation suggests that the in vivo targets of Foxa3, at least in foregut endoderm, differ from those of Foxa1 and Foxa2.

Strikingly, a similar model applies to Gata4 and Gata6. Genetic ablation or mutation combined with siRNA-mediated suppression of the two genes in mice and zebrafish, respectively, showed that these two factors are required redundantly for liver development [60–62]. These genetic data clearly demonstrate that the Foxa and Gata factors are intrinsic mediators of liver development, and without them, no amount of inductive signal can induce the hepatic gene expression program. However, at present, it is not certain that their mechanism of action in vivo is truly that of pioneer factors: opening up the compacted chromatin to allow for access of additional transcriptional regulators. Future work will have to determine whether the absence of either the Foxa or Gata proteins converts endoderm chromatin to an inaccessible state.

Defining the Liver Field: Lineage Segregation Within the Foregut Endoderm

The region of the foregut endoderm from which the liver develops is actually a crowded place. Within the space of a few cell diameters, the lungs, thyroid, liver, hepatobiliary tract, ventral pancreas, stomach, and duodenum all need to be specified. In particular, the liver, ventral pancreas, and the extrahepatobiliary system comprising the common duct, gall bladder, and cystic duct; are very close together. How then are these different lineages separated, and how is the liver field specified? Interestingly, gene ablation and lineage tracing studies suggest that the extrahepatobiliary system has a common origin with the ventral pancreatic bud, while the intrahepatic biliary system is derived from hepatic progenitors.

Two systems have been shown to be involved in lineage segregation in the foregut endoderm. Mice lacking the Notch signaling effector Hes1 exhibit defects in lineage specification. These mice lack the gall bladder, and instead elaborate pancreatic fates in the common duct [63, 64]. One of the effector targets of Hes1 is likely the transcriptional regulator Sox17, because Hes1 mutants elaborate more Sox17^{+} cells in the foregut than wild type control embryos. Sox17 itself is initially expressed broadly in the foregut endoderm, but is then successively downregulated as the organ anlagen of liver, and ventral pancreas are established [65]. If Sox17 is ablated in foregut endoderm using the Cre/loxP system, pancreatic fates are activated in both the liver and extrahepatobiliary system. In a complex feedback loop, Sox17 is required for expression of Hes1, and the Sox17-dependent specification of the biliary and pancreatic fields is dependent on Hes1 [65].

Constructing the Liver Bud

A Transcription Factor Network Controls the Formation of the Hepatic Primordium

Once the first hepatoblasts have been specified through the mechanisms outlined above, they have to expand in number and grow into a true liver bud. This process requires both a dramatic increase in cell number, and the migration of nascent hepatoblasts away from the confines of the foregut epithelium into the mesenchyme of the septum transversum (Fig. 13.2). Liver bud formation is initiated on day 22 of human embryonic development, corresponding to day 9 in the mouse, with the formation of a liver diverticulum, or pouch, by the nascent hepatoblasts. These endoderm-derived cells first adopt a columnar shape, leading to a thickening of the foregut tube at the site of liver formation. Soon thereafter, these cells transition into a thickened, pseudostratified epithelium [66]. This conversion is the result of interkinetic movement of nuclei during mitosis, that is, the repositioning of nascent nuclei to the apex of the dividing cell.

In order to expand in mass and to begin to attain their final position in an organ separate from the gut tube, nascent hepatoblasts have to leave the gut epithelium and migrate through its basement membrane. During this process, hepatoblasts transiently adopt mesenchymal-like morphology, and show decreased expression of the epithelial adhesion protein E-cadherin. Thus, hepatoblasts undergo a partial and reversible epithelial transition in order to form the liver primordium; however, they retain expression of many hepatoblast markers during this time of migration.

This complex behavior of nascent hepatoblasts is controlled by a second set of transcriptional regulators, chiefly among them the homeobox transcription factors Hex and Prox-1, the T-box factor Tbx3, the "onecut" factors OC-2 and HNF6 (also known as OC-1), and the aforementioned factor Gata6 (recently reviewed in [67]). The contribution of the members of this network to liver development was again delineated though gene ablation studies in mice. For instance, Tbx3 promotes liver bud expansion by preventing premature differentiation of hepatoblasts into cholangiocytes, and is necessary for hepatoblast migration via activation of its target Prox-1 [68]. Prox-1, in turn, is required for delamination of hepatoblasts from the early liver bud. Consequently, in absence of Prox-1, hepatoblasts stay in a tight cluster in the hepatic bud [69]. The homeobox gene Hex plays several roles in liver bud formation, both in the nuclear migration mentioned above and in hepatoblast proliferation [66, 70]. Finally, without Gata6, hepatoblasts lose their differentiation markers over time. The overall transcription factor network active in hepatic bud formation is schematized in Fig. 13.2.

Just as is the case for the initial induction of the hepatogenic program from foregut endoderm in the previous

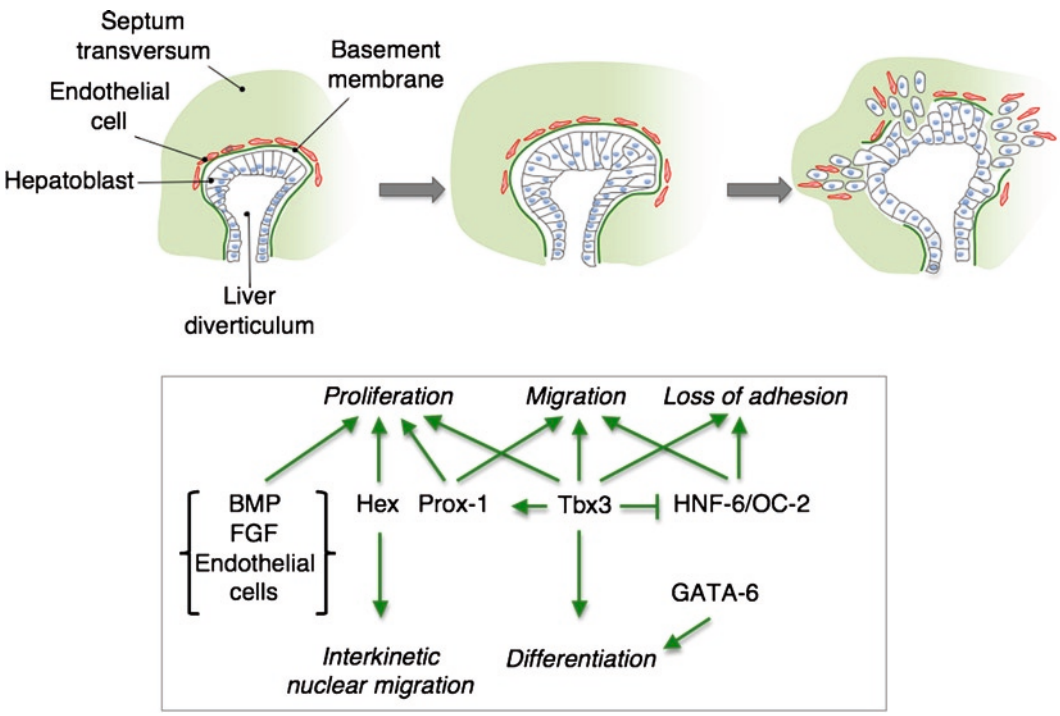

Fig. 13.2 Budding of the liver from the foregut endoderm. The *upper panel* schematizes the changes in morphology of the liver when it emanates from the endoderm. The *lower panel* summarizes the control of key regulatory events by transcription factors and extracellular signaling. From Lemaigre [67] used with permission

section, extrinsic factors are essential in addition to the cell-autonomously acting transcription factor network outlined above. Thus far, three such extrinsic systems have been described. First, when embryos lacking all endothelial cells due to absence of the Flk1 gene, which encodes the receptor for the vascular endothelial growth factor 2, were analyzed, liver development was blocked after the induction of the early hepatogenic program [71]. In fact, using a tissue explant system, Matsumoto et al. could show that without endothelial cells hepatic outgrowth is blocked. Teleologically, it appears to make sense that the growth of the liver is coordinated with that of the vascular system.

A second source of growth factors is the septum transversum mesenchyme, which is in close apposition to the foregut endoderm. Septum transversum mesenchyme is the source of bone morphogenetic proteins 2 and 4 (Bmp2 and 4), which are members of the TGFβ family of signaling molecules. Bmp4 null-embryos show a growth delay in the formation of the liver bud [17]. However, when Bmp4-null tissue explants were placed in culture, liver outgrowth proceeded normally, suggesting the action of a redundant factor, which is likely Bmp2. Thus, when Bmp signaling was impeded further through the addition of the Bmp-inhibitor noggin, liver outgrowth was blocked. Thus, Bmps from the septum transversum mesenchyme are additional factors essential for the growth of the hepatic primordium.

So how do nascent hepatoblasts cross the basement membrane of the foregut? After hepatic induction, nascent hepatoblasts express the matrix metalloproteases MMP14, while the septum transversum mesenchyme secretes MMP2 [72]. Together, these enzymes partially degrade the basement membrane, enabling hepatoblast migration. In fact, when metalloproteases were inhibited pharmacologically in an explant system, hepatoblast migration was blocked [72].

Expanding the Liver Primodium

Once formed, the growth of the liver primordium is extraordinary, so that by mid-gestation it occupies about half of the peritoneal cavity of the embryo. How is this dramatic expansion achieved? Multiple growth factors coordinate this process, each employing an elaborate signal transduction cascade (reviewed in [73]).

One of the major players in liver expansion is the Wnt/β-catenin signaling pathway. May be best known for its role in colorectal cancer, where aberrant β-catenin activation is the initiating step in tumor formation, Wnt/β-catenin signaling is highly complex in the liver, and some of the details are still being worked out. Expression analysis in the mouse found evidence for the involvement of eleven different Wnt ligands and eight of their receptors, termed Frizzled (Frz; [74]). Wnt signaling is also a prominent example of a novel theme emerging in vertebrate organ development, namely that the same signaling pathways can have opposite effects on the same system at different stages of development. Specifically, in the developing *Xenopus laevis* embryo, an antagonist of Wnt signaling, the secreted protein Frp5 (for frizzled related protein 5) is expressed in foregut endoderm during liver induction [19]. Frizzled related proteins act as competitive inhibitors of Wnt signaling, by binding to the ligand in the extracellular space, preventing it from binding to the Frz receptors on the cell surface. Thus, a gradient of active Wnt signaling is established, with high activity favoring posterior endoderm fates, i.e., the intestine, while low Wnt signaling is required for liver (and pancreas) initiation. In fact, McLin et al. could link high Wnt signaling activity to repression of Hex, the transcription factor introduced above as promoting hepatic bud expansion. Thus, only when Wnt/β-catenin activity is low, can the Hex gene be activated and liver expansion proceed [19].

However, just a short developmental time later, the situation is reversed, and Wnt/β-catenin signaling is in fact required for hepatoblast expansion. Thus, when the central mediator of canonical Wnt signaling, that is β-catenin, is conditionally ablated from hepatoblasts using the aforementioned Cre/loxP system, proliferation is blocked. The resulting embryo displays a severely hypoplastic liver, due to both reduced proliferation and increased cell death [22]. Wnt/β-catenin is not only required for the expansion of hepatoblast cell number, but also the acquisition of a fully differentiated hepatocyte phenotype, as β-catenin deficient hepatoblasts exhibit reduced expression of the important hepatocyte transcription factors, C/EBPα and HNF4α [22] (See also the following chapters).

In addition to responding to canonical Wnt signaling, β-catenin also integrates several additional regulatory pathways. for instance, β-catenin can bind to the receptor for hepatocyte growth factor (Hgf), termed c-myc, and become activated in response to Hgf stimulation [75]. In addition, Fgf10 secreted from myofibroblasts also stimulates hepatocyte proliferation via β-catenin [76]. These complex pro-proliferative interactions important for the expansion of the hepatic primordium are schematized in Fig. 13.3.

What about additional growth factors? Prominent among them is the already mentioned hepatocyte growth factor (Hgf). In addition to promoting β-catenin activation, Hgf signals via its cognate receptor, the tyrosine kinase receptor c-met. Once HGF-bound, c-met initiates a signaling kinase including mitogen-activated protein kinase kinase SEK1 (also called MKK4; official name MAP2K4), the mitogen-activated protein kinase p38, and their downstream effectors including ATF2 and ATF7 [77–81] (Fig. 13.3). Mutations in any of these components leads to dramatically reduced liver size, indicative of the importance of this pathway.

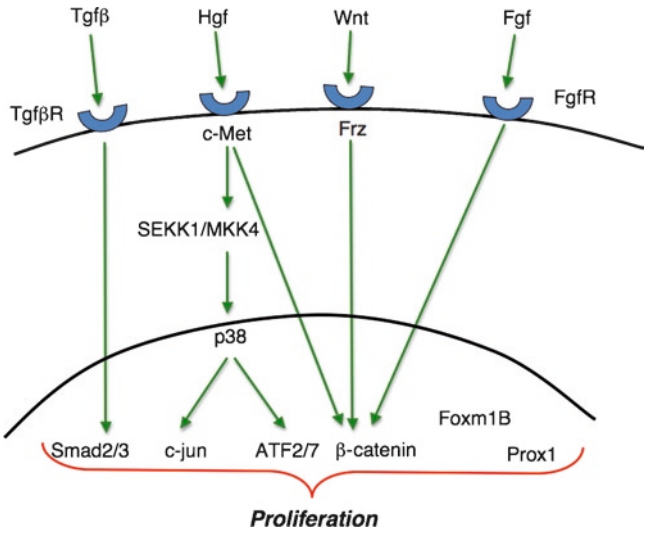

Fig. 13.3 Growth regulation in the hepatic primordium. The signaling factors and downstream cascades that control proliferation of hepatoblasts are illustrated. Liver growth depends on the coordinated control of these biological processes. Modified from Lemaigre [67] used with permission

The Hgf signaling pathway interacts with yet another growth factor system, in this case, TGFβ signaling. Mice heterozygous for two of the downstream signaling mediators, Smad2 and Smad3, develop a hypoplastic liver [82]. The main target in this case is possibly β1 integrin. Through the analysis of chimeric embryos, that is, embryos composed of both wild type and β1 integrin null cells, it had been shown 15 years ago that β1 integrin-deficient endoderm cells are excluded from the developing liver, though the exact mechanism of this defect remains to be elucidated [83]. Regardless, expression of β1 integrin is reduced in liver explants heterozygous for Smad2 and Smad3, but restored by addition of Hgf, thus demonstrating a link between the two pathways [82] (Fig. 13.3).

As before, intrinsic or cell autonomous factors are also essential for continued hepatoblast mass expansion. Using isolated fetal hepatoblasts in culture, Kamiya et al. showed that overexpression of Prox-1 (the same factor shown by gene ablation studies to be required for the migration of nascent hepatoblast out of the foregut endoderm) causes sustained proliferation of hepatoblasts. This proliferative effect is antagonized by Lrh1 (for liver receptor homologue 1), another liver-enriched transcription factor [84]. These findings suggest that the role of Prox-1 is not limited to its function in the delamination of hepatoblasts from foregut endoderm as described above, but also promotes continued hepatoblast proliferation. In the future, it would be valuable to confirm these novel functions of Prox-1 in liver bud expansion using conditional gene ablation.

Another crucial contributor for hepatoblast expansion is the winged helix transcription factor Foxm1B, a relative of the Foxa gene mentioned above. Foxm1B is an important activator of the cell cycle machinery in many settings, specifically the G2 and M phases of the cell cycle. When Foxm1B is removed from hepatoblasts using total or conditional gene ablation, hepatoblast mitosis is dramatically reduced, and hypoplastic livers result [85]. The entire network of signaling pathways and their intracellular effectors operative in the hepatic bud are schematized in Fig. 13.3. It is likely that future discoveries will expand on this already complex system. For those interested in learning about this process in more detail, several recent reviews are recommended [2, 67].

Summary

In the short span of 96 h of development in the mouse, a group of unremarkable cells in the epithelial sheet of endoderm has acquired a hepatogenic program, migrated though the basement membrane to its future location, and expanded dramatically in number and mass. This nascent organ built up of hepatoblasts now forms the substrate for further differentiation events to establish the two major cell types in the liver: the hepatocyte, with its multitude of metabolic and biosynthetic functions, and the cholangiocyte, which sets up a remarkable network, the biliary tree, which allows for the secretion of essential, yet hepatotoxic bile safely out of the liver. The events that lead to the differentiation and expansion of these two cell types are discussed in the following chapters.

Chapter 14
Transcriptional Control of Hepatocyte Differentiation

Joseph Locker

Introduction

The unique gene expression that defines the hepatocyte conforms to a set of general regulatory principles. The genome encodes the programs of mature gene expression and of the preceding developmental stages. Transcription factors execute these programs by binding to specific DNA sequence motifs grouped together as promoters and enhancers. Expression of each gene therefore reflects the synergistic integration of separate regulations via individual factors. Each cell type expresses a distinctive mixture of hundreds of transcription factors. This mixture, superimposed on the epigenetic history of the cell, determines its phenotype.

As the regulator of energy storage and metabolic processing, and the major source of serum proteins, the mature liver maintains a very high level of transcription. Its function as a transcription factory, along with the size and relative homogeneity of the liver, lead to the initial discovery of important transcription factor families by liver – HNF1, FOXA (HNF3), HNF4, HNF6 (Onecut1), and C/EBP [1–7]. Once thought to be liver-specific, *liver-enriched* is a better description of these transcription factors, since all are important in other tissues.

From the beginning, it was apparent that the liver-enriched factors integrate into a hepatocyte-defining network of mutual regulation [4, 8]. Development of this concept has revealed a robust regulatory network around a central core of three factors, FOXA2, HNF4α, and C/EBP (Fig. 14.1) [9, 10]. The network factors appear sequentially during development and their persistent constitutive expression controls the adult liver phenotype. Some are required for development, while others are necessary only for expression of specific genes. Several other transcription factors function in liver development (HEX, PROX1, TBX3, XBP1, and GATA4/6) and persist in adult liver, but there is limited information about their regulation and target genes.

Evolution of Studies on Transcriptional Regulation In Liver

Research on hepatic transcription control has evolved over decades. Studies in the 1970s defined regulation of individual phenotypic genes. Research in the 1980s focused on elements from these genes, and led to characterization of most liver-enriched transcription factors. The research of the 1990s turned to mouse genetic models, progressing through transgenics, global knockouts, and liver-targeted conditional knockout. These showed the importance of regulation, but did not distinguish direct from indirect gene regulation, or direct effects on hepatocytes (cell autonomous) from those due to extracellular factors (noncell autonomous). Research in the 2000s stressed global characterization of gene expression, first by microarray characterization of mRNA abundance. This focus has now shifted to gene-specific analysis of chromatin by chromatin immunoprecipitation (ChIP), first gene-by-gene, then global detection via microarray (ChIP-on chip), and most recently, unbiased global sequencing (ChIP-Seq). Despite the exponential increase in information about gene regulation, there are still fundamental unanswered questions, particularly how individual interactions integrate into tissue specific gene control.

Binding sites for individual factors are ambiguous. This is not simply due to incomplete information. Rather, the weakened binding at sites that deviate from an optimum motif is an essential property. Weak sites are optimum for dynamic gene regulation, because they are highly sensitive to the level and affinity of transcription factors [11]. Binding sites can only be understood by their contextual relationship to neighboring sites, because the factors interact to exert *combinatorial control* of gene expression, best characterized for the β-interferon *enhanceosome* [12]. Complex transcriptional regulatory elements have been defined for several liver

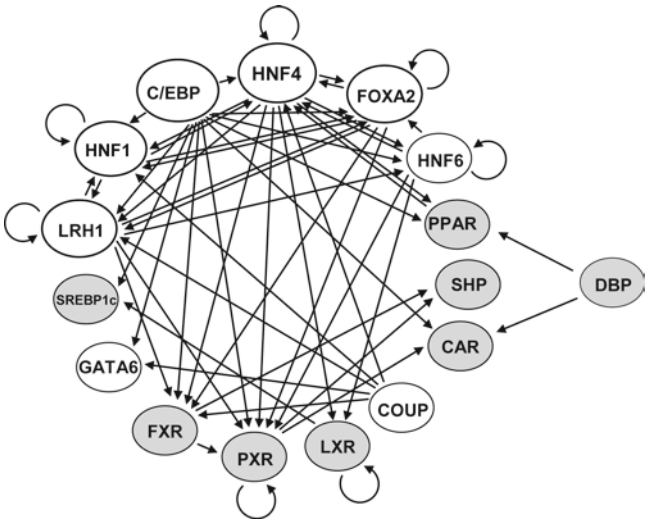

Fig. 14.1 The regulatory network of liver-enriched transcription factors in the mature hepatocyte. The figure is drawn from ChIP data, mostly from Kyrmizi et al. [9] and Odom et al. [10] and represents transcription factor binding to gene regions, not activation or repression. Factors that appear late and do not affect development are marked in *gray*. SHP and DBP are activated by the circadian factor BMAL1. The numerous potential repressive targets of SHP are not marked since no ChIP data are available (see text)

genes, notably albumin, α-fetoprotein (AFP), transthyretin, HNF4α, and phosphoenolpyruvate carboxykinase (PEPCK) [13–18]. All of these regulatory elements are bigger than the β-interferon enhanceosome – none is fully resolved.

The Transcriptional Environment in the Adult Liver

Liver Enriched Factors

Microarray studies have demonstrated that liver expresses several hundred transcription factors and the vast majority of strong detections represent hepatocytes (Fig. 14.2). Basic leucine zipper (bZIP) and nuclear receptor factors dominate the list (Tables 14.1 and 14.2).

bZIP factors combine a characteristic basic DNA-binding domain with a leucine-zipper dimerization domain. They always bind DNA as dimers, commonly as heterodimers of different members of a subfamily. C/EBP and DBP factors dimerize only within their own subfamilies, but are both abundant phenotypic regulators that frequently regulate the same genes through the common binding sites. The ATF/CREB and AP1 families generally regulate housekeeping functions through rapidly activated transcriptional responses. ATF5 and CREBH are liver-enriched, and liver regeneration strongly induces ATF3, otherwise expressed at very low levels. ATF/CREB and AP1 factors also heterodimerize with each other.

The nuclear receptors are dynamic regulators, either constitutively active or ligand dependent. Very strong expression of liver-enriched HNF4α, CAR, EAR2, PPARα, RXRα, FXR, SHP, LRH1, and PXR, dominate the mature hepatic phenotype. Other nuclear receptors prominently, but not selectively, expressed in liver are retinoic acid receptor-related orphan receptors (ROR), estrogen receptor related receptors (ERR), REV-ERB, the thyroid hormone receptors (TR), and the glucocorticoid receptor (GR). The REV-ERBs are heme receptors, but ligands for ROR and ERR are unknown. Other well-known nuclear receptors: Estrogen receptor (ER), vitamin D receptor (VDR), and retinoic acid receptors (RAR), may also be important in hepatocytes, but their expression is significantly lower.

Liver also expresses a diverse set of widely-expressed *housekeeping* factors. Some represent nonphenotypic processes like cell division or apoptosis, but many others collaborate with liver-enriched transcription factors to regulate phenotypic genes. Since various cell types express the general factors at different levels, their abundance in liver is a specific feature of hepatocyte gene regulation.

Transcriptional regulation of the liver develops through four phases:

1. Establishment of *developmental competence* before liver specification.
2. Establishment of definitive hepatic structures.
3. Constitutive regulation of the hepatocyte phenotype.
4. Dynamic gene regulation in mature liver.

Although these phases lack discrete boundaries, they provide a conceptual framework for considering individual transcription factors.

Phase 1: Prehepatic Expression and Developmental Competence

FOXA. The three *Forkhead Box A* proteins (FOXA1, A2, and A3) appear sequentially in visceral endoderm, foregut, and liver (A2, A1, then A3) with persistent expression in adult hepatocytes. They contribute to the regulation of many genes in mature liver, frequently by binding to distant enhancers. FOXA proteins are nearly global regulators in liver, because ChIP studies showed binding to thousands of genes [19, 20]. In mouse knockouts, ablation of individual FOXA genes produced only mild liver pathology with moderate changes in gene expression. However, combined deletion of FOXA1 and FOXA2 in late foregut endoderm prevented formation of the liver, while deletion after liver formation distorted genesis of the bile ducts [21]. The three FOXA proteins have subtle

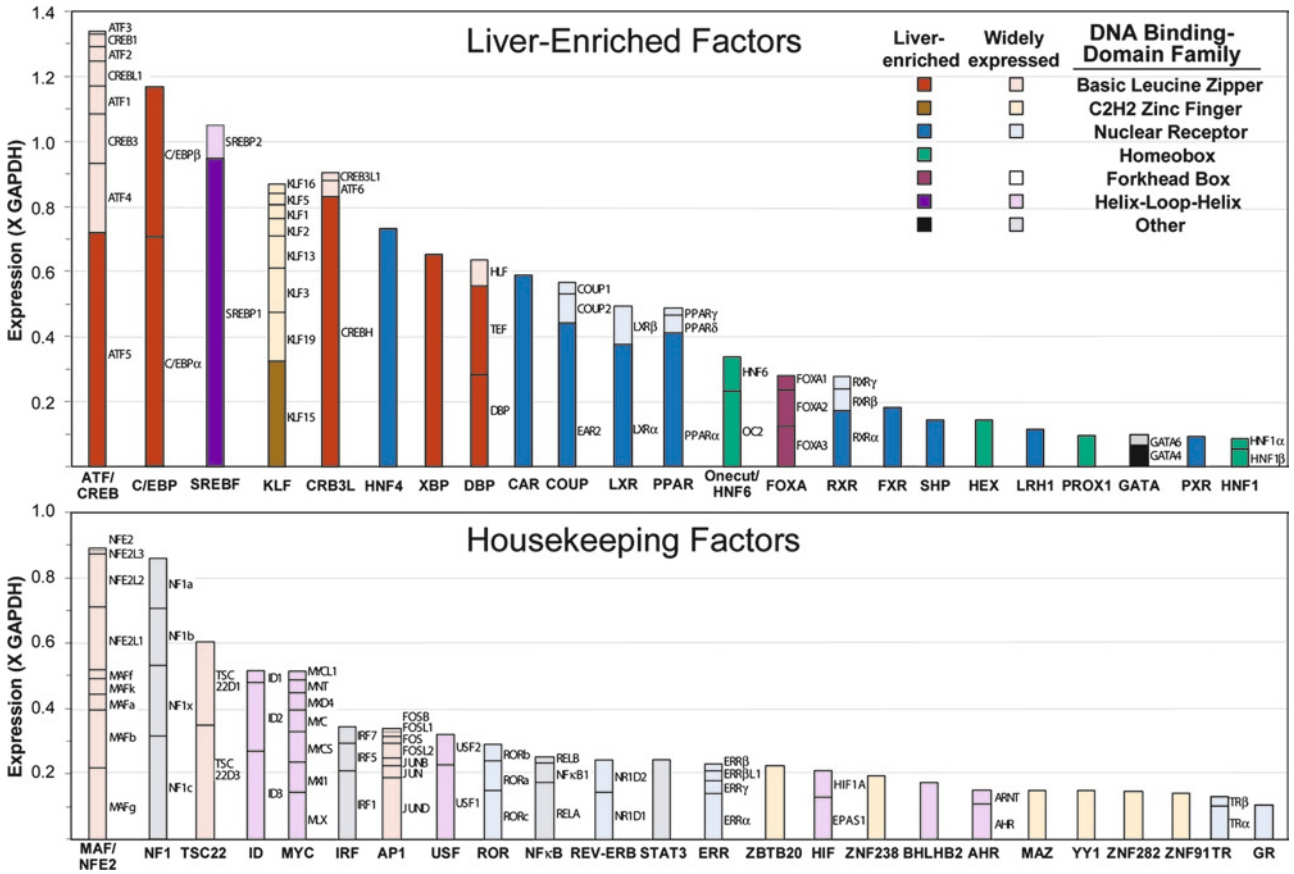

Fig. 14.2 Abundant transcription factor subfamilies in the mature liver. mRNA levels, averaged from microarrays of normal mouse liver RNA, are displayed relative to the expression of GAPDH (unpublished data). The averaging has normalized the levels of factors that show circadian variation. The arrays detect about 450 transcription factors. The 113 expressions displayed in the figure have been verified in expression databases obtained using a different array platform (www.genecards.org). Abundant factors are grouped as subfamilies with detected relatives that heterodimerize or bind equivalently to the same DNA motifs. Three factors activated by posttranslational cleavage (CREBH, ATF6, and CREB3l1) are grouped separately from other ATF/CREB factors. The liver-enriched transcription factors (above) are discussed individually in this chapter. Abundant housekeeping factors (below) are also major components of the transcriptional regulatory milieu of liver

differences in transcriptional function [22]. Such differences occur in virtually every group of seemingly equivalent factors. Nevertheless, the total expression of three similar factors provides the level of FOXA protein necessary for optimum gene regulation.

Molecular studies of the albumin gene enhancer first demonstrated distinctive transcriptional function for FOXA2 as a *pioneer factor* that binds native chromatin and reorganizes nucleosomes. Surprisingly, FOXA2 first binds to the albumin enhancer in endoderm, several cell generations before the liver formation or albumin gene expression. Indeed, the same genomic sites bind FOXD3 in embryonic stem cell, which is then replaced by FOXA2 when the cells differentiate to endoderm. FOX factors therefore establish *developmental competence* – they configure transcriptional regulatory elements for later activation during development [21, 23, 24].

HEX. In mouse, the hepatic primordium appears as a specialized region of the anterior foregut on E8.5, with hepatocyte specification marked by the appearance of albumin mRNA. Hepatoblasts then rapidly grow outward so that a distinct liver bud is apparent by E9.5. HEX, a regulatory target of FOXA2, appears at E8.5 and marks hepatic specification. Knockout models confirm the developmental importance of HEX. Global ablation selectively blocks formation of the liver [25], while targeted ablation shortly after liver bud formation arrests further development. Ablation at a later developmental stage interferes with bile duct formation [26]. Expression of HEX in the liver persists throughout life, but with few known regulatory targets, the relationship of HEX to the mature liver phenotype is unclear [27, 28]. HEX is a multifunctional protein, so it could affect development in many ways. In addition to its action as a DNA-binding transcription factor, HEX is also a coactivator or corepressor of other transcription factors, and an mRNA-binding protein that regulates their transport from the nucleus [29, 30].

GATA4/6. Two closely related zinc-finger proteins, GATA4 and 6, transcriptional activators, also appear in anterior

Table 14.1 Molecular properties of hepatocyte transcription factors

Factor	Family	Complex	Binding motif[a]	Ligand	Coactivators	Corepressors

Table 14.2 Ontogeny of hepatocyte transcription factors

Factor	Onset [1]	Peak[a]	Global knockout	Liver-specific knockout	Target genes and effects
FOXA2	Early gastrula E6.5	Adult	Embryonic lethal at E10	Mild changes in gene expression; reduced induction of gluconeogenesis	Serum proteins, metabolic enzymes; regulate enhancers [21]
FOXA1	Late gastrula E7	Adult	Early postnatal lethal; normal liver; hypoglycemia		
FOXA3	Hepatic bud, E9.5	Adult	Normal liver; mild metabolic changes		
HEX	Foregut E8.5	Adult	Embryonic lethal, fails to form liver bud	Ablation in the hepatic diverticulum blocks further liver development; ablation in fetal liver leads to defective genesis of bile ducts	HNF4α and HNF6?; coactivator, corepressor; mRNA transporter [25, 29, 35]
GATA4, GATA6	Late gastrula E7	Gastrula, early liver	Embryonic lethal, blocks expansion of hepatic bud	–	HNF4α, HEX, albumin, fatty acid binding protein [31–34]
TBX3	Liver bud, E9	Fetal liver	Embryonic lethal, forms small hepatic bud with few hepatoblasts	–	Repressor of p19ARF and other genes [36, 40]
PROX1	Hepatic bud E9	Adult	Embryonic lethal at E14.5 with small liver	–	Represses LRH1- and HNF4α-activated genes [42, 43]
HNF6, Onecut2	Hepatic bud E9	Adult	Single knockouts have little effect on liver development, but die as neonates from biliary abnormalities; double knockout is embryonic lethal with failure to expand the hepatic bud	–	Stimulates hepatoblast proliferation and migration; regulates some genes of metabolism, serum proteins; regulates biliary differentiation [37]
HNF4α	Late gastrula E7	Adult	Knockout dies during gastrulation, from defects in visceral endoderm	Knockout targeted to midgestation liver impairs growth, hepatocyte differentiation; knockout targeted to postnatal liver cause fatty liver, abolishes zonal gene expression	Metabolic regulators; HNF1α, other liver-enriched transcription factors [38, 49, 51, 52, 56]
HNF1β	Visceral endoderm E6; liver bud E9	Visceral endoderm, early liver	Early embryonic death from failure to form visceral endoderm; tetraploid rescue extends development and allows partial formation of liver bud	–	Serum proteins, metabolic enzymes [39]
HNF1α	Liver bud E9	Early liver	Normal development, with early postnatal death from metabolic defects	–	Serum proteins, metabolic enzymes, e.g., albumin, phenylalanine hydroxylase [64]
C/EBPα	Hepatic bud E9	Adult	Normal liver development; Neonates die from hypoglycemia	–	Global regulation of serum proteins, metabolic enzymes [66, 70]
C/EBPβ	Hepatic bud E9	Adult	Viable without liver pathology; impaired liver regeneration	–	
XBP1	Constitutive	Constitutive	Late embryonic death with hypoplastic liver	–	Lipogenesis, steroid synthesis, unfolded protein response [72]

CREBH	Liver bud E9	Adult	Normal liver development; impaired gluconeogenesis	–	Acute phase and ER stress response [79]
KLF15	Liver, E16	Adult	Normal liver development; impaired gluconeogenesis	–	Gluconeogenesis [86]
SREBP1c	Liver bud E9,or earlier	Adult	Normal liver development, increased cholesterol stores, high lethality	Altered feeding-fasting responses; loss of lipogenic responses mediated by LXR	Synthesis of fatty acids, triglycerides and phospholipids [87]
DBP, TEF, HLF	Postnatal day 7Fetal liver, E17 Postnatal day 0	Adult	Single knockouts have normal liver development, dampened circadian expression. Triple knockouts lose circadian expression of many genes, especially those of xenobiotic metabolism	–	Circadian expression of serum proteins, metabolic enzymes, and xenobiotic pathways [90]
LRH1 (FTF)	Fetal liver, E14	Adult	Early embryonic death from endodermal defects	Morphologically normal liver; alterations in cholesterol metabolism and bile acid homeostasis	Cholesterol transport and metabolism, and bile acid homeostasis; transcription factors SHP and FXR [101]
COUP-TF1	Embryonic liver, E11 or earlier	Liver, E11 or earlier	Embryonic death before E10; ± is viable, with altered liver expression of genes controlling lipid homeostasis	–	Lipid homeostasis; antagonizes gene activation by HNF4α and PPAR [106, 108, 109]
COUP-TF2	Embryonic liver, E11 or earlier	Liver, E11 or earlier	Perinatal lethality; liver development unremarkable; no characterization of liver gene expression	–	
EAR2	Embryonic liver, E11 or earlier	Adult	Liver unremarkable, without characterization of gene expression	–	
SHP	Postnatal day 0	Adult	Normal liver with some changes in gene expression	–	Circadian regulator of metabolic genes; antagonizes activation by HNF4α, LRH1, PPAR, CAR, PXR, LXR, FXR and possibly other nuclear receptors [111–113]
FXR	Fetal liver, E17	Adult	Normal liver with increased fat, hyperlipedemia, and reduced bile acid transport	–	Bile acid transport and metabolism, cholesterol catabolism, and lipoproteins [115, 116]
LXRα, LXRβ	Fetal liver, E18	Adult	LXRα –/– has normal liver development, hepatomegaly, fatty liver; phenotype is exacerbated in LXRα–/– LXRβ–/– double knockout	–	Genes of fatty acid and triglyceride synthesis, cholesterol uptake and its conversion to bile acids [119]

(continued)

Table 14.2 (continued)

Factor	Onset [1]	Peak[a]	Global knockout	Liver-specific knockout	Target genes and effects
PPARα	Fetal liver, E18	Adult	Normal liver, but without peroxisome proliferator response to inducing drugs; elevated serum cholesterol and lipoproteins	–	Genes of fatty acid uptake and β-oxidation; peroxisomes [121, 123]
PXR	Postnatal day 0	Adult	Normal liver, with altered drug-induced metabolic responses, and subtle changes in liver regeneration	–	CYP3A4/Cyp3a1/Cyp3a11; drug transport, Phase I, and Phase II modification [130]
CAR	Fetal liver, E16	Adult	Normal liver, with altered drug-induced metabolic and growth responses	–	CYP2B6/Cyp2b1/Cyp2b10; drug transport, Phase 1, and Phase II modification; hepatocyte proliferation [133, 134, 137]
RXRα	Preimplantation embryo	Adult	Embryonic lethal at E13.5 to E 15.5 due to cardiac defects; liver forms normally but shows reduced growth	Normal liver development; develops massive fatty liver and hyperlipedmia	A wide variety of metabolic enzymes [141]
ZHX2	Postnatal	Adult	BALBc/J has null mutation; they have normal development without liver changes	–	Partially represses AFP, GPC3, H19, and lipoprotein lipase [142]
ZBTB20	Postnatal	Adult	Normal liver; impaired glucose metabolism due to nonhepatic effects	–	Partially represses AFP [145, 146]

[a]Data from Li et al. [87] or individual sources

foregut endoderm prior to liver specification. Ablation allows hepatic specification, but blocks subsequent cell expansion. Their function is redundant, although knockout of GATA6 has a milder effect [31]. Both HNF4 and HEX are important transcriptional targets [32, 33]. Liver expression of GATA4 and 6 persist throughout life, and contribute to the expression of several proteins, including albumin and fatty acid binding protein [34].

Phase 2: Establishment of Definitive Hepatic Structures

Hepatic specification, local differentiation of single-layer foregut endoderm into hepatic progenitors occurs at the 18-somite stage embryo (mouse E 8.5), early outgrowth (psuedostratification) at 20 somites (E9.0), and a liver bud of hepatoblasts and stroma is apparent by 23 somites (E9.5) [35, 36]. Several transcription factors that appear during this interval play important roles. Loss of PROX1, TBX3, or HNF6 + OC2 blocks early liver growth [37]. HNF4α appears at about the same time, and its ablation reduces liver bud expansion [38]. HNF1β expression precedes liver specification, but is also required for expansion of the liver bud [39]. It is difficult to define an exact temporal sequence of these factors.

TBX3 knockout leads to a much smaller hepatic bud that is almost devoid of epithelial cells, with decreased expression of HNF4α and C/EBPα, and increased expression of HNF6 and HNF1β [36, 40]. However, it is not clear whether these are direct transcriptional targets of TBX3. With a T-box DNA binding domain, TBX3 binds DNA as a dimer, and acts as a transcriptional repressor. One possible mechanism of hepatic bud expansion is that TBX3 suppresses p19ARF, which is a negative regulator of cell proliferation. Only weak expression of TBX3 persists in adult liver [41].

PROX1. Effects of the PROX1-null mutation are quite similar to those of TBX3 mutation – failure of early expansion of the hepatic primordium [42, 43]. PROX1 is an activating transcription factor that persists in adult liver [44]. PROX1 also acts as a transcriptional corepressor of two liver-enriched factors, HNF4 and LRH1 [45]. As for TBX3, there is little direct knowledge of PROX1 regulatory targets, or whether its main developmental function is activation or repression.

HNF6. Like PROX1, expression of HNF6 (Onecut1, OC1) and its homologue OC2 appear in the liver bud shortly after specification. They are functionally redundant transcription factors in the Onecut family, characterized by a cut domain and an atypical homeodomain [46]. Separate inactivation of HNF6 or OC2 has little effect, but combined inactivation attenuates growth of the early liver bud [37]. High-level expression of both factors persists in mature liver, where they have been detected in the chromatin of more than 200 genes [47]. They are also critical transcriptional regulators of bile duct epithelium, and required for normal biliary differentiation [48].

HNF4α, a central regulator in the network of liver transcription factors [9, 10], has two critical developmental roles, first in formation of visceral endoderm, later in differentiation of early hepatocytes and enlargement of the liver bud [38]. High level expression persists throughout life and HNF4α regulates more than ~900 genes in mature liver [47, 49]. HNF4 is an ancient factor, highly conserved throughout metazoans, and it binds genes as a ligand-independent constitutively active homodimer [50]. Most other liver-enriched nuclear receptors evolved more recently, and they bind DNA as ligand-activated heterodimers with RXR. HNF4α is thus more fundamental and has a broader but less dynamic role in shaping the hepatic phenotype.

Long considered an *orphan* nuclear receptor, the possible ligand regulation of HNF4α has been controversial. A recent study has demonstrated that its ligand-binding domain is occupied in vivo by linoleic acid [50], an appropriate regulator since HNF4α regulates several aspects of fatty acid metabolism [51]. Even so, the function of this "ligand" is problematic, since it does not affect transcriptional activation. The binding might therefore be vestigial, left over from an earlier HNF4 that was dynamically controlled by ligand. Alternatively, other molecules related to linoleic acid, drugs or endogenous molecules, might act as *inverse agonists* that lead to repression of HNF4α targets.

HNF4α directly regulates expression of other liver-enriched transcription factors, and a broad range of metabolic proteins, mediating "reciprocal expression of fatty acid transport and metabolizing enzymes during feeding and fasting" [51]. Thus a liver-targeted HNF4α knockout has fatty liver, and HNF4α is upregulated in fasting, largely due to stimulation by PPARα.

Zonation is a well-known feature of mature liver. Centrilobular hepatocytes selectively express genes of ammonia metabolism, detoxification, glycolysis, and the TCA cycle. In contrast, genes of gluconeogenesis and urea formation show periportal expression. Many zonal genes are direct regulatory targets of HNF4α and its knockout causes periportal gene expressions to spread over the whole lobule [52]. β-catenin signaling also controls zonal expression, activated via Wnt peptides that originate from vascular endothelium of the central vein [53]. While β-catenin itself is not a transcription factor, it functions instead as a latent transcriptional coactivator. Wnt signaling induces dephosphorylation and release from cytoplasmic complexes, allowing β-catenin to translocate to the hepatocyte nucleus [54]. In the nucleus, β-catenin binds and coactivates the four TCF/LEF transcription factors to mediate canonical Wnt responses [55].

Liver expresses low, constitutive levels of all four factors: LEF1 (TCF1α), TCF1 (TCF7), TCF3 (TCF7L1), and TCF4 (TCF7L2). The zonal relationship between Wnt and HNF4α is complex. Where Wnt signaling is strong, β-catenin-LEF1 displaces HNF4α from selected binding sites near the promoters of zonally regulated genes [56]. In the context of these genes, weakly activating HNF4α is replaced by strongly activating β-catenin-LEF1.

Expressed at high levels in liver throughout development, β-catenin is nevertheless a critical developmental regulator of the liver, since its selective depletion in fetal hepatoblasts is lethal. A specific defect in hepatocyte maturation leads to decreased proliferation and a hypoplastic liver [57, 58]. Wnt/β-catenin signaling also has a major role in bile duct differentiation, which is inhibited by β-catenin depletion and accelerated by exogenous Wnt3a [57, 59]. Thus, Wnt signaling through β-catenin has a multitude of effects on hepatocyte proliferation, differentiation, and zonal gene expression in the mature liver. Most of the specific TCF/LEF target genes that mediate these processes are unresolved.

HNF1. Despite their lower abundance, the HNF1 transcription factors were among the first liver-enriched transcription factors to be discovered [1, 3, 60], presumably because of the high site-specific affinity of these dimeric factors. HNF1α and β have nearly identical DNA binding and dimerization domains, which are a distinctive fusion of a homeodomain and part of a POU domain [61]. Rigorously defined as an inverted repeat dimer, GTTAAT N ATTAAC, the binding site motif accommodates either homo- or heterodimers, and typically occurs near promoter regions of genes encoding serum proteins and metabolic enzymes. Almost 200 target genes are apparent in ChIP-Chip studies [47, 62]. During development, HNF1 expression is regulated by HNF4α, and in mature liver, HNF1α regulates expression of several liver-enriched transcription factors, including HNF4α, FOXA2, LRH1, and FXRα.

Early endoderm expresses HNF1β, well before liver formation, and HNF1α appears with liver specification. HNF1β is more critical, because the knockout fails to form visceral endoderm. Tetraploid rescue allows development to continue, but these embryos form only an attenuated hepatic bud [39]. HNF1α knockout has milder phenotype, with normal liver development, but impaired expression of some hepatic genes. The postnatal absence of phenylalanine hydroxylase results in phenylketonuria and early death [63, 64].

Both HNF1α and β are transcriptional activators, but their activation domains differ. Moreover, studies of the albumin and VDP genes have suggested that HNF1α distinctively regulates interactions between promoters and distant enhancers [13, 65].

Phase 3: Establishment of a Constitutive Phenotype

C/EBP. Two closely related bZIP factors, C/EBPα and β, become highly expressed in the liver bud, although C/EBPβ expression is more widespread [66]. The two C/EBPs, both activators, recognize identical DNA motifs, bind DNA as homo- or heterodimers, and function equivalently to activate a large number of liver genes [67, 68]. C/EBPα and β are among the most abundant of all transcription factors in liver, and contribute to the transcriptional activation of many genes. However, C/EBP has relaxed site specificity so that binding motif occur every 200–300 bp within the genome [69]. This has made identification of functional sites very difficult.

Mice with ablation of either gene have normal liver development, but reduced expression of many genes. C/EBPα–/– neonates die from hypoglycemia due to reduced expression of glycogen synthase, glucose-6-phosphatase, and PEPCK [70]. C/EBPβ–/– mice survive with more subtle metabolic defects, but have impaired liver regeneration [68]. Despite similar activation function, C/EBPα distinctively inhibits cell proliferation, by binding and inhibiting Cdk2 and Cdk4, or by binding E2F [71]. Hepatocytes apparently compensate for this inhibition by reducing C/EBPα and increasing C/EBPβ during liver regeneration [68]. Both proteins have short inhibitory isoforms, resulting from translational initiation at internal AUG codons [67]. Since the short isoforms are present at significantly lower levels than the full-length isoforms, their regulatory function is probably subtle.

XBP1. Although its function overlaps with CREB-ATF and AP1 factors, XBP1 is in a special category because its knockout impairs hepatic development. The so-called *X-box binding protein*, XBP1, is a bZIP transcription factor primarily known for its function in B-cells. However, XBP1–/– fetuses die in late gestation with hypoplastic livers. Consistent strong expression is apparent at all stages, but liver expresses more than most other tissues, and XBP1 directly regulates genes of lipogenesis and steroid synthesis. Like several ATF/CREB transcription factors, XBP1 mediates the unfolded protein response, binding as a homodimer on the unfolded protein response element (UPRE) motif, TGACGTGG. The motif is similar to ATF/CREB binding sites [72].

An unusual posttranscriptional regulation controls XBP1-mediated activation of the unfolded protein response. IRE1, a specialized mRNA splicing enzyme found in endoplasmic reticulum (ER) controls the relative levels of two isoforms [73]. Unspliced mRNA encodes XBP1u, a repressing isoform that binds response elements, but lacks an activation domain. ER stress activates latent IRE1, which splices out a small RNA segment to frame-shift the distal part of XBP1 mRNA. The new translation product is the active transcription factor, XBP1s. It displaces XBP1u from binding sites to stimulate target genes.

Phase 4: Dynamic Gene Regulation in the Mature Liver

Stress-responsive bZIP factors. In addition to XBP1, liver prominently expresses three bZIP families: ATF/CREB [74], AP1 [75], and Maf/NFE2 [76] associated with stress responses, carbohydrate metabolism, and fatty acid oxidation [77–79]. Many are inducible factors, regulated by diverse mechanisms of gene transcription (AP1, ATF3), controlled mRNA splicing (XBP1), controlled translation (ATF5), proteolytic activation of latent protein (CREBH, ATF6), or induced phosphorylation (CREB1, 3). The unusually high level of several mRNAs in this group probably reflects these mechanisms of induction, to provide large pools of mRNA for induced splicing or translation, or of latent protein for induced cleavage. The pools allow repeated induction by weak signals. CREB (*cAMP response element binding*) factors mediate cAMP responses, especially stimulation of gluconeogenesis and fatty acid oxidation in liver. The optimum ATF/CREB binding site is TGAC GTCA, an inverted repeat of 4-base motifs that each contact one subunit of the dimer. Induced high-level expression may activate target genes with weaker binding sites, or modulate responsiveness to cAMP by replacement of CREB with ATF [80]. AP1 factors bind DNA as obligate heterodimers, e.g., JUN + FOS, on a shorter motif, TGACTCA. This motif also has two 4-base half sites, but in this case, the half sites overlap at the central base. AP1 factors also heterodimerize with CREB-ATF factors [81]. Leucine zipper factors in the Maf/NFE2 family are also prominent in liver, but without a known relationship to hepatic phenotypes. Maf factors form heterodimers on a larger motif, TGCTGANYCNGNN, that contains an AP1 site (underlined), and therefore share common regulatory targets with AP1 [76].

Transcription of AP1 factors is induced by mitogens, cytokines, injury, etc. They activate dynamic responses in liver and other tissues, including cell proliferation. Quiescent liver has particularly strong expression of JUND, but the significance of this expression is unclear, since the JUND knockout mouse is viable, without apparent liver abnormality [82].

The high abundance of CREBH mRNA stands out among liver-enriched transcription factors. CREBH is a regulatory target of HNF4, and its expression is prominent from late gestation. However, CREBH−/− mice are viable without liver pathology [79]. Gene regulation by CREBH is controlled posttranslationally by regulated intramembrane proteolysis (RIP). Latent CREBH localizes to ER, and RIP is activated by ER stress, e.g., treatment with tunicamycin. RIP liberates an active transcription factor that relocates to the nucleus, where it activates genes of the unfolded protein and acute phase responses.

ATF5 is another strongly expressed liver-enriched factor. Fasting stimulates transcription of ATF5 mRNA, but the main regulation is posttranscriptional, in response to ER stress, oxidative stress, or proteasome inhibition. ATF5 mRNA contains upstream region that normally blocks translation of the ATF5 reading frame. However, stress induces phosphorylation of translation initiation factor, eIF2, which then selectively activates translation from the ATF5 initiation site [80, 83].

ATF3, a mediator of different stress responses is present at low levels in quiescent liver, but strongly induced by partial hepatectomy or endotoxin treatment. In this case, however, ATF3 is a transcriptional repressor, so induction blocks responsiveness to cAMP, and may dampen activation by factors like ATF5 or CREBH [84].

KLF15. *Kruppel-like factor 15* is a prominent liver-enriched transcription factor that first appears in late gestation. Proteins in this family have C2H2 zinc fingers that bind a CACCC binding site motif [85]. Although KLF15 is the most prominent, liver also expresses several other members of this family that may have redundant or competitive function on the same binding motifs.

Dynamically increased by food deprivation and reduced by feeding, KLF15 regulates genes of glucose transport and gluconeogenesis. The KLF15−/− mouse has no pathological changes in mature liver, but lacks fasting-induced gluconeogenesis. Thus KLF15 is an important metabolic regulator [86].

SREBP1, perhaps the most abundant transcription factor in liver, has two isoforms expressed from different promoters, SREBP1a and SREBP1c. They have different activation domains, but a common basic helix-loop-helix (bHLH) domain that mediates dimerzation and DNA-binding. SREBP1c predominates and has regulated transcription, while SREBP1a is constitutively expressed at low levels [87]. Liver also expresses lower levels of SREBP2. They bind DNA as homo- and heterodimers, but with different effects: SREBP1c stimulates fatty acid synthesis, SREBP2 stimulates cholesterol synthesis, and SREBP1a stimulates both pathways equally [88]. Among gene targets, SREBP1c transcriptionally activates its own gene expression, a *feed-forward* stimulatory mechanism.

Transcription of SREBP1c is directly stimulated by LXR, indirectly stimulated by insulin, and repressed by glucagon [87]. However, most active regulation is via unique post-translational controls that respond to intracellular cholesterol. Latent SREBPs are bound to ER, and their activation is controlled by three proteins, SCAP, S1P, and S2P. With cholesterol depletion, SCAP transports SREBP1c to the Golgi complex, where endopeptidases S1P and S2P progressively release an N-terminal region. This cleaved N-terminal peptide is a complete transcription factor, a nuclear-localizing transcriptional activator. As for CREBH, the requirement for a pool of latent SREBP1c may explain the unusually high transcript levels.

SREBP2–/– germline knockout is embryonic lethal, while SREBP1 knockouts are viable with increased liver cholesterol and decreased fatty acid synthesis. Moreover, liver specific knockouts of SCAP and S1P have reduced synthesis of cholesterol and fatty acids, via strong downregulation of SREBP target genes [89]. In addition to regulation by LXR, SREBP1c integrates into the hepatocyte transcriptional network as a direct repressor of HNF4α.

PAR-domain proteins and circadian gene expression. Three proteins, DBP, TEF, and HLF, comprise a subfamily of bZIP factors with an additional PAR (proline and amino acid rich) domain [90]. PAR-domain factors bind DNA as homo- and heterodimers, and are prominent regulators in mature liver. The prototype, DBP, was first discovered by its binding at the D-site of the albumin promoter, which also strongly binds C/EBP. Indeed, the DNA binding domains of DBP and C/EBP differ by only one amino acid, a substitution that makes DBP binding about 20X more selective [69]. Thus PAR factors generally augment transcriptional stimulation at a subset of C/EBP sites, to regulate high level expression of serum proteins and metabolic enzymes. Because the genes encoding CAR and PPARα are direct regulatory targets, PAR factors preferentially activate genes of xenobiotic metabolism.

DBP and TEF are functionally redundant; simple and compound knockouts show additive losses of gene expression [90]. Both factors appear late with full expression only in mature liver [91, 92], where they control circadian gene expression. Indeed, the daily amplitude of both DBP and TEF mRNA is greater than 100-fold, causing, e.g. a tenfold variation in the levels of nascent albumin mRNA. DBP levels typically begin to rise at 2 p.m., reach maximal levels at 8 p.m., and decline sharply during the night [93, 94].

PAR factor transcription is circadian, in a pattern controlled by neuronal and humeral signals from the suprachiasmatic nucleus of the hypothalamus. In response to daylight, these signals stimulate expression of three PAS-family bHLH transcription factors, BMAL1 (ARNTL), and its heterodimeric partners CLOCK and NPAS2. Their dimers bind to E-box motifs of the DBP gene to stimulate its transcription [95]. The gene activation phase of the circadian cycle is terminated by other targets of BMAL1, corepressive proteins Cryptochrome (CRY1), and Period (PER1 and 3), which form inactivating complexes with BMAL1 heterodimers. Another pair of PAS-bHLH factors, the aryl hydrocarbon receptor (AHR) and its dimeric partner, ARNT, may regulate through the same E-boxes. Thus, xenobiotic compounds that activate AHR can override circadian regulation [96].

Nuclear receptors. In addition to HNF4, several nuclear receptors are important phenotypic regulators of mature liver. They do not have critical roles during development, but function as dynamic ligand-activated regulators. Most form heterodimers with a common partner, RXR. With limited exceptions, they all act through similar mechanisms, binding corepressors NCOR1 and SMRT (NCOR2) when unliganded, and p160 coactivators SRC1 (NCOA1), GRIP1 (NCOA2), and ACTR (NCOA3) in the presence of ligand. Some shuttle between cytoplasm and nucleus, also controlled by ligand. Multiple isoforms are typical and have subtle differences in ligand affinity. Their ligands are either endogenous products of metabolic pathways, or xenobiotic compounds. In addition to phenotypic regulation, three receptors, CAR, TR, and PPARα, stimulate hepatocyte proliferation in rodents. Some receptors, LXR and PPARγ, also function as coregulators of other transcription factors, particularly to suppress inflammatory responses [97], but the following discussion will consider only direct gene regulation in hepatocytes.

The late-appearing nuclear receptors can be divided into three overlapping groups: LXR, FXR, PPAR, and LRH1 regulate lipid, cholesterol, and bile metabolism; PXR and CAR regulate metabolism of xenobiotic compounds; RXR, SHP, and COUP are global regulators, binding partners or modulators of other nuclear receptors. The nuclear receptors transcriptionally regulate each other and thus integrate into the hepatocyte regulatory network of transcription factors [9, 98, 99].

With the exception of LRH1, the nuclear receptors bind DNA as dimers, with each subunit contacting a specific half-site motif. The half sites are usually arranged as imperfect direct repeats (DR) or inverted repeats (IR), separated by 0–5 base pairs. As for all transcription factors, binding tolerates wide variation in the motifs, and some flexible dimers may accommodate variable spacing between the half sites. Thus, the motifs are conventions with limited predictive value. They do not readily discriminate the binding of different receptors. DR4 (e.g., AGGTCA NNNN AGGTCA) describes the binding of RXR-CAR, RXR-PXR, RXR-LXR, and RXR-TR dimers, but there is limited overlap among their regulatory targets.

LRH1 (NR5A2) is an unusual nuclear receptor because it binds DNA as a monomer on an extended motif, YCAAGGYCR [100, 101]. Initially found in liver as a regulator of AFP (*fetoprotein transcription factor*, FTF) [102], LRH1 is well integrated into the hepatic transcription factor regulatory network of mature liver, stimulated by both C/EBP, FOXA2, HNF1 and HNF4α, and a stimulator of FXR, PXR, and HNF1 [9]. Knockout mutant embryos have defective visceral endoderm and die before liver formation. In contrast, liver-targeted knockout has a mild phenotype, morphologically normal liver with impaired expression of genes that regulate cholesterol and bile acid metabolism [101].

Various phospholipids can bind LRH1 within the ligand-binding domain, and stimulate transcriptional activation [103], but their relationship to metabolic regulation is unclear. LRH1 can form heterodimers with the incomplete nuclear receptor, SHP, which leads to repression of LRH1-target genes [104]. PROX1, itself a transcription factor, also acts as a corepressor of LRH1 [105].

COUP. Liver expresses three nuclear receptors in the *COUP/NR2F subfamily:* EAR2 (NR2F6), COUP-TF2 (ARP, NR2F2), and COUP-TF1 (EAR3, NR2F1). EAR2, strongly expressed, is liver enriched [106], although most studies have focused on COUP-TF1 and -TF2. All three are most strongly expressed in early liver, but persist at lower levels throughout life. They bind DNA as homodimers on DR1 sites, but can also heterodimerize with RXR and probably with each other [107]. COUP-TF1–/– mutation causes embryonic death before E10. COUP-TF1+/– heterozygotes have moderate changes in liver gene expression and are resistant to steatosis induced by a high fat diet [108]. The COUP-TF2–/– mouse dies perinatally, and the EAR2 –/– mutant is viable without obvious liver abnormalities, though they lack characterization of liver gene expression or metabolic responses [106, 109].

The physiological ligands are not known [107] and the COUP effects on liver gene expression are generally repressive, suggesting activity of unliganded receptors. COUP dimers inhibit gene expression by competing for DR1 sites with HNF4α, RXR-PPAR, and RXR-RXR dimers [110]. Within the hepatocyte regulatory network, COUP acts directly on regulatory elements of HNF4α, HNF1α, HNF6, and LRH1 genes [9].

SHP (small heterodimeric partner, NR0B2), is an unusual nuclear receptor because it does not have an N-terminal DNA-binding domain [104, 111, 112]. No activating ligands are known, and unliganded SHP acts as a repressor by two different mechanisms. First, SHP is a dimeric partner of LRH1, and the LRH1-SHP dimer is strongly repressive [104]. Second, SHP has LXXLL motifs that typify coactivators, not nuclear receptors. These allow SHP to compete for coactivator binding sites, and leads to repression, since SHP recruits corepressors after binding. By this mechanism, SHP can corepress HNF4α, PPAR, LXR, CAR, and FXR [111, 112]. Moreover, FXR and PXR induce SHP expression, and thus induce negative feed-back to dampen their activation of target genes. In normal liver, SHP shows significant circadian expression as a direct transcriptional target of BMAL1. SHP therefore imposes circadian modulation to both constitutive and inducible genes [113].

FXR. The so-called Farnesoid X receptor (NR1H4) is actually a receptor of bile acids, especially chenodeoxycholic acid and its derivatives. FXR generally binds DNA as a heterodimer with RXR on an IR1 binding motif. Farnesoids and retinoids also activate, but only at high nonphysiological levels [114].

Expression appears in liver near the end of gestation. FXR knockouts have normal liver development, but develop moderate fatty liver and hyperlipedemia [115, 116]. The livers have marked changes in gene expression: reduced expression of bile acid transporters, apolipoproteins, and genes of carbohydrate and amino acid metabolism. FXR is therefore a critical regulator of cholesterol catabolism, controlled by the level of bile acids. Within the hepatocyte transcription factor network, FXR is the regulatory target of HNF1, HNF4, Foxa, and LRH1, and in turn activates expression of SHP and PXR [9, 114, 117].

In addition to activation of target genes, FXR represses other genes, notably cholesterol 7-α-hydroxylase gene (CYP7A1), which encodes the rate-limiting enzyme in bile acid synthesis. In this case, the negative regulation is indirect. LRH1 activates CYP7A1 transcription. FXR stimulates expression of SHP, which binds LRH1 and converts activation to repression [118].

LXR. The *Liver X receptors* — liver-enriched LXRα (NR1H3) and widely-expressed LXRβ (NR1H2) — balance the metabolic effects of FXR [119]. LXR, when liganded by oxidized cholesterol derivatives, directly stimulates genes of fatty acid and triglyceride synthesis, cholesterol uptake and its conversion to bile acids. LXR also suppresses genes of gluconeogenesis by an indirect mechanism. Mice with knockouts of LXRα, LXRβ, and double mutants, are all viable with normal liver development [119]. The LXRα–/– develops an enlarged fatty liver, and double knockout exacerbates this phenotype. LXRα stimulates its own transcription by a feed-forward mechanism [120], and integrates into the hepatocyte transcriptional network via stimulation by HNF4α and HNF6 [10].

PPAR. The *Peroxisome Proliferator Activated Receptor* has three isoforms – PPARα (NR1C1), PPARβ/δ (NR1C2), and PPARγ (NR1C3). All are present in liver, but PPARα dominates. PPARα was originally characterized as a drug receptor that regulated a striking response of hepatomegaly with massive accumulation of peroxisomes, accompanied by hypolipedemia. Regulatory target genes include acyl CoA oxidase (ACOX), other components of the peroxisomal fatty acid β-oxidation pathway, and genes regulating fatty acid uptake [121]. PPAR have unusually large ligand-binding pockets that bind diverse ligands including various unsaturated fatty acids, eicosanoids, and clofibrate drugs. The ligand specificity of PPARγ, significantly diverged from PPARα, includes the thiazolidinedione drugs [122]. The PPARα–/– mouse completely loses the pathological responses to PPARα-specific ligands [123]. However, PPARβ and γ are functional in liver, because high doses of drugs specific for β or γ can induce peroxisome proliferation in PPARα–/– mice [124]. Thus, the main difference among the three isoforms is ligand specificity, not DNA binding or target gene selection.

The crystal structure of PPARγ-RXRα dimer is distinctive. Its polarity with RXR is reversed compared to other nuclear receptor heterodimers. The PPARγ subunit is 5' to RXR, each sitting on a half site within a DR1 motif. Also, PPARγ has a C-terminal extension of its DNA binding domain that contacts additional bases 5' to the first half site. These features are conserved in PPARα and β [125].

In addition to its effects on phenotypic genes, PPARα also stimulates a proliferative response in rodent liver. The effect is very significant, since prolonged stimulation leads to hepatocellular carcinoma. PPARα ligands are thus *nongenotoxic carcinogens*, but an elegant study showed that the effect is embodied in rodent but not human PPAR. The PPARα–/– mouse was "humanized" by incorporation of a transgene encoding human PPARα. The human and mouse genes vary at only a few amino acids, and activate an identical set of phenotypic target genes in response to activating ligand. However, human PPARα does not induce the proliferative response [123].

PXR. Another nuclear receptor, PXR (NR1I2), functions primarily as a receptor of xenobiotic compounds [126], although the toxic bile acid, lithocholate, is an endogenous ligand [127]. The induced genes metabolize lithocholate and a wide variety of drugs [128]. Liganded PXR dimerizes with RXR on DR4 binding motifs [129], and the prototype target gene in human is *CYP3A4* (= mouse *Cyp3a11*, rat *Cyp3a1*). Other activations include genes expressing Phase I and II drug metabolizers and drug transporters [130]. The DNA binding domain, and hence target gene specificity, is highly conserved. In contrast, the ligand-binding domain has significantly diverged so many activating ligands are species-specific. Thus, the standard experimental ligand, pregnenolone-16α-carbonitrile (PCN) activates mouse, but not human PXR, while rifampicin has the opposite specificity [126]. The PXR–/– mouse is essentially normal, but with slight impairment of regenerative and injury responses [131]. A human PXR transgene has been incorporated into the PXR–/– mouse, to create a valuable model with humanized drug responses [128].

CAR (NR1I3), the so-called *Constitutive Androstane Receptor*, is another xenobiotic receptor that heterodimerizes with RXR on DR4 binding sites [132]. The classical CAR-responsive gene is human *CYP2B6* (= rat *Cyp2b1*, mouse *Cyp2b10*), a relationship revealed by the response to phenobarbital [132, 133]. CAR mediates detoxification responses by activating numerous genes — p450 cytochromes, sulfotransferases, and transporters — in response to a wide range of ligands. As for PXR, there is divergence of affinity for specific ligands among species, while DNA binding is highly conserved. Beyond its spectrum of gene regulation, CAR has distinctive features compared to other nuclear receptors. Due to the altered structure of the Helix 12 segment of its ligand-binding domain, CAR is a constitutive transcriptional activator in the absence of ligand. Nevertheless, gene responses are inducible because CAR, normally cytoplasmic, migrates to the nucleus when liganded. There are added complexities because phenobarbital, the prototype CAR activator, induces translocation by an unknown mechanism without actually binding as a ligand. In addition, certain compounds, for example, androstanol, are *inverse agonists* that bind to CAR and cause it to become repressive [134].

CAR activates a strong proliferative response in hepatocytes, another distinctive feature. As a consequence, CAR activators like phenobarbital or the mouse-specific ligand, 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene (TCPOBOP) are powerful tumor promoters. These drugs induce liver hyperplasia via a set of gene responses that differs significantly from the compensatory proliferation of liver regeneration [135, 136]. Despite its cancer-inducing potential, CAR-induced growth is presumably an adaptive response that rapidly increases the liver's ability to detoxify injurious compounds. However, CAR is dispensable for normal development and liver function [137].

RXR. Three *Retinoid X Receptor* isoforms: RXRα (NR2B1), RXRβ (NR2B2), and RXRγ (NR2B3), bind DNA as the heterodimeric partners of many nuclear receptors [138]. Among these, RXRα is a liver-enriched transcription factor, not surprising, because of the important metabolic functions of its partners in the hepatocyte. Despite its abundance, however, there is no obvious regulation of RXRα expression by factors in the hepatocyte transcription factor network.

RXRs also homodimerize on DR1 binding sites, with a specific activating ligand, 9-cis retinoic acid [138]. It is difficult to discriminate the direct the targets of RXR-RXR dimers, because 9-cis retinoic acid also activates RXR within *permissive* heterodimers (e.g., RXR-CAR, RXR-PXR, RXR-LXR, RXR-PPAR, and RXR-TR) to increase stimulation of their target genes [139]. Without ligand, RXR generally acts as a passive partner in heterodimers [140].

RXRα knockout is developmentally lethal because of cardiac defects, but a hepatocyte-specific RXR knockout is viable. This mouse develops extreme fatty liver and hyperlipidemia, indicating the importance of RXR as the dimeric partner of numerous factors that regulate lipid metabolism [141].

Repression and the Oncofetal Paradigm

This chapter has portrayed liver development as the progressive acquisition of activating transcription factors. An opposite paradigm developed from studies of AFP, a serum protein that appears during early liver development. AFP reappears in liver cancer and is thus the prototype *oncofetal protein*. This pattern of expression has led to two influential concepts – that development requires repression of fetal or embryonic properties, and that carcinogenesis is a reawakening of these properties. In the adult phenotype, the repressed AFP gene is different from many other nonexpressed genes because dynamic regulation continues via binding of transcription factors and recruitment of corepressors [15]. Nevertheless, the reason for AFP repression is unknown, since persistent expression has no detrimental effects. Three other genes share

the oncofetal expression pattern – Glypican 3 (GPC3), the microRNA precursor H19, and lipoprotein lipase [142–144]. They have limited developmental or oncogenic activity, and recent global studies of gene expression have not significantly enlarged the set of oncofetal proteins in liver.

The repression of AFP is complex and at least four different repressive mechanisms contribute. The first is repression by ZHX2, previously known as AFP repressor 1 (Afr1). Part of an unusual family of transcription factors that have two C2H2 zinc fingers and five homeodomains, it is unclear whether ZHX2 acts as a DNA-binding repressor, or as a corepressor that binds other transcription factors. Many tissues express low levels, but liver expression of ZHX2 is exclusively postnatal. BALB/cJ mice have moderate persistent expression of AFP and GPC3, because this strain carries an inactive gene due to an insertional mutation. BALB/cJ is therefore a naturally-occurring ZHX2-null mutant. C3H mice carry a permissive allele of a second repressive gene, Afr2, which allows persistent AFP expression after liver regeneration [142]. Neither the ZHX2-null mutant nor the permissive allele of Afr2 are associated with developmental abnormalities or liver pathology.

ZBTB20 (DPZF), a third AFP repressor, is a C2H2 zinc finger transcription factor selectively expressed by mature liver. ZBTB20 binds near the AFP gene promoter and a knockout mouse has clear derepression of AFP, although other changes in liver gene expression are nonphenotypic. The knockout has normal development and no liver pathology, but the mice die by 12 weeks. Introduction of a liver-specific ZBTB20 transgene repressed AFP and reversed some other changes in gene expression, but did not rescue the lethality [145, 146]. The major effects of ZBTB20 are therefore nonhepatic.

A final repressive mechanism targets LRH1. This strong positive regulator of AFP [102] is converted to a transcriptional repressor by binding either SHP [104] or PROX1 [45], both abundantly expressed in adult liver.

Beyond the repressive activities that regulate AFP, many other repressors activities modulate liver gene expression. Phenotype-specific repression centers on nuclear receptors, since many are repressive when unliganded. Moreover, SHP and PROX1 are repressing partners or corepressors. Several dynamic housekeeping factors prominent in liver (Fig. 14.2) modulate between repression and activation. For example, repressing NFκB1 (p50) homodimers alternate with activating NFκB1-RELA (p50-p65) heterodimers. The abundance of several zinc-finger proteins that are homologs of known repressors (ZNF238, ZNF92, Z91) also suggest nonphenotypic repression, although their specific gene targets are unresolved. Finally, liver expresses high levels of ID1–3, incomplete bHLH factors that dimerize with and antagonize many activators in this important transcription factor family. The inability to generalize developmental, phenotypic, or pathological mechanisms from the specialized postnatal regulation of AFP is a major disappointment. Instead, most repression dynamically targets individual genes.

Closing

The hepatocyte is a synthetic factory of serum proteins, and appearance of these proteins is synonymous with the early phenotypic development of the liver. This serum-protein defined phenotype depends on a constitutive network of mutually regulated transcription factors, FOXA, C/EBP, HNF1, HNF4, and HNF6, but these always collaborate with housekeeping transcription factors. Beyond their mutual regulation, the early expression of these factors must be driven by HEX and other direct developmental regulators. After birth, the hepatocyte becomes a primary regulator of lipid, carbohydrate and amino acid metabolism, bile synthesis, and detoxification. The enzymes that regulate these processes gradually appear during late gestation after the liver has formed, or even during postnatal maturation. Expression of these metabolic regulators is largely controlled by a new network of nuclear receptor transcription factors (FXR, LXR, PXR, CAR, PPAR, and RXR) that collaborate with the constitutive network. The essential characteristic of these new regulators is that they are dynamic, modulating from repression to activation in response to hormonal, metabolic, and xenobiotic signals. With full maturity, the dynamic regulation becomes integrated into a circadian physiological pattern by DBP/TEF, factors regulated by signals from the central nervous system.

Although this formidable list of transcription factors explains many aspects of liver development and function, the presentation in this chapter has simplified or omitted a number of important issues. One is the complex function of individual factors. Each selectively recruits coactivators and corepressors after they bind to the DNA. These coregulators are part of the machinery of transcriptional regulation, but few are cell specific.

Transcription factors respond to regulatory information that is encoded in the genome, but progress on deciphering this information is limited. Even for well-studied factors, the deduced binding motifs have considerable ambiguity. More important, even the most efficient binding motifs occur widely, and most do not regulate gene expression. The true regulatory sites, often hard to recognize, are clustered with binding sites for other transcription factors. The clustering enables the factors to synergize. The synergy is mediated by cooperative binding of factors to each, cooperative modification of local DNA structure, and cooperative recruitment of coregulators by multiple transcription factors. New research has also revealed another type of factor interaction, a *scripted*

sequence of bindings. The prototype is FOXA binding as a *pioneer factor* to native chromatin, which causes local remodeling of histones to allow eventual binding by a second factor. These interactions will eventually define the language of liver gene expression. It is this language, not individual transcription factors, that makes the liver unique.

Chapter 15
Bile Duct Development and Biliary Differentiation

Frederic P. Lemaigre

Introduction

Bile is excreted by the hepatocytes in the bile canaliculi and flows via the canals of Hering into the intrahepatic bile ducts. See Chap. 1 for more details on liver anatomy. The latter drain the bile to the intestine via the extrahepatic biliary tract, which consists of hepatic ducts, cystic duct, gallbladder, and common bile duct. All segments of the biliary tract are delineated by cholangiocytes, a specialized epithelial cell type that modifies the composition of the bile when it transits through the ducts. An independent chapter describing biliary epithelial cells is included in the textbook (see Chap. 4). Within the liver, the biliary tree forms a branched network in which the ducts are classified with respect to the lobular architecture into ductules and interlobular ducts [1]; an alternative view which takes the functional heterogeneity of the cholangiocytes into account classifies the bile ducts according to their size [2–4].

The cholangiocytes that line the intrahepatic and extrahepatic biliary tracts have different embryonic origins: Intrahepatic biliary cells derive from hepatic precursor cells, extrahepatic cholangiocytes derive directly from the endoderm. Development of the intrahepatic ducts has been intensively investigated at the molecular level, leading to significant improvement of our understanding of the molecular circuitry involved in biliary differentiation and morphogenesis. However, no mechanism has yet been identified that differentiates the development of the large vs. small ducts or of subsegments of the intrahepatic biliary tree. Nor is it clear how ramification of the ducts is programmed. Development of the extrahepatic ducts is even less well understood, and due to their proximity with the ventral pancreatic buds, they have mainly been studied in parallel with the development of the pancreas. In this chapter, we will discuss the mechanisms of cholangiocyte differentiation and of intra- and extrahepatic duct formation with the aim to provide a basis for understanding biliary dysgenesis and dysfunction in human disease.

Development of the Intrahepatic Bile Ducts

Markers of Cholangiocyte Differentiation

The earliest morphological sign of liver development is a thickening of the endoderm on the ventral wall of the gut. This is detectable in the human embryo around the 18th day of gestation, and in the mouse embryo around embryonic day (E) 8.5. Slightly later, the gut forms a diverticulum at the level of this thickening and so generates a liver bud mainly composed of hepatic precursor cells. For more details on liver development, please see Chap. 13. The hepatic precursor cells sprout from the liver bud, invade the septum transversum mesenchyme and interact with the vasculature to progressively form the liver parenchyma [5, 6]. These cells are also called hepatoblasts and based on their gene expression profile are considered to be the progenitors of the hepatocytes and intrahepatic cholangiocytes [7–9]. Although this view of a common origin of the two cell types dates back more than two decades and has since been further supported by numerous morphological and molecular evidences, a rigorous in vivo genetic lineage tracing has not yet been performed. Despite this limitation, the hypothesis that intrahepatic ducts may be formed by ingrowth of the extrahepatic ducts (reference [10], cited in [9]) is no longer considered and the differentiation of intrahepatic cholangiocytes will be discussed in this chapter as resulting from a lineage choice of hepatoblasts.

Biliary development in human and rodent liver starts with the expression of cholangiocyte markers in hepatoblasts adjacent to the mesenchyme surrounding the branches

S.P.S. Monga (ed.), *Molecular Pathology of Liver Diseases*, Molecular Pathology Library 5,
DOI 10.1007/978-1-4419-7107-4_15, © Springer Science+Business Media, LLC 2011

of the portal vein. The identification of cholangiocytes is based upon the expression of specific marker proteins, among which biliary-specific cytokeratins (CK) were long considered as the most useful. In human liver, the earliest hepatoblasts express CK8, 18, and 19. When they give rise to cholangiocytes, the expression of CK19 increases in cholangiocytes, but becomes extinguished in hepatocytes, whereas the expression of CK8 and 18 persists in both cell types. At a later stage, CK7 becomes specifically expressed in the duct cells [11, 12]. In mouse and rat liver, CK19 is absent from hepatoblasts and is only detectable in cholangiocytes albeit with some technical difficulties in early cholangiocytes owing to antibody and sample preparation procedures [13]. The fact that CK19 is not cholangiocyte-specific in humans and the observation that its detection is sometimes difficult in rodent cholangiocytes [13] has prompted the search for early and more specific biliary markers. The recent identification of SRY-related HMG box transcription factor 9 (Sox9) as a biliary marker, opens new perspectives. This transcription factor is detected in periportal hepatic cells starting at E11.5 and remains restricted to biliary cells, except in CC14-injured liver in which Sox9 is also detected in activated stellate cells [14, 15]. Another cholangiocyte marker, osteopontin, becomes expressed slightly later than Sox9 and is also useful to characterize early biliary development [14]. Several other proteins are used as markers of cholangiocyte differentiation. These include γ-glutamyl transpeptidase IV (rat) or VI (mouse and human) [16], connexin 43 [17], integrin β 4 [18], or binding proteins for *Dolichos biflorus* agglutinin [19]; they are either expressed in hepatoblasts and are less specific to biliary cells than Sox9, or were only described at a late stage of biliary development.

