Abstract — **Allergic rhinitis (AR) is a common chronic illness which has a significant impact on patients' quality of life. Current therapeutic options such as avoidance of allergen, medication and immunotherapy are far from ideal due to their adverse effects. The aim of the study was to evaluate the clinical effects of phototherapy to Shangyingxiang Xue on patients with AR. Sixty-one AR patients who met the inclusion criteria were enrolled in this study. Patients were divided randomly into the treating group and control group. Every of them should fill out the informed consent form before treatment and recorded their symptom scores everyday in a diary before and during treatment. Thirty-one patients in the treating group received phototherapy with LED lights consisted of two wavelengths, 660 and 850 nm, applied on bilateral Shangyingxiang Xue. Phototherapy was performed once a day for 7 days. The duration of each treatment was 10 minutes. Thirty patients in the control group received antihistamine (Zyrtec, 10 mg) once a day for 7 days. A symptom score of 0 to 3 was assigned for each of the following rhinitis symptoms: eye itching, nasal itching, nasal obstruction, rhinorrhea, smell impairment, sneezing and size of inferior turbinate. The scores of pre- and post-therapy in both groups were collected after the course of treatments and analyzed by using the paired sample t-test. Scores of the post-therapy were all significantly decreased in the treating group, which means all the symptoms were apparently improved after phototherapy to bilateral Shangyingxiang Xue. Comparing the clinical effects of treating and control groups with repeated measures analysis, no difference was observed except the size of inferior turbinate. In conclusion, phototherapy to Shangyingxiang Xue could relieve the symptoms of allergic rhinitis. It seems to be a safe and effective modality on the treatment of allergic rhinitis.**

Keywords — **allergic rhinitis, phototherapy, Shangyingxiang Xue, infrared, light emitting diode**

I. Introduction

Allergic rhinitis (AR) is a high-prevalence disease in many countries, affecting about 15-30% of the world's population[1]. Unlike most other diseases, which are decreasing in prevalence, AR is on the increase[2]. The clinical symptoms of the nasal allergic response include nasal itching, rhinorrhea, nasal congestion, eye itching, etc. [3]. AR is also an important underlying cause of co-morbidity which includes infective sinusitis and otitis media. Although it is not associated with severe morbidity and mortality, allergic rhinitis has a major effect on the quality of life. Its increasing prevalence, its impact on the individual quality of life and social costs [4,5] and its role as a risk factor for asthma, underline the great need for more and better care of this disease.

The management of allergic rhinitis includes avoidance of the allergen, medication (pharmacological treatment) and allergen immunotherapy. It is no doubt that effective allergen avoidance can lead to substantial relief of symptoms. However, patients are still not able to avoid their confirmed allergens such as mites or atmospheric pollens under many circumstances. Well-established pharmacological therapies with oral and topical H1-antihistamines, topical and systemic glucocorticosteroids, hormones, decongestants and anti-leukotrienes are available for the treatment of the disease. According to the guidelines, oral antihistamines are the first-line therapy [6]-[8]. Intranasal steroids are recommended as first-line treatment in moderate and severe disease, and have been used traditionally to combat nasal congestion, along with the other symptoms associated with allergic rhinitis [9]. Although most of the drugs are effective in treating certain symptoms of AR, they all have limitations due to their adverse effects. Rather than simply to treat the symptoms, immunotherapy has the potential to provide a permanent cure for the disease. However, complete suppression of the clinical symptoms cannot be achieved in most cases with currently managements. Therefore, increasingly, sufferers are seeking alternative therapies for allergic rhinitis

Evidence suggests that acupuncture is a useful complementary or alternative treatment option for people with allergic rhinitis[10]. Treatment for AR may include needling and moxibustion. Low-energy narrow-band illumination has been used as a therapeutic measure in some medical situations. Low-energy narrow-band light in the visible and infrared ranges has various biochemical, cellular, histologic, and functional effects[11]. Although there are some phototherapeutic modalities for the treatment of AR, using both 660 nm and 850 nm as a therapeutic modality has never

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 992–995, 2009
www.springerlink.com

been reported. The aim of the present study was to investigate the effects of illumination at both 660 nm and 850 nm on the acupuncture point (Shangyingxiang Xue) in the treatment of AR.

II. Materials and Methods

A. Patients

Sixty-one patients (28 male and 33 female, average age 34.1 years) with perennial allergic rhinitis were prospectively enrolled in this study. The patients were randomly assigned to one of two groups: 31 were assigned to the experimental group treated with phototherapy and 30 to the group receiving medication (cetirizine) as a control. The history of most patients reported a long period of daily symptoms (average 6.2 years). Patients with severe deviation of the nasal septum causing bilateral nasal obstruction were excluded from the study. Candidates in whom fibroscopy revealed purulent postnasal drip flowing from an edematous and hyperemic infundibulum or with streaks of purulent discharge flowing across the eustachian tube orifice were diagnosed as suffering from sinusitis and were excluded from the study. Also excluded were patients who were convalescing from an upper respiratory tract infection or had used nasal or oral corticosteroids less than 30 days before the start of the study.

After recording their symptoms in a diary for 1 week, all candidates for inclusion in the study underwent videoendoscopic examination of the nose. Each patient was examined by the use of a rigid endoscope introduced as deeply as possible into the nostril for close examination of the mucosa and intranasal structures. In addition, a flexible endoscope was used to penetrate the narrow intranasal passages not accessible by the rigid endoscope, thus enabling close examination of the nasal cavity.

B. Diagnosis of AR

The diagnosis of allergic rhinitis was based on definite symptoms of nasal itching, rhinorrhea, sneezing, nasal obstruction or mouth breathing, as well as positive reactions to blood tests to antigens, such as house dust mite, cockroach, molds, feathers, grass pollen, weed pollens, sage pollen, and local tree pollens, etc. Criteria for positive skin prick test responses were a wheel of 3 mm or greater diameter with erythema of at least 5 mm. Histamine control skin test was read at 10 minutes, allergen and negative control skin tests were read at 15 minutes.

Table 1. Scoring of symptoms

Scoring of eye itching
0: no eye itching
1: rubbing eyes less than 5 episodes a day
2: rubbing eyes 6-10 episodes a day
3: rubbing eyes more than 10 episodes a day
Scoring of nasal itching
0: no nasal itching
1: rubbing nose less than 5 episodes a day
2: rubbing nose 6-10 episodes a day
3: rubbing nose more than 10 episodes a day
Scoring of nasal stuffiness
0: no nasal stuffiness
1: nasal stuffiness without mouth breathing
2: nasal stuffiness with sporadic mouth breathing
3: nasal stuffiness with predominant mouth breathing
Scoring of rhinorrhea
0: no nasal blowing
1: nasal blowing less than 5 episodes a day
2: nasal blowing 6-10 episodes a day
3: nasal blowing more than 10 episodes a day
Scoring of smell impairment
0: no smell impairment
1: hyposmia with mild smell impairment
2: hyposmia with moderate smell impairment
3: anosmia
Scoring of sneezing
0: no sneezing
1: sneezing less than 5 episodes a day
2: sneezing 6-10 episodes a day
3: sneezing more than 10 episodes a day
Scoring of size of inferior turbinate
0: size less than half of nasal cavity
1: mild swelling, nasal septum and middle turbinate are visible
2: inferior turbinate attached to nasal septum, there is space between inferiot turbinate and nasal floor
3: inferior turbinates attached to nasal septum and nasal floor, middle turbinate is invisible

C. Scoring of Symptoms

A symptom score of 0 to 3 was assigned for each of the following rhinitis symptoms: eye itching, nasal itching, nasal stuffiness, rhinorrhea, smell impairment ,sneezing and size of inferior turbinate. All the patients scored the severity of their symptoms on a four-point scale once a day in a diary; 0 = no symptom, 1 = mild, 2 = moderate and 3 = severe symptom (Table 1). All adverse effects observed during the treatment were recorded.

D. Phototherapy

In this group patients, 13 were male and 18 were female; the average patient's age was 34.3 years. A light emitter was used for phototherapy in this group. The wavelengths of this emitter were 660 nm and 850 nm. The emitter was positioned on the point of bilateral Shangyingxiang Xue. The therapeutic time was 10 minutes everyday for 7 days. All the therapies were performed in the morning during 9 am to 12 pm. During the course of the study, the patients did not receive any other anti-allergic management.

E. Drug therapy

In this group patients, 15 were male and 15 were female; the average patient's age was 33.8 years. The patients received cetirizine in the morning for a period of one week. A dosage of 5 mg/d was administered to patients up to 30 kg in weight and 10 mg/d for patients over 30 kg. All patients in this group did not receive any other drug during study period.

F. Statistical analysis

The effects of phototherapy on the clinical symptoms were analyzed by the paired samples t-test. We compared the mean symptom scores before (pre-therapy) and every time after (post-therapy) the patients completed phototherapy or medicine. To the right of the paired differences, we saw the T, degrees of freedom, and significance. Repeated measures analysis was used to compare the experimental group and control group. A p value of less than 0.05 was considered to be statistically significant.

III. Results and Discussion

A. Effects of phototherapy in the clinical symptoms

Thirty-one patients enrolled in the study completed the phototherapy. Mean values of daily registrations for eye itching, nasal itching, nasal stuffiness, rhinorrhea, smell impairment and sneezing are given in Figure 1. The most severe symptom of the pre-treat patients was rhinorrhea, which the mean value of the symptom score was 2.0, followed by sneezing and nasal stuffiness with scores of 1.84 and 1.55, respectively. The least severe symptom of the pre-treat patients was smell impairment with a mean score of 0.71. After the one-week treatment period, significant improvements were observed in all the symptoms of AR patients. The improved clinical symptoms were usually seen 1 to 2 days after the start of therapy, and thereafter the improvement was continuous. However, the smell impairment did not reveal significant improvement until after the 3th therapy.

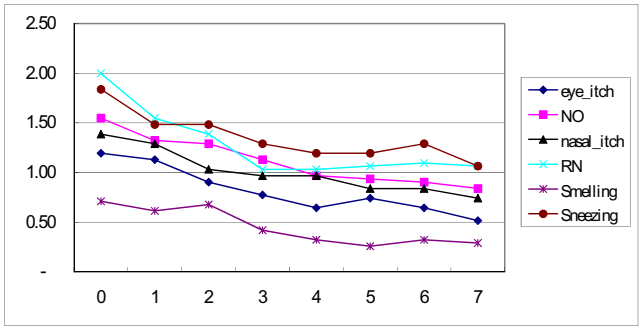

Fig. 1. Mean values of daily scores for symptoms of experimental group by using phototherapy. The score is given on a scale from 0 = no symptom to 3 = severe symptom. The symptom scores decreased over the period of treatment. Pre-treatment (Day 0); during treatment (Day 1-7).

B. Comparison of therapeutic effects between phototherapy and drug

Mean values of daily symptoms of control group are given in Figure 2. Comparison between two groups are shown in Table 2. The results reveal that all the symptoms improved after treatment in both groups. There is no significant difference of therapeutic effect between these two groups except the size of inferior turbinates.

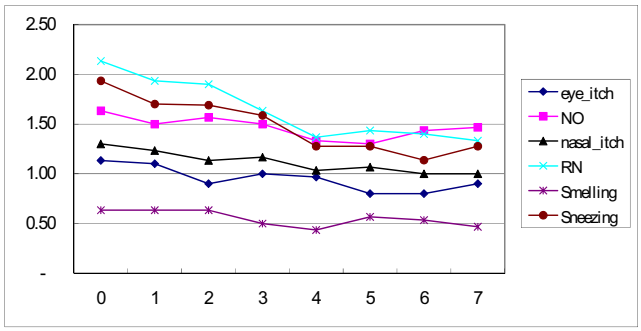

Fig. 2. Mean values of daily scores for symptoms of control group by using drug. The score is given on a same scale as experimental group.

Table 2 Results of comparison between two groups

	eye_itch	NO	nasal_itch	RN	Smelling	Sneezing	IT
Period	S	S	S	S	S	S	S
Group	NS	NS	NS	NS	NS	NS	S

eye_itch: eye itching NO: nasal stuffiness
nasal_itch: nasal itching RN: rhinorrhea
IT: size of inferior turbinate
S: significant difference ($p < 0.05$)
NS: no significant difference ($p > 0.05$)

IV. Discussion and Conclusions

The findings of our study demonstrate that phototherapy to acupuncture point (Shangyingxiang Xue) may improve the clinical symptoms of AR. Most of the symptoms were quickly and significantly improved, however, the smell impairment did not improve until after the 3th therapy. This was probably because the pre-treatment score was lower than the others that there was no much room for decreasing it or phtotherapy to acupuncture point was not so effective on improving olfactory disorder.

Although phtotherapy with combination of 660 nm and 850 nm to Shangyingxiang Xue may therefore be viewed as a useful additional approach in the treatment of AR, the definite mechanism remained unclear. Low-energy illumination therapy has proved effective in some clinical situations such as pain relief and wound healing. Illumination at both the visible and the infrared range were shown to be of therapeutic benefit, but these two types of illumination differ markedly in both photochemical and photophysical properties. The visible light may initiates the cascade of metabolic events at the level of the respiratory chain of the mitochondria, whereas infrared illumination does so by activatin enzymes. Accordingly, on the basis of findings in previous studies, the illumination selected for our study was red light at 660 nm and infrared light at 850 nm.

No adverse side effects of phototherapeutic treatment were observed in this study. During the experimental period, nobody dropped out of this group. We believe that many patients can obtaine relief of symptoms with this new therapeutic protocol. Although there was no much difference of clinical effects between groups of phototherapy and drugs, safety concerns about medical treatment usually pose an important restriction on the use.

In conclusion, AR may be treated effectively and safely by illumination on Shangyingxiang Xue at 660 nm and 850 nm. Further studies are necessary to establish which wavelengths and/or acupuncture points are therapeutically most effective and safe for the treatment of inflammatory disorders of the nasal mucosa.

Abstract — **The sense of one's own body as part of the self is a fundamental aspect of self-awareness. The recent distinction between sense of agency and sense of body-ownership has attracted considerable empirical and theoretical interest. In this study, we compared the strength of virtual hand illusion induced by agency controlled movement, to investigate the contributions of visual-motor stimulation and ownership to body using fMRI and behavioral study. In the synchronous conditions, virtual hand angle scaled by a scale factor of real hand angle, while the asynchronous condition showed virtual hand angle didn't correspond to real hand angle. Left precentral gyrus, left SMA, left anterior cingulate cortex and right parahippocampal were significant differences between synchronous condition and asynchronous condition with visual feedback. Left SMA was correlated positively with ownership score. The SMA function is integrated various sensory inputs and optimized action selected and compare body forward model with proprioception, then estimate body image.**

Keywords — **body ownership, sense of agency, left SMA**

I. Introduction

The development of BMI (Brain Machine Interface) technology is able to human brain to communicate with machine, so people can move the prosthesis their intention [1, 2]. To make the prosthetic feel like the subject's own limb, the functional development of prosthesis is important, as well as it also increases the importance of the psychological element (bodily self-awareness) [3]. The sense of agency and the sense of body-ownership jointly constitute the core of our bodily self-awareness [4]. The sense of agency is the sense of intending and executing actions, including the feeling of controlling one's own body movements, and, through them, events in the external environment [5, 6]. The sense of agency involves a strong efferent component, because centrally generated motor commands precede voluntary movement [4, 6]. Body ownership refers to the sense that one's own body is the source of sensations [4, 6]. The sense of body ownership involves a strong afferent component, through the various peripheral signals that indicate the state of the body [7]. The sense of body ownership is present not only during voluntary actions, but also during passive experience. In contrast, only voluntary actions produce a sense of agency [8]. The recent distinction between sense of agency and sense of body-ownership has attracted considerable empirical and theoretical interest [9]. The respective contributions of central motor signals and peripheral afferent signals to these two varieties of body experience remain unknown [10, 11].

In this study, we were interested in the effects of agency controlled (synchronously and asynchronously) movement on brain areas known to be involved in bodily self-awareness.

II. Methods

A. Subjects

Sixteen healthy volunteers (average age: 24.8, range: 21 ~ 31, SD: 2.51), 8 male and 8 female subjects, were recruited for this study. All were free of neurological or psychiatric illness.

B. Experiment Task

Subjects moved the virtual hand corresponded to real hand angle toward randomized target angle with and without visual feedback. We made a MR-compatible device that allowed us to modify the subject's degree of control of the movements of a virtual hand in MR room. The experiment tasks consisted of four agency controlled conditions (Synch 1, Synch 0.5, Synch 2, Asynch) to modulate participants' visual - motor sense (fig. 1). In the Synch 1, virtual hand angle corresponded to real hand angle (real hand angle × 1), while the Synch 0.5, 2 showed virtual hand angle scaled by a scale factor of real hand angle (real hand angle × 0.5, 2). In Asynch, virtual hand angle didn't correspond to real hand angle (agency controlled).

C. Procedure

At the beginning of task, subjects moved the real hand toward target angle without visual feedback to measure baseline hand movement sensation. Then, they performed four blocks corresponded each condition (fig. 2). One block

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 996–999, 2009
www.springerlink.com

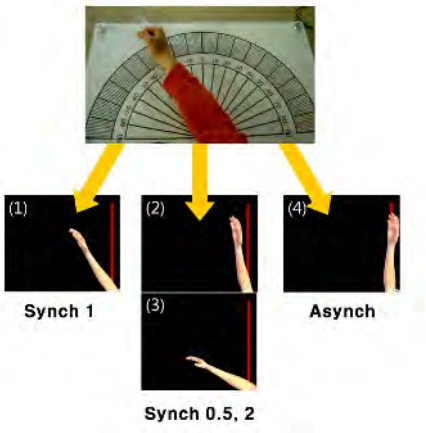

Fig. 1 Consisted of experiment task
(1) Synch 1 : virtual hand angle corresponded to real hand angle (real hand angle × 1), (2,3) Synch 0.5, 2 : virtual hand angle scaled by a scale factor of real hand angle (real hand angle × 0.5, 2), (4) Asynch : virtual hand angle didn't correspond to real hand angle

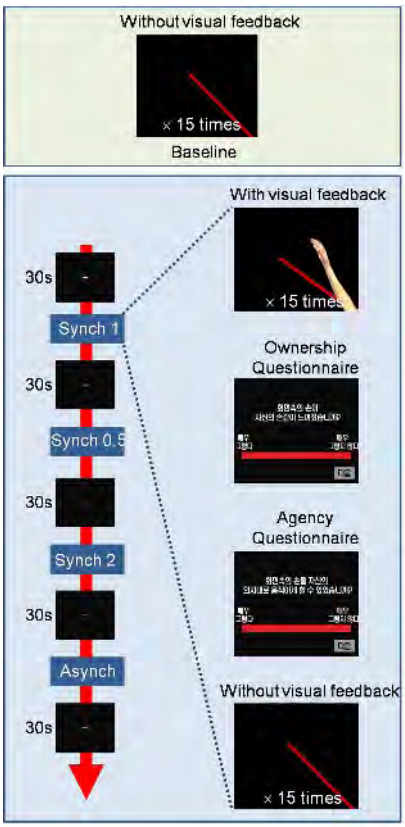

Fig. 2 Experiment procedure
One block consisted of 4 sessions (training session with visual feedback, ownership and agency questionnaire session, test session without visual feedback).

consisted of 4 sessions (training session with visual feedback, ownership and agency questionnaire session, test session without visual feedback). Three kinds of measurement were obtained in this study. One is self-report questionnaire of virtual hand ownership "it seemed like the virtual hand was my hand" and sense of agency "it seemed like I could have moved the virtual hand if I had wanted". Another is the proprioceptive shift, change of hand movement sensation compared baseline with test session (baseline – test session), and the other is brain activity each condition.

D. Data Acquisition

fMRI data was done on a 1.5-T MRI system (Sigma Eclipse, GE Medical Systems). BOLD (blood oxygenation level dependent) signals were obtained using an EPI sequence (Gradient Echo, 64×64×30 matrix with 3.75×3.75×5 mm spatial resolution, TE: 14.3, TR: 2s, FOV: 240 mm, Slice thickness: 5 mm, FA=90, # of slices: 30). A series of high resolution anatomical images was also acquired with a fast spoiled gradient echo sequence (256×256×116 matrix with 0.94×0.94×1.50 mm spatial resolution, FOV: 240 mm, Thickness: 1.5 mm, TR: 8.5s, TE: 1.8s, FA: 12, # of slices: 116).

E. Data analysis

Data analysis was conducted with AFNI (Analysis of-Functional NeuroImages: AFNI, Ver 2007_05_29_1644) freeware developed by R.W. Cox [12]. The first 15 time points in all the time series data were discarded to eliminate the fMRI signal decay associated with magnetization reaching equilibrium. All remaining fMRI data were co-registered to the first remaining time sample to correct for the confounding effects of small head motions during task performance. Then, 'spikes' value are corrected in the 3D+time input dataset despike routine provided in AFNI and performed mean-based intensity normalization. Further processing included temporal smoothing (three-point Low-Pass filter (0.15×(a-1) + 0.7×(a) + 0.15×(a+1)) as well as detrending to remove constant, linear and quadratic trends from the time series data. Spatial Normalization was performed to transform Talairach space using Montreal Neurological Institute (MNI) N27 template provided in AFNI (bilinear interpolation, spatial resolution: 2×2×2 mm^3). Further processing included spatial smoothing (Gaussian filter with 9 mm full-width at half-maximum (FWHM), respectively). After preprocessing, condition-specific effects were estimated according to the general linear model (GLM). According to behavioral data, three synchronously conditions (sync 1, sync 0.5 and sync 2) didn't differ. For this reason, three synchronously conditions data (brain ac-

tivity and behavioral data) averaged one synchronously condition data. We performed a repeated measure ANOVA to test differences in neural activity between synchronously condition and asynchronously condition. Then, correlation analysis conducted between the behavioral data and brain activations.

III. Results

A. Behavioral data

According to the behavioral study, in synchronous condition more felt body ownership and agency score than asynchronous condition. And proprioceptive shift (baseline – test session) was more shifted in synchronous condition (fig. 3).

B. fMRI data

Left precentral gyrus, left SMA, left anterior cingulate cortex and right parahippocampal were significant differences between synchronous condition and asynchronous condition with visual feedback. Left superior orbital gyrus and left hippocampus were significant differences between synchronous condition and asynchronous condition without visual feedback (Table 1, 2).

Table 1 Main effect brain region test differences between synchronously condition and asynchronously condition with visual feedback

Volume	t	x	y	z	region
192	4.4959	-15	-23	68	Left precentral gyrus
160	4.5644	-3	-3	60	left SMA
128	4.4399	-3	39	4	left anterior cingulate cortex
104	4.6158	37	-33	-14	right parahippocampal

Table 2 Main effect brain region test differences between synchronously condition and asynchronously condition without visual feedback

Volume	t	x	y	z	region
176	-4.5188	-11	57	-2	Left superior orbital gyrus
96	4.2105	-27	-21	-2	left hippocampus

C. Correlation analysis

We performed correlation analysis contrasted % signal change (sync – async) with contrasted behavioral data (sync – async). Therefore, left SMA was correlated positively with ownership score (fig. 4).

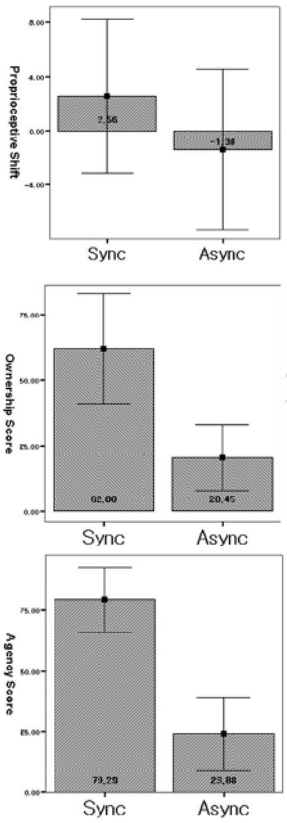

Fig. 3 Behavioral data

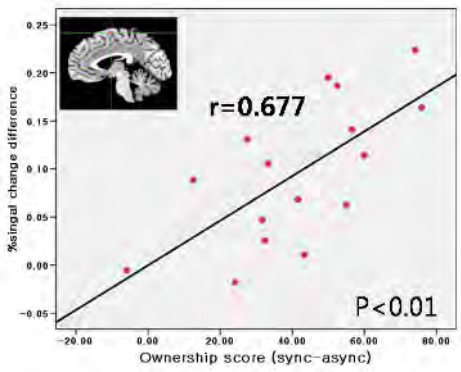

Fig. 4 Correlation with Left SMA % signal change difference (sync – async) and Ownership score difference (sync – async)

IV. Discussion

We investigated the effects of agency controlled (synchronously and asynchronously) movement on brain areas. We particularly focused on the correlation between left

SMA and ownership score. According to few neuroimaging studies, the SMA is implicated in the planning of motor actions and is associated with bimanual control. One could say that the SMA sends a "plan" of the motor action to the primary motor cortex, which executes the action. The SMA is implicated in actions that are under internal control, such as the performance of a sequence of movements from memory [13, 14]. The elicitation of ownership depends on the integration of visual and motor information and the differences between the visual and position sense representations. The period before the ownership develops is critical in this respect, and it probably involves a recalibration of position sense for the hand [15, 16]. Thus, the recalibration of limb position might be a key mechanism for the elicitation of the ownership, and indeed experiencing the ownership has behavioral consequences for arm movements [16]. SMA is one of the region this feature.