Biliary Cells Differentiate Near the Portal Vein

The observation that cholangiocyte differentiation takes place near the portal mesenchyme prompted the search for localized mechanisms that drive differentiation of hepatoblasts to cholangiocytes. In recent years, Activin/Transforming Growth Factor beta (TGFβ) and Notch signaling were found to match the criteria for local inducers of cholangiocyte differentiation. To learn more about Notch and TGFβ signaling cascade, please see Chap. 20. The TGFβ ligands, ActivinA, TGFβ2, and TGFβ3, are predominantly expressed in the periportal mesenchyme, and they bind to differentiating cholangiocytes. TGFβ signaling is strongly active in the periportal region, as shown by the periportal expression of green fluorescent protein in a mouse line that expresses this protein under control of a TGFβ-responsive promoter. In addition, treating cultured liver explants or hepatoblast lines with TGFβ triggers differentiation of hepatoblasts to cholangiocytes, and perturbation of vtion [14, 20, 21].

Notch signaling has been suspected for a long time to regulate the initiation of biliary differentiation. This assumption was based on genetic studies, which identified mutations in Notch signaling components as the cause of Alagille syndrome, a polymalformative disease in which patients are affected with bile duct paucity (OMIM #118450 and #610205). Indeed, mutations in the ligand Jagged-1 and in the receptor Notch2 were identified [22–24], prompting several teams to investigate the involvement of these two proteins in bile duct development. A first issue was to determine which cell types express Notch signaling components in developing and adult liver, and Loomes et al. summarized the often controversial data on this topic [25]. This set of data, the recent immunostainings using Jagged-1 antibodies and the analysis of mice expressing a reporter gene under control of Notch2 regulatory sequences, suggest that Notch2 is expressed in differentiating cholangiocytes, whereas Jagged-1 is found in the periportal mesenchyme [26, 27]. This explains in part how Notch signaling may restrict biliary development to the periportal area. However, Jagged-1 is also expressed in the developing cholangiocytes [27], indicating that cell-autonomous activities of Notch signaling may contribute to cholangiocyte differentiation. Periportal mesenchymal cells constitute a heterogenous cell population and it is not yet determined with accuracy which mesenchymal cells express Jagged-1, except for a recent report indicating that a subset of mesenchymal cells characterized by expression of the p75 neurotrophin receptor also coexpress Jagged-1 [28].

Beyond the analysis of the expression pattern of Notch signaling components, several animal models were investigated to address the function of this pathway. These include the zebrafish [29] and several mouse models that are deficient in Jagged-1, Notch1, Notch2, or combinations thereof [26, 30, 31]. Although the study of these animal models provided compelling evidence for a role of Notch in duct formation, it did not support the notion that Notch signaling controls the initiation of cholangiocyte differentiation, most likely as a result from redundant functions of the various Notch ligands and receptors. However, this potential redundancy was recently bypassed by inactivating Recombination Signal-Binding Protein 1 for J-κ (RBP-Jκ [(καππα)]), a common mediator of Notch signaling. The results revealed that when Notch signaling is inhibited, the number of hepatoblasts differentiating to the cholangiocyte lineage is strongly reduced (27), thereby demonstrating that Notch signaling is required to initiate biliary differentiation. Moreover, when the intracellular domain of Notch, which is cleaved from the Notch receptor upon stimulation by Jagged-1 is overexpressed in liver, it can induce hepatoblasts to differentiate to biliary-like cells [27, 32].

There is also strong evidence for an involvement of other signaling pathways in cholangiocyte differentiation, but in contrast to Notch and TGFβ, these other pathways are not known to contribute to the periportal location of the differentiation process. Wnt signaling has attracted much attention and is now known to play key roles at all stages of liver development [33]. To learn more about Wnt/β-catenin signaling, please see Chap. 20. It is particularly difficult to unravel, given the high number of ligands and receptors expressed in liver, and the involvement of Wnt in a variety of cellular events such as proliferation, apoptosis, and differentiation. A key role for Wnt signaling in biliary differentiation was initially suggested in experiments in which treatment of liver explants with antisense to β-catenin led to absence of ck-19-positive cells and treatment with Wnt3a induced biliary differentiation [34, 35]. This interpretation was later supported by the analysis of mouse mutants in which the activity of the Wnt mediator β-catenin was either inhibited or stabilized: Inactivation of β-catenin by a Cre-loxP-mediated gene targeting approach resulted in multiple liver defects including duct paucity [36], and enhanced activity of β-catenin mediated by depletion of Adenomatosis Polyposis Coli was associated with increased biliary development [37]. The combination of these gain- and loss-of-function approaches suggests that Wnt signaling promotes cholangiocyte differentiation, but it remains unknown, which ligands and receptors participate in vivo in this process.

Finally, a role for the fibroblast growth factor (FGF) and bone morphogenetic protein (BMP) pathways in intrahepatic biliary development has recently been proposed. Using the chick liver as experimental model, it was shown that FGF-2 and FGF-7 synergize with BMP-4 and extracellular matrix components to promote differentiation of hepatoblasts to biliary cells [38]. Interestingly, in parallel experiments with mice, it was shown that the BMP mediator Smad5 is predominantly expressed in the periportal area [39], thereby suggesting one more mechanism to restrict biliary differentiation around the vicinity of the portal vein.

Transcriptional Network Initiating Intrahepatic Biliary Differentiation

Whereas cell–cell signaling mechanisms are essential to ensure that biliary cells are located near the portal vein, cell intrinsic cues must determine how the cholangiocytes acquire their specific properties. Transcription factors stand out in this process and it is not surprising that most of the available information derives from the phenotypic analysis of transcription factor-deficient mouse livers. Hepatocyte nuclear factor-6 (HNF-6), also called Onecut-1, was the first transcription factor shown to control biliary differentiation. It is expressed in hepatoblasts starting at the onset of liver development, and is maintained in hepatocytes and cholangiocytes, with highest levels in the cholangiocytes. In its absence in HNF-6 knockout mice, the expression of biliary markers is initiated prematurely, and periportal hepatoblasts display "hepatobiliary" features, i.e., they coexpress hepatocyte and biliary markers. Onecut-2 (OC-2), a paralog of HNF-6, is redundant to HNF-6, and double HNF-6/OC-2 knockouts display an even stronger phenotype in which not only the periportal hepatoblasts, but all the hepatic epithelial cells appear as hybrid hepatobiliary cells [20, 40]. This phenotype results from a severe perturbation of TGFβ signaling. Indeed, in the double HNF-6/OC-2 knockouts, the activity of the Activin/TGFβ pathway extends further in the parenchyma as compared with wild-type livers, leading to the interpretation that the hepatobiliary phenotype results from a superposition of a TGFβ-induced biliary program on the hepatocyte program. In other words, HNF-6 and OC-2 control biliary differentiation by adjusting TGFβ signaling to appropriate levels; this may occur via a control exerted on the expression of the TGFβ receptor type II (TβRII) and of the Activin/TGFβ inhibitor follistatin [20]. In parallel with its regulation of TGFβ signaling, HNF-6 was also shown to stimulate HNF-1β, another regulator of biliary development [40, 41]. Finally, the role of HNF-6 is conserved in other species. Knockdown of the functional ortholog of HNF-6 in zebrafish (ZfOnecut-3) resulted in fewer and poorly organized ducts and ectopic expression of biliary cytokeratin in the parenchyma [42].

Since HNF-6 and HNF-1β were the first factors identified as transcriptional regulators of biliary differentiation, subsequent studies of transcription factor-deficient mice usually investigated HNF-6 and HNF-1β expression, leading to the somewhat biased view that the cascade linking the two factors is central in the biliary transcriptional network. Taking this remark into consideration, it is still possible to draw a model of this network (Fig. 15.1).

The Notch intracellular domain is a transcriptional coregulator, which represses differentiation of isolated hepatoblasts towards hepatocytes, but promotes induction of the biliary markers CK19, CK7, HNF-6, and HNF-1β [43]. Interestingly, the intracellular domain of Notch, when associated with RBP-Jκ(καππα), binds to the Sox9 gene. These data further extend the notion that the initiation of biliary differentiation is marked by the expression of Sox9 and that Notch signaling contributes to this process. The zinc-finger transcription factor Sa114 has similar effects as Notch: When it is overexpressed in isolated hepatoblasts, it represses hepatocyte differentiation and enhances biliary differentiation [44]. This most likely occurs via the stimulation of Notch signaling, since both Jagged-1 and Notch2 are induced in the cultured cells. Other regulators of biliary marker expression

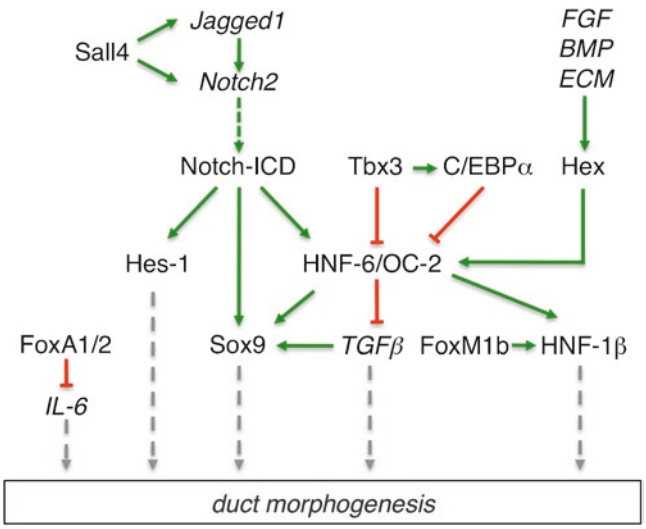

Fig. 15.1 Transcriptional network regulating biliary differentiation and bile duct morphogenesis. Transcriptional regulatory cascades are indicated, with *green arrows* referring to stimulatory interactions and *red bars* to inhibitions. Terms in *italics* are signaling factors or mediators

are the hematopoietically expressed homeobox factor (Hhex) and the forkhead box factor (Fox), FoxM1B. In Hhex knockouts, biliary differentiation is abnormal, and HNF-6 and HNF-1β expression is deficient [45], while in FoxM1B-deficient livers no cholangiocytes are detected [46].

Transcription factors that exert a negative regulation on biliary differentiation have also been identified. The T-box transcription factor 3 (Tbx3) represses HNF-6 and HNF-1β, and it stimulates hepatocyte differentiation. This regulation is somewhat peculiar. Indeed, Tbx3 knockout mice display a premature increase in the expression of HNF-6 and HNF-1β in the earliest hepatoblasts (E9.5) [47]. Therefore, Tbx3 may regulate the timing of differentiation. However, the mode of action of Tbx3 seems very dynamic. Indeed, at a slightly later stage (E12.5), cultured hepatoblasts in which Tbx3 is repressed continue to display increased expression of the biliary markers CK19 and CK7. However, unlike at E9.5, this effect is dependent on $p19^{Arf}$. In wild-type cells, at E12.5, Tbx3 normally represses $p19^{Arf}$ and in that way stimulates hepatocyte differentiation at the expense of biliary differentiation [48]. Interestingly, Tbx3 also initiates a forward negative loop by stimulating the expression of CCAAT/Enhancer Binding Protein alpha (C/EBPα), the latter being known as a repressor of HNF-6 and HNF-1β [49].

Importantly, this transcriptional network only provides the core of gene regulations, but it does not explain how specific biliary functions, such as polarity markers or ion transporters, are induced. This results from the limited number of differentiation genes that were identified as targets of the various transcription factors. The TGFβ receptor type II and the Activin/TGFβ inhibitor, follistatin, have been mentioned above as targets of HNF-6 and OC-2 [20]. Moreover, Sox9 and Hes-1 are targets of HNF-6 and of Notch signaling, respectively, and are transcriptional regulators of duct morphogenesis [14, 27, 50].

Intrahepatic Bile Duct Morphogenesis: A Multistep Process

In parallel to differentiation, cholangiocytes must organize to form ducts. This occurs according to a multistep process that is unique in many ways as illustrated in Fig. 15.2. During the initial morphogenic event, the differentiating cholangiocytes line up around the periportal mesenchyme, thereby forming a single-layered ring of cells called the "ductal plate." The cells that form the ductal plate are cholangiocyte precursors, which are partly polarized i.e., they have a basal pole that is separated from the mesenchyme by a basal lamina, but they have not yet acquired typical apical markers.

In the following stage, cells that display characteristics of hepatoblasts associate with specific areas of the ductal plate; they remain separated from the ductal plate by a lumen and so constitute asymmetrical ducts with the cholangiocyte precursors. These ducts are called primitive ductal structures (PDS), and are considered radially asymmetrical because they are lined on the portal side by cholangiocyte precursors and on the parenchymal side by hepatoblasts [14]. The PDS can be identified using a combination of markers: The cholangiocyte precursors on the portal side express Sox9, Jagged-1 and high levels of E-cadherin, whereas the hepatoblasts on the parenchymal side express HNF-4, TβRII, and lower levels of E-cadherin. Polarization of the cells progresses when the PDS are formed. As soon as a lumen is detectable, all the cells develop tight junctions and express osteopontin at the apical pole. Interestingly, the in vivo data are consistent with the idea that PDS develop by apposition of hepatoblasts to the ductal plate cholangiocytes. However, in an attempt to reconstitute tubulogenesis in vitro, it was shown that this process may be initiated by migration of cells of the single-layered ductal plate [51]. Cells grown in between two layers of extracellular matrix acquire ductal plate cell characteristics and form a monolayer; some cells then depolarize and move upwards to constitute a second layer followed by repolarization and delineation of a lumen. Whether this model faithfully recapitulates in vivo tubulogenesis still needs to be confirmed.

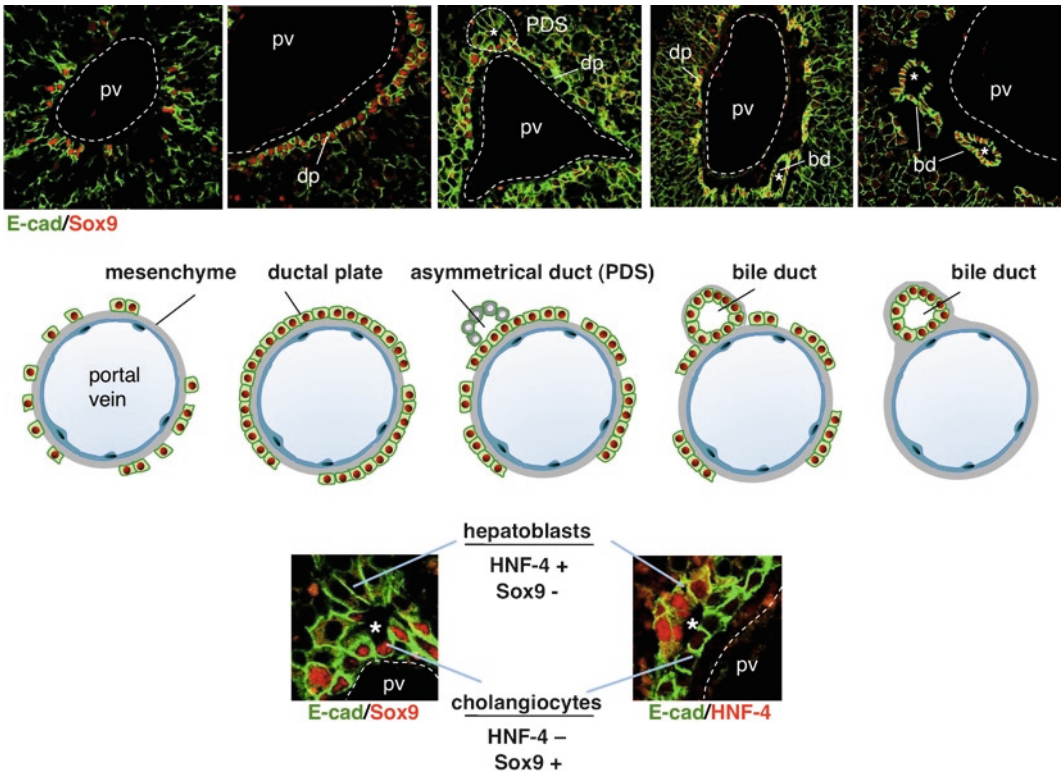

Fig. 15.2 Morphogenesis of the intrahepatic bile ducts. The *upper panels* illustrate the sequential stages of bile duct development on sections immunostained to detect E-cadherin (*green*) and Sox9 (*red*) which are strongly expressed in the cholangiocytes. The *middle panels* show a schematical representation of the corresponding *upper panels*. The *lower panels* illustrate the asymmetrical stage at which the primitive ductal structures (PDS) are lined on the parenchymal side by HNF-4-expressing hepatoblasts, and on the portal side by Sox9-expressing cholangiocytes. *bd* bile duct; *dp* ductal plate; *pv* portal vein

Beyond the stage of PDS, the forming tubules develop into mature and radially symmetrical ducts. The hepatoblasts on the parenchymal side repress the expression of the hepatoblast markers and acquire expression of cholangiocyte markers; all cells become fully polarized as indicated by the baso-lateral location of E-cadherin and the formation of a complete basal lamina surrounding the duct. Eventually the ducts are radially symmetrical as they are entirely lined by cholangiocytes.

During the formation of the PDS and their maturation in ducts, the ductal plate cells not involved in ductogenesis are eliminated, a process called "ductal plate remodeling." How this takes place is not well understood. It has been proposed that apoptosis contributes to the regression of the ductal plate in humans [52]. However, in mice, no obvious sign of apoptosis could be detected (unpublished). In addition, in the light of recent knowledge on the asymmetrical mode of biliary tubulogenesis, it is surprising that the apoptotic cells shown in human liver seem to correspond to the portal layer of PDS [52]; these cells are not those expected to be eliminated during ductal plate remodeling. Therefore, there is most likely a need to re-evaluate the fate of ductal plate cells in developing liver.

In the next step of duct morphogenesis, the periportal mesenchyme encircles the bile ducts. This step is often referred to as the "incorporation stage," but its mechanism is poorly understood. It could result from migration of the ducts in the portal mesenchyme, or of proliferation of mesenchymal cells around the ducts, or both. Duct migration would require that matrix proteinases are secreted by cholangiocytes and two studies indeed report that this is the case [53, 54].

Whereas the paragraphs above describe how a duct structure is formed, they do not explain how the ducts grow. In the prenatal period in mice, duct growth essentially results from differentiation of cholangiocytes and maturation of PDS. Duct development progresses from the hilum to the periphery of the lobes and this explains why in developing liver all stages of duct maturation can be found within a liver lobe. At the end of gestation, the number of proliferating cholangiocytes increases, indicating that further duct extension in length and diameter also depends on proliferation.

When duct development is terminated, the cholangiocytes become mitotically quiescent.

Cell-Cell Signaling and Intrahepatic Bile Duct Development

The two signaling pathways that have been best characterized at the cholangiocyte differentiation stage are also involved in tubulogenesis. Indeed, beyond the stage of ductal plate formation, Notch and TGFβ signaling remain important for duct morphogenesis.

Jagged-1 expression in developing ducts is first restricted to the cells located on the portal side of the PDS. However, when these structures mature to form radially symmetrical ducts, Jagged-1 expression becomes detectable in all cholangiocytes [27]. From a functional point of view, elegant studies in which Notch signaling was inhibited by temporal-specific Cre-mediated ablation of RBP-Jκ(καππα) indicated that this signaling pathway is required both for differentiation and tubulogenesis [27]. These data extended earlier findings in which the Notch-induced gene Hes-1 was shown to be required for duct formation. In Hes-1 knockout mice, the ductal plate develops normally, but no PDS can be detected [50]. In addition, mice deficient in Jagged-1 and Notch2 showed abnormal bile duct formation [26, 30, 31].

TGFβ signaling promotes differentiation of hepatoblasts to cholangiocytes and was therefore a good candidate to regulate the maturation of PDS into symmetrical ducts. The analysis of TGFβ signaling in the PDS revealed unexpected features, whereas the cholangiocytes of the single-layered ductal plate express TβRII, this receptor is repressed in cholangiocytes on the portal side of the PDS. The hepatoblasts on the parenchymal side of the PDS maintain TβRII expression until they have matured to cholangiocytes [14]. Interestingly, in mice with inactivation of Sox9, duct maturation is delayed and this is associated with prolonged expression of TβRII in PDS [14]. Therefore, based on the expression of TβRII, it is suggested that TGFβ signaling plays a dynamic role during duct maturation.

Other signaling pathways were considered when investigating bile duct morphogenesis, but these studies were performed before the notion of transient asymmetry became known. Much effort has been devoted to understand the role of extracellular matrix components, which may control duct development by interacting with integrins expressed by the cholangiocytes. The latter express a specific and complex set of laminin receptors, namely integrins α(αλπα)6β1,α 2β1,α 3β1, and α6β4 [18]. The demonstration that growth of hepatoblasts in a laminin gel can induce differentiation and polarization of the cells as well as lumen formation further supports the role of laminin [55]. Tenascin, another extracellular matrix constituent, is detected in the vicinity of ducts, only at the stage when they become surrounded by mesenchyme. This suggests that tenascin may play a role at this specific stage of biliary development [56].

In the phase of duct extension, it is likely that cell–cell signaling regulates cholangiocyte proliferation. Extracellular factors involved in cholangiocyte proliferation were in most cases identified in experimental models in which proliferation was induced by cholestasis, leaving open the question of their involvement in normal cholangiocyte proliferation [57]. However, cholangiocytes proliferate in response to Insulin-like growth factor-1, growth hormone, estrogen, histamine, and Interleukin-6 (IL-6), suggesting that these factors participate in normal duct extension [58–60]. At the intracellular level, the cAMP-, phosphatidylinositol-3-kinase- and Ca^{2+}-regulated pathways control proliferation (reviewed in [2, 57]).

Gene Regulation and Intrahepatic Bile Duct Development

The phenotypic analysis of mice knockout for the transcription factors HNF-6 and HNF-1β not only revealed differentiation anomalies, they also suggested that these factors regulate duct morphogenesis. Mice with a liver deficient in either of the two factors show abnormal cyst-like biliary structures and persistence of biliary cells, which are not involved in tubulogenesis. The latter phenomenon is very similar to human DPM [40, 41]. Gene targets of HNF-6 and HNF-1β have not yet been identified, with the exception that the HNF-1β gene contains HNF-6 binding sites and is stimulated by HNF-6 in vivo and in transfection experiments. Sox9 is required for proper timing of duct maturation and is also downstream of HNF-6, but it is unknown if this regulation is direct or indirect [14]. In other organs, HNF-6 and HNF-1β were found to regulate genes that are involved in polycystic diseases. Indeed, in the pancreas, HNF-6 stimulates *Cys1* and *Pkhd1,* and in kidney, HNF-1β controls the expression of *Ift88/Tg737/Polaris, Pkd2,* and *Pkhd1* [61, 62]. Although it is not yet known if HNF-6 and HNF-1β target the same genes in cholangiocytes, it is tempting to speculate that they do so.

Since HNF-6 and HNF-1β were the first transcription factors shown to regulate bile duct morphogenesis, most subsequent studies included the analysis of their expression. This showed that mice deficient in C/EBPα, which have ductal plate-like malformations, overexpress HNF-6 and HNF-1β in the abormal biliary cells [49]. Interestingly, in Hhex knockout livers, HNF-6 expression in hepatoblasts is reduced

only when *Hhex* has been deleted at the earliest stage of liver development. However, when the *Hhex* gene is inactivated at later stages, HNF-6 expression seems normal despite that biliary cells develop cystic structures; the latter are lined by a mixed cell population comprising hepatobiliary cells of which many fail to express HNF-1β [45]. These data can be integrated into the model describing transcriptional regulation of bile duct development (Fig. 15.1). However, since differentiation and morphogenesis are tightly linked, it is often unclear if a specific transcription factor is a regulator of differentiation or tubulogenesis, or both. This is further illustrated by the functional analysis of the transcription factor Sa114, which when overexpressed in hepatoblasts grown on Matrigel, stimulates differentiation and induces formation of bile duct like structures [44].

As indicated above, bile duct development is terminated when cholangiocytes stop proliferating. This proliferation arrest is critically dependent on the presence of the transcription factors FoxA1 and FoxA2 [60]. By using a conditional gene deletion approach, it was shown that in the absence of these factors, the cholangiocytes continue to proliferate and generate hyperplastic bile ducts. To induce proliferation arrest, FoxA1 and FoxA2 normally recruit the glucocorticoid receptor to the IL-6 gene promoter, and this results in repression of IL-6 production. In contrast, in the absence of FoxA1 and FoxA2, the hormone receptor cannot bind to the IL-6 gene and is replaced by nuclear factor καππα-light-chain-enhancer of activated B cells (NF-κ(καππα)B), a positive regulator of IL-6. In that case, overexpression of IL-6 stimulates proliferation of cholangiocytes, leading to biliary hyperplasia.

Finally, whereas most efforts have been devoted to the study of transcriptional regulation of duct morphogenesis, recent work addressed the importance of posttranscriptional regulation of duct development by microRNAs. Liver-specific ablation of Dicer, which results in the inhibition of synthesis of all miRNAs, did not reveal an involvement of miRNAs in biliary development. However, in these experiments microRNA depletion only occurred after birth, thereby precluding any analysis of duct development [63, 64]. In contrast, using a knockdown approach in zebrafish, it was found that miR-30a and miR-30c, two microRNAs specifically expressed in developing bile ducts, are necessary for normal biliary development. Although the exact mode of action of these two microRNAs is not known, it is supected that they regulate duct development by targeting the mRNAs coding for the Epidermal Growth Factor receptor and Activin A, which control cholangiocyte proliferation and differentiation, respectively [65]. A further function of miRNAs in duct development has been found when studying the miR23b miRNA cluster. Inhibition of miR-23b miRNAs during differentiation of a cultured liver stem-cell line, promoted expression of biliary genes and of the TGFβ mediators Smads, whereas ectopic expression of miR-23b during biliary differentiation of the stem cells had the opposite effect. These data indicate that tight regulation of miR-23b is required for development of the ducts [66]. Finally, a role for microRNAs in cholangiocyte proliferation has also been uncovered: miR-15a represses the cdc25 mRNA, and this results in repression of proliferation [67].

Development of the Extrahepatic Biliary Tract

Much less is known about the development of the extrahepatic biliary tract, as compared with the intrahepatic ducts. The extrahepatic biliary tract develops from a diverticulum located at the ventral part of the liver. This part has often been referred to as pars cystica, to distinguish it from the liver bud, which is then referred to as pars hepatica. The extrahepatic biliary tract grows in length and develops into a gallbladder, cystic duct, and common bile duct. Their lumen is lined by cholangiocytes derived from the endoderm, whereas the outer layers derive from the mesenchyme. The hepatic ducts develop from the liver bud (pars hepatica) and anastome with the rest of the extrahepatic biliary tract (reviewed in [9]).

The extrahepatic biliary tract develops in the neighborhood of the ventral pancreas. Importantly, the relationship between the two organs extends beyond their anatomical location. Indeed, genes involved in pancreas development also impact on extrahepatic bile duct development. This is the case for Hes-1, which controls endocrine development in the pancreas and prevents extrahepatic cholangiocytes from differentiating into pancreatic tissue [68, 69]. Similarly, the pancreatic and duodenal homeobox factor-1 (Pdx-1) is required for development of the pancreatic bud, as well as for differentiation of mucin-producing cells and peribiliary glands in the extrahepatic ducts [70]. Also, Hhex is required for ventral pancreas organogenesis and epithelial morphogenesis of the liver bud, and in its absence the extrahepatic ducts are replaced by duodenal-like tissue [45].

During development of the extrahepatic ducts, the mesenchyme condenses around the epithelium, suggesting that this process is regulated by molecular interactions between the epithelium and the mesenchyme. This hypothesis is substantiated by observations revealing that the absence of the epithelial factors HNF-6 or HNF-1β and the haploinsufficiency of the mesenchymal transcription factor FoxF1 are associated with gallbladder and common bile duct dysgenesis [40, 41, 71]. Moreover, during gallbladder and cystic duct elongation, the orphan leucine-rich repeat-containing G protein-coupled receptor 4 (LGR4) is expressed in the epithelium; at later stages it is found in the mesenchyme. In hypomorphic *Lgr4* mutant mice, the gallbladder and cystic ducts are absent, again pointing to possible mesenchyme–epithelium interactions [72].

Lessons from Developmental Diseases of the Biliary Tract

The understanding of biliary development not only relies on basic science, but also on a thorough analysis of the mechanisms that are dysfunctional in human diseases. Providing a complete overview of the hereditary and developmental diseases of the biliary tract goes beyond the scope of this chapter, and we refer to reviews that address this issue [73–76]. However, some important conclusions were drawn about normal development based on the analysis of human disease.

Bile Duct Paucity

Bile duct paucity, also called "ductopenia," may be a manifestation of abnormal biliary development. The Alagille syndrome, which results from defective Notch signaling, is a good illustration of ductopenia. However, whereas studies in mice concluded that Notch signaling is required for biliary differentiation and duct formation, the analysis of patient biopsies revealed in some cases that the bile duct/portal tract ratio decreases with age [77]. In line with this, a patient showed normal ducts near the liver hilum, but ductopenia was observed at the periphery of the lobes [78]. Since there was no sign of bile duct destruction, these observations suggest that in humans, the Notch pathway may be involved in elongation and branching of the ducts, two processes which are still poorly characterized at the molecular level.

Deficient HNF-1β/TCF2 function was recently identified in humans as another rare cause of ductopenia [79]. The patient showed bile duct paucity, which is somewhat in contrast to mouse *Hnf1b* knockout livers in which bile duct paucity occurs in association with bile duct dysplasia, a feature not found in the patient [41]. Therefore, the exact role of HNF-1β in biliary development deserves more investigation.

Ductopenia is also observed in patients with "Arthrogryposis-Renal dysfunction and Cholestasis syndrome." This syndrome is associated with mutations in the *VPS33B* gene, a regulator of vesicular membrane fusion which interacts with SNARE proteins [80]. Therefore, intracellular trafficking is essential for normal biliary development. This was further investigated at the genetic level in zebrafish, in which knockdown of *vps33b* leads to duct paucity, and in which the expression of VPS33B was shown to be stimulated by the HNF6/HNF1β cascade [81]. The data on VPS33b in humans prompted the search for other vps genes linked with biliary development. In zebrafish again, it was shown that *vps18* is required for normal duct development, since zebrafish deficient in this gene develop cholestasis as a result from bile duct paucity and bile canalicular defects [82].

Ciliopathies

In a number of diseases, bile ducts are present but develop abnormally. This is the case in autosomal dominant polycystic kidney disease (ADPKD), in which hepatic biliary cysts may develop in parallel with renal cysts. Biliary cysts are characterized by cholangiocyte hyperproliferation, and this results from increased sensitivity to estrogens and Insulin-like growth factor-1 [83]. This in turn induces overproduction of vascular endothelial growth factor, which promotes proliferation of the cyst cholangiocytes [84]. The study of ADPKD not only uncovered a role of proliferation regulators, but it also highlighted the role of primary cilia. Indeed, *PKD1* and *PKD2,* the two genes whose mutations are associated with the disease, code for Polycystin-1 and -2, which together form a calcium channel located at the membrane of primary cilia. This and other observations brought these organelles to light in the context of polycystic diseases. Primary cilia are situated at the apical pole of the cells and play a role in osmo-, mechano-, and chemosensing [85]. In ADPKD, the cholangiocyte cilia are shorter or absent [83], and dysfunction of Polycystin-1 and -2 is associated with perturbed intracellular levels of Ca^{2+} and cAMP, two regulators of proliferation [86]. Therefore, dysfunctional cilia are associated with biliary dysgenesis and cilia must be considered to fully understand the mechanisms of biliary development.

In patients affected with autosomal recessive polycystic disease (ARPKD), the liver may show multifocal dilations of the bile ducts. The disease is associated with mutations in *PKHD1,* a gene which codes for a transmembrane protein known as polyductin or fibrocystin [87, 88]. The function of the latter is unknown, but it is located at the cilia, basal body, and apical membrane of the cholangiocytes. Development of hepatic cysts in ARPKD is, like ADPKD, dependent in part on hyperproliferation, which results from increased cAMP signaling and reduced intracellular calcium levels [89], as well as from decreased levels of miR-15a [67]. Moreover, animal models of ARPKD include the cpk and Oak Ridge polycystic kidney disease mouse models, which have mutations in the *Cys1* and *Ift88/Tg737/polaris* genes that code for proteins associated with Polycystin-1 and -2 at the primary cilia [90–92]. Therefore, the study of ARPKD opened new venues in the search for regulators of biliary development.

Importantly, not all polycystic diseases result from defects that primarily affect the cilia. Indeed, Autosomal Dominant Polycystic Liver Disease, a rare disease affecting the liver and not the kidneys, is associated with mutations in Hepatocystin and Sec63p, two proteins which are involved in glycosylation and transport of glycoproteins [93–96].

Ductal Plate Malformations

Such lesions are found in ARPKD, Jeune syndrome, congenital hepatic fibrosis, the embryonic form of biliary atresia, Caroli syndrome, as well as in Meckel–Gruber syndrome and related diseases (Joubert syndrome and nephronophthisis). DPM are defined as abnormal remodeling of the ductal plate leading to persistence of embryonic biliary structures [97]. In most cases, the genes associated with the syndrome have been identified [75, 76, 98], but often the exact function of the corresponding proteins remains elusive. Given the concept that DPM results from persistence of embryonic structures, it is likely that these genes are involved in regression of the ductal plate. Along these lines, Meckel syndrome-affected patients show DPM associated with decreased apoptosis of the ductal plate cells [99]. The Jeune syndrome-associated gene codes for IFT80, a protein regulating transport of proteins in the cilium; ARPKD was mentioned above to result from mutations in the cilium-associated protein polyductin/fibrocystin. This indicates that the phenotypic spectrum of ciliopathies extends from cyst formation to DPM and that ductal plate regression in normal conditions is controlled by cilium function.

Diseases of the Extrahepatic biliary Tract

The most common hepatobiliary disorder in children is biliary atresia, characterized by a progressive and inflammatory process that leads to sclerosing obliteration of the extrahepatic biliary tree. The fetal or syndromic form of the disease shows several organ malformations in addition to the biliary defect. These include laterality defects, such as situs inversus, suggesting that cilium-associated proteins that regulate left–right asymmetry participate in the disease process. These proteins include Inversin, Cryptic, and Zic3. *Inv* knockout mice show situs inversus and hepatobiliary defects [100], whereas mutations in *CRYPTIC* and *ZIC3* were found in patients with biliary atresia [101, 102]. In addition, when the transcriptome of livers from patients with the fetal form of biliary atresia was compared with that from patients suffering from the nonsyndromic form of biliary atresia, it was found that the laterality genes *SPROUTY4, LEFTYA*, and *ZIC3* were differentially expressed in the two forms of the disease [103]. Also, when comparing normal liver with nonsyndromic biliary atresia liver, it was shown that genes regulating morphogenesis were abnormally expressed in the disease [104]. Whether these gene expression anomalies contribute to the pathogenesis of biliary atresia, remains to be determined.

Finally, the study of rare familial cases of choledocal cysts is expected to provide insight into the mechanisms of extrahepatic biliary development. In this case, clinical work may also benefit from the recent identification of the neurofibromatosis type 2 (*NF2)* gene as a regulator of common bile duct development. Indeed, a mutant zebrafish screen uncovered that *Nf2* mutants develop gallbladder and choledocal cysts, in association with cystic intrahepatic ducts [82].

Conclusions

In recent years, rapid progress has characterized the field of biliary development. An increasing number of regulators have been identified, leading to a better understanding of human disease. In the opposite direction, knowledge gained from the analysis of patients has considerably fed the research on normal biliary development. Such a fertile dialog between basic research and clinical science – "from bench to bedside" and from "bedside to bench" – is obviously the best guarantee for future progress.

Chapter 16
Hepatic Progenitors in Development and Transplantation

David A. Shafritz, Michael Oertel, and Mariana D. Dabeva

High Regenerative Potential of the Liver

The rationale for studies to repopulate the liver with transplanted cells is essentially based on three observations: (1) The well-known finding that the liver can fully regenerate after acute hepatotoxic injury or surgical reduction in liver mass, (2) the regenerated liver functions normally, without long-term impairment, and (3) a unique portal (venous to venous) circulation exists in the liver that provides ready access of transplanted cells to the parenchyma through the hepatic sinusoids.

In the normal adult liver, hepatocytes are in a quiescent state, turning over very slowly (only 2–3 times/year). However, in 1931, Higgins and Anderson reported that after removal of the large median and left lateral lobes of the rat liver by a simple surgical procedure (two-thirds partial hepatectomy), the remaining lobes increase rapidly and replace the lost hepatic tissue [1]. After this procedure, hepatocytes rapidly enter the cell cycle, undergo mitosis and massively proliferate (peaking between 24 and 36 h), during which 70–90% of the remaining host hepatocytes engage in DNA synthesis [2]. From these and other studies, it has been concluded that the proliferative activity of residual adult hepatocytes in the normal liver is sufficient to regenerate the parenchymal mass following two-thirds partial hepatectomy (PH) and that participation of stem cells is not required [3]. A comprehensive description of cellular and molecular events occurring during liver regeneration is presented in Chap. 18.

Role of YAP in Molecular Regulation of Liver Mass

The liver size (mass) is proportional to total body weight, ranging from 3 to 5% in different mammalian species. Since the adult liver is essentially quiescent, it is quite surprising how rapidly the liver regenerates after two thirds PH and that the liver mass returns to normal, despite the fact that the lobular architecture is permanently modified. The remaining lobes increase in size and cell number, and restore a normal liver-to-body weight ratio. This process is referred to as "compensatory hyperplasia," as there is no actual regeneration of the removed lobes. In humans, when an undersized liver is transplanted, it grows to the expected full size for the host and when an oversized liver is transplanted, it subsequently reduces in size to the appropriate mass compared to total body weight. However, until very recently, nothing was known regarding how this process is regulated.

In most interesting studies, Pan et al. [4] have shown that mammalian genes, homologous to Drosophila genes that regulate wing mass during development (members of the Drosophila Hippo kinase signaling cascade), control hepatocyte proliferation. When YAP, the mammalian counterpart to Drosophila Yorki (the last gene in the Drosophila Hippo signaling pathway), is overexpressed in a transgenic mouse model, hepatocyte proliferation becomes unchecked and there is massive liver hyperplasia, as well as hepatic carcinogenesis. When YAP hyperexpression is turned off, liver size returns to normal [4]. Similarly, knockout of the mst1 and mst2 genes that are upstream of Yap in the mammalian hippo kinase signaling cascade also leads to liver hyperplasia and tumorigenesis [171].

Yap is a transcriptional activator of many target genes and is considered to be a "tumor suppressor gene," operating through a phosphorylation/dephosphorylation mechanism. However, when this gene is hyperexpressed, it leads to cellular hyperplasia and oncogenesis. Which downstream targets of Yap either suppress or induce oncogenesis and other questions concerning how the mammalian hippo kinase signaling cascade regulates liver mass still remain to be addressed. In addition, whether Yap is a normal physiologic regulator of liver size and whether its expression or phosphorylation changes during liver regeneration also remains to be determined. Once these issues are better understood, it may be possible to modify the mammalian hippo kinase signaling cascade or use Yap to engineer hepatocytes with augmented proliferative potential that can effectively repopulate the liver.

Hepatocyte Transplantation into the Regenerating Liver

Since many genetic-based liver disorders are caused by simple dysfunction of hepatocytes without underlying liver injury, it should be possible to treat these disorders by transplantation of normal (wt) hepatocytes, This is especially true under circumstances in which replacement of a small percentage of cells would be therapeutically effective. Representative examples of such disorders include hemophilia, hyperbilirubinemia, ornithine transcarbamylase deficiency, hypercholesterolemia and phenylketonuria. In some of these disorders, cell transplantation could, in principle, also be performed under circumstances in which the patient's own cells are genetically manipulated ex vivo and then transplanted back into the liver (autologous cell transplantation). This would circumvent the need for immunosuppression and indeed this has been done, but with only temporary success [5]. In other genetic-based disorders in which there is active and continuous liver injury, such as Wilson's disease, α1-antitrypsin deficiency (P_1ZZ phenotype), and inherited hemachromatosis, these disorders could also, in principle, be alleviated by transplantation of wt hepatocytes, but this would require substantially greater levels of hepatocyte replacement. However, a major current difficulty is, only a small percentage of the total hepatocellular mass (~1–2% maximally) can be replaced by hepatocyte transplantation without causing portal hypertension and hepatic infarction. Therefore, to obtain effective cell therapy, in most instances it will be necessary to expand the cells in the host after they have been transplanted.

Attempts to increase the number of transplanted hepatocytes in the repopulated liver simply by stimulating liver regeneration (for example, through the use of PH or carbon tetrachloride (CCl_4)-induced hepatic necrosis) have generally been unsuccessful. This is not surprising, since, on an average, hepatocytes need to undergo only one or two rounds of cell division to replace all of the liver mass removed by two thirds PH [2, 6]. Both endogenous and experimentally transplanted hepatocytes should contribute equally to this limited proliferative response. Therefore, one would not expect the percentage of transplanted hepatocytes to increase significantly simply by inducing liver regeneration. Although performing repeated partial hepatectomies or cell transplantations increases the level of liver repopulation by transplanted hepatocytes, the results are quite modest [7, 8]. However, high levels of liver repopulation can be achieved with adult hepatocytes under circumstances in which there is both massive and sustained liver injury and preferential selection of transplanted cells, or under circumstances in which host hepatocytes have been rendered incapable of cellular proliferation (see below).

Special Animal Models to Repopulate the Liver by Transplanted Hepatocytes

For many years, it was thought that mature hepatocytes could undergo only 2–3 divisions after which they become terminally differentiated and are incapable of further proliferation. However, during the last decade, it has been shown in several rodent models that under specialized circumstances, hepatocytes exhibit high proliferative capability and can extensively repopulate the liver. In the first such model, Sangren et al. [9] developed a transgenic mouse in which a protease, urokinase plasminogen activator (uPA), is expressed exclusively in hepatocytes under control of the albumin promoter. This protease was supposed to be expressed exclusively on membrane-bound polyribosome of the endoplasmic reticulum and then secreted into the serum. However, small amounts of uPA remained in the liver tissue causing extensive liver injury. This led to sub-fulminant hepatic failure and death of the mice at 4–6 weeks of age. However, some mice survived and in these mice, there were nodules of normal liver tissue of varying sizes scattered throughout the hepatic parenchyma (Fig. 16.1a). This occurred by deletion of the uPA transgene from individual hepatocytes, which then expanded clonally into large clusters and replaced damaged tissue. Subsequently, Rhim et al. [10] transplanted normal hepatocytes, marked with a β-galactosidase transgene, into uPA mice and observed extensive liver repopulation (Fig. 16.1b). They estimated that, on average, each transplanted hepatocyte that had engrafted into the uPA host liver underwent ~12–14 cell divisions [10].

Grompe et al. [11] developed a second mouse model to repopulate the liver by mature hepatocytes through targeted disruption of fumarylacetoacetate hydrolase (Fah), the last gene in tyrosine catabolism. Deletion of Fah leads to accumulation of upstream intermediates in tyrosine catabolism, some of which (primarily fumarylacetoacetate) are toxic and cause extensive and continuous liver injury. The Fah null mouse represents an animal model for the human metabolic disorder Hereditary tyrosinemia, Type 1 (HT1), which causes extensive liver injury, hepatocellular carcinoma, and death at an early age [12]. Administration of 2 (2-nitro-4-trifluoromethylbenzoyl)-cyclohexane-1,3-dione (NTBC), a pharmacologic inhibitor of tyrosine catabolism upstream of homogentisic acid, prevents accumulation of fumarylacetoacetate and is partially successful in treating patients with HT1 [12], although it does not prevent hepatocarcinogenesis [13].

In Fah null mice, Grompe et al. demonstrated that liver repopulation by transplanted wt hepatocytes can be totally regulated by NTBC administration. They showed specifically that NTBC suppresses repopulation by transplanted wt hepatocytes in Fah null mice, because, under these conditions,

there is no selective advantage for wt hepatocytes to survive over host Fah null hepatocytes. When wt hepatocytes are transplanted into Fah null mice maintained on NTBC, only scattered small clusters of transplanted hepatocytes are detected (Fig. 16.1c). However, if NTBC treatment is discontinued at the time of cell transplantation, liver injury resumes and transplanted cells proliferate extensively, forming large clusters within 3 weeks and replacing most of the liver mass within 6 weeks (Fig. 16.1d). Therefore, cyclic administration and withdrawal of NTBC can be used

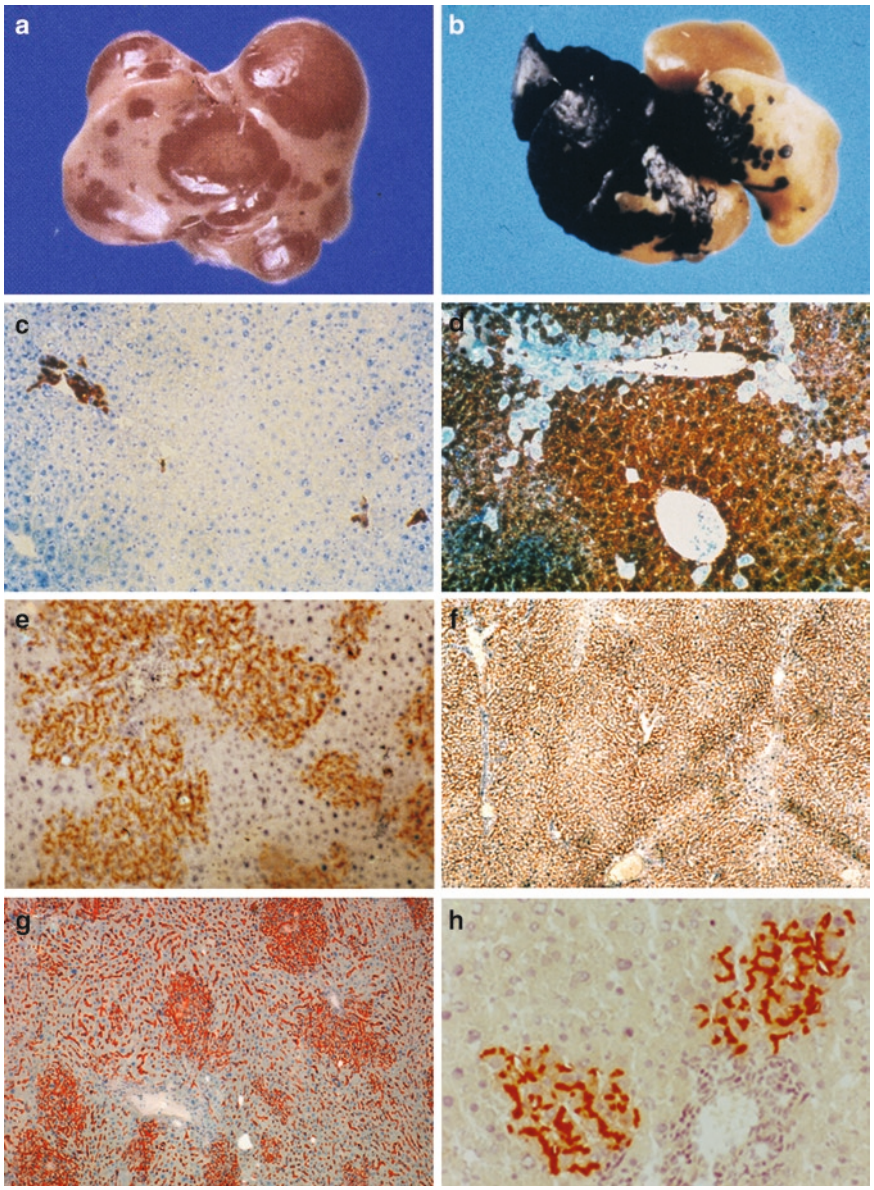

Fig. 16.1 Major models for liver repopulation by transplanted hepatocytes. From Malhi et al. [21], used with permission

as a tool to control liver failure in Fah null mice and this allows transplanted normal hepatocytes (expressing the Fah gene) to expand when NTBC administration is discontinued. Fah null mice with livers repopulated by wt hepatocytes remain healthy, have normal liver function tests and show a relatively normal liver structure for many months after hepatocyte transplantation [11]. These studies were the first to show that liver repopulation can effectively cure a metabolic disease, namely, the mouse equivalent to HT1.

In Fah null mice, not only do transplanted wt hepatocytes replace Fah null hepatocytes, but the transplanted cells can also be serially transplanted through seven consecutive Fah null mice, while retaining full ability to proliferate and replace host hepatocytes [14]. In these studies, it was calculated that each serially transplanted hepatocyte underwent an average of at least 69 cell divisions. Thus, murine hepatocytes exhibit essentially infinite capacity to proliferate and restore liver function under circumstances in which there is (1) both massive and continuous liver injury and (2) the transplanted hepatocytes have a significant selective advantage for survival compared to host hepatocytes. (Both of these conditions have been produced experimentally in uPA transgenic and Fah null mice.)

A third method to obtain a high level of liver repopulation by transplanted hepatocytes is to impair proliferation of endogenous hepatocytes, i.e., render them incapable of cell division, and then transplant normal hepatocytes in conjunction with a liver proliferative stimulus. This was first achieved by treating rats with retrorsine, a plant alkaloid that is taken up and metabolized by hepatocytes to produce an active intermediate that crosslinks cellular DNA and disrupts hepatocyte division [15]. When retrorsine or a closely related compound, monocrotaline, is administered to rats or mice [15–18], there is a long-lived inhibition of hepatocyte proliferation. However, essential metabolic functions are maintained in these DNA damaged hepatocytes and the animals survive. After the effects of acute chemical injury have subsided (2–4 weeks), the animals are subjected to two-thirds PH or CCl_4 administration in conjunction with transplantation of hepatocytes from normal animals. This leads to a brisk regenerative response by transplanted hepatocytes and there is extensive replacement of DNA-damaged host hepatocytes within several months [15–18]. What was most surprising in the retrorsine/PH model is that the transplanted hepatocytes do not develop into hyperplastic nodules, i.e., the liver remodels and the transplanted hepatocytes become fully integrated into the hepatic plates (Fig. 16.1e). Transplanted hepatocytes form hybrid canaliculi with neighboring host hepatocytes; the liver structure becomes and remains essentially normal for many months after cell transplantation and more than 99% of host hepatocytes can be replaced (Fig. 16.1f) [15]. Using the retrorsine/PH model, we have transplanted wt allogenic hepatocytes into albumin deficient Sprague Dawley rats, i.e., the Nagase analbuminemic rat, under an immunosuppressive protocol. Under these conditions, there was extensive replacement of albumin-deficient host hepatocytes by wt albumin expressing hepatocytes, which led to a 7,000-fold increase in albumin production and restoration of serum albumin levels to the normal range [19].

Another method to achieve effective liver repopulation by transplanted hepatocytes is to induce DNA damage by selective liver irradiation in conjunction with hepatocyte transplantation and either two-thirds PH, CCl_4 administration or ischemic liver injury [20, 21]. In the retrorsine/PH model, thyroid hormone (an hepatocyte mitogen in rats) can partially replace PH as an inducer of liver repopulation [22]. Most recently, in x-irradiated mice, administration of HGF has been used to replace PH as a liver regenerative stimulus [23]. With retrorsine or monocrotaline treatment of the host liver, transplanted hepatocytes have a proliferative advantage over host hepatocytes, as the latter have been rendered incapable of cell division. After retrorsine-induced DNA damage, host hepatocytes also exhibit an increased level of apoptosis [22], which also contributes to liver replacement by transplanted cells.

Other methods to achieve liver repopulation are to transplant donor hepatocytes that have augmented proliferative potential or a selective survival advantage into a host with a normal liver and stimulate cycles of regeneration by repeated liver injury. The latter has been achieved by transplanting Bcl-2 transgenic mouse hepatocytes that are resistant to apoptosis into wt mice in which apoptosis has been induced by repeated injections of anti-FAS Ab [24]. $p27^{KIP1}$ is a cyclin kinase inhibitor that regulates the cell cycle, and deletion of this gene provides a proliferative advantage to p27 null hepatocytes over normal host hepatocytes when transplanted in conjunction with repeated liver injury induced by CCl_4 injection [25]. In both of these models, there was a modest to moderate level of liver repopulation (2–16% range). Hopefully, in the future, pharmacologic methods will be developed to achieve these same effects, which might then be adapted for clinical applications.

Progenitor ("Oval") Cells for Liver Repopulation

The term "oval cells" was introduced by Farber [26] to describe non-parenchymal cells in the periportal region that were present after treating rats with carcinogenic agents, such as ethionine, α-acetaminobenzene (2-AAF), and 3-methyl-4-diethylaminobenzene. Other methods to induce proliferation of "oval cells" are to treat rats with D-galactosamine [27, 28], a choline deficient/ethionine substituted

diet [29, 30], or allyl alcohol [31], or to treat mice with dipin [32], or 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC) [33]. In each of these models, cells are induced that have a small oval-shaped, pale-stained blue nucleus and very scant, lightly basophilic cytoplasm. Farber did not believe that "oval cells" are hepatocyte progenitors [34], but Thorgeirsson and coworkers [35] demonstrated that "oval cells" induced to proliferate in the periportal region after treatment of rats with 2-AAF, followed by two-thirds PH, subsequently differentiate into distinct clusters of basophilic hepatocytes. This was demonstrated by pulse labeling of the liver with ^{3}H-thymidine and following the progression of labeled cells from the periportal region into clusters of hepatocytes in the mid-parenchyma [35, 36]. Other indirect evidence suggesting that "oval cells" are hepatic progenitors came from reports that "oval cells" express c-kit [37], CD34 [38], flt3 receptor [39], and LIF [40], all known to be markers for hematopoietic stem cells or their immediate derivatives. Sca-1, another cell surface protein expressed by hematopoietic stem cells in the mouse, is also expressed in fetal liver epithelial cells [17] and in "oval cells" of the adult mouse liver [41, 42]. Most recently, using lineage tracing studies in a double transgenic mouse expressing a β-galactosidase reporter gene under control of the Fox11 promoter, Greenbaum and coworkers [43] showed production of both hepatocytes and bile duct epithelial cells from progenitor cells that were induced to proliferate by bile duct ligation or feeding mice a DDC-containing diet. These findings strengthen conclusions from earlier studies in rats using 2-AAF/PH treatment [35, 36].

"Oval cells" are induced massively when liver injury is superimposed on circumstances in which hepatocyte proliferation is impaired. These cells exhibit many features of progenitor cells, dividing rapidly and appearing to differentiate into both hepatocytes and bile duct epithelial cells. Thorgeirsson et al. [44] performed extensive immunohistochemical and ultrastructural studies in which they demonstrated that "oval cells," induced to proliferate by 2-AAF/PH, are derived from undifferentiated cells in the Canals of Hering. Subsequently, these cells pass through discontinuities in the laminar basement membrane of the ductal limiting plate and join together with stellate cells as they enter the hepatic parenchyma, proliferate, and differentiate into hepatocytes.

Attempts to establish specific markers for "oval cells" to distinguish them from mature hepatocytes and bile duct epithelial cells and to determine their lineage origin (mesoderm or endoderm) have led to conflicting findings. All investigators agree that "oval cells" express common liver epithelial progenitor cell markers, such as α(alpha)-fetoprotein (AFP) and albumin (Alb) for hepatocyte progenitors and CK-19 (and OV6 in the rat) for bile duct progenitor cells. However, the term "oval cells" is used to identify a highly heterogenous population of cells. Multiple different cell types are induced in livers undergoing "oval cell" activation, and it is not clear whether "oval cells" from different animal species or from different hepatic injuries are in fact comparable. "Oval cells" were initially thought to express hematopoietic stem cell markers, c-kit, CD34, and Thy 1 [37, 38, 45, 46], but several recent studies have shown that both fetal liver progenitor cells and "oval cells" are negative for c-kit, CD34, and Thy1 [47–50]. It has also been demonstrated recently that Thy1 is expressed in stellate cells that proliferate together with "oval cells" in various activation models [51]. These issues may be clarified through the use of antibodies to detect "oval cells" in rats [52, 53] and mice [33, 54, 55], once the specificities of these antibodies have been fully established.

Transplantation of "Oval Cells"

Since hepatocytes do not effectively repopulate the normal adult liver, an obvious alternative would be to transplant progenitor ("oval") cells that should have a higher proliferative potential than adult hepatocytes. Twenty years ago, Faris and Hixson [56] reported that "oval cells," isolated from the liver of rats fed a choline-deficient (CD) diet, treated with 2-AAF and transplanted into the liver of secondary hosts, produced "colonies" or clusters of cells with an hepatocytic phenotype in recipients that had also been subjected to the CD diet. However, the level of liver repopulation by transplanted CD/2-AAF "oval cells" was not determined. "Oval cells" isolated from the liver of rats treated with D-galactosamine also proliferate and differentiate into hepatocytes after transplantation into rats undergoing two-thirds PH [57]. However, in these studies, which were conducted in a nonselective tissue environment, liver repopulation by transplanted D-galactosamine-induced "oval cells" was low (not quantified). Duct-like epithelial cells, isolated from the atrophic pancreas of rats treated with a copper chelating agent, also proliferate modestly after transplantation into normal rat liver in conjunction with two thirds PH [57]. This probably occurs by reprogramming of epithelial progenitor cells in the Cu-deficient pancreatic ducts to the hepatocytic lineage, as evidenced by their expression of AFP and Alb. This appears to represent a reversible switch between the hepatic and pancreatic lineages, similar to a process recently described by Chan and coworkers called "transdetermination," in which hepatocytic progenitor cells switch their lineage program to pancreatic islet cell-like gene expression after in vivo transduction of mice with an adenovirus vector expressing neurogenin 3 [58]. This is distinct from "transdifferentiation" in which a fully differentiated cell type switches its gene expression program to another fully differentiated cell type, a process that will be discussed later in this chapter in

reference to studies reporting bone marrow cells differentiating directly into hepatocytes. After transplantation of "lineage-switched" pancreatic progenitor cells into the hepatic microenvironment, these cells fully differentiate into hepatocytes [57]. Isolated pancreatic cells from normal mice also repopulate the liver of Fah null mice [59]. "Oval cells" isolated from the liver of DDC-fed mice also repopulate the liver of Fah null mice, although perhaps with a reduced efficiency compared with mature hepatocytes [60]. Similarly, "oval cells" from GFP transgenic mice maintained on a DDC diet also repopulate the liver of wt mice treated with monocrotaline in conjunction with PH [61]. Other recent studies have shown effective repopulation of the liver by purified "oval cells" in both retrorsine treated rats [62] and Fah null mice [60], but not in animals with a normal liver.

Most recently, "oval cells" have been isolated from normal mouse and dog liver [42, 63, 64]. These cells exhibit properties characteristic of hepatic progenitor cells in culture, but in vivo repopulation data are very limited. Numerous studies have reported the isolation and in vitro passage of "oval cells" and "oval cell" lines from mice and rats, as well as from humans. These cells are clonal, bipotent and exhibit other stem and progenitor cell properties in vitro and in vivo [47, 63, 65–73]. However, liver repopulation by "oval cell" lines has generally been very low, even under conditions in which the host liver is highly compromised (highly selective conditions).

Properties of Stem and Progenitor Cells Relevant to Liver Reconstitution/ Repopulation

Based on studies conducted in vivo in the bone marrow, skin and intestinal epithelium, stem cells are generally considered to exhibit four major properties:

- Self-renewal or self-maintenance (generally slowly cycling)
- Multipotency (producing progeny in at least two lineages)
- Functional, long-term tissue reconstitution;
- Serial transplantability

Two methods to identify self-maintaining stem cells in the liver are:

- To show that specific populations of cells are undergoing asymmetric division [74, 75], during which one of the progeny remains undifferentiated, whereas the other differentiates into an hepatocyte or cholangiocyte
- To identify cells that retain a nuclear marker of DNA synthesis long after the tissue has turned over or undergone regeneration, i.e., the cells have presumably undergone proliferation and have then become quiescent ("label retaining cells")

Both of these methods have been established in rapidly turning over tissues, but, in principle, they could be used to study specific populations of cells in a slowly turning over tissue, such as the liver, following an acute liver injury. However, this would require a large or sustained liver regenerative stimulus. Although one study on asymmetric cell division has been conducted in vitro with hepatic-derived cell lines [76], none have been reported in vivo.

Regarding "label retaining cells," most studies have been conducted in the skin and intestinal epithelium. In one of these studies, using the nuclear marker histone 2B-GFP, "bulge cells" in the hair follicles retained the label [77]. "Bulge cells" have been shown to generate complete new hair follicles [78], but studies in hair follicles are complicated, as other populations of stem cells have also been identified [79]. The validity of the label-retaining method to identify stem cells has also recently been challenged [80].

In the liver, recent studies have reported four distinct populations of "label-retaining cells," i.e., Canal of Hering cells, intralobular bile duct cells, periductular "null" or undifferentiated cells, and peribiliary hepatocytes [81]. These cells were identified by pulse labeling with BrdU during acute liver injury with acetaminophen, followed 2 weeks later by a second liver regenerative stimulus using acetaminophen to "wash out" the label. Animals were then examined for cells retaining BrdU in the liver at 4 and 8 weeks after the second acetaminophen treatment. However, further studies will be necessary to establish the specific importance of these various populations of "label-retaining cells" in liver biology.

Most recently, lineage tracing experiments with double transgenic mice (Fox11-cre x rosa 26-loxP-β-gal) have demonstrated that β-galactosidase marked hepatic progenitor cells induced by DDC, are permanently labeled after they have been induced and can differentiate into both hepatocytes and mature bile duct epithelial cells [43]. This represents a significant step forward; however, the contribution of progenitor cells vs. adult hepatocytes to new hepatic mass generated following acute liver injury, as well as during normal liver cell turnover, still remains to be determined.

In adult tissues, stem cells are maintained at low levels and then proliferate very slowly. Progenitor cells, the progeny of stem cells, proliferate rapidly and differentiate into somatic populations; however, they do not maintain themselves. Like stem cells, progenitor cells may have multi-lineage potential, but they may also be unipotent. Regardless of whether they are multipotent or unipotent, progenitor cells are capable of only short-term tissue reconstitution. In reality, there may be a continuum of progenitor cells along the

hepatic lineage that progressively lose their stem cell properties as they differentiate toward more mature phenotypes.

The proliferative capability and differentiation properties of a specific cell may also vary depending on the tissue context in which that particular cell is located. Therefore, the designation of a particular cell as a stem or progenitor cell may be somewhat arbitrary. As new liver progenitor cell marker genes are established, these and other related issues can be addressed. In other tissues that are rapidly turning over, progenitor cells have also been termed "transit amplifying cells" [82]. "Oval cells," that have been activated to proliferate in various rodent model systems, exhibit many features of "transit amplifying cells" and thus may represent the liver counterpart to progenitor cells identified in other organs, such as the skin and intestinal epithelium.

Hepatic Stem Cells in the Developing Liver

Cellular, molecular, and morphologic studies have traced the proliferation and differentiation of stem cells during liver development. In the mouse, stem cells begin to proliferate from the ventral wall of the endoderm when it becomes positioned next to the developing heart, which occurs on embryonic day (ED) 8.0 [83–85]. Specification toward hepatic epithelial lineages occurs at ED8.5 and requires fibroblast growth factor (FGF) signaling from the cardiogenic mesoderm [86], as well as bone morphogenic protein (BMP) signaling from the septum transversum mesenchyme [87]. These cells begin to express GATA4 and liver-enriched, nuclear transcription factor HNF4α on ED 9.0–9.5, as well as liver-specific genes, AFP followed by Alb [84, 85, 88]. The hepatic-specified cells are now referred to as hepatoblasts, which proliferate massively and invade the septum transversum mesenchyme that contains stellate cells and sinusoidal endothelial cells. These latter cells secrete a variety of cytokines and growth factors that are known to be involved in liver development, such as EGF, FGF, HGF, TGFβ, BMPs, TNFα, and IL-6 [84–87, 89]. A visible liver structure is formed at ED11, at which time the hepatoblasts continue to expand rapidly and begin to express numerous liver-specific genes [90–92]. Some cells express genes that are specific for both the hepatocytic (AFP or Alb) and cholangiocytic (cytokeratin-19) lineages, and these cells are considered bipotential. Just prior to ED16, hepatoblasts diverge along these two distinct lineages, hepatocytes and cholangiocytes [88, 93], with Notch signaling promoting cholangiocytic differentiation and HGF and oncostatin M expression promoting hepatocytic differentiation [94]. After ED16, the percentage of bipotent cells falls dramatically, and most of the cells are unipotent and irreversibly committed to either the hepatocytic or cholangiocytic lineage [95–97]. As organogenesis proceeds, intrahepatic bile ducts are formed in the vicinity of large portal vein branches, beginning on ~ED17 [98]. A more comprehensive discussion of liver development can be found in Chap. 13.

Thus, the fetal liver contains cells that are in different stages of hepatic epithelial lineage progression. These cells have been isolated, cultured and transplanted into various animal model systems and fetal liver epithelial cells exhibit highly superior properties compared to either mature hepatocytes or adult liver progenitor cells when they are transplanted into the normal adult liver under nonselective conditions [57, 96, 99]. In contrast, under selective conditions, all three cell types (fetal liver cells, progenitor cells from the adult liver, and mature hepatocytes) efficiently repopulate the massively injured liver [10, 11, 15–21, 60–62, 96, 100]. However, the level of repopulation varies, depending on the animal species and the specific injury model used.

Liver Repopulation Using Fetal Liver Stem/Progenitor Cells

As indicated previously, the ultimate test for a putative stem cell is to demonstrate its ability to functionally repopulate a tissue or organ, long-term. Sandhu et al. [96] reported 5–10% repopulation of DPPIV$^-$mutant F344 rat liver by transplanting wt ED14 fetal liver epithelial cells in conjunction with two thirds PH. The transplanted cells were integrated into the host parenchyma, forming hybrid canaliculi with host hepatocytes, and the bulk of the repopulating clusters contained both hepatocytes and mature bile duct cells [96]. Liver repopulation by transplanted ED14 fetal liver cells increased slowly and progressively, and remained stable over 6 months. These results were obtained in a normal (nonselective) tissue environment, requiring only a two thirds PH to initiate the repopulation process. These findings are comparable to those in the hematopoietic system, where extensive ablation is required for bone marrow replacement by transplanted hematopoietic stem cells. Thus, transplanted rat ED14 fetal liver epithelial cells exhibit three major properties of stem cells: (1) extensive proliferation, (2) bipotency, and (3) long-term repopulation in vivo.

In ED14 rat fetal liver, there are three distinct populations of epithelial cells, those positive for AFP and Alb but negative for CK-19; those positive for AFP, Alb and CK-19; and those positive for CK-19, but negative for AFP and Alb [95, 96]. The number of AFP$^+$/Alb$^+$/CK-19$^+$ cells decreased

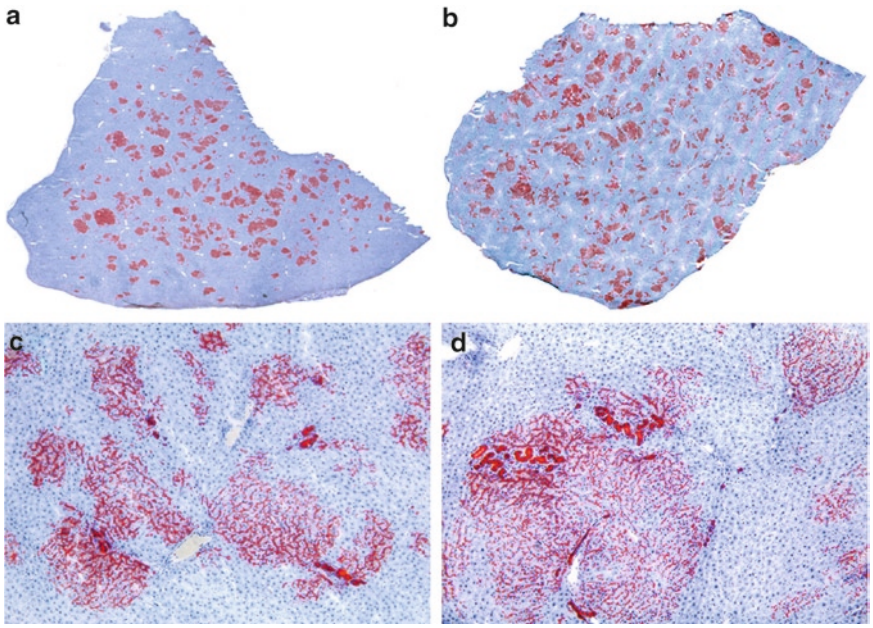

Fig. 16.2 High repopulation of the normal (non-retrorsine treated) rat liver by transplanted ED14 fetal liver stem/progenitor cells. Major lobes from two rat livers repopulated with fetal liver stem/progenitor cells scanned with a high resolution scanner (**a**, **b**) and at original magnification, 100× (**c**, **d**). Note: The majority of repopulating clusters derived from transplanted cells contain both hepatocytes (incorporated into the liver parenchyma) and cholangiocytes (incorporated into bile ducts)

dramatically at ED16, after which liver repopulation potential of rat fetal liver cells also decreases dramatically [96]. The level of liver repopulation by ED14 fetal liver cells under nonselective conditions (i.e., in a normal liver) can also be increased to 20–25% simply by increasing the number of ED14 fetal liver cells transplanted (Fig. 16.2) [99]. Repopulation continues to increase for up to 1 year, reaching an average of ~30% for the total liver. Repopulation remains stable for the life of the animal, which is consistent with the slow turnover of parenchymal cells in this organ [Oertel et al., unpublished data]. In this normal rat model, there is a several thousand fold amplification of transplanted fetal liver epithelial cells in the repopulated normal host liver [99]. Both hepatic parenchymal cords and mature bile ducts are formed by transplanted fetal liver cells, as well as whole new liver lobules, and the progeny of the transplanted cells express normal levels of hepatocytic and cholangiocytic genes in the respective cell types. As serial transplantation (an indicator of self-renewal) has not yet been demonstrated with fetal liver epithelial cells, they are referred to as fetal liver stem/progenitor cells [99, 101].

The mechanism for liver repopulation by rat fetal liver stem/progenitor cells has been shown to be cell competition between the transplanted cells and host hepatocytes [99], a process originally described in Drosophila during wing development [102, 103]. Rat fetal liver stem/progenitor cells have been cryopreserved with full ability to repopulate the normal adult liver after thawing [104] and they have been enriched to 95% purity by selection with immunomagnetic beads [105].

Liver Repopulation by Extrahepatic and Embryonic Stem Cells

Various studies have reported that cells released from the BM into the circulation migrate to the liver and differentiate into hepatocytes. However, the extent to which this occurs and the mechanism(s) involved remain controversial (for reviews, see [106–109]). Originally, Petersen and coworkers reported that BM stem cells from DPPIV$^+$ F344 rats transplanted into sublethally irradiated DPPIV$^-$ F344 rats, repopulate the BM and then migrate to the liver and "transdifferentiate" into hepatocytes through the liver "oval cell" progenitor pathway [110]. Subsequently, Theise et al. [111, 112] and Alison et al. [113] reported that mouse and human BM cells "transdifferentiated" in hepatocytes, and Lagasse et al. [114] that liver repopulation by BM cells or hematopoietic cells was much higher (30–50%) in Fah$^{-/-}$ mice. However, studies by Wang et al. [60] showed that BM cells did not enter the "oval cell" pool in mice treated with DDC. Menthena et al. [115] also showed that DPPIV$^+$ BM

cells transplanted into DPPIV$^-$ rats contributed <1% to the "oval cell" pool in three different models of "oval cell" activation: (1) 2-AAF/PH, (2) retrorsine/PH or (3) D-gal induced liver injury. These [60, 115] and other studies in both mice and rats [107–109] have demonstrated that "transdifferentiation" of hematopoietic stem cells into "oval cells" is at best a rare event, which probably does not have physiologic significance.

In Fah$^{-/-}$ mice and other model systems, it has been shown that cell fusion and reprogramming, rather than transdifferentiation, is the mechanism by which hematopoietic cells acquire a hepatocytic phenotype. Initial studies in cell culture showed that BM and neuronal cells can fuse with ES cells in culture [116, 117]. Wang et al. [118] and Vassilopoulos et al. [119] subsequently showed that hematopoietic stem cells fuse with hepatocytes in Fah null mice to produce cells that express the deficient enzyme, which then expand massively to restore liver mass and function [118]. Fusion also occurs between hematopoietic cells and neurons or muscle cells [120, 121], and it has been shown that myelomonocytic cells can fuse with hepatocytes [122, 123] or muscle cells [124] to produce somatic hybrids expressing genes from both parental cell types.

Other studies have reported that fusion is not required for BM-derived cells to differentiate into hepatocytes [125–127]. Unfractionated or CD34$^+$ enriched cells from human cord blood [128–131], multipotent adult progenitor cells (MAPC) [132, 133], or mesenchymal stem cells [134–136] have been transplanted into the liver of immunodeficient mice. These transplanted cells express a differentiated hepatocytic phenotype [128–139], but liver repopulation was once again very low. Several studies have reported that mesenchymal stem cells isolated from adipose tissue can also engraft in the liver parenchyma and contribute to liver regeneration [140, 141]. One of these studies [141] reported large repopulation clusters with hepatocyte-differentiated mesenchymal stem cells, but this required retrorsine pretreatment of the recipients and the overall level of liver repopulation was not reported. These studies are promising, as mesenchymal stem cells from adipose tissue are readily available through liposuction and could be used clinically if more robust liver repopulation could be achieved.

Many studies have demonstrated that ES cells in culture can be induced along the endodermal and hepatocytic lineages by addition of specific cytokines and growth factors [142–151]. The first step typically involves the generation of embryoid bodies, followed by the induction of definitive endoderm using activin A. The endodermal population is then further specified towards the hepatic lineage using BMP-4 and basic FGF. Cells produced in this fashion express typical hepatocytic markers, such as AFP and Alb. They can then be transplanted into the liver with differentiation into both mature hepatocytes [148–151] and bile duct epithelial cells [149], but the level of liver repopulation obtained with hepatocyte-differentiated ES cells is very low, although somewhat higher when the cells are transplanted into MUP-uPA/SCID mice [151]. To date, all ES differentiation protocols generate "hepatocyte-like" cells [148–151], but not fully mature hepatocytes. More mature "hepatocyte-like" cells have been selected using surface markers, such as the asialoglycoprotein receptor, and selected cells have shown higher levels of differentiated function after their transplantation [151]. Such methods may ultimately be successful in the future to isolate lineage-specified ES cells that will be therapeutically effective.

Induced Pluripotent Stem Cells

Because of their extensive proliferative capacity, pluripotent stem cells are an attractive potential source of transplantable hepatocytes [152]. Not only can these cells divide extensively, but they also retain the ability to differentiate into many different mature cell types [152]. Pluripotent cells can now be derived by direct genetic reprogramming of somatic cell types, such as dermal fibroblasts [153–156] and most recently, iPS cells derived from human skin fibroblasts have been differentiated along the hepatocytic lineage (B,C). In one of these studies, hepatocytic differentiated human iPS cells have been injected into the liver parenchyma of newborn mice with maintenance of hepatocytic morphology and human albumin expression [172].

Human "Oval Cells" and Stem Cells

A human counterpart to "oval cell" activation has been described in liver tissue obtained from patients with extensive chronic liver injury or submassive hepatic necrosis i.e., the so-called "ductular reaction" (for detailed description, see [157]). "Ductular reactions" are comprised of cells in ductular arrays that have the same morphologic appearance and immunohistochemical markers as found in rodent "oval cells." These cells are present primarily in the portal tracts, and express both hepatocytic and bile ductular markers, as well as certain neuroendocrine genes [157–160]. Using double and triple label immunohistochemistry, Zhou et al. [161] have shown that "ductular reactions" are bipolar structures with cells at one pole exhibiting hepatocytic morphology and gene expression (HepPar1 or HepPar1/NCAM), and cells at the other pole exhibiting biliary morphology and gene expression (CK-19 or CK-19/NCAM). Undifferentiated epithelial cells are found in the center of these bipolar structures and express only NCAM. Cells with similar morphologic and immunohistochemical properties have also been

identified in the human fetal liver beginning in the 4th week of gestation [162].

Several investigators have isolated, cultured, and/or passaged human fetal liver epithelial cells with bipotent properties, and several of these studies have demonstrated their differentiation into hepatocytes after transplantation into SCID or nude mice [71–73, 163]. Schmelzer et al. [163] have identified two populations of hepatic progenitor cells from human fetal, neonatal, and pediatric liver that exhibit stem cell properties. One population is thought to represent a hepatic stem cell (AFP^-/Alb^+) and the other a slightly more differentiated hepatoblast (AFP^+/Alb^+). More recently, Schmelzer et al. [164] reported data suggesting that these cells may reside in the Canals of Hering. One unexpected difference from their rodent counterpart is that human hepatic-specified stem cells are Alb positive but AFP negative. This is opposite to what one might expect based on expression of AFP before Alb during liver development [88]. Nonetheless, these studies suggest that a human liver somatic stem cell might exist and hopefully future studies will demonstrate in vivo self-renewal and long-term repopulation of the liver by these cells, proving that they are indeed stem cells.

Xenorepopulation Models

Two models capable of supporting extensive repopulation of the mouse liver with human hepatocytes have been reported. In 2001, Dandri et al. first showed that immune-deficient uPA transgenic mice could be engrafted with human hepatocytes and used as a model for hepatitis B [165]. Subsequently, this model has been further developed to permit extensive repopulation, reaching levels as high as 90% human cells [166, 167]. Fah knockout mice can also be repopulated extensively with human cells from a variety of sources when they are crossed onto severely immune deficient backgrounds [168]. This model has the advantage that the level of hepatic injury can be titrated by NTBC. Both systems are likely to be important in identifying stem cell derived "hepatocytes" that can be used in cell therapy. Table 16.1 summarizes the results of all cell transplantation/liver repopulation studies reviewed above, and indicates the model systems and specific physiologic or pathophysiologic circumstances, i.e., selective or nonselective conditions, under which liver repopulation has been achieved.

Future Horizons

Although substantial progress has been made during the past 10–15 years concerning the possibility of liver repopulation by transplanted cells, much still needs to be learned. Factors governing engraftment of transplanted cells into the liver and their homing to the correct niche, factors regulating proliferation and differentiation of transplanted cells into specific phenotypes required for organ function and specific host conditions under which effective liver replacement can be achieved, all need to be determined. The best starting point for therapeutic liver repopulation will probably be a genetic disorder with ongoing liver injury, which will hopefully induce or augment proliferation of transplanted cells in the host liver. One example of such a condition is Wilson's disease, in which transplanted cells might also have a modest selective advantage [169], since they will not store high levels of copper. Another example is α_1-antitrypsin deficiency, in which a mutated form of α_1-antitrypsin (PiZZ phenotype) remains within the hepatocyte and causes liver injury [170].

To date, very few patients have been transplanted with fetal liver cells. Studies in rats have shown that fetal liver cells, i.e., fetal hepatoblast, have the capacity to proliferate in the host, replace hepatic mass with functional hepatocytes and maintain differentiated hepatic function, long-term [96, 99]. This requires a liver proliferative stimulus or liver injury at the time the cells are transplanted, but no selective advantage other than the inherent ability of fetal hepatoblasts to replace host hepatocytes by cell competition, a process during which the transplanted fetal liver stem/progenitor cells, which have a higher proliferation potential than normal mature hepatocytes, induce apoptosis in the latter and replace them in the liver tissue [99]. Cells with similar properties to fetal liver progenitor cells have been identified in the normal adult liver and these cells can be activated to proliferate under conditions in which there is an impairment in the ability of mature hepatocytes to undergo cell division These are the so called "oval cells," but their ability to effectively repopulate the adult liver occurs only under highly selective conditions.

Stem cells from pediatric or adult cadaveric liver or from other sources, such as bone marrow, cord blood or ES cells, as well as cell lines from various sources, are possibilities for liver repopulation, as well as cultured fetal liver cells or adult hepatocytes modified to favor engraftment and proliferation in the host. However, this will require substantial additional research. Unfortunately, existing cell lines show only limited repopulation potential in the normal liver at the current state-of-the-art. To further advance the field of liver cell therapy, it will be necessary to find conditions under which cells and cell lines derived from ES cells, iPS cells, fetal liver or adult liver, can be expanded in culture and successfully repopulate the liver under conditions that will be clinically acceptable. Although we are not yet there, restoration of liver function by therapeutic cell transplantation holds great promise for the future.

Table 16.1 Liver repopulation by transplanted cells of hepatic and nonhepatic origin

Type of cell	Model systems used	Comments	Selected publications
Cells of hepatic origin			
Adult hepatocytes[a]			
Mouse, rat or human	uPA transgenic mouseFah null mouse Retrorsine (or monocrotaline) treated rat or mouse plus PH or CCl_4 administration x-Irradiation of rat or mouse liver plus pH, HGF or ischemic liver injury Bcl-2 transgenic mouse hepatocytes into anti FAS Ab treated mouse p27 null mouse hepatocytes into wt mouse plus CCl_4 at 4–8 weekly intervals	Effective repopulation (range, 30–90%), requires highly selective conditions, including: Massive and continuous liver injury or sustained disruption of host hepatocyte proliferation Selective advantage for transplanted cells to survive compared to host hepatocytes With Bcl-2 transgenic hepatocytes in normal mice treated with weekly injections of anti FAS Ab for 8–12 weeks, repopulation was 3–16% With p27 null mouse hepatoytes in normal mice with 4–8 weekly injections of CCl_4, repopulation was 2–6%	Rhim et al. Oval/progenitor cells[b]			
Mouse and rat (2-AAF or D-gal activated liver)	Fah null mouseRetrorsine/PH treated rat	Effective repopulation requires highly selective conditions (range, 20–80%)	Wang et al. [60]Song et al. [61] Yovchev et al. [62]
Fetal hepatoblasts			
ED14 rat	$DPPIV^-$ rat/PH	Effective repopulation occurs under nonselective conditions (5–25%)	Sandhu et al. [96]Oertel et al. [99]
ED11.5–13.5 mouse	$DPPIV^{-/-}$ mouse/$CCl_4$$DPPIV^{-/-}$ mouse retrorsine/CCl_4 Alb-uPA/$Rag2^{-/-}/\gamma_c^{-/-}$ mouse	Repopulation <1% (nonselective conditions)Repopulation 10–80% (highly selective conditions) Repopulation 2–20% (highly selective conditions)	Nierhoff et al. [17]Haridass et al. [100]
"Stem" cells			
Human fetal, neonatal or adult liver	NOD/SCID mouse/±CCl_4	Short-term repopulation (2–8 days), similar results ± CCl_4 (% repopulation not determined)	Schmelzer et al. [164]
Cultured hepatic epithelial cells and cell lines			
Mouse, rat and human	$DPPIV^-$ ratsMouse/CCl_4 SCID mouse/CCl_4 uPA/SCID mouse $Rag2^{-/-}$ mouse/ retrorsine/CCl_4 $Rag2^{-/-}/\gamma_c^{-/-}$/50% PH Fah null mouse	Repopulation minimal under nonselective conditions (<0.1% or not determined)Under highly selective conditions, repopulation still very low (≤2%)	Coleman et al. [66]Yasui et al. [67] Suzuki et al. [68] Strick-Marchand et al. [69] Fougère-Deschatrette et al. [70] Suzuki et al. 2008 [63] Malhi et al. [71] Mahieu-Caputo et al. [72] Dan et al. [73]
Cells of nonhepatic origin			
Bone marrow or cord blood (hematopoietic) stem cells[c]			

(continued)

Table 16.1 (continued)

Type of cell	Model systems used	Comments	Selected publications
Mouse and human	Rat/2-AAF/CCl_4SCID mouse NOD/SCID mouse Fah null mouse Patients with BM or liver transplants	Human "hepatocyte-like" cells observed in all cases, but repopulation generally low, except for one human liver biopsy from patient with chronic HCV infection (40%) and in FAH null mice under highly selective conditions (30–50%)	Petersen et al. [110]Theise et al. [111] Theise et al. [112] Alison et al. [113] Lagasse et al. [114] Danet et al. [128] Kakinuma et al. [130] Kollet et al. [131] Newsome et al. [125]
Mesenchymal stem cells			
Cultured mouse and human	NOD/SCID mouse*Pfp*/$Rag2^{-/-}$/CCl_4 mouse uPA/$Rag2^{-/-}$ mouse	Repopulation generally very low or not studied (nonselective conditions)	Jiang et al. [133]Aurich et al. [139] Brulport et al. [135] Kuo et al. [136]
Adipose stem cells			
Cultured rat or human	Balb c nude mouseDPPIV$^-$ rat/retrorsine	Scattered cells observed expressing human alb or α_1-AT, levels of repopulation not studied	Banas et al. [140]Sgodda et al. [141]
Embryonic stem (ES) cells			
Mouse and human	DPPIV$^{-/-}$/$Rag2^{-/-}$ mouse/Retrorsine/CCl_4 uPA/SCID mouse NOD/SCID mouse	Scattered cells or cell clusters with "hepatocyte-like" phenotype; % repopulation low or not reported, except for [149] (1.94%)	Gouon-Evans et al. [148]Heo et al. [149] Duan et al. [150] Basma et al. [151] Si-Tayeb et al. [172] Sullivan et al. [173]
Induced pleuripotent stem (iPS) cells			
Mouse and human	Differentiation of human iPS cells along hepatocytic lineage in cell culture and expression of human albumin after transplantation directly into newborn mouse liver parenchyma		

[a]In a normal rat or mouse host liver, repopulation by transplanted hepatocytes was minimal (usually less than 1%), even after repeated liver injuries or multiple cell infusions (Rajvanshi et al. [7, 8])

[b]In a normal host liver (rat), repopulation by transplanted oval/progenitor cells is <1% (Dabeva et al. [57])

[c]In Fah null mice, fusion between transplanted hematopoietic cells and hepatocytes has been reported (Wang et al. [118]; Vassilopoulos et al. [119]; Camargo et al. [122]; Willenbring et al. [123])

Acknowledgements The authors would like to thank Anna Caponigro and Emily Bobe for assistance in typing this manuscript.

Chapter 17
Adult Liver Stem Cells

D. Hunter Best and William B. Coleman

Introduction

The search for stem-like progenitor cells of the adult liver has been ongoing for many decades. However, as recently as 20 years ago the existence of liver cells with stem-like potential was critically questioned and not generally accepted [1, 2]. In contrast, it has long been known that tissues with high cellular turnover (like skin, intestine, and bone marrow) contain stem cells that function to maintain tissue homeostasis through continuous renewal of the cell lineage [3–8]. Evidence for stem-like liver progenitor cells first emerged from studies of liver injury, regeneration, and carcinogenesis in rodent models. Some evidence for stem-like progenitor cells of the adult human liver has appeared in the literature during the last 20 years. Since that time, investigations into the roles that these stem-like progenitor cells play in response to hepatic injury and carcinogenesis have escalated. In addition, there is tremendous interest in pursuing the potential application of stem-like progenitor cells for treatment of liver disease through gene therapy and cell transplantation approaches [9–13].

New insights into cell lineage generation and new understanding of the relationships of cells composing a lineage in adult organisms have modified the traditional thinking that stem-like progenitor cells are necessarily undifferentiated cells with a limited degree of potency [14]. However, modification of the paradigm has not resulted in a universally accepted definition of what a stem-like progenitor cell represents [15]. Rather, there has been a reevaluation of the contributions of various cell types, both differentiated and undifferentiated, to normal lineage renewal, response to injury, and tissue regeneration. In the liver, these changing concepts have given rise to a recognition that there are multiple liver epithelial cell types that have the potential to originate new cell populations [16, 17]. In addition, a number of intriguing new observations have been made that suggest the stem cells may yield progeny that evince a high degree of phenotypic plasticity [18, 19]. Several reports have demonstrated that adult stem-like progenitor cells from one tissue can be induced to differentiate into parenchymal cells of other tissues when transplanted into appropriate sites, including the derivation in the liver of hepatocytes by transplantation of stem-like progenitor cells from extrahepatic sources [20, 21]. These new results suggest that stem-like progenitor cells of adult tissues may not be intrinsically restricted in their differentiation commitment, and/or that they are capable of responding to different tissue microenvironments with an alternative cellular differentiation that is appropriate for the new site [22].

In this chapter, we review the evidence for stem-like progenitor cells of the adult liver, including (1) the types of cells in the liver that exhibit stem-like potential, (2) sources of liver stem-like progenitor cells from extrahepatic tissues, (3) evidence for human liver stem-like progenitor cells, (4) isolation, culture, and characterization of liver stem-like progenitor cells from rats, and (5) evidence for the differentiation potential of cultured rat liver stem-like progenitor cells. Given the scope of this undertaking and the large number of published studies on these topics, we have not attempted to comprehensively review the literature. Therefore, in the latter sections of this chapter, we will focus our review on studies of the well characterized WB-F344 rat liver epithelial stem-like progenitor cell line [23]. Furthermore, where possible, the reader is directed to the excellent reviews on these subjects that are available in the literature. There are additional chapters in this textbook on cell therapies, liver development, and cancer stem cells for readers interested in these topics.

History of Liver Stem-Like Progenitor Cell Biology

The idea that the liver of adult rodents contain stem-like progenitor cells that can give rise to the epithelial cell types of the liver (hepatocytes and biliary epithelial cells) developed

from evidence accumulated from over a hundred years of investigation [17, 24]. Early in the last century, potential lineage relationships among biliary epithelial cells, transitional cells, and hepatocytes were recognized in several studies of liver regeneration [25–28]. Studies on hepatocarcinogenesis in experimental animals produced additional evidence that hepatocytes could be generated through the activation, proliferation, and differentiation of transitional cells possessing features of both ductular cells and hepatocytes [29, 30]. Subsequently, Wilson and Leduc [31] suggested that cells contained in the cholangioles or terminal bile ductules constitute a compartment of stem-like progenitor cells that can proliferate and generate hepatocytes in some forms of liver injury. Since then, the concept of the liver stem-like progenitor cell has generated considerable controversy, argument, and discussion [1, 2, 16, 32–36].

The debate surrounding the liver stem-like progenitor cell is fueled by the fact that stem cells and their phenotypic characteristics are largely intuitive concepts. As it is true for other tissues, putative stem-like progenitor cells of the liver have not been identified microscopically in situ and have not been prospectively isolated from the normal liver in pure form. In addition, hepatocytes and biliary epithelial cells of the normal liver demonstrate very little cellular turnover and do not operate as a typical stem cell-fed lineage system [37, 38] like those of other self-renewing tissues, such as intestine [5, 39–41], skin [42–44], and bone marrow [45, 46]. These observations and the fact that the adult liver retains the capacity for complete and rapid renewal of cell numbers in response to cell loss through activation and proliferation of fully differentiated cells (both hepatocytes and biliary epithelial cells) seem to argue against the need for a stem-like progenitor cell in the adult liver tissue. However, these observations do not eliminate the possibility that cells possessing a broader differentiation potential are present in the adult liver as a "reserve" [32] or "facultative" [47, 48] stem-like progenitor cell compartment, or that cells with stem-like properties may serve a physiological function other than (or in addition to) lineage renewal. It has been suggested that participation of stem-like progenitor cells in liver growth processes may depend upon several factors, including the presence or absence of liver injury, the type and extent of injury, and the capacity of hepatocytes to respond to growth stimuli [10], consistent with the concept of the "facultative" liver stem cell [47, 48]. Despite the controversy surrounding the concept of the liver stem-like progenitor cell, considerable evidence has accumulated that supports the notion that the adult rodent liver contains cells with stem-like properties that can serve as progenitor cells for both hepatocytes and biliary epithelial cells under certain pathophysiological circumstances [17, 49]. Three major sources of evidence support the existence of liver stem cells: (1) the founding of lineages of hepatocytes and biliary epithelial cells from hepatoblasts during embryonic development of the liver and the expression of differentiated cell-specific traits in cultured hepatoblasts; (2) the reestablishment of epithelial lineages following the proliferation of simple epithelial cells (oval cells) in livers subjected to carcinogenic or noncarcinogenic liver injury; (3) the isolation and propagation from the livers of adult rodents of simple epithelial cells that demonstrate the ability to differentiate into hepatocytes and/or biliary epithelial cells when transplanted into appropriate sites in vivo, or when cultured under specific conditions ex vivo. These sources of evidence have been comprehensively discussed in several reviews [17, 32, 49–57].

Essential Properties of Stem-Like Progenitor Cells

The major properties thought to characterize stem-like progenitor cells have been inferred from investigations of classic stem cell-fed lineage renewal systems, including bone marrow, intestinal epithelium, and skin. Essential properties expected of stem-like progenitor cells include the capacity to (1) proliferate repeatedly, (2) renew the stem cell population, and (3) generate sufficient differentiated progeny to maintain or regenerate the functional capacity of a tissue [39, 43]. Classic stem cells are thought to exhibit undifferentiated cellular phenotypes, to express variable differentiation potentials, and to be able to proliferate continuously (actual stem cells), or to be proliferationally quiescent until needed (potential or facultative stem-like progenitor cells) [39, 43]. While classic stem cell-fed lineage systems have been used to infer the properties of stem-like progenitor cells, evidence now suggests the existence of stem-like cells in many tissues that do not contain active stem cell-fed lineages [58], such as the central nervous system [59–63] and liver [17, 24, 49]. These newly discovered stem-like cells appear to have properties that differ from those proposed for classic stem cells.

Stem-Like Progenitor Cells of the Adult Liver

Unlike rapidly renewing epithelial tissues (such as the intestinal mucosa or skin), in which an active stem cell lineage system continually initiates replacement of differentiated cells that are shed [64, 65], the liver is normally a quiescent organ with minimal/slow rates of cell turnover in the adult [66]. Nonetheless, the liver possesses an extraordinary capacity for the regeneration of tissue mass following loss of normal hepatocyte numbers due to partial tissue loss (surgical resection) or hepatotoxic injury (necrosis). A number of different cell types can be activated to repair or regenerate the liver depending

upon the nature and extent of injury and/or tissue deficit [17, 49]. In an otherwise healthy liver, the replacement of hepatocytes (and tissue mass) lost to surgical resection or toxic injury is achieved through the proliferation of differentiated, normally quiescent hepatocytes contained in the residual (viable) tissue (Fig. 17.1). For additional information on the subject of liver regeneration, please refer to Chap. 18. However, certain forms of liver injury impair the capacity of the remaining differentiated hepatocytes to proliferate in response to liver tissue deficit. When this occurs, a reserve or facultative stem-like progenitor cell compartment is activated to proliferate and replace the lost hepatocytes. Recent evidence suggests that there are at least two distinct cell populations that can be activated to generate new hepatocytes and/or cholangiocytes. Rodent livers contain a population of normally quiescent (facultative), undifferentiated stem-like progenitor cells that reside in or around the biliary ductules of the portal tracts, which can be activated under certain pathological conditions to reestablish a proliferating-differentiating lineage (the oval cell reaction), capable of generating hepatocytes and some other cell types [67, 68]. In addition, the adult liver contains a population of incompletely differentiated small hepatocyte-like progenitor cells (SHPC) that can be activated to replace lost hepatocytes in some forms of tissue injury [69]. These observations combine to suggest that there are at least three distinct populations of cells with stem-like potential in the adult rat liver (Fig. 17.1). It is conceivable that all these stem-like progenitor cells of the adult liver are derived from the same primordial stem cell population of the developing liver. In the following sections, the evidence for the existence of each of these stem-like progenitor cell populations in liver will be reviewed.

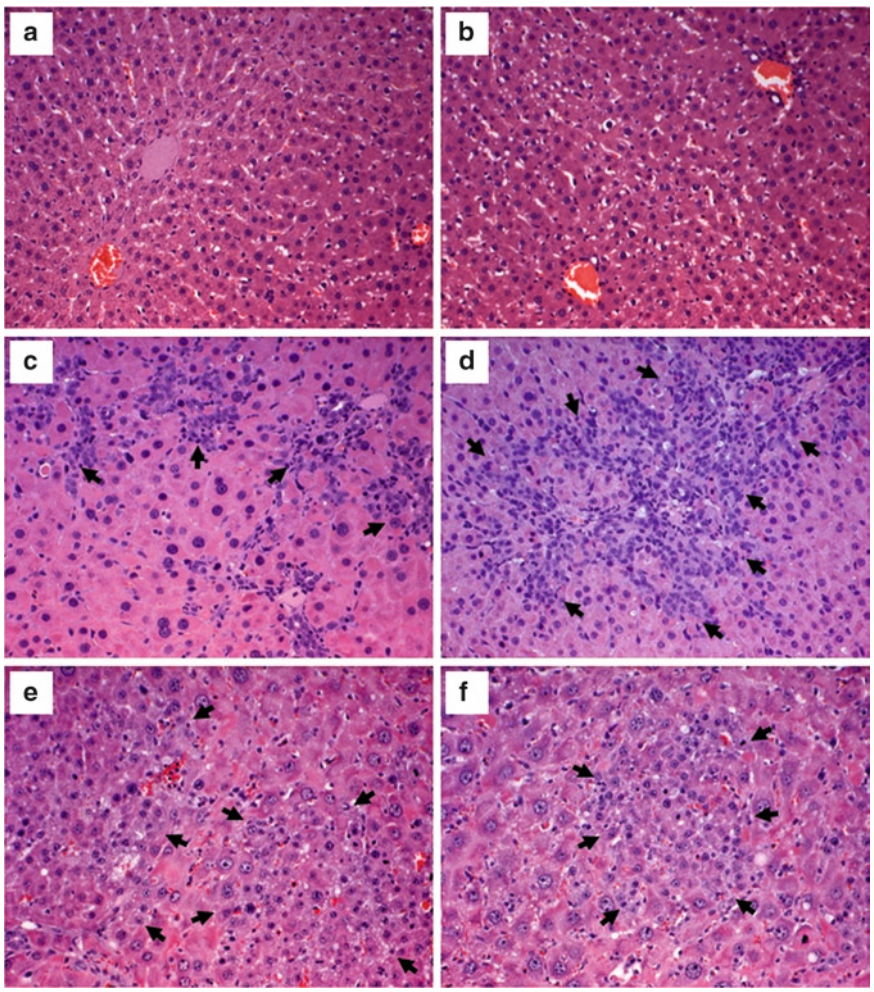

Fig. 17.1 Stem-like progenitor cell responses to signals for liver regeneration. liver regeneration after surgical partial hepatectomy involves proliferation of differentiated hepatocytes (**a**, **b**). However, when differentiated hepatocytes cannot proliferate in response to the regenerative stimulus, other liver progenitor cell populations are activated, such as oval cells in the 2-AAF model of liver injury (**c**, **d**), or small hepatocyte progenitor cells (SHPC) after retrorsine-mediated liver injury (**e**, **f**). *Arrows* denote oval cells (**c**, **d**) and SHPC (**e**, **f**). Original magnification: ×10

Unipotential Liver Stem-Like Progenitor Cells: Differentiated Hepatocytes and Biliary Epithelial Cells

The liver possesses an enormous capacity to replace cells that are lost to surgical resection or necrosis [10, 70–74]. Activation of undifferentiated stem-like progenitor cells does not occur after cell loss when mature hepatocytes and biliary epithelial cells are capable of proliferating to restore the normal liver mass and structure [75, 76]. In rats subjected to surgical partial hepatectomy, the residual (viable) hepatocytes undergo a rapid burst of proliferation that ultimately restores the normal hepatocyte number [66, 77–79]. Likewise, biliary epithelial cells proliferate after partial hepatectomy to form expansions of the intrahepatic duct system [66, 80, 81]. Irrespective of their location within the parenchyma (periportal to pericentral), virtually all hepatocytes proliferate and divide at least once during restoration of the hepatocyte number [82, 83]. The ability of quiescent hepatocytes to reenter the cell cycle and proliferate in response to liver deficit has fascinated investigators throughout history. More recently, the extensive growth potential and enormous proliferative (replicative) capacity of the mature hepatocyte has become evident. In rats, hepatocytes proliferate and divide at least 8–12 times during the prolonged process of liver growth following five consecutive partial hepatectomies [84]. In transgenic mice that express the urokinase gene in the liver under the direction of the albumin promoter-enhancer, the majority of hepatocytes succumb to the toxic transgene product [85]. In this model, the toxic transgene becomes inactivated in random hepatocytes enabling them to proliferate, undergoing 10–12 cycles of cell division to yield discrete nodular aggregates (clones) that repopulate the liver parenchyma [86]. In a similar experimental system, transplanted normal hepatocytes repopulate the livers of transgenic mice that lack fumarylacetoacetate hydrolase ($FAH^{-/-}$) enzyme activity [87] due to the targeted disruption of exon 5 of the *Fah* gene [88]. In this model, the transplanted FAH-expressing hepatocytes exhibit a selective growth advantage over host FAH-deficient hepatocytes, allowing the former to repopulate the livers of mutant mice. In these studies, it was estimated that transplanted hepatocytes proliferated through at least 15 cell divisions during repopulation of mutant livers [87]. In other studies, wild-type male hepatocytes were serially transplanted at limiting dilution through the livers of female $FAH^{-/-}$ mice [89]. Complete repopulation of the diseased liver was accomplished in each round. The complete replacement of host liver by the progeny of transplanted hepatocytes through seven rounds of transplantation suggests that the transplanted hepatocytes were capable of at least 100 population doublings [89]. In addition, these investigators found that both diploid and polyploid hepatocytes were capable of liver repopulation in the $FAH^{-/-}$ mouse model system [90]. More recently, immunodeficient $FAH^{-/-}$ mice were pretreated by infection with an adenovirus expressing urokinase followed by transplantation of human hepatocytes [91]. In these animals, the engrafted human hepatocytes replaced up to 90% of the liver parenchyma, and could be serially transplanted through several animals, suggesting that human hepatocytes have an extensive replicative capacity similar to that of rodent hepatocytes [91]. Together, these studies demonstrate the incredible capacity for cell proliferation by differentiated hepatocytes (including human hepatocytes), consistent with the suggestion that these cells represent a unipotential stem-like progenitor cell population of the adult liver.

Unipotential Liver Stem-Like Progenitor Cells: Small Hepatocyte Progenitor Cells

In several experimental models, hepatocytes are rendered incapable of proliferation through treatment with mito-inhibitory compounds, facilitating the outgrowth of stem-like progenitor cells in response to liver deficit. We have described the cellular responses and time course for liver regeneration after surgical partial hepatectomy (PH) in rats with retrorsine-induced hepatocellular injury [69]. Similar to other models of chemical liver injury [17, 24], systemic exposure to retrorsine, a member of the pyrrolizidine alkaloid (PA) family, results in a severe inhibition of the replicative capacity of fully-differentiated hepatocytes [69, 92–94]. When confronted with a strong proliferative stimulus such as PH [69, 92, 93] or hepatocellular necrosis [95], retrorsine-injured hepatocytes synthesize DNA, but are unable to complete mitosis, and arrest as non-proliferative giant cells (megalocytes). In this model, neither retrorsine-injured, fully-differentiated hepatocytes nor oval cells proliferate sufficiently to contribute significantly to the restoration of liver mass after PH. Instead, the entire liver mass is reconstituted after PH through a novel cellular response that is mediated by the emergence and rapid expansion of a population of small hepatocyte-like progenitor cells (SHPCs), which share some phenotypic traits with fetal hepatoblasts, oval cells, and fully-differentiated hepatocytes, but are morphologically and phenotypically distinct from each [69]. SHPCs emerge in all regions of the liver lobule (periportal, pericentral, and midlobular) after PH and are derivative of the modest oval cell outgrowth in periportal regions, suggesting that SHPCs represent a novel cell population [69].

Small hepatocyte progenitor cells morphologically, most closely resemble differentiated (but small) hepatocytes at early time-points after PH, perhaps suggesting that SHPCs are a subset of retrorsine-resistant hepatocytes and not a novel progenitor cell population. However, the phenotype of SHPCs

indicate that they are in fact distinct from fully-differentiated hepatocytes, since a subset of SHPCs express the oval cell/bile duct/fetal liver markers OC.2 and OC.5 through 5 days post-PH [69]. Co-expression of hepatocyte markers and oval cell markers by early-appearing SHPCs suggest that these cells are not fully-differentiated, and that they display a phenotype similar to that expected for a cell type transitional between the bipotential hepatoblast (E14) and a fetal hepatocyte (E18–E20). Retrorsine-exposed rats are able to regenerate their liver mass completely after PH as is evidenced by liver weights and liver/body weight ratios [69]. At 30 days post-PH, liver weights and liver/body weight ratios do not differ significantly after either retrorsine/PH, or control/PH [69]. By this time, the progeny of SHPCs occupy virtually the entire parenchyma in retrorsine/PH rats (~90% by area). However, comparison of the time-course for liver regeneration in control and retrorsine-exposed rats after PH shows that liver regeneration through activation and expansion of SHPCs is a much more protracted process. Complete regeneration of the liver mass in retrorsine-exposed animals requires nearly 30 days, compared to about 10 days in control rats [69].

Using a combined approach involving gene expression analysis of tissues isolated using laser capture microdissection and in situ immunohistochemistry, the expression patterns of select mRNAs and proteins were examined in the earliest (least-differentiated) SHPCs that emerge after PH in retrorsine-exposed rat livers [96]. The results show that early-appearing SHPCs (at 3–7 days post-PH) express mRNA and/or protein for all of the major liver-enriched transcription factors (HNF1α, HNF1β, HNF3α, HNF3β, HNF3γ, HNF4, HNF6, C/EBPα, C/EBPβ, and C/EBPγ), WT1, α-fetoprotein, and P-glycoprotein [96]. Compared to surrounding hepatocytes, early-appearing SHPCs lack (or have significantly reduced) expression of mRNA for hepatocyte differentiation markers tyrosine aminotransferase and α1-antitrypsin [96]. Likewise, SHPCs that emerge and proliferate during the early phases of liver regeneration lack or have reduced expression of several hepatic CYP proteins that are known to be induced in rat livers after retrorsine exposure (CYP2E1, CYP1A2, and CYP3A1). However, by 30 days post-PH, expression patterns of all markers expressed by SHPCs mirrors those expected for fully-differentiated hepatocytes. Both α-fetoprotein and WT1 protein are uniquely expressed by SHPCs during the early phase of liver regeneration, suggesting that these markers may be used to identify the earliest progenitors of these cells [96]. These results suggest that SHPCs represent a unique parenchymal (less-differentiated than mature hepatocytes) progenitor cell population of adult rodent liver [69, 96]. The progenitor cell of origin of the SHPCs is a hotly debated topic with some investigators suggesting that these cells represent an intermediary between oval cells and mature hepatocytes [10, 97], others suggesting that these cells are derived from mature (fully-differentiated) hepatocytes [98–100], and still others suggesting that these cells represent an independent progenitor cell population [69, 101, 102]. As a result, several studies have been performed by our group and others to elucidate the origins of the SHPCs [100, 103, 104].

To address the possible progenitor relationship between oval cells and SHPCs, retrorsine-exposed Fischer 344 rats were treated with the mitoinhibitory agent 2-acetamidofluorene (2-AAF), 7 days prior to PH [103]. In marked contrast to animals treated only with retrorsine, the livers harvested from 2-AAF/retrorsine-treated rats at 3 and 7 days post-PH showed extensive proliferation of oval cells, but no proliferation of SHPCs [103]. Clusters of "small hepatocytes" are first observed 10 days post-PH, continue to proliferate through 14 days post-PH, and restore liver weight to control levels by 21 days post-PH [103]. Labeling of proliferating oval cells with bromodeoxyuridine (BrdU) at 6 days post-PH demonstrated that the "small hepatocytes" observed at 10 days post-PH in this model are progeny of oval cells and not an independent cell population [103]. Further evidence that these "small hepatocytes" are not the same population as SHPCs was obtained by treating retrorsine-exposed rats with 2-AAF 7 days post-PH. In these animals, the administration of 2-AAF resulted in a blockade of SHPC expansion suggesting that these cells are susceptible to 2-AAF poisoning [103]. As the "small hepatocytes" observed in 2-AAF/retrorsine-exposed animals proliferate in the presence of 2-AAF, this is strong evidence that, although histologically similar, these cells are not SHPCs. The suggestion that oval cells and SHPCs do not share the same cellular origin has been confirmed recently in studies by Pichard et al. [100]. Additional evidence that oval cells are not the source of SHPCs emerged from experimental models that employ the bile duct toxin diaminodiphenylmethane (DAPM) [104]. In this study, retrorsine-exposed Fischer 344 rats were treated with DAPM 24 hours prior to PH. In this model, DAPM treatment results in significant damage to the bile ducts, but had no effect on liver regeneration. Oval cells were never observed in DAPM/retrorsine treated animals but SHPC clusters were observed beginning at 1–3 days post-PH. These clusters continued to proliferate and expand through the subsequent interval in a manner identical to that observed in animals treated only with retrorsine until liver weight was restored by the end of the 30 day experimental period [69, 104]. These results provide direct evidence that oval cell proliferation is not necessary for SHPC-mediated liver regeneration and provides the strongest evidence yet that these cells are not derived from oval cells. Instead, the findings of this study suggest that the cell of origin of the SHPC is likely to be located in the liver parenchyma. However, the exact cell type giving rise to these cells remains unknown. Our group has posited that SHPCs may arise from a population of cells that are histologically

similar to mature hepatocytes but are phenotypically distinct [101, 102]. This is based on the original characterization of the SHPCs where it was demonstrated that SHPCs exhibit characteristics of fetal hepatoblasts, oval cells, as well as mature hepatocytes [69, 96]. These characteristics suggest that a mature (fully-differentiated) hepatocyte is unlikely to be the source of a less differentiated cell population. Regardless, studies have been published suggesting that mature hepatocytes are the source of SHPCs. In one recent study, Ferry and colleagues used a method of genetically labeling hepatocytes in a modified version of the retrorsine model of liver injury to investigate the possibility that mature hepatocytes are the source of SHPCs [98]. In this study, the authors utilize a retroviral vector containing the β-galactosidase gene to label mature hepatocytes in retrorsine-treated Sprague Dawley rats. The animals were then subjected to PH, biopsied 28 days post-PH, and euthanized 56 days post-PH [98]. The authors observed the presence of SHPCs in the livers of these animals at both the time of biopsy and sacrifice. β-galactosidase staining was observed in some of the cell clusters present in the livers of these animals suggesting that some retrovirally labeled cells were the source of the SHPCs [98]. Based on these findings, the authors concluded that mature hepatocytes are the source of SHPCs. However, these findings do not address the phenotypic differences between those observed in SHPCs and that of mature (fully-differentiated) hepatocytes. In addition, the findings of this study do not rule out the possibility that the cell of origin of the SHPC is a less differentiated cell type located in the liver parenchyma. As such, additional studies are required to definitively establish the source of these interesting cells.

Multipotential Liver Stem-Like Progenitor Cells: Oval Cells

Oval cells, which proliferate in several hepatocarcinogenesis models and in some forms of noncarcinogenic liver damage, may be related to liver stem-like progenitor cells. A number of different experimental models elicit the proliferation of oval cells [17, 50, 76, 105]. All of these models are characterized by concurrent stimulation of liver growth and inhibition of normal mechanisms for liver tissue restoration (i.e. blockade of the proliferation of hepatocytes). The stimulus for liver growth can be satisfied through several different methods, including surgical resection, nutritional stress, or chemically-induced necrosis. Blockade of hepatocyte proliferation is frequently achieved by the use of chemicals (such as 2-acetylaminofluorene) that impede or prevent mitotic division of mature hepatocytes [67, 68]. The cellular response common to each of these models involves the proliferation of small cells with scant cytoplasm and ovoid nuclei that are morphologically described as oval cells [106]. While most of the models of oval cell proliferation involve rats, similar models have been developed using carcinogen-treated mice and transgenic mice that express viral oncogenes or other transgenes [107–112].

The timing of cellular events differs, sometimes dramatically, among the various models of oval cell proliferation [17]. However, the majority of oval cell proliferation models share a common sequence of events: (1) Proliferation of oval cells in or around the portal spaces, (2) invasion of the lobular parenchyma by the proliferating oval cells, (3) appearance of transitional cell types and immature hepatocytes, and (4) maturation of hepatocytes and restoration of normal liver structure. Oval cells are initially seen in the portal zones of the liver lobule in the regions of terminal bile ductules or cholangioles [32, 113]. Proliferating oval cells are recognized to represent a collection of phenotypically distinct cells that compose a heterogeneous cell population or "compartment" [37, 114, 115]. Morphologically, the typical oval cell possesses cellular characteristics similar to those cells of terminal bile ductules [116–118]. However, the oval cell compartment also contains transitional cells that display morphologic features intermediate between oval cells and hepatocytes [118, 119].

Proliferating oval cells form irregular duct-like structures that are connected to pre-existing bile ducts [118, 120, 121]. As they proliferate, oval cells migrate from the portal regions into the lobular parenchyma, sometimes occupying a large percentage of the liver mass. Groups of small basophilic hepatocytes appear among oval cells, and these immature hepatocytes proliferate and differentiate as the oval cells gradually disappear and the normal liver structure is restored [118, 122–125]. The possibility that oval cells might possess stem-like properties and give rise to hepatocytes and/or biliary epithelial cells has been recognized for some time [29, 31, 106]. Several studies have attempted to document the fate of oval cells that proliferated in various hepatocarcinogenesis models and after noncarcinogenic liver injury, producing evidence that oval cells are precursors of hepatocytes [122–126]. Using the modified Solt-Farber model of oval cell proliferation, Evarts et al. [122, 124] demonstrated unequivocally that oval cells radiolabeled with ^{3}H-thymidine could directly give rise to tagged basophilic hepatocytes. More recently, Alison and colleagues examined the proliferation and fate of oval cells in rats using the modified Solt-Farber model with various doses of 2-acetylaminofluorene [127]. Proliferation of oval cells also has been described in the chronic injury produced in mouse liver by transgenic expression of both hepatitis B virus [111] and SV40 T antigen [109]. Bennoun and colleagues [109] demonstrated a transition between proliferating oval cells in SV40 T antigen transgenic mice and newly formed hepatocytes. Likewise in mice treated with diethylnitrosamine, oval cells proliferate

and subsequently differentiate into hepatocytes [107]. Employing the D-glactosamine model of oval cell proliferation in rats, Lemire et al. [125] and Dabeva and Shafritz [123] also demonstrated the transfer of the radiolabel from oval cells to small hepatocytes. In both of these studies, transition from oval cells to hepatocytes was accompanied by a shift from the biliary epithelial/oval cell phenotype (expression of α-fetoprotein, γ-glutamyltranspeptidase, and biliary epithelial-type cytokeratins) to a cellular phenotype characteristic of hepatocyte differentiation (expression of albumin, glucose-6-phosphatase, and other hepatocyte markers; reduction of α-fetoprotein expression) [123, 125].

Liver Stem-Like Progenitor Cells from Extrahepatic Tissues

In addition to the progress characterizing stem-cell responses in liver and the various populations of liver cells with stem-like potential, advances have also been made in the identification of multipotent adult stem cells with broad differentiation potential that includes liver. A number of studies have identified extrahepatic sources of stem-like cells that can colonize the liver and/or give rise to hepatocytes in vivo or in culture. Most recently, several investigators have reported that progenitor cells contained in bone marrow or peripheral blood can give rise to cells of the liver [21]. In somewhat older studies, the ability of pancreatic cells to give rise to hepatocytes has been described. In addition to these two extrahepatic sources of stem-like progenitor cells for liver epithelial cells, several other sources have also been suggested, including neural stem cells. Evidence that extrahepatic stem cells can give rise to liver is summarized in the sections that follow.

Liver from Progenitor Cells of the Bone Marrow

Bone marrow contains several different cell types with stem-like potential, including hematopoietic, stromal, and mesenchymal stem cells. In addition to these progenitor cell types, it has been suggested that bone marrow contains a multipotent adult stem-like progenitor cell that expresses a broader tissue differentiation potential. However, whether this multipotent progenitor cell compartment of the bone marrow represents a single cell type with broad differentiation capacity, or whether it represents an admixture of several tissue stem cell types has not been resolved [128]. In fact, the multipotent stem-like progenitor cell of bone marrow may be related (or identical) to one of these cell types (hematopoietic or mesenchymal stem cells) of the bone marrow. Bone marrow transplants generate cell lineages of the blood, and have now been suggested to give rise to a number of other cell types, including cardiac muscle [129], skeletal muscle [130, 131], neurons [132–134], and lung epithelium [135]. In the liver, bone marrow-derived stem-like progenitors have been suggested to give rise to oval cells [136], hepatocytes [137–141], and biliary epithelial cells [135, 138]. Putative bone marrow progenitor cell-derived hepatocytes have been described in rats [136], mice [137, 140, 141], and humans [138, 139]. A recent review of much of the literature related to the potential derivation of hepatocytes from bone marrow progenitor cells concluded that hematopoietic cells do not transdifferentiate into hepatocytes and that these cells do not significantly contribute to formation of new hepatocytes under normal physiological conditions, or in pathology [142]. Despite this conclusion, some of the evidence that suggests that bone marrow-derived stem-like progenitor cells can give rise to hepatocytes in experimental models and humans will be reviewed.

Transdifferentiation of bone marrow progenitor cells into hepatocytes has yielded variable replacement of liver, possibly related to the animal model employed. Transplantation of unfractionated bone marrow from male donors into lethally irradiated syngeneic female mice (B6D2F1) resulted in efficient reconstitution of the host hematopoietic system and generation of donor-derived hepatocytes in the host livers [137]. The bone marrow-derived hepatocytes were identified within the hepatic plates of recipient livers using Y-chromosome in situ hybridization [137]. Quantitative analysis suggested that 1–2% of hepatocytes were bone marrow-derived [137]. These results suggested that bone marrow-derived stem cells could engraft and give rise to hepatocytes, albeit at low frequency, in normal liver. Grompe and colleagues employed the murine model of hereditary tyrosinemia type I [87, 88] to investigate the potential for bone marrow-derived stem cells to repopulate diseased liver [140, 141]. Transplantation of unfractionated bone marrow into $FAH^{-/-}$ mice resulted in replacement of 30–50% of the liver mass after a period of selection [140]. Furthermore, when highly purified KTLS ($c\text{-}kit^{high}Thy^{low}Lin^{-}Sca\text{-}1^{+}$) hematopoietic stem cells from male ROSA26/BA mice were transplanted into lethally irradiated female $FAH^{-/-}$ mice, liver engraftment and hepatocytic differentiation of transplanted cells was observed [140]. The hepatocyte phenotype of engrafted cells was confirmed by expression of albumin and bile canalicular dipeptidylpeptidase IV [140]. In addition, the engrafted cells expressed the FAH protein and were positive for β-galactosidase and the Y-chromosome [140]. It was also suggested that the $c\text{-}kit^{-}$ and Lin^{+} fractions of the bone marrow do not contain significant numbers of progenitor cells that can give rise to hepatocytes [140]. While substantial liver repopulation by bone marrow-derived hepatocytes was observed when selective conditions were employed [140, 141], negligible hepatocyte replacement

was observed in the absence of selective pressure [141]. In a similar study, unfractionated bone marrow from transgenic mice expressing Bcl2 under the control of the liver pyruvate kinase gene promoter was transplanted into normal mice, some of which were subjected to lethal irradiation [143]. In this study, the frequency of hepatocyte differentiation from transplanted bone marrow progenitor cells was rare. However, when selection pressure was applied through the administration of anti-Fas antibodies, the small numbers of bone marrow-derived hepatocytes present in the livers of recipient mice expanded 6-fold to 20-fold, ultimately occupying approximately 1% of the liver mass [143]. These studies show that positive selection pressure can result in a higher degree of replacement of liver by bone marrow-derived hepatocytes. Other investigators have failed to detect donor-derived hepatocytes in undamaged livers after bone marrow transplant, despite reconstitution of the hematopoietic system and replacement of the liver endothelium [144, 145]. These observations suggest that generation of hepatocytes from bone marrow stem cells is uncommon in the absence of strong selective pressure, such as that in the $FAH^{-/-}$ mouse model.

A few studies have examined the differentiation potential of bone marrow-derived progenitor cells in vitro. Verfaillie and colleagues have isolated and established cultured, multipotent, adult progenitor cells from bone marrow of humans, mice, and rats [146, 147]. These multipotent adult progenitor cells co-purify with the mesenchymal stem cell fraction of the bone marrow [146, 147]. When these cells are propagated on Matrigel in the presence of FGF-4 and HGF, hepatocyte-like cells expressing albumin, CK18, and HNF3β resulted after 14 days of culture [148]. Furthermore, these multipotent adult progenitor cell-derived hepatocytes expressed several functional characteristics of mature hepatocytes, including secretion of urea and albumin, expression of phenobarbital-inducible cytochrome P450, the capacity to store glycogen, and the ability to take-up LDL [148], suggesting that the bone marrow of adult mammals contains progenitor cells with the potential to give rise to hepatocytes, and that these cells can be propagated in culture without loss of potency [148].

Liver from Stem-Like Progenitor Cells of the Pancreas

Several experimental models have been developed in which large eosinophilic cells that morphologically and phenotypically resemble hepatocytes are induced in the pancreas of rats and hamsters following severe pancreatic injury. Rats maintained on a copper deficient diet for 8–10 weeks show widespread injury to exocrine elements of the pancreas [149, 150]. When the copper-deficient diet is replaced with a normal diet, hepatocyte-like cells develop during the regeneration of the pancreatic tissue [149, 150]. In this model, cells that resemble hepatic oval cells are thought to represent the progenitor cells for pancreatic hepatocytes [150]. These observations coupled with other studies, led to the suggestion that liver and pancreas may share a common stem cell [151]. To examine the possibility that pancreatic oval cells could serve as liver progenitor cells, proliferating pancreatic oval cells were isolated and introduced into the livers of dipeptidylpeptidase IV-deficient rats via transplantation into the spleen [152]. Following transplantation, hepatocyte-like cells that express dipeptidylpeptidase IV activity were observed in the livers of recipient dipeptidylpeptidase IV-deficient animals, suggesting that oval cells proliferating in response to pancreatic injury caused by the copper-deficient diet can serve as hepatocyte progenitor cells [152]. In a similar study, suspensions of pancreatic cells from normal adult mice were transplanted into $FAH^{-/-}$ mice to examine the possibility that the normal pancreas contains a population of hepatocyte progenitor cells [153]. When selection pressure was applied, extensive liver repopulation (>50% replacement of liver) was observed in a subset of recipient mice, and another subset showed nodules of donor-derived hepatocytes [153].

Chen et al. [154] have examined the fate of normal rat pancreatic ductal epithelial cells following implantation into the abdominal subcutaneous tissue or intraperitoneal cavity of adult syngeneic rats. In these studies RP-2 pancreatic duct epithelial cells [154] were embedded in a gel composed of extracellular matrix (collagen I and Matrigel) prior to implantation [154]. Eight weeks following subcutaneous implantation, nests of eosinophilic epithelioid cells and rare duct structures were observed in the recovered extracellular matrix gel [154]. Six weeks following intraperitoneal implantation, trabeculae and clusters of large polygonal epithelioid cells with granular eosinophilic cytoplasms, resembling mature hepatocytes of the adult liver, were observed [154]. These hepatocyte-like cells expressed high levels of tyrosine aminotransferase, albumin and transferrin, and stained positively with HES6 monoclonal antibodies [154].

These studies demonstrate that normal pancreatic duct epithelial cells can differentiate into functional hepatocytes following implantation into an appropriate host microenvironment. They provide additional support for the suggestion that liver and pancreas share a similar stem cell whose differentiation options are determined by the tissue microenvironment.

Liver from Neural Stem Cell Cultures

Cultured neural stem cells isolated from mice [155], have been shown to give rise to neurons and glia following transplantation into brain tissue of host animals [156]. Such neural

stem cells have been suggested to have a differentiative plasticity when transplanted into various tissue microenvironments other than the brain. For instance, neural stem cells derived from adult donor tissue differentiate into hematopoietic lineages when engrafted into the bone marrow [157]. When introduced into developing mouse blastocysts, neural stem cells contribute to cells of various germ layers and tissues of chimeric embryos, including the liver [158]. Additional studies will be required to demonstrate whether neural stem cells can give rise to differentiated hepatocytes in the adult liver.

Human Liver Stem-Like Progenitor Cells

Evidence for Liver Stem-Like Progenitor Cells in Humans

In recent years numerous investigators have attempted to identify and isolate human liver stem-like progenitor cells and/or have made observations in pathological human livers that suggest the existence of these cells. In many instances, investigators have attempted to determine if activation and proliferation of oval cells occurs in humans in a fashion similar to the oval cell reaction observed in rodents [159]. Using morphologic criteria and/or immunohistochemical staining, several reports suggest the presence of cells resembling oval cells in several different human liver diseases (reviewed in [17, 49]). In some studies, cells exhibiting a phenotype that is consistent with oval cells were observed in normal human liver [160, 161].

Liver from Bone Marrow Stem-Like Progenitor Cells in Humans

In rodents, bone marrow has been suggested to contain stem cells with hepatocytic differentiation potential. Likewise, several studies have suggested that human bone marrow contains stem-like progenitor cells that can differentiate into hepatocyte progeny under various conditions [139]. The first evidence that bone marrow-derived progenitor cells give rise to hepatocytes in humans emerged from a study of archival autopsy or biopsy liver specimens from gender-mismatched transplant patients [138]. Liver tissue from two female patients who received therapeutic bone marrow transplants from male donors, and four male patients who received orthotopic liver transplants from female donors were studied [138]. Variable numbers of Y-chromosome-positive hepatocytes and biliary epithelial cells were detected using in situ hybridization [138]. In the latter study, the interval from transplant to liver sampling was 1 month to 2 years, and the numbers of Y-chromosome-positive hepatocytes observed varied from 1 to 8% among the patients [138]. However, when the investigators adjusted the data to account for their assessment of the insensitivity of Y-chromosome in situ hybridization, the corrected results suggested that 5–40% of hepatocytes observed were derived from circulating progenitor cells, probably of bone marrow origin [138]. In a similar study, the livers of nine female patients who received bone marrow transplant from male donors and the livers of eleven male patients who received orthotopic liver transplants from female donors were evaluated for Y-chromosome-positive hepatocytes [139]. Among these two groups of patients, 0.5–2% of hepatocytes were found to be derived from extrahepatic progenitor cells, and clusters of Y-chromosome-positive hepatocytes were observed in several instances, suggesting that hepatocyte progeny had clonally expanded after colonization of the liver by circulating progenitor cells [139]. In a third study, patients with hematologic or breast malignancies received high-dose chemotherapy and transplants of allogeneic peripheral blood stem cells from donors that were pretreated with granulocyte colony-stimulating factor [162]. Y-chromosome-positive hepatocytes were detected as early as 13 days post-transplant, and 4–7% of hepatocytes examined were found to be donor-derived [162]. In all of these studies, small numbers of hepatocytes that were derived from bone marrow (or other circulating progenitor cells) were detected, and the interval from transplant to sampling of the liver was short (less than a year in most cases). It has been suggested that the engraftment of bone marrow-derived stem cells in the liver may represent an early feature in liver transplants, but that hepatocytes derived from bone marrow progenitor cells may not persist as a long-term feature of grafted livers [163]. In a study of gender-mismatched liver transplant patients with long interval between liver transplant and biopsy (1.2–12 years), no host-derived hepatocytes were detected when the Y-chromosome was used in in situ hybridization experiments [163].

Isolation and Culture of Adult Liver Stem-Like Progenitor Cells

Several types of epithelial cells can be isolated from rodent livers and established in primary or propagable cultures [47, 48]. Differentiated hepatocytes and bile duct cells can be maintained in primary culture for short periods of time, but generally these cell types exhibit limited propagablity and lifespan in culture [164, 165]. In contrast, simple (undifferentiated) liver epithelial cells can be readily established and propagated in culture [166]. These simple liver epithelial cell

types possess some stem-like properties, suggesting that they may represent the cultured counterpart of epithelial stem cells in the adult liver [167].

Early Studies of Propagable Liver Epithelial Cells

Early long-term rat liver epithelial cell cultures were established from cell outgrowths in liver tissue explant cultures [168]. Development of enzymatic techniques for the preparation of viable single-cell suspensions of liver cells made possible the selective culture of several liver epithelial cell types [169, 170]. Brief digestion of liver tissue with collagenase produces liver cell suspensions enriched for hepatocytes [169, 171], whereas enrichment of nonparenchymal epithelial cell types can be accomplished by the selective removal of hepatocytes from collagenase-dispersed liver using various strong proteases, such as Pronase or trypsin [172]. The nonparenchymal cells that remain following protease treatment of liver cell suspensions include macrophages (Kupffer cells), endothelial cells, bile ductular cells, Ito cells, and various hematopoietic cells [172, 173]. Also present in dispersed liver cell suspensions are simple epithelial cells [166, 174].

Rat Liver Epithelial Stem-Like Progenitor Cells: Oval Cell Lines

Oval cells have been isolated from diseased liver and established in culture by several laboratories. Morphologically, cultured oval cells are cuboidal and grow in a monolayer [175, 176]. Some established lines of oval cells are stably diploid or pseudodiploid, are nontumorigenic, and do not proliferate in soft agar [175–177]. Ultrastructurally, cultured oval cells exhibit catalase-positive peroxisomes that proliferate in response to treatment with clofibrate [176]. Cultured oval cells generally express glucose-6-phosphatase activity and lactate dehydrogenase isozymes 2–5, and they are variably positive for albumin and α-fetoprotein [176–179]. A few oval cell lines have been characterized for cytokeratin expression and shown to express CK8 and CK18, and to variably express or not express CK7 and CK19 [176, 177]. As with some other liver epithelial cell lines, cultured oval cells tend to be antigenically simple. Cultured LE/6 oval cells do not express antigens for monoclonal antibodies OC.1, OC.2, BD.1, H.1, or H.2 (reviewed in [24]). The presence of peroxisomes and glucose-6-phosphatase activity in cultured oval cells suggests that these cells are part of the hepatocyte lineage.

Rat Liver Epithelial Stem-Like Progenitor Cells: The WB-F344 Cell Line

Several lines of rat liver epithelial cells have been established from the livers of normal adult rats [24]. The WB-F344 rat liver epithelial cell line represents one such propagable rat liver epithelial cell line that was clonally derived from a single epithelial cell [23]. WB-F344 cells are small (9–15 μm diameter) polygonal cells that grow in a monolayer and are phenotypically similar to other established rat liver epithelial cell lines [24]. Ultrastructurally, WB-F344 cells exhibit a relatively simple cytoplasm with few organelles. Adjacent cells in confluent monolayers are joined by numerous desmosomes [23] and nexus junctions containing connexins 26 and 43, and are dye coupled. Cells are polarized, surfaces directed to the growth medium interface contain microvillus-like projections, and a basement membrane-like material containing fibronectin is deposited at the substrate interface [23]. WB-F344 cells possess a stable diploid or quasidiploid karyotype [23]. They do not proliferate in soft agar culture and are nontumorigenic following transplantation into neonatal syngeneic rats [23]. WB-F344 cells share some phenotypic traits with both hepatocytes and biliary epithelial cells, but their overall phenotype differs distinctively from either differentiated cell type [23]. Most notably, WB-F344 cells are null for the major antigens that typify and distinguish hepatocytes or biliary epithelial cells.

Stem-Like Progenitor Cells from the Human Liver

Very few studies have appeared that report the isolation and culture of human liver cells. Strom and colleagues have isolated a cell population from human liver and established it in propagable culture [180]. The resulting cell line, AKN-1, has been characterized in culture, and shows many characteristics of biliary epithelial cells [180]. It is tempting to speculate that AKN-1 cells represent a cultured counterpart to putative undifferentiated human liver stem cells. However, these cells contain chromosomal abnormalities, display an aneuploid DNA content, and are tumorigenic following transplantation into nude mice [180], indicating that the AKN-1 cell line may not represent propagable normal human liver stem cells. In a similar study, cells expressing c-kit and CD34 have been isolated and cultured from diseased human liver [161]. These cells were localized to portal tracts in close proximity to bile ducts in cirrhotic livers [161]. In cell culture, these cells expressed markers (such as CK19) that suggested differentiation towards the biliary epithelial cell lineage [161]. Of great significance, cells positive for c-kit

and CD34 were also isolated from normal human liver, albeit in smaller numbers, and these cells also acquire biliary epithelial differentiation in vitro [161].

Evidence for the Multipotential Differentiation of Adult Liver Stem-Like Progenitor Cells In Vivo

The ultimate proof that a rat liver epithelial cell line represents cultured stem-like cells requires the demonstration that these cells can give rise to hepatocytes and/or biliary epithelial cells following transplantation into appropriate sites in host animals. To investigate the differentiation potential of cultured rat liver stem-like progenitor cells, WB-F344 cells have been transplanted into livers or extrahepatic sites of syngeneic animals to examine their fate in vivo. Several weeks following the transplantation of WB-F344 cells into the interscapular fat pads of syngeneic Fischer 344 rats, small clusters of cells morphologically resembling hepatocytes were identified [167]. However, whether these cells possessed functional attributes of hepatocytes was not determined. Nonetheless, this observation suggested that transplanted WB-F344 cells could acquire characteristics of hepatocytes in vivo. In order to demonstrate a precursor-product relationship between transplanted cells and differentiated cell types in the liver, methods had to be established that would allow the definitive identification of the progeny of the transplanted cells among host cells in the adult liver. We have utilized three different strategies to examine the fate of WB-F344 rat liver epithelial cells following transplantation into adult rat livers: (1) Introduction of a genetic tag/marker enzyme into WB-F344 cells [167, 181], (2) transplantation of normal WB-F344 cells into the livers of rats that are deficient for dipeptidylpeptidase IV enzyme activity [182], and (3) transplantation of normal WB-F344 cells into the livers of Nagase analbuminemic rats [183]. In all of these model systems, transplanted WB-F344 cells (or BAG2-WB cells) integrated into hepatic plates, and morphologically and functionally differentiated into hepatocytes. The results from these studies combine to show that WB-F344 cells are multipotent and differentially responsive to the tissue microenvironment of the transplantation site.

Hepatocytic Differentiation by Transplanted WB-F344 Rat Liver Stem Cells

To facilitate transplantation studies, WB-F344 rat liver epithelial cells were genetically modified by infection with the CRE BAG2 retrovirus which encodes the *Escherichia coli* β-galactosidase gene and the Tn5 neomycin resistance gene [184]. The resulting cells, termed BAG2-WB, were transplanted into the livers of adult Fischer 344 rats and the livers of these rats were examined for the presence of β-galactosidase-positive cells at various times following transplantation. In these studies, β-galactosidase-positive hepatocyte-like cells were detected in the hepatic plates of recipient rats among the host hepatocytes phenotypically similar to other established rat liver epithelial cell lines [181]. The size and morphologic appearance of these cells is indistinguishable from that of the host hepatocytes [167, 181]. β-galactosidase-positive cells were observed at all time points examined, up to greater than one year following transplantation. Subsequent studies demonstrated that the β-galactosidase-positive hepatocyte-like cells express functional differentiation typical of hepatocytes, including expression of albumin, transferrin, α1-antitrypsin, and tyrosine aminotransferase [167]. Several methods were utilized to demonstrate further that the β-galactosidase-positive cells observed in these livers were derived from the transplanted BAG2-WB cells. In some studies, cells were labeled with the lipophilic fluorescent membrane dye PKH26-GL [181]. Examination of liver sections demonstrated the presence of fluorescent cells in the hepatic plates of the host livers, consistent with the observations made using the β-galactosidase marker enzyme [181]. In addition, the neomycin resistance gene of the CRE BAG2 retroviral construct could be detected by PCR in genomic DNA prepared from livers of rats that received BAG2-WB cell transplants [181]. Together, these studies demonstrate that transplanted WB-F344 rat liver epithelial cells incorporate into the hepatic plates of the host liver, morphologically and functionally differentiate into hepatocytes, and remain a stable component of the hepatic parenchyma over long periods of time.

In other transplantation studies [182], normal WB-F344 cells were transplanted into the livers of German Fischer 344 rats, which are deficient for dipeptidylpeptidase IV enzyme activity [185, 186] to examine the fate of these cells in a transplantation model that does not depend upon the use of exogenous marker enzymes. Dipeptidylpeptidase IV is a bile canalicular enzyme that is expressed by mature hepatocytes in normal rats [187, 188]. The WB-F344 cell line was isolated from an American strain adult Fischer 344 rat [23] that expresses normal levels of dipeptidylpeptidase IV activity in hepatocytes. Following transplantation into the dipeptidylpeptidase IV-deficient rats, WB-F344 cells incorporate into hepatic plates and morphologically differentiate into hepatocyte-like cells that express dipeptidylpeptidase IV enzyme activity [182]. These dipeptidylpeptidase IV-positive hepatocytes are easily distinguished from the host hepatocytes using a histochemical staining reaction for dipeptidylpeptidase IV activity. The dipeptidylpeptidase IV-positive hepatocytes in hepatic plates were comparable to adjacent

host hepatocytes in size and morphology. Close physical contact between the differentiated progeny of the transplanted cells and host hepatocytes was verified through co-localization of dipeptidylpeptidase IV staining and ATPase staining of hybrid bile canaliculi. In addition, the localization of dipeptidylpeptidase IV staining to bile canaliculi shows that the surface membranes of differentiating WB-F344 cells acquired the polarization characteristic of fully differentiated hepatocytes [182]. These results provide additional evidence that WB-F344 cells morphologically and functionally differentiate into hepatocytes following their transplantation into the liver microenvironment of adult rats.

In a third transplantation model, wild-type WB-F344 cells were transplanted into Nagase analbuminemic rats [189, 190] to examine the efficacy of liver stem-like cell transplant for phenotypic correction of a genetic liver defect [184]. In previous studies, transplanted WB-F344 cells (or BAG2-WB cells) gave rise to differentiated hepatocyte progeny that expressed albumin [167, 182]. Therefore, in this transplantation model, albumin serves dual roles: (1) As a marker for detection of the progeny of transplanted WB-F344 cells, and (2) as a metabolic marker for monitoring phenotypic correction of analbuminemia. Albumin-positive hepatocytes were detected in the hepatic plates among albumin-negative host hepatocytes in all rats receiving cell transplants. In some cases, individual albumin-positive hepatocytes were observed, whereas in other instances, clusters of albumin-positive hepatocytes were detected. The WB-F344 cells were transplanted into Nagase rats that were treated with cyclosporin to minimize rejection of the transplanted cells due to strain-specific differences between the Fischer 344 rat cells and the Sprague Dawley rat hosts [183]. However, once engrafted into the livers of these rats, albumin-positive WB-F344 hepatocyte progeny could be detected for up to four weeks following the cessation of cyclosporin treatment [183].

Multipotential Differentiation of Adult Liver Stem Cells in Culture

Various approaches have been used to examine the differentiation potential of cultured rat liver stem cells. These include modification of culture mediums to contain differentiation-promoting agents, and the use of combinations of extracellular matrix materials as culture substrates. These studies have yielded evidence that cultured stem-like epithelial cells can be induced to express characteristics of differentiated liver cell types in culture. In the following sections we will review the results of our studies with WB-F344 rat liver epithelial cells, as well as some studies from the literature on the differentiation of oval cells in culture.

Hepatocytic Differentiation of Oval Cells In Vitro

Oval cell cultures established from rats treated with 3′-methyl-4-dimethylaminoazobenzene exhibit a typical epithelial morphology in culture, express various cytokeratins, vimentin, γ-glutamyltranspeptidase, and BDS7 antigen [191]. The phenotype of these cells can be modified by culturing them on fibronectin-coated dishes in medium containing various differentiation-promoting agents. Inclusion of sodium butyrate in the growth medium inhibits cellular proliferation and produces dramatic morphological alterations in the cultured oval cells [191]. In the presence of sodium butyrate alone or in combination with dexamethasone, cultured oval cells synthesize albumin and express tyrosine aminotransferase activity [191]. Steinberg and co-workers have also examined the effects of differentiation-promoting chemicals on the phenotypic characteristics of cultured oval cell lines [177]. Oval cell lines (OC/CDE) were established from cells isolated from rats maintained on a choline-deficient diet supplemented with ethionine [177]. Exposure of OC/CDE cell lines to either sodium butyrate or dimethylsulfoxide resulted in cessation of cell proliferation, increase in cell size, expression of albumin (in 35–40% of cells), and enhancement of glucose-6-phosphatase, γ-glutamyltranspeptidase, and alkaline phosphatase activities [177]. Tyrosine aminotransferase activity was not detected in OC/CDE cell cultures treated with either sodium butyrate or dimethylsulfoxide [177]. These studies combine to demonstrate that cultured oval cells can be induced to express some characteristics of differentiated hepatocytes.

Fausto and colleagues [192] developed a three dimensional cell culture system that supports the hepatocytic differentiation of oval cell lines. In this system, LE/2 and LE/6 oval cells were cultured within a collagen I gel matrix, supported by a fibroblast feeder layer. After several weeks in culture, these oval cells acquired a phenotype characterized by typical hepatocyte morphology and ultrastructure, expression of an hepatocytic cytokeratin pattern ($CK8^+$, $CK18^+$, $CK19^-$), and production of albumin [192]. In the absence of a fibroblast feeder layer, oval cells cultured in this model system with defined growth factors HGF and/or KGF) produced ductal structures, suggesting differentiation towards the biliary epithelial cell lineage [192]. This study shows that cultured oval cells are bipotent and that their differentiation fate is influenced by soluble factors (growth factors and others) produced by stromal cells.

Hepatocytic Differentiation by RLE-13 Rat Liver Epithelial Cells in Culture

A number of different simple epithelial cell lines have been established in culture from normal rat livers (reviewed in [17]), including RLE-13, which was established from a normal adult Fischer 344 rat [193]. Thorgeirsson and colleagues have induced hepatocytic differentiation of RLE-13 cells by treatment with 5-aza deoxycytidine, followed by culture in defined growth medium containing FGF1/2, oncostatin M, HGF, and dexamethasone [194]. Culture of the RLE-13 cells under these conditions resulted in significant enlargement of cell size, increased organelle complexity, and decreased proliferation. Concurrent with the morphological alterations, differentiating RLE-13 cells expressed hepatocyte-specific markers, including tyrosine aminotransferase, and liver-enriched transcription factors, including HNF4 [194]. These results combine to suggest that RLE-13 cells acquire an hepatocytic phenotype when maintained in culture under defined conditions.

Hepatocytic Differentiation of WB-F344 Rat Liver Stem-Like Progenitor Cells in Culture

Exposure to sodium butyrate in culture inhibits proliferation, alters normal cellular morphology (increased cell size and decreased nuclear/cytoplasmic ratio), and dramatically increases cellular protein synthesis in WB-F344 rat liver epithelial cells [195]. Ultrastructurally, sodium butyrate-treated WB-F344 cells demonstrate a complex cytoplasm with extensive rough endoplasmic reticulum, numerous mitochondria, and large numbers of primary and secondary lysosomes. Sodium butyrate-treated WB-F344 cells also express dexamethasone-inducible tyrosine aminotransferase enzyme activity [195], which is a marker of hepatocyte differentiation. The dexamethasone-inducible tyrosine aminotransferase activity developing in these sodium butyrate-treated WB-F344 cells responds to the modulating effects of insulin and L-tyrosine in a manner that closely resembles that of cultured hepatocytes and hepatoma cell lines [196, 197]. These studies demonstrate that WB-F344 cells can be induced to express traits of differentiated hepatocytes in vitro.

Using a similar cell culture system, Couchie and colleagues have evaluated the ability of WB-F344 cells to differentiate into the biliary epithelial cell lineage [198]. WB-F344 cells cultured on dishes that were coated with laminin-rich Matrigel in the presence of growth medium containing sodium butyrate demonstrated a reduction in proliferation and formed cord-like structures between islets of cells [198]. WB-F344 cells in the cord-like structures were elongated, and expressed several biliary markers, including BDS7, CK19, and γ-glutamyl transpeptidase [198]. These results suggest that WB-F344 cells adopt a biliary epithelial cell phenotype in response to specific factors/signals in cell culture. More recently, Yao and colleagues [199] demonstrated that stable transfection of WB-F344 cells with RhoA expression vectors drives biliary differentiation in vitro.

Stem-Like Progenitor Cell Responses in Liver Injury and Repair

The mammalian liver possesses tremendous flexibility in its capacity to respond to injury and loss of cell numbers (function). At least three different cell populations have been implicated in liver regeneration: (1) differentiated hepatocytes (in otherwise normal liver), (2) SHPC (observed in retrorsine-exposed rats), and (3) oval cells (observed in numerous models of liver injury). Given multiple sources of regenerative cells and the observed differences in timing of activation of these cell populations in response to liver deficit, it is intriguing to speculate that there is a hierarchy of potential cellular responses and that the nature of the regenerative cell population is determined by (a) the presence or absence of liver injury, (b) the type and extent of injury, and (c) the capacity of each cell population to respond. In this model, activation and proliferation of mature hepatocytes represents the primary (preferential) cellular response, and the activation, emergence, and proliferation of reserve stem-like progenitor cell populations (SHPC or oval cells) represent secondary cellular responses, occurring only when the primary response is blocked or impaired. Several studies from the literature suggest that IL6 may be a common signaling molecule that functions to regulate the liver's response to injury [200–203]. There may be redundancy in the cellular reactions to liver injury, but a common regulatory pathway that directs the process of regeneration. Thus, following a signal for liver regeneration, all possible progenitor cell populations may be concurrently primed for activation (IL6-mediated), but that the secondary reserve progenitor cell responses do not manifest unless the primary response (hepatocyte-mediated) fails. Further studies are required to address these possibilities.

Chapter 18
Liver Regeneration

George K. Michalopoulos

General Considerations

Loss of tissue in large proportions compromises the functional capability of an organ or the entire organism. Small wounds in skin, muscle and soft tissues are usually associated with local inflammatory response and restoration of the local structural integrity, mediated by processes collectively termed as "wound healing". This typically occurs in skin and mesenchymally derived tissues such as bone, muscle and heart, and the central nervous system. However, in cases of major loss of tissue, especially in tissues derived from endoderm, the affected organs have the capacity to expand in size and attempt to restore the totality of the original function by increasing the size of the residual organ to eventually approximate the initial size as it was before the tissue loss. Kidney, an organ with epithelial components but derived from mesenchyme, has a substantial capability to slowly increase the residual size of the organ to restore most of function as it was prior to tissue loss. Thyroid, pancreas, intestine, and lungs also display significant capacity to restore part of the original function and mass.

Liver has received special attention as a regenerative champion, because it outstrips other organs in the speed, magnitude, and the capacity for multiple repeats of its regenerative response [1–5]. Loss of tissue in a clinical setting occurs as a result of a diffuse acute injury, mediated by toxic chemicals, viruses, metabolic abnormalities, or acute vascular disorders. Such episodes lead to a massive loss of hepatocytes and compromise the capacity of the organ to deliver functions vital for body homeostasis. Such episodes are associated with parallel development of both an *inflammatory* and a *regenerative* response. Inflammation involves mobilization of extrahepatic and intrahepatic macrophages (Kupffer cells), and polymorphonuclear leucocytes, mobilized to remove necrotic or apoptotic cells, tissue debris, etc. Other humoral and cellular components of the immune response (e.g. lymphocytes of different types) are mobilized to combat specific offending agents, especially viruses. Chronic liver damage is often mediated by exposure to the same offending agents causing the acute offense. Even though the tissue responses in the acute and chronic setting are probably mediated by the same signaling mechanisms, the net results are often different, with chronic offenses resulting in distortion of the hepatic tissue architecture.

It has been the challenge of experimental tissue biology to study the mechanisms associated with initiation and termination of the regenerative response and to establish the scientific basis to explain how a prolonged response to offending agents, mobilizing regenerative events on a chronic basis, leads to permanent tissue damage. In order to dissociate the otherwise confabulated occurrences of inflammatory and regenerative signals associated with diffuse loss of hepatocytes, the model of liver regeneration after *two-third partial hepatectomy (PHx)* was established by Higgins and Anderson in 1931 [6]. Taking advantage of the existence of multiple lobes in rodent liver, a simple operation was designed that allowed rapid surgical removal of two-third of the liver, leaving structurally intact two residual liver lobes, which then grow to the size of the original liver mass. The anatomical architecture of the original liver (four or five lobes based on anatomic conventions) is not re-established. The regenerated liver returns to two lobes, but the final mass after regeneration is that of the total of the original five lobes. The advantages of this approach for study of liver regeneration are several:

- The process of removal of two-third of the liver is of very short duration, since the removal of the large lobes is done after the lobes have been externalized. Thus, the sequence of signaling events following surgery can be very precisely timed.
- There is no histologic damage to the residual lobes. Thus, there is no inflammatory response to remove dead hepatocytes and no cell migration into the liver that is required to assist with removal of the tissue debris. The signals observed after PHx are purely those associated with the regenerative response.

Despite the obvious merits of PHx as a tool to study liver regeneration, it does not bear resemblance to most of the

clinical situations causing liver damage, since those typically involve diffuse hepatocyte necrosis and apoptosis. Partial hepatectomies are performed in humans as well for specific circumstances, such as following trauma or for the removal of solitary metastatic lesions. However, in most situations associated with massive loss of hepatocytes, exposure to the offending agent, associated inflammation, and regenerative signals proceed in tandem. Thus, it should be always understood that full explanation of restoration of tissue architecture in diseased liver should at some level integrate the regenerative and the inflammatory signals. The latter may affect (positively or negatively) the effects of the former. However, the lessons learned from PHx and other experiments models have defined the repertoire of signals controlling hepatocyte proliferation, and the proliferative behavior of hepatocytes in an inflammatory setting is still governed by the same signals.

How Much Liver Does the Body Need? Is There a "Hepatostat"?

Before discussing the current understanding on signaling pathways associated with liver regeneration, it is important to emphasize that the overall parameters determining the normal liver to body weight ratio are not fully understood. Early studies have shown that transplantation of livers of small animals into larger ones caused an enlargement of the liver size until a new size proportionate to the larger body of the host had been attained [7]. This has been shown for dogs [8] as well as humans [9]. Unfortunately, there were no detailed studies of cellular kinetics etc. in these early studies to help us understand the process. The same phenomena were observed when a baboon liver was transplanted to an immunosuppressed human. The baboon liver grew to a size of a normal liver within 7 days [7]. It is intuitively postulated that a sensor system ("hepatostat", for the purposes of this chapter) operates between the liver and peripheral tissues to facilitate this process. A primary candidate agent is the overall flow of the portal blood. A small liver would face an increased portal vein blood flow immediately after transplantation. Expansion of the liver mass would result in a portal flow to liver size ratio comparable to the expected for the body size. Thus, the portal vein flow would be the body weight "surrogate" in the "hepatostat" signaling, for appropriate adjustment of liver size. This hypothesis is bolstered by experimental and clinical findings following diversion of portal vein flow from the liver directly into the inferior vena cava. This procedure is called portacaval shunt. It results in substantial decrease in liver weight to less than half the original size, with decrease in size of individual hepatocytes, measurable hepatocyte apoptosis, and a mild inflammatory response [10, 11]. Restoration of the flow by reversal of the shunt is associated with rapid liver enlargement mediated by multiple mitoses and increase in the size of the individual hepatocytes. The same effects can be seen by injecting insulin alone [10, 11]. Insulin is present at high concentration in the portal blood, secreted by the beta cells of the pancreatic islets, and appears to be involved in mediating these changes. On the one hand, the role of other potential portal blood components such as epidermal growth factor (EGF) may have such an effect, though they were not found to be as effective as insulin when directly infused in dogs after portacaval shunt [12]. Also, in support of the role of portal blood flow as a component to the stimuli leading to adjustment of liver size is the fact that after PHx, the entire flow of the portal vein is proceeding through the liver remnant (one-third of the original size), thus mimicking the situation in which a liver from a smaller animal is transplanted into an animal of a much larger size. However, it is not clear whether the relative increase in blood flow per se or the enhanced availability (per hepatocyte) of specific portal blood components is responsible for the observed effects. Partial diversion of the portal vein flow after PHx is associated with a decreased regenerative response and decreased activation of hepatocyte growth factor (HGF), a very important hepatocyte mitogen (see below) [13].

The "hepatostat" may be adjusted to reflect specific physiologic needs. Pregnancy is associated with liver enlargement [14]. Estrogens are known to enhance the effects of EGF and HGF on hepatocytes, in parallel with a decrease of the mito-inhibitory effects of TGFβ(beta) (see below) [15]. Administration of estrogens to normal rats is associated with increase in liver body weight and increase in size of hepatocytes [16, 17]. On the other hand, the effect of pregnancy on liver size is abrogated in mice that are genetically deficient in FXR, a transcription factor which binds and mediates effects of bile acids [14]. These studies suggest that in addition to portal flow, other superimposed physiologic signals may adjust the hepatostat, and that hormones and hepatocyte products such as bile acids may play a role in this process. Since bile acids are produced exclusively by the liver, they are candidate products for acting as "sensors" for the hepatostat, but their role in this regard has not been examined. Recent discoveries have implicated the Hippo kinase homologues Mst1 and Mst2 and the protein known as YAP for their involvement in regulation of specifically the size of liver [18–20]. This is presented in more detail in the section "Termination of Liver Regeneration," below. These findings bring YAP in the forefront of regulation of liver size. Studies related to ILK [21] and GPC3 (see below) suggest that this YAP protein related system is in part under control of ECM signaling, but the pathways connecting these signaling systems remain to be established, hopefully in the near future.

Liver Regeneration After PHx

An outline of the signals described in this section is shown in Fig. 18.1.