Abstract — **The chronic disease diabetes mellitus is increasing worldwide. It is caused by absolute or relative deficiency of insulin, and is associated with a range of severe complications including renal and cardiovascular disease as well as blindness. Preventive care helps in controlling the severity of this disease; however, preventive measures require correct educational awareness and routine health checks. Medical doctors help in effective diagnosis as well as treatment of diabetes, although it is associated with high costs. With this view, the purpose of the present research is to develop a low-cost automated knowledge-based system that helps in self-diagnosis and management of this chronic disease for patients as well as doctors. Our knowledge-based system has an easy computer interface, which performs the diagnostic tasks using rules acquired from medical doctors on the basis of patient data. At present our system consists of 26 rules and it has been implemented using Prolog programming. Some real-life experimentations were performed, which confirmed the effectiveness of the developed system.**

Keywords — **Diabetes mellitus, insulin deficiency, disease diagnosis, health care management, knowledge-based (expert) system.**

I. Introduction

In the year 2000, a study [1] among 191 World Health Organization (WHO) member states confirms that 2.8% people for all age groups had diabetes, and this is expected to be 4.4% by the year 2030. This implies that the total number of people with diabetes is projected to rise from 171 million in 2000 to 366 million in 2030. In Bangladesh, diabetes is reaching epidemic proportions; in some sectors of our society more than 10% of people have diabetes [2]. Diabetes causes [3] severe life threatening complications, such as hypoglycemic coma, blurred vision, loss of memory, severe impairment of renal function, insulin allergy, acute neuropathy, etc. Diabetes management requires dietary control, physical exercise and insulin administration. Medical doctors help in effective diagnosis as well as treatment of diabetes. However, it obviously associates with high costs. Despite remarkable medical advances, patient self-management remains the cornerstone of diabetic treatment. Knowledge-based intelligent system has been proven effective in solving many real-world problems requiring expert skills. Hence, to reduce the cost and to improve the early detection as well as self-awareness of diabetes mellitus, automated expert system might be a promising solution. Knowledge-based system for diagnosis can be used in variety of domains: plant disease diagnosis, credit evaluation and authorization, financial evaluation, identification of software and hardware problems and integrated circuit failures etc. [4]-[6].

The main objective of the present research is to develop a low-cost automated knowledge-based system incorporating the skills of medical experts to help the patients in self-diagnosis and management of this chronic disease. Recently, expert systems have been developed in laboratory stage for diabetes awareness and management, and insulin administration [7]-[11]. Compared to these systems, our approach is more simple and pragmatic.

The paper is organized as follows. In Section II the medical knowledge about diabetes is described briefly, Section III presents system architecture, Section IV describes rule-based decision-making process as well as some experimental results, and finally Section V draws the conclusions.

II. Medical knowledge of diabetes

Diabetes mellitus is a clinical syndrome characterized by hyperglycemia, due to absolute or relative deficiency of insulin. [12]

A. Classification of diabetes

1. Type-I (Insulin-Dependent Diabetes Mellitus—IDDM) diabetes tends to occur in the young. Type-II (Non-Insulin-Dependent Diabetes Mellitus—NIDDM) diabetes mellitus occurs more often in older people who are obese and had sedentary lifestyles.
2. Gestational diabetes mellitus (GDM) is a glucose intolerance detected in a pregnant woman who was not known to have these abnormalities prior to conception. [3]

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1000–1003, 2009
www.springerlink.com

B. Diagnosis

Diagnosis [13]-[14] is a process, by which a doctor searches for the cause (disease) that best explains the symptoms of a patient. Our knowledge-based system is mainly used for performing diagnosis based on patient data. Patient data can be demographic or clinical. Demographic data relates the information such as patient's age, sex, location, income, etc. Clinical data is divided into physical signs and laboratory results. Physical signs are those detected by a physical examination of patient, like BMI (body-mass index), pulse rate and blood pressure. Laboratory results are those detected via laboratory tests, like blood test, urine test, etc. The diagnosis system is based on following patient data. [12]

1. Test urine for glucose and ketones.
2. Measure random or fasting blood glucose:
   - Fasting plasma glucose >= 7.0 mmol/l
   - Random plasma glucose >= 11.0 mmol/l.
3. Oral glucose tolerance test:
   - Fasting plasma glucose 6.1-6.9 mmol/l
   - Random plasma glucose 7.0-11.0 mmol/l.

C. Method of Treatment

- Diet alone— 50% can be controlled adequately.
- Diet + oral hypoglycemic agent— 20-30% can be controlled.
- Diet and insulin— 30% can be controlled.

III. System Architecture

The computer-based system consists of a user interface, an inference engine, knowledge base, working memory and case history file. The case history file contains the demographic and clinical data of the patient. The knowledge base contains the heuristic knowledge encoded in some form (e.g., rules) for diagnosing diabetes. The working memory contains the (initial) patient data, partial conclusions, data given by user and other information related to the case under consideration. It provides facts and serves as a store for inferences or conclusions.

Inference engine mimics the expert system's reasoning process. It woks on the facts in the working memory and uses the domain knowledge contained in the knowledge base to derive (or infer) new facts as well as conclusions. [5] It achieves this by searching through the knowledge base to find rules whose premises match the facts contained in the working memory. If such a match is found, it adds the conclusion of the matching rule to the working memory. This process continues until the inference mechanism is unable to match any rules with the facts in the working memory. And finally, the user interface allows interaction with the inference engine to diagnose diabetes.

The structure of our expert system is shown in Fig. 1.

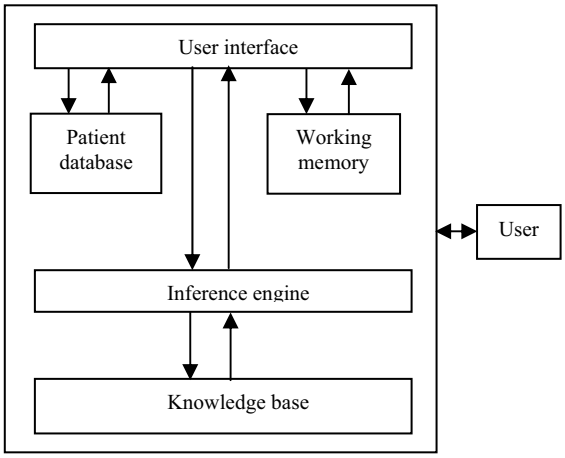

Fig. 1: Architecture of the proposed system.

IV. Diagnostic approach and experimental results

Diagnostic approaches can be grouped into four classes: model-based, rule-based, neural-network based and case-based. The knowledge representation schemes of model-based and rule-based diagnoses can be treated as symbol-oriented, while neural network and case-based diagnoses are instance-oriented. [4] In our system we use rule-based approach. A rule-based expert system is an expert system based on a set of rules that are used to make decisions. [6] To design an expert system a knowledge engineering process is needed, in which the rules used by human experts are accumulated and translated into an appropriate form for computer processing.

In our expert system we divide the treatment of diabetes into three categories.

1. Type-I diabetes— only insulin is used.
2. Gestational diabetes— only insulin is used, and
3. Type-II, where the oral hypoglycemic agent, diet, and sometimes insulin are used. In this category, there are special treatments:
   - The drugs for obese and lean patients.
   - The drugs, which should not used for the patient who have renal diseases, lactic acidosis, liver disease, etc.

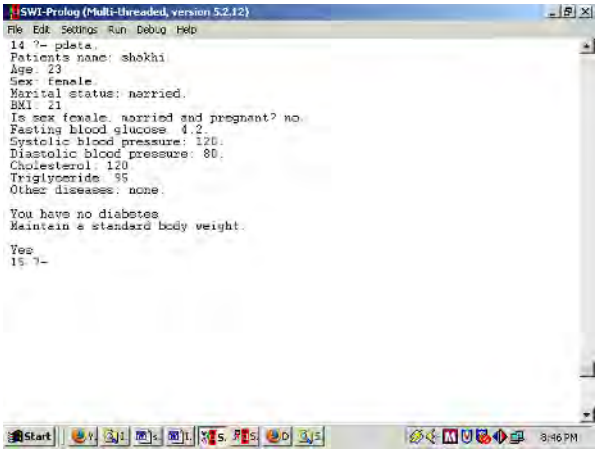

Fig. 2: Sample test result (case1).

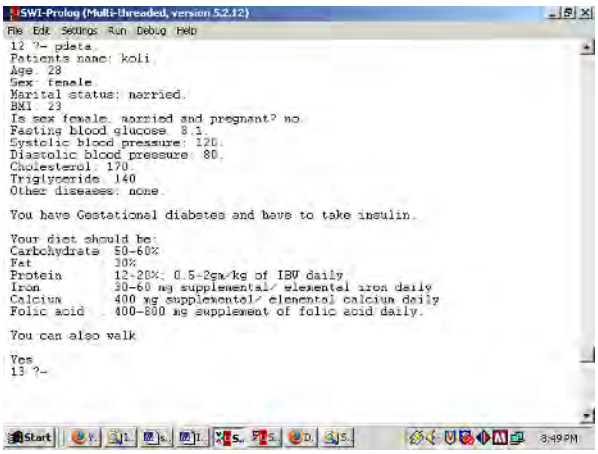

Fig. 3: Sample test result (case2).

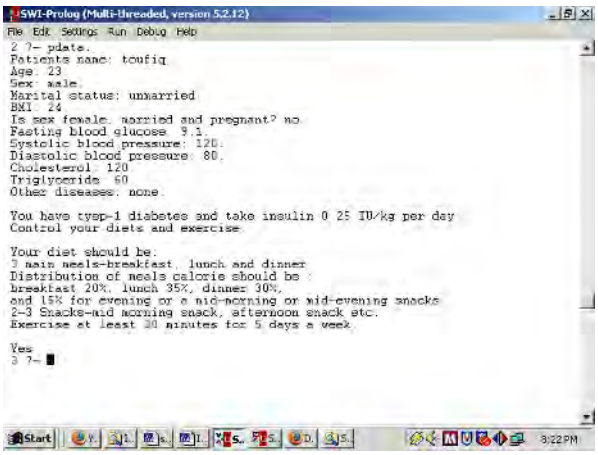

Fig. 4: Sample test result (case3).

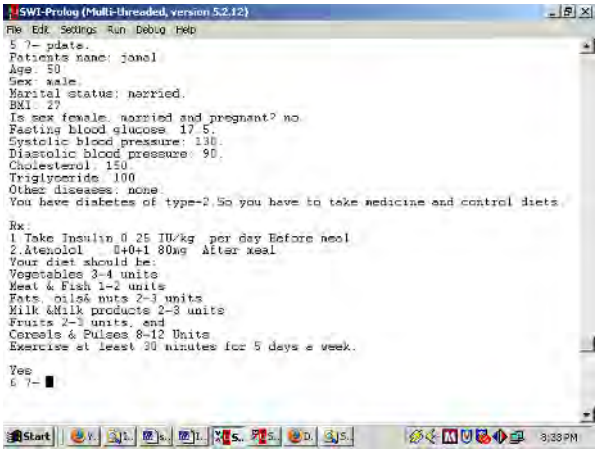

Fig. 5: Sample test result (case4).

At present, the system uses 26 rules and is implemented using Prolog programming language. We did experimentations using data of 100 patients. Some self-explanatory sample test results are shown in Figs. 2- 5.

V. Conclusions

A rule-based expert system for diagnosis of diabetes has been introduced in this paper. The aim of our expert system is to help the diabetes patients in low-cost treatment and management. Some real life experimentations were performed, which confirmed the effectiveness of the proposed system. The system can be used in both home and hospital environments.

There are some limitations in the developed knowledge-based system. For example, the number of rules is not sufficient for a general robust expert system. Moreover, wide real-life experimentations were not performed yet. Rooms are also available for improvement of the expert system on the basis of patients' feedbacks. Our future goal is to overcome the above limitations to make it a robust one.

Modeling and Mechanical Design of a MRI-Guided Robot for Neurosurgery

Z.D. Hong[1], C. Yun[1] and L. Zhao[2, 3]

[1]Robotics Institute, Beihang University, Beijing, China
[2]Harvard Medical School and Brigham and Women's Hospital, Boston, USA
[3]XinAoMDT Technology Co., Ltd., Hebei, China

Abstract — **Magnetic resonance imaging (MRI) has established itself as a standard tool in clinical diagnostics and advanced brain research, and is one of the real time modalities currently being an intra-operative image of neurosurgery. Robots are known to be accurate manipulation device that can share the digital workspace of MR imagers. It is, therefore, conceivable that MRI-guided robot could improve the accuracy of neurosurgery, and provide great assistance for surgeons to execute the planned neurosurgical maneuver in precise manner. This paper deals with a particular hybrid robot developed for keyhole neurosurgery. The kinematics model, dynamic simulation, the control system, and the functional design of the robot are treated, which focus on the necessary actuators' features characterized on the basis of the dynamic simulations.**

Keywords — **MRI, Robot, Neurosurgery, Kinematics and dynamics**

I. Introduction

Magnetic resonance imaging (MRI) is superior to X-ray CT in terms of good soft tissue contrast, lack of ionizing radiation, and functional imaging. MRI which has a relatively wide opening has been developed and spread recently. This kind of MRI is called Open MRI. But the opening is still narrow for sufficient number of surgeons and assistants to stand by the patient. In addition, manual positioning of tools is not as precise as the coordinate information provided by tomography. MRI-compatible robots provide surgeon in attractive way: The robots eliminate hand tremors and enable accurate and dexterous operation; In robotic surgery with MRI-guidance, recurrence of tumors will be reduced because surgeons can confirm the removal of tumor cells and improve the reduction rate of the tumor cells, because MRI can distinguish tumors or other lesions from normal tissues; Furthermore MRI can eliminate exposure to radiation from computer tomography (CT) or positron emission tomography (PET).

A variety of MRI-compatible robots are being developed and reported recently. Chinzei, et al. developed a Cartesian type surgical robot using an X-Y-Z table for use in an intra-operative MRI for biopsy needle or pointing device according to preoperative planning [1]. T. Mashimo, et al. developed a manipulator using a spherical ultrasonic motor which is constructed of three ring-shaped stators and a spherical rotor and has two or three degrees of freedom [2]. S.P. DiMaio, et al. designed a comprehensive robotic assistant system with steady needle placement and high-fidelity MRI imaging [3]. Kerieger et al. presented a 2-DOF passive, unencoded and manually manipulated mechanical linkage to aim a needle guide for transrectal prostate biopsy with MRI guidance [4].