Histologic Changes and Cellular Proliferation Kinetics

Earlier studies of nuclear labeling following injection of tritiated thymidine or bromodeoxyuridine (BRDU) have demonstrated that regeneration after PHx involves practically all hepatocytes in the liver for at least one round of DNA synthesis. It should be clearly emphasized that all cell types and pre-existing cell populations in the liver enter into cell proliferation and carry out the regenerative process. Liver regeneration after PHx under normal circumstances is not mediated by a growth of a selective "stem cell" population. Hepatocytes are the first liver cells responding to the regenerative signals by entering into DNA synthesis and cell proliferation [22]. Short labeling pulses demonstrate a peak of hepatocyte DNA synthesis at 24 h after PHx for the rat (approximately 36 h for the mouse) [22]. Most, but not all, hepatocytes are involved in this first proliferative event. A smaller wave of hepatocyte proliferation follows the first one, with a peak between 48 (rat) and 72 h (mouse) [22]. These observations have been registered in animals with very precisely defined conditions of light/dark cycles and feeding, as it has been shown that these events influence the timing of regeneration [23]. In most recent studies, there is no strict adherence to these issues and there is considerable variation in the observed results between different groups. (Adherence to some form of standardized regimen is important within each laboratory to obtain more reproducible results). Hepatocyte proliferation proceeds as a "wave" from periportal to pericentral areas of the hepatic lobule [24]. TGFβ(beta) immunoreactivity on hepatocytes also proceeds as a wave in the same direction, with a band of hepatocytes in mitosis following the TGFβ(beta) +/−interface [25]. Expression of metalloproteinases on hepatocytes follows the same pattern [26]. Proliferation of stellate cells and biliary epithelial cells occurs very shortly after proliferation of hepatocytes. Proliferation of endothelial cells proceeds as a much broader process from day 2 to 6 after PHx [22]. There is a small wave of apoptosis at the end of regeneration, perhaps reflecting a corrective mechanism to avoid hepatocyte surplus [27]. The early proliferation of hepatocytes prior to the initiation of proliferation of endothelial cells creates small nests of poorly vascularized hepatocytes [28]. Endothelial cells, stimulated by angiogenic factors produced by these hepatocytes (Angiopoietins 1 and 2, VEGF, FGF1, FGF2, and TGFβ(beta), see below) enter into proliferation and invade the nests of the

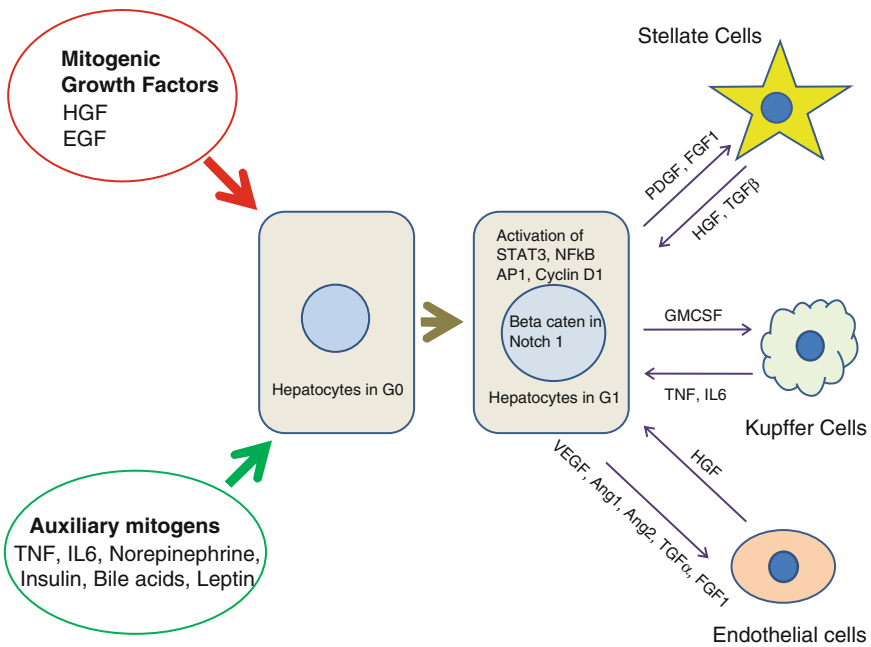

Fig. 18.1 Combined signals initiated by the mitogenic growth factors HGF and EGF and by the auxiliary mitogens impinge upon hepatocytes in G0 phase of the cycle and induce entry into the G1 phase. This is associated with multiple signaling events, including activation of STAT3, NFKB, formation of AP1, activation of cyclin D1, and migration of beta-catenin and Notch1 intracellular domain (NICD) to hepatocyte nuclei. the activated new gene expression patterns facilitate the trajectory of hepatocytes from G1 to S to G2 and mitosis. During this stage and thereafter, hepatocytes receive and transmit mitogenic signals from other hepatic cell types, such as stellate cells, endothelial cells, and kupffer cells (macrophages)

poorly vascularized hepatocytes, separating them into the typical hepatocyte plates, and eventually re-establishing sinusoidal architecture [29].

Extracellular Matrix

Most epithelial cell types in multicellular organisms are surrounded by extracellular matrix (ECM). This is composed of multiple proteins, with various degrees of glycosylation. Such proteins include various forms of collagen, fibronectin, tenascin, laminin, and many others. Each of these proteins exists in multiple isoforms. Several proteins with heavy degrees of glycosylation are also present as glycosaminoglycans (GAG) in the "pericellular" space and are often anchored with GPI linkages to the plasma membrane. Such proteins include glypicans, syndecans, perlecan, brevican, decorin, etc. Several heparin-binding growth factors including HGF, HB-EGF, FGF1, etc., are present in this complex milieu, contained on low affinity binding sites on GAG. There are complex relationships between growth factors and their receptors with the complex milieu of ECM [30, 31]. Many growth factors are available to the epithelial cells from the ECM reservoir consisting of low affinity binding sites. ECM components often bind to the growth factor receptors serving as co-receptors or antagonists. Decorin, capable of binding TGFβ(beta)1, EGFR, and MET, is a good example of this complexity of interactions between ECM components and plasma membrane receptors and ligands [32–35]. ECM components directly interact with receptors of their own, belonging to the integrin family of proteins [36]. Integrins also have extensive signaling cross-talk with growth factor receptors [37]. Members of the discoidin family of proteins are functioning as receptors for specific collagen types in addition to integrins [38]. Multiple types of proteinases (metalloproteinases (MMP), members of the ADAMS, etc.) and inhibitors to the proteinases are also present [39]. The complexity of the system and the interactions between all its parts allow for multiple degrees of freedom in terms of stimuli and observed responses.

Epithelial cells proceed to remodel the ECM through complex pathways prior to cell proliferation. There are two pathways that control this process. The first pathway is initiated by urokinase plasminogen activator (uPA), which catalyzes activation of plasminogen to plasmin. The latter is involved in activation of multiple MMP [40]. uPA activity rises within less than 5 min after PHx and it is the first demonstrable biochemical event following surgery [41]. This is also associated with increase of uPA receptor on hepatocyte plasma membrane [41]. There is subsequent activation of plasminogen to plasmin and activation of MMP9 [26]. There is intense expression of MMP9 in regenerating hepatocytes and it proceeds as a wave from periportal to pericentral areas following the wave of the regenerative response. The second pathway for ECM remodeling is activated by participation of MT MMP ("membrane type metalloproteinase", bound to the plasma membrane) and TIMP2. Acting in partnership, these two proteins activate MMP2. This pathway also operates during liver regeneration starting at 12 h after PHx. These events lead to decrease of several ECM associated proteins within a few hours after PHx [42] and with release of large amounts of hyaluronic acid in the peripheral circulation [43]. The degradation of ECM is reversed towards the later stages of LR. Increased synthesis of different collagen types and pericellular ECM proteins has been noted in the rat starting at 72 h after PHx [44, 45]. Glypican 3, a protein which is intensely over-expressed in human hepatocellular carcinomas, but which appears to have growth inhibitory effects on hepatocytes also increases towards the end of LR and seems to play a growth regulatory role in association with a tetraspanin protein known as CD81 [46]. The remodeling as well as the subsequent re-synthesis of ECM is associated with growth enhancing (early stage) or growth inhibitory signals (later stages) of LR.

Signals Associated with Hepatocyte Mitogenesis

There are complex mitogenic signals mobilized very early after PHx which drive and control the progress of hepatocytes during the cell cycle. Several recent publications have provided detail review of the literature associated with this topic [1–5, 43, 47]. Earlier work involving transplantation of hepatic fragments [48], implantation of isolated hepatocytes [49] and animals connected through parabiotic circulation [50, 51] had demonstrated that after PHx there is a set of signals appearing in the peripheral blood which drives hepatocytes into proliferation, even in ectopic sites. Subsequent work utilizing hepatocyte cultures resulted in the isolation and characterization of hepatocyte growth factor [52–54] (HGF, see below). Because the isolation assay was directed towards detecting substances mitogenic for hepatocytes in culture, other substances which are not directly mitogenic, but which have a regulatory signaling role and also become elevated after PHx, were overlooked. The list includes TNFα(alpha), norepinephrine, IL6, leptin, serotonin, bile acids, components of complement, etc. These non-mitogenic participants should be viewed as auxiliary mitogens. The role of these two groups and their members will be discussed below.

Mitogenic Growth Factors

Stimulation of DNA synthesis in hepatocyte cultures maintained in chemically defined serum free media is the basis for defining this group. Additionally, its members stimulate

hepatocyte DNA synthesis and liver enlargement when injected in sufficient amounts in normal rodents. Two such growth factors fulfill that role, HGF [55, 56] and the ligands of EGFR [57, 58]. Some members of the FGF family have weak mitogenic effects on hepatocytes in culture, but have not been shown to stimulate hepatocyte DNA synthesis and liver enlargement when injected into normal rats and mice [59]. Receptors for other growth factors are expressed in hepatocytes, and they become activated in culture, without stimulating hepatocyte DNA synthesis [60].

HGF and Its Receptor (cMET)

There are several detailed reviews of the functions associated with HGF and its receptor [61, 62]. Additional details are also found in Chap. 20. HGF is synthesized by mesenchymal cell in many organs, especially in lungs and liver [63]. It receptor (cMET) is expressed mostly in epithelial cells. In the central nervous system, both glial cells and neurons, variably in specific locations, express either HGF or its receptor [64]; recent evidence has shown that HGF may be involved in the early migration of cells supporting the layering and design of the cerebral cortex [65]. In liver, HGF is synthesized by predominantly by stellate cells [66] and (after PHx) also by endothelial cells [67]. In liver, the receptor for HGF is expressed in hepatocytes, biliary cells, and endothelial cells. Stellate cells appear to synthesize HGF on a continual basis, as a single chain polypeptide of 100 kDa with heavy degree of glycosylation. The single-chain HGF is biologically inactive and bound to GAG in the pericellular matrix, especially in periportal areas of the hepatic lobule [68]. Large quantities of HGF can be extracted from hepatic ECM [63]. The single chain inactive HGF can be activated to the active form by uPA [69]. The immediate enhancement of uPA activity after PHx is associated with release of HGF from GAG (due to ECM remodeling and degradation) and activation of single chain HGF to active two chain HGF, which is in part utilized locally and in part released to the peripheral blood [52]. The precise contributions of the local or peripherally released HGF are not clear, but the HGF receptor shows increased tyrosine phosphorylation within 30–60 min after PHx [70]. Following a measurable decline of HGF concentration in hepatic ECM in the first 3 h after PHx, there is enhanced synthesis of new HGF from both stellate and endothelial cells, starting at 3 h and reaching a peak at 24 h [71]. It should be noted that there is increased synthesis of new HGF not only in the liver but also in lungs [72]. The precise role of the newly synthesized HGF is not clear. "Knockdown" of HGF mRNA using ShRNA against HGF resulted in elimination of synthesis of new HGF, but only a small decline in hepatocyte DNA synthesis [73]. On other hand, ShRNA against cMET had strong suppressive effects of the hepatocyte cell cycle with complete elimination of the events of the first 24 h after PHx and absence of mitoses [73]. However, there was also an increase in several pro-apoptotic genes, without measurable increase in hepatocyte apoptosis [73]. The effects on cell cycle were eventually compensated with a rebound at 48 h after PHx, after the cDNA expression plasmid for the ShRNA was gradually eliminated. These results are most compatible with hepatocyte mitogenesis being driven primarily by the stores of existing HGF, and with the new HGF synthesized after 3 h post PHx, having a smaller role to play for this part of the regenerative process. The impact of the new HGF may be more relevant to other cell populations expressing c-met, such as biliary cells and endothelial cells. The triggering of new HGF synthesis in lungs after PHx suggests a hitherto not fully appreciated systemic response in support of liver regeneration. Only norepinephrine [74] and IL6 [75] have been shown to directly stimulate synthesis of new HGF in mesenchymal cells, and they both rise in the blood after PHx [52, 76]. It should also be noted that mice with hepatocyte-targeted elimination of MET develop hepatic fatty change and fibrosis and have deficient regenerative responses [77]. Mice systemically deficient in uPA also have a compromised regenerative response [78].

EGF, TGFα(alpha) and the EGFR Ligand Family of Proteins

Most of the members of the EGFR ligand family have been shown to be mitogenic in hepatocyte cultures [55, 57]. Injection of EGF by itself to unoperated rats, leads to hepatocyte DNA synthesis [58, 79]. Mice with hepatocyte-targeted transgenic expression of TGFα(alpha) have very enlarged livers [80] and develop hepatocellular carcinomas [81]. EGF itself is produced in exocrine glands. Removal of the salivary glands (a major site of EGF production) in male mice is associated with decreased regeneration [82]. EGF is also produced by Brunner's glands of the duodenum, histologically similar to salivary glands, but underlying the duodenal mucosa [83]. Norepinephrine and epinephrine, rising in the blood after PHx (see below) are known to stimulate production of EGF from Brunner's glands [83]. EGF is taken avidly by liver and is deposited in periportal sites [84]. There is no measured increase in EGF in the plasma after PHx. However, the EGFR is phosphorylated in tyrosine sites with the exact same time kinetics as cMET [70]. There is literature documenting interactions and cross-talk between MET and EGFR in several studies [85], though a direct interaction has not been reported in liver regeneration.

TGFα(alpha) expression increases in hepatocytes within 2–3 h after PHx and lasts for most of the regenerative response [86].

Since hepatocytes express TGF α(alpha) and EGFR, it has been proposed that an autocrine loop between TGF α(alpha) and EGFR contributes to the signaling leading to hepatocyte proliferation. On the other hand, mice with systemic elimination of TGF α(alpha) do not suffer any major abnormalities (none reported in liver) and complete liver regeneration normally [87]. However, mice with systemic elimination of amphiregulin (another member of EGFR ligand family), do have defective regeneration [88, 89]. HB-EGF, another member of the same family, enhances hepatocyte proliferation during liver regeneration especially in mice subjected to a limited hepatectomy [90]. HB-EGF expression changed in proportion to the amount of tissue resected whereas that of HGF and TGF α(alpha) did not [90].

Intracellular Signaling Events

It is widely accepted that the final event of the early, pre-S-phase, in hepatocytes after PHx (a time known as "priming" [91, 92], roughly corresponding to G1 phase of the cycle), is the activation of Cyclin D1 and its move to the nucleus [93]. This represents the culmination of multiple events following activation of receptors of both mitogenic growth factors (see above) as well as non-mitogenic cytokines (see below). Several cell cycle associated genes including c-jun, c-fos, c-myc, p53, and p21 show enhanced expression at different times in the first 1–10 h after PHx [94]. Activation of Stat3 is also enhanced within 1–3 h after PHx [76]. NFkB is activated as well (from 2 to 4 h after PHx) [95, 96]. β(beta)-catenin migrates to the nucleus within 15 min after PHx [97], an event that may be related to Wnt activities, but also to enhanced tyrosine phosphorylation by cMET and EGFR [98]. Mice genetically deficient in β(beta)-catenin or rats injected with β(beta)-catenin antisense exhibited delayed liver regeneration in response to hepatectomy [99–101]. Mice genetically deficient in IL6 have deficient activation of Stat3 and delayed regenerative response [76]. Mice deficient in TNF α(alpha) receptor 1 have defective activation of NFkB and delayed regenerative response [102]. In both situations, regeneration eventually completes as evidenced by restoration of the liver weight. Changes in hepatocyte associated transcription factors include a decrease in the ratio of C/EBP α(alpha) to C/EBPβ(beta), but no measurable changes in HNF4 [103]. Another signaling system involved with hepatocyte proliferation and liver regeneration is the Notch/Jagged signaling pathway. The Notch intracellular domain (NICD) migrates to hepatocyte nuclei within 15 min after PHx with subsequent activation of HES1 gene. Notch and Jagged do co-localize on hepatocyte plasma membranes during days one and two after PHx. Treatment of liver with ShRNA expressing cDNA plasmids directed against either Notch or Jagged1 causes a decrease in hepatocyte DNA synthesis during regeneration [104]. Genetically induced elimination of Notch on the other hand is associated with spontaneous hyper-proliferation of hepatocytes in unoperated livers, but the response of hepatocytes to PHx is decreased as well [105].

The onset of liver regeneration is associated with rapid changes in hepatocyte gene expression [106, 107]. In addition to genes related to cell cycle, there are others of no such obvious connection (e.g. IGF binding proteins) [108]. These changes are rapid and more than 100 new genes are expressed in the first hour after PHx. However, it is remarkable that despite the rather cataclysmic events associated with cell division, there is little apparent impact on overall hepatic functions. Most of the proteins synthesized by the liver change very little in the peripheral blood and their rate of synthesis is minimally affected, if at all. Albumin, coagulation factors, serum amyloid proteins, complement components, etc. are very little affected during liver regeneration.

Auxiliary Mitogens

This term reflects a group of molecules which, independent of each other, have been found to cause delay in liver regeneration when their signaling is interfered. The list, originally small, has expanded through the years. There have been many instances in which such discoveries were associated with pronouncements to the effect that liver regeneration was caused by "a" specific factor. We have to understand that multiple extracellular signaling agents converge upon hepatocytes very soon (within minutes) after PHx and that each one plays an important role, but none alone either causes or fatally disrupts (after its elimination) the regenerative response. However, this should not undermine the significance of these auxiliary mitogenic signals. Regeneration is a very complex response. While there are compensatory signaling pathways to overcome specific signaling blocks under normal circumstances (as with experimental animals), this is most often not the case in catastrophic human diseases associated with massive hepatic necrosis. In these situations, any less than optimal regenerative response can make a significant difference in the balance between life and death of the organism. Thus, the role of the auxiliary mitogens in optimizing the regenerative response is of extreme importance, and it should be further studied in relation to the pathways associated with liver regeneration and liver failure [109].

TNF α(alpha)

This cytokine is produced in liver by hepatic macrophages. TNF α(alpha) levels in the plasma rise quickly after PHx [102, 110, 111]. Mice deficient in TNF α(alpha) receptor 1

(TNFR1) have delayed liver regeneration and defective activation of the transcription factor NFkB [95, 110, 111]. Antibodies against TNF α(alpha) delay liver regeneration and interfere with activation of Jun kinase [112]. The findings are enigmatic because administration of TNF α(alpha) to normal rats and mice is associated with hepatocyte apoptosis and levels of TNF α(alpha) are elevated in liver failure [3, 113]. However, these findings are consistent with the effects of TNF α(alpha) in other tissues. TNF α(alpha) is enhancing pro-mitogenic pathways in cells stimulated towards mitogenesis, primarily by enhancing activation of NFkB. As its name implies, it can also activate apoptotic pathways in normal cells [114]. The outcome of TNFR1 signaling in part depends on increased concentration of reactive oxygen species [115] and on other factors regulating the dissociation of NFkB from IkB, controlled by the kinase IKK [116, 117]. In general, activated NFkB confers resistance against apoptosis induced by a variety of agents [118]. TNFα(alpha) by itself is not mitogenic in hepatocyte cultures in the absence of serum, but it does enhance the mitogenic effects of HGF and EGF and, when administered in vivo in animals submitted to a limited hepatectomy, it also enhances their in vivo mitogenic effects [119]. Studies utilizing adenovirus vectors expressing a form of IkB resistant to IKK (NFkB "super-repressor and thus preventing NFkB activation) showed that PHx is followed by massive hepatocyte apoptosis [113]. On the other hand, selective targeted expression of the same IkB "super-repressor" form, in an inducible system of gene expression, showed that suppression of NFkB and PHx were not associated with apoptosis [120]. Thus, the mechanism of action of TNFR1 in relation to liver regeneration may be more complex, with other studies suggesting that enhanced processing of TGF α(alpha) via TACE [121], as well as stimulation of IL6 synthesis [102], might also contribute to its effects.

Interleukin 6

Mice with systemic genetic elimination of Interleukin 6 (IL6) had deficient response to PHx in one study [76], whereas a subsequent study showed that liver weight was restored in $IL6^{-/-}$ mice as in the wild type animals [27]. However, in both studies, there was delayed activation of the transcription factor STAT3. This transcription factor, a very important component of the JAK/STAT signaling system in hepatocytes, contributes to the signaling cascade coordinating the transition of hepatocytes through the cell cycle [122, 123]. In addition to IL6, its activation also seems to be dependent on the norepinephrine [124] (see below). Mice with genetic elimination of STAT3 have rather small defect in regeneration, but this may be due to compensatory effects exerted by increased levels of STAT1 [123]. IL6 is not a mitogen for hepatocytes in culture, but it is a mitogen for bile duct epithelial cells [125]. IL6 is a well known trigger of the acute phase response [126] and there are several proteins associated with the acute phase response that increase shortly after PHx [47]. IL6 levels in plasma also increase after PHx [76]. There is a presumption that IL6 is produced by Kupffer cells, but the possibility that other hepatic cell types, including hepatocytes, also produce IL6, has not been ruled out. Overexpression of both IL6 and its soluble receptor causes periportal hyperplasia in hepatic lobules, but has not been associated with hepatic neoplasia [127]. However, in a different study, excretion of large levels of IL6 from Chinese hamster ovary (CHO) cell lines producing excess IL6 under constitutive promoters, was associated with massive hepatic enlargement when the CHO cells formed tumors in mice [128].

Bile Acids

A recent study demonstrated that mice with genetic elimination of the transcription factor FXR had deficient liver regeneration [129]. Depletion of bile acids also had a negative effect on the regenerative process. Bile acid levels do rise after PHx, peaking at 3–6 h. The study demonstrated that the FXR-bile acid pathway is relevant to optimizing the regenerative response [129]. The pathways associated with this are not clear.

Norepinephrine

Levels of norepinephrine and epinephrine rise in the plasma after partial hepatectomy [130]. In primary cultures of hepatocytes in chemically defined serum-free medium, norepinephrine enhances the mitogenic effect of EGF [131] and HGF, and it decreases the mito-inhibitory effects of TGFβ(beta)1 [132, 133] and Activin, the latter effect mediated via induction of Smad7 [134]. These effects are exercised through the alpha-1 adrenergic receptor [131]. Activation of this receptor in both normal hepatocytes and hepatoma cell lines results in activation of STAT3 via involvement of Src kinase and EGFR [124]. The effects of norepinephrine on liver regeneration are even more global. Norepinephrine induces expression of HGF from fibroblasts [74]. Since norepinephrine increases rapidly after PHx, it may be involved in the enhanced expression of HGF in the lung, seen after PHx [72]. In addition, norepinephrine and epinephrine also enhance production of EGF from Brunner's glands of the duodenum [83]. The combination of effects at

both the level of the mitogenic receptor signaling as well as enhanced production of HGF and EGF suggests that the involvement of norepinephrine in liver regeneration is rather crucial. Blockade of the alpha-1 adrenergic receptor by the specific blocker prazosin delays regeneration by 72 h [130]. The same effects are also observed following sympathetic denervation of the liver [130]. Recent studies have also shown that in addition to its origins from sympathetic neurons, norepinephrine may be locally available to hepatocytes from the stellate cells, which have now been shown to produce norepinephrine [135, 136].

Insulin

Insulin exerts multiple effects on many aspects of hepatocyte biochemistry and function, especially in the areas of carbohydrate and lipid metabolism. Insulin, produced by the pancreatic islets, is made available directly to the liver via the portal circulation, prior to entering the systemic circulation. Portacaval shunt (diverting portal vein flow to the inferior vena cava) causes hepatic atrophy [137]. This is reversed when insulin is injected directly into the liver, and this reversal of atrophy is associated with hepatocyte mitosis [138]. Insulin is required for hepatocyte viability in primary culture, though it is not a mitogen per se [139]. In its absence, the mitogenic effects of both EGF and HGF are substantially diminished [55]. Insulin receptor appears to be a modulator of hepatocyte metabolic responses, by activating of PIK3CA, AKT, mTOR, [47] and other pathways. Recent studies have shown that there is a drop in plasma glucose after PHx and that administration of glucose has suppressive effects on liver regeneration, associated with increased expression of C/EBPα(alpha), p21 and p27, and decreased expression of FoxM1. These effects may be mediated through activation of p21 [140]. It is not clear whether plasma insulin plays a role in these events.

Termination of Liver Regeneration

Most of the studies in the field have focused on pathways leading to initiation of liver regeneration. As a consequence, not as much is known about the pathways leading to termination of liver regeneration. These pathways must be very carefully orchestrated. They accomplish the remarkable endpoint of returning the liver to the original mass with a high degree of precision! Whatever the pathways may be, they do serve that role very effectively. We can hypothesize that a critical determinant of the size of the liver is the flow through liver of the portal circulation, and that when a certain proportion between portal flow and live size is reached, further growth stops [1]. While this is a self-fulfilling truism, it does not guide to further speculation as to which, if any, component of the portal blood (or the amount of the flow) is important. Furthermore, proliferation of hepatocytes is almost entirely over at the end of day two, post-PHx in the rat (day 3 in the mouse). However, liver mass is still expanding at those time points due to proliferation of non-parenchymal cells and enlargement of the proliferated hepatocytes. Thus, the proliferation kinetics of hepatocytes and the end of their active growth occur before the original proportion between portal vein flow and hepatic mass is restored. In view of that, testable hypotheses can be easier, generated by exploring the role of specific signals known to have growth inhibitory effects on hepatocytes and exploring how they affect proliferation of specific cell types and liver regeneration as a whole.

Transforming Growth Factor Beta 1 (TGFβ(beta)1)

This multifunctional cytokine is produced in the liver by stellate cells. Hepatocellular carcinomas (as most cancers) also produce TGFβ(beta)1 [141], but it is not clear whether this reflects a type of epithelial-mesenchymal transition (seen in many tumors), or whether hepatocytes can also produce TGFβ(beta)1 under specific circumstances. TGFβ(beta)1 is a member of a family of three TGFβ(beta) molecules, each from a separate coding gene, and all expressed in the liver [141]. It is not clear whether the members of TGFβ(beta) family have different functions. TGFβ(beta)1 binds to decorin, a protein present in the hepatocyte pericellular space and anchored to hepatocyte plasma membrane by a GPI linkage [142, 143]. Immunohistochemical stains localize TGFβ(beta)1 on hepatocytes and it appears to be removed from hepatocytes when they enter the cell cycle [25] (see section "Histologic Changes and Cellular Proliferation Kinetics" above). Plasma levels of TGFβ(beta) also rise rapidly after PHx, with the same time kinetics as HGF [43]. This may reflect mobilization of TGFβ(beta)1 following remodeling of the pericellular matrix. Circulating TGFβ(beta)1, if not attached to its LAP protein, is bound by α(alpha)-2 macroglobulin and transferred to LRP receptors on hepatocytes for degradation [144].

The effects of TGFβ(beta)1 on specific cell types differ. It enhances production of extracellular matrix by mesenchymal cells (fibroblasts, stellate cells, etc.) [145]. It facilitates formation of capillaries resulting from tube formation by endothelial cells [146]. It also inhibits proliferation of hepatocytes and most other epithelial cells [132]. The effects of TGFβ(beta)1 are mediated after binding to TGFβ(beta)R2. More details on TGFβ(beta) signaling are provided in Chapter 23. The complex then binds to TGFβ(beta)R1 and activates its serine-threonine kinase function (known as ALK5).

This generates a signaling cascade involving Smad proteins, which migrate to the nucleus and transmit relevant messages altering expression of specific genes [147].

The second half of liver regeneration (loosely defined as days 3 to 7 after PHx) is a time when hepatocyte proliferation stops; there is also extensive endothelial cell proliferation and formation of sinusoids lined by fenestrated endothelial cells; in addition, there is synthesis and restoration of the extracellular matrix degraded immediately after PHx. Since TGFβ(beta)1 is known to affect such types of events, and since TGFβ(beta)1 expression is at its highest levels in the second half of the regenerative process, it is logical to postulate that the enhanced expression of TGFβ(beta)1 is involved in the eventual termination of regeneration and the restoration of histologically intact liver tissue at the lobular level. Such considerations, plausible as they are, are derived primarily from extrapolation and not from direct evidence. Expression of TGFβ(beta)1 begins to rise at 2–3 h after PHx [148] (about the same time as the enhanced expression of HGF, see above). It remains expressed at high levels for more than 72 h after PHx. This does not seem to affect proliferation of regenerating hepatocytes, reaching their peak of proliferation in that time frame. Hepatocytes isolated from regenerating liver are more resistant to the effect of TGFβ(beta)1 [132]. There are several contributing factors that probably facilitate this resistance. Expression of TGFβ(beta)1 receptors (TGFβ(beta)R1 and TGFβ(beta)R2) on hepatocytes decreases during liver regeneration [149]. In addition, there is less immunoreactive TGFβ(beta)1 around hepatocytes during regeneration [25]. Furthermore, norepinephrine, known to inhibit the mito-inhibitory effects of TGFβ(beta)1, rises rapidly in the plasma during the first two days after PHx and also perhaps plays a role in promoting "resistance" of the regenerating hepatocytes to the mito-inhibitory effects of TGFβ(beta)1 [130]. The origin of the rising TGFβ(beta)1 have been examined in a study involving cell isolation and it appears that all main cell types including hepatocytes are involved in TGFβ(beta)1 production [150].

Despite all expectations from the above studies, mice with hepatocyte-targeted transgenic expression of TGFβ(beta)1 do not seem to have problems with liver regeneration [151]. Additionally, genetic elimination of TGFβ(beta)RII also does not seem to prolong liver regeneration, unless activin is also inactivated by administering follistatin [152]. Activin itself is also a mito-inhibitor for hepatocytes. However, it is known to be produced by hepatocytes [153]. Potential interactions between activin and TGFβ(beta)1 towards the later stages of liver regeneration may include effects on termination of proliferation and tissue building. Regardless of its potential role in termination of liver regeneration, TGFβ(beta)1 seems to also play a role in keeping hepatocytes in G_0 stage of quiescence. Inhibition of TGFβ(beta) receptor II or the activin receptor II in rats with dominant negative constructs resulted in stimulation of proliferation of hepatocytes in normal (not subjected to PHx) animals [154, 155]. The results suggest that TGFβ(beta)1 and perhaps activin, under normal conditions, exercise a continued effect on hepatocytes maintaining a state of proliferative quiescence. The stimulation of hepatocyte proliferation when this effect was removed, however, also suggests that mitogenic stimuli present in the immediate environment of the hepatocytes continually exert an opposing pro-mitogenic effect which is balanced by TGFβ(beta)1. Candidates for that role, among others, maybe HGF and EGF. The former is present in the immediate periportal hepatic ECM, bound to glycosaminoglycans. The latter is continually produced by the Brunner glands of the duodenum and made available to the liver through the portal circulation.

Extracellular Matrix

Initiation of liver regeneration is associated with remodeling and breakdown of many ECM components, mediated by a proteolytic cascade involving uPA, plasmin and MMPs (see above). The process is reversed at the end of regeneration, with re-synthesis of many ECM components (see above). The re-synthesis of ECM proteins may be part of the signaling process leading to the termination of liver regeneration. Support of this hypothesis comes from hepatocytes in primary culture, in which hepatocytes enter into cell proliferation under the influence of HGF and/or EGF [55]. However, they lose most of their hepatocyte specific differentiated functions and there are associated changes in hepatocyte-specific transcription factors. Addition of extracellular matrix in the form of type I collagen gel or a (high in laminin and glycosaminoglycans) extract of EHS mouse sarcoma leads to restoration of hepatocyte differentiation with simultaneous cessation of cell proliferation [55, 156]. It should be noted (see "Intracellular Signaling Events", above) that during regeneration, despite the involvement of hepatocytes in the complex process of cell proliferation, the hepatocyte-specific patterns of differentiation are overall maintained, in contrast to cell culture. It can be speculated that the complete absence of matrix in hepatocytes cultures (other than a dry film of type I collagen) may not be sufficient for providing signaling required to maintain differentiation, in contrast to the in vivo situation, in which (despite matrix remodeling) there is sufficient ECM still remaining for signaling related to differentiation.

Signaling of ECM through integrins, in addition to cooperative signaling with growth factors and their receptors, proceeds primarily through two proteins, namely focal adhesion kinase (FAK) and integrin linked kinase (ILK) [157, 158]. The latter forms a complex with proteins PINCH and parvin and establishes complex association and signaling

through the cytoskeleton, and it may be even directly associated with intranuclear signaling events [159]. Elimination of ILK in liver was used as a surrogate approach for interfering with ECM signaling. Acute elimination of ILK was associated with massive hepatic necrosis [160]. Gradual elimination through genetic approaches (expression of Cre recombinase under the albumin promoter) was compatible with embryonic development. However, there was a wave of spontaneous hepatocyte proliferation after birth resulting in altered matrix deposition and liver enlargement [161]. The results suggest that ILK and ECM/integrin signaling have control over what constitutes normal liver size. Furthermore, when these mice were subjected to PHx, the final liver weight was much larger than liver weight prior to PHx by about 60%, due to prolonged hepatocyte proliferation [21]. The data demonstrate that ECM and integrin signaling are important in termination of liver regeneration. Of interest, excessive growth of the ILK deficient livers was not only seen after PHx but also in response to chemical mitogens such as phenobarbital [162].

In addition to direct signaling contributions, ECM is also involved by maintaining proper proportions of concentrations of heparin-binding growth factors (e.g. HGF and HB-EGF) and growth inhibitors (such as TGFβ(beta), bound to decorin). Reconstitution of ECM may be resulting in rebinding of excess growth factors and inhibitors and thus allowing hepatocytes to exit the cycle and stay in G_0 phase of quiescence.

Glypican 3

Glypican 3 (GPC3), a component of pericellular matrix, is linked to hepatocyte plasma membranes by GPI linkage. Its expression is highly upregulated in hepatocellular carcinomas [141, 163]. However, loss-of-function mutations of GPC3 in humans are associated with the Simpson-Golabi-Behmel syndrome, in which there is enlargement of internal organs and bone structures. The same is observed with GPC3 loss-of-function mutations in mice [164]. GPC3 expression becomes elevated after day 3 post PHx, and associations of GPC3 and its binding partner CD81 are seen on hepatocytes and non-parenchymal cells at the end of their proliferation kinetics [46]. Inhibition of expression of GPC3 in hepatocytes in primary culture leads to prolonged cell proliferation. The latter finding establishes the fact that at least in hepatocytes, GPC3 is associated with inhibition of growth.

Yes-Associated Protein

Several recent publications have established yes-associated protein (YAP) as a key protein involved in liver size regulation. Hepatocyte targeted over-expression of YAP is associated with massive hepatic enlargement and development of hepatocellular carcinomas within 10 weeks after birth [19]. Mst1 and Mst2 are two related kinases, which are homologous to the *Drosophila* Hippo, pathway. These two kinases, in association with an adaptor protein known as SAV1 phosphorylate and activate kinases Lats1 and Lats2, which in turn associate with another adaptor, Mob and phosphorylate YAP in the nucleus. Phosphorylated YAP leaves the nucleus. YAP itself is a coactivator transcription factor of many genes associated with cell cycle. Critical to this chapter is the finding that systemic genetic elimination of both MST1 and MST2 (resulting in increase of YAP in the nucleus) affected specifically the liver as the only organ, and caused massive hepatomegaly and hepatocellular carcinoma [20, 165]. These findings are extremely important and their significance is not yet fully developed in relation to liver biology. The specific impact on only the liver size when MST1 and 2 were systemically eliminated, establishes a unique importance of the Hippo kinase homologues and YAP protein in regulation of the hepatic size. It is of interest that during liver enlargement and enhanced regeneration in hepatocyte-targeted elimination of ILK (see above), there is increase of YAP protein in the nucleus and decrease of phospho-Yap in the cytoplasm of hepatocytes [21]. The same is true with the enhanced growth response to phenobarbital in the same mice [162]. Conversely, in mice with over-expression of GPC3 in hepatocytes and suppressed liver regeneration, there is decrease of YAP in the nucleus and increase of phospho-YAP in the cytoplasm. These findings suggest that the Hippo/MST1&2/YAP system is at least under partial control by integrins and ECM signaling and that GPC3 (through pathways yet to be identified) is also playing an important role in YAP regulation. Studies related to this system are undoubtedly going to be of importance for understanding of issues related to liver size regulation.

Exchange of Growth Regulatory Signals Between Hepatic Cell Types During Liver Regeneration

As mentioned above, of the different hepatic cell types, hepatocytes are the first to enter into DNA synthesis. Proliferation of the other hepatic cell types (non-parenchymal cells: stellate cells, biliary epithelial cells and sinusoidal endothelial cells) occurs following hepatocyte proliferation [22]. Stellate cells and epithelial cells can be seen proliferating as early as 24 h after PHx whereas endothelial cells have a longer time span for proliferation and restoration of sinusoidal vascular architecture [28]. It is now clear that replicating hepatocytes

synthesize several growth factors capable of stimulating proliferation of adjacent non-parenchymal cell types. These include platelet derived growth factor (PDGF) [166] and fibroblast growth factors 1 and 2 (FGF1 and 2) [167, 168]. Both of these are mitogenic to stellate cells and endothelial cells. Hepatocytes also synthesize Angiopoietins 1 and 2 [169] as well as vascular endothelial growth factor (VEGF) [67, 170, 171]. These are also mitogenic for sinusoidal endothelial cells. TGFα(alpha), a member of the family of ligands of EGFR, is also synthesized by replicating hepatocytes [86]. Though TGFα(alpha) is mitogenic for endothelial cells, hepatocytes also express EGFR and it has been speculated that hepatocytes may establish an autocrine loop between EGFR and TGFα(alpha). However, this has not been verified and mice genetically deficient in TGFα(alpha) do not have defects in liver regeneration [87]. This would imply that such autocrine loop does not exist; it may also imply that other compensating members of the EGFR ligand family known to be involved in liver regeneration (amphiregulin, HB-EGF, and EGF) compensate for the loss of this autocrine effect, also suggesting that this autocrine loop is dispensable or can be replaced by paracrine loops from the other members of the EGFR ligand family. Hepatocytes are also on the receiving end of mitogenic signals. Stellate cells synthesize HGF [172] and endothelial cells stimulated by VEGF in VEGF R1 do the same [67], creating a potential for a mutual growth-promoting feedback between replicating hepatocytes and sinusoidal endothelial cells. However, hepatocytes cease most of their proliferation by post-PHx day two (in the rat) and three (in the mouse), a time when proliferation of endothelial cells is barely beginning. This suggests that the bidirectional growth stimulating interactions between hepatocytes and endothelial cells, while possible in principle, may not be occurring in reality. Synthesis of norepinephrine, a recently discovered property of stellate cells [135], also has many ramifications for regulation of both production of growth factors (EGF and HGF) as well regulation of the responsiveness of their receptors (see section "Termination of liver regeneration" above). TGFβ(beta)1 is produced by stellate cells, by Kupffer cells, and hepatocytes [150] and it effects a variety of processes from formation of vascular endothelial tubes to stimulation of synthesis of ECM, and thus is a key regulator for this process. Though its mitoinhibitory effects seem to be "resisted" by regenerating hepatocytes via down-regulation of the TGFβ(beta)1 receptors (see section on "Transforming Growth Factor beta 1", above), its importance for the overall regenerative process appears very significant. TNFα(alpha) and IL6 are produced by Kupffer cells. In view of the involvement of these two cytokines in regulation of activation of NFkB and IL6, Kupffer cells are also important contributors to the mitogenic signaling for hepatocytes. Injury of the hepatic macrophages by use of gadolinium chloride causes delays in regeneration [119, 173]. Biliary cells also participate in cell proliferation during liver regeneration. In fact they show histochemical evidence of DNA synthesis (e.g., Ki67 positive nuclei) with almost the same kinetics as hepatocytes. Studies with primary cell cultures of biliary epithelium have shown that it shares the same mitogenic receptors with hepatocytes, namely EGFR and MET. However, IL6 is a mitogenic substance for biliary cells in culture, in contrast to hepatocytes [125].

Clinical Implications of Liver Regeneration

As mentioned in the beginning of this chapter, liver regeneration after PHx has allowed the study and mechanistic analysis of the regenerative stimuli controlling liver regeneration and growth, independent of involvement of other signaling pathways associated with the inflammatory events associated liver disease [3]. We now understand that there are two main mitogenic receptors for hepatocytes, namely the EGFR and the HGF receptor (MET). All others tested in vivo, or in vitro, are not effective (with mild effects seen by FGF family members) [55, 60]. We also understand that auxiliary mitogens are of great importance, and they include TNFα(alpha), IL6, norepinephrine, insulin, bile acids, and possibly serotonin (see section on "Auxiliary mitogens," above). This does not imply that other such signals may not exist that will be discovered in the future. As the recent evidence regarding YAP protein suggests, there is much room for future discoveries. In order to understand the pathways associated with hepatocyte proliferation in the context of liver disease, we need to concentrate on what signaling pathways associated with inflammation may do that would impinge (inhibit or enhance) the pathways already understood as controlling hepatocyte proliferation. Relevant considerations in this topic follow.

Generation of Growth Enhancing or Inhibitory Signals as Part of the Inflammatory Process

Both macrophages and polymorphonuclear leukocytes are known to produce HGF [174]. Macrophages are also known to produce TGFα(alpha) [174]and TGFβ(beta) [149]. The balance of these signals in relation to hepatic tissue damage by toxins and viruses has not been fully studied and it may vary between specific settings. The same signals are associated with well known biologic effects of acute and chronic inflammation in other tissues, and are generally viewed as related to local wound healing [175].

Effects of Viruses and Toxins on the Capacity of Hepatocytes to Replicate

This is also an area which should receive further attention. Though it is intuitively assumed that infection with viruses and exposure to toxins is likely to be inhibitory to cell proliferation, this may not be the case. As an example, Hepatitis C virus (HCV) utilizes CD81, the partner of GPC3, to enter into hepatocytes [176, 177]. The latter, also known as "target of the anti-proliferative antibody" is associated with growth regulation in many cell types, including hematopoietic cells and astrocytes [178], and it is known to be associated with integrins, including the α(alpha)3-β(beta)1, the main hepatocyte associated integrin [179]. HCV may be acting as agonist of CD81 and thus be a positive long term regulator of hepatocyte growth. This may have effects on hepatocyte gene expression and potentially be of relevance with the well known promoting effects of HCV on hepatic neoplasia. Furthermore, as discussed independently in Chap. 38, the HCV genome directly regulates several signaling pathways that are of relevance in hepatic pathobiology. Hepatitis B virus (HBV) often inserts next to genes related to cell cycle, and thus may be the source of clones of hepatocytes with enhanced proliferation [180]. Similarly, many different components of the HBV are also known to influence cell signaling as discussed in Chap. 37. Overall viral studies in hepatocytes are hampered by the lack of well defined culture systems capable of sustaining viral infection. On the other hand, there are opportunities for further studies using histopathologic material and immunohistochemically demonstrable cell proliferation markers (e.g. PCNA and Ki67). Such studies are needed to answer these questions. Commonly encountered toxins such as acetaminophen and alcohol seem to have a uniformly inhibitory effect on hepatocyte proliferation and associated with hepatocyte apoptosis or necrosis. It is not paradoxical, in view of the discussion on the "hepatostat" above, that agents which inhibit proliferation or cause necrosis of a portion of hepatocytes enhance proliferation of the residual cells by stimulating the same signaling pathways as liver regeneration after PHx. This is perhaps the single most important message from the study of liver regeneration, namely that loss of hepatocytes regardless of any cause triggers the established regenerative mechanisms to restore cell loss. While this result is desirable in restoration of acute injury, if it becomes a prolonged situation as with chronic liver injury, it leads to distortion of hepatic architecture (see below). It is also likely that proliferating hepatocytes may more likely succumb to cell death from the effects of toxins, and this may create scenarios of vicious cycles in the liver, in which the very attempts of hepatocytes to restore hepatic cell loss makes them more vulnerable to the toxins which caused the loss. It is also well known from earlier studies that proliferating hepatocytes are much more susceptible to neoplastic transformation induced by carcinogenic chemicals [181].

Cirrhosis as a Chronic Regeneration Process

Cirrhosis is a result of chronic injury to the liver by agents that are primarily known to cause hepatocyte loss. While there are multiple types of cirrhosis based on viral, toxic, metabolic or vascular etiologies, it is generally applicable that there is no etiology of cirrhosis that is not associated directly or indirectly with some degree of localized or panlobular hepatocyte damage and death. This is definitely the case with some of the most common etiologies of cirrhosis, associated with chronic viral infections or caused by alcohol. Loss of hepatocytes on a continued basis is a hallmark of pathogenesis leading to cirrhosis. At the beginning of the process, loss of hepatocytes may be related to the main offending etiologic agent. However, at the end stage, vascular alterations such as arteriovenous shunts at the lobular level causing decreased availability of blood to hepatocytes confound the deleterious effects of the etiologic agents and add on to the causes of hepatocyte death [182–184]. Another hallmark of cirrhosis is the increased deposition of extracellular matrix by stellate cells and portal fibroblasts that become activated during development of cirrhosis. A more detailed account on pathogenesis of fibrosis and cirrhosis is provided in Chap. 30. Also, a detailed account on stellate cell (Chap. 5) portal fibroblasts (Chap. 31) is also included in this textbook. Liver regeneration after PHx is also associated with both remodeling and re-synthesis of ECM. The pathways associated with ECM changes during normal liver regeneration (involving urokinase, MMPs, etc. in the beginning of regeneration, and re-synthesis of ECM at the end) are all also relevant in cirrhosis [185, 186]. During normal liver regeneration, there is maintenance of a balance between ECM degradation and synthesis. However in cirrhosis, due to altered performance ("activation") of stellate cells, an imbalance between ECM degradation and deposition leads to a net gain of ECM, which results in an alteration of the hepatic architecture. Simple histochemical studies have shown that there is a high rate of proliferation of hepatocytes in cirrhotic liver [187]. This is a compensatory reflex (i.e. liver regeneration related) in which the hepatocytes of the cirrhotic liver proliferate in order to restore total hepatocyte mass (as governed by a need defined by the "hepatostat", discussed in the beginning of this chapter). While the role of activation of stellate cells in cirrhosis is currently at the center stage of research, the impact of the signals from the continually replicating hepatocytes on the stellate cells (see section "Exchange of Growth Regulatory Signals Between Hepatic Cell Types During Liver Regeneration," above) also

deserves further exploration. It is the cumulative impact of such signals during the later stage of liver regeneration that induce synthesis of ECM by stellate cells and restore hepatic microarchitecture. Thus, replicating hepatocytes signaling on stellate cells may contribute to the development of the end-stage cirrhotic histologic changes by continually stimulating stellate cells towards synthesis of extracellular matrix, as at the second half of the regenerative process. Another area which deserves further study is the stereotactic relationship between hepatocytes and stellate cells. Under normal conditions, hepatocytes have intimate contact with stellate cells. Under conditions of chronic hepatocyte loss, since the associated injurious agents are mostly hepatocyte-specific, it is likely that a large number of stellate cells may be left "orphan" from hepatocytes. The biochemical and signaling disturbances of stellate cells associated with such a permanent change have not been studied, due to lack of suitable models. However, at a minimum, it has been shown that at the time of hepatocyte death, mere phagocytosis of fragments of dying hepatocytes may lead to stellate cell activation [188, 189]. This may also set the scenario for a vicious cycle. HGF has cytoprotective effects on hepatocytes [190, 191]. It is also known that activated stellate cells produce less HGF [192]. Thus, a decrease in production of a major cytoprotective agent for hepatocytes is seen precisely when such cytoprotection is needed the most, i.e. in the face of chronic exposure to hepatocyte-damaging agents. This may further enhance hepatocyte susceptibility to injuring agents and exacerbate their effects, accelerating development of cirrhosis. HGF has specifically been shown to ameliorate chronic liver injury and prevent or reverse development of cirrhosis in animal models [190, 191].

Overall Conclusions

Hepatic growth biology has benefited from well defined studies on hepatocyte cultures, surgical models leading to liver regeneration, and genetic models of mice in which signaling pathways can be neatly delineated. Newer approaches with nucleic acid constructs aimed to interfere with specific signaling pathways are also likely to be helpful. Now that considerable fundamental knowledge on signals related to both initiation and termination of regeneration has been accumulated, it is appropriate to capitalize on such knowledge to better understand how such signals are affected in the setting of liver disease. Mobilization of such signals may lead to desirable effects on repair. However, distortion of these signals, particularly in the setting of chronic liver disease may lead to the opposite result, namely irreparable liver damage. The underlying pivots that determine the balance between these two outcomes can only be understood on the basis of defined studies of liver growth biology, as exemplified liver regeneration after PHx. The body of knowledge gained so far on hepatocyte growth biology (and its corollary, pathways to hepatocyte death) will be of paramount importance for development of rationally based future therapeutic approaches for host of liver diseases.

Chapter 19
Senescent Liver

Nikolai A. Timchenko

The decline of cellular functions is a main characteristic of aging. Although the senescent liver preserves its functions relatively well, there are a number of alterations which create conditions for the development of age-associated diseases and which cause problems with drug therapy in the elderly. Aging liver is characterized by morphological alterations of hepatocytes and sinusoids, by alterations in functions of Kupffer cells, by steatosis, and by chronic inflammation. One of the most significant age-associated alterations in the liver is the reduction of its regenerative capacity. Aging causes alterations of many signal transduction pathways in the liver which change expression and activities of transcription factors and chromatin remodeling proteins. The age-associated alterations in the liver cover several levels of regulation of gene expression including transcription, translation, and posttranslational modifications. Senescent livers increase expression of the histone deacetylase 1 (HDAC1) and accumulate multi-protein C/EBPα-HDAC1 and HDAC1-C/EBPβ complexes, which occupy and silence E2F-dependent and C/EBP-dependent promoters. This epigenetic silencing of the promoters seems to play a critical role in the inhibition of liver regeneration. The age-associated appearance of the multi-protein complexes is the result of multiple alterations in translation and posttranslational modifications of HDAC1, C/EBPα, and CUGBP1. Decline of growth hormone (GH) and GSK3β with age is also a critical event in the development of senescent phenotype in the liver.

Introduction

It is now recognized that aging changes expression of senescence-specific genes and alters signal transduction pathways, leading to significant alterations in the biology of many tissues. It has been shown that telomere shortening is the main reason for the senescence of human cultured cells and for the reduced lifespan [1]. The mechanisms of senescence in animals and humans are much more complicated and involve the senescence of individual tissues as well as alterations in communications between different tissues. Recent studies have revealed a significant role of epigenetic regulation in the development of senescent phenotype in cultured cells and in organismal aging. It has been shown that chromatin structure is dynamic and is the subject of extensive remodeling, and that chromatin remodeling is critical for cellular and organismal aging [2–4]. The decline of cellular functions in vertebrates seems to be associated with alterations in the circulatory system. It has been shown that the systemic environment of young organisms contains certain factors, which support normal cellular functions of the tissues and which might correct dysregulations of some biological processes observed in tissues of old animals. Elegant work from Rando's group with parabiotic pairs has clearly shown that a young systemic environment rejuvenated skeletal muscle, liver, and other tissues in old mice [5]. GH is one of the components of the circulatory system that supports cellular functions on tissues in young organisms. The decline of GH with age plays a critical role in the reduction of tissue function. In addition to age-associated changes of the systemic environment, aging also affects each tissue individually. These age-associated changes in the systemic environment and in individual tissues lead to the development of age-associated diseases and aberrant body homeostasis. Although the most dramatic age-associated alterations are observed in musculoskeletal and cardiovascular systems, the senescent liver is also characterized by many serious abnormalities. This chapter summarizes recent findings which advance our knowledge of the molecular mechanisms by which aging changes liver biology, with the focus on the alterations of molecular pathways responsible for the reduction of the regenerative capacities of the senescent liver.

Liver Functions and Age

Liver size is reduced with age, and in patients over 65 years, it is around 30% smaller than in people under 40 years [6, 7]. In addition to the reduction of liver size,

analyses of many normal subjects of different age revealed that the hepatic blood flow is decreased with age [8, 9]. Despite these alterations, the senescent liver preserves its functions on relatively high levels until it receives challenges such as surgical resections. One of the important functions of the liver is the production of proteins (albumin, transferrin, ceruloplasmin, etc.) for secretion into the blood. The initial studies of this liver function were focused on the examination of albumin since this protein is a major liver product. These studies have shown contradictory observations. Singh et al. have shown that the transcription of albumin genes is reduced in livers of old rats and that this reduction is associated with a high level of methylation of the albumin promoter at CCGG sequences [10]. On the contrary, observations by Shah and Mooradian have shown no age-related differences of the levels of albumin messenger RNA (mRNA) and protein in the liver despite the shortening of poly A tail of the albumin mRNA in livers of old rats [11]. Although investigations of the protein secretion in aged rodents generate contradictory data, the work with humans clearly shows that the concentration of albumin in blood is reduced with age [12]. Recent studies of healthy human subjects have confirmed the reduction of albumin in the blood of old individuals. Giovannini et al. have evaluated the concentrations of albumin in 92 patients of different ages before and after surgical resections and found that older patients have reduced levels of albumin both before and after surgeries and that this hypoalbuminemia is a marker of pathophysiologic frailty [13]. Additional examinations of blood parameters as the measurements of liver functions showed the reduction of albumin with age [14]. In agreement with these findings, it has been shown that age is a critical factor for the number of days required for serum albumin to return to normal levels after partial hepatectomy (PH) in humans [15]. A recent study of the liver function test (LFT) revealed that the age has a small but significant effect on LTFs [16]. These data are obtained by examination of 5,380 twin pairs with the range of age 18–81 years [16]. In support of these findings, examination of age-dependent alterations of liver functions in chimpanzees revealed a decrease in liver function including the reduction of albumin [17]. The liver is also responsible for the production of lipids and enzymes into the blood. Investigations of serum parameters of the blood in young and old patients showed that serum levels of cholesterol, high-density lipoprotein, and triglycerides increase with age. These age-associated alterations are summarized in several earlier reviews [18–22]. Taken together, various studies have convincingly shown that aging has small but significant effects on liver function.

Morphological Changes in Senescent Liver

Many morphological alterations are observed in the aging liver. However, the interpretations of some of these alterations in human livers are complicated since many samples have been taken from elderly subjects with liver disease. The most consistent results have been obtained in studies of old animals. The liver consists of a number of different cells which are differentially affected by aging. Although the size of hepatocytes is variable in young and old livers, the aging liver contains a much higher portion of macrohepatocytes with increased nuclei due to polyploidy [18, 22]. Chipchase et al. have found that livers of 2-year-old mice have abundant hepatocytes containing enlarged nuclei with increased ploidy, while livers of 3-month-old mice contain a much smaller portion of enlarged hepatocytes [23]. The number of enlarged hepatocytes reach up to 30% in livers of old mice. The premature liver polyploidy has also been described in DNA repair (Ercc1) deficient mice [23].

One of the main characteristics of the old livers is lipid accumulation in the hepatocytes [24]. The majority of studies have shown that lipids are accumulated in hepatocytes with age, leading to steatosis or fatty liver [24, 25]. Cree et al. have applied magnetic resonance spectroscopy to evaluate the age-dependent accumulation of liver fat and intramuscular lipids in patients of different ages and have found that the elderly had a significantly greater accumulation of liver fat [26]. In addition, these authors showed that elderly patients with fatty livers have increased insulin resistance [26]. Independent studies attest to the age-associated accumulation of lipids in hepatocytes [27, 28]. However, there are also reports that did not find any age-associated increase of lipid accumulation in the liver [29, 30]. Although the differences in these studies suggest that the "old" livers might not accumulate lipids, it is likely that the calendar and biological ages are not identical in some patients and that some "old" livers are phenotypically young. Independent of age, the accumulation of lipids in the liver leads to impaired glucose metabolism and to reduced insulin clearance [24, 31–33].

Age-dependent morphological alterations in the hepatic sinusoid have also been recognized. The liver is a highly perfused tissue receiving blood from the heart and the portal vein. The circulation of the blood within the liver is mediated by hepatic sinusoids. The sinusoids form a rich capillary network, which provides extensive endothelial surface area for interactions of liver cells with circulating factors including immune cells and other soluble macromolecules [34, 35]. The sinusoids contain several types of cells, most importantly, the liver sinusoidal endothelial cells (LSEC). The orchestrated work of these cells is required for endocytotic and host defense functions of the liver, especially in response

to toxicants [34]. Although early studies did not detect significant alterations in the LSEC in old age livers [36], recent studies clearly demonstrated multiple age-associated changes in the sinusoids [35, 37–39]. Particularly, these studies demonstrated age-associated reduction in the number of perfused sinusoids, which correlated with reduction of sinusoidal blood flow [38]. In addition, it has been shown that the expression of several markers of sinusoids, such as von Willlebrand factor, is increased in old age [35, 38–41]. It is interesting to note that caloric restriction, which extends life span, also corrects age-associated alterations in sinusoids [39]. Investigations of Kupffer cells in livers have provided contradictory results. While some studies have revealed an increase in the number and activity of Kupffer cells in old age [42], other reports have shown that volume densities of Kupffer cells in the livers of rat are the same at 2 and 24 months of age [43]. However, it is likely that aging reduces the ability of Kupffer cells to mount an effective immune response [35]. Thus, a large body of evidence shows that old age causes significant alterations in functions of the hepatic sinusoid, in activities of LSEC, and in expression of some endothelial antigens.

HCV Infections and Nonalcoholic Fatty Liver Diseases Are the Major Risk Factors for Hepatocellular Carcinoma in Elderly

Several liver diseases increase with age including hepatitis B virus (HBV) infections, hepatitis C virus (HCV) infections, nonalcoholic and alcoholic fatty liver diseases, and hepatocellular carcinoma (HCC) [18, 20, 44–46]. It has been shown that HCV infections are prevalent with age and it is expected that the burden of HCV infections in elderly persons will be significantly increased during next two decades [47]. A number of investigations showed the correlation between outcome of HCV and patients age [18, 47–49]. A recognized complication of HCV infection is the development of HCC in old patients. Investigations of HCC in 463 patients of different ages with chronic hepatitis C in Japan showed the age-dependent increase in the rate of HCC starting from 60 years age [50]. Another recent study of the incidence of HCC in patients with hepatitis C infections has examined 693 patients with HCV showed that elderly patients developed HCC more often than young patients [51]. Nonalcoholic fatty liver disease (NAFLD) is also being recognized as a risk factor for the HCC development in the elderly [18]. NAFLD refers to a wide spectrum of liver diseases ranging from simple steatosis to nonalcoholic steatohepatitis (NASH) [52]. In patients with type 2 diabetes, the prevalence of NAFLD might be as high as 70%. Given a burgeoning epidemic of diabetes in an aging population, NAFLD is expected to be a serious risk factor in the elderly. Examination of 34 NASH patients with HCC and 348 NASH patients without HCC revealed that old age and advanced fibrosis were the main risk factors for HCC, and that HCC was the major cause of mortality in NASH patients [53]. Recent studies of the methylation of 19 epigenetic markers in aging liver, chronic hepatitis, and HCC showed that methylation of DNA in HCC occurs in a gene-specific manner and that HCV infections accelerate the methylation process [54]. Methylation in HCC and HCV infected patients disrupts components of signaling pathways that are involved in tumor formation, such as p16, p53, and WNT/APC [54]. The development of HCC in HCV infected patients appears to be mediated by alterations in epigenetic regulation of gene expression. Hepatic steatosis, which is observed in NASH and HCV infected patients and in livers of old patients, is a risk factor for HCC [55]. Ikeda et al. have examined 2,215 patients with chronic viral hepatitis and found the appearance of cancer to be age-dependent [56]. Benvegnu et al. have examined 312 old patients with HBV and HCV and found HCC to be the most frequent complication in these patients [57]. Two recent reports have also confirmed age to be a risk factor in development of HCC [58, 59]. Thus, age is an important risk factor for development of HCC in HCV-infected patients and patients with NASH.

Aging Reduces Regenerative Capacity of the Liver

Liver is a unique tissue which is able to regenerate itself in response to injury and after surgical resection [60–63]. Liver regeneration after PH is a widely used experimental system for investigations of molecular mechanisms of liver proliferation and mechanisms by which aging inhibits liver regeneration. Liver regeneration in young animals is controlled by a complex cooperation of many signal transduction pathways which are described in several recent reviews [60–63]. Investigations of liver regeneration using genetically altered mouse models has now revealed that the deletion or modification of a single gene is insufficient to arrest liver regeneration completely and that there is much signal transduction redundancy in this event [61, 63]. It would be relevant to briefly review those critical steps in the regulation of liver regeneration in young mice that are affected by aging in old animals. Hepatocytes are normally quiescent cells. In response to PH, hepatocytes undergo one or two rounds of replication and restore the original size of the liver. The transition of cells from quiescence to proliferation requires activation

of S-phase and mitotic-specific genes, which are usually repressed in quiescent cells by E2F-Rb family complexes [64–66]. At the early stage of liver proliferation after PH, several genes of the cytokine network are activated and this activation is required for proper liver regeneration [60, 61]. The next step of liver regeneration includes activation of tyrosine kinase receptor, c-met, and IGF ligands, which in turn activate expression of transcription factors involved in liver regeneration. The important transcription factors activated by PH are c-jun, C/EBPβ, and CREM [60, 67–69]. At later time points after PH, the liver activates the expression of a group of proteins that are required for transition through S-phase and mitosis. These proteins include DNA polymerase α, c-myc, cdc2, and Fox M1B [70–75]. Under normal conditions, the quiescence of liver is mediated by C/EBPα, which inhibits cyclin dependent kinases, and by Rb-E2F complexes, which repress E2F-dependent promoters. In young livers, PH eliminates C/EBPα-dependent inhibition of liver proliferation by the reduction of C/EBPα mRNA and protein levels and by activation of Akt-PI3K signaling, which de-phosphorylates C/EBPα at S193 [76, 77]. The elimination of Rb-E2F complexes after PH is achieved by phosphorylation of Rb [64]. Thus, activation of liver regeneration after PH involves a complex cascade of alterations in gene expression which include activation of cell cycle proteins and elimination of growth inhibitory activities of Rb and C/EBPα proteins.

The reduction in the regenerative capacity of liver with age was discovered over 50 years ago. In experiments with PH in rat liver, Bucher et al. found that young animals had two sharp peaks of DNA synthesis after PH while livers of old rats showed one significantly reduced peak of DNA synthesis which occurred at much later time points after PH [78]. Many follow-up studies clearly demonstrated that the liver regeneration is significantly reduced with age. The results of these publications are summarized in a recent review [63] and are presented with more details in the section discussing epigenetic silencing of liver regeneration in the elderly. In addition to PH, liver regeneration in animals might be initiated by several stimuli including treatments with carbon tetrachloride (CCl_4) and with mitogenes such as the peroxisome proliferator, 1,4-*bis*[2-(3,5-dichloropyridyloxy)] benzene (TCPOBOP) [60, 61]. Studies from the Columbano and Leda-Columbano groups have shown that molecular mechanisms of initiation of liver proliferation by TCPOBOP differ from those initiated by PH [79–81]. For example, although the activation of cyclin D1 is required for liver proliferation after PH, the loss of cyclin D1 does not inhibit the proliferative response of mouse liver to mitogenic stimuli [80]. One of the critical differences of liver regeneration after PH and TCPOBOP treatments is that liver regenerates identically well in young and in old mice after TCPOBOP treatments [82, 83]. A caveat to the studies is that the studies comparing liver proliferation after PH and after TCPOBOP were performed in young (2-month-old) and "old" (12-month-old) mice. Although the differences in the liver proliferation between these two age groups are easy detectable, 12-month-old mice are not really "old" and might not develop the complete set of the age-specific alterations which strongly inhibit liver proliferation in 22–24-month-old mice.

Telomere Shortening in Senescent Liver and Its Possible Contribution to the Inhibition of Liver Proliferation in Elderly

Studies of the aging phenotype in senescent human cultured cells have revealed a critical role of telomere shortening in cellular senescence [1, 84]. Since telomere shortening inhibits its proliferation of cultured cells, one of the hypotheses is that it might also be involved in the age-associated loss of regenerative response in old livers. Telomeres are short repetitive DNA elements (TTAGGG) which are located at the ends of chromosomes. During cell division, telomeres shorten after each round of DNA replication, leading to significant loss of the telomeres after many rounds of cell division. The length of telomeres is maintained by a telomerase reverse transcriptase (TERT) which adds TTAGGG to telomeric DNA using a telomerase RNA component [85]. It is important to note that telomere shortening is quite different in humans and in rodents. In humans, telomeres are approximately 15–20 kb in length while mouse telomeres are much longer and reach up to 150 kb [1, 84]. The most important difference between mice and humans is that the majority of human cells do not express hTERT, except specific germ lines and immortal cancer cells, while the majority of mouse tissues contain active TERT [84]. Therefore, the proliferation of human cells leads to the telomere shortening and growth arrest (replicative senescence) to protect cells from catastrophic death; while mouse and rat cells do not have significant telomere shortening within one generation and are using a different mechanism for cellular senescence [84, 85]. In agreement with this difference, mice with deletion of the telomerase RNA component can survive for many generations [86]. For humans, it has been shown that telomere length is reduced in livers of older patients [87, 88] suggesting that telomere shortening might be involved in the inhibition of liver proliferation in humans. Since telomeres are much longer in mice, they do not shorten significantly within one generation and do not seem to play a role in the inhibition of liver proliferation in old animals. Nevertheless, several reports revealed that the telomerase activity is important for proper liver regeneration. It has been shown that telomerase activity is increased in regenerating rat [89] and pig livers [90]. In addition, the liver-specific deletion of a

telomeric protein, TRF2, in mice leads to the inhibition of liver proliferation after PH [91]. In this case however, hepatocytes regenerate liver functions via endoreduplication and cell growth [91]. Thus, although telomerase activity is activated after PH, it is unlikely that telomere shortening is critical for the inhibition of liver proliferation in older animals [92].

Epigenetic Silencing of Liver Regeneration in Old Mice

The initial studies of molecular mechanisms which reduce liver regeneration in old animals have been focused on examination of single genes and on the comparison of their expression in young and old animals after PH. It has been found that the livers of old mice failed to activate c-myc [71, 93], DNA polymerase alpha [70], and FoxM1B [73, 75] to the levels observed in young mice after PH. Although these studies provided important information, further investigations revealed that the alterations of the cell cycle proteins in senescent liver are much more complex. A number of recent reports provide a strong support for the hypothesis that alterations of multiple signal transduction pathways and chromatin remodeling cause the inhibition of regenerative capacities of the liver. Comparison of protein–protein complexes in livers of old mice and rats identified a chromatin remodeling protein, Brm, to be increased with age and forming a multiprotein complex with transcription factors E2F4, C/EBP α, and tumor suppressor protein Rb [5, 71]. This age-specific C/EBPα-Brm complex occupies E2F-dependent c-myc, DHFR, and cdc2 promoters in livers of old mice blocking their activation after PH [71, 94, 95]. Consistent with this growth inhibitory role of C/EBP α-Brm complex, Brm knockout mice showed an increased rate of liver proliferation [96]. Since Brm is the chromatin remodeling protein, the appearance of the C/EBP α-Brm complex in aging liver suggested that this complex inhibited E2F-dependent promoters through epigenetic silencing. However, the precise mechanisms of this putative silencing of the chromatin have been not identified because the composition of C/EBP α-Brm complex appeared to be much more complex than originally suggested. Biochemical purification of the C/EBPα-Brm complex led to the identification of additional components like histone deacetylase 1 (HDAC1) and heterochromatin protein 1α (HP1α) [97]. HDAC1 is the catalytic unit of the complex which de-acetylates histone H3 at K9 on the E2F-dependent promoters leading to epigenetic inhibition of these promoters [97, 98] (Fig. 19.1).

In addition to alterations of transcription in the liver, aging also changes translation of the proteins by activation of RNA binding protein CUGBP1 and forming the translational CUGBP1-eIF2 complex [99]. HDAC1 mRNA is one of the targets of this translational complex [97, 98]. The CUGBP1-eIF2 complex binds to the 5′ region of HDAC1 mRNA and increases translation of HDAC1 mRNA in the livers of old mice [97]. The elevation of HDAC1 in livers of old mice also leads to the increased amounts of complexes of HDAC1 with another member of C/EBP family, C/EBPβ [100]. The C/EBPβ-HDAC1 complex is associated with C/EBPβ-dependent promoters and represses expression of these promoters [100–102] (Fig. 19.1). In agreement with the elevation of HDAC1 complexes in livers of old mice, Kawakami et al. reported decreased amounts of a target of HDAC1, histone H3 acetylated at K9 in livers of old animals [103]. Thus, the elevation of HDAC1 in livers of old animals suppresses gene expression through the interactions with C/EBPα-Brm and with C/EBPβ leading to epigenetic silencing of the E2F-dependent and C/EBP-dependent promoters (Fig. 19.1). It is interesting to note that the liver-specific elevation of HDAC1 in transgenic mice develops steatosis [104], which is the main characteristic of the aging liver [24]. It has been also shown that the ectopic expression of HDAC1 in livers of young mice alters expression of cell cycle genes [105]. Since C/EBPβ protein regulates expression of a number of genes involved in the regulation of lipids accumulation, it is likely that HDAC1-C/EBPβ complexes might be involved in the development of "fatty" phenotype in the liver of old mice. Because HDAC1 interacts with many transcriptional factors, it is likely that the elevation of HDAC1 in livers of old mice might repress promoters of other genes to which HDAC1 binds through the interactions with additional transcription factors (Fig. 19.1). In this scenario, the elevation of HDAC1 might be involved in several additional alterations in biology of senescent liver.

Mentioned earlier, livers of old mice proliferate well if the liver regeneration is initiated by TCPOBOP [82, 83]. Why is there such a difference in the ability of old liver to proliferate after TCPOBOP treatment and not after PH? In the light of recent data for epigenetic silencing of liver regeneration, it is likely that the activation of nuclear receptors by TCPOBOP leads to the removal of the epigenetic silencing by elimination of C/EBPα-Brm-HDAC1 and C/EBPβ-HDAC1 complexes.

Signal Transduction Pathways Which Change Epigenetic Control in Livers of Old Mice

The age-associated appearance of the C/EBPα-Brm-HDAC1 and C/EBPβ-HDAC1 complexes is caused by alterations of several pathways, which operate upstream of the individual components of the complexes. It has been shown that C/EBPα is hyper-phosphorylated at S193 in livers of old mice and that this phosphorylation is required for the interactions

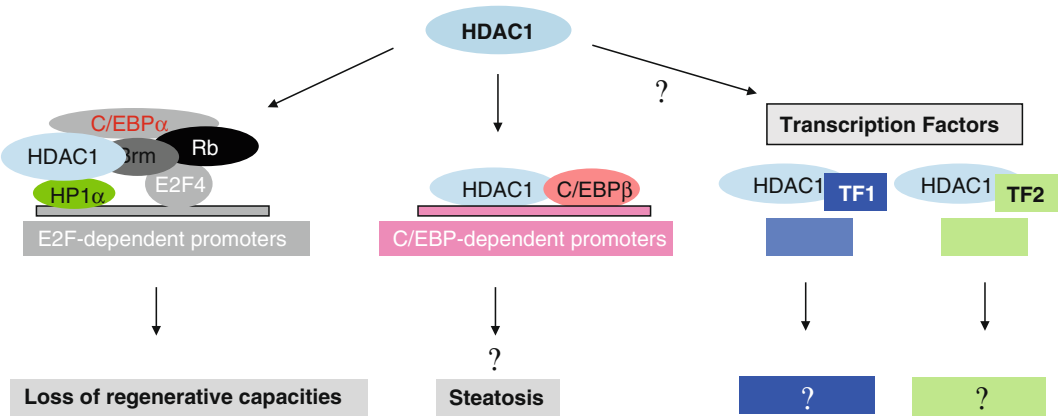

Fig. 19.1 Epigenetic silencing of liver regeneration in old mice. The increase of HDAC1 with age of the liver leads to accumulation of two complexes, C/EBPα-BRM-HDAC1 and C/EBPβ-HDAC1, which occupy and repress E2F-dependent and C/EBPβ-dependent promoters [71, 95, 97, 100, 101]. The silencing of E2F-dependent promoters inhibits liver regeneration after PH. Although the role of C/EBPβ-HDAC1 complexes in senescent liver is not known, these complexes might be involved in the development of steatosis. The possible interactions of HDAC1 with other transcription factors might be also involved in other age-associated alterations in the liver

of C/EBPα with Brm and HDAC1 [94, 95, 97]. Cyclin D3-cdk4 is the kinase which phosphorylates C/EBPα at S193. Senescent livers have higher expression of cyclin D3 through stabilization, which leads to activation of cdk4 and phosphorylation of C/EBPα at S193 [94, 98]. In the liver, stability of cyclin D3 is controlled by GSK3β-mediated phosphorylation of cyclin D3 at Thr283 [100–102]. In young livers, GSK3β binds to and phosphorylates cyclin D3 leading to a partial degradation of cyclin D3. Because the levels of GSK3β decline with age, cyclin D3 is de-phosphorylated at Thr283 and stabilized [100]. It has been shown that senescent liver reduces GSK3β by repression of the GSK3β promoter via elevation of C/EBPβ-HDAC1 complexes [100–102]. In agreement with these findings, recent observations have shown that the reduction of GSK3β by specific inhibitors or by siRNA effectively induces senescence phenotype in human liver-derived Chang cells [106]. A number of reports have shown that the reduced proliferative capacities of old livers and epigenetic alterations in livers of old mice are associated with the reduction of GH [63, 75, 95]. Elegant work from Costa's group has shown that GH is one of the components of young systemic environment which corrects liver regeneration in old mice [75]. It has been later shown that the normalization of GH levels in old mice is sufficient to reduce cyclin D3 and to eliminate the C/EBPα-Brm-HDAC1 and HDAC1-C/EBPβ complexes [95, 97]. Moreover, examination of GH-deficient Little mice showed that the GSK3β-cyclin D3 pathway is altered in young Little mice the same way as in WT old mice [100]. These data show that the decline of GH with age leads to the alterations on cyclin D3-GSK3β pathway and to appearance of multiprotein complexes in the liver causing epigenetic silencing of cell cycle genes and inhibition of liver regeneration (Fig. 19.2).

In livers of old mice, cyclin D3 is elevated in nucleus and in cytoplasm [95, 99]. While in nucleus, cyclin D3-cdk4 phosphorylates C/EBPα, the cytoplasmic accumulation of cyclin D3 leads to phosphorylation of RNA CUG binding protein CUGBP1 [95]. CUGBP1 has been discovered as RNA binding protein which is involved in development of myotonic dystrophy type 1, DM1 [107–110]. Further studies showed that CUGBP1 is also involved in the development of the aging phenotype in adipose and liver tissues [97, 99, 111]. In the liver of old mice, cyclin D3-cdk4-mediated phosphorylation of CUGBP1 at S302 increases the interactions of CUGBP1 with eukaryotic translation initiation complex eIF2 and formation of the translational CUGBP1-eIF2 complex [99]. The CUGBP1-eIF2 complex has several targets in the liver. Particularly, CUGBP1-eIF2 binds to the 5′ regions of HDAC1 and C/EBPβ mRNAs and increases translation of these proteins [97–99]. It is interesting to note that a recent report has described the accumulation of the CUGBP1-eIF2 complexes in patients with myotonic dystrophy type 2 (DM2) which have expansion of RNA CCUG repeats [112]. Consistent with these findings, the CUGBP1-eIF2 complex is elevated in transgenic mice expressing the mutant CCUG repeats [112]. These observations suggest that the patients with DM2 might develop age-associated alterations in the liver at younger age. Since the CUGBP1-eIF2 complex increases translation of HDAC1 and C/EBPβ in livers of old mice [97, 99], it would be important to examine if these proteins form HDAC1-C/EBPβ complexes in DM2 patients and if epigenetic control is altered in livers of DM2 patients.