The goal of our project is to design, fabricate, and test an Ultrasonic Motor actuate MR compatible robotic system for automatically and interactively aligning and orienting the surgical needle throughout the intra-operative MRI guided neurosurgical procedures, such as biopsy and brachytherpy. This paper design a particular hybrid robot developed for keyhole neurosurgery. The robot consists of a DELTA parallel mechanism with 3 DOFs and a serial manipulator with 2 DOFs, which function alignments and orienting of the needles respectively. The kinematics model, dynamic simulation, singularity analysis and control system design of the robot are accomplished. The necessary actuators features were characterized on the basis of the multi-body package MSC.ADAMS.

II. Material and method

A. System infrastructure

MRI-guided robotic system requires surgical planning, MR-image acquisition, human-machine interface, navigation, and sensing. To address these components required for MRI-guided intervention, a schematic diagram of the proposed infrastructure is illustrated in Fig.1. The entire system consists of three main subsystems as follows: MRI scanner and its image processing console, navigation computer and monitor, and robot. MR images are transferred across a local area network (LAN) in DICOM format from the MRI console (in the MRI console room) to the navigation computer (inside the operation room). The navigation computer provides pre-operative surgery planning, intra-operative image processing, MRI scanning controls, motion planning, remote actuation, and control of the robotic components. The surgeon is able to control and command the entire system through interactive interface on the navigation consoles.

www.springerlink.com

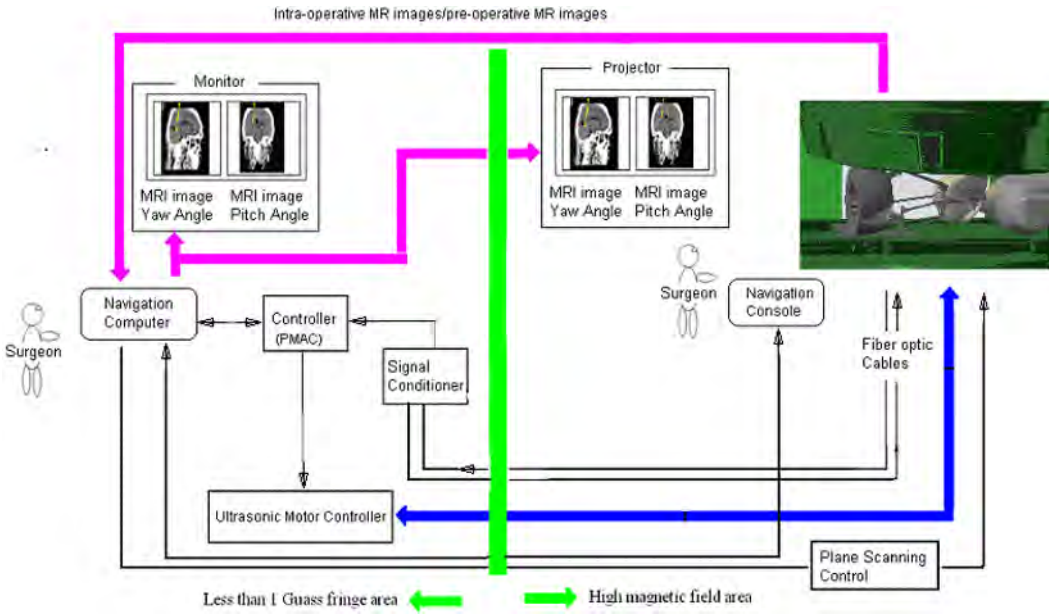

Fig. 1 Entire robot system

B. Mechanical modeling of Robot for neurosurgery

Parametric assembly of the robot, shown in Fig. 2, has been developed by means of the solid modeler NX5.0. The robot comprises DELTA mechanism, developed by L.W. Tsai [5-7], and serial manipulator which function the alignments and orienting of the needles respectively. DELTA mechanism is characterized by three identical kinematical chains, symmetrically placed at 120^0 between each other, which drive a moving platform with respect to a fixed base. The following elements are the elements of the topological structure of one of the three kinematical closed chains, respectively: an engine, an intermediary mechanism with four bars, which are parallel two to two, and finally a passive revolute link connected to the moving platform.

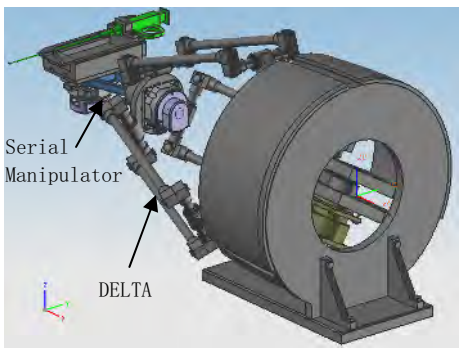

Fig. 2 3D robot model

C. Kinematics analysis

Delta only provides the function as X-Y-Z Cartesian type mechanism [5-7] without any rotation of moving platform. So the equivalent freedoms, labeled in 1 - 6, of the complete robot were described in Fig. 3. $z_i(i=1,2,3)$ are the moving axis of freedom 4, 5, and 6.

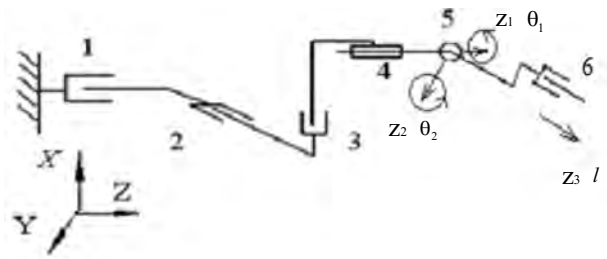

Fig. 3 Equivalent kinematics diagram of the robot

Let O_{XYZ} (Fig. 4) be a fix Cartesian frame, and its origin be set on the center point of the fix platform, and $\phi_0 = 0$. p is set at the center of moving platform, the length of the link connecting with moving platform is l_1, and the offset between serial manipulator and needle is d.

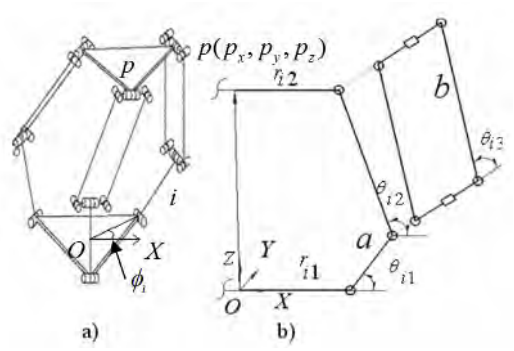

Fig. 4 a) Schematic of the 3 DOF Delta parallel mechanism and b) Description of the joint angles and link lengths for leg i

The direct and inverse kinematical equations of the DELTA were analyzed in [6-7]. The analytical solution proposed by [7] for the direct and inverse kinematical analyses are shown in Eq. 1 and Eq. 2 respectively.

$$ {}^{o}T_p = \begin{bmatrix} 1 & 0 & 0 & x_P \\ 0 & 1 & 0 & y_p \\ 0 & 0 & 1 & z_p \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{1} $$

$$ \begin{cases} \theta_{i3} = \pm \arccos \dfrac{p_y \cos\phi_i - p_x \sin\phi_i}{b} \\ \theta_{i1} = 2\arctan t_i \qquad ,i = 1,2,3 \\ \theta_{i2} = \arcsin \dfrac{p_z - a\sin\theta_{i1}}{b\sin\theta_{i3}} \end{cases} \tag{2} $$

where $\begin{cases} \mathrm{y_p} = \mathrm{c}\cos\theta_{13} \\ x_p = \dfrac{c}{\sin\phi_2}\left(\cos\theta_{13}\cos\phi_2 - \cos\theta_{23}\right) \\ z_p = k_0\cos\theta_{13} + k_1\sin\theta_{13} + k_2\cos\theta_{23} - k_1\sin\theta_{23} + k_3 \end{cases}$,

$k_i(i=0,1,2,3)$ and $\theta_{i3}(i=1,2)$ are the functions of geometric parameters and positions of DELTA mechanism; $t_i = \dfrac{l1_i \pm \sqrt{l1_i - 4l0_i l2_i}}{2l0_i}$, $l0_i, l1_i, l2_i$ are the function of θ_{i3}, a, b, p_x, p_y, p_z. More details were found in [7].

The direct kinematics of the 2-DOF serial manipulator (Fig. 3) was completed in Eq. 3 based on D-H parameters shown in Table 1, where c_1, c_2, s_1, and s_2 represent $\cos\theta_1$, $\cos\theta_2$, $\sin\theta_1$, and $\sin\theta_2$ respectively. The inverse kinematical model of the 2-DOF serial manipulator was shown in Eq. 4.

$$ {}^{p}T_E = \begin{bmatrix} c_1c_2 & -c_1s_2 & -s_1 & lc_1c_2 \\ s_1c_2 & -s_1s_2 & c_1 & ls_1c_2 + d \\ -s_2 & -c_2 & 0 & -ls_2 + l_1 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{3} $$

Table 1 Denavit-Hartenberg parameter of serial manipulator

Link	α_i	a_i	d_i	θ_i
1	0	0	0	θ_1
2	-90^0	0	0	θ_2
3	0	0	l	0

$$ \begin{cases} \theta_1 = \pm \arctan\left(\dfrac{y_E - d}{x_E}\right) \\ \theta_2 = -\arctan\left(\left(\dfrac{z_E}{y_E - d}\right)\sin\theta_1\right) \\ l_2 = -(z_E - l_1)/\sin\theta_2 \end{cases} \tag{4} $$

So the overall direct kinematics ${}^{B}T_N = {}^{B}T_P \times {}^{P}T_N$ is then determined. The overall inverse kinematics was obtained from Eq. 2 and Eq. 4.

When $\theta_{i3} = \begin{cases} 0 \\ \pi \end{cases}$, or $\theta_{i2} - \theta_{i1} = \begin{cases} 0 \\ \pi \end{cases}$, i=1 2 3, innerve singularities of Delta mechanism appeared. The direct singularities are solved analytically, but not all singularities are determined easily. Some typical singularities are $\theta_{i3} = \begin{cases} 0 \\ \pi \end{cases}$, or $\theta_{i2} = \begin{cases} 0 \\ \pi \end{cases}$.

D. Dynamic simulation

The model was exported to the multi-body package MSC.ADAMS, in order to obtain both kinematical and dynamic simulations of the neurosurgery procedures. Moreover, using the FEM analyzer MSC.MARC, the elements' stresses in dynamic conditions were assessed to optimize the detailed design of each component. Finally the necessary actuators' features were characterized on basis of the dynamic simulations.

In Table 2 the maximal torques of all actuators were calculated. The largest torque is 3.5 $N.m$, and the Ultrasonic motor meet the demand (Ultrasonic motor's rate torque is 0.6 $N.m$, ratio of reducer is 20:1).

Table 2 Simulation results

DOF	θ_{11}	θ_{21}	θ_{31}	θ_1	θ_2
Maximum actuator torque (N.m)	3.56	1.22	1.22	0.06	0.001

In Fig. 5 the torque exerted by the actuators at θ_{11} and θ_1 is presented for the cases analysis of maximal torque. The maximal absolute value (dash line) is about 3.56 $N.m$.

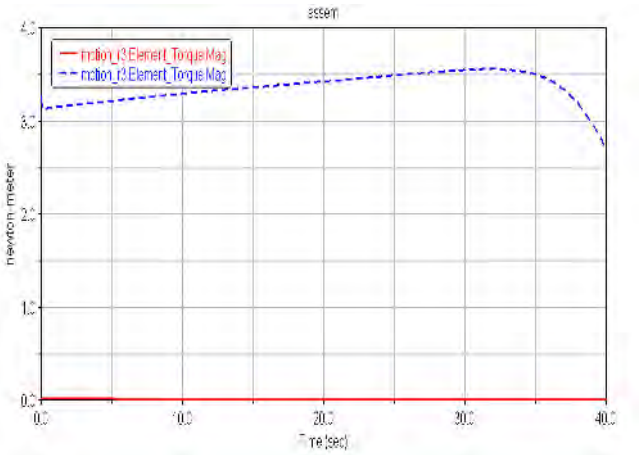

Fig. 5 Actuators' torque of first motor and fourth motor

If a serial mechanical architecture, for example Cartesian, were used to move the same masses along the same trajectories, the requested power would be much greater due to the robot moving masses, which are pre-eminent if compared to the equipment mass.

E. Control system

For the control of the robot the commercial motion controller PMAC has been chosen (8 axes, DSP56303, 40 MHz, endowed with teach pendant). It offers the user the possibility to implement her/his own defined model based control laws and coordinate transformation between the world Cartesian coordinate system and the robot internal coordinate system minimizing the effort of writing interpolating algorithms. The programming environment runs on Windows NT based personal computers and, besides allowing writing compile and debugging the application software, it permits to evaluate the behaviors of the controlled machine and then to choose the vast solution. The control diagram was shown in Fig. 6. PMAC communicate with PC according to RS232 interface. Surgical planning and joint interpolation were conducted in PC and PMAC respectively.

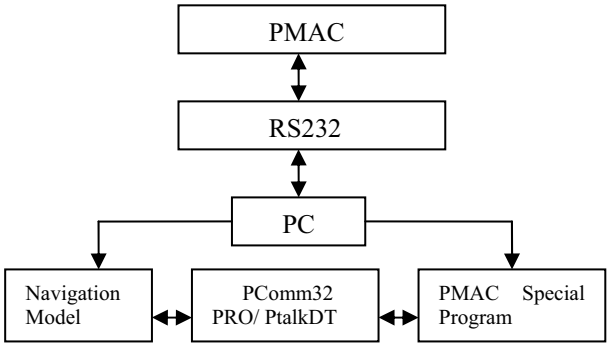

Fig. 6 Control system

III. Conclusions

We are designing a MR-compatible robotic system that can be used for automatically or interactive orientation and alignment of a needle based on the neurosurgical procedure, such as biopsy and brachytherapy, with intra-operative MRI-guidance. The robot has been designed such that it will perform desired tasks inside open MRI scanner. The direct and inverse kinematic equations that describe the robot behaviors can be implemented on a commercial motion controller for robotic application, such as PMAC, and singularities were considered during the design of control system. Ultrasonic motor were selected based on dynamic simulation. Current and future work includes the integration of the robot subsystem and performance of series of experimental test inside the MR scanner using the first physical prototype.

Acknowledgment

The test was performed by XinAoMDT Technology Co., Ltd. (Langfang, Hebei, China). The authors would like to thank XinAoMDT Technology Co., Ltd. for providing help and equipments.

The Study for Multiple Security Mechanism in Healthcare Information System for Elders

C.Y. Huang[1] and J.L. Su[1]

[1]Department of Biomedical Engineering, Chung Yuan Christian University, 200, Chung Pei Rd., Chung Li, Taiwan 32023, R.O.C.

Abstract — **There were many information systems that were applied to healthcare for recent decades. They were consisted of data, databases, and management tools, etc. and the most important works are going to maintain the security and integrity of system and data. In this study, we have used DICOM 3.0 as the data structure of vital signs and images in order to exchange data easier among heterogeneous system and Web service as the port for database connectivity. We used LDAP in JNDI to set a homepage with username and password to authenticate user has entrance authority or not. Key generation in JCE and X.509 in JCA for digital signature achieved encryption and decryption of personal profile and vital signs/images inside DICOM file for private key at client site and public key at server site to ensure the privacy of personal data and integrity of vital signs/images. All of JNDI, JCE, and JCA are security libraries which provided by Java JDK 1.6. We have tested the system security by user with authority or not, and different keys to verify the correctness of decryption/encryption for personal profile and vital signs/images. The preliminary result shows that the healthcare information system for elders we developed has the abilities to check who has the authority to access the data stored in database, personal profile consists inside the DICOM files will keep privacy except the persons who has correct key to decrypt, and also ensure vital signs or image integrity to display. Finally, the system used Java JDK can be easier to achieve the purposes to maintain authority, privacy, and integrity for data and system.**

Keywords — **Digital Imaging and Communications in Medicine (DICOM), JAVA development kit (JDK), Security, Healthcare Information System (HIS).**

I. Introduction

There were many medical information systems developed in recent decades for specific clinical usage. Such as CoMed system that was a real-time collaborative medical system about images and audio of teleconference and relative information of laryngeal diseases by using a multimedia medical database system [1]. It had gotten better security by distinguished degrees of login level. But just used this matter was not enough to make sure the integrity and privacy of data if someone got these data by abnormal manner. Besides, NEMA of USA has announced DICOM 3.0 PS 15 as the standard of security of medical data and medical information system [2] and the law of medical information security and privacy protection in Taiwan was according to Health Insurance Portability and Accountability Act (HIPAA) [3]. Therefore, data encryption before delivery or communication will be necessary to improve data security and privacy. For this reason, there were many researches focus on privacy or security, e.g. data security about remote vital [4], used security agent to implement interconnection of systems [5], and DICOM-Network Attached server oriented in safety to improve the safety for original server in PACS [6].

The previous study implemented the healthcare information system for elders was focused on DICOM files generation middleware for vital signs, stored into a SQL database, and used ActiveX technique to display on homepage [7]. It was not yet concerned about security and integrity of data and personal privacy. As mentioned above, the personnel profile and facial information encapsulated in DICOM file that can be reconstructed personal face must be encrypt for security and privacy. For this purpose, in this study we used the security components supplied by Java JDK version 1.6 [8] to implement the essential authentication control and achieved the security of contents of file for the purposes of system safety and data privacy. The following sections will descript infrastructure of system, materials and methods used for this study, results, and finally will give some discussions and conclusion.

II. System description

The concept architecture of the healthcare information system for elders was implemented as figure 1. At client site, there are two capture devices including vital signs of electrocardiogram and image for visual light real-time image. These data accumulated by a data accumulation PC located beside elders and operated by users who have essential computer knowledge. Before the work of upload and download files, the data should be encoded and encrypted to transfer into an encrypted DICOM file. Then users need to login the website by username and password that are stored in lightweight directory access protocol (LDAP) server to get authentication. In the end, the files were sent through web server would be decrypted and checked integrity and

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1009–1013, 2009
www.springerlink.com

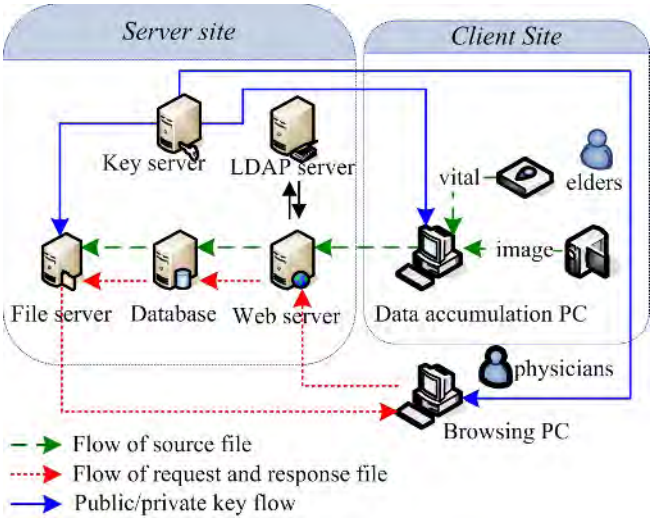

Fig. 1 System architecture

then stored in database/file server. For those who have authorization would review the data about personal profile and other secured profiles by browsing PC.

In this study, we have used the non-encrypted DICOM files included vital signs transferred from MIT-BIH arrhythmia database [9] and visual-light images captured from environment by a real-time USB webcam. The equipments of system were consisted of a Intel® Pentium 1.7 GHz Notebook installed Windows® XP service pack 2 acted as a data accumulation PC and a Intel® Core™ 2 2.4 GHz desktop PC installed Windows® server 2003 acted as web server, database server, and file server. The JSP homepages and Java application were coded both by NetBeans IDE 6.1.

III. Methods

There were many methods used in this study included of JSP, LDAP server, key pair generation, and DICOM encryption/decryption using the keys.

A. DICOM as file format

A DICOM file was constructed of file preamble, 4 chars of 'DICM', and many object groups, e.g. patient, study, series, equipment, image/waveform, etc. and a set of data elements grouped an object. The data elements were consists of tag, optional value representation, value length, and value field. Both of group and element were assigned 2-byte number to consist a specific tag that describes a data element. Then the value length and value field would supply to readout the value of data element correctly. Thus, encryption these object groups were concerned about data security. In this study, we focused on patient profile for privacy and vital/image which were part of analysis data/facial information that were with regard to personal security or integrity.

B. Java server pages (JSP) with Java applications as user interface

For JSP is a server- and platform-independent technology to create dynamic web content. It can change the overall page layout without altering the underlying dynamic content. For the contents of DICOM files are dynamic, JSP would be the adaptive method for implement the Web-based application that is announced by DICOM. Java applications used Java JDK can perform decode/encode, encryption and decryption DICOM files and it will achieve easy implement. Also, the applications can be called and executed by JSP.

C. Security of system and data

- Apache Directory Studio as LDAP server

LDAP server as multi-system entrance has reduced complication for user management by single account/password. Beside, it can distinguish user level and encode data to protect user privacy. Therefore, we used Apache Directory Studio as the role of LDAP server [10]. It provided with LDAP protocol and could run on multi-platform, e.g. Linux and Windows. Using Java naming and directory interface (JNDI) in JDK, JSP and Java application could connect to LDAP server, manage account, and achieve the authentication and authorization service for security of system.

- Key pair generation and Signature certificate

Here we have used Java cryptographic extension (JCE) and Java Cryptography Architecture (JCA), JCE is a part of JCA from JDK 1.4. [11]. Server used KeyPairGenerator to start with key pair generation. First, it decided key length to generate key pair by generateKeyPair() and used getPrivate{}/getPublic{} to get private/public key. The X.509 in JCA used to encode private keys before sent to client by X509EncodedKeySpec Class before transmission and Encoded method returned the key bytes according to the X.509 standard. After that, sent the private key and saved in client to use for DICOM files encryption and the public key was stored in server site for decryption. The digital signature (DS) was generated by using an instance of the Signature class for files in client. Following, file and DS both sent to server site to certificate integrity of data in transmission period.

- Encryption and decryption

As DICOM PS3.15 suggested RSA key pair as the public and private key pair shall be transmitted in an X.509 signature certificate. According to private RSA key encrypts digital signature, there are four tag values shall be embedded into DICOM file including MAC Algorithm (0400,0015) value could be one of "RIPEMD160", "MD5", or "SHA1". Value of Certificate Type (0400,0110) is "X509_1993SIG", Certified Timestamp Type (0400,0305) is "CMS_TSP", and Certified Timestamp (0400,0310) is "Internet X.509 Public Key Infrastructure; Time Stamp Protocols; March 2000".

While accumulation PC got original DICOM files, encryption and transmission progressed. The flowchart for DICOM files encryption and decryption shown as figure 2. In client site, DICOM files encryption would have to decode original DICOM files and then to decide which objects need to be encrypted or non-encrypted. Encrypted-objects were encrypted used private key in encryption process. Finally, all objects would merge with the related public key ID and DS to generate encrypted DICOM files. Then these files transmitted to server through network. When server received encrypted DICOM files, used the public key ID to access the public key stored in server and decoded non-encrypted and encrypted objects simultaneously. Then decrypted the encrypted objects and merged with non-encrypted objects to reconstruct the decrypted DICOM file if DS has certificated correctly.

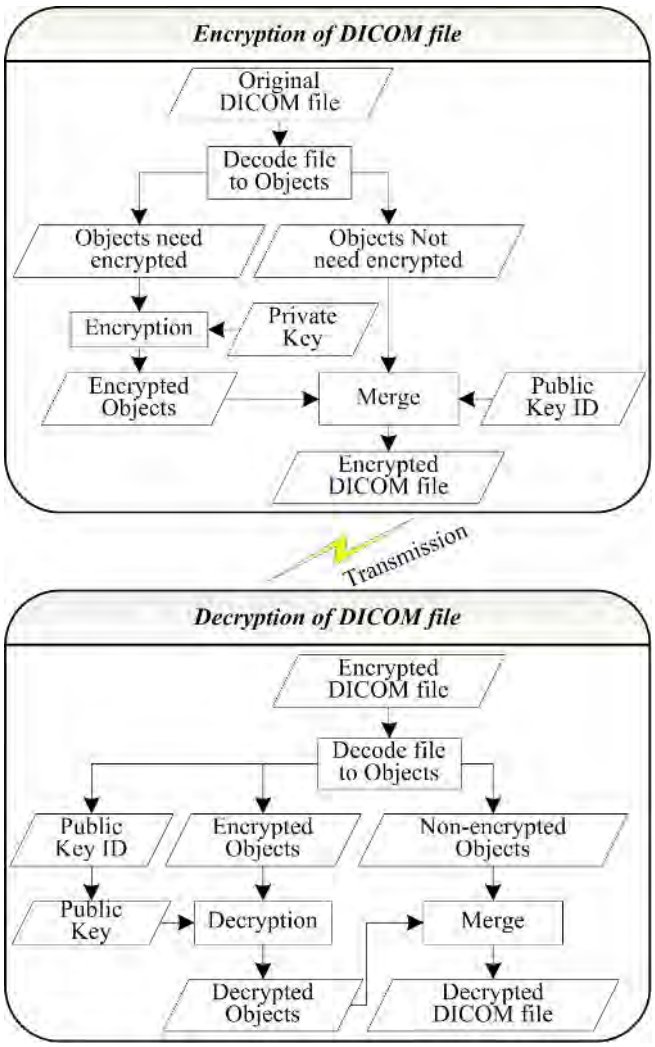

Fig. 2 Flowchart of encryption and decryption of DICOM files

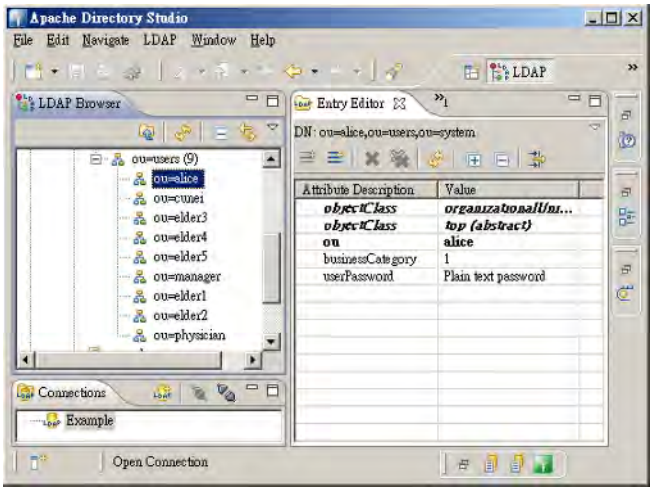

Fig. 3 Apache DS setting for levels of authorization

IV. Results

A. Authentication and Authorization

In this study, we have set three roles of level for users by setting the ApacheDS LDAP server as figure 3 to test authentication for users and about authorization for distinction of data process. Figure 4 shows the implement result of the username and password fields for users to input in main homepage were sent to check coincidence compared to the contents setup in LDAP server by web server. Then it was redirected to achieve the distinguish homepages for levels setting that integrated different functions for Care taker, Care giver, and Management status. It has supplied a mean to authenticate users and give users authorization to achieve the correct procedures resulted from setting LDAP server properly.