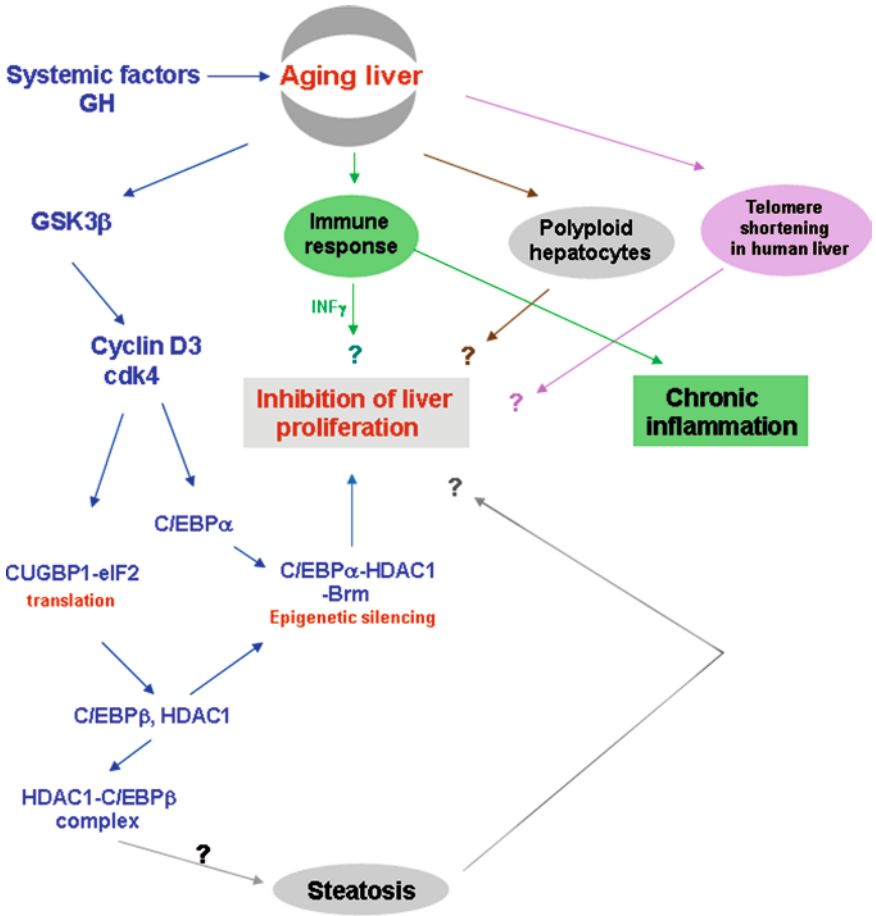

Fig. 19.2 Age-associated changes of biology of the liver and alterations of signal transduction pathways in senescent liver. The diagram summarizes recent data showing alterations of signal transduction pathways in senescent livers. The young systemic environment rejuvenates old livers [5] suggesting that systemic factors in circulating systems are responsible for maintenance of "young" phenotype of the liver. It has also been shown that a component of systemic environment, growth hormone (GH), corrects liver regeneration in old mice. *Blue arrows* and pathways show alterations in livers of old mice which are mediated by the decline of GH with age. Steatosis, alterations in the expression of genes of immuno response and polyploidy might also contribute to the inhibition of liver regeneration. Telomere shortening does not seem to be involved in the inhibition of liver proliferation in mice, but might contribute to the inhibition of proliferation in human liver

Additional Alterations that Might Contribute to the Decline of Proliferation in Senescent Liver

Although epigenetic repression of E2F targets by C/EBPα-HDAC1-Brm complex is the major mechanism of the inhibition of proliferative response of old livers, there are additional alterations in the liver which might be also involved in the inhibition. The accumulation of fat in hepatocytes of old mice might be involved in the inhibition of liver proliferation. It has been shown that liver regeneration is inhibited in leptin deficient ob/ob mice that have increased hepatic steatosis [113]. However, the correction of hepatic steatosis by prolonged administration of leptin or by food restriction does not improve liver regeneration in ob/ob mice [114] showing that steatosis is unlikely to be the major cause of the inhibition. Another well-documented alteration in the livers of old mice is the increased frequency of polyploid hepatocytes. Experimental work from Melton's lab showed that livers of 24-month-old WT mice contain a much higher number of polyploid hepatocytes than young animals and that Ercc1 mutants accumulate polyploidy hepatocytes at the age of 3 weeks [23]. Although the portion of polyploidy hepatocytes in senescent liver is relatively small, this polyploidy might also contribute to the inhibition of liver proliferation. The investigations of global gene expression by Darlington's lab in GH-deficient, long-lived Ames dwarf and Little mice have shown age-associated alterations in expression a number of genes [115, 116]. Particularly, these studies have revealed elevation of genes involved in xenobiotic metabolism in Ames dwarf and Little mice, suggesting that old GH-deficient mice are maintaining metabolic homeostasis at higher levels than WT animals of the same age [115, 116]. Further studies from this group have shown that old livers contain elevated expression of immune response genes [117]. Although no

alterations in expression of cell cycle genes have been detected in these investigations, the elevation of some genes in old mice might contribute to the inhibition of liver regeneration. One of these elevated genes is interferon gamma (INFγ). It has been shown that the overexpression of INFγ in livers of young mice inhibits hepatocyte replication after PH [118], suggesting that the elevation of INFγ in old mice might also contribute to the inhibition of liver proliferation. Further investigations of the role of the increase of inflammation-related genes in liver functions showed that aged liver exhibits a marked inflammation status which is accompanied by increased immune cell infiltration [117]. It is possible that these changes might be involved in the inhibition of liver proliferation.

Liver Surgery and Liver Transplantation in Elderly

Liver resections and liver transplantation are common ways to correct liver functions in individuals who suffered from liver diseases. The age of the liver transplant donors and recipients is quite important for the successful liver transplantation. The reduction of regenerative capacity of old livers is one of the problems for the recovery after surgeries in old patients and for survival of transplanted liver grafts from older human donors. The initial studies by Fortner and Lincer have examined the effects of age on the operative mortality rate and have shown that the patients below 50 years had 0.7% of mortality; while patients after 64 years had 11.1% of mortality [119]. Further studies have confirmed these observations [15, 18]. The multivariate analysis of the impact of 52 donor characteristics in 5,150 liver grafts patients has been performed by Cuende et al. to show that increasing age of the donors has a negative effect on liver graft survival [120]. The studies on 301 independently transplanted patients have showed similar findings [121]. Berenguer et al. have examined 522 cirrhotic patients after liver transplantation and, in agreement with previous data, have shown that main cause of death after liver transplantations to be high donor age [122]. Rull et al. have evaluated the role of donor age in the liver functions and final outcome after liver transplantation by analyzing 228 liver graft transplantations and found that the donor age over 65 years was associated with worse prognosis in terms of immediate liver functions and long-term survival [123]. Several recent reports also confirm the above findings [124–127]. In addition to investigations of transplantations in humans, Koh et al. have performed a detailed examination of the impact of donor age on the growth and liver functions of young recipient rats after liver transplantation from donors of different ages. These studies showed that transplantation of the liver from 11-weeks-old donors did not have any negative effects on the liver functions and survival; however, 52-week-old grafts transplanted into 11-week-old recipient resulted in deficient liver growth and a decline in serum albumin [128]. Although the majority of these studies revealed that the age of donor is one of the major risk factors for liver transplantation, there are examples of successful graft survival using old liver donors [129–131]. There might be several reasons for such exceptions. It might be that the successful transplantation of old liver is associated with young systemic environment of the recipients, which is known to rejuvenate old livers [5]. It is important to note that, in some cases, the calendar age does not correlate with biological age of the patients suggesting that some "old" donors did not develop age-associated changes and the liver functioned rather as the "young" tissue. The interpretations of successful and unsuccessful transplantations as functions of age are complicated because of different health conditions of recipients.

Development of Approaches to Improve Liver Regeneration and Graft Survival in Older Patients

Given the problems with liver regeneration and graft survival after liver transplantations, it is important to develop therapeutic approaches for the correction of liver regeneration in elderly. As discussed above, recent studies have revealed that the inhibition of liver proliferation in old organisms is mediated mainly by epigenetic silencing. Several reports suggested that treating with GH might be one approach to correct the proliferative capacity of old livers [75, 95]. GH can eliminate epigenetic silencing of E2F-dependent promoters by disrupting the C/EBPα-Brm complex and GH can eliminate silencing of C/EBPβ targets by reduction of C/EBPβ-HDAC1 complexes [95, 97, 98]. Despite the fact that this approach looks promising, the precise strategy for the treatments with GH needs to be further developed. It has been shown that GH treatments increase onset of diabetes and liver proliferation in quiescent livers without surgical resections [132], suggesting that the latter may lead to development of liver tumors. On the other hand, these studies applied relatively long-time exposures to GH. It is likely that examination of shorter treatments with GH might provide better conditions for correction of liver proliferation without significant side effects. Another promising approach to correct proliferation in old livers has been suggested by experiments with TCPOBOP. Columbano and Ledda-Columbano have found that aged livers proliferate well if proliferation is initiated by the activation of nuclear hormone receptors using the mitogene TCPOBOP [82, 83]. It might be possible to establish conditions under which TCPOBOP might correct liver proliferation in

the elderly. Recent examinations of the role of GSK3β in liver proliferation showed that expression of GSK3β is reduced in the liver with age and that the correction of GSK3β in livers of old mice also corrects liver regeneration [100]. The genetic modulations of the GSK3β in liver can also be considered as a potentially promising approach for correction of liver regeneration in elderly.

Concluding Remarks

Aging changes the biology of the liver at different levels. The main alterations include: (1) small but significant reduction of liver functions; (2) changes in the liver morphology including polyploidy of hepatocytes, steatosis, and alterations in sinusoid, as well as alterations of functions of Kupffer cells; (3) activation of immune response leading to chronic inflammation; (4) the decline of regenerative capacities of the liver; and (5) high rate of mortality after surgical resections and after transplantations of livers from old donors. Figure 19.2 shows liver pathways that are affected by age. The most critical, age-associated change of molecular pathways is epigenetic silencing of E2F-dependent and C/EBPβ-dependent promoters. So far, it has been shown that the epigenetic silencing of E2F-dependent promoters is a key event in the age-associated inhibition of liver regeneration. Since HDAC1 does not bind to DNA directly and displays its activity through interactions with transcription factors, the elevation of HDAC1 in livers of old mice could have a larger impact in gene expression. The age-associated epigenetic silencing is the result of alterations of several signal transduction pathways that finally lead to formation of the multi-protein complexes. The studies within the last few years have also emphasized a critical role of the decline of GH in the development of senescent phenotype in the liver. Figure 19.2 depicts the pathways (blue) which are affected by the reduction of GH in livers of old mice.

Chapter 20
Signaling Pathways in the Liver

Abigale Lade and Satdarshan Pal Singh Monga

Introduction

As molecular executors, proteins are at the heart of tissue homeostasis. They are necessary for determining the state and fate of a cell and ultimately the basis of health of the tissue. This chapter is a generalized but succinct introduction to many signaling pathways that are of relevance to liver physiology and pathology. While these pathways will be discussed in separate chapters based on their relevance to specific states of the liver, this chapter will only introduce the readers to the important components and functioning of the relevant pathways with a brief mention of their known roles in liver pathobiology. The listing of the signaling pathways is in alphabetical order and does not represent their relative importance in the liver.

The proteins that are the components of various signaling pathways dictate the molecular basis of health and disease. This also applies to the liver. Signal transduction is the process by which a cell responds to changes in extracellular or intracellular conditions through the conversion of an external stimulus into a change in cell behavior. Signaling events typically involve molecular cascades in which multiple protein players are activated in succession, ultimately converging on changes in specific cell activities, such as alterations in gene expression, cytoskeletal rearrangement, cell death, or entry into the cell cycle.

Signaling cascades typically commence with the binding of a ligand to a receptor. Ligands can be molecules of various classes, including growth factors, cytokines, chemokines, hormones, neurotransmitters, and extracellular matrix components. They may be soluble factors secreted from cells nearby (paracrine signaling), from distal cells, which release them into the blood stream (endocrine signaling), or from the same cell receiving the signal (autocrine signaling); or may involve interactions between a cell and non-secreted factors of the extracellular matrix (matricrine), or a membrane-bound receptor on an adjacent cell (juxtacrine). Receptors for the ligands may be either extracellular or intracellular. Extracellular receptors include receptor tyrosine kinases, G-protein coupled receptors (GPCRs), integrins, and toll-like receptors, all of which pass through the cell membrane and transmit signals across it by changing their conformation, and consequently activity, upon ligand binding. Intracellular receptors are located within the cell, and are activated by internal factors, such as small lipophilic molecules that are able to traverse the cell membrane or intracellular secondary messenger molecules downstream of other signaling activities. Intracellular receptors include hormone receptors, peroxisome proliferator activator receptors, and IP_3 receptors. Following is an overview of the key signaling pathways with relevance to liver biology.

β(Beta)-Catenin Signaling

The importance of the Wnt/β-catenin signaling pathway in liver is becoming increasingly evident. β-Catenin is unique in that it has dual roles in cells. As a structural component of adherens junctions, it links the actin cytoskeleton to the transmembrane adhesion protein E-cadherin. Also, as an effector of the canonical Wnt signaling pathway, it translocates into the nucleus to transactivate expression of target genes by displacing the inhibitor Groucho from T-cell factor/lymphoid enhancement factor (TCF/LEF) family transcription factors. Activation of the signaling activity of β-Catenin occurs downstream of extracellular binding of Wnt family glycoproteins to their transmembrane Frizzled (Fz) receptors (Fig. 20.1). The Wnt family is comprised of 19 secreted proteins that are activated by lipid modification and act as morphogens in the context of embryogenesis, cancer, and normal tissue physiology. Wnt proteins act as ligands for receptor proteins in the Frizzled family, which, in conjunction

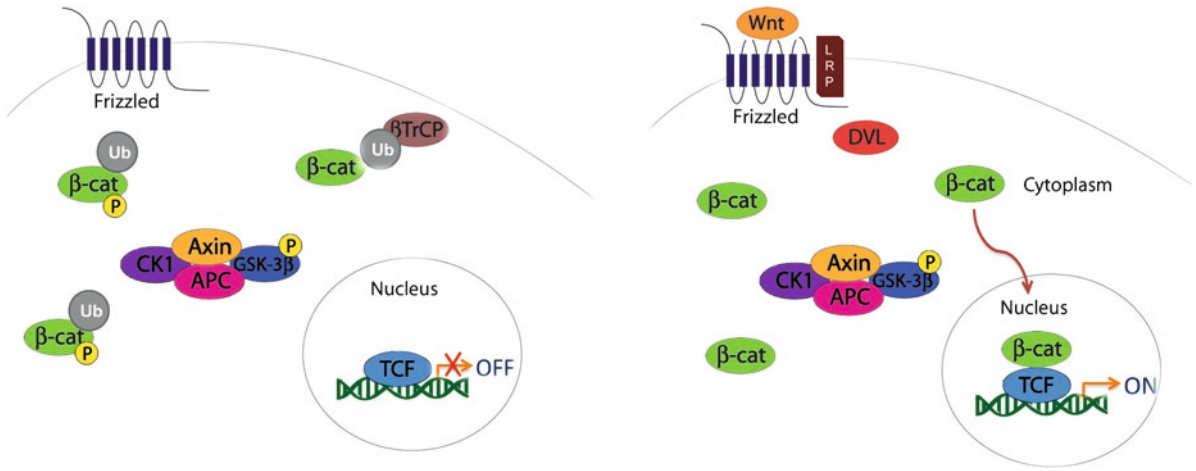

Fig. 20.1 The Wnt/β-catenin signaling pathway in absence of Wnt signal or in "off" mode (*left*) results in phosphorylation of β-catenin at specific serine/threonine residues in its amino-terminal by the degradation complex that results in its recognition by the β-transducin repeat containing protein (βTRCP) for ubiquitination and proteosomal degradation. In the presence of Wnt signal in an "on" mode (*right*), β-catenin translocates to the nucleus and binds to TCF family to induce target gene expression

with co-receptor LDL related protein 5/6 (LRP5/6), triggers the cascade that involves Disheveled (Dvl) and components of the β-catenin degradation complex, thus resulting in their inactivation. This inhibits serine/threonine phosphorylation of β-catenin, and prevents its recognition by a ubiquitin ligase, β-transducin repeat containing protein (β-TrCP), which normally targets β-catenin for constitutive degradation by the proteasome. Specifically, recognition of β-catenin by β-TrCP is dependent on phosphorylation of specific residues on β-catenin located in exon-3 (Ser 33, Ser 37, Thr 41, and Ser 45) by a protein complex composed of Axin, glycogen synthase kinase-3β (GSK3β), Casein kinase-1α (CK1α), and adenomatous polyposis coli gene product (APC), which occurs in the absence of Wnt signal or in the presence of upstream inhibitors of the Wnt pathway such as Fz-related proteins, Dickkopf, and others. Stabilization of β-catenin permits its nuclear translocation, thereby promoting Wnt pathway target gene expression through interactions with TCF family proteins, other relevant co-activators, and histone acetyl transferases to eventually alter cell proliferation, survival, differentiation, and migration.

Phosphorylation of several tyrosine residues by both receptor and non-receptor tyrosine kinases alters the activity of β-catenin, including Y86, 142, 654, 670, and others. Phosphorylation of Y654 by kinases such as c-src, Bcl-Abl, Met, EGFR, and ErbB2, decreases the affinity of β-catenin for E-cadherin, leading to disassembly of the adherens junctions complex, decreased cell–cell adhesion, and translocation of β-catenin into the nucleus to promote cell proliferation [1–7]. Likewise, Fer or Fyn phosphorylation of β-catenin at tyrosine 142 regulates its affinity for α-catenin, its other key adherens junction binding partner [8].

β-Catenin-independent Wnt signaling pathways also exist, the chief examples being the "non-canonical" planar cell polarity (PCP) and Wnt/calcium signaling pathways. Not only do these cascades operate independently of β-catenin, but they also actively suppress canonical β-catenin activity [9, 10]. Non-canonical Wnt signaling cascades utilize Wnt and Fz proteins, and while they are highly complex and incompletely understood, evidence is emerging that the particular Fz protein that is activated dictates whether canonical or non-canonical signaling occurs downstream [11].

Roles for β-catenin have been established for nearly every aspect of liver biology including embryogenesis, organogenesis, regeneration, zonation, and maintaining tissue and organ homeostasis. It has critical responsibilities in the regulation of multiple cellular functions, including lineage specification, differentiation, proliferation, survival, maintenance of redox state, morphogenesis and metabolism [12].

As is so often the case, the importance of a pathway in liver physiology means its dysregulation is often seen in pathological liver conditions. Hepatoblastomas, hepatocellular carcinomas (HCCs), cholangiocarcinomas, focal nodular hyperplasias, and hepatic adenomas all have been linked to β-catenin dysregulation, as have liver fibrosis and steatohepatitis [12, 13].

ERBB/EGFR Family

Another pathway with particular relevance to liver function is that activated by the epidermal growth factor receptor (EGFR) or ErbB family. EGFR family proteins are cell-surface

receptor tyrosine kinases of which there are four members, designated as EGFR (ErbB1, HER1), ErbB2 (HER2, neu), ErbB3 (HER3), and ErbB4 (HER4). Typically, binding of epidermal growth factor (EGF) ligands to the extracellular region activates these receptors. The extracellular ligand-binding region of EGFR proteins is comprised of two leucine-rich repeat domains denoted by L1 and L2 [14] which are interspersed with two cysteine-rich, beta-helix containing domains [15] (referred to as CR1 and CR2). The intracellular portion of the receptor contains a kinase domain. Ligand binding induces receptor oligomerization, and triggers autophosphorylation of cytosolic tyrosines, which can then recruit adaptor proteins or kinases involved in major signaling pathways including the ras/Raf/MAP kinase, JAK/STAT, Akt/PI3 kinase/mTor, src/NFκB, Pak1/rac, Wnt/β-catenin, and PLC pathways [16]. In addition to these pathways, EGFR signaling exhibits crosstalk with integrin [17], PKC [18], STAT [19], and steroid receptor signaling [20], and is also affected by VEGFR and PDGFR RTK pathways [21].

EGFR ligands are expressed as inactive precursors. They become anchored to the membrane and are activated by membrane-associated proteases, which remove regulatory domains and release the receptors from the cell surface [22]. The four EGFRs have distinct sets of binding partners. ErbB2 lacks ligand binding activity, but can heterodimerize with other ligand-bound EGFRs to become active. ErbB3, on the other hand, while capable of ligand-binding, does not possess kinase activity and must associate with ErbB2 or ErbB4 to activate signaling cascades. ErbB3 and ErbB4 bind different sets of a family of EGFR ligands called neuregulins; ErbB4 binds the four neuregulin family members NRG1β, NRG2β, NRG3, and NRG4, while ErbB3 binds NRG1α and NRG2α. Finally, ErbB1 binds both soluble and heparin-bound (HB) EGF, TGFα, the androgen receptor (AR), betacellulin (BTC), and epiregulin (EPR) [23].

As a pathway linked to inflammation, survival and growth signaling, EGFR is poised to mediate many key aspects of liver biology. In rats, ErbB2 is expressed by liver progenitors and persists through postnatal liver development, and ErbB3 expression occurs both in developing and adult liver [24]. Perinatal deletion of EGFR in mice results in impaired liver regeneration [25], as does the inhibition of EGFR signaling via infection of adult mice with a virus encoding the EGFR pathway inhibitor suppressors of cytokine signaling (SOCS) [26], and these impairments appear to stem from defective G1-S cell-cycle progression and stress response [25], possibly mediated through STAT3 activation [26]. Given the capacity of EGFRs to promote liver growth, it is perhaps not surprising that many studies have identified links between overactive EGFR signaling and hepatocellular and biliary carcinomas [27–40]. Recently, EGFR expression was also shown to be increased in hepatoblastomas of both fetal and embryonal types [41]. Overall, a picture emerges from studies of this pathway that EGFR signaling regulates hepatocyte proliferation and survival in response to stress.

Hepatocyte Growth Factor (HGF) Signaling

Hepatocyte growth factor (HGF) was discovered independently in several systems and was shown to promote a diverse array of context-specific effects including cell migration [42–44], growth [44–48], morphogenesis [49], and inhibition of tumor growth [50] before molecular characterization revealed a single protein behind these effects [51–53]. Structurally, HGF is related to the blood protein plasminogen, which is the precursor of the clotting protein plasmin. Along with apolipoprotein, HGF and plasminogen share an N-terminal plasminogen activation peptide domain, a serine protease modality, and "kringle" domains that are loop-in-a-loop structures formed by disulfide linkages between four cysteine residues [54]. Cleavage of the 728 amino acid HGF-precursor produces an α-chain comprised of residues 1–494 and a β-chain comprised of residues 495–728. Heterodimerization of these chains produces an active ligand capable of activating its tyrosine kinase receptor.

The receptor for HGF, c-Met, is a heterodimer consisting of a 50-kDa extracellular ligand-binding subunit linked to a 140-kDa transmembrane subunit containing an intracellular kinase domain. The active, 185-kDa dimer undergoes autophosphorylation at residues Y1234 and Y1235 to activate its kinase domain [55, 56]. Phosphorylation of residues Y1349 and Y1356 allows c-Met to recruit various SH2/SH3-domain containing signaling and adaptor proteins [57] including growth factor receptor-bound protein 2 (Grb2), Shc transforming protein 1 (Shc), GRB2-associated binding protein 1 (Gab1), Signal transducer and activator of transcription 3 (STAT3), phosphatidylinositol 3-kinase (PI3-kinase), phospholipase C gamma (PLCγ), as well as Src, V-crk sarcoma virus CT10 oncogene homolog, and the related Crk-like (CrkL) [57, 58].

Recruitment of different signaling proteins by c-Met-bound adaptors allows for the activation of a constellation of signaling pathways. One example is the activation of the Ras-MAPK and PI3-kinase/AKT pathways that promote cell migration, invasion, and branching morphogenesis [59–61]. Another is the Crk/Crkl recruitment of C3G and DOCK180 to activate Rap1- and Rac1-mediated regulation of cytoskeletal rearrangement, cell spreading, and cell adhesion [62]. A third example is the induction of tubule morphogenesis and anchorage-independent cell growth promoted by Stat3 [63, 64]. In addition to these mechanisms that activate signaling, Grb can also induce ubiquitinylation and targeting of Met for proteasomal degradation by recruitment of the ubiquitin ligase c-Cbl [65, 66].

Though its name suggests its primary role in the liver is to promote hepatocyte growth, HGF itself can actually inhibit proliferation of transformed rat liver cells in vitro [62] and in vivo [61], and further work has revealed that it is expression of c-Met rather than HGF, which is critical for mitogenesis [67]. However, during development, HGF and c-Met are expressed more highly in liver than any other tissue [68], and both $HGF^{-/-}$ and $c\text{-}Met^{-/-}$ mice die in utero, and exhibit decreased liver parenchymal cell mass and a failure of hepatocyte differentiation [69–71], thus pointing to a role for HGF/Met signaling in prenatal liver growth. Of note, the earliest discovery of HGF came from studies in which it was isolated from the conditioned medium of cultured rat HCC cells, as a factor that had mitogenic effects on normal rat hepatocytes. Met was first detected as an oncogene in a osteosarcoma cell line transformed by carcinogen treatment [72, 73] until further characterization revealed it to be a chromosomally-rearranged fusion between Met and Tpr [74, 75], missing the Met residue Y1003 that is necessary for its negative regulation [75]. However, though overexpression of HGF or Met is seen in some HCCs [76–82], further studies assessing the effect of activation of this pathway on transformed cells in vivo or in vitro conversely suggest anti-tumorigenic effects including growth inhibition [78, 83, 84] and promotion of apoptosis [78], and no correlation is observed between Met expression and tumor size [67, 76, 85]. Interestingly, mice lacking Met in hepatocytes showed a paradoxical increase in HCC in response to chemical hepatocarcinogenesis [86]. Critically, patient studies do not address whether Met mutations exist in the analyzed samples that could affect the downstream signaling outcomes. In some cases, rather than playing a causative role in HCC development, the upregulation of these proteins may be secondary to tissue damage or cellular stress associated with cancer. HGF is among the first proteins upregulated after liver injury, and active Met increases concordantly [87], as well as the protease responsible for its activation [88]. While the mechanism leading to these changes is still being elucidated, hypoxia promotes transcriptional activation of Met [89, 90], as do inflammatory mediators such as IL-1 α, IL-6, TNF-α [91], and prostaglandins [90], and this may account for the increases seen in cancers. Given their upregulation in response to liver injury and ability to promote hepatocyte growth, it is no surprise that extensive research has revealed HGF and Met to be critical in supporting liver regeneration. Of note, Met also can inhibit apoptosis by binding the Fas receptor and hindering the trimerization necessary for its activation [92], another function that would facilitate a role in responding to tissue injury. Furthermore, Met phosphorylation of β-catenin at residue Y654 induces its translocation to the nucleus along with activation of target gene expression, some of which promote cell cycle entry [1, 7, 93]. In the widely-utilized 2/3 partial hepatectomy (pHx) rodent model of liver regeneration (please see Chap. 18 for additional details on the process of liver regeneration), hepatocytes have been shown to increase utilization of existing HGF stores between 0 and 3 h after hepatectomy, and then, once these are depleted, they drastically increase their synthesis from hour 3 to hour 21 after pHx [94]. Activation of Met by tyrosine phosphorylation is seen between 30 and 60 min after partial hepatectomy [95]. Mice with hepatocyte-specific [96] or conditional Met deletions [97] exhibit severe impairments in regeneration. While the precise context-specific outcomes of Met activity are still being investigated, Met clearly has a critical role in many aspects of liver physiology.

Hedgehog Signaling

Hedgehog signaling instructs patterning of embryos through specification of cell fate, and regulates proliferation and stem cell maintenance in adult tissues [98]. The pathway is named after the three (sonic hedgehog, shh; Indian hedgehog, ihh; and desert hedgehog, dhh) secreted ligands of the Hedgehog family that bind the seven-transmembrane receptor Patched. Hedgehog ligands are expressed as 45 kDa precursors, and then autoproteolyzed to a 19 kDa form to which a palmitoyl group and cholesterol group are attached before secretion [99]. Binding of Hedgehog proteins inhibits the activity of Patched, releasing its inhibition of Smoothened and thus results in an increased activity of the transcription factor Gli3 (Fig. 20.2). In the absence of Hh, Gli3 is targeted for cleavage by the proteasome, generating a C-terminally cleaved fragment that functions as a transcriptional repressor. Active Hh signaling results in translocation of transcriptionally active Gli proteins into the nucleus and expression of target genes such as *Gli* and *Ptc* [100].

Hedgehog signaling plays a role in liver development, as well as homeostasis, regeneration and pathologies including alcoholic liver disease [101], hepatic [102] and biliary [103–107] fibrosis, HCC [108–110], hepatoblastoma [108–114] and cholangiocarcinomas [115]. Hedgehog expression is often increased in HCCs [108, 112] and hepatoblastomas [109, 116], and inhibition by the hedgehog antagonist cyclopamine decreases tumor growth, Hedgehog target gene expression, and promotes apoptosis [110]. Shh expression is seen throughout the foregut endoderm at embryonic day E8.5, and then disappears in the liver bud during the onset of liver specification at E9.0–E9.5. Its expression appears once more at E11.5, appearing to drive cell proliferation with a subsequent decline thereafter. This is apparently critical for hepatocyte differentiation [100]. Interestingly, loss of expression of Ihh also occurs at E11.5, with its expression increasing throughout prenatal development and then decreasing to a

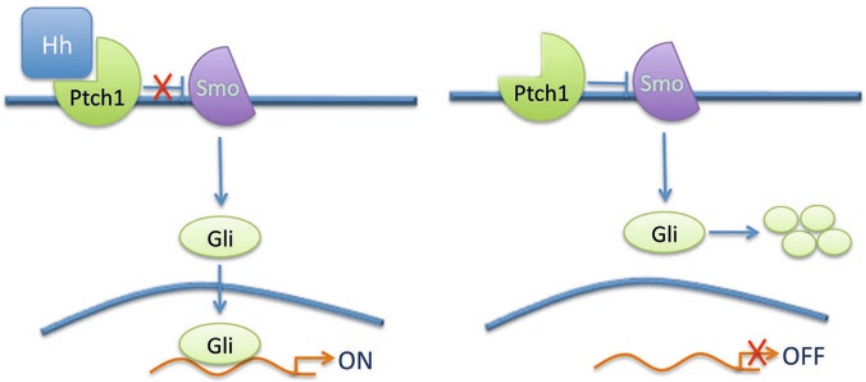

Fig. 20.2 The hedgehog signaling pathway, which in presence of the hedgehog ligands results in target gene expression (*left*), and in the absence of ligands results in activation of smoothened with resulting degradation of Gli3 (*right*) and thus lack of target gene expression

lower level that appears to be maintained postnatally [100]. Cholangiocarcinoma growth appears to be stimulated by Hedgehog signaling [115].

JAK/STAT Pathway

JAK-STAT signaling is initiated by binding of cytokine signals, such as growth factors, interferons (IFN), and interleukins, to their transmembrane receptors, ultimately leading to activation of Stat transcription factor family proteins. A classical example of this signaling is demonstrated by the IL-6/Stat3 interaction in the liver biology. The Jak, or Janus kinase receptor-activated tyrosine kinase, family consists of JAK1, JAK2, JAK3, and Tyk2. The Jak proteins act as mediators of signaling by binding to receptors and becoming activated in response to changes in conformation triggered by ligand binding (Fig. 20.3). Jak then phosphorylates tyrosine residues on the receptor to create a binding site for Stat, which then becomes phosphorylated and translocates into the nucleus. STATs possessing SH2 domains and capable of binding these phosphotyrosine residues are recruited to the receptors, and are themselves tyrosine-phosphorylated by JAKs. They are then able to bind other STATs via their SH2 domains, and result in homo- or hetero-dimers capable of activating gene transcription. JAK-independent, direct phosphorylation of STATs by EGFR and other receptor tyrosine kinases, the cytoplasmic kinase src, also occurs.

JAK-STAT pathway is regulated by two major classes of proteins: SOCS and PIAS or protein inhibitors of activated STATs. SOCS proteins bind and inhibit JAKs or STATs [117] and prevent STAT activation, and PIASs use various inhibitory mechanisms, such as blocking STAT binding sites on promoters, recruiting transcriptional co-repressor proteins, and/or promoting protein sumoylation to alter cellular trafficking [118]. Additionally, protein phosphatases regulate

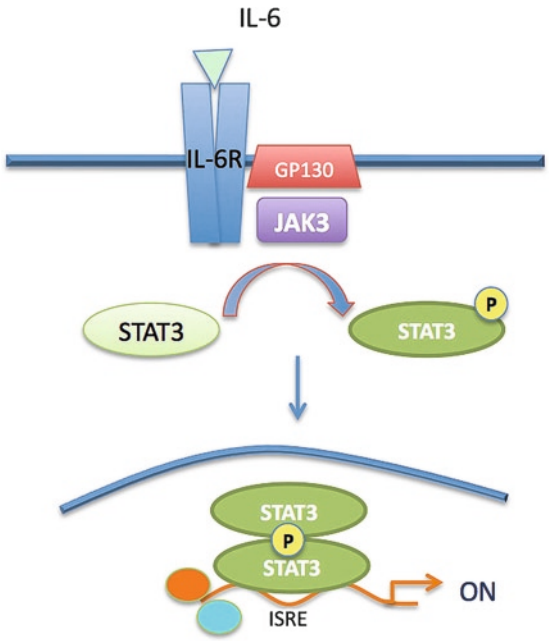

Fig. 20.3 The IL-6/JAK/STAT signaling pathway shows activation of JAK3 in response to IL-6 stimulation, which leads to Stat3 phosphorylation and nuclear translocation, where it interacts with co-factors to turn on target genes containing interferon stimulated response elements (IRSE)

JAK-STAT signaling by dephosphorylating receptors or STATs [119].

Seven Stat proteins exist in mammals, designated STAT1, 2, 3, 4, 5A, 5B and 6, each activated by a different set of cytokines. STAT1 activation occurs via binding of IFN α/β and γ, and plays roles in cellular responses to viral infection, tumor activity, inflammation, and promotes apoptosis. Similarly, STAT2 is also activated by IFN α/β and IFNλ, and also mediates antiviral responses. STAT3 responds to IL-22 as well as IL-6 family cytokines, and participates in acute phase response in addition to playing a key role in liver

regeneration, glucose homeostasis, and lipid metabolism. IL-12 activates STAT4, whose role is currently undefined, but may promote ischemia/reperfusion injury of liver. STATs 5A and 5B, activated by growth hormones, regulate expression of genes involved in growth and metabolism. Finally STAT6, activated by IL-4 and IL-13, promotes and mediates ischemia/reperfusion injury [120].

IL-6/STAT3 activity possesses particular relevance to liver physiology and pathology, and thus has been extensively studied in that context [121] (Fig. 20.3). During liver regeneration in rats treated with PHx, levels of IL-6 in circulation increase within the first hour [122]. Resident liver macrophages, and possibly hepatocytes themselves produce this cytokine, which acts not as a hepatic mitogen, but rather promotes biliary cell proliferation and function [123, 124]. Although increases in IL-6 occur early in regeneration, work done with liver-specific IL-6 pathway knockout animals suggests that this pathway is not responsible for initiating regeneration. Also, IL-6 deficient mice reveal the role of the interleukin-6/glycoprotein 130/signal transducers and activators of transcription-3 pathway in mediating liver steatosis and injury [125] and prevention of alcohol-induced liver damage and cirrhosis [123]. In addition to the aforementioned activities, activation of JAK/STAT pathway is common in HCC. One recent study found elevated Jak/Stat pathway activity in all HCCs relative to non-tumor adjacent tissue and normal livers [126], thus underscoring a need to better understand and target this pathway in liver cancers.

MAP Kinase Pathway

A major signaling pathway controlling a diverse set of cellular functions, the mitogen activated protein kinase (MAPK) pathway includes five distinct classes of MAPKs: MAPK/ERK kinase/extracellular regulated kinase (MEK/ERK), c-Jun N-terminal kinase (JNK), p38, ERK5, and ERK3 [127, 128]. The pathway acts downstream of activation of many growth factor receptors, and can effect cell proliferation, adhesion and differentiation through both cytosolic and nuclear targets. Growth factors such as EGF, vascular endothelial growth factor (VEGF), insulin, neurotrophins, and inflammatory cytokines activate MAPKs.

The MAPK/ERK kinase/extracellular related kinase (MEK/ERK) pathway is activated by receptor tyrosine kinases, which recruit the SH2-containing protein Grb2, to intracellular phosphotyrosine residues after activation by ligand binding (Fig. 20.4). Grb2 associates with a Ras-activating protein called Sos, which is activated when Grb2 binds activated RTKs, and thus can activate Ras. The activity of Ras, a GTPase, is dependent on binding to GTP (guanosine triphosphate) and can thus be modulated by GTPase activating proteins (GAPs) which inactivate Ras by promoting GTP hydrolysis, and guanine nucleotide exchange factors (GEFs) that activate Ras by catalyzing the exchange of a GDP molecule for a GTP. Active Ras proteins recruit Raf kinases to the membrane, enabling them to activate MEK-1 and -2 by phosphorylation, which then activate ERK-1 and -2. ERKs dimerize upon activation and can further phosphorylate cytosolic or nuclear targets, generally involved in proliferation or differentiation.

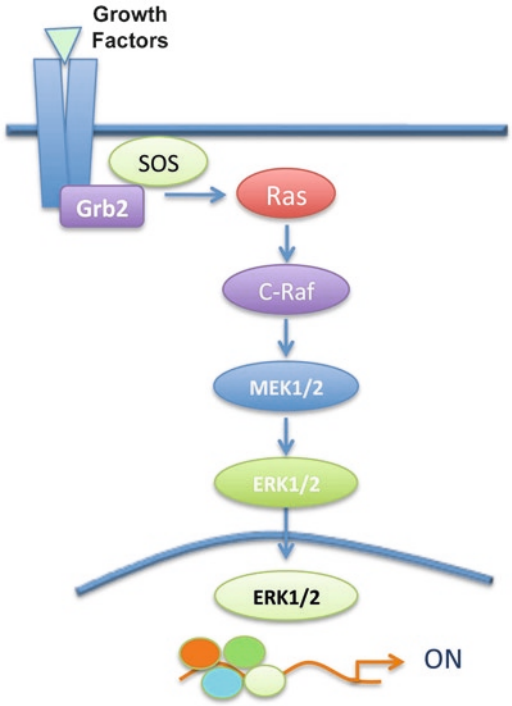

Fig. 20.4 The MAP kinase pathway is stimulated by certain growth factors that activate receptor tyrosine kinases, which lead to signaling through adapter molecules such as Grb2 and eventually lead to activation of ERK1/2, which induces target gene expression

A second MAP kinase signaling cascade is the JNK pathway, which is typically activated by GPCR, or cytokine signaling, or cell stress. This cascade proceeds through activation of MEK4 or MEK7, either of which may phosphorylate ubiquitous JNK family members JNK-1, -2, or -3, allowing their translocation to the nucleus. Once in the nucleus, they can activate transcription factors such as STAT3, ATF-2, c-Jun, and HSF1 and thereby regulate processes such as heat shock response, apoptosis, proliferation, and differentiation.

A third class of MAP kinases, activated by GPCRs, cytokines and cell stress, as well as some hormones, are the p38 family kinases. The four p38 family members α, β, γ, and δ are targeted by MEK3 and MEK6 and also target substrates such as eukaryotic initiation factor 4e (eIF4e) and MAPK interacting kinases Mnk1 and Mnk2 to regulate diverse

cellular processes including cell differentiation, proliferation, apoptosis, and inflammation.

Evidence exists for roles for multiple MAP kinase pathways in liver physiology as well as several hepatic pathologies. The roles of the most relevant growth factor receptors upstream of these pathways will be discussed separately, but activation and dysregulation of MAP kinase pathways bear some discussion. Sustained activation of ERK is seen in liver during embryogenesis [129], and activity of p38 kinase regulates hepatocyte proliferation during rat liver development [130]. Dysregulation of the JNK pathway is often a characteristic of HCCs [131–135], and Ras activation is commonly increased in HCC relative to adjacent non-tumor tissue [126]. Implications of MEK/ERK pathway aberrations in HCC are revealed by evidence that inhibition of ERK1/2 activation by RNAi knockdown of the upstream kinase MEK1 abrogated growth of human hepatocarcinoma cell lines both in vitro and in mouse tumor xenografts [136]. Additionally, p38 kinase activity is suppressed in HCC [137].

Notch Signaling

Another pathway with a critical role in liver function is the Notch signaling pathway. Notch signaling regulates tissue growth and differentiation [138]. It is activated via juxtacrine interactions, in which a ligand on the surface of one cell binds a receptor on a neighboring cell. The Notch receptor is expressed as a precursor that is cleaved to form an extracellular N-terminal fragment and a transmembrane/intracellular C-terminal fragment that assemble to form a functional, heterodimeric, transmembrane receptor [138]. Ligands for the Notch receptor are designated "DSL" ligands, as they include the Delta and Serrate/Jagged family members in Drosophila and mammals, and LAG-2 in *C. elegans*. DSL ligands are type I transmembrane proteins containing up to 36 extracellular EGF-like repeats that bind a corresponding EGF-like repeat domain on Notch. Upon ligand-receptor binding, Notch changes conformation to expose an intracellular cleavage site and is cut by a furin-like convertase to produce a soluble intracellular fragment referred to as NICD (*N*otch *I*ntra*c*ellular *D*omain) (Fig. 20.5). NICD is transported into the nucleus and participates with CSL family transcription factors to promote expression of genes such as Hes1, Hey1, and PDGFRB [138, 139]. In terms of the role of this pathway in liver, Notch signaling via Notch2 underlies the commitment of hepatoblasts to biliary epithelial cells, and absence or inhibition of the pathway leads to impaired intrahepatic biliary development including that seen in Alagille syndrome [140–146]. Notch pathway aberrations have also been linked to HCC [147–149] as well as hepatoblastoma [41, 150, 151].

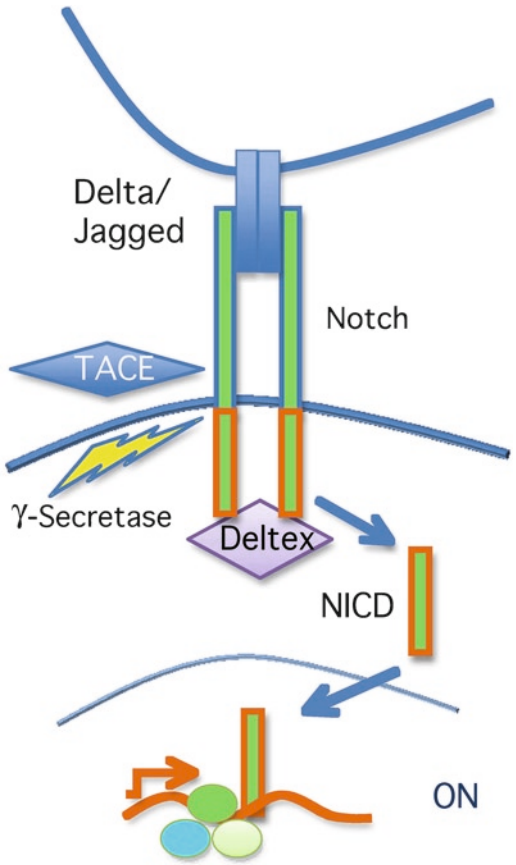

Fig. 20.5 The Notch signaling pathway is activated when signal from a neighboring cell in the form of a membrane bound ligand such as jagged/delta binds to its receptor notched that leads to proteolytic cleavage and the release of the intracellular domain, which enters the nucleus and transactivates specific target genes

PDGF/PDGFR Signaling

Platelet-derived growth factor (PDGF) receptors are prototypical receptor tyrosine kinases activated by binding by extracellular growth factors (for a recent review, see [152]). Receptors in this family include PDGFRα and PDGFRβ, and VEGFR1, 2, and 3, all of which are comprised of five extracellular Ig loops and a split intracellular tyrosine kinase domain that becomes active upon ligand-stimulated receptor homo- or hetero-dimerization. The activated kinase domains target the receptor itself, creating phosphotyrosine residues that serve as binding sites for downstream signaling molecules, many of which contain SH2 (Src homology 2) domains. Major signaling pathways triggered by PDGFR activation include: activation of PI3-Kinase, leading to cytoskeletal reorganization, migration, proliferation, and cell survival; PLCγ activation that leads to release of intracellular calcium stores and activation of the kinase PKC, and ultimately promotion of cell growth and motility; and the Ras-MAPK pathway, which activates

transcription of target genes involved in cell growth, differentiation, and motility. In addition, PDGFRs can interact with integrins, linking PDGFR signaling to focal adhesions and action to regulate cytoskeletal remodeling.

PDGFR ligands include four PDGFs denoted PDGFA, B, C, and D; four VEGFs designated VEGFA, B, C, and D, and one additional growth factor, the placenta growth factor (PlGF) [152]. PDGF-A and PDGF-B are expressed and secreted by most tissues, but as inactive propeptides that must be activated intracellularly by cleavage of N-terminal pro-domains by furins or other convertases. PDGF-C and D are activated extracellularly, by plasmin or tPa in the case of PDGF-C, or plasmin alone the in the case of PDGF-D. An additional level of regulation of PDGF activity is instituted by variable inclusion of a C-terminal, a positively-charged extracellular matrix-binding domain that promotes extracellular retention. This inclusion is regulated by alternative splicing in the case of PDGF-A and proteolytic processing in the case of PDGF-B (though the responsible protease has not been definitively identified).

Several studies provide evidence for the promotion of liver fibrosis by PDGFR signaling [153–156]. More recently, work has been done revealing a link between this pathway and HCC in preclinical and clinical studies and additional characterization is underway [157–159].

Peroxisome-Proliferator-Activated Receptors (PPARs)

As the name suggests, peroxisome-proliferator-activated receptors (PPARs) were first identified as proteins activated by peroxisome proliferation in Xenopus [160]. PPARs are a class of nuclear receptor proteins which exist as three isotypes: PPARα, PPARγ, and PPARβ/δ with distinct patterns of tissue-specific expression. PPARα is expressed by liver, heart, kidney, muscle, and adipose, where it orchestrates fatty acid uptake and lipoprotein metabolism; PPARγ, expressed by adipose, macrophages, heart, muscle, kidney, pancreas, retina, spleen, and large intestine, regulates insulin response and differentiation of adipocytes, finally, PPARβ/δ has the highest expression in brain, adipose tissue, and skin and lower expression in most other tissues. Upon ligand binding, these proteins can heterodimerize with retinoic x receptor (RXR) and adopt a conformation capable of binding to peroxisome proliferator hormone response elements in promoters of the target genes. Depending on association with co-activators and co-repressors, this binding may promote expression or repression of targets.

While PPARα agonists promote hepatic proliferation and may contribute to development of HCC [161, 162], hepatocyte-specific overexpression of PPARα alone does not appear to be sufficient to induce HCC [163]. Defects in PPARα activity lead to severe hepatic steatosis in fasting animals, underscoring the role of this pathway in fatty acid oxidation in liver [164–167].

PI3-Kinase/AKT Pathway

The PI3-kinase (PI3K) pathway is classically recognized as a pro-survival signaling pathway due to its ability to activate PKB/Akt, but can also promote cell proliferation, differentiation, motility, intracellular trafficking, and protein synthesis in different contexts.

PI3-Kinases themselves are divided into three classes based on structure and function. Class I PI3Ks are the most well-studied, and promote the generation of phosphatidylinositol-3-phosphate (PI3P), phosphatidylinositol (3,4)-bisphosphate ($PI(3,4)P_2$), and phosphatidylinositol (3,4,5)-trisphosphate ($PI(3,4,5)P_3$) by phosphorylation of the hydroxyl group at the third position of the inositol ring of phosphatidylinositol lipids [168]. These modified lipids then serve as second messenger molecules triggering the downstream effects of the pathway. This is chiefly mediated through phosphorylation of PDK1 and eventually of Akt, which in turn acts as upstream effector of a host of proteins including mTOR, GSK3β, MDM2, IKKα, and others to regulate diverse biological activities (Fig. 20.6).

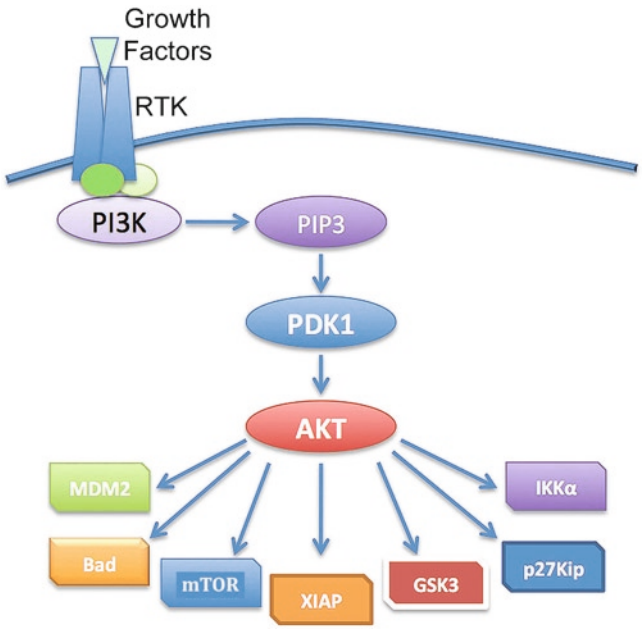

Fig. 20.6 The PI3 kinase pathway is activated upon binding of a growth factor to a receptor tyrosine kinase (RTK), which induces phosphorylation and activation of PI3 kinase, and eventually induces activation of AKT, which can have an effect on a wide variety of downstream molecules to induce biological response in a stage- and tissue-dependent context

Within class I, PI3-kinases are subdivided into Class IA and Class IB based on the proteins that activate them and the adaptor proteins they recruit. Active class IA PI3-kinases function as heterodimers of a p110 subunit with catalytic activity and a p85 subunit with a regulatory domain [168]. Three p110-subunit isoforms exist: p110α, p110β, and p110δ, encoded by *PIK3CA*, *PIK3CB*, and *PIK3CD*, respectively. Three isoforms exist for p85 subunits as well: p85α, p85β, and p55γ encoded by *PIK3R1*, *PIK3R2*, and *PIK3R3*, respectively, of which alternative splicing of *PIK3R1* can generate shorter isoforms p55α and p50α. Activation of Class IA PI3-Kinases is downstream of receptor tyrosine kinase activity.

Class IB PI3-kinases are activated by G protein-coupled receptors (GPCRs) and consist of heterodimers between a p110 γ catalytic subunit and a p101 regulatory subunit, or one of the p101 homologues p84 or p87PIKAP (PI3Kγ adaptor protein of 87 kDa) [169]. The second class of PI3-kinases differs from Class I in many ways. These Class II kinases contain a unique C-terminal C2 domain and include PIK3C2α and PIK3C2β, which are expressed in all tissues, and the PIK3C2γ isoforms expressed exclusively in liver, and are activated by receptor tyrosine kinases, integrins, and cytokine receptors. While the outcomes of their activation is less well understood than that of the Class I kinases [170], it is known that they phosphorylate PtdIns and PtdIns(4)P, localize to clathrin-coated pits and lack adaptor subunits, and it is believed that they may regulate membrane trafficking and/or endocytosis [169].

Finally, class III PI3Ks exist as heterodimers between a 100 kDa Vps34 catalytic subunit and a p150 adaptor subunit, and regulate mTor activity and autophagy, with outcomes ultimately affecting cell growth and survival. This class of PI3Ks phosphorylate phosphatidylinositol only.

PI3 kinases can be activated by a number of kinases, including both receptor tyrosine kinases and non-receptor tyrosine kinases. The RTKs known to phosphorylate PI3 kinases include EGFRs, fibroblast growth factor receptors (FGFR), platelet-derived growth factor receptors (PDGFR), insulin-like growth factor receptor-1 (IGFR-1), IFN receptor, integrin receptor, and VEGFRs. These receptors get activated by growth factors and directly activate Class I PI3K p85 subunits, while the downstream MAP/MEK/ERK pathway protein Ras activates the p110 subunit.

Activation of PI3Ks can also occur via protein kinase C, which is activated by release of intracellular calcium stores, as well as other non-receptor tyrosine kinases such as Src and Shp1, and kinases Rac and Rho involved in cytoskeletal remodeling and regulation of intracellular calcium release. Once active, PI3Ks phosphorylate membrane-associated phospholipids, converting them into second messengers. In the case of Class I PI3Ks, phosphorylation of a hydroxyl group on PI(4,5)2 creates PI(3,4,5)P3, which activates proteins containing pleckstrin homology domains (PH), such as protein kinase B/Akt, guanine nucleotide exchange proteins (GEFs), GTPase-activating proteins (GAPs), Tec family tyrosine kinases, and adenosine diphosphate (ADP)-ribosylating factor 6 (ARF6) as well as proteins containing FYVE, Phox (PX), C1 or C2 domains [168].

The pro-survival activity of the PI3 kinase pathway immediately suggests a possible role in promoting liver regeneration and cancer, and indeed, several studies have investigated PI3K activity in both. In regenerating livers, the PI3K pathway is rapidly activated and inhibits apoptosis [171, 172]. PI3-kinase promotes invasion and metastasis in HCC [173], and Akt is increased in some HCCs and correlates with disease progression and prognosis [174–178]. Interestingly, increased Akt expression is also seen in cholangiocarcinomas, but existing evidence points to a correlation between Akt and positive prognosis in that context [179, 180]. More analysis needs to be done to better understand the meaning of the opposing PI3-kinase/Akt pathway changes in liver cancers of different origins, but it seems clear that this pathway has a meaningful role in regulation of liver cell growth, survival, and migration.

TGFβ Signaling

TGFβ superfamily proteins are growth factors that play roles in growth, differentiation, migration, adhesion, cell death, and homeostasis in multicellular organisms [181] The family includes over 30 members including TGFβ isoforms, growth and differentiation factors (GDFs Nodal and Activin), and BMPs (bone morphogenetic proteins). Beginning with their role in establishment of the first embryonic axes, TGFβ signaling is indispensible throughout the life of both invertebrate and vertebrate organisms [181]. TGFβ receptors exist as heterodimers of type I and type II transmembrane serine/threonine kinases that tetramerize upon ligand binding, allowing the type II receptors to phosphorylate the associated type I receptors. Different combinations of the seven type I receptors and five type II receptors found in mouse and human genomes result in different signaling outputs. While several pathways are activated by TGFβ receptors, the Smad pathway is the best-studied. C-terminal serines of the receptor-regulated Smads 1, 2, 3, 5, and 8 are targeted by TGFβ, allowing them to complex with the co-Smad, Smad4 to form a complex capable of transcriptional activation or repression. Briefly, TGFβ and other ligands such as Activins and Nodal utilize TGFβ receptors type II and type I, inducing their phosphorylation and activation, which in turn induces phosphorylation of receptor-activated Smads (Smad2/3) and their binding to co-smad (Smad4) (Fig. 20.7). This heteromeric complex translocates to the nucleus and interacts with histone

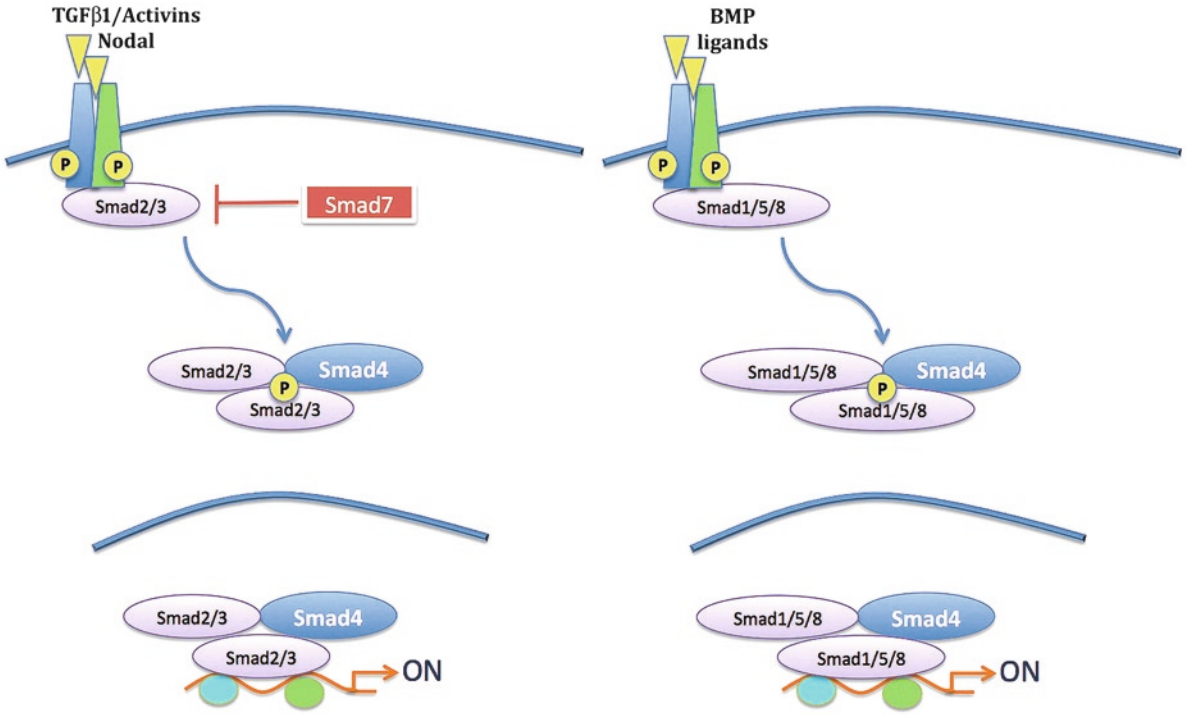

Fig. 20.7 The TGFβ pathway activation (*left*) occurs upon binding of ligands such as TGFβ1, Activins or Nodal to the TGFβ receptor type 2 and sequential activation through phosphorylation of receptor type I, smads 2 and 3 (inhibited by smad7), and smad4, eventually leading to the nuclear translocation of the complex of smads 2/3/4 and induction of target genes. In analogous situations, BMP ligands induce sequential activation of receptor type II, type I, smad1/5/8 and smad4 leading to the nuclear translocation of smads and target gene expression

acetyltransferases and transcriptional components to regulate target gene expression. Similarly, BMP ligands (2, 4, and 7) utilize receptors type II and I in the same way but induce phosphorylation and activation of Smad1/5/8. This also favors complex formation with Smad4 and induces nuclear translocation of the heteromeric complex to induce expression of distinct target genes in cooperation with transcriptional factors and co-factors (Fig. 20.7). Genes targeted by Smad complexes depend on the presence of transcriptional co-factors, which include FoxH1 and Mix family transcription factors [181]. TGFβ signaling can also activate the MAP kinase pathway, or pathways involved in epithelial-to-mesenchymal transition (via PAR6) or cytoskeletal rearrangement (via PAK2).

Links have been identified between loss of TGFβ expression by liver stem cells and development of HCC [182], and aberrant TGFβ activity has also been implicated in liver fibrosis [183].

TNFα/NFκB Signaling

Tumor necrosis factor alpha (TNFα) is a pro-inflammatory cytokine best known for roles in inflammation and apoptosis, but which also plays roles in cell proliferation and differentiation [184]. TNF superfamily receptors are primarily type I transmembrane proteins characterized by extracellular cysteine-rich domains and intracellular regions containing either a death domain or sites for recruitment of TRAF proteins [184]. TNF ligands are type-II transmembrane proteins with an intracellular N-terminus and an extracellular C-terminus that is typically cleaved by a protease to allow differential binding to TNFRs. In total, the TNF superfamily of proteins is comprised of 19 ligands and 29 receptors. The pathway is named for the first-identified member, TNFα, which was so named after it was found to promote necrosis of transplanted tumors in mice [185]. The signaling pathway initiated by TNFα that leads to cell death has since been well-characterized, and related signaling pathways have also been described in increasing number and detail [182]. Binding of TNFα to TNF receptor 1 (TNFR1) triggers the recruitment of TNFR1-associated death domain protein (TRADD), TRAF1 (TNF receptor-associated factor 1), and receptor-interacting protein (RIP). A more detailed account and a diagram depicting the pathway are included in Chap. 24. TRADD binding to TNFR1 can lead to three major outcomes: activation of NF-κB, promoting transcription of pro-survival target genes, initiation of the stress-associated Jun kinase (JNK) signaling pathway, which is generally pro-apoptotic, but can promote proliferation or differentiation, and recruitment of Fas-associated protein

with death domain (FADD), which can recruit caspase 8 in sufficient concentrations to trigger its autoproteolytic activation and subsequent activation of the apoptotic cascade. The overall outcome of TNF signaling in a cell is dependent on various factors such as levels of reactive oxygen species and other pro- or anti-inflammatory cytokines.

Roles are emerging for the TNF pathway in cytoskeletal rearrangement in a wide range of processes such as cell adhesion, cell migration, tissue morphogenesis, membrane blebbing, axonal growth cone collapse, and cell polarity (reviewed in [186]) TNFα may be responsible for the promotion of fatty liver by alcohol consumption [187], and, emerging evidence suggests that certain TNFα alleles may increase predisposition to alcoholic liver disease [188]. Additionally, TNFα plays a key role in driving liver regeneration [189], and in particular, activation of NFκB downstream of TNFα signaling seems to be critical in the regenerative response [190, 191].

The NFκB arm of TNFα signaling possesses additional relevance to liver biology. NFκB (nuclear factor kappa-light-chain-enhancer of activated B cells) is a family of transcription factors that regulate immune response in the context of various types of cell stress that include cytokine signals, UV radiation, oxidative stress, and infection. NFκB proteins are regulated by the constitutive binding of the inhibitory protein IκBα, which can be phosphorylated by IκB kinase (IKK), ubiquitinated, and proteasomally degraded to activate NFκB in response to cell stress. NFκB is then free to translocate into the nucleus and promote expression of target genes involved in stress response, including cytokines, chemokines, p53, pro-survival and pro-apoptosis proteins [192]. The NFκB protein family consists of five members (RelA/p65, RelB, c-Rel, p105/p50 and p100/p52) that contain a Rel homology domain (RHD) involved in dimerization, DNA binding, and nuclear localization [193].

Mice lacking the NFκB family protein, p65, die at embryonic day 16 with massive liver degeneration due to apoptosis, pointing to a key role for the NFκB pathway in late fetal liver development [194]. At this time in development, the liver increases its size threefold owing to a massive rise in hepatocyte proliferation and a high resistance to apoptosis, though it is unclear whether this resistance is mediated by NFκB transcriptional activity [195]. Studies utilizing conditional p65 knockouts report that it is not critical in postnatal development, though it does confer resistance to TNFα induced apoptosis [196].

Given the importance of NFκB proteins in regulating cell survival in the context of inflammation and stress, it is perhaps unsurprising that they can be oncogenic [197]. Inflammation is a significant contributor to the development of HCC [198], and sustained activation of NFκB activity is observed in many human HCC patients. However, interestingly, both overactivity and inhibition of NFκB contribute to HCC in mouse models [199–201].

Conclusion

Underlying every physiological process are signal transduction events that allow cells to respond to changes in their internal or external environment by modifying cell behavior. Such pathways control physiological liver processes, such as specification, growth, differentiation, metabolism, and homeostasis, but also are implicated in disease states such as cancer and fibrosis. This introduction gives a broad overview of some major signal transduction pathways and their relevance to liver biology, to serve as a foundation for the more in depth discussions to follow.

Chapter 21
Hepatocyte Transplantation

Mirela-Patricia Sirbu-Boeti, Kyle Soltys, Alejandro Soto-Gutierrez, and Ira J. Fox

Introduction

The scientific foundation for clinical hepatocyte transplantation was developed over the last 40 years by extensive laboratory work in animals. The first attempts at human hepatocyte transplantation were performed by Mito et al. who used autologous hepatocytes to treat patients with chronic liver disease [1]. Habibullah et al. [2] later transplanted allogeneic fetal hepatocytes to treat patients with fulminant hepatic failure. The first attempted treatment of a metabolic disorder was performed in patients with familial hypercholesterolemia using autologous retrovirus-transduced hepatocytes by Grossman et al. [3]. Several years later, allogenic hepatocytes were used to treat a different metabolic liver disorder with some success in a patient with Crigler-Najjar syndrome type I [4].

While modest success has been documented in treating metabolic disease, data concerning the efficacy of hepatocyte transplantation for hepatic failure in humans have been difficult to interpret. Although clinical experience has failed to show that transplanted cells lead to liver regeneration, as found in animal experiments, hepatocyte transplantation remains partially effective as a treatment to bridge patients to orthotopic liver transplantation, potentially reducing the risk of organ transplantation in patients with clinical complications. Although the numbers of patients treated and the lack of controlled clinical trials are limited, liver cell therapy has been applied in many medical centers around the world [5]. While hepatocyte transplantation has proven beneficial to some degree, development and application in humans is also constrained by the availability of human hepatocytes. Before hepatocyte transplantation can become conventional therapy for liver failure or liver-based metabolic disorders, several additional hurdles must be overcome.

Indications for Human Hepatocyte Transplantation

Hepatocyte transplantation has been used as an alternative therapeutic option for patients with liver-based metabolic diseases. Inborn errors of metabolism are rare disorders with a collective incidence of one in 1,500 persons [6]. Normally, such patients must adhere to very specific and limited diets and may require additional interventions and medications throughout the day to avoid metabolic crises and chronic complications. Medical interventions may also affect the quality of life. The only definitive treatment available at this time is orthotopic liver transplantation, which offers up to 90% long-term survival in children with metabolic diseases [7]. However, orthotopic liver transplantation still has associated risks of morbidity and mortality [5]. Inborn errors of metabolism have been an important target for liver cell therapy due to the less variable clinical condition of the patients and the availability of objective measures to unequivocally determine the efficacy of treatment. Only rarely is the situation immediately life threatening and there are often-acceptable moderating therapies so that transplantation can be performed electively.

Acute or fulminant liver failure is a rapidly progressive condition where the only effective therapy is liver transplantation. Hepatocyte transplantation has been considered as an experimental option for these patients as well. Viral hepatitis, idiosyncratic drug reactions, acetaminophen, and mushroom ingestion are common causes of acute liver failure although on many, if not most, occasions the cause is unknown. Acute liver failure can also be encountered in patients following extensive liver resections where a marginal hepatocellular mass is left to sustain the metabolic needs of the patient [8, 9]. It can occur following a relatively small liver resection, after any procedure in a patient with preexisting liver disease, or it can occur in patients suffering primary allograft nonfunction after liver transplantation (Table 21.1) [10–12]. Delay in availability of a functioning new-liver allograft, rapid deterioration of the patient, and the existence of contraindications for re-transplantation, lead to

Table 21.1 Human liver cell transplantation

Liver disease	No. of patients	Injection of hepatocytes	Type of transplantation	Results	References
Metabolic					
Familial cholesterolemia	5	Intraportal	Autotransplant. Gene therapy (transduction with LDL receptor gene)	Cholesterol decreased in patients, transgenic expression <5% ≥4 months	[3]
α1 AT-deficiency	1	Intraportal	Allotransplant	OLT after 4 days	[10]
Crigler Najjar type I	5	Intraportal/ hepatic artery	Allotransplant	Decrease of serum bilirubin. Patients ultimately required OLT or APOLT	[4, 30, 43, 69, 96]
Urea cycle defect	5 OTC deficiency	Intraportal/ umbilical vein	Allotransplant	Decrease of ammonia levels, improvement of neurological outcome for up to 1 year; most patients underwent OLT or APOLT	[17, 54, 97, 98]
	1 ASA lyase deficiency	Intraportal	Autotransplant	Metabolic control was achieved together with psychomotor catch-up	[99]
Glycogen storage 1a	1	Intraportal	Allotransplant	Satisfactory correction of hypoglycemia, 30–40% decrease of blood triglyceride concentration for more than 9 months	[5, 57, 94]
Factor VII deficiency	3	Intraportal	Allotransplant	Reduced administration of exogenous Factor VII for up to 6 months. Patients ultimately required OLT	[100, 101]
Infantile refsum disease	1	Intraportal	Allotransplant	Total bile acids and abnormal dihydroxy-coprostanoic acid markedly decreased in the patient's serum, pipecholic acid decreased by 40%	[31]
Progressive familial intrahepatic cholestasis	2	Intraportal	Allotransplant	No clear benefit was seen. OLT	[39]
Acute liver failure					
Drug induced	20	Intraportal, intraperitone-alIntrasplenic (splenic artery)	Allotransplant	Ammonia reduction, improvements in encephalopathy. One patient with complete recovery after intraportal cell transplantation alone and two patients with complete recovery after intraperi-toneal transplantation with fetal hepatocytes	[2, 5, 60, 98, 102]
Viral	8	Intraportal, intraperitone-alIntrasplenic (splenic artery)	Allotransplant	One patient completely recovered after cell transplantation alone	[5, 10, 60, 74]
Idiopathic	6	Intraportal, intraperitone-alintrasplenic (splenic artery)	Allotransplant	Significant ammonia reduction, measur-able improvements in encephalopathy. Two patients with complete recovery. One patient died at day 1 posttransplant	[2, 5, 60, 102]
Mushroom Poisoning	1	Intraportal	Allotransplant	Full recovery	[103]
Posthepatectomy	1	Intrasplenic (splenic artery)	Allotransplant	Patient died at day 2 posttransplant	[10]
Acute fatty liver during pregnancy	1	Intraperitoneal	Allotransplant	Complete recovery within 7 days	[104]
Chronic liver failure					
Cryptogenic	1	Intraportal	N/A	Decreased levels of ammonia. OLT at 1 week	[5]
Idiopathic fibrosis	1	Intraportal	N/A	Decreased levels of ammonia and encephalopathy score. OLT at 6 weeks	[5]

(continued)

Table 21.1 (continued)

Liver disease	No. of patients	Injection of hepatocytes	Type of transplantation	Results	References
Total parenteral nutrition and sepsis	1	Intrasplenic (splenic artery)	Allotransplant	Hyperammonemia and encephalopathy improved. The effect was transient	[56]
α1 AT-deficiency	2	Intrasplenic (splenic artery)	Allotransplant	Significant decrease of hyperammonemia. OLT at day 2 and 4	[10, 56]
HCV	1	Intrasplenic (splenic artery)	Allotransplant	Unclear	[60]
Ethanol	5	Intraportal/ intrasplenic (splenic artery)	Allotransplant	Unclear	[10, 60]
Multicausal cirrhosis	10	Intrasplenic (splenic pulp)	Autotransplant	No clear benefit	[1]

OLT orthotopic liver transplantation; *APOLT* auxiliary partial orthotopic liver transplantation; *HCV* hepatitis C virus; *α1 AT-deficiency* alpha-1 antitrypsin deficiency; *OTC* ornithine transcarbamyl; *ASA* argininosuccinate; *ICH* intracranial hypertension

death in these patients [13]. Hepatocyte transplantation may provide rapid support for such failing livers, providing time for either complete recovery, or as a bridge to organ transplantation.

The scenario associated with end-stage chronic liver disease is more problematic. Besides functional hepatocyte abnormalities, the hepatic architecture contributes to the altered liver function. Moreover, intrahepatic portal-to-portal venous shunts may prevent efficient exchange of oxygen and nutrients to hepatocytes. Thus, the benefit of transplanting hepatocytes into the liver without restoring normal liver architecture is questionable.

In general, the potential advantages of hepatocyte transplantation over orthotopic liver transplantation include the following:

- Preservation of the native liver.
- Reversibility of the cellular transplant, should complications of immune suppression occur.
- Lack of interference with subsequent liver transplantation if needed.
- Simplicity of the minimally-invasive procedure and low procedural morbidity and mortality.
- Lower cost.
- Availability of unused cadaveric donor organs or resected hepatic grafts from reduced liver transplants as sources of hepatocyte grafts.
- Possible use of small numbers of hepatocytes from multiple donors for a single recipient.
- Possible use of hepatocytes isolated from a single liver for multiple recipients.
- Potential for hepatocyte banking for later use.
- The possibility of performing repeat hepatocyte transplantation with low morbidity.
- The possibility of ex-vivo modification of hepatocytes with gene-targeted techniques.

Despite the numerous advantages to cell therapy for liver diseases, there are important issues that need to be overcome: the lack of predictability in hepatocyte engraftment, function, and expansion following transplantation and apparent failure of long-term hepatocyte survival after transplantation.

Hepatocyte Preparation: Source, Isolation, and Quality

Cell Sources for Human Hepatocyte Transplantation

One of the major factors limiting the clinical advancement of human hepatocyte transplantation is a shortage of mature, functioning human hepatocytes. This is due to the extensive and growing use of whole livers for transplantation. Currently, donor hepatocytes are primarily obtained from livers rejected for orthotopic liver transplantation. Recent studies have shown that with current hepatocyte isolation protocols, it may be possible to obtain adequate numbers of viable human hepatocytes from many livers not suitable for whole liver transplant [12, 14, 15]. Livers are generally rejected for whole-organ transplantation based on biopsy findings of macrosteatosis, fibrosis, cirrhosis, and extended warm ischemic times [16]. Successful isolation of functioning hepatocytes from steatotic livers has been recently reported [14, 15]. To date, it has not yet been established whether unfractioned hepatocytes isolated from cirrhotic livers can be utilized for

hepatocyte transplantation, and further investigation is needed to determine the engraftment and functional capabilities of cells recovered from cirrhotic livers [5]. Autotransplantation of hepatocytes recovered from resected sections of the liver has been reported in an attempt to treat liver failure from cirrhosis in the past [1].

Unused segments of livers from reduced grafts used in pediatric recipients may provide a useful, untapped source of hepatocytes [17]. An unlikely but possible future source of hepatocytes might also include cells recovered from liver segments resected for nonmalignant disease or for malignancy, if, at some point, complete removal of tumor cells can be accomplished by selection using magnetic beads [18]. More likely, organ perfusion techniques might be able to recover good quality hepatocytes in the near future from livers injured from prolonged warm ischemia [19].

Despite their high capacity to proliferate in vivo, hepatocytes cannot be cultured in vitro for long periods of time. Due to advances in telomere biology and aging research, prolonged hepatocyte cultures have been accomplished using genetically modified, nontumorigenic, immortalized hepatocyte cell lines [20–22]. Reversible immortalization has been accomplished using the Cre-lox recombination and excision system using genes encoding hTERT and the SV40 large T antigen [21, 23]. The disadvantage of these immortalized cells for clinical application is poor differentiated function [24] and high tumorigenic potential [25].

Fetal liver cells have also been proposed as an alternative source of functional hepatocytes for transplantation and it is discussed in greater detail in Chap. 16 [2, 26]. Selection of fetal cells for transplantation has been accomplished in animals by sorting for liver progenitor cells [27]. Fetal liver cells appear to have some advantages for transplantation compared to adult liver cells: high proliferation capacity, potentially diminished immunogenicity, high capacity for integration in the liver, and greater tolerance for cryopreservation [24, 28, 29]. However, their metabolic functions may be less mature when compared to freshly isolated human hepatocytes and they may be more useful for treating specific inborn errors of metabolism [24]. Since fetal hepatocytes for clinical use would have to come from aborted fetuses, which are performed in the vast majority of cases during the first trimester of pregnancy, the engraftment potential and function of early gestational age fetal liver cells will need to be investigated. To this end, a 1-year-old-girl with biliary atresia was recently treated by hepatic progenitor cell infusion through the hepatic artery. Following transplantation, the bilirubin in this child decreased and hepatobiliary scintigraphy showed improved liver cell function [30]. Whether this improvement is related to cell therapy will need to be determined by further prospective controlled studies.

Finally, based on recent scientific advances, autologous cells could become a source of hepatocytes, should hepatocytes become safely generated in vitro from stem cells. Mesenchymal stem cells have shown potential for hepatic differentiation [31] and sustained efforts are now being directed toward establishing improved efficiency in generating induced pluripotent stem cells and differentiation of induced pluripotent cells into hepatocytes [32].

Hepatocyte Isolation and Storage

A standardized protocol of hepatocyte isolation is the mainstay for large-scale clinical application of liver-cell therapy. Since first used in 1969, collagenase perfusion has remained the cornerstone of hepatocyte isolation from whole livers [33, 34]. The traditional two-step collagenase perfusion technique has been further developed aiming to improve hepatocyte viability [12]. Enzymatic digestion of the liver yields a mixture of cells containing approximately 90% hepatocytes and 10% nonparenchymal cells. The cells are then passed through a mesh and centrifuged at low *g*-forces to isolate only the hepatocytes. In contrast to "regular" hepatocytes, which cannot be expanded in primary culture, small hepatocytes have been reported to have a higher potential for proliferation. However, their utility is limited by their small numbers [35].

A three-step perfusion procedure has been reported to yield an average of 2.6×10^6 viable cells per gram of whole liver tissue [12, 36]. Cell yield from infant donor livers has been considerably higher; however, the relationship between donor age and isolation efficiency has not been consistent [37, 38]. While some authors have found no correlation between hepatocyte viability and cold ischemia time, reducing both cold and warm ischemia time before processing has proven to be beneficial by others [37, 39]. Donor variables that can negatively impact hepatocyte viability include use of non-heart-beating donors [39] and severe steatosis [38]. Using current techniques, isolation of hepatocytes from cirrhotic livers is very inefficient [12]. Special, hand-made multiperfusion systems may be required for successful hepatocyte isolation from resected liver segments, which can yield approximately 10^6 human hepatocytes per gram of tissue with viability from 55 to 86% [40].

Like whole-liver transplantation, transplantation of fresh hepatocytes must be done as soon as possible after isolation, since metabolic function and engraftment efficiency deteriorates even at 4°C. Cryopreservation and storage of isolated hepatocytes have been described in the literature [41, 42]; however, viability and engraftment of thawed cells have been inconsistent and less than that of freshly isolated hepatocytes [43–45]. Current research also focuses on augmenting hepatocyte viability after isolation. The isolation procedure exerts significant stress on cells by disrupting cell–cell and

cell–matrix interactions. Use of antiapoptotic molecules and matrices has been investigated with mixed success [46].

Although hepatocyte transplantation has been performed with cell viability as low as 50% [13], it is generally preferred that transplantation be performed only if cell viability is greater than 60% [39]. This level of viability maximizes the functional hepatocyte mass and minimizes portal vein induced pressure changes.

Assessment of Hepatocyte Quality for Transplantation

Isolation, cryopreservation, and storage procedures require conditions of "good manufacturing practice" for clinical application. This requires use of HEPA filters, positive pressure rooms, and aseptic handling of tissues and cells using comprehensive quality control processes. Organ recovery, by definition, is a clean-contaminated procedure that can result in contamination by organisms in the bile and upper digestive tract. In one study, bacterial contamination after organ recovery was detected 37.5% of the time in the preservative solution used to transport donor livers into cell isolation units [47]. After tissue processing, this contamination was reduced to approximately 5% in the final hepatocyte product. The most common organism recovered was coagulase-negative staphylococci, a skin contaminant. Preparations of these hepatocytes were used for cell transplantation with no evidence of sepsis in recipients [47].