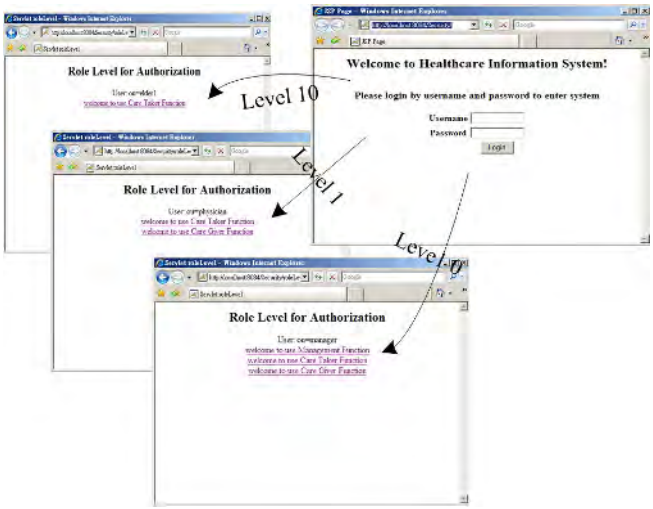

Fig. 4 Homepage for user login with different level to get authorization

B. Encryption and Decryption

There were three kinds of data have been tested for encryption and decryption extracted from DICOM files. They were text-numeric for personal profile, one-dimension vital signs, and two-dimension image. The length of key we used was 512 bits for it was properly for time consumed in CPU operation. Figure 5 was the results have tested by an encryption and decryption Java application. The left side of figure was the original data and right side was decrypted results by corresponding public key about the part of text data as personal profile, graphic vital signs, and environment image. The results of decryption compared by original data and processed data, there were no difference when used the corresponding key of pair but not match when used incongruous keys.

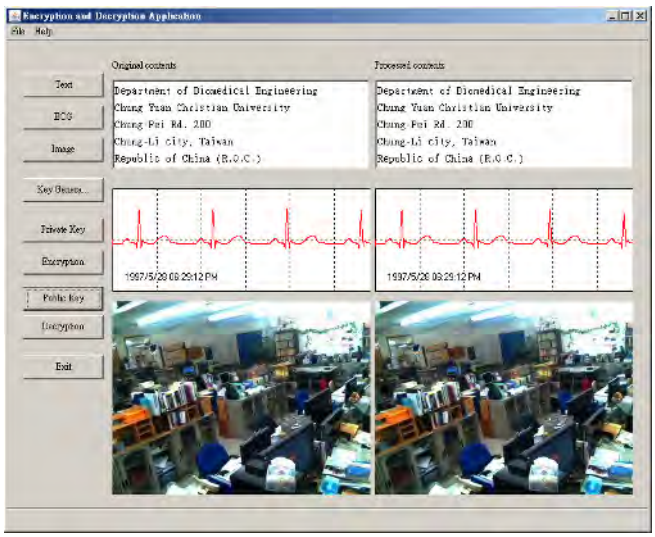

Fig. 5 Test results of encryption and decryption by Java application

V. Discussion

According to the results, we have shown that using Java language and JDK 1.6 supplied by Sun Microsystems® could achieve the purposes of authentication and authorization combined with LDAP server. It means that the levels of users could set and distinguish efficiency. We also could use the LDAP information to enter other information systems only need to connect the LDAP server. Besides, used keys pair generated by JDK security classes would maintain privacy and integrity of data by encryption and decryption worked well by using proper keys length. To combine encrypted data into DICOM files would spread through the heterogeneous healthcare information systems without falsification and readable by users with correct key.

VI. Conclusions

In this paper, we have presented to use JSP and JDK to achieve authentication by connecting LDAP server, keys pair of generation for encryption and decryption to reach the purpose of data privacy and integrity. For development of HIS for elders, next we will focus our efforts on software agents for automatic events detection and upload events with encryption. It is necessary for health care giver to reduce necessary of manpower by avoiding operation of the routine works about reviewing vital signs and images and uploading recorded files.

Abstract — **A project in innovation technology for the advancement of smart home to help elderly is conducted. The aim is to anticipate the dangerous situations that may happen at home (fall, restlessness, fainting, running away etc.) trough individual data collection and analysis of movement trajectories. This paper describes a conceptual space/time model of movement trajectories (beginning, end, stop and move). These models can be used for danger prevention in smart home. Results are presented for apartment scenarios and individual movement trajectories.**

Keywords — **individual movement trajectory, elderly, multisensor home system.**

I. Introduction

The problem of caring for elderly and people with physical disabilities will become more serious when a significant part of the increasing global population is in the 65 or over age group. In addition, the existing welfare model is not able to meet the increased needs. According to Eurostat, 12.1 % of the Europeans will be aged over 80 and 30 % will be over 60 in 2060 [1]. The wish to improve the quality of life for disabled and the rapid growth in the number of elderly has prompted an uncommon effort from both industry and academia to develop smart home technology. Currently, a significant number of dedicated smart home projects are being carried out throughout the industrialized world [2]. It has been shown that the ability to correctly identify mobility of occupants may have significant implications and applications in smart home. For example it may support independent living as people age at low costs [3]. Due to progress in electronics and information technology, one of key components in the development of smart home is detection and recognition of activities or mobility of daily life. For instance, in an attempt to develop a smart home environment, we introduce the concept of individual movement trajectory to monitor the mobility of the occupants. Individual movement trajectories have been considered as the path followed by an individual moving in space and time. Each point in this path represents one location in space and one instant in time. Typically, trajectory data are obtained from devices that capture the location of individual at specific time intervals. The background geographical information on which the individual is moving indoor or outdoor is of fundamental importance for the analysis of trajectory data. In this paper, we define the concept of individual movement trajectory as a set of moves and stops with a beginning and an end and the geographical location [4]. Some examples of movement trajectories of subject living in an institution and the system used to gather raw data are presented. The discovered travel patterns are stored in the movement trajectory database with the events linked to the data, in order to help the user (physician, caregiver, family members) to comprehend, visualize and question movement trajectory pattern relationships of elderly and disabled living alone for safety purpose.

II. Material and Method

A. Case Study

Multisensor system: The system is composed of infrared sensors (S1 to S10) with a binary output, a personal computer (PC), and a communication network connecting the sensors to the PC. Software collects raw data and processes them to assess automatically among variables (getting up, getting out, going to bed, going to washroom, and restlessness in bed or in apartment) the travel patterns of selected residents. The multisensor system is installed in a room of a setting for elderly. Ten areas are defined according to Figure 1. The PC is in the staff room. When a participant travels through the areas of the room, the sensors are activated. In real time the PC through the acquisition card acquires the

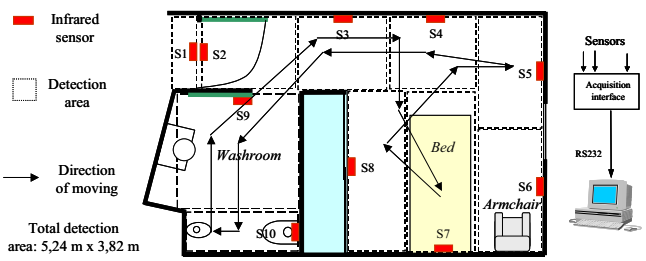

Figure 1. Multisensor system

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1014–1018, 2009
www.springerlink.com

data, which are a collection of 10 binary bits (1 or 0) corresponding to the activity of each sensor (on or off). The date of the day is stored with the data [3].

B. Trajectories: Definitions

Definition 1 (Trajectory): A trajectory is a set of ordered stops and moves in a precise geographical location indoor or outdoor, with a beginning and an end.

Definition 2 (Stop): A stop occurs when the subject is motionless. A non-empty time interval represents a stop.

Definition 3 (Move): A move in a trajectory has a time interval; it is preceded by a stop and is followed by another stop.

Definition 4 (Spatial characteristic type): A spatial characteristic type is located in the geographical earth surface indoor or outdoor.

Definition 5 (Sub-trajectory): Each trajectory is a set of sub-trajectories.

C. Sub-trajectories: Definitions

In a movement trajectory, a participant's activity is represented as a sub-trajectory. The participant must be alone; the multisensor system can't distinguish the movements of two participants in the same area. Indeed, the participant doesn't carry any electronic device.

Definition 6 (Going to bed): The participant activates a series of sensors as shown in Figure 1, from stop 1, an area adjacent to bed (S6, S5, S4, S3 or S8) he gets to stop 2, which is bed area.

Definition 7 (Getting up): The reverse procedure of going to bed confirms getting up.

Definition 8 (Getting in): The participant from stop 1 (area 1) gets to stop 2 (area 2).

Definition 9 (Getting out): The participant wanders in the room and then gets out. From stop 1 (area 2), he gets to stop 2 (area 1).

Definition 10 (Going to washrooms): The participant from stop 1 (area 2) gets in stop 2 (area 9).

Definition 11 (Going out to washroom): The participant from stop 1 (area 9) gets in stop 2 (area 2).

Definition 12 (Immobility or stop): The area 0 is artificial or virtual; if the area is 0 in stop 1, that means 10 sensors are in inactive state. In Table 1, from stop 1 (area 0) to stop 2 (area 3), the duration of immobility is 2.5 s. The multisensory system detects the participant at area 3 at 21:19:12.5, but doesn't know where the motionless participant is at 21:19:10.0.

Definition 13 (Restlessness): The multisensor system observes the series of sensor activations as shown in Table 2. In order to optimize data storage, raw data are stored as shown in Table 4. In this case, several stops and moves are in the same area, as shown in Table 3. In this case, a threshold t_s is defined, the participant in a specific area triggers the sensor at t_i and, at t_{i+1}. If $(t_{i+1} - t_i) > t_s$, the participant is quiet, and if $(t_{i+1} - t_i) < t_s$, the participant is restless [5].

Definition 14 (Mobility or move): The participant travels from stop 1 (area 7) to stop 2 (area 3), the time intervals is 50.5s. From stop 1 (area 3) to stop 2 (area 6), the time interval is 4s as shown in Tabs 4 and 5.

D. Results

A subject of 81 years old took part in the trial. The participant or his family signed an informed consent administered by the nursing staff before the trial. During the eight

months trial, he occupied his apartment in the night and was observed from 9 pm to 7 am. During the day, he was out of his apartment and took part in group activities in the institution. The participant got up 36 nights. Table 6 gives the results obtained with these 36 nights. The nursing staff noticed their getting in and out the participant room and the participant night activities after direct observation. These staff ratings allowed the concordance between staff ratings and automatic data processing to be verified and validated for assessing the resident travel behaviors.

25	1	0	21:25:32-21:25:37	5
26	1	2	21:25:37-21:25:39	2
27	2	1	21:25:39-21:25:40	1
28	1	0	21:25:40-21:43:59	19
29	1	2	21:43:59-21:44:00	1
30	2	1	21:44:00-21:44:01	1
31	1	0	21:44:01-21:44:05	4
32	1	2	21:44:05-21:44:07	2
33	2	0	21:44:07-21:44:09	2
34	2	3	21:44:09-21:44:14	5
35	3	8	21:44:14-21:44:20	6
36	8	7	21:44:20-21:44:36	16

The movement trajectory as shown in Table 7 includes several sub-trajectories:

- Motionless or stop in area 7 during 61s.
- Restlessness in areas 5, 10, 9 and 8 during respectively 50 s, 95 s, 102s and 16s.
- Going out in area 1 during 19s.
- Going from one area to another area with durations ranging between 1s and 6s.
- For area 5, which is a location adjacent to bed, the participant may remain restless 50s or in his bed. The multisensory system distinguishes with difficulty restless period in bed or in area 5 as shown in Figure 1. A pressure sensor placed in bed could really prove the participant in bed.
- Areas 6, 5, 4, 3, 8 are locations for traveling from one stop to another stop.
- Table 8 shows durations of moves or stops for different areas that the participant traveled.

Table 8. Mobility sub-trajectories

Area	Duration (s)	Mobility/Immobility
9	102	in washroom and restless
10	95	in washroom and restless
7	61	in bed and motionless
5	50	restless
1	19	outside
8	16	restless
9	15	restless
6, 5, 3	6	restless
7, 9, 8, 2, 1	5	restless
3, 2, 1	4	restless and outside (area 1)
5, 6, 4, 3, 2, 1	2	restless and outside (area 1)
7, 5, 2, 8, 1	1	restless and outside (area 1)

Table 9. Duration of stop or move in each area

Area	Duration (s)
1	19, 5, 8, 2 x 2, 1
2	5x2, 4, 2, 4 x 1
3	6, 4, 2 x 2
4	2
5	50, 6, 2, 1
6	6, 2
7	62, 5, 1
8	16, 5, 1
9	102, 15, 5
10	95, 4

Tabs 8 and 9 summarize the results given in Table 7 and shows that the participant got up once from 21:20:11 to 21:44:36. He was in bed in the beginning and immobile (area 0). He was restless in 10 areas and remained restless in 9 and 10, and was probably preparing to get up in 5, he

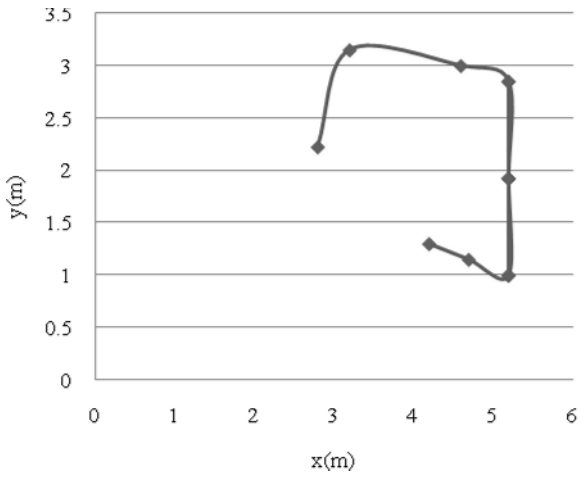

Figure 2. Participant movement sub-trajectories

remained restless during 50s, that was probably the bed area and not really area 5. At 21:21:12, he was in area 7, but probably not in bed.

Figs 2 and 3 show a participant movement trajectories from one location to another location. The location of the beginning is area 7 (Figs 2 and 3) and the location of the end is area 3 (Fig 2) and area 7 (Fig 3). Figure 3 shows 3 activities according to Table 7 (getting up, wandering in the bedroom, going to washroom and going out three times) and most sub-trajectories are direct (from bed to washroom). If it is supposed that from one area to another area, the subject covers approximately 1m. The speed of the move from area 5 to area 2 is 0.23m/s or 830m/h (duration 13s and covered distance 3m according to Table 6). Covered distances and travel speeds could be calculated for sub-trajectories and distance and speed thresholds could be defined for elderly monitoring procedure for safety purpose.

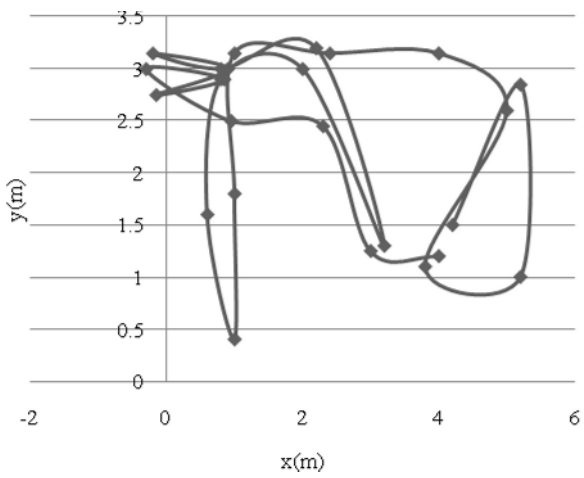

Figure 3. Participant movement trajectory

III. Conclusions

Using a multisensor system allows to collect individual movement trajectory and to estimate covered distances and travel speeds. Due to adjacent areas in the room specifically around the bed (areas 6, 5, 4, 3 and 8), the individual trajectory pattern relationships are hard to be visually identified because the adjacent areas are not easy to be visually identified and can lead to some errors. So a precise location of the infrared sensors is crucial. An attempt to classify different patterns of individual movement trajectories was carried out. Only sub-trajectories were classified [6]. The results show here the participant occupying bed and washroom (respectively 61s, 95s and 102s) and some direct movement sub-trajectories [7]. Choosing a beginning area and an end area for an individual movement trajectory and ordering the durations for moves and stops as shown in Table 8 and Table 9 allow better to comprehend the relationship between stop or move durations and areas in movement trajectories, even covered distances and speeds. Individual movement trajectories could be used to better identify abnormal trajectories in order to ensure security and safety of older individuals living alone instead of condemning then to go to institution and to leave their own home.

MR Image Reconstruction for Positioning Verification with a Virtual Simulation System for Radiation Therapy

C.F. Jiang, C.H. Huang, T.S. Su

Department of Biomedical Engineering, I-Shou University, Kaohsiung, Taiwan, R.O.C

Abstract — **This paper proposes a systematic method for 3D reconstruction of the MR images of a head to create a virtual radiation target for positioning verification in the treatment planning of radiotherapy. According to different features in the scalp and the brain, two different methods were applied to segment the entities. The scalp was detected by auto-thresholding and the brain was segmented by region-growing. The detected contours were then reconstructed as the 3D polygon meshes and transformed into VRML format to be presented in the virtual simulation environment. This scheme is further implemented as a module embedded in a virtual simulation system of 3D Conformal Radiotherapy (3D-CRT). System verification was achieved by using a full scale AP model of a human head as a target volume for positioning verification. We compared the positioning of the AP model in the real and virtual systems and found that the measurements were very close (difference < 0.3 cm). This state of the art integrates the techniques of image processing, computer graphics and virtual reality. With the assistance of the system, the position verification process may become more efficient and accurate than the conventional positioning toolkit only based on 2D image registration.**

Keywords — **MR image, 3D reconstruction, positioning verification, radiotherapy.**

I. Introduction

Radiotherapy is one of the most important methods to treat cancers nowadays. Since radiation can also damage the normal cells, treatment planning, which includes beam field design and dose calculation prior to radiotherapy is an essential work to reduce the chance of receiving radiation by the normal cells. Patient positioning verification is a routine work to confirm the meet of the radiation target to the planning target, in such a way to reduce the harm of the radiation to the normal tissue and meanwhile to increase the radiation effect to the malignant tissue. Thus patient positioning verification is the first key to a successful radiotherapy.

The three dimensional conformal radiotherapy (3D-CRT) has been introduced to improve the limitation of the regular field shape in the conventional 2D treatment planning system by shaping a target volume in a 3D imaging study, namely, the 3D treatment planning [1]. During the 3D planning, the target shape in MRI images has to be delineated manually on a slice-by-slice basis. After that the target volume is reconstructed and projected into 2D images planes from different angles within a cycle of gantry rotation by using the proprietary software, which is usually bundled with the radiation system. The optimal radiation field is determined by inspecting the target position in the projected image planes from the radiation beam's eye view. Accordingly, the 3D irregular field shape, called prescription volume, which conforms to the target volume can be achieved by figuring the beam portals at each angle and adjusting the length of each leaf in the multi-leaf collimator (MLC). However, the planning process of the 3D-CRT is labor intensive and sometimes need recurring verifications with the patient on site. The overall process can be a physical as well as spiritual torture for a patient. Thus, the 3D-CRT need to encompass a component which can save the labor, accelerate the time, and most importantly decrease the occurrences of patient visits.

Recent works have proposed a collaborative virtual environment as a platform of radiation treatment planning for easy communication in telemedicine [2-3]. In our previous works, we had at first developed a virtual radiation simulator for the training purpose [4]. A virtual linear accelerator associated with a virtual MLC was later integrated with the simulator as a double-platform simulation system [5]. The setting parameters, such as the gantry rotating angle, and the altitude and position of the patient table in the simulation room can be exactly transferred into the treatment room in order to verify the adequacy of both environment setting. However, the target volume used in this prototype is a virtual head, obtained by laser scanning of a full scale 3D solid anthropometric model (AP model) to replace the real patient for positioning and verification in treatment planning. The high-expense and non-deformability of the AP model make it not adapted to case varieties. As a result, the application of the virtual system is restricted to training purposes.

In this study, we propose an MRI image reconstruction scheme based on image segmentation techniques to create a target volume. This scheme is then further integrated into the virtual system as the rendering module of target volume for positioning verification directly in a 3D space. With the

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1019–1023, 2009
www.springerlink.com

assistance of this module, the target volume can be generated in an efficient way and the virtual radiation simulation system is prone to an economical solution for clinical application.

II. Methods

A. MR Image Reconstruction

In order to create a 3D polygon mesh of the target, we need to detect the target contours first. Two methods are applied to segment the tissue according to its appearance differentiable by its intensity or by its texture from its surroundings. The MR images used in this pilot study are obtained from the Database of the Virtual Human Project [6]. An example of the original MR image is given in Fig. 3a where the brain is more texture-like, while the head contour is the outmost layer brighter than the background. The segmentation is described in details as follows.

1. Image Segmentation by thresholding

For the tissue with great intensity gradient in the MR images, such as the scalp, we applied the auto-thresholding method developed by Ostu [7] to binarize the image. Due to the double-mode nature of the intensity histogram of MR images, we modified the one-threshold algorithm to a double-threshold one for detection of the head contour. The algorithm derives the optimal thresholds k_1^* and k_2^* to separate objects by maximizing the between-class variance σ_B^2.

$$\delta_B^2(k_1,k_2) = w_0(\mu_0-\mu_T)^2 + w_1(\mu_1-\mu_T)^2 + w_2(\mu_2-\mu_T)^2 \quad (1)$$

$$\delta_B^2(k_1^*,k_2^*) = \max_{1\le k_1<k_2<L} \delta_B^2(k_1,k_2) \quad (2)$$

where w_0, w_1 and w_2 are the probabilities of the three non-overlapping classes in the images, μ_0 , μ_1 and μ_2 are their mean gray values, and μ_T is the mean gray value of the entire image. An optimal set of thresholds k_1^* and k_2^* can be selected by maximizing σ_B^2.

Following that, we used morphological image processing techniques [8] to refine the segmented entity—first using 'fill' to seal the holes inside the head and then 'opening' to remove the resulting binarization debris outside the head.
"fill" operation :

2. Image Segmentation by region growing

For the tissue with its texture different to its surroundings in the MR images, such as the brain, we applied the region growing algorithm for its segmentation [9]. It starts by selecting a seed point, *s*, inside the brain area and forms the grow regions by appending to the seed the four orthogonal neighboring pixels that meet the growing criteria. Two major criteria control the growing process — a similarity criterion that selects the pixel to merge into the region and a stopping criterion that stops the growth of the region. The region growing proceeds with the similarity criterion, which is defined as a limited intensity difference, δ, between the target pixel, *p*, and the seed, *s*.

$$R^i = R^{i-1} \cup \{p \mid I(p) - I(s) < \delta\} \quad (3)$$

The seed, *s*, is updated as the mean intensity of the new growing region for each iteration. The stopping criterion is predefined as the region that exceeds the union of the brain areas manually outlined in the three orthogonal planes.

3. Contour Detection

Once the region of interest (ROI) is segmented by using the pre-described methods, the contours of the regions can be simply detected by searching the first gradient radiating outwards from the centroid of the ROI.

4. Polygon Mesh Creation

Based on these detected contours, the polygons mesh interconnecting the contours can be created by using minimum distance method [10], which is performed by looking the nearest points at the contours in two adjacent slices. The baseline of the first triangle was drawn by joining the first point of each adjacent contour. The next point in each adjacent contour with the minimum distance to the baseline was selected. These three points formed a triangle. The following points are connected together in the same way to form a polygon mesh.

B. Integration into the VSS

The created polygon mesh was transformed into VRML format and its size was adjusted according to the scale ratio predefined by the measures of objects' sizes in real and in virtual. All objects in the system had been scaled down according to this scale ratio. A virtual head holder was created at a fixed position on the table to allocate the virtual target when the VRML file was read into the virtual simulation system.

C. System Verification

System verification was achieved by using the full scale AP model of a human head created in our previous approach [4-5] as a target volume for positioning verification. (Fig.1 and Fig.2) We assumed that if the calibration of the virtual system simulation was correct, when transferring the whole setting in the real environment into the virtual sys-

tem, the position of the isocenter (the center of the beam) in the virtual system should be the same as in the real. There was a minute difference (< 0.3 cm) between these two measurements. This error could be due to the projection bending of the scalar on a head contour in real case (Fig. 1) rather than on a plane in virtual case (Fig. 2).

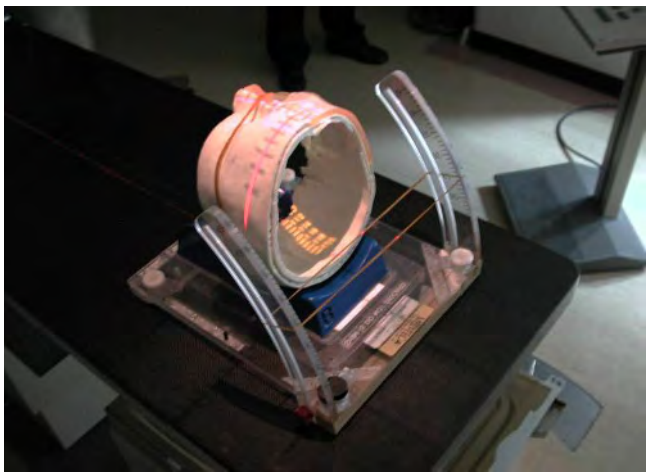

Fig. 1 The position of AP model within the head frame is set to align the tumor (facing inside) with the isocenter.