Cell viability, attachment efficiency, and metabolic testing have been used as objective criteria for assessment of isolated hepatocyte quality. The viability of hepatocyte suspensions is usually estimated by vital staining with trypan-blue exclusion. Overnight plating efficiency of isolated hepatocytes can also be used as an estimate of viability, and has been associated with engraftment potential [48]. DNA content of plate-attached cells after 50 min roughly quantifies adherence capacity to fibronectin/collagen-coated dishes [49], and metabolic function can be assessed by urea and albumin synthesis, drug-metabolism, MTT assay, and other measures of protein synthesis [48]. Cytochrome P450 activity by isolated hepatocytes can be assessed following a 30-min incubation with a cocktail of selective substrates (CYP1A2, 2A6, 2C9, 2C19, 2D6, 2E1, and 3A4) [49]. However, these tests have not been used reliably to predict the percentage of hepatocytes that engraft [50]. While not used routinely, retrospective assessment of engraftment following transplantation of an aliquot of fresh donor cells is probably the most accurate measure available to assess the quality of the cell preparation. Unfortunately, this information is only available after the decision to transplant cells has already been made.

Enhancement of hepatocyte function can theoretically be accomplished with genetic manipulation of the cells prior to infusion into the recipient. Transplantation of genetically modified autologous hepatocytes was evaluated in a clinical trial of patients with familial hypercholesterolemia. After isolation from the left lateral sector of the patient's own liver, LDL-receptor gene deficient hepatocytes were genetically modified in vitro using a replication-defective recombinant virus that transferred expression of the gene encoding the LDL receptor. The genetically modified hepatocytes were then transplanted back into the patient. Unfortunately, the results of this first human trial of liver-directed gene therapy were limited by low expression of the transferred gene [51].

Hepatocyte Transplantation: Location and Engraftment

It is estimated that the human liver consists of approximately 250×10^9 cells, organized into 10^6 hepatic lobules, each containing approximately 250,000 liver cells. Because 65–70% of these cells are hepatocytes, the estimated total number of hepatocytes in a human liver is thought to be approximately 175×10^9 cells [52]. For a single enzyme deficiency, such as that found in Crigler-Najjar syndrome, a relatively small number of hepatocytes may be needed to improve the bilirubin level. It is believed that the number of transplanted hepatocytes should represent 5–10% of the liver cell mass ($200–400 \times 10^6$ cells/kg, body weight). It is also estimated that 5–20% of the liver mass may be required to support liver failure in adults, or $10–15 \times 10^9$ cells [18]. Unfortunately, the actual hepatocyte volume required to restore enzyme activity or reverse liver failure is largely unknown.

The liver appears to be the most accommodating site for hepatocyte transplantation due to its unique hepatic organization and its mechanism for biliary drainage, access to hepatotrophic factors, and interaction with nonparenchymal liver cells. Injection of hepatocytes directly into the portal vein has been used in patients with a normal hepatic structure, a situation encountered in patients with inborn metabolic liver diseases and those with acute liver failure. There are different methods of accessing the portal circulation: (1) percutaneous transhepatic portal-vein catheterization; (2) transjugular transhepatic portal-vein catheterization; (3) insertion of a catheter through a patient's umbilical vein (Fig. 21.1); and (4) open insertion of a catheter through a branch of the mesenteric vein [53–55]. Investigators have shown that immediately after injection into the portal vein, transplanted hepatocytes are deposited in the portal region and the sinusoidal spaces. However, the capacity of the sinusoidal spaces limits the number of hepatocytes that can be transplanted. Therefore, direct hepatocyte delivery into the portal system

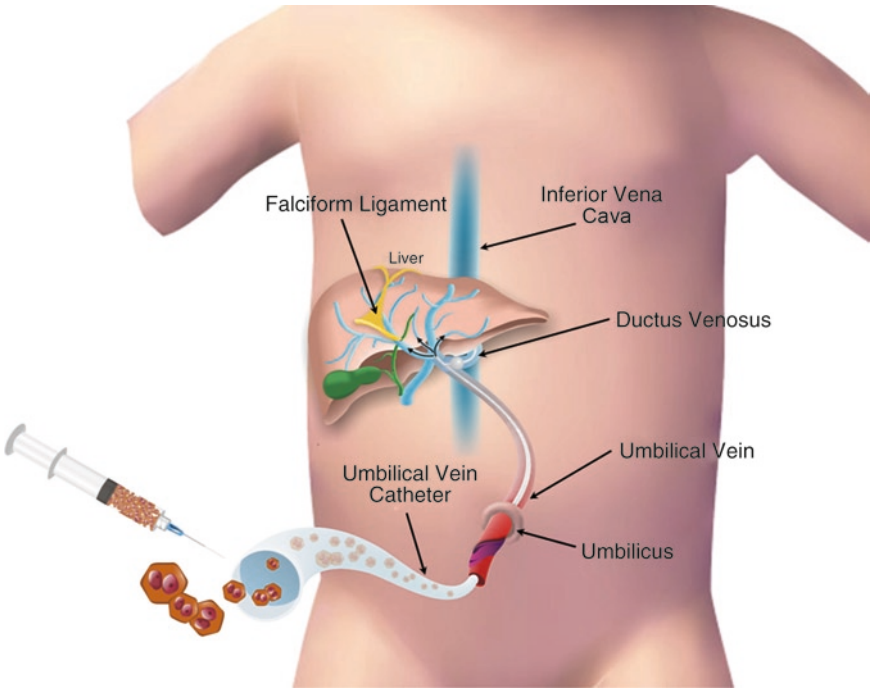

Fig. 21.1 Hepatocyte transplantation through the umbilical vein. In an infant, access to the portal circulation can be obtained through the umbilical vein. The vein extends from the umbilicus to the left portal vein. To transplant hepatocytes, a catheter is placed through the umbilicus and passed into the portal circulation. If patent, the ductus venosus needs to be temporarily occluded during the hepatocyte infusion to avoid translocation of cells through inferior vena cava into the systemic circulation

can induce portal hypertension and portal-vein thrombosis [4, 56–58]. The risk of portal-vein thrombosis after cell infusion is higher in parenchymal liver disease than in metabolic disorders due to the associated inflammation and fibrosis with resultant lower portal blood flows [11].

To minimize the risk of portal hypertension and thrombosis, heparin can be added to the cell suspension and the number of cells should be limited to approximately 100×10^6/kg of body weight [59]. Portal-vein pressure and flow monitoring should be carried out during the infusion with prompt discontinuation of infusions until portal pressures return to near baseline. A moderate increase in pulmonary pressure and transient pulmonary dysfunction with hypoxemia has been reported in one patient who received hepatocytes. This likely represented secondary hepatocyte translocation into the lung parenchyma [11]. Examination of lung tissue in the laboratory has confirmed the presence of hepatocytes in the alveoli and blood vessels following intraportal infusion; however, macroscopic infarction has not been documented [13, 60]. A significant percentage of the liver mass can be infused over a prolonged period of time and several investigators have used multiple hepatocyte infusions to maximize the total number of cells engrafted. Questions about the timing of repeat infusions and the efficacy of infusions over a period of time have yet to be answered.

Following infusion through the portal vein, most hepatocytes undergo blood-flow-mediated translocation to the hepatic sinusoids. Entrapment within periportal sinusoids is mediated by passive sinusoidal occlusion and receptor-mediated interactions between the transplanted hepatocytes, hepatic endothelial cells, and hepatic matrix cell-surface protein interactions with sinusoid matrix ligands [61]. Hepatocytes are very large in comparison to the sinusoid lumen, thus, entrapment of the donor cells in the sinusoids takes place. The hepatocytes then integrate into liver parenchyma by disrupting the sinusoidal endothelium and entering the space of Disse. Translocation of transplanted hepatocytes into liver cords and restoration of the normal sinusoidal barrier requires up to 7 days [62]. It is believed that only a fraction of transplanted cells survive the early posttransplantation period and a maximum of 20–30% of transplanted hepatocytes, under ideal conditions, ultimately engraft into the liver parenchyma [58]. Pharmacologic disruption of endothelial integrity and sinusoidal dilatation has been shown experimentally to improve cell engraftment [63, 64]. Once infused hepatocytes engraft, they must become functional. One study found hepatic function as early as 48–72 h after transplantation, based on significant improvement in aminopyrine and caffeine clearance [13]. While immediate hepatocellular function is not essential after hepatocyte transplantation in

patients with liver-based metabolic disease, lack of immediate function could be problematic in patients with acute liver failure.

Cirrhosis limits hepatocyte engraftment because of its abnormal circulation to regenerative nodules, sinusoidal endothelial changes that result in an increased endothelial barrier for donor hepatocyte engraftment, intra- and extrahepatic portosystemic shunts that permit translocation of hepatocytes into the pulmonary circulation, and portal hypertension that increases the risk of portal thrombosis [28]. Investigators have injected hepatocytes into the splenic artery via a transfemoral hepatic artery catheterization in the face of cirrhosis with limited success [5, 13].

In most human studies of hepatocyte transplantation, donor cell engraftment appears to approach only 1% of the liver mass. However, in animal models, replacement of >90% of host hepatocytes can be accomplished by using a relatively small number of transplanted cells in a process referred to as "liver repopulation" [65]. In this setting, the transplanted cells have a growth advantage over endogenous hepatocytes. Several laboratories have developed strategies to induce preferential proliferation of engrafted hepatocytes in settings where this may not occur naturally [66]. An approach that might be developed for clinical application, consists of preparative hepatic irradiation, which reduces mitotic capacity of the host hepatocytes [67, 68] and treatment with factors that promote hepatocyte expansion. Inhibition of hepatocyte cell cycle with hepatic irradiation appears to increase liver repopulation by transplanted hepatocytes without affecting native hepatocellular function.

Injection of hepatocytes into the peritoneal cavity is simple and has been considered an option in patients where transplantation into the liver is not feasible or might be dangerous. This is because the peritoneal cavity is easily accessible, can accommodate a large number of cells, and there is no risk of embolism of hepatocytes to the lungs [2, 13, 56, 69]. Habibullah treated a number of patients with acute liver failure by intraperitoneal transplantation with some success [2]. Unfortunately, hepatocytes engraft poorly unless they are encapsulated or microencapsulated in semipermeable membranes [70–72]. Whether this approach will be utilized with success using techniques allowing hepatocyte attachment to the peritoneum remains unanswered at this time.

Posttransplantation Hepatocyte Engraftment and Immune Response

When hepatocytes are transplanted into ectopic locations, such as the spleen, definitive histologic evidence of transplanted hepatocytes can be obtained and nuclear scanning can help confirm the presence of engrafted hepatocytes. Engraftment in the liver cannot be easily assessed histologically or by nuclear studies at this time. Hepatocytes isolated from male donors and transplanted into female patients may be detected on liver biopsy by fluorescent in situ hybridization (FISH) [13]. Real time PCR analysis of the Y chromosome is also useful and permits detection as low as 0.25% engraftment [73]. DNA extraction from liver biopsies and assessment of donor and host cells can be accomplished by similar nucleic acid determination [74]. For liver-based metabolic disease, measurement of enzyme activity on liver biopsies can be definitive for documenting hepatocyte engraftment.

Similar to vascularized allografts, allogenic hepatocytes are subject to both antibody and cell mediated rejection. Gene products of the major histocompatibility complex are the primary targets involved in the host immune response. Presentation of these alloantigens on the surface of antigen presenting cells is an early event in the recognition and proliferation of alloantigen-specific lymphocytes and production of antibodies [75, 76]. Unstimulated hepatocytes do not express class II major histocompatability complex antigens, but hepatocyte preparations may occasionally be contaminated by immunogenic antigen presenting cells or Kupffer cells [77]. In cases of viral hepatitis, hepatocytes can express aberrant major histocompatability complex class II antigens and can function as antigen presenting cells [78].

Transplantation of hepatocytes from animals that differ genetically at the major histocompatability complex results in sensitization and rapid disappearance of allografts in 4–7 days [79]. Hepatocytes are rejected by $CD4^+$ and $CD8^+$ mediated immune responses and also destroyed by the innate immune system [80]. Granulocytes and Kupffer cells destroy even syngeneic hepatocytes early after transplantation [81] and granulocytes have been documented as surrounding transplanted cells 24 h after their infusion [82]. Portal microvascular occlusion by cell emboli also induces ischemic injury, oxidative stress, and impaired cell viability, which cause both a local inflammatory response and subsequent stimulation of Kupffer and stellate cells, resulting in further cell loss. Survival of transplanted hepatocytes has been augmented with granulocyte-depletion and pretreatment with gadolinium chloride, which significantly impairs Kupffer-cell function [83].

Although infusion of allogenic or xenogeneic cells through the portal circulation has been shown to induce donor-specific tolerance in rodents and pigs [84, 85], this tolerance has not been readily duplicated following infusions containing hepatocytes. This may be due to the fact that hepatocyte preparations do not contain significant numbers of antigen presenting cells [86]. Whether cotransplantation with donor bone marrow cells and transient immunosuppression, which induces tolerance in some studies, will allow intraportally transplanted hepatocytes to induce tolerance is not known. The immune response to cellular grafts has also

been altered by gene transfer using recombinant adenoviruses containing the genes encoding immunosuppressive cytokines. Transduction of donor cells with a number of genes has effectively blocked allograft and xenograft rejection [87]. Adenovirus mediated expression of CTLA4Ig, a fusion protein of the extracellular domain of CTL4A and the Fc portion of the IgG2a molecule, downregulates the immune response to cellular grafts by costimulatory blockade [88, 89]. Unfortunately, there is little understanding of the mechanisms responsbile for rejection of transplanted allogenic hepatocytes in humans, making optimization of immunosuppressive regimens difficult.

The most common immunosuppressive medications used for solid organ transplantation consist of calcineurin inhibitors (CNI), such as tacrolimus or cyclosporine, and steroids. Conventional immunosuppression with cyclosporine, azathioprine, tacrolimus and antilymphocyte serum can prolong donor hepatocyte survival in laboratory animals [90]. Induction therapy using IL-2 receptor antibodies (e.g., basiliximab, daclizumab) [91] or antithymocyte globulins (e.g., ATG Fresenius or Thymoglobulin) may also be considered. Depending on the patient's underlying disease and existing comorbidities, minimal immunosuppressive regimens are favored. In addition, reduction or replacement of CNIs may be possible using agents such as mycophenolate mofetil (MMF) or sirolimus [92]. As there are limited data regarding the immunosuppression required for hepatocyte transplantation, it is not known whether requirements after hepatocyte transplantation may be different than those required after solid organ transplantation.

Finally, unlike whole organ transplantation, transplantation of hepatocytes does not easily allow real-time modulation of immunosuppression because there are no current techniques available to document rejection of hepatocytes. The utility of liver biopsy in hepatocyte transplantation is limited by the consequences of sampling errors. In addition, documentation of donor-hepatocyte loss leaves few therapeutic options available for reversal of the rejection process. Cessation of immunosuppression may be indicated in patients who received hepatocyte transplantation and completely recovered from acute liver failure. For these patients, withdrawal of immune suppression will depend on liver histology that indicates recovery of host hepatocellular mass [74].

Overview of Current Clinical Experience

Promising results with hepatocyte transplantation in preclinical animal models of human disease have led investigators to attempt to reproduce these results in humans. In clinical trials, hepatocyte transplantation has offered some measurable clinical benefit in a variety of settings [93].

Studies in patients with acute liver failure and chronic liver disease have been difficult to interpret. Some studies have demonstrated modest improvement in neurologic and biochemical parameters, but there has been limited evidence of altered survival (Table 21.1). In addition, if hepatocyte transplantation proves to be effective in improving the physiologic abnormalities associated with chronic liver disease, portal hypertension will need to be controlled by surgery or TIPS, and surveillance for the development of hepatocellular carcinoma will need to be augmented.

Due to the high variabililty in the natural history of acute liver failure, evaluation of the success of potential therapies in this population is difficult. Prognosis can be affected by the multiple etiologies, confounding standard support treatments, and spontaneous recovery rates approach 40% [94]. Although there is some suggestion that the transplanted hepatocytes provided a benefit to some patients, convincing evidence for engraftment and function of transplanted cells has not been obtained. Part of the problem could be that relatively small numbers of liver cells were transplanted in many of the patients.

Treatment of liver-based metabolic disease with hepatocyte transplantation has met with more success (Table 21.1). Immediate correction of metabolic activity as a result of transplantation in these patients has been documented in a variety of diseases. After 4–8 weeks, metabolic and clinical effects have been reported and have been observed for up to 2 years after cell transplantation [5]. However, for long-term engraftment and function, transplanted hepatocytes may require a selective survival advantage over the recipient's cells. In many metabolic diseases, the liver-based deficiency does not influence the survival of host hepatocytes and transplanted hepatocytes cannot be expected to survive better than host cells. For other metabolic liver diseases, such as Wilson's disease, where there is a defect in the copper transporting ATPase ATP7B protein that causes copper to accumulate and leads to deterioration of hepatocytes [95], transplanted wild-type cells would have a selection advantage over the recipient's hepatocytes. In most settings, donor cells will not have a survival advantage over host hepatocytes, and strategies, such as preparative hepatic irradiation, may be required to improve outcome [68].

Conclusions

Laboratory studies and clinical trials spanning several decades have demonstrated that hepatocyte transplantation has great potential for the correction of a variety of liver disorders. An improved understanding of normal hepatocyte turnover, normal hepatic regeneration after injury, techniques to improve hepatocyte isolation, cell delivery, and hepatocyte engraftment will help to improve clinical translation.

Additional cell sources continue to be sought. Controlled clinical trials in patients with liver failure must contain standardized regimens for assessment of donor hepatocyte quality, delivery techniques, and immune-suppression regimens. Recipient characteristics need to be documented in detail as does the post transplant course. Documentation of engraftment in the liver must be recorded. For treatment of liver-based metabolic disorders, similar attention to standard approaches will be required, and for the most part, are in place. Additional efforts will be needed to understand impediments to long-term donor hepatocyte engraftment and function. This will need to be the major focus of future efforts. Coordinated effort of multiple investigators will be required to overcome the remaining hurdles before the enormous potential of this therapeutic strategy can be fully realized.

Chapter 22
Hepatic Tissue Engineering

Jing Shan, Kelly R. Stevens, Kartik Trehan, Gregory H. Underhill, Alice A. Chen, and Sangeeta N. Bhatia

Introduction

Liver tissue engineering aims to provide novel therapies for liver diseases and create effective tools for understanding fundamental aspects of liver biology and pathologic processes. Approaches range from bio-mimetic in vitro model systems of the liver to three-dimensional implantable constructs. Collectively, these cell-based approaches endeavor to replace or enhance organ transplantation, which is the current standard treatment for liver diseases in most clinical settings. However, the complexity of liver structure and function as well as the limited supply of human hepatocytes pose unique challenges for the field. This chapter reviews advances in the field of liver tissue engineering within the context of current therapies for liver diseases, and clinical alternatives such as cell transplantation strategies and extracorporeal bioartificial liver devices.

Current Treatments for Liver Failure

Liver failure, representing the cause of death for over 40,000 individuals in the United States annually [1], can result from acute or chronic end-stage liver diseases. Current treatments for liver failure include administration of fluids and serum proteins, but these continue to be largely palliative. Liver transplantation is the only therapy proven to directly alter mortality, and therefore, remains the standard of care for liver disease patients. In order to maximize the therapeutic benefits of the limited supply of transplantable livers, a number of surgical techniques have been investigated, including the use of non-heart-beating donors or split liver transplants from cadaveric or living donors [2]. Partial liver transplants take advantage of the body's ability to regulate liver mass and the innate capability of mammalian livers to undergo significant regeneration [3]. However, although partial liver transplants have demonstrated some effectiveness, liver regeneration is difficult to regulate in clinical settings, and biliary and vascular complications are major concerns in these procedures [2]. Despite these surgical advances in expanding single donor livers into multiple grafts, the ballooning discrepancy between the number of livers available and the number of patients requiring liver transplants [4] indicates that organ transplantation alone is unlikely to fulfill the increasing demand for transplant-grade organs. Furthermore, patients who do receive transplants are subject to the costs and complications associated with major surgery as well as a lifetime of immunosuppressive regimens. Consequently, alternative approaches are actively being pursued. These include non-biological extracorporeal systems, such as hemoperfusion, hemodialysis, plasma exchange, and plasmapheresis over charcoal or resins [5–7]. They have shown only limited success, presumably due to the narrow range of functions supported by these acellular devices. Recapitulation of a more substantial number of the liver's purported 500+ functions will likely be needed to offer effective liver support.

Cell-Based Therapies

To provide the large array of known and currently unidentified liver functions, cell-based therapies have been proposed as an alternative to both liver transplantation and strictly non-biological systems [8]. These cell-based therapies range from approaches that provide temporary support, such as bioartificial liver (BAL) devices, to more permanent interventions, such as cell transplantation and implantable tissue engineered liver constructs (Fig. 22.1).

Extracorporeal devices primarily aim to offer transient support during liver regeneration or to serve as a bridge to transplantation. These devices process the blood of patients in a manner analogous to kidney dialysis systems. Substantial efforts have been invested in developing extracorporeal BAL devices containing hepatic cells to supply the multitude of

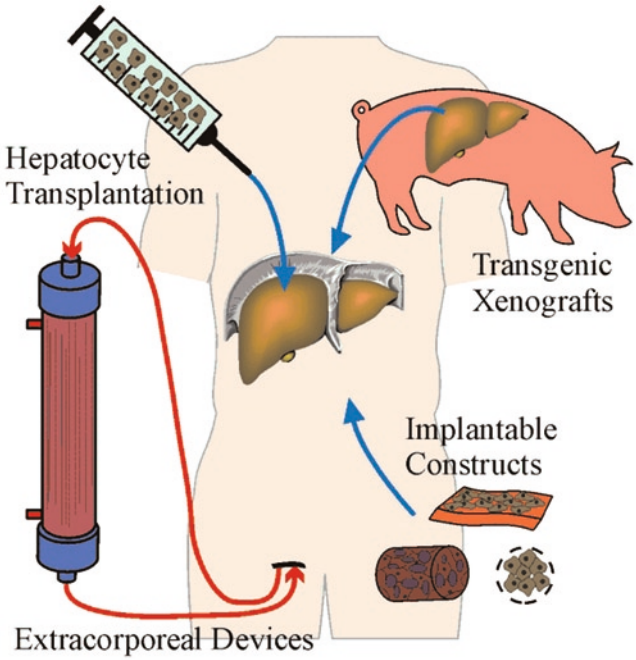

Fig. 22.1 Cell-based therapies for liver disease and failure. Extracorporeal bal devices provide temporary support by processing patient blood and plasma. more permanent interventions include tranplantation of isolated mature hepatocytes and hepatocellular constructs. Transgenic animal tissue have also been pursued. Reproduced from Allen et al., [5] used with permission

essential liver functions. There are four main categories of BAL devices [9, 10]: (1) hollow-fiber devices, (2) flat plate and monolayer systems, (3) perfusion bed or porous matrix devices, and (4) suspension reactors; each of these general designs exhibit innate advantages and disadvantages. Overall, a clinically useful BAL device must be scalable to therapeutic levels and exhibit key properties such as efficient bidirectional mass transfer and maintenance of cell viability and liver functions. Several BAL devices have been tested in clinical settings and researchers continue to improve device and trial designs. Ultimately, even if current BAL systems do not represent effective therapeutic options, information gained from these studies, along with advancements in cell sourcing and functional maintenance of hepatocytes *ex vivo*, promises to empower the next generation of devices.

In addition to temporary support, more permanent cell-based therapies are being actively developed to replace damaged or diseased liver tissue. One such approach is the transplantation of isolated hepatocytes, which has been demonstrated to be safe, and in some cases, effective, in both animal models and human trials [11–13]. A more comprehensive account of cell transplantation is provided in Chap. 21. Hepatocyte transplantation therapy is less invasive than organ transplantation [14] and could circumvent immunosuppressive regimens through the use of autologous cells. In rodent models, transplanted hepatocytes were further demonstrated to exhibit substantial proliferative capacity [12, 15–17]. This in vivo proliferation of transplanted cells is highly dependent on the presence of a "regenerative" environment, which can be provided by transgenic injury, partial hepatectomy (PHx), or the introduction of hepatotoxic agents prior to cell transplantation. The feasibility of hepatocyte transplantation is limited by the availability of appropriate cell populations, as only mature hepatocytes have been repeatedly and consistently shown to provide sufficient rescue of liver functions [18], and only organs deemed inappropriate for transplantation can be perfused to yield scarce supplies of these cells. This constraint of limited availability of highly functional hepatocytes is unfortunately universal to all cell-based approaches for liver disease treatment.

Another emerging therapeutic approach for liver failure is based on the development of implantable tissue engineered hepatocellular constructs. Similar to cell transplantation, this strategy relies on transplanted hepatocytes to perform liver functions. Tissue-engineering approaches further consider that hepatocytes are known to be anchorage-dependent; thus to maximize cell viability and functionality, hepatocytes are cultured *ex vivo* to form "organoids," immobilized on scaffolds, or encapsulated in aggregates prior to surgical implantation in a number of anatomical sites, including the spleen, liver, pancreas, peritoneal cavity and mesentery, and subcutaneous tissues [19, 20]. Proposed constructs have utilized scaffolds of various composition and architecture, both of which clearly influence hepatocyte survival and function. Despite advances in key aspects of hepatocyte maintenance in vitro, implantable systems remain largely experimental due to a number of obstacles that must be overcome before qualifying as a viable clinical modality. Specifically, hepatic tissue engineering shares many of the limitations of BAL devices and cell transplantation, but additionally faces challenges in establishing transplant vasculature and promoting transplant integration and remodeling. Details of these features will be discussed in later sections.

Cell Sourcing

Studies into cell-based therapies suggest great promise, but progress has been hindered by the propensity of hepatocytes to lose both phenotypic functions and the ability to proliferate in vitro [21, 22]. Thus, the continued elucidation of molecular mediators that regulate hepatocyte function and proliferation will be critical for the advancement of cell-based therapies and their routine use in clinics to treat compromised liver functions. In addition, the potential of alternative cell-sourcing approaches, based on stem cell differentiation and reprogramming, are active areas of investigation.

Mature Hepatocytes

Primary human hepatocytes are functionally the most robust cell type for cell-based therapies of liver diseases [8, 23]. Within their native microenvironments in vivo, human hepatocytes have phenomenal proliferative capability. Following resection of two-thirds of the liver through a surgical procedure known as PHx, the residual mature cell populations, comprised mainly of hepatocytes, are able to proliferate and restore lost liver mass [24]. Chap. 18 covers this topic in more detail. This full regenerative response can be seen after each of at least 12 sequential PHxs [25]. To demonstrate the clonogenic potential of the hepatocyte itself, mouse models were generated, in which livers were rendered incapable of supporting animal life through experimentally induced defects. Healthy hepatocytes injected into these compromised livers can proliferate, generate nodules of normal hepatocytes, and rescue the animals [26]. As low as 1,000 normal hepatocytes were found to be sufficiently therapeutic. Furthermore, cells from newly formed nodules of normal hepatocytes can be isolated and serially transplanted, through as many as four generations, to rescue other animals. Mathematical calculations based on this model predict that a single hepatocyte can undergo at least 34 cell divisions to give rise to 1.7×10^{10} cells, suggesting that a single rat hepatocyte can generate 50 rat livers of 300 million hepatocytes each [27].

Various attempts have been made in the last several decades to harness ex vivo this tremendous replication potential of mature human hepatocytes (Fig. 22.2). It is recognized that proliferating hepatocytes in vivo are presented a complex and dynamic mixture of soluble factors via the blood while maintained within an interactive support system of extracellular matrix (ECM) and non-parenchymal cells. Thus, early studies focused on providing select key components to in vitro culture systems, including humoral and nutritional supplements as well as ECM and supportive cell types [28]. To specifically promote hepatocyte expansion in vitro, primary cultures have been treated with serum and cytosol collected from livers that underwent PHx [29], and with more defined soluble factors including various growth factors [30, 31], sugars [30], amino acids [30], hormones [31, 32], vitamins [30, 33], serum proteins [30, 34], and trace metals [30, 34]. The effect of any individual supplement on hepatocyte proliferation can be difficult to determine directly, as the effect depends on the state of the hepatocyte, which is synergistically determined by the combination of all culture components [28]. Nevertheless, investigations have yielded a multi-factor media formulation, which can be used for moderate expansion of rat hepatocytes through a dedifferentiated bi-potential intermediate [30]. Non-soluble culture components such as different ECM [30, 35] and supportive cell types [35–38] have also been examined for mitogenic effects on hepatocytes. These include physiologic liver ECM proteins, and non-physiologic tumor-secreted protein mixtures in different configurations, in addition to co-cultures of hepatocytes with various intrahepatic and extrahepatic cell types, both live and dead. Many different combinations of culture components have been shown to support moderate expansion of rat hepatocytes although translation of these findings to human cultures has not been reported.

Human cells are critical for cell-based therapies due to substantial species-specific differences between animal and human hepatocellular functions including apolipoprotein expression, metabolic regulation of cholesterol, and phase I detoxification enzymes [39–41]. To overcome the growth limitations of primary human cells, investigations are underway to develop highly functional human-hepatocyte cell lines. A common approach is to introduce oncogenes through retroviral transduction. The Simian virus 40 tumor antigen gene (SV40 Tag) is a common immortalization agent, whose product binds to cell cycle regulator proteins Rb and p53 [42, 43]. Cell lines have also resulted from spontaneous immortalization of

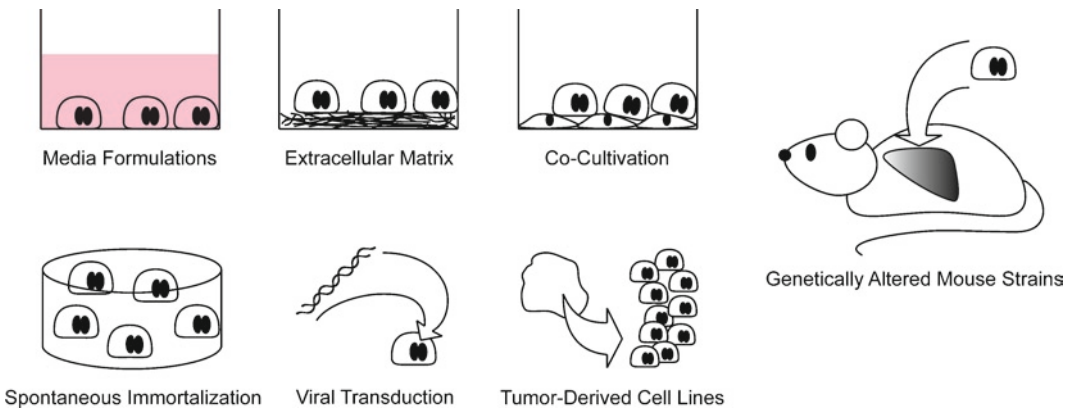

Fig. 22.2 Ex vivo expansion of mature human hepatocytes. Approaches have focused on providing essential culture components, generating hepatocyte cell lines, and leveraging in vivo regenerative environments

hepatocytes in co-cultures or collagen gel sandwich cultures [44], and additionally can be derived from liver tumors, as in the case of the HepG2 hepatoma cell line [45]. Although these cell lines are growth-competent, they introduce new safety concerns and typically underperform primary cells in terms of liver functions [46, 47].The principal safety concern is the transmission of oncogenic agents to the host, especially in the case of implanted cells. To address this, researchers have developed mechanisms to inactivate transduced oncogenes through temperature-sensitive SV40 Tag [48], Cre–*loxP*-mediated oncogene excision [49], and suicide genes such as herpes simplex virus thymidine kinase (HSV-tk) [50].

Another intriguing approach for human hepatocyte expansion, particularly as a model system, is the transplantation of human hepatocytes into genetically-altered mouse strains [17, 51–53]. This strategy takes advantage of the in vivo mitogenic environment, known to orchestrate many rounds of hepatocyte replication and can be generated through experimentally induced defects to host livers. Such defects can be produced by large amounts of urokinase, which can be abnormally over-expressed under the influence of the albumin promoter in hepatocytes [3, 12, 51, 54]. While effective as a hepatic xeno-repopulation system, these mice are fragile and present only a limited time window for transplantation. Alternatively, Grompe and colleagues have produced regeneration-inducing liver defects through an experimentally introduced deficiency in the catabolic enzyme fumarylacetoacetate hydrolase (Fah). After pretreatment with a urokinase-expressing adenovirus, Fah-deficient mice can be very receptive hosts to human hepatocytes [17]. Findings from these animal studies suggest that human hepatocytes do retain their considerable proliferation potential upon isolation and can expand given the appropriate stimuli. However, similar to the use of hepatocyte cell lines, the therapeutic utility of hepatocytes expanded in animal models is limited by safety concerns such as the transmission of pathogenic agents and the incorporation followed by expression of animal glycoproteins on human hepatocyte cell surfaces.

Ultimately, sustainable proliferation of highly functional human hepatocytes could generate patient-specific cell populations. These cells can be used to provide sufficient autologous materials for cell-based treatments, thus circumventing post-surgical immunosuppressive regimens. In vitro, the ability to expand human hepatocytes can enable drug therapies to be selected according to the characteristics of individual patients, thus minimizing adverse drug reactions.

Stem Cells and Progenitor Populations

Due to limitations in mature hepatocyte expansion in vitro, alternative cell sources are being pursued. These include various stem cell populations, which can self-renew in vitro and exhibit pluripotency or multipotency and thereby serve as a possible source of hepatocytes, as well as other non-parenchymal liver cells.

Studies have shown that embryonic stem cells can be induced to differentiate down the hepatic lineage in culture through the carefully orchestrated addition of various growth factors, and when supported by the appropriate ECM [55–57]. More recently, studies are also exploring in more scope and detail, the functional capacity of these differentiated populations, both in vitro and in vivo [58–60]. Such endeavors are being guided by improved insight into how different cell types are specified in embryonic development. This insight is typically gained through observations of cellular responses to individual inductive signals. Zaret and colleagues have further investigated how different inductive signals interrelate and have reported complex, dynamic signaling networks that could help explain incomplete cell programming in stem cell differentiation protocols [61].

In addition to embryonic stem cells, a wide range of fetal and adult progenitor cell types have been explored. Continuing investigations are focused on determining the differentiation potential and lineage relationships of these populations. Fetal hepatoblasts are liver precursor cells present during development that exhibit a bipotential differentiation capacity, defined by the capability to generate both hepatocytes and bile duct epithelial cells [62]. Furthermore, within the adult liver, a rare percentage of resident cells have been demonstrated to exhibit properties consistent with their designation as adult hepatic stem cells [63, 64]. It has been suggested that these cells represent precursors to adult progenitor cells, termed oval cells, which share phenotypic markers and functional properties with fetal hepatoblasts. In adult livers suffering certain types of severe and chronic injury, oval cells can mediate liver repair through a program similar to hepatic development [65, 66]. Various cell lines exhibiting characteristics comparable to fetal hepatoblasts and oval cells have been developed, e.g. lines derived from mouse E14 embryos by Weiss and colleagues. These bipotential mouse embryonic liver (BMEL) cells are proliferative, can be induced to be hepatocyte-like or bile duct epithelial-like in vitro [67], and can home to the liver to undergo bipotential differentiation in vivo within a regenerative environment [68].

Outside the liver, there may also exist multipotent stem/progenitor-like cells that are of therapeutic and biomedical interest [69]. For example, multipotent adult progenitor cells (MAPCs) derived from the bone marrow have been shown to generate hepatocyte-like cells in vitro [70]. Similarly, various mesenchymal stem cell preparations have been reported to give rise to cells exhibiting many characteristics of mature liver cells [71–74], including the ability to engraft in vivo; however, the extent of functional liver repopulation has been modest [69]. Other sources of extrahepatic liver cell progenitors include human amniotic fluid and membranes, which may contain cells capable of hepatic differentiation [75–79].

Reprogrammed Adult Cells

Fully differentiated adult cells, such as skin cells, were recently demonstrated to be reprogrammable to an undifferentiated, pluripotent state through forced expression of reprogramming factors Oct3/4 and Sox2, along with either Klf4 [80–83] or Nanog, and Lin28 [84]. These reprogrammed cells are termed induced pluripotent stem (iPS) cells and highly resemble embryonic stem (ES) cells, sharing many characteristics such as significant self-renewal capabilities in vitro and pluripotent differentiation potential. However, iPS cells offer an additional advantage of sourcing from adult somatic cells for the generation of patient-specific cell populations, potentially enabling therapies to be developed according to the characteristics of an individual patient. Work done by Duncan and colleagues, as well as other researchers, demonstrated that through iPS reprogramming and a subsequent multistep differentiation protocol, skin cells can give rise to hepatocyte-like cells, which not only exhibit a variety of hepatocyte-specific functions in vitro, but can also be induced to generate intact fetal livers in mice in vivo [85–87].

As a parallel strategy, work done by Melton and colleagues has demonstrated that it is also possible to directly reprogram one adult cell type into another, without an undifferentiated pluripotent intermediate. Similar to the use of master transcriptional regulators in the reprogramming to iPS cells, the expression of a key set of transcription factors in pancreatic exocrine cells in vivo induced conversion into cells that highly resemble β(beta)-cells [88]. These findings raise future possibilities for deriving hepatocytes directly from another adult cell type.

Ultimately, understanding the mechanisms governing the fates of stem and progenitor cell populations can empower the development of cell-based therapies. However, many challenges remain, including the ability to program differentiation completely. Furthermore, regardless of the cell source, phenotypic stabilization of hepatocytes ex vivo remains a primary issue. Accordingly, the development of robust in vitro liver models is an essential stepping-stone towards a thorough understanding of hepatocyte biology and improved effectiveness of cell-based therapies for liver disease and failure.

In Vitro Platforms and Applications

An important component of liver tissue engineering is the development of in vitro hepatocyte culture platforms. Such cultures can be used for applications aimed at studying fundamental hepatocyte biology, understanding and developing remedies for liver pathophysiology, and evaluating the liver metabolism and toxicity of pharmaceutical drug candidates. A summary of previously developed liver platforms is provided in Table 22.1. [89–104] When selecting a platform for a particular application, it is crucial to consider the necessary model criteria given the specific strengths and weaknesses of each approach.

Within these model systems, isolated primary hepatocytes are generally considered the most appropriate cell source; however, primary hepatocytes are notoriously difficult to maintain in culture due to a rapid decline in viability and liver-specific functions post-isolation [89–91]. Research has thus focused on providing the stimuli necessary to maintain the hepatocyte phenotype, and this research is gradually giving way to a systems-level picture of the molecular signals that furnish phenotypic stability of hepatocytes. In this section, we focus on methods that have been developed to stabilize

Table 22.1 Summary of liver platforms

Platform	Pros	Cons
Perfused whole organs, wedge biopsies, and precision-cut liver slices	More normal in vivo microenvironment and architecture Can use human liver samples [89, 95, 96]	Short-term viability (<24 h), limited nutrient/oxygen diffusion to inner cell layers, low availability, inter-donor variability [90]
Purified liver fractions (organelles, membranes) and single enzyme systems	Used in high-throughput systems to identify enzymes involved in the metabolism of new pharmaceutical compounds [97, 98]	Lack gene expression and full cellular machinery to execute liver functions
Cell lines from hepatoblastomas or immortalization of primary hepatocytes	Reproducible, inexpensive models of hepatic tissue [99–103]	Abnormal levels and repertoire of hepatic functions [91]
Isolated primary hepatocytes in suspension or cultured upon extracellular matrix	Functionally more representative of normal liver than cell lines. Can cryopreserve to overcome inter-donor variability	Difficult to maintain in culture due to dedifferentiation, low availability [89–91]
Engineered tissue models	Improved stabilization of primary hepatocytes and better reproduction of normal tissue architecture [92, 94, 104]. Can be translated to in vivo through implantation [93]	Models can be challenging and expensive to fabricate

the hepatocyte phenotype. We discuss in parallel how such models have been used in tissue engineering applications including drug development and disease modeling.

2-D Culture Platforms

Several parameters of two-dimensional culture can be modulated to enhance primary hepatocyte morphology, survival, and liver-specific functions. Three such parameters are culture medium, extracellular matrix, and heterotypic interactions with non-parenchymal cells.

Culture media supplemented with serum and physiological factors such as hormones, corticosteroids, growth factors, vitamins, amino acids, or trace elements [90, 105], as well as non-physiological factors such as phenobarbital and dimethylsulfoxide [106, 107], have been shown to modulate the hepatocyte phenotype. Hepatocytes have also been maintained in media without serum [108]. Investigators utilizing a co-culture system (co-culture configurations discussed in detail below), with endothelial cells in serum-free medium under high (95%) oxygen, recently demonstrated support of hepatocyte-gene expression and drug metabolism functions better than co-culture in serum medium at 21% oxygen [109]; furthermore, the oxygenated model s stabilized more quickly. Jindal et al., have additionally identified the amino acid proline as the key factor secreted by endothelial cells in co-culture responsible for mediating the acceleration of hepatocyte recovery [110].

ECM plays an important role in hepatocyte culture; ECM preparations of different composition and topology have different effects on hepatocyte morphology and function. For instance, the presence of collagen I on a substrate enhances hepatocyte attachment, although hepatocyte spreading on adhesive substrates is often associated with loss of liver-specific functions [111]. Culture of hepatocytes on a monolayer of "biomatrix," a complex ECM mixture extracted from the liver, has been shown to improve hepatocyte function over culture on a monolayer of pure collagen [111, 112]. To screen in greater throughput the effects of various ECM proteins on hepatocyte physiology, a microarray platform was developed by Flaim et al., [113]. This system enabled investigation of the synergistic impact of ECM combinations on hepatocyte function with potential implications for the cross-talk between integrin-signaling pathways initiated by various ECM molecules. However, monolayers of ECM are not the only means of presenting ECM molecules to hepatocytes. In the standard "double gel" configuration, hepatocytes are sandwiched between two layers of collagen gel. In this format, hepatocytes demonstrate desirable morphology and liver functions for approximately 1 week [90]; rat hepatocytes in particular show P450 induction and a contiguous, anastomosing network of bile canaliculi, indicative of polarized structures [22, 114]. Limitations of this format include the fact that phase I/II detoxification processes typically become imbalanced over time [115], and that an ECM gel above the hepatocytes may inhibit the diffusion of paracrine signals or other molecular stimuli in the culture medium. Additionally, surface modifications such as polyelectrolyte chemistries have been tested for effects on hepatocyte function in vitro [116, 117]. Specifically, Chen et al., developed a two-dimensional model consisting of polyelectrolyte multilayers that enables independent variation of both substrate mechanical compliance and ligand presentation. By enabling optimization of chemical and mechanical cues, such culture techniques could prove useful in rational design of culture platforms for applications such as tissue engineering.

Heterotypic interactions with non-parenchymal cells have been used successfully to preserve the viability, morphology, and function of hepatocytes from a range of species for several weeks. Through extensive studies beginning with initial work by Guguen-Guillouzo and colleagues [118], the "rescue" of hepatocytes within co-culture settings has been demonstrated by utilizing a wide variety of non-parenchymal cells from both within and outside the liver and across species barriers, suggesting that the mechanisms responsible for stabilization are conserved [119]. Overall, substantial experimental efforts continue to explore various co-culture systems as potential models of physiologic and pathophysiologic processes in the liver. Furthermore, the identification of the important mechanisms underlying stabilization within non-parenchymal co-cultures could provide the basis for the addition of key factors and increased functionality within hepatocyte-only culture platforms.

3-D Spheroid Culture

Certain substrates promote the aggregation of cultured hepatocytes into three-dimensional spheroids and can affect functionality [120–124]; this is potentially due to the retention of a 3-D cytoarchitecture, the presence of ECM surrounding the spheroids, and the formation of homotypic cell–cell contacts between neighboring hepatocytes [125]. On non-adhesive surfaces, for example, hepatocytes aggregate over 1–2 days first into smaller spheroids of ~50 μm, which over weeks, gradually fuse into larger 150–175 μm spheroids [111]. These spheroids have functions superior to standard collagen monolayer culture [126, 127]. On Matrigel (a laminin-rich basement membrane extract), hepatocytes also form spheroids that retain hepatic functions [128, 129] though it is difficult to pinpoint the cause of these effects due to the contamination of Matrigel with proteins, hormones, and growth factors [90, 130]. Further, Matrigel-based platforms

suffer from the gradual imbalance of phase I/II detoxification processes (CYP450 decline) over a few days in culture [115]. Upon transfer to static collagen surfaces, the spheroids disassemble and the hepatocytes spread and dedifferentiate [131, 132]. Spheroid cultures have also been produced with support cells. A recent study produced an array of spheroids made from fetal mouse liver cells containing fetal hepatocytes and other liver cell types; hepatospecific function and differentiation induction were enhanced by co-culturing these spheroids with non-parenchymal feeder cells [133]. Other methods such as rotation have been used to make hepatocyte spheroids. Recently, a rocking method was employed to produce spheroids [134], generating spheroids faster and with fewer non-adherent hepatocytes than rotational methods, and also exhibiting preserved stable expression for many typical liver-specific genes.

Spheroids can in turn be encapsulated to control cell–cell interactions. In one method, spheroids suspended in methylated collagen are syringe-extruded into terpolymer solution to form microcapsules [135], but other methods have made use of various synthetic and natural scaffolds. Spheroid cultures have been utilized for both small-scale [91, 136, 137] and large-scale bioreactor systems [138]. While spheroid cultures can demonstrate desirable liver functions, there are several limitations including the fusion of small spheroids into larger aggregates, and death in the center of such aggregates due to limiting influx of nutrients and efflux of waste products. Thus, platforms for optimizing spheroid size and handling are under ongoing development.

Bioreactor Cultures

Though useful for many applications, the types of in vitro models described above provide a relatively homogeneous view of liver function. In vivo, there is a significant distribution of hepatic functions along the length of the sinusoid associated with translobular gradients in nutrients, oxygen, hormones, and ECM. Some bioreactor cultures attempt to capture these differences. In order to study the effects of oxygen variation across the liver lobule, a small-scale, parallel-plate bioreactor was developed that exposes hepatocyte/non-parenchymal co-cultures to a steady-state oxygen gradient [139]. These cultures were able to replicate the heterogeneous expression distribution of the drug metabolism enzymes CYP2B and CYP3A observed in vivo, and expression could be controlled with chemical inducers and growth factors. Furthermore, exposure of the culture to acetaminophen caused greatest cell death in areas of low oxygen, replicating the centrilobular death pattern observed in vivo.

Bioreactors have also been produced to culture hepatic aggregates. One device consisted of a 1 cm^2 planar polymer scaffold with 900 micro-containers that could each culture a uniformly-sized 3-D hepatic aggregate [136, 137]. The aggregates were perfused via a pore, laser-drilled within each micro-container and retained desirable morphology and liver functions for 2 weeks. Another device consists of hepatic spheroids cultured in an array of micro-channels etched into silicon wafers using deep reactive ion etching [91]. In this system, culture medium was passed across the top of the array, enabling spheroids to retain liver-specific characteristics for 2–3 weeks in culture, as assessed by gene expression profiling, protein expression, and activity of drug metabolism enzymes [91]. Recently, Domansky et al., have integrated multiple perfused bioreactors into a multi-wellplate format in which each bioreactor houses hundreds of microscale hepatic monolayers; the format of this device could be applied towards studying perfused tissue units in high-throughput [140].

Bioreactors have been developed in several other studies as well. A flat plate bioreactor was designed to study the effects of oxygenation and shear stress on hepatocyte function [141]. Additionally, alternative bioreactor configurations have been developed to minimize shear stress effects, and have included, for example, grooved substrates to protect hepatocytes from shear, or adjacent channels separated by a gas-permeable membrane to decouple oxygen exchange and volumetric flow rate [142, 143]. Such bioreactors can also be scaled for clinical applications; in one particular demonstration, grooved-culture substrates were stacked in a radial flow bioreactor [144]. To improve oxygen delivery, collagen sandwich co-cultures of hepatocytes and non-parenchymal cells from the liver were cultured in a 96-well perfused microbioreactor with a biocompatible, gas-permeable membrane [89]; hepatocytes in this system maintain liver functions such as albumin and urea expression, expression of phase I/II detoxification enzymes, and inducible expression of CYP1A1. Finally, bioreactors may be used to study more dynamic physiological processes that are not possible with conventional culture platforms; for example, a recent bioreactor device describes the ability to monitor invasion of metastatic cells into hepatic parenchyma by recreating relevant features of the liver tissue such as fluid flow and length scales [145]. Collectively, bioreactors enable complex control over hepatocyte culture parameters [146–148] and in turn hepatocyte function; as such, they will continue to be useful in studying liver biology and in applications such as drug development.

Microtechnology Tools

Microtechnology tools afford micron-scale control of tissue architecture as well as cell–cell and cell–matrix interactions, facilitating investigations of the mechanisms underlying tissue

development and function [149]. Based on methods used in the semiconductor industry, microtechnology approaches allow fine control over cell adhesion, shape, and multi-cellular interactions [150]. Consequently, they are enabling studies of biological phenomena at cellular length scales [151, 152], as well as techniques for miniaturizing and parallelizing biomedical assays (e.g. DNA microarrays, microfluidics) [92, 153].

In order to study the effects of homotypic and heterotypic cell–cell interactions between hepatocytes and non-parenchymal cells, a photolithographic-cell -patterning technique was employed to make micropatterned co-cultures in which hepatocyte islands of controlled diameters were surrounded by non-parenchymal cells [119]. Initially employed for rat hepatocyte culture, the highest levels of liver-specific functions occurred at an intermediate island diameter, implying that optimal function results from an optimal balance of homotypic/heterotypic interactions. Using soft lithography, this co-culture pattern has been recently miniaturized and adapted into a multi-well format to serve as a microscale human liver tissue model for drug development [92]. The utility of this platform for drug development has been shown through gene expression profiles, phase I/II metabolism, canalicular transport, secretion of liver-specific products, and susceptibility to hepatotoxins. Fine control over the spatial distribution of cells is also demonstrated in a recent platform developed by King et al., which uses a microfabricated device with quantitative live cell imaging to measure gene expression in real-time of individual living cells [154]; the tool is used to investigate gene-expression changes in the course of hepatic inflammation.

Another application of microtechnology is the use of microfabrication and microcontact printing techniques to develop a microarray containing hepatocyte spheroids of a uniform size [155]; this method reduces aggregate heterogeneity and minimizes cell necrosis resulting from oxygen/nutrient depletion or waste accumulation. These spheroids retain liver functions including expression of liver-enriched transcription factors, albumin secretion, and expression of urea cycle enzymes. Another application of microtechnology tools in building multicellular hepatic structures is the formation of hepatic tissue sheets by release of confluent hepatocytes from surfaces coated with the temperature-responsive polymer, poly(*N*-isopropylacrylamide) (PIPAAm) [156].

Microtechnology tools can also be used to create culture platforms in which stimuli are dynamically modified, in contrast to typical culture platforms in which stimuli are static; such tools should enable investigation and optimization of cellular responses that exhibit spatiotemporal components and thus contribute to tissue engineering applications. Microfluidic devices are typical examples of systems that permit spatiotemporal control over delivery of nutrients and other soluble mediators to cultured cells. Recently, Chao et al., described a microfluidic platform that simulates flow through the liver to predict the in vivo hepatic clearance of pharmaceutical compounds [157]. Dynamic cellular responses can also be interrogated using other nascent microfabrication approaches. In one example, a mechanically actuated "comb" device was fabricated that enabled investigation of cell–cell interactions by permitting micron-scale temporal control of cell–cell interactions [158]. When used to study hepatocyte-stromal cell interactions, this platform revealed that phenotypic stabilization of phenotypes by the non-parenchymal cells required direct contact for hours followed by a sustained short-range paracrine signal.

The fine spatial and temporal control afforded by microtechnology tools has already accelerated studies of basic liver biology and applications that were impossible without such methods.

Application of In Vitro Liver Models: Studying Liver Pathophysiology

In vitro hepatocyte cultures and co-cultures have been utilized to investigate various physiological and pathophysiological processes, including host response to sepsis, mutagenesis, xenobiotic toxicity, response to oxidative stress, lipid metabolism, and induction of the acute-phase response [119]. Among the many applications of in vitro liver tissue models is the study of the behavior of pathogens that target hepatocytes and screening for therapeutics of the associated diseases. Hepatitis C virus (HCV) and malaria are two such pathogens.

HCV is an enveloped RNA virus whose genome consists of a single positive-stranded RNA that replicates in the cytoplasm of infected hepatocytes without integrating into the host genome. The first in vitro model enabling studies of replication and screens for small molecule inhibitors of the replicative enzymes of HCV consisted of a subgenomic replicon stably-transfected into carcinoma cells [159]; however, with this system, it was not possible to study the complete viral life cycle as the structural proteins were omitted from the replicon. Collectively, at this time, researchers were unable to find a viral genotype capable of executing the full viral life cycle in vitro. In 2001, Kato et al., [160] found and sequenced a genotype-2a strain of HCV that caused fulminant hepatitis in a Japanese patient. This genotype was named JFH-1, and in 2005 it was shown that JFH-1 and a chimeric variant were able to complete the entire viral life cycle in the Huh7 carcinoma cell line and more robustly in certain Huh7 sublines [161–163]. More recently, it has become possible to study HCV infection in primary human hepatocytes [164–166]. Ploss et al., [166] demonstrate that a microscale human liver tissue model [92] is capable of recapitulating the entire viral

life cycle and can act as drug screening platform for compounds that suppress HCV replication.

Plasmodium infection is responsible for malaria disease, and distinct species, such as *P. falciparum* and *P. vivax*, are associated with different degrees of severity and patterns of pathogenesis. After transmission of the *Plasmodium* sporozoites to the human blood circulation from mosquito saliva, the sporozoites infect hepatocytes in the liver. There, they eventually proliferate and differentiate into merezoites, which then go on to infect red blood cells, where they rapidly amplify in number. In vitro liver models have the potential to enable studies of the hepatocyte stage of the malarial life cycle and presumably vaccine development and screening of small molecules that inhibit viability or proliferation of the parasite in its liver stages. Several lines of research have recently explored this possibility, for example, in a two-dimensional collagen monolayer culture model of primary human hepatocytes, investigators were able to recapitulate the complete liver development stage of *P. falciparum* [167] and *P. vivax* [168]. A similar culture model has been used to characterize the mechanistic basis of CD81-dependent invasion of hepatocytes by *Plasmodium*, with the conclusion that SR-BI enhances permissiveness to infection by increasing plasma membrane cholesterol and organizing CD81 into an entry-favorable configuration [169]. van Schaijk et al., use this model to show that disruption of the p52 gene in *P. falciparum* leads to arrest in the liver stages of development, potentially, providing a source of genetically attenuated sporozoites for vaccination purposes [170]. By reproducing key physiologic properties of liver tissue, in vitro liver models enable applications such as drug development and the study of liver pathophysiology. As discussed in this section, numerous culture configurations have been attempted, where each serve different functions. In pursuing a particular application, investigators must decide what critical aspects of the in vivo liver tissue must be replicated in their systems, informing the selection of an appropriate model.

Implantable Engineered Tissue Constructs

Transplantation of hepatocytes to perform liver functions shows great potential for the treatment of liver disease and in the development of humanized liver mouse models, but direct injection of cells is associated with variable seeding efficiency and poor long-term survival and engraftment. Hepatocyte delivery in a tissue-like structure that preserves cell attachments could increase engraftment efficiency, reduce the need for a repopulation advantage in donor cells and reduce the overall lag phase before clinical benefit is attained [171–173]. Thus, hepatic tissue engineering technologies, which seek to generate liver-like tissue in vitro prior to in vivo implantation, may provide an alternative delivery method to transplantation of suspension cells, as well as a means to implant cells and/or additional biological cues that interact with the host and ultimately serve to improve liver function.

Implantable engineered hepatic tissues have typically been created by immobilizing or encapsulating hepatocytes using biomaterial scaffolds. As such, scaffold properties and cell sourcing are both critical in the development of engineered tissue. Though great strides have been made in this field, many issues must be addressed before implantable hepatic tissue becomes a clinical reality. As work in this field advances, careful attention needs to be paid to issues that dictate the ultimate clinical translation of these therapies.

Scaffold Properties

Highly functional 3-D implantable liver tissue will likely require dense population with functional and stable hepatocytes, while also facilitating the transport of nutrients and large macromolecules. Cell seeding and nutrient transport are ultimately dictated by scaffold properties, which include material and chemical modifications, porosity, and 3-D architecture.

Material and Chemical Modifications

The choice of material determines the physicochemical and biological functions of the scaffold. For example, natural, biologically-derived materials containing binding sites for cell attachment can enhance function since hepatocytes are anchorage-dependent cells. Hepatocytes have been attached to collagen-coated dextran microcarriers and transplanted intraperitoneally into two different Gunn rat genetic models for replacement of liver-specific functions [174]. Microcarriers provide a platform for cell attachment and enhanced survival and function of the transplanted hepatocytes. Cellulose [175–177], gelatin [178], and gelatin–chitosan composite [179] microcarrier chemistries have also been explored for hepatocyte attachment. Additionally, hepatocytes have been encapsulated within natural, extracellular matrix-derived scaffolds, including the collagen gels [180, 181], hyaluronic acid [182], peptides [183], or alginate and alginate-based composites [184–187]. Microencapsulation of hepatocytes in these types of systems can facilitate hepatocyte aggregation and improve function. For instance, alginate-based encapsulation platforms have been shown to support hepatocyte spheroid culture [184, 185, 187] and thus have been proposed for use in implantable constructs.

Synthetic polymers have afforded hepatic tissue engineers an improved control over scaffold physicochemical and biological properties. The most common synthetic polymers utilized in the generation of porous tissue engineering constructs are polyesters such as poly(l-lactic acid) (PLLA) and poly(d,l-lactide-co-glycolide) (PLGA). These materials are biocompatible and biodegradable, support hepatocyte culture, and have been widely used as scaffolds for hepatocyte transplantation [93, 188–197]. A key advantage of these polyesters is the ability to finely tune its degradation time, based on the relative contribution of the PLLA versus PLGA components, each of which exhibit distinct hydrolysis kinetics. Material modifications of PLGA scaffolds have also been shown to improve hepatocyte functionality. Specifically, the addition of hydrophilic poly(vinyl alcohol) (PVA) into PLGA scaffolds enhanced hepatocyte seeding [191]. Alkali hydrolysis and ECM coating of PLGA constructs can similarly enhance hepatocyte attachment [195, 196, 198]. Importantly, a composite PLLA–PLGA scaffold coated with PVA supported long-term engraftment of hepatocytes after transplantation in the mesentery in a rodent injury model [93]. Despite these advances, the accumulation of hydrolytic degradation products upon PLLA and PLGA degradation has been shown to produce an acidic environment within the scaffold and initiate peptide degradation, stimulate inflammation, or result in poor tissue engraftment [199, 200]. As such, groups have explored methods to control peptide degradation in PLGA as well as explore alternative synthetic polymer-based systems for use in tissue engineering.

The synthetic hydrogel system based on polyethylene glycol (PEG), has also been widely utilized for various tissue engineering applications [201–219] including, recently, for hepatocellular platforms [220]. PEG-based systems are particularly useful in tissue engineering due to their high water content (which give them similar mechanical properties to tissues), hydrophilicity and resistance to protein adsorption, biocompatibility, and capacity for customization through the modification of chain length and the addition of bioactive elements [219, 221]. An additional advantage of PEG is that it can be polymerized through photo-crosslinkable diacrylate (DA) endgroups in the presence of cells, which provides for the generation of 3-D constructs with uniform cellular distribution. Studies examining PEG-DA hydrogel encapsulation of hepatic cells have utilized immortalized hepatocytes, hepatoblastoma cell lines, and primary hepatocytes, and together have shown that tailoring the design of the hydrogel network dictates hepatocyte survival and function [8, 94, 222]. Taken together, these results demonstrate that synthetic hydrogel systems represent promising platforms for implantable constructs as well as investigating in vitro hepatocellular responses in a model 3-D environment.

Although synthetic polymer scaffolds offer numerous advantages, the absence of natural cell-binding sequences in these systems often limit their capacity to promote cell adhesion. The inert nature of synthetic systems can also be used as a tool to study the basic biology of hepatocellular adhesion, by facilitating the controlled incorporation of biologically active elements aimed at regulating different aspects of cell function. Multiple approaches have been explored for modulating hepatocyte interactions with synthetic platforms by non-specific adsorption or chemical conjugation of biological molecules, including the incorporation of (1) ECM molecule coatings [195, 196], (2) various sugar residues such as lactose, heparin [223], and galactose [224, 225], (3) poly(*N*-*p*-vinylbenzyl- 4-*O* β(beta)-d-galactopyranosyl-d-glucoamide) (PVLA) in PLLA scaffolds [192, 226, 227], and (4) epidermal growth factor (EGF) in polyethylene terephthalate (PET) fabric scaffolds [227]. Each of these modifications has been implicated in improving hepatocyte adhesion within polymer scaffolds and, therefore, highlight modifications of the polymer scaffold backbone that influence hepatocyte processes. As an alternative to the incorporation of entire biomolecules, polymer scaffolds can also be conjugated with bioactive adhesive peptide sequences. Adhesive peptides, which interact with integrin receptors in the cell membrane, have been extensively utilized to promote cell attachment within polymer networks. For example, inclusion of the RGD peptide sequence within biomaterial scaffolds dramatically influences the adhesion and function of a diverse assortment of cell types [228]. In experiments using hepatocytes, grafting RGD peptides to PLLA scaffolds similarly enhanced hepatocyte attachment [197]. Notably, RGD conjugation also significantly improved the long-term stability of primary hepatocyte function in PEG hydrogels [94]. Incorporation of additional adhesive peptides that bind other integrins might further enhance hepatocyte function within synthetic polymer substrates. Additionally, the incorporation of hydrolytic or protease-sensitive peptide sequences (such as matrix metalloproteinase-sensitive peptide sequences) into hydrogel networks as degradable linkages has been shown to permit cell-mediated degradation and remodeling of the gel [210, 212, 229–232]. Although these systems have not yet been applied to hepatocellular technologies, it is interesting to note that liver regeneration proceeds in conjunction with a distinctive array of remodeling processes such as protease expression and ECM deposition [233–235]. Therefore, cell-mediated material degradation could provide a mechanism for the efficient integration of implantable constructs. The ability to modify biomaterial scaffold chemistry by introducing biologically active factors will likely allow for fine-tuned regulation of cell function and graft-host interactions.

Porosity

Many natural and synthetic implantable tissue-engineering approaches utilize porous scaffolds, which provide mechanical

support and often biological cues for growth and morphogenesis. The material's pore size can be controlled over several orders of magnitude, thus allowing materials to be tailored for purposes such as the optimization of protein exchange [94], cell–cell interaction and survival [94, 236], or the promotion of wound repair and tissue ingrowth [237]. Collagen or various alginate and chitosan composites are the most frequently used biologically-derived scaffold materials for hepatocyte tissue engineering [180, 184–187, 236, 238–251]. Collagen sponges have been utilized as scaffolds in a diverse array of cell systems and also as substrates for promoting wound repair [252–258]. In a study in which hepatocytes were seeded onto collagen scaffolds exhibiting a variety of pore sizes (10–82 μm), pore size was found to be an important factor regulating cell spreading and cell–cell interactions [236]. Additionally, alginate scaffolds with pore sizes of approximately 100 μm have been shown to encourage spheroidal aggregation of hepatocytes owing to the weakly adhesive properties of the material, and spheroid formation in turn promoted hepatocyte stabilization[239]. Variations in alginate formulation, such as an alginate–galactosylated chitosan–heparin composite system [250], can further enhance cell aggregation and viability [184, 186, 238, 249, 250]. A variety of porous synthetic materials such as PLLA and PLGA have also been used in hepatic tissue engineering, as detailed above. Porous, acellular scaffolds are normally seeded using gravity or centrifugal forces, convective flow, or through cellular recruitment with chemokines [259–261]. However, incorporation of hepatocytes into scaffolds is hindered by insufficient or non-homogeneous cellular distribution and by the relatively immotile nature and limited proliferation of hepatocytes *ex vivo*. Additionally, despite the fact that porous scaffold systems continue to be explored for use in engineered liver tissue, many of these scaffold architectures contain pores that are many times larger than individual hepatocytes, essentially making them 2-D surfaces from the hepatocyte perspective. This may limit the ability of porous scaffolds to fully recapitulate 3-D cues.

3-D Architecture

An alternative approach for tissue-engineered scaffolds strives to more closely mimic in vivo microarchitecture. The 3-D architecture of native tissues influences cellular function, mechanical properties of the tissue, and the integration of grafted engineered tissue with the host. The ability to fabricate cellular scaffolds with highly defined structure could facilitate the recapitulation of the appropriate microscale environment for cell viability, cell function, and cell–cell interactions, as well as desired macroscale properties that determine mechanical properties and nutrient delivery.

Porous scaffolds were initially produced by solvent casting or particulate leaching methods. These techniques did not permit for pre-designation of the internal scaffold structure or pore connectivity. More recently, CAD-based rapid prototyping strategies have been developed that allow for defined control by utilizing multiple assembly modes, including fabrication using heat, light, adhesives, or molding, as reviewed elsewhere [262]. Briefly, 3-D printing with adhesives combined with particulate leaching has generated porous PLGA scaffolds that were used for hepatocyte attachment [263]. Microstructured ceramic [264] and silicon scaffolds [265, 266] have additionally been proposed as systems for the culture of hepatocytes. Furthermore, molding and microsyringe deposition have been utilized to fabricate specified 3-D PLGA structures [267].

Microfabrication techniques have also been employed to pattern cells within natural and synthetic hydrogels. For example, microfluidic molding has been used to create biological gels containing patterned cells in multi-layer structures [268, 269]. In addition, syringe deposition and micropositioning were recently used to generate patterned gelatin hydrogels containing hepatocytes [270]. The ability to polymerize synthetic PEG hydrogels using ultraviolet (UV)-initiation allows for the use of photolithography to generate hydrogel networks with defined microscale patterns. In this process, patterned masks printed on transparencies localize UV exposure to selected regions of the prepolymer solution and therefore dictate the structural features of the resultant hydrogel. Photolithography-based techniques have been employed to pattern biological factors [271], produce hydrogel structures with a variety of shapes and sizes [272, 273], and build multilayer cell networks [222]. Hydrogel photopatterning is thus ideal for the regulation of scaffold architecture at the multiple size scales required for engineered hepatocellular constructs. As one example, perfusion of hepatocellular constructs is known to improve hepatocyte functions [224, 263]; therefore, photopatterning of PEG hydrogels containing hepatocyte–fibroblast co-cultures was used to create a branched 3-D network that was cultured under flow conditions for improved oxygen and nutrient transport and encapsulated hepatocyte functions [094]. At the microscale, dielectrophoretic gradients field gradients have been employed to pattern hepatocytes and fibroblasts within a pre-polymer solution of PEG prior to photoencapsulation [274]. The combined utility of photopatterning and dielectrophoresis-mediated cell patterning thus allows the construction of hepatocellular hydrogel structures with an organization defined at both the macroscale and cellular scale. Finally, the recent introduction of a new family of PEG-based photodegradable hydrogels, which allow selective degradation of hydrogels using light, will allow real-time manipulation of spatial features and mechanical properties at the microscale. Such materials create new opportunities to

study the effects of changes in scaffold microarchitecture, chemistry, and mechanics over the course of culture time [275]. In summary, the ability to dictate scaffold architecture coupled with advances in scaffold material properties, chemistries, and the incorporation of bioactive elements will serve as the foundation for the future development of improved tissue-engineered liver constructs.

Cell-Sourcing for Implantable Liver Tissues

Cell sourcing for implantable engineered liver tissue faces challenges similar to cell transplantation. Specifically, hepatocytes cultured in 3-D within biomaterial scaffolds lose phenotypic functions and the ability to proliferate in vitro in the absence of the appropriate biological cues [8]. In the effort to optimize both, phenotypic function and cell proliferation, various groups have explored the use of mature primary hepatocytes, hepatic progenitor cells, and non-parenchymal supporting cells in tissue-engineered constructs.

Mature Hepatocytes Versus Hepatic Progenitor Cells

Most tissue-engineering strategies outlined in the scaffolds section above have utilized immortalized hepatocytes, hepatoblastoma cell lines, or primary mature hepatocytes as the cell source [8, 94, 132, 201, 270, 276–278]. Of these, primary hepatocytes are the preferred cell type for clinical therapies due to safety concerns associated with cell immortalization and potential tumor formation [48]. However, similar to whole organs, the supply of primary hepatocytes is limited [8]. Additionally, the limited proliferative capacity of mature hepatocytes in vitro often results in low cell density in engineered tissues and ultimately limits the success of hepatic tissue engineering. In the attempt to identify more proliferative hepatocyte-cell sources, recent work has turned to testing the efficacy of the wide variety of hepatic progenitor cell populations (as described in detail above) in engineered tissues. As one example, bipotential mouse embryonic liver (BMEL) cells have been shown to survive and differentiate towards the hepatic lineage in PEG hydrogels [94]. Additionally, mouse embryonic stem cell-derived hepatocytes have been implanted in a tissue engineered assist device and shown to improve mouse hepatic failure [60].

While hepatic progenitor populations are an exciting alternative to primary hepatocyte-cell sources, work to further refine the unknown advantages and disadvantages of proliferative hepatic progenitors versus fully mature hepatocytes in tissue engineering is necessary. For example, it is currently unknown whether the proliferative capacity of hepatocyte progenitors in tissue engineered constructs will result in superior engraftment, tissue density, and tissue function following implantation compared to constructs containing fully functional mature hepatocytes. In fact, a major concern in the use of progenitor cell-populations for implantation therapy is that these cells may exhibit uncontrolled cell proliferation and/or differentiation towards undesired cell fates [279]. Implantation of proliferative hepatic progenitors could indeed result in "over-population" of tissue engineered constructs. In the worst situation, implantation of undifferentiated pluripotent cell types could result in teratoma formation [279]. Current work therefore speaks to address issues whether progenitor cell populations need to be pre-differentiated to cells dedicated to the hepatic lineage prior to culture in three-dimensional scaffold materials and implantation [60], whether hepatic progenitors need to be fully mature and exhibit no expression of fetal programs prior to implantation, and whether signals can be engineered strategically into the scaffold to guide appropriate differentiation within the scaffold itself [280–282]. In summary, a wealth of exciting new hepatocyte progenitor-cell sources has recently become available for use in implantable liver devices, and future studies will be needed to evaluate their therapeutic potential.

Cell–Cell Interactions

Similar to two-dimensional culture, homotypic [94, 136] and heterotypic [94, 222, 283] interactions have been found to be essential in the maintenance of hepatocyte function and survival in culture in biomaterial scaffolds. For example, pre-aggregation of primary hepatocytes or BMEL progenitor cells in PEG gels enhanced both cell survival upon encapsulation and also hepatocyte function [94], suggesting that homotypic cell interactions are important in this system. Numerous groups have also co-encapsulated non-parenchymal cell populations such as fibroblasts, endothelial cells, mesenchymal stem cells, and stellate cells with hepatocytes in biomaterial scaffolds, and some studies have shown improved hepatocyte function in the presence of non-parenchymal cell populations [94, 126, 284–290]. For example, co-encapsulation of primary hepatocytes and 3T3 fibroblasts in PEG hydrogels has been shown to improve hepatocyte survival and function [94]. Hepatocytes have also been shown to affect the morphogenesis and phenotype of non-parenchymal cells in biomaterial scaffolds. For example, when hepatocytes and microvascular endothelial cells are cultured on a collagen gel scaffold in a microfluidic device, endothelial morphogenesis is dependent on diffusion from one cell compartment to the other [291]. Additionally, 3-D culture of hepatocytes with liver sinusoidal endothelial cells allows for maintenance of the SE-1

marker in the endothelial cells, an indication of persistence of liver-specific endothelial cell phenotype [283]. Taken together, these results show that non-parenchymal cell populations have played a significant role in the development of robust engineered liver tissue to date.

Future iterations of engineered liver tissue need to further refine the non-parenchymal cell types that are necessary in implantable constructs. For example, the non-parenchymal cell types utilized in liver tissue engineering to date have typically been non-human and non-native to the liver (e.g., J2–3T3 mouse fibroblasts [94, 283]). Clinical impact of engineered liver devices will be accelerated through the use and study of human cell sources. Additionally, ease of large-scale manufacturing will likely be enhanced by minimizing the number of cell types required in any given device. In order to reduce the number of cell types in a given device, a detailed mechanistic understanding of the cues involved in cell–cell interactions, as well as liver development and regeneration is necessary. Techniques to micropattern the spatial configuration of multiple cell types with respect to one another [274], precisely regulate the spatial and temporal release of growth factors and morphogens [281], and model cell-signaling networks [61, 292, 293] should aide in determining the mechanistic roles of different cell types and biological cues. Such knowledge could be used to design engineered therapies that incorporate key signaling molecules, but limit the number of exogenous cell types needed to improve hepatocyte survival and function in engineered tissues [294]. Thus, cell–cell interactions have been shown to be important in the development of engineered liver tissue and the exact molecular mechanisms responsible for the functional benefits derived from cell–cell interactions is an area of investigation that will be critical to the design of advanced liver tissue-engineered devices.

Clinical Translation for Human Therapy

Prior to the translation of implantable device therapies to the clinic, animal models must be developed that adequately assess the safety and efficacy of these therapies. These tissues will also need to integrate with the patient's vascular and biliary systems. Finally, it will be essential that implantable engineered therapies are composed of immune-compatible cell and material components that are fit for use in humans.

Assessment in Animal Models

Prior to the translation of any cell-based liver to the clinic, the safety and therapeutic efficacy of these therapies must be demonstrated in animal models. Animal models for testing these therapies include genetic, toxic, ischemic, PHx, and total hepatectomy models. Several extensive reviews outline important criteria used in the development of animal models of fulminant hepatic failure [295–297]. These criteria include reproducibility, reversibility, liver failure-induced cell death, and presence of sufficient time interval for diagnosis and therapeutic intervention [298]. Genetic models of liver injury include the urokinase plasminogen activator overexpression (uPA++/SCID) and FAH knockout mouse models [299, 300]. Chemical induced injury models include exposure to toxic doses of carbon tetrachloride, D-galactosamine, or acetaminophen, all of which induce localized centrilobular necrosis [301, 302]. Chemical induced injury models are especially useful for testing the efficacy of cell-based liver therapies because these models most closely mimic acute liver injuries commonly found in humans (e.g. drug toxicity). Surgically induced injury models include PHx and have been widely employed because the injury stimulus is well-defined [303]. Despite the fact that the hepatectomy model is less clinically relevant (with the exception of liver resection patients), it serves as a well-controlled system to examine the importance of regenerative cues in the engraftment of hepatic constructs implanted in extrahepatic sites [303]. To this end, the optimal implantation site of implantable engineered tissue will also need to be determined. Tissue engineered constructs are frequently evaluated after implantation into subcutaneous or mesenteric spaces due to the ease of surgical access and improved imaging options. Early work in injury damage models suggested that orthotopic transplantation was necessary for hepatocyte survival due to interaction with "hepatotrophic factors" available in the portal vein. However, the effectiveness of implanted extrahepatic scaffold based systems in supporting hepatic function following hepatectomy has been demonstrated in some studies with rodent models [60, 303, 304] in which constructs were implanted subcutaneously, peritoneally, or in the fat pad, suggesting that injury cues originating in the host liver can reach extrahepatic sites. The utilization of numerous surgical and chemical animal models will be instrumental in testing the efficacy of cell-based liver therapies. Concurrently, knowledge of the mechanisms of liver injury and regeneration obtained from these experiments will influence the future design of next-generation engineered liver tissue.

Integration with Host Tissue Vasculature and Biliary System

To derive maximal therapeutic benefit from implantable engineered liver tissue, grafted tissue must integrate with the host tissue, and in particular, with the host vasculature and biliary system. Within the normal liver environment,

hepatocytes are supplied by an extensive sinusoidal vasculature [305]. This vasculature allows for the efficient transport of nutrients to the highly metabolic hepatocytes. A significant challenge in the design of implantable liver constructs is the need to sustain thick implanted tissue in the face of transport limitations prior to the establishment of functional vasculature. One strategy is to incorporate "pre-formed" vasculature into engineered constructs prior to implantation. For example, microfabricated vascular units could be created and followed by surgical anastomosis during implantation [266, 305]. Polymer molding using microetched silicon has produced channel networks with capillary dimensions [266]. Additionally, recent muscle engineering studies have demonstrated that prevascularization of engineered tissue using endothelial and mesenchymal cells (in addition to muscle cells) in vitro improves survival and vascular integration of engineered tissue with host tissue after implantation [306–308]. A second strategy is to incorporate angiogenic factors within the implanted scaffolds so that these factors can recruit the ingrowth of host vasculature immediately upon implantation. Specifically, integration of cytokines that play critical roles in angiogenesis, such as VEGF [309, 310]. bFGF [311], and VEGF in combination with PDGF [312], promotes the recruitment of host vasculature to implanted constructs. A final strategy is to "prime" the implantation site through prevascularization. For example, pre-implantation of VEGF releasing alginate scaffolds prior to hepatocyte seeding enhances capillary density and improves engraftment [313].

Finally, inclusion of excretory capabilities associated with the biliary system may be necessary in future engineered liver tissue. To date, studies have focused on the developing in vitro models that exhibit biliary morphogenesis and recapitulation of the appropriate polarization and bile canaliculi organization [314–316], as well as platforms for engineering artificial bile duct structures [317]. Future studies will determine whether the inclusion of biliary elements is necessary in implantable liver tissue.

Immune Response

Similar to whole liver or cell transplantation, an understanding of the host immune system responses following transplant of tissue-engineered constructs will be paramount to the success in translating these therapies to the clinic. To minimize the host immune response to implantable constructs, all parenchymal and non-parenchymal cells populating engineered tissue should be entirely human. Similarly, implantable tissue should be free of xenogenic materials. Towards this end, engineered tissues must be cultured under serum-free conditions and should not contain naturally-derived xenogenic biomaterials [318, 319].

The road to the ultimate immuno-compatible implantable liver therapy may be multi-tiered and will likely parallel that of cell transplantation therapies. For first-generation therapies, immunosuppressive treatments could be combined with the establishment of allogenic human primary hepatocyte or ES-derived hepatocyte cell banks that contain immunologically diverse phenotypes [320]. Next-generation therapies may be populated by autologous-cell sources such as iPS-derived hepatocytes and therefore reduce the need for rigorous immunosuppressive treatment. Furthermore, harnessing the liver's ability to induce antigen-specific tolerance [321, 322] could improve the immune acceptance of engineered grafts. Overall, immune biology challenges will be critical in the successful translation of cell-based therapies. Multiple options exist for building immune-compatible cell therapies, and careful attention to these issues during the design and development of implantable engineered liver tissue will facilitate the ease and efficiency of clinical translation of these therapies.

Conclusion

Substantial advances have been achieved in the field of liver tissue-engineering, as shown by the concurrent improvements in bio-mimetic in vitro liver systems and implantable hepatocellular constructs. This progress is enabled by integrating knowledge bases from various disciplines, including fundamental liver biology, medicine, and biomedical engineering. Although many challenges remain, our evolving understanding of key regulators of liver function and regeneration, promises to lay solid ground work for the next generation of clinically effective tissue-engineered liver systems.

Chapter 23
Hepatic Gene Therapy

Hiroyuki Nakai

Introduction

Around the turn of the new millennium, after its 20-year history, gene therapy experienced both an exciting success [1] and an unexpected failure [2, 3], which significantly changed our perspectives on gene therapy from "versatile therapy" that we expected would soon become available to cure difficult-to-treat diseases to "potentially effective therapy" that would surely be superior over conventional therapies, but still needs further refinement towards clinical applications. Since then, within less than a decade, exciting discoveries and the development of emerging technologies pertinent to gene therapy have occurred, re-inspiring a greater-than-ever interest to gene delivery approaches. As for hepatic gene transfer, we have already become able to deliver genes of interest to target cells in the liver at extremely high efficiency and with minimum toxicity, at least in mice. With the contemporary hepatic gene delivery methods in our hands, any disease can be effectively treated or even cured in animal models, as long as the right therapeutic targets have been identified in the liver. At the current stage of the development of new molecular therapeutics, in addition to seeking new breakthroughs, it is critical to further refine the technologies, to understand the underlying mechanisms of action, to explore the methods to minimize undesired reactions and side effects, and importantly to further the knowledge of disease pathogenesis. With this introduction, this chapter provides an overview of contemporary methods and applications of hepatic gene transfer with an emphasis on the underlying mechanisms of action of each gene delivery approach.

Liver in Gene Therapy

Liver: A Major Target Organ in Gene Therapy

The liver is the largest and most blood-rich solid organ in the body, with multiple important biological functions essential for maintaining good health of animals and humans. The liver consist of hepatocytes (60–65% of total liver cells), sinusoidal endothelial cells (15–20%), Kupffer cells (8–12%), hepatic stellate cells (HSCs) or Ito cells (3–8%), biliary epithelial cells (3–5%), liver dendritic cells (<1%), cells constituting blood vessels, and blood cell components passing through the hepatic circulation. Hepatocytes produce, secrete, store, and/or degrade various molecules essential for normal biological activities of organisms. Hepatic dendritic cells (DCs), Kupffer cells (KCs), sinusoidal endothelial cells, and hepatocytes in some cases, serve as antigen presenting cells (APCs). Disruption of these biological functions and metabolic homeostasis in the liver occurs due to a variety of causes including congenital genetic defects, acquired disorders, and exogenous factors including drugs, alcohol, and faulty nutrition, and leads to various hepatic and systemic diseases. Thus, the liver is involved in the development and progression of many diseases; therefore it represents the primary target organ for therapeutic interventions, especially for gene therapy. In addition, the liver is the major organ responsible for various adverse events associated with therapies.

Hepatic gene therapy approach is not limited to the treatment of diseases that affect biological functions of the liver. The liver is well equipped with cellular machinery required for production and secretion of a large quantity of proteins to be released into the blood. Therefore, hepatic gene therapy is very effective in continually producing therapeutic proteins and secreting them into the blood circulation. In this regard, skeletal muscle also serves as a protein factory in gene therapy owing to its large mass, large capacity of protein synthesis, and ability to secrete proteins. Although easier accessibility and potentially less vector spillover to remote

sites make muscle-directed approach attractive, liver-directed approach could transduce a greater number of target cells and may result in more reduced immune responses against therapeutic products expressed by vectors. Potential therapeutic molecules expressed and secreted by the liver with this type of approach include blood coagulation factors, hormones, growth factors, cytokines, metabolic enzymes, and anti-proteases. In addition, gene therapy technique and the increased knowledge of developmental biology of the digestive system have made it possible to transdifferentiate hepatocytes into insulin-secreting β(beta) cells in the liver [4].

Liver also becomes a target organ to deliver therapeutic genes aiming at treating primary and metastatic liver tumors, although gene therapy for liver cancer is not generally considered as hepatic gene therapy per se. In this context, the major target cells are cancer cells and not parenchymal or non-parenchymal liver cells; however, therapeutic vectors are in general delivered to the liver through the hepatic circulation similar to the hepatic gene therapy approaches to treat non-malignant diseases.

Understanding Biological Functions of the Liver: Rare Monogenic Diseases as Targets for Hepatic Gene Therapy

The liver is a multi-tasking organ comprised of various types of professional cells as mentioned earlier, with the hepatocytes being the most versatile of them all. Hepatocytes can carry out approximately 500 biochemical reactions in a single cell and are responsible for the major metabolic processes in vertebrates. Hepatocytes are involved in the metabolism of fuels (carbohydrates, lipids, and nitrogen compounds), bilirubin, porphyrin, bile acids, steroid and thyroid hormones, vitamins and coenzymes, minerals, xenobiotics, drugs, and alcohol. All of these metabolic reactions are under the strict control of various regulatory systems. Even a single defect in one of the chains in a particular chemical reaction within a metabolic pathway can disrupt the metabolic homeostasis of the liver, leading to potentially fatal results. Although a majority of metabolic pathways and their individual chemical reactions have been biochemically well characterized, many inborn errors of metabolism are devoid of an effective therapy. Current treatment modalities include whole organ transplantation, but the global lack of donor organs requires alternative strategies for patients in need of functional liver activity. Therefore, congenital monogenic liver diseases have become ideal targets for the use of gene therapy vectors. Metabolic diseases that are potential targets for hepatic gene therapy are summarized in Table 23.1. It is important to note that hemophilia A and B, although they do not cause liver disease, are considered to be treatable by hepatic gene therapy protocols due to the exclusive production of coagulation factors in liver cells.

Understanding Molecular Pathogenesis of Diseases: More Common Diseases as Targets for Hepatic Gene Therapy

Increased knowledge regarding the cellular biology of liver cells in conjunction with the molecular pathogenesis of human diseases has allowed for the identification of new targets for molecular therapy. From the standpoint of hepatic gene therapy, an immense amount of effort has been directed toward establishing new gene therapies to treat liver fibrosis, liver ischemia-reperfusion injury, diabetes, viral hepatitis, and liver cancers. However, the development of therapeutic strategies will not likely be straightforward compared to monogenic diseases. Over the last decade, significant progress has been made in the development of new vectors and methodologies to deliver genes to the liver with high efficiency and safety. For example, genetic materials can be introduced stably and safely into a significant fraction of hepatocytes following intravenous administration of helper-dependent or gutted-adenoviral vectors and recombinant adeno-associated virus (AAV) serotype 8 vectors. Using the recently developed hydrodynamics-based method [5, 6], naked DNA or RNA could be delivered via intravenous routes to hepatocytes efficiently and globally even without a need of viral or non-viral vehicles. The newly developed gene delivery methods and the identification of new molecular targets have enabled therapeutic applications to be expanded from rare life-threatening monogenic diseases to more difficult-to-treat, but prevalent polygenic diseases.

Understanding Liver Immunology: A Key to Successful Hepatic Gene Therapy

In addition to being a protein factory and the major site of metabolic processes, the liver is considered to be a reticuloendothelial system (RES). This would constitute liver as an important and distinctive part of the immune system in the body, which would be constantly exposed to foreign antigens delivered by the portal blood flow from the digestive system. Liver sinusoidal cells, including KCs and liver sinusoidal endothelial cells (LSECs), act as a bodily defense by scavenging exogenous agents to prevent them from entering the systemic circulation (see Fig. 23.1). KCs and LSECs constitutively express major histocompatibility complex (MHC) molecules and co-stimulatory molecules allowing for the

Table 23.1 Preclinical and clinical studies of representative hepatic gene therapies

Disease	Therapeutic gene/molecule	Vector	Preclinical/clinical studies
Monogenic disease			
Hemophilia A	Factor VIII	HDAd	Human, Dog [26, 27, 29], Mouse [27, 30]
		Retro	Human [71], Dog, Mouse
		AAV	Dog [48], mouse [48, 49]
		Nonviral	Mouse [144, 150]
Hemophilia B	Factor IX	AAV	Human [8], NHP [14, 47], dog [46, 52, 53], Mouse [53, 54]
		HDAd	Dog [28], Mouse
		LV	Mouse [87, 88, 91]
		Nonviral	Mouse [148, 151, 214]
α(alpha)1-antitrypsin deficiency	α(alpha)1-antitrypsin	AAV	Mouse [294]
		HDAd	Mouse [25]
GSD type Ia	Glucose-6-phosphate-α(alpha)	AAV	Dog [295, 296], Mouse [296, 297]
		HDAd	Mouse [32]
GSD type Ib	G6PT	FGAd	Mouse
GSD type II (Pompe)	Acid α(alpha)-glucosidase	AAV	Mouse [298, 299]
		HDAd	Mouse [31]
MPS I	α(alpha)-L-iduronidase	LV	Mouse [94, 96]
		Retro	Mouse [216], Dog [73]
MPS IIIA	Sulphamidase	LV	Mouse [97]
MPS IIIB	α(alpha)-N-acetylglucosaminidase	LV	Mouse [95]
MPS VII	β(beta)-glucuronidase	AAV	Mouse [219, 300]
		Retro	Dog [74], Mouse [74, 217]
Fabry disease	α(alpha)-galactosidase A	AAV	Mouse [43]
		LV	Mouse [92]
Gaucher's disease	Glucocerebrosidase	AAV	Mouse [42]
Niemann-Pick syndrome	Acid sphingomyelinase	AAV	Mouse [44]
OTC deficiency	OTC	FGAd	Human [2, 9], NHP, Mouse
		HDAd	Mouse [33]
Crigler-Najjar syndrome	UGT1A1	LV	Rat [85, 93, 218]
		Retro	Rat [75]
Familial hypercholesterolemia	LDL receptor	Retro	Human [69], Rabbit [68]
		HDAd	Mouse [34]
Phenylketonuria	Phenylalanine hydroxylase	AAV	Mouse [45, 220]
Polygenic/acquired disease			
Liver fibrosis	MMP1/MMP8/uPA	FGAd	Rat [225, 227–229]
	TIMP antagonists[a]	FGAd/nonviral	Rat [231, 232], Mouse [230]
	Anti-HSC molecules[b]	FGAd/nonviral	Rat [233–237]
	HGF	Nonviral/FGAd	Dog [116], Rat [115, 239], Mouse [238]
Liver ischemia-reperfusion injury	Anti-ROS molecules[c]	FGAd/nonviral	Rat [242, 243, 245–247], Mouse [244]
	Others[c]	FGAd/nonviral	Rat [249, 250], Mouse [248]
Diabetes mellitus	Proinsulin precursor	FGAd/nonviral/AAV/retro	Rat [251, 253, 259, 260], Mouse [157, 257]
	Transcription factors for β(beta) cell transdifferentiation[d]	HDAd/FGAd/AAV	Mouse [262–266]
Hepatitis B	RNAi against viral RNA	AAV/FGAd/nonviral	Human, Mouse [50, 51, 155, 268–271]
Hepatitis C	RNAi against viral RNA	Nonviral	NHP [281], Mouse [120, 200, 280]
Liver cancers	p53	FGAd	Human [284, 285], Rat [283]
	None	Oncolytic Ad	Human [288–292]. Mouse

[a]TIMP (tissue inhibitors of metalloproteinases) antagonists include MMP mutants, antisense RNA and siRNA

[b]Anti-HSC (hepatic stellate cell) molecules include dominant-negative TGF-β(beta) receptor, TGF-β(beta) antisense RNA, BMP-7, CTGF shRNA, and PDGF receptor β(beta) shRNA

[c]Anti-ROS molecules include SODs, catalase, HO-1 and ferritin. Others include Bcl-2, IL-1 receptor antagonist, and CD40Ig

[d]Transcription factors for β(beta) cell transdifferentiation include Pdx-1, NeuroD, Btc, Ngn3, and MafA

Abbreviations: *FGAd* first-generation adenoviral vector, *HDAd* helper-dependent adenoviral vector, *NHP* nonhuman primate, *GSD* glycogen storage disease, *MPS* mucopolysaccharidosis, *G6PT* glucose-6-phosphate transporter, *OTC* ornithine transcarbamylase, *UGT1A1* UDP glucuronosyltransferase 1 family, polypeptide A1, *MMP* matrix metalloprotease, *uPA* urokinase-type plasminogen activator

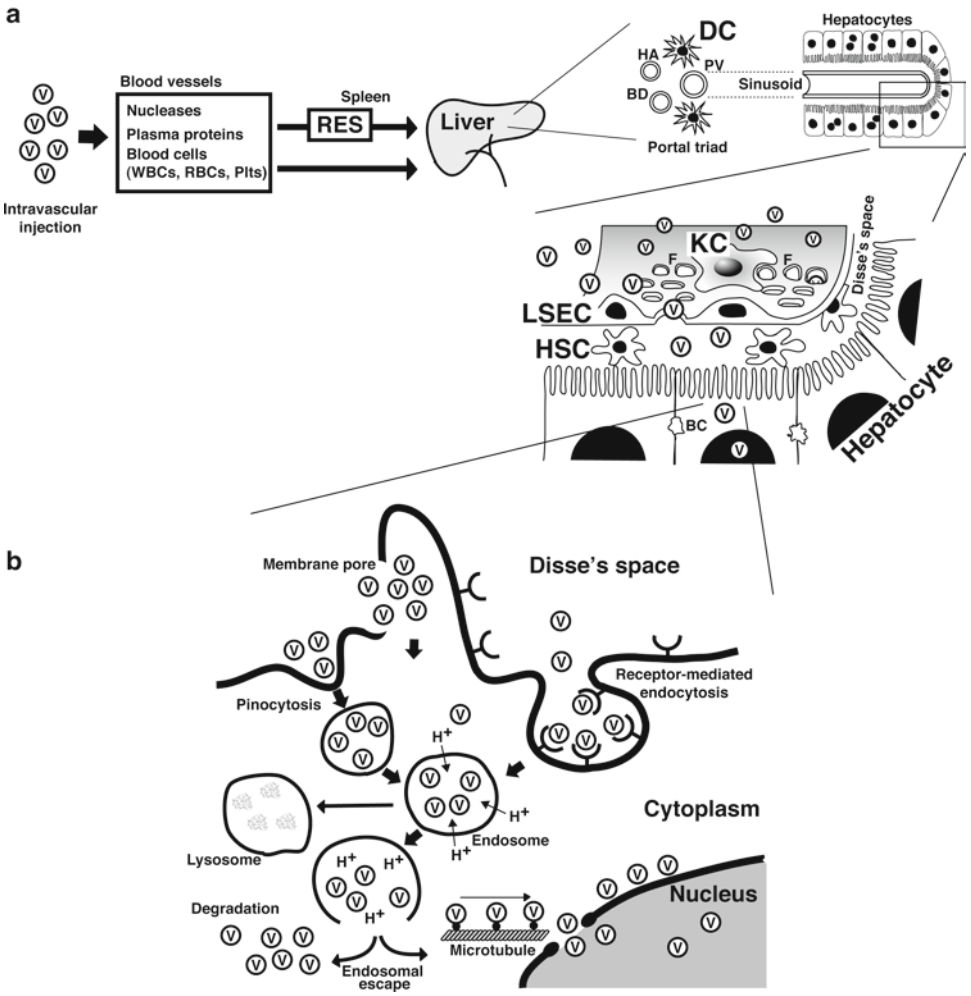

Fig. 23.1 Extra- and intra-cellular barriers in hepatic gene transfer. (**a**) *Potential extracellular barriers*. Intravascularly infused vector particles or molecules (depicted as *circled* V's) first encounter obstacles present in the blood (i.e., nucleases, plasma proteins and blood cells that degrade or sequester vectors). Before vectors reach the liver, the host's extrahepatic reticuloendothelial system (RES) such as spleen macrophages may take up vectors. Once vectors enter the hepatic circulation, vectors may be taken up by hepatic dendritic cells (DCs) that reside around the portal triads. The vector-engulfing DCs migrate to draining lymph nodes for antigen presentation, which may elicit a series of immune reactions. In liver sinusoids, Kupffer cells (KCs) and liver sinusoidal endothelial cells (LSECs) may trap vectors and eliminate them from the blood circulation. The LSEC barrier has small pores of 100–200 nm in diameter termed fenestrae (F) that allow small molecules to enter the space of Disse, where vectors can directly associate with hepatocytes. PEGylation of vectors (i.e., covalent attachment of polyethylene glycol to vector molecules) can overcome many of the above-mentioned extracellular obstacles. (**b**) *Potential intracellular barriers*. Vectors cross the plasma membrane by several different mechanisms that include receptor-mediated endocytosis, non-receptor-mediated endocytosis (pinocytosis), and internalization via membrane pores created by physical or mechanical methods. Endocytosed vectors need to disrupt the vesicles and escape from endosomes by taking advantage of viral machinery or endosomolytic properties of agents incorporated in nonviral vectors. Once vectors are released into the viscous cytoplasm, vectors need to be transported to the nucleus. Viruses can associate with dynein (depicted as black circles on a microtubule in the figure), the motor protein that walks along microtubules toward the nucleus, and are translocated to the perinuclear space. Nuclear import of viruses is an active process by which either viral genome or intact capsid can enter the nucleus. Unlike viral vectors, many nonviral vectors need to be equipped with artificial machinery that can overcome intracellular obstacles. Please note that the intracellular trafficking of vectors and potential barriers therein in this figure do not necessarily apply to all the vector systems. Abbreviations: *WBCs* white blood cells, *RBCs* red blood cells, *Plts* platelets, *HA* hepatic arteriole, *PV* portal vein, *BD* bile duct, *F* fenestrae, *HSC* hepatic stellate cell, *BC* bile canaliculus

presentation of internalized antigens to T cells. Surrounding the portal triads, reside a small number of DCs, the most important professional APCs, that migrate to draining lymph nodes and present engulfed antigens to T cells. Although KCs, LSECs and DCs all function as APCs, the hepatic DCs are relatively immature and are considered to be tolerogenic in comparison to their corresponding cells in the periphery [7]. This unique immunological microenvironment in the liver maintains a balance between immunity against pathogens and tolerance to harmless substances, such as food-derived foreign antigens. A disruption of the homeostatic balance between immunity and tolerance, leads to various

immune-mediated liver diseases, such as viral hepatitis, autoimmune hepatitis, and certain types of drug-induced hepatitis.

Recently, it has become evident that immune responses in gene delivery could pose a significant barrier to successful gene therapy. This is clearly the case from our experiences of the adverse events observed in adenoviral and AAV vector-mediated, liver-directed gene therapy trials in humans [2, 8]. Intrahepatic arterial infusion of a replication-defective first generation adenoviral vector led to the tragic death of Jesse Gelsinger, an 18-year-old boy who voluntarily participated in a dose escalation safety study of adenoviral vector-mediated gene therapy to treat ornithine transcarbamylase (OTC) deficiency [2, 9]. The infusion of a relatively high dose of adenoviral vector into the liver of Mr. Gelsinger induced an unexpectedly strong innate immune response against the adenovirus capsid proteins. This resulted in an overwhelming systemic inflammatory reaction leading to disseminated intravascular coagulation (DIC) and multiple organ failure (MOF) [2]. Since adenoviral vectors are selectively taken up by APCs in the liver and spleen in humans, it is presumed that APCs engulfing pathogenic adenovirus immediately secreted proinflammatory cytokines including IL-6, initiating systemic inflammatory reactions [2].

Similar immune-related effects were observed in a clinical trial investigating the therapeutic potential of recombinant AAV serotype 2 (AAV2) vectors for the treatment of severe hemophilia B. Intrahepatic arterial infusion of AAV2 vector induced AAV2 capsid-specific cytotoxic T lymphocytes (CTLs), eventually destroying vector-transduced hepatocytes in combination with mild liver toxicity [8]. This was unexpected since recombinant AAV was long considered to have little to no immunogenicity. These immune-related observations that were not predictable from all of the preclinical animal studies have prompted researchers to start devoting a substantial amount of effort to better understand the immunology of the liver so that more effective hepatic gene therapy applications can be established. Towards addressing these issues, significant advances have been made over the past several years in understanding the adenovirus-mediated innate immune responses [10]. Recent studies have elucidated the molecular sensors of adenovirus and subsequent signal transduction pathways that trigger the cascade of immune responses, which include the Toll-like receptor (TLR)-9/myeloid differentiating factor 88 (MyD88)-dependent and independent pathways that are activated by adenoviral genomic DNA [11] and the interleukin-1α(alpha) (IL-1α(alpha))-mediated proinflammatory pathway that is triggered by β(beta)3 integrin activation through binding to the arginine-glycine-aspartic acid (RGD) motifs of the viral capsid [12]. In addition, recent studies have underscored the roles of CD4+ CD25+ regulatory T cells (Treg) in AAV-mediated adaptive immune responses [13] and provided clues on how to avoid undesirable immune responses effectively either through the use of immunosuppressive regimens [14] or even by hepatic gene transfer itself [15]. Intriguingly, hepatic gene transfer can be utilized as a therapeutic strategy to suppress autoimmunity by taking advantage of the tolerogenic properties of the liver [16]. Although our knowledge in this new area is in its infancy, autoimmune diseases may become a common therapeutic target for hepatic gene therapy.

Vectors and Methods for Hepatic Gene Transfer and Their Mechanism of Action

Barriers in Hepatic Gene Therapy

For therapeutic molecules to function in target cells within a particular organ, gene therapy vectors and the *de novo* expressed therapeutic molecules need to overcome a number of extracellular and intracellular obstacles (Fig. 23.1). It is important to note that many viral vectors have evolved machinery to overcome intracellular barriers with high efficiency, but they are quite vulnerable to extracellular host defense systems when infused into the blood circulation. Entry of a significant amount of wild type virus particles into the blood does not occur in the course of a natural infection. For this reason, nature has never provided viruses the opportunity to evolve mechanisms to overcome extracellular barriers posed in such an artificial infection process, which is important aspect to consider for gene therapy processes. Unlike viruses, non-viral vectors require mechanisms to surmount not only extracellular hurdles but also intracellular ones that viral vectors can generally get over.

For the in vivo hepatic gene transfer approaches, vectors are first infused into blood circulation in most of the cases. Immediately after vectors are mixed with the blood, their journey to the site of action in the target cells is full of hardships as shown in Fig. 23.1a. Serum components represent the first obstacles for many vectors. Naked DNA and RNA are rapidly degraded with nucleases in the blood. Cationic liposomes and polymers become associated with negatively charged serum proteins and aggregate, forming particles too large to pass through capillary beds and become trapped in the first pass organ, mostly the lung. Adenoviral vectors become trapped by platelets, decreasing their bioavailability [17]. Vectors trapped by the blood components are then captured by the RES and quickly cleared from the blood circulation. Therefore, gene delivery vectors exhibit pharmacokinetic profiles unfavorable for systemic administration in most of the cases. Upon successful arrival to the liver, vectors face the next barriers, KCs and LSECs. KCs are macrophages

residing in the liver sinusoids and efficiently take up foreign particles. LSECs also contribute to the removal of vectors to some extent. LSECs are interspersed with fenestrae of approximately 100–200 nm in diameter and form a physical barrier to Disse's space into which microvilli of hepatocytes extend. It is difficult for particles bigger than the size of fenestrae to reach the hepatocytes [18]. Upon entry to Disse's space, vectors need to cross the negatively charged hydrophobic plasma membrane of hepatocytes, which represents the biggest barrier in gene delivery (Fig. 23.1b). Receptor-mediated endocytosis is the most desirable mechanism for vector uptake; however, in most of the cases, vectors enter cells in a nonspecific manner by mechanisms that remain largely unknown. Cytoplasmic degradation and nuclear transport represent the next obstacles. Endocytosed vectors are subject to degradation and need to escape from endosomes for nuclear transport before they are transported to lysosomes. Adenovirus capsid proteins can catalyze the lysis of endosomal membranes under acidic conditions [19], while many nonviral vectors need to be equipped with endosomolytic agents. It should be noted that cationic polymers such as polyethylenimine (PEI) have some intrinsic endosomolytic properties by the proton sponge mechanism [20]. Nonetheless, viral vectors, in general are very good at surmounting the above mentioned intracellular hurdles. The barriers in nucleus include uncoating vector particles [21], genome processing [22], chromatinization, and gene silencing [23, 24].

Adenoviral Vectors

Recombinant adenovirus (Ad) vectors are the most frequently used viral vectors for in vitro and in vivo experiments, in large part due to their high transduction efficiency in a wide range of cell types in a cell cycle-independent manner, including quiescent hepatocytes in the liver. The most commonly used Ad vectors are those derived from human Ad type 5 (Ad5). In nature, wild type Ad5 is pathogenic and causes self-limited upper respiratory tract infection (i.e., common cold); however, intravascularly infused recombinant Ad5 vectors exhibit strong tropism to the liver, which makes them highly attractive for hepatic gene therapy. For the purpose of hepatic gene transfer, first generation Ad (FGAd) vectors have been extensively studied since the early 1990s to examine their ability to treat monogenic diseases, including hemophilia, OTC deficiency, familial hypercholesterolemia, and α(alpha)1-antitrypsin deficiency. Although these pre-clinical studies showed some encouraging results, the increasing body of evidence from other pre-clinical studies and the unexpected tragic death of Jesse Gelsinger in 1999 demonstrated that early generation Ad vectors have significant drawbacks that limit their further clinical use for the treatment of monogenic diseases due to a number of immune-related problems. They are currently being superseded by helper-dependent Ad (HDAd) vectors, which can direct persistent transduction and exhibit less toxicity [25] as described later. Better safety profiles and persistent therapeutic efficacy of HDAd vectors have been shown in animal models for hemophilia A and B [26–30], glycogen storage diseases (GSDs) [31, 32], OTC deficiency [33], and familial hypercholesterolemia [34].

Adenoviruses are nonenveloped, icosahedral viruses of approximately 100 nm in diameter and their virions contain a single copy of double-stranded linear DNA genome. Wild type Ad5 has a 36-kilobase pair (kb) DNA genome containing a set of the early genes (E1, E2A, E2B, E3, and E4) and a set of the late genes (L1–L5). The tropism of the adenovirus was initially believed to be attributed to the 12 protruding fiber proteins bound to the penton base on the viral capsid. However, there are more recent studies demonstrating the importance of another part of the capsid, which is predominantly comprised of hexons. All of these three major Ad capsid proteins (fiber, penton base, and hexon) appear to play crucial roles in Ad5 infection. In most of the cases, Ad5 infection is mediated by the two-step infection mechanism. First, Ad5 fiber knob positioned at the end of each spike first binds to the coxsackievirus-adenovirus receptor (CAR). Second, the RGD motif in Ad5 penton base protein interacts with α(alpha)vβ(beta)3 or α(alpha)vβ(beta)5 integrins on cell surface, mediating virus internalization. However, infection of intravascularly infused Ad5 to hepatocytes occurs in a CAR independent manner [35], and the most recent studies support a model in which hepatocytes transduction with Ad5 in vivo is mainly mediated by coagulation factor X which bridges Ad5 hexons and an alternative receptor on the surface of hepatocytes [36].

Traditional FGAd vectors are replication-defective viruses with the E1 gene or often both E1 and E3 genes being deleted and replaced with an exogenous gene to be expressed. The E1 gene expression is essential for expression of other viral genes; therefore, E1-deleted Ad vectors do not replicate or produce progenies in infected cells and provide a level of safety with this vector system. Ad vectors with further modifications or deletions that abolish the functions of the E2 and/or E4 genes are referred to second or third generation Ad vectors; however, their advantages over FGAd vectors have remained unclear. Although they are still used for animal studies, early generation of Ad vectors are not appropriate for human use except for vaccination purposes or cancer gene therapy due to the following reasons.

First, to attain therapeutic benefits for hepatic gene therapy, early generation Ad vectors required high vector doses, which inevitably induced significant activation of innate immune responses, which, in some cases, were fatal. Mechanistically, intravascularly infused Ad vectors are first

taken up exclusively by phagocytic cells in the RES, particularly KCs, resulting in sequestration of infused Ad vector particles. The interaction between Ad vectors and KCs is, in part, mediated by blood components, especially platelets, forming virus-platelet aggregates that are eventually entrapped by KCs, leading to thrombocytopenia [2]. The sequestration of the Ad vector by the RES substantially reduces the number of vector particles that can reach hepatocytes and thereby necessitates the use of higher vector doses to achieve efficient hepatocyte transduction. This phenomenon is known as the "threshold effect" [37]. This effect makes it difficult to safely administer therapeutic doses of Ad vectors in humans. In addition, soon after vector administration, Ad vector-activated immune cells, particularly KCs and splenic macrophages initiate the production of various proinflammatory cytokines and chemokines by yet-to-be determined mechanisms. However, there is evidence that the activation of both intracellular sensors such as Toll-like receptor 9 (TLR9) and cell surface receptors such as integrin β(beta)3 are involved [11, 12]. Ultimately, this results in the induction of dose-dependent innate immune responses leading to significant systemic toxicity.

Second, therapeutic gene expression from early generation Ad vectors is transient and generally lasts for only a few weeks following hepatocyte transduction. This is primarily due to the induction of adaptive immune responses against viral proteins and therapeutic gene products, which generate cytotoxic T lymphocytes (CTLs) that specifically eliminate vector-transduced hepatocytes. It has been determined that Ad viral proteins, which in theory should not be expressed from E1-deleted Ad vectors, can be expressed at low levels from the adenoviral backbone genome sequence and serve as their own adjuvant in adaptive immune responses.

To overcome these drawbacks of early generation Ad vectors, HDAd vectors have been developed and become more widely examined as a viable gene transfer vehicle for the liver. HDAd vectors are devoid of all the viral coding sequences with only the viral inverted terminal repeats (ITRs) and packaging signal remaining in the vector genomes, which theoretically makes them safer than the early generation Ad vectors. The nomenclature "helper-dependent" comes from the fact that propagation of HDAd vectors in cells requires the co-infection of a helper virus to produce viral proteins in trans. HDAd vectors can accommodate therapeutic genes of up to 35 kb, but are often stuffed with noncoding mammalian genome-derived sequences, such as an intron from the human hypoxanthineguanine phosphoribosyltransferase (HPRT) gene containing matrix attachment regions (MAR). Care must be taken not to include heterologous DNA with negative effects on the vector, such as lambda phage DNA [38]. Although it is not possible to completely avoid the vector sequestration by the RES and the induction of innate immune responses, HDAd vectors can, in general, direct persistent transgene expression from the liver even though the adaptive immune responses against the viral capsid proteins are elicited. Encouraging results in early preclinical studies led to the advancement to the use of HDAd vectors in a clinical trial to treat a patient with severe hemophilia A in the early 2000s [30], but it lacked therapeutic efficacy while promoting acute hepatotoxicity and thrombocytopenia. More recent studies have greatly advanced HDAd-mediated hepatic gene transfer technologies toward clinical applications. Vector doses and liver transduction efficiency can be significantly decreased and increased, respectively, by delivering HDAd from the hepatic artery with the hepatic vein outflow temporarily blocked by a balloon occlusion catheter percutaneously inserted into the inferior vena cava [39]. In all, HDAd vectors are a significant improvement in the rational design of adenoviruses as gene therapy vehicles, but it is clear that further study is necessary to fully understand their potential as a consistently safe gene therapy modality.

Adeno-associated Virus Vectors

Recombinant adeno-associated virus (AAV) vectors are the most robust in vivo gene delivery vehicle for hepatic gene transfer among all of the currently available viral and nonviral vectors. Although the classical recombinant AAV vectors derived from AAV2 can transduce only 5–10% of hepatocytes in the liver at maximum, contemporary recombinant AAV vectors derived from newly identified serotype such as serotype 8 (AAV8) can achieve almost 100% hepatocyte transduction without any noticeable acute and chronic toxicity in animal models [40, 41]. And importantly, transduction or therapeutic gene expression can stably persist lifelong, as long as hepatocytes do not undergo substantial regeneration due to liver injury. Therefore, recombinant AAV vectors are particularly suitable for gene therapy for diseases that require persistent therapeutic gene expression in hepatocytes such as inborn errors of metabolism and hemophilia, and for diseases that require nearly complete hepatocytes transduction such as viral hepatitis. In fact, their therapeutic efficacy has been shown in the corresponding animal models [42–54].

AAV is a non-enveloped icosahedral replication-defective virus of approximately 20 nm in diameter. Unlike other viral vectors created from pathogenic viruses, AAV has never been associated with any human and animal diseases and elicits minimal or no innate immune responses, making recombinant AAV vectors attractive for clinical use. Wild type AAV has a single-stranded DNA genome of approximately 4.7 kb. Recombinant AAV vectors are devoid of all the viral genome sequence except for the 145-nucleotide

inverted terminal repeat (ITR) at each genome terminus. Recombinant AAV vectors derived from serotypes other than AAV2 have become widely available and are referred to recombinant AAV1, AAV5, and AAV8 vectors and so on. Except for recombinant AAV2 vectors, new serotype vectors are, in general, those that have recombinant AAV2 vector genome encapsidated with a viral coat derived from a serotype other than AAV2 (i.e., pseudoserotyped); therefore, they are often referred to AAV2/1, AAV2/5, and AAV2/8 and so on (genotype/serotype). For in vivo hepatic gene transfer, AAV2 vectors were widely used in preclinical and clinical studies; however, they are being superseded by more robust vectors such as AAV8 vectors [40] and surface-exposed tyrosine mutated AAV vectors [55]. AAV2 vectors become uncoated quite inefficiently in hepatocytes while uncoating of AAV8 vectors is a very rapid process, which might explain the robustness of AAV8 in hepatocytes [21]. Laminin receptor has been identified as one of the potential receptors for AAV8 [56]; however, the exact viral entry pathways of robust serotype vectors remain elusive at present. Capsid ubiquitination, which triggers AAV degradation by the ubiquitin proteasome system, requires phosphorylation of several key tyrosine residues by epidermal growth factor receptor protein tyrosine kinase (EGFR-PTK). Therefore, tyrosine mutated AAV capsids are resistant to ubiquitination and hence they can escape from degradation resulting in enhanced transduction [55]. Double-stranded (ds) or self-complementary (sc) AAV vectors have also become increasingly popular as a means to substantially increase transduction efficiency, although their packaging capacity is decreased to half [57]. DsAAV vectors can skip one of the rate-limiting steps in AAV vector transduction (i.e., conversion from single-stranded genomes to double-stranded DNA) and show 1–2 log higher transduction efficiency in the liver and other tissues compared to the conventional single-stranded vectors [58, 59].

The mechanisms of the persistent expression from AAV vector-transduced hepatocytes are yet to be fully understood. Unlike integrating retroviral or lentiviral vectors, the persistent nature of AAV vector-mediated hepatocytes transduction does not result from vector genome integration into the host genome [60]. In hepatocytes, vector genomes predominantly reside as episomal double-stranded circular genomes comprised of only therapeutic gene sequences and AAV-ITRs. The advantage of this genome configuration is that, as demonstrated with minicircles vectors [61], the episomal circular monomer AAV vector genomes have the ability to escape from gene silencing and allow long-term transgene expression presumably due to a lack of negatively-acting cis elements. Induction of immune tolerance to transgene products expressed by AAV vectors also contribute to the persistence in some instances. Studies have shown that recombinant AAV vector-mediated hepatic gene transfer quite often induces immune tolerance to immunogenic transgene products (heterologous proteins or neoantigens), particularly when the transgene expression is restricted to hepatocytes by the use of liver specific promoters [62]. AAV vector-mediated transgene expression in hepatocytes efficiently induces transgene product-specific CD4+ CD25+ regulatory T cells (Tregs) that suppress production of transgene-specific antibody and induction of cytotoxic T lymphocytes against vector-transduced hepatocytes, leading to immune tolerance to the transgene products and transgene-expressing hepatocytes [13].

Although vector genome integration is not the mechanisms for AAV vector-mediated persistent transgene expression in most cases, integration does occur in hepatocytes at nonrandom genomic sites with the ribosomal RNA gene, transcriptionally active genes, and DNA palindromes being significantly preferred [63, 64]. The frequency of integration in hepatocytes is low, but not negligible and is reported to be approximately 0.1% hepatocytes when vector is injected into newborn mice [65]. One study has shown that vector genome integration could cause insertional mutagenesis leading to hepatocarcinogenesis in wild type and mucopolysaccharidosis (MPS) type VII mice when newborn mice received AAV vector [66]. Others failed to show the link between AAV vectors and liver cancer development [67]. Although a question remains as to whether or at what frequency insertional mutagenesis could occur in larger animal models and humans, recombinant AAV vector-mediated liver gene transfer, in general, is considered to be safe.

Retroviral Vectors

Recombinant retroviruses are most commonly derived from gammaretroviruses, which are best exemplified by the murine leukemia virus (MLV). Retroviral vectors were first explored for hepatic gene transfer prior to any other type of viral vectors becoming available. Because of the intrinsic ability of retroviruses to integrate into the host genome, these viruses were initially touted as an ideal gene therapy system, particularly for the treatment of monogenic liver diseases that required life-long therapeutic gene expression. In fact, retroviral vector-mediated ex vivo hepatic gene therapy for familial hypercholesterolemia was shown to be effective in a rabbit disease model [68] and safe in a human clinical trial [69]. However, retroviral vectors are currently limited in use for hepatic gene transfer due to their inefficient ability to transduce hepatocytes in vivo. Induction of liver regeneration by administration of hepatocyte growth factor (HGF) is required for transduction in adult animals [70]. In addition, intravascular injection of retroviral vectors into adult animals induces CTLs against transduced hepatocytes [70]. A phase I trial of intravenous infusion of a retrovirus vector expressing human

coagulation factor VIII into adult severe hemophilia A patients did not show any efficacious outcomes [71], which discouraged further pursuit of this type of in vivo approaches to treat genetic diseases. At present, preclinical and clinical applications of retroviral vector-mediated in vivo hepatic gene therapy are considered mainly in the context of neonatal gene transfer. Neonatal hepatic gene therapy for mucopolysaccharidosis (MPS) type I, MPS type VII, and Crigler-Najjar syndrome by in vivo retroviral vector approaches has been studied in small and large animal models and has been shown to be effective and safe [72–75]. Taken together, retroviral vector-mediated approaches do not appear to be suitable for hepatic gene therapy for adult patients, and they are effective only in ex vivo or neonatal approaches. In addition, there remain ethical issues that need to be addressed for this type of approach to be utilized in fetuses or neonates.

Retroviruses are enveloped, spherical, positive-sense strand RNA viruses of 80–100 nm in diameter with glycoprotein surface projections. Their nucleocapsid contains two copies of polyadenylated single-stranded linear RNA genome of 7–11 kb. MLV has 8.3-kb genome containing the gag, pol and env genes. Recombinant retroviral vectors are made replication defective by replacing the most of the viral genome with a transgene, leaving only the long terminal repeats (LTRs) and short cis-acting elements including the packaging signal and primer binding site. Gammaretroviral vectors integrate into the host genome and express their transgenes only after the host cells undergo a cell division because viral genome integration requires nuclear membrane breakdown. The liver is a quiescent organ with very slowly dividing hepatocytes, the life span of which is several hundred days or more; therefore, it is difficult to transduce hepatocytes with retroviral vectors without any pharmaceutical or surgical intervention. In vivo administration of retroviral vectors are only effective in developing babies whose hepatocytes are still actively dividing, or when liver regeneration is induced physically (i.e., partial hepatectomy, blockage of hepatic circulation, etc.) or chemically (i.e., administration of liver damaging agents such as carbon tetrachloride, growth factors such as HGF and keratinocyte growth factor [KGF or fibroblast growth factor 7, FGF7], and hormones [e.g., thyroid hormone, T3]) [76, 77]. Although retroviral vector-mediated gene therapies were considered to be safe until recently, leukemia caused by gene therapy developed in five patients with X-linked severe combined immune deficiency (SCID) who were treated with retroviral vector-transduced hematopoietic stem cells [3, 78, 79]. This has raised a significant concern about retroviral vector-mediated insertional mutagenesis. It turned out that MLV vectors preferentially integrate near transcription start sites of the host genome [80], which decreases the chance of disrupting open reading frames of cellular genes while increasing the chance of activating a particular set of growth promoting genes/oncogenes (e.g., Lmo2) by inserting the strong viral LTR promoter near the 5′ end of the genes. In hematopoietic stem cell gene transfer, continuous cell division might help accumulate harmful genetic alterations and facilitate the selection for cells with growth advantage; however, this is likely not the case in hepatic gene transfer. Although the potential risk of retroviral vector-mediated hepatocarcinogenesis is considered to be low and no MLV vector-related hepatocellular carcinoma has been reported in animal studies [81], this issue may need further investigation. The use of self-inactivating (SIN) retroviral vectors with a deletion within U3 region of the LTR may overcome this issue to some extent and reduce the risk of insertional mutagenesis and vector mobilization. The U3 deletion abolishes the viral LTR's strong enhancer-promoter activity, and hence it is expected to avoid the activation of neighboring genes and transcription of viral genomic RNA upon integration. However, unfortunately, retroviral vectors with SIN LTRs are hampered by low titers. In addition, it remains to be addressed whether SIN retroviral vectors can indeed substantially decrease their oncogenic potential.

Lentiviral Vectors

Recombinant lentiviral vectors have recently gained much attention and have become increasingly popular in many gene delivery applications due to their ability to integrate into the host genome of not only dividing, but also non-dividing cells in vitro and in vivo and hence, stably transduce quiescent cells, including hepatocytes in the liver [82, 83]. The most widely used lentiviral vectors are those derived human immunodeficiency virus type 1 (HIV-1) coated with an envelope containing the glycoprotein (G) of vesicular stomatitis virus (VSV) (i.e., VSV-G pseudotyped HIV vectors). In hepatic gene transfer, the ability to integrate in both dividing and non-dividing cells has made lentiviral vectors particularly suitable for permanent genetic modifications of hepatocytes by both ex vivo and in vivo approaches. Primary hepatocyte transduction with MLV vectors in vitro is highly inefficient and requires induction of DNA synthesis or cell cycling by growth factors such as HGF. On the other hand, lentiviral vectors can achieve high or even nearly complete in vitro hepatocyte transduction without supplementation of a growth factor using a cell suspension of either freshly isolated hepatocytes or those thawed from frozen stocks [84]. Therapeutic efficacy of the lentiviral vector-mediated ex vivo approach has been shown in Gunn rats [85], an animal model for Crigler-Najjar syndrome, and its feasibility and safety has been demonstrated in non-human primates [86]. In vivo approaches, i.e., intravascular injections of lentiviral vectors, have been studied in animal models of hemophilia A and B [87–91] and several types of inborn errors of metabolism

including Fabry disease [92], Crigler-Najjar syndrome, [93] and mucopolysaccharidoses (MPSs) [94–97]. These studies have shown partial to full correction of the disease in prenatal, neonatal, and adult animals. Hepatocytes in prenatal and neonatal livers are more susceptible to transduction with lentiviral vectors than those in adult livers; therefore, in vivo intervention in the earlier stages of life is more effective than vector administration into adult animals [92, 96]. One drawback in lentiviral vector-mediated hepatic gene transfer is the potential induction of cytotoxic T lymphocyte (CTL)-mediated immune responses against the expressed transgene products, limiting the duration of transgene expression [88, 89, 93, 98]. However, this issue has recently been overcome in mouse models by using a combination of a liver-specific promoter and a microRNA (miRNA)-regulated system that maximally abolishes transgene expression in cells in hematopoietic lineages including APCs [99].

Lentiviruses are in the family, Retroviridae, and their vial genomes contain accessory genes in addition to the gag, pol, and env genes. HIV-1 has six accessory genes, the vif, vpr, vpu, tat, rev, and nef genes, which are involved in the pathogenesis of AIDS. Among these accessory genes, only the rev gene product is important for recombinant HIV vector production, and it can be supplied in trans. The third generation VSV-G pseudotyped HIV vectors, the most widely used lentiviral vectors at present, are devoid of all the accessory genes as well as the gal, pol, and env genes, are in a self-inactivating (SIN) configuration, carry only minimal cis elements, and are produced from at least four split components. This multi-component system minimizes vector genome recombination in packaging cells that may cause inadvertent production of replication competent viruses; therefore, it offers maximal biosafety. The VSV-G envelope facilitates fusion with cellular membranes of a variety of cell types and significantly increases the host range. When VSV-G pseudotyped HIV vectors are infused intravascularly in mice, the vectors mainly transduce the liver and spleen. Specifically, liver sinusoid endothelial cells (LSECs), KCs, and splenic macrophages, dendritic cells, and B cells are more efficiently transduced than hepatocytes [100, 101]. This not only poses the immune-related problem as described earlier, but also causes sequestration of vectors by non-hepatic cells, which makes gene transfer to hepatocytes inefficient and necessitates administration of relatively high vector doses for hepatocyte transduction [100, 101].

Despite the ability of lentiviral vectors to integrate non-dividing cells and transduce hepatocytes better than MLV vectors, the quiescent nature of hepatocytes makes hepatocyte transduction relatively inefficient as some studies have shown that efficient hepatocyte transduction in vitro and in vivo requires cell cycling [102, 103]. However, liver transduction could be enhanced by the use of newer versions of lentiviral vectors that carry additional cis-acting elements including the sequence responsible for forming a central DNA flap found in the HIV pol gene (i.e., the central polypurine tract (cPPT) and central termination sequence [CTS]) and woodchuck hepatitis virus posttranscriptional regulatory element (WPRE) [87, 100, 101, 104]. The inclusion of the central DNA flap markedly enhances nuclear transport of vector genomes in non-dividing cells [105, 106] and increases transduction efficiency in hepatocytes in vivo.

Insertional mutagenesis is always a concern in any integrating vectors and so is it to lentiviral vectors. Unlike MLV vectors, lentiviral vectors preferentially integrate in transcriptionally active genes with no preference for near transcription start sites [107]. This represents a safer spectrum of integration sites than that of MLV vectors [108]. In mouse models, SIN HIV-1 vectors are less oncogenic than MLV vectors [109], and in humans, there has been no evidence of oncogenesis attributed to HIV integration in patients with active HIV infection. For these reasons, the risk of insertional mutagenesis by lentiviral vectors has been considered to be significantly lower than MLV vectors. However, in May 2009, the French Medicine Agency reported that clonal dominance emerged in one of two β(beta) thalassemia patients infused with hematopoietic stem cells modified by a SIN HIV-1 vector. Clonal dominance is a consequence of insertional mutagenesis potentially leading to carcinogenesis, and has been observed in patients treated with retroviral vector-transduced hematopoietic stem cells [3, 78, 79]. Although leukemogenesis and hepatocarcinogenesis involve different oncogenic processes, the risk of insertional mutagenesis leading to liver cancer will need to be carefully addressed. One study has reported a frequent occurrence of murine liver cancers in lentiviral vector-mediated in utero and neonatal gene transfer [110]. The lentiviral vectors used in this study was equine infectious anemia virus (EIAV)-based vectors in SIN configuration and not HIV-1 vectors. To date, the cause of the tumorigenesis in this study has yet to be determined. In all, lentiviral vectors remain the most commonly used integrating vectors for hepatic gene transfer. Because integration is not an absolute requirement for persistent transgene expression in hepatocyte as demonstrated by other viral and nonviral vectors, and because there is a potential problem with insertional mutagenesis, non-integrating lentiviral vectors are being pursued as alternative methods to mediate persistent transgene expression in hepatocytes [111, 112].

Non-viral Vectors

Commonly used non-viral vectors can be categorized into the three main groups, according to the type of vector particle formulations; lipoplex, polyplex, and naked nucleic acids

in which cargos are complexed and protected with liposome, linear or spherical (dendritic) polymers, and nothing, respectively. In general, nonviral vectors have three major advantages over viral vectors; ease to manufacture on a large scale, absence of products derived from potentially infectious agents, and potentially low immunogenicity. Disadvantages include low in vivo transfection efficiency and short-lived transgene expression. In addition, certain types of vectors such as lipoplexes exhibit significant dose-dependent acute toxicities. Over the last two decades, there have been significant advances in nonviral vectors in the following three aspects: the development of new and improved nonviral carriers; the development of new technologies to physically or mechanically deliver genes to target cells; and the improved design of cargos (e.g., plasmid DNA) to avoid cellular innate responses and transgene silencing. In the context of hepatic gene transfer, particularly important are liver-targeting nonviral vehicles and naked DNA vectors in conjunction with hydrodynamics-based gene delivery [5, 6]. These new vectors and methods are currently under intensive investigation toward the establishment of gene therapy for hemophilia, liver fibrosis, diabetes, liver ischemia-perfusion injury, hepatitis and liver cancers, demonstrating proof-of-principle of the approaches in various animal models (Table 23.1).

Naked DNA vectors represent the simplest type of nonviral vectors. The proof-of-concept that naked DNA can be delivered and function in animal tissue by direct in vivo injection was first established in the muscle [113] and subsequently in other organs including the liver [114]. However, unless the hydrodynamics-based strategy is applied, simple intravascular injection of naked DNA vectors can achieve only limited transfection efficiency in the liver, which is too low to attain therapeutic efficacy to treat genetic diseases. Although nonparenchymal liver cells (i. e., KCs, LSECs, and HSCs) can be transfected to some extent, it is very difficult to transfect hepatocytes. Notwithstanding such inherent inefficiencies, intravascular infusion of naked DNA has still remained as one of the appealing approaches to treat acquired diseases that do not require high levels of transgene expression in the liver, such as liver fibrosis [115, 116].

In nonviral hepatic gene delivery, development of liver-targeting nonviral vectors is key to success and has been the major focus in the research. In most of the settings in hepatic gene therapy, vectors should be delivered intravascularly to the liver because local or regional transfection in liver cells should not be sufficient for therapeutic purposes. Since nonviral vehicles by themselves are not normally equipped with tissue or organ-specific targeting machinery, dissemination of vectors to non-target tissues is a significant concern in systemic administration of nonviral vectors. In this regard, it has been shown that liver targeting can be achieved by the incorporation of a liver-homing device into chemical formulations of the vehicles. Such a modification not only helps vectors home in the liver, but also has a potential to facilitate vector uptake by target cells by hijacking a receptor-mediated endocytosis pathway(s). Liver-targeting devices include: asialoglycoprotein receptor ligands such as asialoorosomucoid [117–119], apolipoprotein A-I [120] and hepatitis B virus (HBV) L antigen [121] for hepatocyte targeting; hyaluronan, which is the ligand for hyaluronan receptor for endocytosis (HARE), for targeting to LSECs [118]; vitamin-A for hepatic stellate cell targeting [122]; and liver-targeting synthetic peptides indentified from random peptide libraries by selection [123]. Using these targeting nonviral vehicles, therapeutic nucleic acids (plasmid DNAs, siRNAs, and oligonucleotides) can be delivered to hepatocytes or LSECs following intravascular vector injection. Therapeutic levels of blood coagulation factors VIII or IX could be expressed in mouse livers by intravenous infusion of a hepatocyte-targeting polyplex or LSEC-targeting nanocapsule encapsulating each corresponding therapeutic plasmid DNA [117, 118], or by intravenous injection of a human hepatoma cell-targeting HBV L particle-based vector in a mouse xenograft model of hepatocellular carcinoma [121]. A recent study has shown that efficient in vivo delivery of siRNA specifically to hepatocytes can be achieved by intravenous injection of siRNA conjugated with a polyethylene glycol (PEG)-shielded asialoglycoprotein receptor-targeting polymer that only disassembles in acidified endosomes and therefore mediates dynamic activation of siRNA specifically in hepatocytes [124]. Relatively efficient albeit no or less-specific delivery of cargos to hepatocytes via intravascular routes can be achieved by polyethylenimine (PEI) polyplexes, cationic liposomes including HVJ liposome [125], polycationic lipid-cholesterol liposome [126], and cationic-lipid protamine DNA complex [127]. However, vectors unequipped with a liver-targeting or shielding device may need to be infused directly into the hepatic circulation for efficient liver transfection. This is because cationic polyplexes and liposomes tend to associate with negatively charged blood components due to electrostatic attraction, resulting in aggregation and entrapment by capillary beds in the first pass organ, which is the lung, when infused intravenously. siRNAs conjugated with cholesterol or those conjugated with a liposomal formulation termed SNALP (stable nucleic acid lipid particles) can deliver siRNAs efficiently, although not specifically, to hepatocytes to knockdown target gene expression (e.g., the apolipoprotein B gene) [128–130]. Cholesterol-conjugated antagomir (i.e., chemically modified single-stranded RNA oligonucleotides complementary to microRNAs) can be delivered to hepatocytes in mice efficiently but not specifically by intravenous injection and mediate a marked reduction of endogenous microRNAs including liver-enriched miR-122 [131], which is a potential target for the therapy of hepatitis C [132] and hyperlipidemia [131].

Another important key to success is the design of cargos, which are most of the time plasmid DNA. Transgene expression cassettes constitute an integral part of plasmid DNA vectors; therefore, it is critical to design expression cassettes that can direct efficient and persistent liver-specific transgene expression. Hepatocyte-specific, strong enhancer-promoter elements that are currently widely used are chimeric elements comprising a promoter derived from either the α(alpha)1-antytripsin gene or the thyroid hormone-binding globulin (TBG) gene and an enhancer or a regulatory sequence derived from either the apolipoprotein E gene, the α(alpha)1-microglobulin/bikunin precursor gene or other types of liver specific elements [54, 133–136]. However, even with such strong liver-specific promoters, transgene expression from conventional plasmid DNA vectors persist only for a short period of time in hepatocytes, declining to baseline levels in days to weeks. Initially, the short-lived hepatic expression from plasmid DNA vectors was presumed to be mainly due to their non-integrative nature causing gradual loss of vector genomes overtime. However, it has turned out that plasmid DNA vector genomes can be stably maintained and do not necessarily disintegrate in hepatocytes even if transgene expression has disappeared. Now it has become clear that plasmid backbone sequences covalently attached to a transgene expression cassette can cause heterochromatinization of the neighboring transgene, leading to transgene silencing in hepatocytes for a not-yet-defined mechanism [23, 137, 138]. In addition, the presence of unmethylated CpG motifs derived from bacterial sequence in DNA cargos can have significant detrimental effects on transgene expression as described below [139–141]. Therefore, attention needs to be paid not only to transgene expression cassettes, but also to plasmid DNA backbones composed of bacteria-derived sequences.

An important issue in systemic intravenous injection of plasmid DNA vectors is that, when complexed with cationic liposomes (i.e., injected as lipoplex), vectors induce production of proinflammatory cytokines including interferon γ(gamma) (IFN-γ(gamma)) and tumor necrosis factor α(alpha) (TNF-α(alpha)) leading to acute inflammatory responses and hepatocyte damage [139–141]. These adverse effects are usually self-limited, but can be fatal. Studies have identified unmethylated CpG motifs present in plasmid DNA vectors as the main culprit of this toxicity [139]. CpG motifs in mammalian genomes occur at a much less frequency than those in bacteria-derived sequences, and cytosine residues in the motifs are frequently methylated. On the other hand, CpG motifs in bacteria-derived sequences are all unmethylated. This makes plasmid DNA vector genomes unusually unmethylated CpG-rich molecules serving as pathogen-associated molecular patterns (PAMPs) that are recognized by toll-like receptor 9 (TLR9) [142]. TLR9 mediates activation of the NF-κ(kappa)B pathway resulting in production of pro-inflammatory cytokines, although alternative pathways seem to be involved [142]. Interestingly, plasmid DNA or liposome alone does not cause the above toxicities, indicating complexity of the reaction [141].

Nevertheless, recent advances in understanding the mechanisms of action of nonviral vectors have led to clues on how to overcome the obstacles. CpG-methylated or CpG-depleted plasmid DNA have been created and proved to reduce acute toxicity [143]. It has been shown that plasmid DNA vectors linearized with a restriction enzyme(s) in such a way that plasmid backbone sequence is completely separated from its neighboring transgene expression cassette can avoid gene silencing and mediate life-long transgene expression at high levels in hepatocytes in rodents [23, 138]. In this approach, the DNA fragments containing only the transgene cassette and devoid of all bacterial sequences are self-circularized in hepatocytes, forming supercoiled double-stranded monomeric molecules termed "minicircles," which have the ability to escape from gene silencing [61, 137]. Minicircles can be produced in E. coli on a large scale using a bacteriophage Φ(phi)C31 integrase-based system and can mediate stable and long-term transgene expression in hepatocytes in vivo [61]. Certain types of liver-specific enhancer-promoters have been shown to escape the plasmid backbone silencing effects to some extent even in the presence of covalently attached bacterial sequences. Such liver-specific elements consist of a combination of one or more of the following elements: the human apolipoprotein E hepatic locus control region, the human albumin enhancer and/or promoter, the human α(alpha)1-antitrypsin promoter, and human coagulation factor IX intron A [136, 144, 145].

Hydrodynamics-Based In Vivo Transfection Method

Naked DNA vectors have recently gained significant attention as simple and potentially more efficient and safer nonviral vectors for hepatic gene transfer. This is mainly due to the advent of the hydrodynamics-based hepatic gene delivery, which was developed in late 1990s by two independent research groups [5, 6]. In mouse models, this method involves a rapid (5–7 s) injection of naked DNA in a volume of 8–10% body weight saline through the tail vein. With this rapid and high volume injection, up to 40% of hepatocytes can be transfected in mouse liver. The application of this approach is not limited to gene delivery with naked plasmid DNA vectors and can be extended to delivery of siRNAs, oligonucleotides, and other types of nucleic acids [146], and argumentation of transduction efficiency with viral vectors [147]. In fact, the therapeutic efficacy of this approach has been demonstrated in small animal models for various human diseases including

hemophilia [144, 148–151], inborn errors of metabolism [152–154], viral hepatitis [155], acute liver failure [156], diabetes [157] and cancers [158–162]. This method also provides an important tool to create new mouse models of human diseases [155, 163], to study biological functions of various gene products in vivo, and to optimize transgene expression cassettes in gene therapy vectors [134, 145]. One drawback is that the hydrodynamic method, even though effective in rodents, cannot readily be translated into the clinic due to the requirement of a large-volume intravenous infusion in a very short period of time, which would not be tolerated in humans. To overcome this obstacle, a computer-controlled hydrodynamic gene delivery system has been developed in which a computer connected to the infusion device monitors real-time intravenous pressure and controls the rate of infusion to follow the most appropriate venous pressure-time curve for hepatic gene transfer [164]. This system has been shown to direct plasmid DNA transfection in hepatocytes in pig liver at 2–3 logs higher efficiencies than those in previous pig studies by a minimally invasive procedure [165]. This approach will become increasingly feasible by further studies on efficacy and safety in large animal models.

The mechanism of action of hydrodynamic gene delivery has been partially elucidated. Rapid injection of a large volume of solution containing DNA significantly increases venous return to the heart, thereby increases cardiac preload which is far in excess of cardiac output, causing transient cardiac congestion. Rapidly elevated central venous pressure produces a backflow to the liver, and a significant volume of injected solution, which is minimally contaminated with the nuclease-rich blood, enters the liver sinusoids in retrograde. The increased fluid volume in the liver and the resulting force enlarge the fenestrae of LSECs, partially disrupt the structure of LESC layers, and create small pores in the plasma membranes of hepatocytes [166, 167], the process of which is called hydroporation [166]. This allows easier extravasation of DNA-containing solution, and enables DNA uptake via the membrane pores. Alternative mechanisms have been proposed that involve massive formation of endocytic vesicles in hepatocytes [168] or a receptor for DNA [169]. For more details, the reader is referred to the two review papers by the groups who have done pioneering research in this field [170, 171].

Transposon and Phage Integrase-Based Approaches: Sleeping Beauty Transposon and Phic31 Integrase Systems

Permanent insertion of transgenes into the host genome leading to stable expression of therapeutic gene products is an attractive approach for the treatment of many genetic diseases and some of acquired diseases. Until late 1990s, efficient in vivo vector genome integration could be attained only by the use of viral vectors. With the awakening of Sleeping Beauty (SB) transposons that can transpose (jump from one chromosomal location to another) in mammalian cells [172] and with the discovery that bacteriophage site-specific integrase phiC31 mediates integration of donor DNA sequences in specific genomic sites in mammalian cells [173], it has become possible to establish systems that allow insertion of foreign genetic materials into the host genome of mammalian cells with high efficiency and in a predicted manner. In both SB transposon and phiC31 integrase-based systems, donor DNA (vector) carrying a transgene is delivered to target cells together with transposase or integrase-expressing elements in a form of either DNA or mRNA. This results in integration of a portion of donor DNA containing the transgene (in the SB transposon system) or the whole donor DNA sequence (in the phiC31 system) into the host genome at relatively random locations (in SB transposon system) or at a limited number of locations (in phiC31 system). These two systems are currently widely used as efficient integrating vector systems in various in vitro and in vivo applications. Transposition or integration occurs in adult quiescent hepatocytes in mouse liver and human primary T cells without prior stimulation, making it most likely that the systems have the ability to modify the host genome in nondividing cells [148, 151, 174]. In the context of hepatic gene therapy, naked plasmid DNA vectors equipped with this integration machinery have been shown to mediate stable marker gene expression and have curative potential for hemophilia [118, 148, 151, 175] and metabolic diseases [152, 153, 176]. Although the systems have been utilized mostly in the context of naked DNA vectors, the integral elements can be incorporated in helper-dependent adenoviral vectors [177, 178] or nonintegrating lentiviral vectors [179, 180]. The advantage of the system is the ability to direct persistent and stable transgene expression upon hepatocyte division or liver regeneration, which may occur in association with normal growth in young children, hepatitis, or drug-induced liver injury, and experimentally in association with partial hepatectomy or administration of hepatotoxic agents such as carbon tetrachloride [60, 148, 175, 177]. Another potential advantage could be the ability to escape transgene silencing, which is an issue of episomal plasmid DNA vectors, although a study has shown that a significant fraction of integrated SB transposon vector genomes become silenced in vitro [24].

SB transposon is a synthetic DNA transposon that belongs to the Tc1/mariner family of mobile elements. This member of DNA transposons have been found in a wide range of lower and higher eukaryotes. Although nematodes and flies contain active elements, Tc1/mariner transposons in vertebrates are defective due to multiple inactivating mutations; therefore they are viewed as fossils that were once active at their birth. Phylogenic analysis of dead copies of the salmonid

subfamily of fish elements, identified consensus DNA and protein sequences, which led to successful reconstitution of a fully active transposase, SB10, by directed mutagenesis [172]. The SB transposon vector system involves co-transfection of a plasmid DNA containing a transgene placed between the two terminal inverted repeats of approximately 0.2 kb derived from a Tanichthys albonubes Tc1-like transposon and the second plasmid DNA or RNA expressing the SB transposase. In transfected cells, SB transposase binds on the two inverted repeats, precisely excises the transgene, cuts the target sequence at a TA dinucleotide, and mediates insertion of the excised piece of DNA into the host genome, the process of which is called a "cut and paste" mechanism [172]. Unlike HIV-1, MLV, and AAV vectors, which show significant integration site preference for particular genomic regions [63, 80, 107], SB transposons integrate relatively randomly although there are minor preferences for AT-rich regions and microsatellites [181]. Since the original SB10 was constructed, several new versions of hyperactive SB transposases have been identified by site-directed mutagenesis or using directed evolution techniques. Such newly evolved transposases can mediate transposition reactions at up to 100-fold higher efficiency in vitro; however, their in vivo activities have yet to be better characterized [182].

PhiC31 integrase is an enzyme encoded by Streptomyces bacteriophage phiC31 and mediates site-specific recombination between the attP site (attachment site Phage) in the phiC31 phage genome and attB site (attachment site Bacteria) in the host Streptomyces genome. In the recombination process, a crossover occurs between the attB and attP sites and allows insertion of the whole circular genetic material containing the attP site (donor) into the attB site in the host genome (recipient). The crossover creates two attB and attP hybrid sequences (i.e., the attR and attL sites) between which the donor sequence is inserted. An excision reaction between the attR and attL sites can occur, but it requires the phage-encoded excisionase. In mammalian cells, phiC31 integrase can recognize somewhat degenerate attachment sites, and mediate integration of attB site-carrying episomal circular donor DNA into degenerate attP sites in the host genome. Such degenerate attP sites are called pseudo attP sites. In mammalian genome, there are only a limited number of pseudo attP sites that are recognized by phiC31 integrase, which confers site specificity of the system [151, 173, 183]. Recent studies using in vitro culture cells have shown that at least 80% of integration events are likely a consequence of phiC31 integrase-mediated attB-pseudo attP recombination with 7.5–8.7% of integrations occurring at a specific pseudo attP sites in the human chromosome 19q13.31 [183, 184]. Other pseudo attP sites that have been identified as hot spots are the one at human chromosome 8p22 [173] and the mpsL1 site in the mouse genome [151]. The mpsL1 was originally identified as a hot spot of vector genome integration in the liver of mice that received a hydrodynamic injection of naked DNA vectors with phiC31 integration machinery; however, it did not represent a hot spot when the phiC31 integrase system was used in mouse liver in the context of helper-dependent adenoviral vector [178]. Although this system offers an attractive tool to restrict vector genome integration sites, recent studies have revealed that the system induces various types of genomic aberrations including deletions, rearrangements, and chromosomal translocations in vitro [183–185]. Such genomic aberrations are rarely found in the SB transposon vector system. Whether phiC31-induced genomic aberrations occur in vivo is yet to be determined. Studies are ongoing to further improve the system, which include the identification or creation of integrase variants with improved properties [186].

Gene Repair and Gene-Targeting-Based Approaches

Targeted repair of defective genes in somatic cells in vivo, if successful, would be the perfect approach for gene therapy for genetic diseases. The approach would result in no insertion of genetic materials that may contain elements detrimental to the host. In addition, it would not disrupt functional sequences in the host genome. Furthermore, repaired genes would be regulated in a physiological manner by their own autologous promoters. On the other hand, gene targeting approaches can insert therapeutic genes into a specific safe locus in the host genome or specifically disrupt dominant-negative disease genes. Different types of methods for targeted gene repair have been developed and are currently available. Among them, gene targeting by homologous recombination using zinc finger nucleases [187, 188] and gene targeting adeno-associated virus (AAV) vectors [189] represent the systems that are most efficient and have become increasingly popular. Studies have demonstrated efficient gene targeting or gene correction in vitro with the above-mentioned techniques using clinically relevant experimental models [190, 191], showing promise of these approaches for ex vivo gene and cell therapies. However, in vivo gene modification would be a significant challenge because efficiencies achievable with currently available methods are too low to be therapeutic. In the in vivo context, gene targeting AAV vectors could correct defective genes in hepatocytes only at frequencies of 10^{-4} to 10^{-5} of hepatocytes in mouse liver [192]. Other gene targeting strategies include single-stranded oligonucleotides, triplex-forming oligonucleotides, small fragment homologous replacement (SFHR), and chimeraplasts (RNA/DNA oligonucleotides) [193]. With these methods, successful targeted gene modifications can be achieved but at low frequencies, and improving targeting efficiency remains

as a significant challenge. Chimeraplasts-mediated in vivo hepatic gene correction once gained significant attention due to its impressively high gene modification frequencies with up to ~50% alleles being modified in rats [194, 195]. However, the efficacy of chimeraplasts has remained controversial because many laboratories have failed to reproduce such high efficiencies [196].

RNA Interference-Based Approach

RNA interference (RNAi) was discovered a decade ago and rapidly emerged as powerful tool to inhibit gene expression in a gene-specific manner [197]. Since then, introduction of RNAi into cells has quickly evolved into a novel approach with enormous potential for the treatment of various diseases [198, 199]. In general, RNAi-mediated targeted gene knockdown can be achieved by delivering either of the following elements into cells: small interfering RNAi (siRNAs), which are double-stranded linear RNA molecules of 19–25 bp with 2-nucleotide overhangs at each terminus; or nonviral or viral RNAi vectors that express short hairpin RNA (shRNA) transcribed by either RNA polymerase pol II or pol III promoter. In 2002, in vivo RNAi in mammals was first demonstrated in mouse liver by delivering naked siRNA to hepatocytes using a hydrodynamics-based in vivo transfection method [200]. Since then, many studies have investigated therapeutic potential of RNAi delivery as well as its mechanism of action using various animal models. In the context of hepatic gene therapy, we have now come to the point that one can deliver siRNA or shRNA to a substantial fraction or virtually all of hepatocytes and attain dramatic and persistent reduction of target gene expression in the liver, at least in animal models, by a single intravenous injection of AAV8 vectors [51] or repeat intravenous injections of newly-developed polyplexes [129]. Therapeutic efficacy or phenotypic changes due to targeted gene knockdown in the liver have been demonstrated in animal models of chronic hepatitis B virus (HBV) infection by HBV RNA shRNA expression [50, 51, 201, 202], acute liver failure by delivering siRNA against Fas or caspase 8 [156, 203], non-alcoholic fatty liver disease by fatty acid transport protein 5 (FATP5) shRNA expression [202], and arterial atherosclerosis by introduction of cholesterol-conjugated siRNA against apolipoprotein B (ApoB) [128].

However, accumulated experience of RNAi in mammalian cells has revealed new obstacles that impose significant challenges particularly in the in vivo use of RNAi for therapeutic purposes. First, although siRNAs had been thought to be short enough to evade the recognition of RNA sensors (e.g., protein kinase R (PKR), TLR3 and retinoic acid inducible gene-1 (RIG-1)) that trigger type I interferon responses, recent studies have revealed that siRNAs also serve as potential triggers of innate immune responses [204, 205], particularly when delivered with chemically synthesized vehicles [130]. Second, it has become evident that it is not easy to specifically knockdown only the target gene due to the difficult-to-control, widespread, off-target gene silencing effects [206]. This unintended gene silencing is mainly due to the microRNA-like off-target effects, the result of gene silencing mediated by a short ~7-nucleotide region analogous to the "seed region" found in microRNA [206]. The microRNA-like silencing of many unintended target transcripts has been demonstrated in the liver of mice receiving siRNA, adding greatly to the challenge of identifying siRNAs with perfect specificity in vivo [207]. Third, exogenously introduced siRNAs or shRNAs can be toxic in vivo and even lethal when they are highly expressed. AAV8 vector-mediated overexpression of shRNA in mouse hepatocytes could result in functional saturation of exportin 5, the endogenous microRNA nuclear export machinery, leading to fatal damage of hepatocytes [51]. Thus, although RNAi-mediated targeted gene knockdown represents a promising approach, the method is still in its infancy for clinical translation. Nevertheless, the research in this field is progressing very rapidly, and some of the obstacles have been overcome to some extent by the use of noninflammatory 2′ O-methyl-modified siRNAs [208], asymmetric interfering RNAs (aiRNAs) which reduce off-target silencing [209], or shRNAs expressed by a Pol II promoter [201], or by expressing interfering RNAs in the context of microRNA [210, 211].

Preclinical and Clincal Applications of Hepatic Gene Therapy

A summary of preclinical and clinical applications of representative hepatic gene therapies is provided in Table 23.1. The reader is referred to the references cited therein for details.

Hemophilia

Hemophilia is a group of X-linked inherited bleeding disorders caused by deficiency of either blood coagulation factor VIII (hemophilia A) or IX (hemophilia B). Hemophilia, particularly hemophilia B, is the genetic disease that has been most extensively studied in the context of hepatic gene therapy. This is attributed to the following features that make hemophilia the most attractive target disease for gene therapy. Only >1% levels of coagulation factors in the blood can significantly improve the symptoms of severe hemophilia (patients with <1% levels of coagulations factors).

In addition, the therapeutic window of transgene expression levels is pretty wide from 1% to supraphysiological levels; therefore, tight control of transgene expression by a regulated promoter is not necessary. Furthermore, both murine and canine hemophilia A and B models are available that faithfully recapitulate the human disease, and therapeutic efficacy in these animal models can be easily and reliable assessed.

In the 1990s and early 2000s, many preclinical studies using hemophilia animal models demonstrated safety and potential therapeutic efficacy of liver-directed approaches using retroviral, adenoviral, and AAV vectors. However, the studies have also revealed some limitations. The representative limitations in these earlier studies include very low transduction efficiency with retroviral vectors, short duration of transgene expression with adenoviral vectors, and occasional production of inhibitors against factor VIII or IX with any types of vector. Nonetheless, the strong safety profiles with many encouraging results in the earlier preclinical studies led to the initiation of the three liver-directed gene therapy phase I clinical trials in the United States between 1999 and 2001. These liver-directed trials were the single-treatment, dose-escalation study of gene therapy for severe hemophilia A by intravenous infusion of an MLV vector expressing B-domain deleted factor VIII [71], the trial of factor VIII gene transfer for severe hemophilia A by intravenous infusion of a minimal adenovirus (mini-Ad) vector carrying the full-length factor VIII gene [30], and the safety study in subjects with severe hemophilia B by hepatic arterial infusion of AAV2 vector expressing factor IX [8]. Although >1% levels were detected in all the trials with the highest level being 11% in the AAV2 trial [8], none of the clinical studies demonstrated persistent and stable expression of circulating blood coagulation factors in the blood, and the maximum duration of expression at therapeutic levels was limited to 8 weeks [8]. It is important to note that mini-Ad and AAV2 trials experienced significant adverse events; thrombocytopenia and hepatotoxicity in the mini-Ad trial resulting in early termination of this trial, and hepatotoxicity in the AAV2 trial [8]. A body of evidence has indicated that AAV2-capsid specific cytotoxic T lymphocytes were activated upon AAV2 vector infusion and destroyed AAV2-transduced hepatocytes in humans, which caused hepatotoxicity and limited the duration of transgene expression [8, 212]. Facing such immunological impediments, the current main research focus of hepatic gene therapy for hemophilia has been directed toward understanding immunology in gene therapy and establishing the strategy to avoid inhibitor formation and immune responses against viral capsids. An appropriate regimen that suppresses unwanted adaptive immune responses has been identified as a combination of mycophenolate mofetil (MMF) and sirolimus (rapamycin), an immunosuppressive regimen that does not eliminate Tregs [14]. This regimen is currently under investigation in a new clinical trial for AAV2-mediated liver-directed gene therapy for severe hemophilia B [90]. Self-complementary AAV8-factor IX vector [47] will also be tested in an upcoming clinical trial [90]. Although the following approaches are still in preclinical stages, safety and therapeutic efficacy has been demonstrated with hepatic gene delivery by AAV factor VIII vectors [48, 213], helper-dependent adenoviral vectors [26, 28, 29], and nonviral vectors [118, 148, 150, 214].

Inborn Errors of Metabolism

Inborn errors of metabolism constitute a wide range of categories of genetic diseases caused by defects of a gene involved in various metabolic pathways. Among them, GSDs and lysosomal storage diseases (LSDs) including MPSs are the representative target diseases for hepatic gene therapy. These storage diseases result from inability to catalyze a biochemical reaction(s) in a particular metabolic pathway(s) due to deficiency of an enzyme or an enzyme-associated protein (e.g., enzyme activator protein). The diseases also could be attributed to impairment of other types of biological activities such as deficiency in a transport protein. As a consequence, upstream or incompletely processed metabolites accumulate in multiple organs including the liver, spleen, brain, muscle, heart, bones, joints, eyes, vessels, bone marrow, and lymph nodes, showing complex and progressive clinical symptoms. The liver is commonly affected and often exhibits massive enlargement. Although many of GSDs and LSDs are monogenic diseases, not all of them are good targets for gene therapy. Some enzyme defects in GSDs affect only liver or skeletal muscle; however, many LSDs including GSD type II (Pompe's disease), affect various types of cells in multiple organs, making it in theory difficult to genetically correct all the affected cells by gene delivery. What makes hepatic gene therapy approaches quite feasible for the treatment of such systemic lysosomal diseases is "cross-correction" [215], the mechanism by which affected cells, remote from the liver, endocytose soluble lysosomal enzymes that are secreted into the bloodstream from genetically corrected cells. This endocytosis process involves mannose 6-phosphate receptors on the surface of the plasma membrane of cells to be corrected. In cells, lysosomal enzymes receive mannose-6-phosphate tags in the Golgi apparatus and are directed to and fused with lysosomes through binding to mannose-6-phosphate receptors on the inner surface of the Golgi membrane. A majority of lysosomal enzymes traffic to lysosomes in this manner under normal conditions; however, they can traffic to the plasma membrane and can be secreted when overexpressed in hepatocytes by gene transfer.

Gene therapy approaches to treat GSDs and LSDs favor intervention at earlier ages (i.e., neonatal gene transfer) rather than adult ages [72, 215]. Although vector injection at adult ages has been shown to be effective in animal models, it generally shows less therapeutic efficacy than neonatal injection and is often hindered by inhibitor formation [72, 96, 98, 215]. Neonatal gene therapy approaches have advantages, in that they can prevent many clinical manifestations before they become overt and potentially prevent unwanted immune responses against therapeutic proteins due to the immaturity of the immune system. In many applications of the neonatal gene therapy, the main target organ to be transduced is the liver, where hepatocytes and nonparenchymal cells undergo many cycles of cell division associated with growth of the host. Therefore, MLV and lentiviral vectors appear to be preferable because liver transduction with these integrating vectors in theory should not decline with growth once transduction has been established. In fact, neonatal gene therapy with MLV and lentiviral vectors has been shown to be effective in small and large animal models of MPS I [73, 96, 216], MPSVII [74, 217], Fabry disease [92] and Crigler-Najjar syndrome [75, 218]. In contrast, AAV vector-mediated hepatocyte transduction dramatically drops by >100-fold in weeks due to the episomal nature of AAV vectors when vector is injected into neonates [65]. However, AAV vector-mediated neonatal gene therapy is also effective in MPS VII mice [219]. Neonatal injection of AAV vectors can mediate transient albeit early elevation of transgene expression at high levels in the liver [65], which appears to be critical for successful prevention of clinical manifestations of the disease [72]. AAV8 vectors are outstanding in treating animal models of symptomatic inborn errors of metabolism due to their ability to transduce hepatocytes stably and at extremely high efficiencies when vectors are injected at older ages [42–45, 220].

Liver Fibrosis

Liver fibrosis is the consequence of chronic liver injury caused by a variety of causes, most commonly alcohol abuse, viral hepatitis, and non-alcoholic steatohepatitis (NASH). The process of fibrosis involves continuing hepatocyte damage and loss, continuing hepatocyte regeneration, and a progressive increase in extracellular matrix (ECM), which eventually leads to disruption of the architecture of the liver and severe hepatic dysfunctions. Historically, advanced liver fibrosis or cirrhosis was viewed as an irreversible disease stage. However, in the last two decades, our understanding of molecular pathogenesis of liver fibrosis has been greatly advanced, and now it is viewed as a dynamic process that involves a perturbed balance between profibrotic and antifibrotic mechanisms, and therefore liver fibrosis is potentially reversible by augmenting the antifibrotic mechanisms [221, 222]. Such contemporary concepts of the disease have opened a new avenue to the treatment of liver fibrosis by intervening the profibrotic and antifibrotic processes using gene delivery techniques. The potential gene therapy approaches include, inhibition of collagen production and enhancement of collagen degradation, the blockage of HSCs activation and induction of HSC apoptosis, protection from hepatocyte apoptosis and augmentation of hepatocyte regeneration, and modulation of inflammatory responses by cytokines.

The key players in liver fibrosis are hepatocytes, KCs, HSCs, a series of chemical mediators and enzymes derived thereof, and collagen, the major constituent of ECM in fibrotic livers. Hepatocyte injuries caused by various insults induce inflammation and release a variety of chemical mediates (cytokines, chemokines, and reactive oxygen spices (ROS)) from dying hepatocytes and their neighboring cells. These mediators activate HSCs directly and indirectly through the mediators released from KCs and T cells that become activated in the process of the innate immune responses. Upon activation, quiescent HSCs proliferate and undergo substantial phenotypic changes and transform into myofibroblast-like cells. The HSC-derived myofibroblasts are the major source of the increased collagen [223] and tissue inhibitors of metalloproteinases (TIMPs) in ECM. Myofibroblasts are also recruited from bone marrow [224]. HSCs produce metalloproteinases (MMPs) for tissue remodeling; however, their collagenolytic activity has been inhibited by increased levels of TIMPs secreted from activated HSCs. Based on such current knowledge about molecular pathogenesis of liver fibrosis, the following gene therapy approaches have been investigated and proven to be effective in liver fibrosis animal models such as carbon tetrachloride and bile duct-ligation models. Adenoviral vector-mediated overexpression of MMPs [225–228] or urokinase-type plasminogen activator (uPA) [229] in hepatocytes have been shown to enhance ECM degradation and hence regress liver fibrosis. Similar effects have been observed when the function of TIMPs is inhibited by TIMP antagonists delivered by adenoviral or nonviral vectors. Such antagonists include inactive MMP mutants [230], TIMP antisense RNA [231], and TIMP siRNA [232]. Transforming growth factor-β(beta) (TGF-β(beta)), platelet-derived growth factor (PDGF), tumor necrosis factor-α(alpha) (TNF-α(alpha)) and connective tissue growth factor (CTGF) have been identified as cytokines that activate HSCs and promote fibrogensis. Therefore, antagonizing these cytokines using gene delivery techniques represents potential approaches to inhibit HSC transformation and reduce the production of ECM. These types of approaches have been shown to be effective in the context of adenoviral vector-mediated hepatic expression

of dominant-negative TGF-β(beta) receptor [233], TGF-β(beta) antisense RNA [234] and bone morphogenetic protein-7 (BMP-7) that counteracts the TGF-β(beta)'s fibrogenic signaling [235], and plasmid DNA vector-mediated expression of shRNA against CTGF or PDGF receptor β(beta) subunit [236, 237]. Forced expression of hepatocyte growth factor (HGF) in the liver by viral or nonviral gene delivery [115, 116, 238, 239] has been shown not only to protect hepatocytes from apoptosis and augment regeneration, but also to possess antifibrotic activity, in small and large animals, by the mechanisms that include the suppression of the profibrotic TGF-β(beta) pathway and induction of MMPs [115]. A recent report demonstrates that intravenous injection of a vitamin A-coupled liposome can target HSCs via receptors for retinol binding protein and successfully ameliorate fibrosis in rat livers when this vehicle carries siRNA against the rat homology of human heat shock protein 47 (HSP47), a chaperone that facilitates collagen secretion [122]. Improvement of current vector systems and further elucidation of the molecular mechanisms of liver fibrosis will make gene therapy for liver fibrosis a more efficient and feasible approach for clinical application.

Ischemia-Reperfusion Injury

Hepatic ischemia-reperfusion injury is one of the serious complications in liver transplantation and could cause graft dysfunctions in the early phase after transplantation. It also occurs in many other pathologic conditions including trauma, shock, and surgical hepatectomy. Studies have identified key players and various important molecular mediators and signal transduction pathways responsible for the onset and progression of cellular damage in the dynamic process of hepatic ischemia-reperfusion injury. They include KCs, T cells, neutrophils, reactive oxygen species (ROS), damage associated molecular pattern molecules (DAMPs), proinflammatory cytokines such as TNF-α(alpha) and IL-1, nitric oxide (NO), and signal transduction pathways involving TLRs and NF-κ(kappa)B. Briefly, hepatic ischemia-reperfusion triggers release of an excess of ROS from activated KCs and induces oxidative stress in hepatocytes and sinusoidal endothelial cells. These liver cells also become exposed to increased levels of endogenous ROS released from mitochondria. This oxidative environment damages hepatocytes releasing DAMPs. ROS and DAMPs activate signal transduction pathways involving NF-κ(kappa)B and activator protein 1 (AP-1) in KCs, releasing proinflammatory cytokines and chemokines, which subsequently activate T cells and recruit neutrophils. Recruited neutrophils also release ROS and damage hepatocytes. Although it remains difficult to establish effective preventive or curative treatment of ischemia-reperfusion injury that is readily translatable into the clinic, several targets for molecular therapy have been identified and tested in animal models [240, 241].

The most common approach is to express antioxidant genes to counteract ROS and prevent tissue damage. In this context, over expression of superoxide dismutase 1 (SOD1 or Cu/Zn SOD) or SOD2 (Mn SOD) [242, 243], catalase [244], heme oxygenase 1 (HO-1) [245, 246], or ferritin [247] by hepatic gene delivery has been shown to attenuate liver tissue damage in animal models of liver ischemia-reperfusion injury. SODs and catalase scavenges ROS; HO-1 has cytoprotective effects; and ferritin sequesters ferrous ions (Fe^{2+}), the source of ROS. Other hepatic gene delivery approaches include expression of anti-apoptotic genes such as Bcl-2 in hepatocytes [248], expression of IL-1 receptor antagonist to suppress proinflammatory signals [249], and blocking the CD40-CD154 co-stimulatory pathway by CD40Ig expression, which suppresses T cell activation by APCs expressing CD40 on the surface membrane [250]. The majority of reported preclinical studies have utilized first generation adenoviral vectors to transduce donor livers in situ, which in some studies was followed by orthotopic liver transplantation in recipient animals. Adenoviral vectors have been preferred for this purpose due to the ease of production of high titer stocks, the high liver transduction efficiency, and the rapid onset of transgene expression; however, clinical application of this approach may require the use of more advanced and safer viral or nonviral vector systems.

Diabetes

Despite remarkable progress in the management of diabetes mellitus by oral drugs, insulin replacement therapy, and pancreatic islet transplantation with improved immunosuppressive regimens, no curative therapies are available and the current treatment still remains unsatisfactory. In this regard, gene delivery-based approaches hold promise as a long-term curative therapy for diabetes, in particular for type I diabetes. The approaches include delivery of cytoprotective and/or growth promoting genes to pancreatic β(beta) cells, genetic manipulation of immunomodulatory systems to prevent autoreactive T cell-mediated destruction of β(beta) cells, and gene delivery to hepatocytes to make insulin-producing cells in the liver.

A straightforward approach in liver-directed diabetes gene therapy is to deliver the preproinsulin (proinsulin precursor) gene to hepatocytes by means of viral or nonviral vectors [251]. This approach is often referred to hepatic insulin gene therapy (HIGT) [252, 253]. Since non-β(beta) cells including hepatocytes do not possess the specific endoproteases (prohormone convertases) that cleave proinsulin into mature insulin, the insulin gene used for HIGT has

generally been engineered in such a way that proinsulin can be efficiently processed into active and mature insulin by a ubiquitously-expressed endoprotease such as furin [254]. Physiological control of insulin secretion from engineered hepatocytes is possible to some extent by incorporating hormone and glucose-responsive elements in transgenes. Such positive and negative regulatory elements include those derived from the genes for insulin-like growth factor binding protein (IGFBP), L-type pyruvate kinase, glucose-6-phosphatase (G6Pase), glucose transporter-2 (GLUT2) and insulin [255–258]. In preclinical animal studies, various types of the insulin gene constructs with or without regulatory machinery have been delivered to hepatocytes in the contexts of adenoviral, retroviral, AAV, and naked DNA vectors, demonstrating sustained insulin secretion and phenotypic improvement of diabetic animal models [157, 251, 253, 259–261].

Although it is still in its infancy, an emerging and more compelling hepatic gene transfer approach is the induction of transdifferentiation of hepatic cells (hepatocytes and hepatic progenitor cells) to insulin-secreting β(beta) cells. The proof-of-concept that this approach can reprogram liver cells into β(beta) cells and indeed ameliorate the disease was first demonstrated in streptozotocin-induced diabetic mice injected with an adenovirus vector expressing the pancreatic and duodenal homeobox gene 1 (Pdx-1) [4]. NeuroD, betacellulin (Btc), neurogenin 3 (Ngn3), and RIPE3b1 (MafA), which are downstream factors of Pdx-1 in the course of pancreatic differentiation, also have the ability to drive the transdifferentiation process when they are delivered to mouse livers by adenoviral or Ad/AAV hybrid vectors [262–264]. When Pdx-1 or Ngn3 was expressed in the liver in the context of AAV or naked DNA vectors, their effect was substantially diminished [265, 266], but could be restored by irrelevant adenoviral vector coinfection [266]. This suggests potential roles of host proinflammatory responses in the transdifferentiation process triggered by overexpression of the key transcription factors. Nonetheless, generation of self surrogate β(beta) cells in the liver would provide a promising and effective approach and potentially solve many issues inherent to other therapies.

Viral Hepatits

Chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections are prevalent diseases, and approximately 400 and 200 million people are affected worldwide, respectively. They pose a significant health threat eventually leading to liver cirrhosis and hepatocellular carcinoma in a substantial portion of affected individuals. Currently available antiviral therapies using interferon α(alpha) (IFN-α(alpha)) and nucleoside/nucleotide analogs are effective only in a minority of the patients. Facing the limitations of current therapeutics, there has been an increasing enthusiasm for developing novel effective therapies by taking advantage of the emerging RNAi technology. HBV is an enveloped spherical virus containing a partially double-stranded DNA genome of approximately 3.2 kb. The genome is in a relaxed circular form maintained by overlapping 5′ ends of the two DNA strands. HBV life cycle is unique among DNA viruses, in that the viral DNA genome replicates via reverse transcription of viral mRNA. The negative-sense DNA strand is transcribed into four overlapping mRNAs with 3′ regions being shared. The longest is the 3.5-kb pregenomic RNA from which negative sense DNA strand is reverse-transcribed during viral replication. HCV is an enveloped spherical virus containing a positive-sense single-stranded RNA genome of approximately 9.6 kb. The 5′ untranslated region (UTR) of the viral genomic RNA contains an internal ribosome entry site (IRES) essential for translation of viral polyproteins, and in the 3′ UTR resides an element responsible for replication. HCV genome replication occurs through negative sense strands and is catalyzed by the virally-coded RNA-dependent RNA polymerase. Although the viral life cycles of HBV and HCV are significantly different, both involve RNA intermediates in viral genome replication. This makes RNAi-based approaches particularly effective for both viruses because RNAi not only eliminates viral proteins but also directly inhibits virus replication by destroying viral pre-genomic or genomic RNAs. Successful suppression of viral protein expression and viral replication by over 90% has been demonstrated in vitro and in vivo experiments in which RNAi was delivered into cells in a form of shRNA or siRNA using viral or nonviral vectors [267]. To introduce persistent RNAi to hepatocytes, adenoviral and AAV8 vectors expressing pol II or pol III promoter-driven shRNAs have been used [50, 51, 268, 269]. However, highly efficient nonviral methods for in vivo delivery of siRNA to hepatocytes have begun to emerge [124, 199, 270, 271] and they are expected to become increasingly common in the near future although repeated injections will be required for sustained effects.

In vivo efficacy of RNAi-based hepatitis B therapies have been investigated in mouse models of chronic HBV infection. The first model is HBV transgenic strains, the hepatocytes of which carry episomally replicating HBV genomes and secrete high titers of HBsAg, HBeAg, and HBV DNA into the blood circulation [50, 51, 268]. The other commonly used model is the murine hydrodynamic injection model of HBV replication, in which HBV DNA genome is delivered to the liver as plasmid using hydrodynamic tail vein injection [155]. This model also recapitulates HBV replication in human hepatocytes chronically infected with HBV. Target genomic sites for effective HBV RNAi are the sites that are contained in multiple HBV RNA species, such as the surface

antigen coding region [50, 51, 155, 268, 272]. Long-term inhibition of HBV replication in hepatocytes that lasts for at least 5 months has been demonstrated with AAV8 vectors [50, 51], while adenoviral vector-mediated shRNA delivery results in limited persistence up to several weeks [268, 269] and could trigger interferon responses even in the context of helper-dependent adenoviral vectors [273]. One shortcoming of the above animal models is that they do not develop chronic hepatitis; therefore, a question remains as to whether or not RNAi therapies can ameliorate chronic hepatitis in humans. Nonetheless, the first clinical trial for liver-directed RNAi-based therapy was initiated in United States in 2008. In this trial, plasmid DNA expressing four shRNAs that target different sites of the HBV genome are conjugated with liposome and delivered to patients' liver to treat chronic hepatitis B, according to the sponsoring company's press release.

As for hepatitis C gene therapy, although in vitro HCV replicon systems has been established [274], and significantly accelerated research on HCV virology and anti-HCV drug discovery, preclinical studies of hepatitis C gene therapy have been hampered by the lack of convenient animals models. The best mouse model for hepatitis C at present is SCID-Alb-uPA mice with humanized liver [275]. In this model, human hepatocytes transplanted in SCID-Alb-uPA mouse livers repopulate and replace mouse hepatocytes by selective destruction of mouse hepatocytes expressing urokinase-type plasminogen activator (uPA) [275]. However, this model is not readily available and has several issues including complexity of the system. Nonetheless, with the in vitro replicon system, RNAi-mediated suppression of viral protein expression and inhibition of viral genome replication by at least 80–90% has been demonstrated [276–279]. Targets for effective HCV RNAi include the NS5B region coding RNA-dependent RNA polymerase and 5′UTR [276–278]. Preclinical studies using rodents have shown that intravascularly delivered siRNAs or shRNAs by means of nonviral or viral vectors could substantially eliminate RNA molecules containing HCV-derived target sequences and suppress protein expression in hepatocytes [120, 200, 280]. However, whether RNAi-based approaches can inhibit HCV replication in vivo has yet to be addressed. In this regard, inhibition of viral replication by RNAi therapy has been demonstrated in the GB virus B/monkey system, a nonhuman primate model for hepatitis C [281].

Although RNAi-based therapies for chronic hepatitis B and C hold promise, there are issues as described in above (RNA Interference-Based Approach). Another important issue is that viruses would eventually become resistant to RNAi making the therapies ineffective. Because HBV's reverse transcriptase and HCV's RNA-dependent RNA polymerases are not proofreading enzymes and prone to introduce mutations, viruses can rapidly evolve in vivo and make a large pool of quasispecies, a population of viruses exhibiting genetic diversity. Antiviral therapies provide the power of selection that leads to the emergence of resistant clones from the pool of quasispecies. It is the Achilles' heel of RNAi that a single mismatch generated during virus evolution is enough to abolish the effect. Targeting multiple sites or alternative strategies will be required to overcome this issue.

Liver Cancers

Hepatocellular carcinoma (HCC) and metastatic colon cancer in the liver are difficult to treat with currently available therapeutic modalities due to their multifocal and chemoresistant nature. Therefore, gene therapy approaches for these two cancers have been enthusiastically investigated in preclinical animal studies and human clinical trials. The strategies can be classified into three categories: delivery of therapeutic molecules (genes or other types of nucleic acids) to cancer cells, delivery of therapeutic molecules to nonmalignant cells surrounding or associated with liver tumors, such as hepatocytes or tumor vessels, and virotherapy using oncolytic viruses. The first category includes p53 gene therapy, suicide gene therapy based on herpes simplex virus thymidine kinase or cytosine deaminase, TRAIL (TNF-related apoptosis inducing ligand) gene therapy, and immunomodulation by introducing cytokine genes. The second strategy creates the milieu suppressive to tumor growth by expressing cytokines, antiangiogenic factors, and antiproteolytic factors. In the context of hepatic gene delivery for liver cancers, adenoviral vectors have been most commonly used. Representative approaches that have been studied in human clinical trials are intravascular or intratumoral administrations of adenovirus p53 (Ad-p53) or oncolytic adenoviruses.

Ad-p53 gene therapy has been extensively studied in patients with advanced lung cancers, showing excellent safety and proof-of-principle of the approach [282]. This approach has also been shown to be effective against HCC in a rat liver tumor model, in which restoration of wild type p53 in p53 deficient liver tumors could suppress tumor growth and induce apoptosis following intrahepatic arterial infusion of Ad-p53 [283]. In the Ad-p53 human clinical trials, Ad-p53 was delivered to the liver via hepatic artery in combination with hepatic transcatheter arterial chemoembolization (TACE) in patients with advanced HCC [284, 285]. Although Ad-p53-mediated gene therapy for HCC in the current form did not appear to provide significant additional benefits over conventional therapies [284], the clinical studies demonstrated safety profiles of the therapy [284, 285].

Oncolytic adenovirus or conditionally-replicating adenovirus (CRAd) is an Ad that is designed to kill cancer cells by

taking advantage of its lytic life cycle. The principle of this strategy is to allow adenovirus to progress into the lytic life cycle only in cancer cells, leading to cancer-specific cell lysis. This can be achieved by either of the following: deletion or mutation of the Ad E1A or E1B gene, the gene product of which binds to Rb and p53, respectively, and inhibits their function; or driving the Ad E1 gene by a tumor-specific promoter such as the α(alpha)-fetoprotein (AFP) gene promoter. An oncolytic adenovirus in the former type, named *dl*1520 (ONYX) [286], was originally predicted to replicate and lyse cells only in cancer cells that do not express p53; however, it has turned out that cancer selectivity is not dependent on the status of p53 and rather it is mediated by other mechanisms including the loss of E1B55K-mediated late viral RNA transport that limits viral replication in normal cells [287]. Nonetheless, the excellent tumor specificity has led to dl1520-mediated clinical trials for metastatic liver cancers [288, 289], HCC [290], and hepatobiliary carcinomas [291]. The studies demonstrated safety, but revealed no significant responses. It should be noted that one patient who received dl1520 via the intrahepatic artery developed transient albeit grade 4 systemic inflammatory response [288], which is a reminiscent of the fatal adverse event in the Ad-OTC clinical trial [2]. A subsequent clinical study of dl1520 for the treatment of metastatic colon cancer in patients who failed prior chemotherapy has shown potential clinical benefits [292].

These earlier clinical studies with Ad-p53 and dl1520 showed only limited responses. However, various novel and potentially more effective approaches are currently under investigation in culture cells and experimental animals [293]. With the advanced technologies of in vivo gene delivery and novel therapeutic modalities such as RNAi, increasing knowledge about molecular pathogenesis of liver cancers will provide new opportunities for gene therapy to substantially improve therapeutic outcomes in difficult-to-treat liver cancers.

Conclusions

The liver is the most studied organ for in vivo gene transfer because the liver is involved in a variety of diseases, many vectors have inherent preference for the liver, and the liver provides an excellent platform to study various types of biologicals and drugs. Gene delivery technologies are rapidly progressing and it appears that we have started overcoming the biggest hurdle in hepatic gene transfer, i.e., inefficient delivery of therapeutic cargos to target cells in the liver. We now have modalities to deliver cargos to the liver with high efficiency and safety, at least in animal models. Immunological barriers, nonspecificity of vectors, requirement of high doses that may be toxic to humans, and uncertainty of long-term safety including the risk of hepatocarcinogenesis in humans, still remain as issues to be addressed and solved. With the solution of these issues, hepatic gene delivery would become an indispensable and common modality to treat various hereditary and acquired, and benign and malignant human diseases.

Acknowledgement Preparation of this chapter is in part supported by the National Institution of Health (R01 DK078388) and Cystic Fibrosis Foundation (R883-CR02). The author is most grateful to Nicole Kotchey, Frank Park and Christopher Naitza for their invaluable assistance in preparation of the manuscript.

Part IV
Basic Principles of Hepatobiliary Pathology

Chapter 24
Liver Cell Death

Harmeet Malhi and Gregory J. Gores

Introduction

Hepatocyte cell death is an indispensible and cardinal element that precipitates and perpetuates liver injury [1]. Accordingly, liver injury can result in acute or chronic liver disease. This distinction between acute and chronic liver disease is arbitrary; a reflection of the etiology and time course of liver injury. Hepatocytes are the predominant parenchymal cell type in the liver. Commonly encountered injurious stimuli, such as viruses, alcohol, fatty acids, and bile acids, primarily target hepatocytes [2–9]. Cholangiocytes and sinusoidal endothelial cells are targeted in a stimulus-specific and disease-specific manner, such as, in biliary disease, allograft rejection, and vascular insults [10–14]. These insults result in cell death which leads to secondary pathologic processes such as the occurrence of inflammatory infiltrates which further accentuate liver injury. The inflammatory cells mediate and facilitate cell death via secretion of cytokines [15]. Homeostatic renewal in the liver also hinges on cell death. In this instance, senescent or damaged cells are removed by apoptosis, as liver mass and function are renewed. This process ensues continuously and seamlessly from birth to death and is not associated with inflammation or with liver injury.

Several modes of cell death are described in liver diseases as in other organ systems [16, 17]. Apoptosis and necrosis in the liver can occur in any cell type and in response to various stimuli [2, 6, 7, 9, 13, 18–20]. Knowledge of these modes of cell death and their recognition in the liver is based on specific morphologic features and detection of specific signaling mechanisms in human disease as well as experimental models. One or both modes of cell death can be detected in the liver depending on the nature of the injurious stimulus. While features of both apoptosis and necrosis are observed at the organ level and activated at a cellular level, in the death of an individual cell only one mode of cell death is exclusively operative, i.e., either apoptosis or necrosis. When both pathways are activated, an intrinsic failure of one pathway to progress or exogenous blockage of one pathway leads to cell death via the alternative pathway [21, 22]. Necroptosis, a relatively newly named mode of cell death, refers to necrotic cell death that is manifest under very specific and well-defined conditions and is "programmed" similar to apoptosis. Necroptosis occurs in cells with a genetic, e.g., lack of caspase 8, or chemical, e.g., caspase inhibitors, blockade of apoptosis, upon stimulation with death receptors (DRs), Fas ligand, or tumor necrosis factor α(alpha) [23–25]. Thus, apoptosis and necrosis share many similarities. For example, they can be activated by the same stimulus and both are dependent on mitochondrial dysfunction. On the other hand, the cellular signaling pathways and resultant morphology are indeed distinct. In either case, understanding the mechanisms that lead to death is more important than classifying the morphology of the dead cell. In this chapter the authors first provide an overview of each mode of cell death; the role of membrane-bound intracellular organelles is also discussed in the context of each mode of cell death. The later portion of this chapter is focused on select molecular mediators of apoptosis that have a well-recognized role in liver cell death.

Overview of Apoptosis

Apoptosis is morphologically characterized by condensation of nuclear chromatin, membrane blebbing, nuclear fragmentation, and breakdown of the dying cell into membrane-bound apoptotic bodies [26]. This morphology is affected by a series of well-defined, active, energy-requiring, biochemical pathways that are conserved across cell types and intrinsic to the dying cell, which culminate in the activation of caspases (cysteine proteases which cleave at aspartate residues) [27] and endonucleases. Mechanistically, apoptosis can be triggered by extracellular or intracellular pathways (Fig. 24.1). Cell surface DRs and their cognate ligands activate the extracellular pathway of apoptosis. The intracellular (mitochondrial) pathway of apoptosis can be activated by a

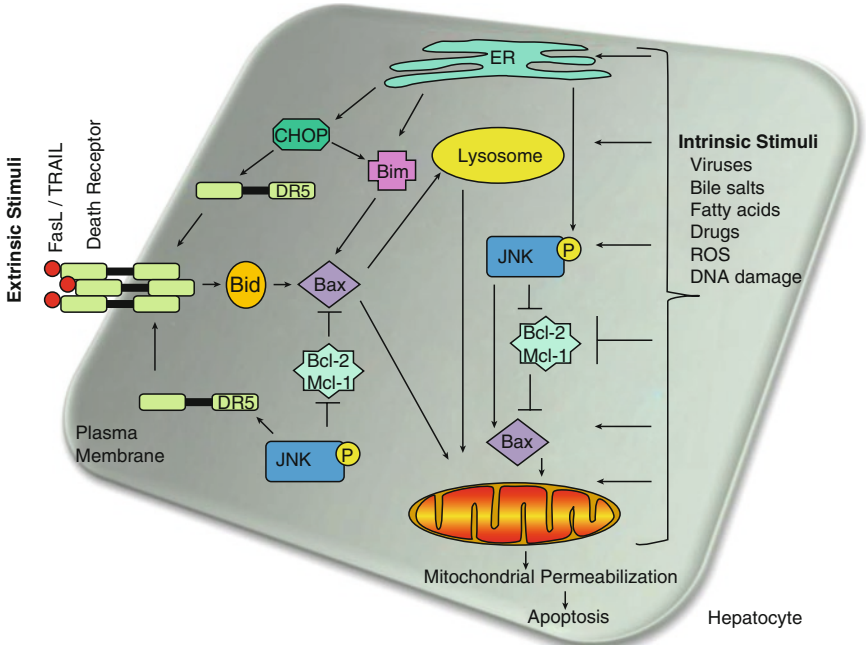

Fig. 24.1 Shared cellular apoptotic machinery. The extrinsic and intrinsic apoptotic pathways converge on mitochondria in hepatocytes. Extrinsic death stimuli, Fas Ligand (FasL) and tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), ligate with their cognate receptors, leading to receptor oligomerization and intracellular signal transduction. Tumor necrosis factor alpha (TNFα(alpha)), not shown here, activates a different signaling pathway. The success of death ligands in inducing hepatocyte apoptosis is further governed by the proapoptotic (Bid, Bax, Bim) and antiapoptotic (Bcl-2, Mcl-1) Bcl-2 family proteins. These can be activated by transcriptional or posttranslational events. Bid is cleaved by activated caspase 8 (not shown here), further activating Bax, which can permeabilize lysosomes and mitochondria. This process is inhibited by Bcl-2 and Mcl-1. Intrinsic apoptotic stimuli cause intracellular perturbations that activate the apoptotic machinery. Endoplasmic reticulum (ER) stress results in transcriptional upregulation of C/EBP homologous protein (CHOP), which further transcriptionally upregulated DR5 and Bim expression. C-jun N-terminal kinases (JNK) can activate Bax and inactivate Bcl-2 via phosphorylation. JNK can also transcriptionally enhance the expression of DR5. All these events culminate in mitochondrial permeabilization and postmitochondrial events, resulting in the activation of effector caspases and apoptosis

myriad of cellular stressors, e.g., metabolic stress including oxidative stress, DNA damage, chemotherapeutic agents, toxins, and intracellular calcium [1]. In type II cells, defined exclusively in the context of Fas signaling, hepatocytes being a prime example, mitochondrial involvement is an obligate requirement for the execution of apoptotic cell death, therefore apoptotic signals from the extracellular pathway also converge on mitochondria [28]. In isolated hepatocytes, attached to collagen or matrigel, Fas-induced apoptosis occurs in the absence of mitochondrial activation, converting the cells to type I; however, this phenomenon has only been observed in hepatocytes isolated from C57/Black 6 mice upon attaching the cells to collagen or matrigel matrix [29].

Homeostatic apoptosis in the liver, similar to developmental apoptosis, is nonimmunogenic, and apoptotic bodies are presumably effectively removed by hepatic macrophages, i.e., Kupffer cells within the liver. This process is difficult to detect in vivo; however, in experimental models, Kupffer cells effectively phagocytose hepatocyte apoptotic bodies [30]. This is based on recognition of specific cell surface signals on apoptotic bodies; the best recognized is phosphatidylserine. In health, a balanced activation of both proinflammatory (TNF-α(alpha)) and anti-inflammatory (TGF-β(beta) and IL-10) signals is observed in Kupffer cells upon engulfment of apoptotic bodies. On the other hand, apoptosis of infected or injured hepatocytes results in the activation of immune response and inflammatory pathways. The exact underlying mechanisms for immune activation by apoptosis of infected or pathologically injured hepatocytes are not fully understood. One possible, albeit simplistic, explanation is that this is a purely quantitative phenomenon. Homeostatic apoptosis and resultant immune activation are well regulated and of low-grade and occur without tissue injury. Pathologic apoptosis, on the other hand, either overwhelms the regenerative capacity of the liver as in fulminant hepatitis, or activates inflammatory cascades as in chronic hepatitis, leading to liver injury. The more complex and probable explanation is that injured and infected cells display distinct cell surface signals that communicate this "diseased death" to macrophages, leading to the activation of inflammation and immune cells. It is also probable that the actual contents of the apoptotic body contribute to the ultimate tissue response, inflammatory vs. noninflammatory. Activated lymphocytes and other immune cells are also removed by apoptosis; derangements in this process could also amplify

liver injury. Ongoing liver apoptosis activates regenerative pathways in the liver, and indeed, in an experimental model of Fas-induced apoptosis, hepatocytes resistant to apoptosis expand and repopulate the liver [31]. Furthermore, stellate cell (cells that line liver sinusoids and function as pericytes in health and myofibroblasts in disease) activation occurs upon engulfment of apoptotic bodies leading to hepatic fibrogenesis [32]. Stellate cell apoptosis, in turn, terminates the fibrogenic response activated upon engulfment of hepatocyte apoptotic bodies [19, 33, 34]. In animals resistant to Fas-induced hepatocyte apoptosis, abrogation of apoptosis is associated with decreased inflammation, injury, and stellate cell activation, thus mechanistically linking apoptosis, inflammation, and fibrosis in the liver [35].

The Extracellular Pathway

DR signaling forms the basis of the extracellular pathway of apoptosis. DRs are members of the tumor necrosis factor (TNF)/nerve growth factor superfamily [36, 37]. They are type I transmembrane proteins with an intracellular C-terminal tail and an extracellular N-terminal domain. These receptors share sequence homology in their intracellular or cytoplasmic portion that is designated the death domain (DD) and functions in the propagation of apoptotic signaling by permitting homotypic interactions with adaptor proteins that also contain the conserved DD. DRs are activated upon ligation by their cognate ligands. The receptor ligand pairs of significance in liver injury and disease are: tumor necrosis factor alpha (TNF-α(alpha)) and its receptor tumor necrosis factor receptor 1 (TNF-R1); Fas (CD95/Apo-1) and Fas Ligand (FasL); tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) and its receptors TRAIL receptor 1 (TRAIL-R1/DR4) and TRAIL receptor 2 (TRAIL-R2/DR5/KILLER/TRICK).

Oligomerized, ligand-bound receptors undergo conformational change bringing together the functional DDs and forming the death inducing signaling complex (DISC), which recruits adaptor proteins Fas-associated death domain (FADD) to form Fas and TRAIL-induced death inducing signaling complexes or TNF receptor-associated death domain (TRADD) in the case of TNF-α(alpha) via their DD (Figs. 24.2 and 24.3) [36, 38]. FADD and TRADD also possess death effector domains (DED) that share homology with the DED of procaspase 8 and 10. Procaspase 8 and 10 bound to the DISC undergo activation by presumably an "induced proximity" model, according to which there is autoproteolytic cleavage and activation of caspase 8 and 10 [39]. Caspase 8 cleaves the cytoplasmic protein proapoptotic Bcl-2 family protein Bid into two fragments; one of these two fragments designated tbid (retains the BH3 domain) translocates to the mitochondria and leads to mitochondrial permeabilization via activation of proapoptotic proteins Bax and Bak (discussed further in the following text). This is the so called Type II signaling paradigm in hepatocytes [28, 40]. In contrast, lymphocytes produce sufficient active caspase 8 at the DISC to directly activate the effector caspase 3, bypassing the need for mitochondrial dysfunction, in Type I signaling.

Cellular FLICE like inhibitory protein (cFLIP) is an important regulator of the extrinsic pathway of apoptosis at the level of the DISC [41]. cFLIP shares sequence homology with procaspase 8, and therefore, binds to FADD interfering with binding and activation of procaspase 8. The expression of cFLIP is upregulated by nuclear factor κ(kappa)-B (NF κ(kappa)B), such as in response to TNF-α(alpha) signaling or dexamethasone signaling [42]. Degradation of cFLIP via ubiquitination and the proteasome is a regulated process and sensitizes cells to apoptosis [43].

The BCL-2 Family of Apoptosis Regulators

Proteins of the Bcl-2 family are important intrinsic regulators of the mitochondrial apoptosis pathway [44]. Bcl-2 proteins share 1–4 structural domains designated Bcl-2 homology (BH) domains, which impart different functions to these proteins. The antiapoptotic members share all four BH domains and include Bcl-2, Bcl-XL, Mcl-1, A1, Bcl-W, and Boo. BH123 proteins and BH3-only proteins form the two subfamilies within the proapoptotic Bcl-2 proteins. Bax and Bak are the BH123 proteins of importance in hepatocyte apoptosis as they are essential for mitochondrial permeabilization [45]. The BH3-only proteins are the most numerous Bcl-2 proteins, including Bad, Bim, Puma, Noxa, Bid, Bik, Hrk, and Bmf [46]. The Bcl-2 antiapoptotic proteins and Bax and Bak, in addition to their well-recognized role in mitochondrial permeabilization, also are associated with other membrane-bound organelles, including the endoplasmic reticulum (ER) and nuclear membranes [47]. The BH3-only proteins vary in subcellular localization and abundance. They are either activated or expressed in response to specific intrinsic apoptotic stimuli and with respect to Bid, extrinsic DR signaling. The variety is not an expression of redundancy, but provides the ability to respond to different intrinsic apoptotic stressors by activating distinct BH3-only proteins, e.g., JNK activates Bim, and DNA damage leads to p53-dependent expression of Noxa and Puma [48, 49].

Activation of Bax and Bak by intrinsic apoptotic stimuli is proposed to occur by several different mechanisms. Some BH3-only proteins are direct activators of Bax and Bak, e.g., tBid, Bim, and Puma [50]. Some other BH3-only proteins act indirectly as "activators" of Bax and Bak by facilitating their release. In this model, the antiapoptotic proteins bind and sequester Bax and Bak, and these "activators" displace Bax

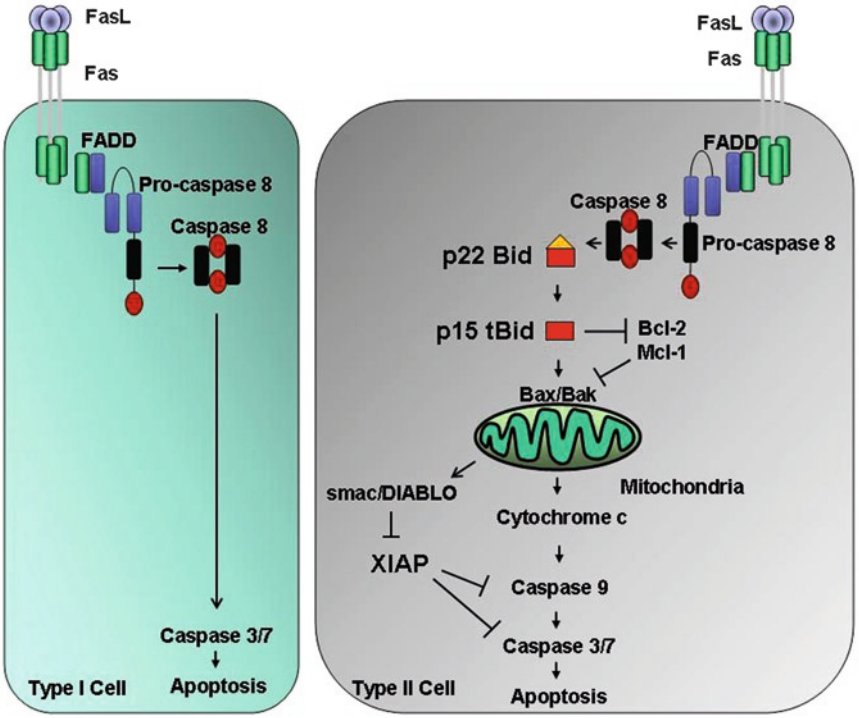

Fig. 24.2 Fas signaling. The death receptor Fas is activated upon ligation with its cognate receptor, Fas Ligand (FasL), on its extracellular domain. This results in receptor oligomerization and intracellular signal transduction based on homotypic interaction between the intracellular death domains (shown in *green*) of Fas and Fas-associated death domain (FADD), an adaptor protein. FADD recruits procaspase 8 via conserved death effector domains (shown in *blue*), resulting in autoproteolytic cleavage and formation of active caspase 8. In a type I cell, such as a lymphocyte, active caspase 8 is sufficient to activate caspase 3 and 7, leading to apoptosis. In a type II cells, such as a hepatocyte, Bid is cleaved by caspase 8 to truncated Bid (tBid), followed by tBid-induced activation of Bax/Bak and mitochondrial permeabilization. Mitochondrial permeabilization releases proapoptotic effectors, including second mitochondrial activator of caspases/direct IAP binding protein with low pI (smac/DIABLO), which inhibits X-chromosome linked inhibitor of apoptosis (XIAP), releasing active caspase 3 from inhibition. Bid and XIAP expression are critical determinants of type II signaling

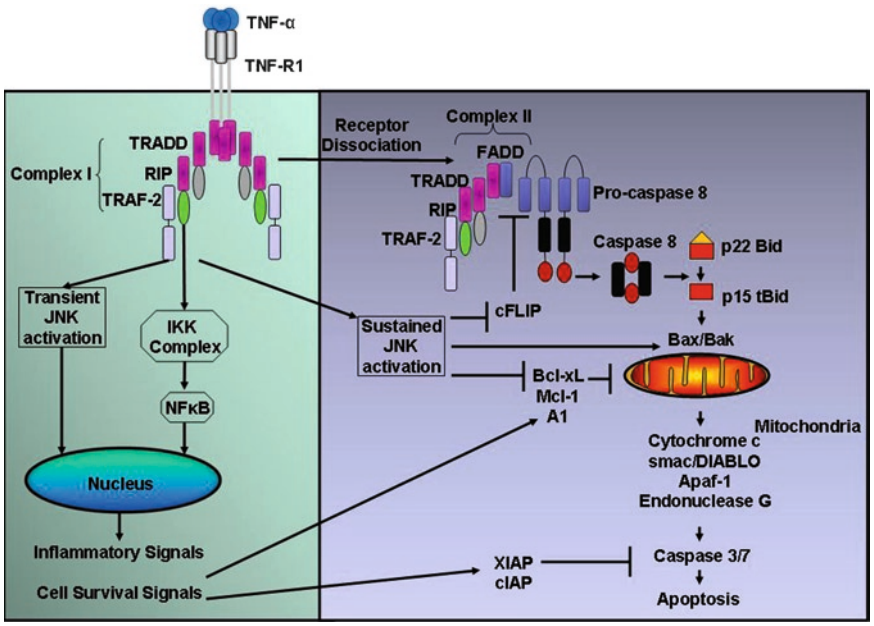

Fig. 24.3 Tumor necrosis factor alpha signaling. Tumor necrosis factor alpha receptor 1 (TNF-R1), upon activation by binding its ligand, tumor necrosis factor alpha (TNFα(alpha)), initiates two sets of signals, designated complex I and complex II. The adaptor proteins tumor necrosis factor receptor-associated protein with death domain (TRADD), RIP, and TNF-associated factor 1 (TRAF-2) form the adaptor protein complex that activates nuclear factor κ(kappa)B (NFκ(kappa)B) and c-jun N-terminal kinase (JNK). Following this, the receptor complex dissociates from TNFα(alpha), undergoes a conformational change, and is internalized. With recruitment of the adaptor protein Fas-associated death domain (FADD), complex II is formed with processing and activation of caspase 8, Bid, and mitochondrial permeabilization

and Bak from antiapoptotic Bcl-2 protein binding and inhibition, so that they can execute mitochondrial permeabilization. Other BH3-only proteins can directly neutralize antiapoptotic Bcl-2 proteins; however, this would not be sufficient to trigger cell death without the activation of Bax and Bak [51].

The Mitochondrial/Intracellular Pathway

Mitochondria are organelles consisting of two specialized membranes, an inner mitochondrial membrane and an outer mitochondrial membrane, and two compartments. This dual membrane structure forms the intermembrane space which contains proapoptotic proteins. The inner mitochondrial membrane is folded into cristae and the compartment it forms contains the mitochondrial matrix. The proapoptotic proteins contained in the intermembrane space are cytochrome c, SMAC/DIABLO (second mitochondrial activator of caspase/direct IAP binding protein with low pI), HtrA2/Omi, AIF (apoptosis-inducing factor), and endonuclease G [52, 53]. The outer mitochondrial membrane is impermeable to these proapoptotic proteins, thus sequestering them till mitochondrial permeabilization signals are received. Bax translocates to mitochondria from the cytoplasm upon activation, and Bak, which is located on the mitochondrial outer membrane, undergoes a conformational change upon activation, form homooligomers that lead to mitochondrial outer membrane permeabilization (MOMP), and permit the release of cytochrome c [54]. Cytochrome c release occurs well before mitochondrial swelling or rupture. Cytochrome c associates with apoptotic protease activating factor 1 (Apaf 1) and adenosine triphosphate (ATP) to form the apoptosome that cleaves and activates procaspase 9. Caspase 9 then leads to the activation of terminal, effector caspases 3 and 7 [39]. These effector caspases and endonucleases released from mitochondria target cellular and nuclear proteins and result in the well-recognized apoptotic morphology. The magnitude of caspase 3 activation and its interaction with XIAP also determine cellular response to Fas. Robust caspase 3 activation leads to Type I cells, whereas in Type II cells, XIAP binds to and inhibits active caspase 3 [40]. The alternative theory of mitochondrial permeabilization is based on the mitochondrial permeability transition pore complex (MTP) and mitochondrial permeability transition (mPT) and does play a role in other modes of cell death such as ischemic cell death and it is discussed further in the section on necrotic cell death.

Lysosomes

Lysosomes are membrane-bound organelles that contain hydrolytic enzymes that function at an acidic pH and perform the vital role of breakdown and degradation of endocytosed macromolecules and obsolete and senescent subcellular components; the later process is known as autophagy. Lysosomes contain a variety of hydrolytic enzymes including proteases, known as cathepsins, and therefore possess the tools necessary for participation in cell death [55]. Total lysosomal rupture with release of all their content leads to necrotic cell death, whereas selective permeabilization, such as by the proapoptotic protein Bax, participates in apoptosis. In hepatocytes, lysosomal permeabilization leads to selective release of cathepsins and occurs upstream of mitochondrial permeabilization in the apoptotic cascade [56]. It is well accepted that cathepsins B, D, and C, of the known 11 mammalian cathepsins, participate in apoptosis. Furthermore, lysosomal involvement in hepatocyte apoptosis is not universal and occurs only in response to specific stimuli. It can be secondary to extrinsic or DR-mediated signals or be activated by the intrinsic pathway [57, 58]. Lysosomal participation has been observed in apoptosis secondary to Fas, TNF-α(alpha), bile salts, free fatty acids, ceramide, photodamage, and reactive oxygen species.

The availability and utilization of cathepsin B deficient mice in various models of liver injury has demonstrated a role for the lysosomal pathway in hepatocyte apoptosis. Isolated hepatocytes treated with TNF-α(alpha)/Actinomycin D to induce apoptosis demonstrate cathepsin B release into the cytosol [56]. Furthermore, purified lysosomes can be permeabilized by caspase 8, and cathepsin B can in turn permeabilize mitochondria, a process enhanced in the presence of cytosol. Cathepsin B deficient mice are protected from the apoptotic effects of TNF-α(alpha) administration. In this model Bid is required for selective lysosomal permeabilization; however, Bax activation is independent of cathepsin B release [59]. In the bile duct-ligated mouse model of cholestatic liver injury, cathepsin B deficiency protects against hepatocyte apoptosis and its consequences, liver injury, and fibrosis [60]. Free fatty acids can activate Bax leading to lysosomal permeabilization and release of cathepsin B [57]. Furthermore, Bax inhibition prevents free fatty acid-induced Cathepsin B release [61]. Animals fed a high fat diet develop liver steatosis and increased hepatic cathepsin B activity. Glycyrrhizin stabilizes lysosomal membranes and prevents free fatty acid-induced and high fat diet-induced increase in cathepsin B activity [62]. Lysosomal enzyme activity in serum is elevated in chronic liver diseases [63, 64]. Nonselective or total lysosomal permeabilization likely plays a role in necrotic cell death as elevated lysosomal enzymes are also observed in fulminant hepatic failure [65].

Endoplasmic Reticulum

The ER forms a network of specialized and dynamic membrane-bound organelles that hepatocytes and other secretory cells are enriched in. The unfolded protein response

is activated upon accumulation of misfolded or unfolded proteins in the ER, a state of ER stress due to excess "client proteins." [66] Alterations in calcium homeostasis, glucose deprivation, tumicamycin, UV irradiation, oxidative stress, and obesity can also lead to ER stress (Fig. 24.4). A series of ER stress-specific responses are activated that are aimed at minimizing misfolded proteins from accumulating [67]. The ER-associated degradation of proteins (ERAD) facilitates removal of defective proteins. Global translation attenuation decreases new protein synthesis, with selection upregulation of specific proteins, such as ER chaperones to allow the ER to adapt to the misfolded protein load. Lastly, apoptosis mediators are activated as well, especially during unresolved or protracted ER stress. The UPR is characterized by the activation of three resident ER transmembrane stress sensors, inositol requiring enzyme 1 alpha (IRE-1 alpha), activating transcription factor 6 alpha (ATF-6 alpha), and RNA-activated protein kinase (PKR)-like ER kinase (PERK). Each of these is temporally regulated and has distinct downstream effects. IRE-1 alpha functions as a protein kinase as well as endoribonuclease. It cleaves the transcription factor XBP1 to form spliced XBP1 (sXBP1) that activates many genes involved in the UPR and ERAD. IRE-1 alpha can also bind the TNF receptor-associated protein 2 (TRAF2) leading to JNK activation and can interact with Bax and Bak, thus effecting apoptosis. PERK is a Ser/Thr protein kinase, activated by autophosphorylation, which phosphorylates and inactivates eukaryotic translation initiation factor 2 alpha (eIF2α(alpha)); however, activating transcription factor 4 (ATF4) remains active and induces C/EBP homologous protein (CHOP) expression. ATF6 is cleaved and released into the cytosol, and then translocates to the nucleus. The transcription factor CHOP has binding sites for ATF4, ATF6, and XBP1 in its promoter, and its expression is partially regulated by all three ER stress sensors.

Sustained or severe ER stress can activate apoptotic pathways in several ways. Calcium homeostasis is sensitive to the Bcl-2 family proteins [68]. Bcl-2 and Bcl-xL can reduce

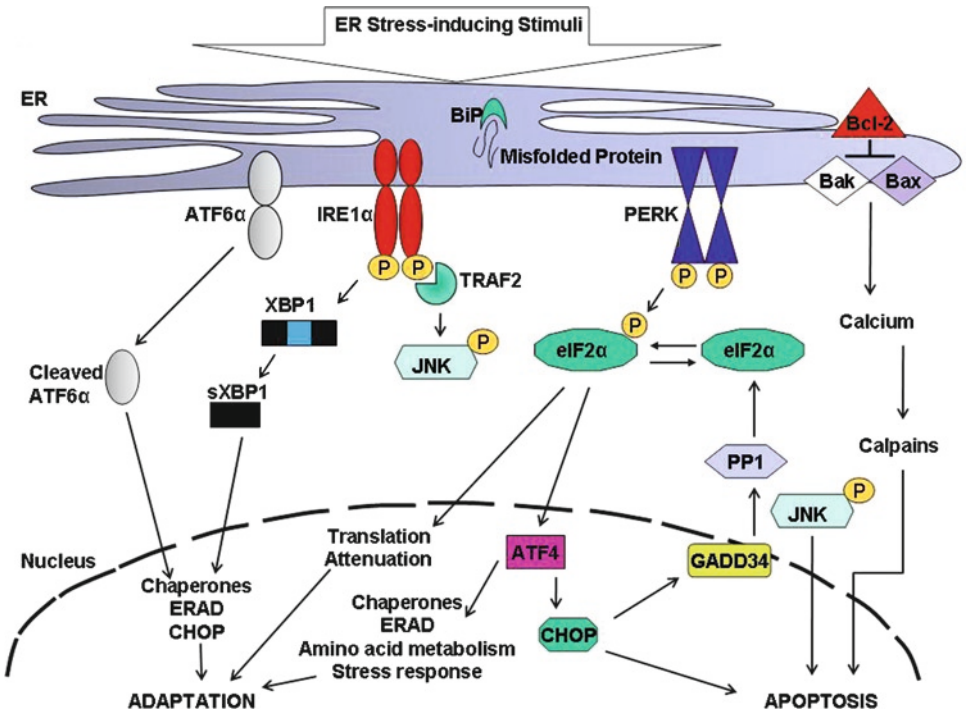

Fig. 24.4 Endoplasmic Reticulum stress signaling. The accumulation of misfolded client proteins in the endoplasmic reticulum (ER) creates ER stress and activates the unfolded protein response. Some other ER stress inducing stimuli include Thapsigargin, Tunicamycin, lipid excess, and increased polypeptide synthesis. The chaperone BiP/GRP78 (heavy chain binding protein/glucose-regulated protein 78) binds to client proteins. Three known ER stress sensors, each possessing a lumenal domain, a transmembrane domain, and a cytoplasmic domain, are activated upon dissociation of BiP from their lumenal domains. Activating transcription factor 6 (ATF6) is cleaved and the cleaved N-terminal fragment translocates to the nucleus, increasing the expression of adaptive genes. Inositol requiring kinase (IRE) 1α(alpha) is activated by autophosphorylation. It also has endoribonucleolytic activity leading to the splicing of the transcription factor X-box binding protein 1 (XBP1) to its spliced form (sXBP1), which selectively upregulates expression of adaptive genes as well. IRE1α(alpha) also activates JNK via the adaptor protein TRAF2. PKR like ER protein kinase (PERK) phosphorylates eukaryotic initiation factor 2 alpha (eIF2α(alpha)), leading to global attenuation of transcription to decrease the client load in the ER. It also selectively upregulates activating transcription factor 4 (ATF4) and CHOP. Sustained ER stress is associated with a failure of adaptation and apoptosis. Apoptosis can occur due to the transcription factor CHOP-induced upregulation of the proapoptotic protein Bim, or TRAIL receptor, DR5. Bax and Bak-regulated calcium release from the ER as well as IRE1α(alpha)-dependent JNK activation can also determine apoptotic cell fate

basal calcium concentration in the ER, and Bax can increase basal calcium concentration in the ER. In cells lacking Bax and Bak, basal calcium levels are lowered. Alterations in calcium can affect many intrinsic apoptotic pathways, including calpains (calcium dependent proteases), and direct effects on mitochondria. CHOP is a transcription factor, activated by the ER stress response and known to regulate the proapoptotic protein Bim and TRAIL-R2 expression, sensitizing cells to apoptosis [69, 70]. ER stress kinases can activate c-Jun N-terminal kinase [71], which can then activate the mitochondrial pathway of apoptosis [72]. Bax inhibitor-1 (BI-1), an inhibitor of Bax-induced apoptosis, has recently been shown to suppress the IRE1-α(alpha) branch of the UPR resulting in decreased sensitivity to ER stress-induced cell death [73]. The role of ER stress pathways in liver injury has been studied in several experimental models. Cycloheximide induces acute ER stress followed by liver cell death and injury [74]. GCDC can activate ER stress pathways in isolated hepatocytes leading to increased apoptosis; and in the bile duct-ligated mouse model of cholestasis, in CHOP-deficient animals, abrogation of hepatocyte apoptosis and fibrosis are observed [75, 76]. Recently, it has been demonstrated that the transcription factor Foxa 2 is essential for bile acid metabolism in hepatocytes; its deletion leads to intrahepatic cholestasis and activation of ER stress pathways [77]. Nutritional obesity is associated with ER stress and JNK activation [78]. In free fatty acid-induced lipoapoptosis, saturated fatty acids activate ER stress pathways [79]. Cholesterol accumulation also activates the UPR, expression of CHOP, calcium depletion, and activation of apoptosis [80]. In a model of alcohol-induced hepatocyte apoptosis, CHOP-deficient mice are protected against hepatocyte apoptosis, in spite of developing hepatic steatosis and activating the ER stress response [81]. On the other hand, the acute and severe induction of ER stress results in hepatic steatosis mediated via the transcriptional control of de novo lipogenesis and VLDL secretion [82].

Overview of Necrosis

Necrotic cell death is recognized in the liver under conditions of massive metabolic disturbance, mitochondrial dysfunction, and ATP depletion leading to swelling of mitochondria and other organelles, rupture and release of intraorganelle contents, and cellular swelling, cell membrane bleb formation with eventual bleb rupture and release of intracellular contents [1]. Spillage of intracellular contents stimulates an inflammatory response. Necrotic cell death is seen with ischemic reperfusion injury, uncoupling of mitochondrial oxidative phosphorylation, and drug-induced liver injury. The same stimulus, differing only in magnitude, can activate apoptotic or necrotic cell death within hepatocytes. As in apoptosis, mitochondrial dysfunction plays a significant and central role in necrotic cell death. Historically, necrotic cell death was defined morphologically, and cellular signaling pathways involved in necrotic cell death were not well defined [16]. Mechanistically, necrosis was a definition of exclusion, based on the absence of apoptotic or autophagic cell death. Emerging data have highlighted some of the signaling molecules that mediate necrotic cell death. Some of this information has been obtained from studies based on the inhibition of apoptotic signaling, either by utilizing molecular inhibitors, or cells genetically deficient in certain molecules and hence incapable of apoptotic signaling [25, 83]. Nevertheless, signaling pathways that mediate necrotic cell death are being defined by such experiments, though liver-specific information may not be available.

Receptor-interacting proteins (RIP) are intracellular adaptor kinases with homologous N-terminal kinase domains; the kinase domains are essential for induction of necrosis, which has primarily been described upon TNFα(alpha) treatment of cells [84–86]. RIP1 and RIP2 interact with DRs and caspases through shared DD and caspase recruitment domain (CARD). RIP3 interacts with RIP1 via a RIP homotypic interaction motif (RHIM). RIP1 is recruited to the TNFα(alpha) signaling complex, Complex I, formed upon ligation of TNFR1. Signals emanating from this Complex I lead to prosurvival signals, e.g., activation of NFκ(kappa)B and mitogen-activated protein kinases (MAPK), in a RIP1-dependent manner [87, 88]. Inactivation of RIP1 signaling, by deubiquitination, or the genetic absence of RIP1 sensitizes cells to TNFα(alpha)-induced cell death. However, RIP1 also mediates TNFα(alpha)-induced necrotic cell death and the production of reactive oxygen species (ROS). RIP1-induced necrotic cell death requires the participation of RIP3. RIP3 phosphorylates and stabilizes RIP1 in a heterodimeric complex that leads to necrotic cell death. RIP3 was also identified as a molecular switch between apoptotic and necrotic cell death in NIH 3T3 cells upon treatment with TNFα(alpha). RIP3 activation was linked to the metabolic state of the cell. RIP3 associated with seven metabolic enzymes under conditions of TNFα(alpha) + caspase inhibitor treatment. Modulation of expression of some of these metabolic enzymes, which play a key role in breakdown of glycogen or the utilization of amino acids as an energy source, correlated with the production of ROS and necrotic cell death [89].

The Mitochondria in Necrosis

The MTP is formed by the voltage-dependent anion channel (VDAC) on the outer mitochondrial membrane and adenine nucleotide transporter (ANT) on the inner mitochondrial

membrane along with cyclophilin D and other proteins in the mitochondrial matrix [90]. The inner mitochondrial membrane contains the respiratory chain that performs oxidative phosphorylation and ATP generation for the cell. As electrons are transported through the respiratory chain, protons are pumped out of the matrix creating a transmembrane electrochemical gradient, the inner mitochondrial membrane potential (Δ(delta) Ψ(psi) m). The mPT refers to a rapid increase in the permeability of the inner mitochondrial membrane that results in rapid membrane depolarization, uncoupling of oxidative phosphorylation, release of the contents of the mitochondrial matrix, eventual rupture of the outer membrane, and release of apoptotic mediators. ATP depletion can also occur from lack of blood flow as occurs in ischemic injury leading to necrotic cell death. The role of this mPT in cell death regulated by Bcl-2 family proteins is unclear, as in mice lacking cyclophilin D, hepatocyte mitochondria are efficiently permeabilized by Bax and tBid, but are resistant to calcium-induced permeabilization [91]. Mitochondria isolated from hepatocytes from mice lacking ANT or VDAC are susceptible to cell death induced by various stimuli [92, 93], which contradicts data that Bax and Bak-induced MOMP is followed by the mPT [90, 94]. Furthermore, neither Bax and Bid, nor calcium-induced or oxidative stress-induced mitochondrial permeabilization was dependent on VDAC. This observed difference may be a function of the experimental models used or the existence of discrete mutually exclusive pathways of mitochondrial permeabilization. These studies further highlight the involvement of mitochondria in hepatocyte cell death, whether the stimulus is apoptotic or necrotic.

Molecular Mediators of Apoptosis

Fas

Fas is a DR protein expressed on every cell type in the liver. Upon ligation with its cognate ligand, Fas Ligand (Fas L), on the extracellular domain of the receptor, the Fas receptor oligomerizes and activates caspase 8 and caspase 10 [28]. Caspase 8 cleaves Bid to tbid which leads to mitochondrial permeabilization and activation of effector caspases. In health, Fas is expressed at low levels on the plasma membrane; a majority of Fas localizes to the Golgi complex and trans-Golgi network in hepatocytes. This prevents spontaneous unwanted apoptosis and provides a reservoir for the rapid translocation of Fas to the cell surface by injurious stimuli as is seen with bile salts [95]. FasL in the liver is derived from activated cytotoxic T cells and natural killer cells. Proteolytic cleavage of FasL from the cell membrane of T cells results in a soluble form (sFasL), the toxicity of which is unclear, though elevated circulating levels are found in many liver diseases. The ligated Fas receptor signals through the DISC (vide supra), leading to cleavage of Bid to tBid, mitochondrial permeabilization, and apoptosis (Fig. 24.2). The importance of Fas in hepatocyte apoptosis is underscored by the observation that exogenously administered anti-Fas antibody leads to massive hepatocyte apoptosis and fulminant hepatic failure in mice [96]. Mice deficient in Fas are protected. As hepatocytes are Type II cells, the antiapoptotic Bcl-2 proteins can inhibit Fas-induced apoptosis. Indeed, transgenic mice overexpressing human Bcl-2 are protected against the lethal apoptosis induced by Fas [97]. Bid is required for Fas-induced apoptotic signaling, as mice deficient in Bid do not develop the characteristic hepatocyte apoptosis and fulminant hepatic failure induced by exogenous administration of Fas [98]. X-chromosome linked inhibitor of apoptosis (XIAP), an antiapoptotic protein, governs sensitivity to Fas-induced cell death downstream of Bid [40]. In the combined absence of XIAP and Bid, hepatocytes that were resistant to Fas-induced apoptosis in the absence of Bid alone were sensitized to Fas-induced cell death. Mice deficient in XIAP alone were more sensitive to the fatal effects of anti-Fas agonistic antibody. Thus, XIAP functions as a negative regulator or Fas signaling.

Following the observation of fulminant hepatic failure induced by anti-Fas antibody, there has been an explosion of research on the role of Fas in liver pathobiology and hepatocyte apoptosis. Though not essential for organogenesis, as Fas-deficient animals develop normal livers, Fas is important in maintaining hepatic homeostasis and renewal. In Fas-deficient mice, with age, hepatic hypertrophy develops [99], more hepatocytes are seen per liver lobe, and within hepatocytes nuclear abnormalities are seen. The cell surface expression and availability of Fas control a cell's susceptibility to Fas-induced apoptosis. Most Fas in located within the cell, thus limiting its availability to bind to its ligand. Cell surface Fas is bound to the hepatocyte growth factor receptor, Met [100]. This interaction effectively sequesters Fas and inhibits spontaneous death signaling. Met and FasL are competitive in their binding to Fas, and Met prevents FasL binding to Fas at low concentrations of FasL. On the other hand, on the addition of exogenous HGF, Met dissociates from Fas and sensitizes hepatocyte cell lines to apoptosis. High concentration of FasL can overcome the Met–Fas interaction. Thus, the complex interaction between Met and Fas results in either life or death for a stressed hepatocyte. Indeed, this paradigm has been advanced further by the observation that in fatty liver Fas is dissociated from Met, both in human fatty liver samples and in animal models [101]. Mice with diet-induced hepatic steatosis are sensitized to Fas-induced apoptosis [102]. Human biopsy samples from patients with nonalcoholic steatohepatitis demonstrate enhanced Fas expression as

well as hepatocyte apoptosis [103]. In cell culture models of free fatty acid-induced steatosis, sensitization to Fas-induced apoptosis is also observed [5].

Chronic viral hepatitis, both due to hepatitis B virus (HBV) (see Chap. 37) and hepatitis C virus (HCV) (see Chap. 38), demonstrates activation of the Fas-FasL death signaling cascade [104]. Indeed, in both forms of viral hepatitis, hepatocyte Fas expression is upregulated. FasL expressing cytotoxic T lymphocytes infiltrate the liver in chronic viral hepatitis. Fas and FasL expression is geographically localized to areas of inflammatory activity within hepatic lobules [105]. Circulating levels of soluble Fas (sFas) and sFasL are elevated in patients with chronic hepatitis B, more so than in inactive carriers [106]. Fas-induced apoptosis is also seen in patients with fulminant hepatitis B infection [107]. Similarly, in chronic hepatitis C elevated sFasL levels are observed [108].

The accumulation of toxic, hydrophobic bile acids within the liver is a key feature of cholestatic liver injury. Toxic bile acids, e.g., glycochenodeoxycholate (GCDC), induce Fas-dependent and Fas-independent apoptosis in hepatocytes [95, 109]; detoxification of bile acids is discussed in Chap. 12. In cultured hepatocytes, GCDC treatment leads to Fas oligomerization and activation of caspase 8 [109]. Cellular trafficking of Fas is also regulated by GCDC, which enhances translocation of Fas from the cytosol to the cell surface [95]. Spontaneous receptor oligomerization and activation of downstream death signals results from increased cell surface expression of Fas. Bile salts can also activate the Src family kinase Yes, resulting in activation of the epidermal growth factor receptor and phosphorylation-induced activation of Fas [110]. Further proof of the importance of Fas is established on the basis of studies in mice lacking Fas receptor (*lpr*). Following bile duct ligation, hepatocyte apoptosis, liver injury, and fibrosis are abrogated in the Fas receptor-deficient mouse [35].

TRAIL

Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) is a death ligand, related to FasL and TNF-α(alpha) [111]. TRAIL is of particular interest in liver disease, as normal hepatocytes are resistant to TRAIL-induced apoptosis [112]. TRAIL receptors, especially DR5 and DR4, can, however, mediate apoptosis in sensitized hepatocytes. Under normal conditions, the expression of TRAIL and its receptors in human livers is low. TRAIL has been shown to mediate hepatic steatosis in animal models of alcoholic hepatitis and acute adenoviral hepatitis [113]. Metabolic or viral stress may sensitize hepatocytes to TRAIL toxicity. Susceptibility to TRAIL-induced cell death can be regulated by cell surface expression of DR5 and DR4 as well as the production of TRAIL ligand for paracrine activation of its receptors. Indeed, in models of acute viral hepatitis, adenoviral infection sensitizes hepatocytes to TRAIL-induced apoptosis [112]. TRAIL also mediates *Listeria monocytogenes*-induced acute hepatitis and concanavalin A-induced acute liver injury. Further support for the role of inflammation in preferentially sensitizing the liver to TRAIL is demonstrated in an experimental model of constitutive hepatocyte-specific NF-κ(kappa) B activation. These mice demonstrate upregulation of DR5 expression on hepatocytes and constitutive activation of NK cells within the liver [114].

In chronic liver disease, such as in nonalcoholic fatty liver disease (see Chap. 34) and chronic viral hepatitis, upregulation of TRAIL receptors with concomitant sensitization to TRAIL-induced cell death is observed [115]. In patients with chronic hepatitis B infection, cytokine-induced enhancement of TRAIL expression on intrahepatic NK cells and DR5 expression on hepatocytes is observed [116]. This correlates with serum ALT levels as well as flares of inflammation. In cell culture models, hepatitis C viral proteins as well as hepatitis B viral proteins can selectively modulate the expression of cell surface TRAIL receptors [117, 118]. This may have a proapoptotic or antiapoptotic effect. For example, hepatitis B core antigen levels correlate inversely with sensitivity to TRAIL-induced cell death via modulation of DR5 expression [119]. The emerging model in viral hepatitis suggests an important role for TRAIL-mediated apoptosis in removal of virus infected cells. Failure of this or viral trickery to subvert this process may play a role in persistence of chronic viral infection. Nutritional stress, such as free fatty acids and intracellular ER stress, can lead to enhanced DR5 expression, the later via the transcription factor CHOP [70, 120]. The stress kinase, JNK, can also enhance DR5 expression [120]. Thus, the potential for hepatic toxicity of TRAIL agonistic antibodies, which are in clinical trials for cancer chemotherapy, exists especially in patients with acute or chronic hepatitis, justifying careful and necessary monitoring.

TNF-Alpha

Tumor necrosis factor alpha (TNF-α(alpha)) is a pleiotropic cytokine that plays important roles in liver regeneration, inflammation, injury, cell survival, and cell death [37]. It is produced predominantly by activated macrophages, but can be expressed by other cell types as well. Circulating TNF-α(alpha) is a ligand for two characterized receptors, tumor necrosis factor receptor 1 (TNF-R1) and tumor necrosis factor receptor 2 (TNF-R2). TNF-R1 is widely expressed in tissues, and TNF-R2 expression is generally restricted to immune cells; however, both are expressed on hepatocytes.

TNF-R1-mediated apoptosis is better described. The opposed effects of TNF-α(alpha) emanate from the same receptor complex (Fig. 24.3) [121]. Both receptors lack intracellular catalytic domains and rely on adaptor proteins to propagate their signals. Upon receptor ligation, the trimerized TNF-R1 recruits intracellular adaptors via a conserved DD. Downstream signals from the receptor–ligand complex are arbitrarily designated as complex I and complex II.

Complex I is formed by tumor necrosis factor receptor-associated protein with death domain (TRADD), TNF receptor-associated factor-2 (TRAF-2), and receptor-interacting protein1 (RIP). Via a kinase cascade involving RIP1, the transcription factor, nuclear factor-κ(kappa) B (NF- κ(kappa) B) is activated and translocates to the nucleus. NF- κ(kappa) B target genes are subsequently activated and fall broadly into two categories, inflammatory genes, such as interleukin 6, iNOS, and antiapoptotic genes, such as, cFLIP, XIAP. TNF-α(alpha)-induced JNK activation also occurs via complex I and the adaptor protein TRAF2. Thus, complex I mediates the cell survival and inflammatory signals of TNF-α(alpha). Following this, the adaptor complex undergoes a conformational change, dissociates from trimerized TNF-R1, and recruits the adaptor protein FADD to form complex II. Caspase 8 activation occurs in this secondary complex. Apoptosis can occur downstream of this, both via Bid cleavage and in a Bid-independent manner. In the later scenario, JNK-dependent Bim phosphorylation occurs downstream of TNF-α(alpha) signaling [122]. Due to the earlier formation of complex I, the predominant consequences of TNF-α(alpha) signaling are cell survival and the activation of inflammatory pathways. Furthermore, due to the activation of opposing forces, in order to induce apoptosis, TNF-α(alpha) survival signals have to be overcome or inactivated. Experimentally, in cultured hepatocytes or liver cell lines, this can be achieved by inhibition of NF-κ(kappa)B, inhibition of transcription (actinomycin D), or translation (cycloheximide). The role of protracted JNK activation as an in vivo switch in TNF-α(alpha) signaling has been recognized [43]. It has been demonstrated that prolonged JNK activation results in cFLIP degradation which shifts the balance of TNF-α(alpha) signaling toward cell death.

In spite of and due to its varied potential effects, there is no doubt that TNF-α(alpha) plays an important role in hepatic homeostasis and disease. The predominant consequences of in vivo activation of TNF-α(alpha) signaling are promotion of hepatic regeneration and inflammation. In many chronic liver diseases TNF-α(alpha) signaling is upregulated and plays a role in liver injury, though this is most likely not due to hepatocyte apoptosis. Mice deficient in TNF-R1 demonstrate impaired liver regeneration and increased mortality following partial hepatectomy [123]. Further dissection of this pathway has demonstrated the requirement for interleukin 6 for liver regeneration [124]. Constitutive increase in TNF-α(alpha) expression and activity in the liver leads to spontaneous hepatocyte cell death and inflammation and failure of liver regeneration following partial hepatectomy due to apoptosis secondary to sustained activation of TNF-α(alpha) [125].

TNF receptor expression is upregulated on hepatocytes in acute and chronic liver diseases. Indeed, experimental models of fulminant hepatitis are based on massive activation of TNF-α(alpha) signaling, and in patients with fulminant hepatic failure elevated circulating levels of soluble TNF-α(alpha), TNR-R1, and TNF-R2 can be detected. Soluble TNF-R1 levels also correlate inversely with survival [126, 127]. Similarly, in alcoholic hepatitis circulating TNF-α(alpha) and TNF-R1 are elevated and correlate with mortality [128, 129]. In a murine model of alcoholic hepatitis, utilizing mice deficient in TNF-R1 or TNF-R2, it was demonstrated that TNF-R1 is essential for alcohol-induced liver injury [130]. Analysis of a TNF-α(alpha) gene promoter polymorphism associated with increased TNF-α(alpha) expression has demonstrated that this polymorphism is associated with increased susceptibility to steatohepatitis [131]. Similarly in patients with chronic viral hepatitis, secondary to hepatitis C viral infection or hepatitis B viral infection, TNF-α(alpha) signaling is activated [132, 133].

JNK

C-jun N-terminal kinases (JNKs) are members of the MAPK family [134, 135]. They are ubiquitously expressed and mediate cellular responses to myriad extracellular and intracellular stresses. The three known JNK genes encode ten JNK isoforms by alternative splicing, of which JNK1 and JNK2 isoforms are expressed in the liver. JNKs are activated via a kinase signaling cascade that links the extracellular or intracellular stress to JNK phosphorylation. Upon activation, JNKs phosphorylate and regulate mediators of cell survival, inflammation or cell death in a stimulus-specific and time-dependent manner. MAP kinase phosphatases (MAP) dephosphorylate JNK and thus serve as negative regulators of JNK signaling. Chemical inhibition and genetic deletion studies have demonstrated that depending on the model of injury, there is either a redundancy in the role of JNK 1 and JNK 2 or each can modulate specific aspects of liver injury. Temporal kinetics of JNK activation also influence the outcome; the early phase of JNK signaling favors cell survival, and therefore if JNK activation is transient, survival is the likely outcome. However, sustained JNK activation promotes apoptotic signaling.

JNK can regulate cell death by modulation of many pro- and antiapoptotic proteins, either transcriptionally or via phosphorylation (Fig. 24.1). The cytokine TNF-α(alpha) leads to JNK activation, and JNK in turn is a positive regulator of TNF-α(alpha) expression. In TNF-α(alpha)-induced cell

death, the sustained activation of JNK leads to phosphorylation and activation of the E3 ubiquitin ligase Itch. Itch activation leads to ubiquitination and degradation of cFLIP, releasing caspase 8 from cFLIP-inhibition promoting TNF-α(alpha)-induced apoptosis [43]. Utilizing models of fulminant hepatitis based on Concanavalin A or lipopolysaccharide injection, others have demonstrated that JNK 1/2 in bone marrow-derived cells is required for TNF-α(alpha) production, but not for TNF-α(alpha)-mediated cell death, and hepatocytes that lack JNK 1/2 are equally susceptible to TNF-α(alpha)-induced cell death [136]. In another model of TNF-α(alpha)-induced hepatocyte apoptosis, JNK 1-mediated Mcl-1 phosphorylation increases the half life of Mcl-1 lending an antiapoptotic role to JNK 1. Acetaminophen (APAP)-induced liver injury is also mediated by JNK. In mouse models, APAP treatment leads to robust JNK activation as well as Bax translocation [137]. Pharmacologic inhibition of JNK activation attenuates liver injury, as does absence of apoptosis signal-regulating kinase 1 (ASK 1). The toxic bile acid, deoxycholic acid, also activates JNK and increases hepatocyte apoptosis by JNK-dependent TRAIL-R2 expression [138]. In this model, JNK1 mediated cell death, whereas JNK2 was protective.

JNK is chronically activated in the liver in obesity-associated fatty liver; this mediates cellular insulin resistance [78]. Free fatty acids, which are elevated in patients with nonalcoholic fatty liver disease, can also induce JNK-dependent lipoapoptosis by enhancing the expression of Bim, a proapoptotic BH3-only protein, as well as sensitize to DR toxicity by enhanced expression of Fas and TRAIL-R2 [5, 120, 139]. In high fat diet (HFD)-induced steatohepatitis in mice, JNK 1-deficient mice are resistant to weight gain, whereas JNK 2-deficient mice are significantly more obese than their wild type controls [140]. JNK 1-deficient mice also demonstrate less injury and inflammation in the liver, which may be a consequence of less adiposity, whereas JNK 2 is a negative regulator of Bim expression and sensitivity to apoptosis in spite of greater liver steatosis. JNK activation is also linked to the redox state of the cell, and oxidative stress-induced apoptotic signaling [141]. In TNF-α(alpha)-induced cell death, oxidative inactivation of MAP kinase phosphatases promotes prolonged JNK activation and cell death [142]. JNK activation occurs in ischemia–reperfusion injury of the liver, and pharmacologic inhibition of JNK activation decreased hepatocyte cell death in experimental orthotopic liver transplantation [143–145].

Conclusion

Hepatocyte cell death is a central event in liver injury, regardless of etiology, even though the susceptibility of an individual hepatocyte to intracellular or extracellular stressors is variable. The effects of TNFα(alpha) are pleiotropic, and in the absence of NF-kappaB inhibition favor cell proliferation, survival, and inflammation. Fas signaling results in apoptotic cell death with characteristic morphologic changes; and diseased hepatocytes are sensitive to TRAIL-induced apoptosis as well. Recent studies have highlighted the "program" of necrotic signaling, specifically the role of RIP kinases in mediating necrotic cell death. Intracellular perturbations, such as protracted ER stress, sustained JNK activation, or lysosomal permeabilization can also trigger hepatocyte cell death. In cell death induced by any of these stimuli, mitochondrial dysfunction is mandatory for the cell to die. Hepatocyte cell death promotes inflammation and fibrosis in the liver, perpetuating the injury cascade. Advancements in the exact molecular pathways of hepatocyte cell death present several areas, such as caspase inhibitors and JNK inhibitors, which have therapeutic potential.