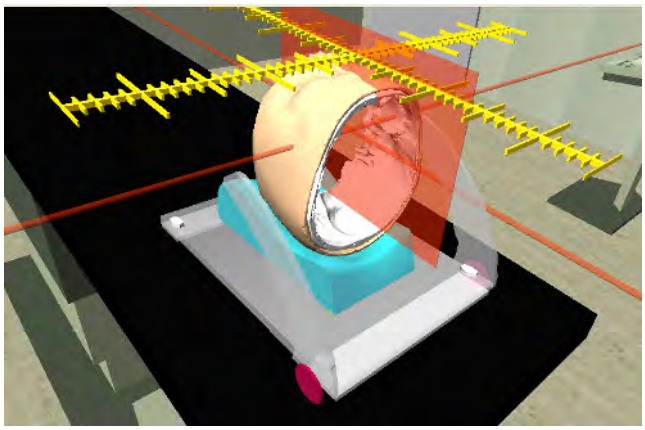

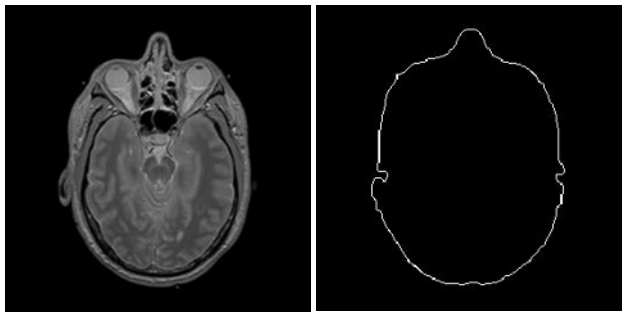

Fig. 2 The calibration in virtual system is verified by the same position setting as in Fig.1 with the virtual scalar on the top of the virtual AP model. The vertical plane at the center is an extension of the laser beam for easy identification of the isocenter location.

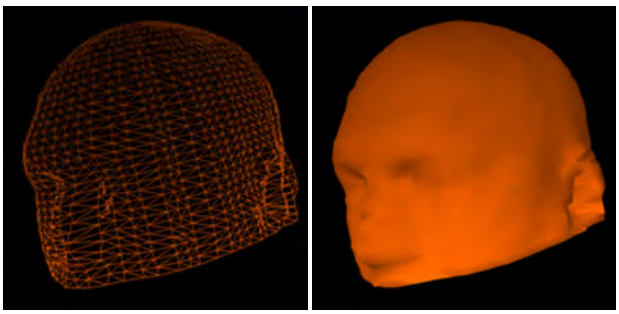
III. Results

The results will be presented in two aspects— first regarding the MR image segmentation and reconstruction, and second about integration of the target loading module with the virtual simulation system.



A. Image Processing and Reconstruction

Figure 3b shows the detected contour of Fig. 3a via the double-thresholding technique followed by two-step morphological image processing and maximum gradient detection. Fig. 4a demonstrates the polygon mesh achieved by interconnected the adjacent contours with minimum distance criteria and Fig 4 (b) shows its rendering surface. The same way is applied to generate the brain mesh except the segmentation method that is based on region growing. The two meshes are created separately as two data sets and can be combined together when being loaded by using the target loading module described later.

(a) (b)

Fig. 3 (a) MR image of a head and (b) the corresponding detected head contour (see details in the text.)

(a) (b)

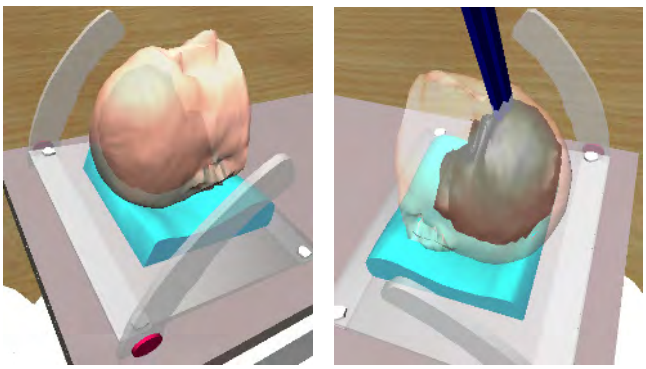


Fig. 4 (a) polygon mesh of the head and (b) surface rendering of the head

B. Integration of the Module into the VS System

In this module, an interface was designed to select and load the polygon mesh files into the VR-scene on the virtual head holder. The VRML-format mesh files can be multi-selected and rendered together as an entity, such as the head with a brain inside (Fig.5a).

The virtual system also provides a MLC configuration function and immediately reveals the 3D beam with color as

the result of the configuration. The visibility of the beam provides an easy way to assure that the 3D radiation beam cover the target volume optimally as shown in Fig.5b. In the position verification, the virtual scalar can be turned on as the reference for the radiation field delineation in comparison with that in the portal film.

(a) (b)

Fig. 5 (a)The reconstructed head with the brain inside had been load into the virtual system; (b) preview of the beam shape and irradiation fields in the virtual system with different rotation angles of the gantry.

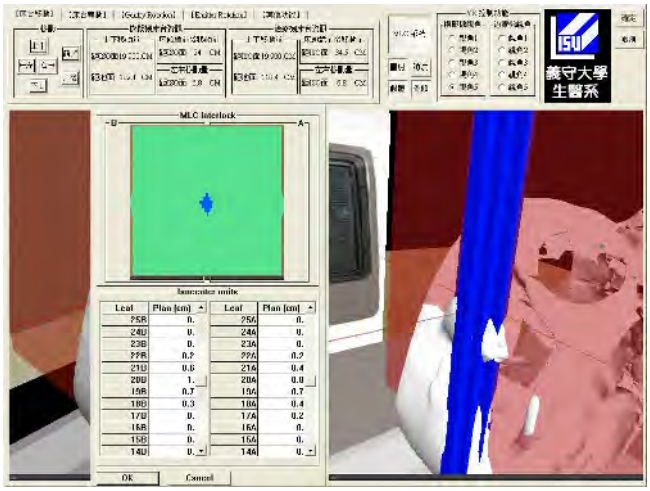

Fig. 6 An example to demonstrate that the VS system also provide a function of on-line MLC design. The result can be viewed immediately with the loaded virtual target.

The intersection of the virtual beam and the target volume can be inspected from different angles as shown in Fig.6 to verify the adequacy of the gantry angle and the MLC configuration.

IV. Discussion and Conclusions

We propose the MR image processing method to reconstruct the target volume for positioning verification in 3D Conformal Radiotherapy. A module with this MR image processing function is integrated into a virtual simulation system previous developed by us in order to load the reconstructed 3D target in this virtual scene such that the commitment between the radiation beam field and the target can be investigated with a 3D global view. The system verification shows the precision less than 0.3 cm. To achieve this precision, the VR system needs to be customized according to the real objects in the radiation treatment room. Nevertheless, this is easy to fulfill by the commercialized computer graphic packages. The key to make this system applicable in clinics is the capability to embed the various target volume of the real patients in this system. In other words, to make a virtual system able to contain a real 3D data from medical images is the aim of this study. Thus we believe that the upgraded system with the newly developed module has the potential for clinical use.

At this stage we only consider the targets in the same image data set; therefore registration is not necessary. However, the image processing module will be further expand is this regards.

Abstract — **Mechanical models of the human larynx have been used to validate mathematical vocal cord models, but most lack the applicability for ex-vivo surgical experiments. To our best knowledge, no technical evaluation has been reported using mechanical models to study vocal cord wound closure techniques. We design and develop a customizable and versatile mechanical hemilarynx with direct simulation of vocal cord vibration and airflow that can facilitate ex-vivo surgical experiments on the vocal cord. This setup enables experimental validation on the mechanical stability of novel devices, which are currently developed for epithelial wound closure in microlaryngeal surgery.**

Keywords — **hemilarynx, microlaryngeal surgery, wound closure.**

I. Introduction

Current practices in wound closure following endoscopic surgery to the vocal fold include sutures or tissue adhesives. These methods have proven technically difficult to achieve in such minimal access surgeries or yield less than optimum healing results respectively [1, 2, 3]. Our team is in the process of design and development of novel epithelial wound closure devices that can be easily handled and inserted onto the vocal fold cover with microlaryngeal surgical instruments. These devices must be able to withstand loadings induced by vocal fold vibration and glottal airflow. Experimental validation of these novel wound closure devices via a mechanical larynx model is a crucial and integral step to address limitations and complement results of other analyses, such as Finite Element simulation on these devices.

Many mechanical models of the human larynx have been designed to validate mathematical models of the vocal fold [4, 5]. However, none of these models has been applied in the study of vocal fold wound closure techniques to our best knowledge. These mechanical setups of the larynx lack the applicability and customizability for ex- vivo surgical experiments.

In this paper, we design and develop a simple and customizable mechanical larynx setup for ex- vivo surgical experiments with direct simulation of vocal fold vibration and glottal airflow. This setup serves as a medium to study vocal fold wound closure methods in ex-vivo surgical experiments, with focus on prototype wound closure devices that our team has designed. The efficacies of anchoring and mechanical stability of these devices under flow and vibration conditions can be assessed and evaluated using the model.

A mechanical hemilarynx setup, with one vocal fold replica opposite a flat wall, was designed [4, 6]. The use of a hemilarynx setup eliminates geometrical incongruence that occurs due to inconsistent membrane construction and adhesion on opposing airway walls [6]. This setup correlates most closely with the clinical situation when patients undergo removal of a diseased vocal fold (cordectomy).

II. Materials and Methods

The mechanical hemilarynx consists of a detachable vocal cord piece within a Perspex flow channel. This fits into a wooden casing connected to an external airflow supply.

The components of the Perspex flow channel consist of 2 Perspex boards of thickness, interconnected with a Perspex board of thickness, with a hole serves as an airflow outlet. Four guiding screws of size M5 connect a detachable vocal fold replica piece made of Perspex onto the medial surface of one of the Perspex boards. These screws have partial threads removed, such that the vocal cord piece can slide freely along the screw track. It is assembled as shown in Figure 1. The dimensions of the designed Perspex channel follow closely that of the glottal airway- The depth of the

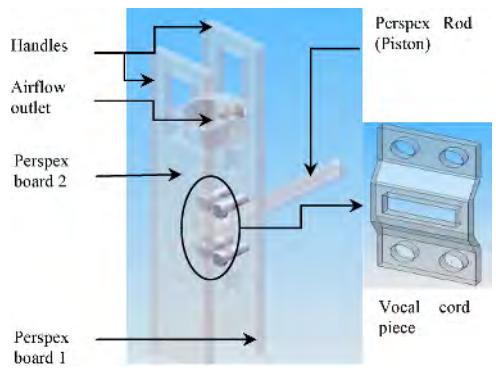

Figure 1: Assembly of Perspex Channel with Perspex rod (piston) and vocal cord piece

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1024–1027, 2009
www.springerlink.com

airway channel, enclosed by the sides of the encasing box is 25mm, the width of the channel is 27mm and the length of the channel (from airway entry at the bottom to the top of the vocal fold) is 90mm [4].

The geometrical contour of the detachable vocal fold piece shown in Figure 1 follows that of the outer geometrical contour of the vocal cord described by Alipour et al [4]. This piece is kept to a uniform 2mm in thickness and has a rectangular slot of 15mm by 5 mm removed from its middle section to allow greater clearance for wound closure devices to be inserted without being pushed off by the Perspex rod indicated in Figure 1. The thin structure of the vocal fold piece coupled with the rectangular slot drastically reduces the inertial properties of the vocal fold such that it could slide with ease along the guiding screw tracks.

A single layer of polyurethane film with tensile strength of approximately 3,000psi, tensile break length of 500% is slightly stretched over the detachable vocal fold piece [7]. The top and bottom ends of the sheet are secured to the distal ends of the detachable vocal fold piece using laboratory Parafilm® .This film serves as the primary medium for ex vivo microlaryngeal surgery experiments. It simulates the compressive stresses acting on the novel wound closure devices at the interface areas of contact.

The wooden encase is designed a high degree of versatility and customizability for a wide variety of laryngeal ex vivo surgical experiments on the vocal folds. It is equipped with an I- shaped recess to allow ease of insertion and removal of the Perspex channel. It is also equipped with multiple observation holes for an endoscopic camera system with a stroboscope feature to track the vibration of the vocal cord replica under different flow and vibratory parameters. A portable stroboscope is used in place of the endoscope camera system for this phase of experimentation. A picture of the assembled wooden encase with base supports and a flange that connects to external airflow via a compressor is shown in Figure 2.

A selected prototype of one of the novel wound closure devices is secured onto the film using laboratory forceps. The Perspex channel is then assembled and fitted into the wooden encase as shown in Figure 3. The flat end of the Perspex rod is pushed through corresponding slots on the walls of the wooden encase, Perspex channel and detachable cord piece until it comes into direct contact against the polyurethane sheet. The circular end of the piston is then connected to the core of the linear vibrator, placed on a Perspex stand. A loudspeaker that serves as an external linear vibrator then closed in towards the wooden encase, until that a premade mark of 4mm from the distal flat end of the piston is level with the slot on the slot of the wooden encase. The piston-vibrator system serves as an external simulation of the vocal cord vibration.

A signal function generator, with frequency and amplitude control is calibrated to generate sinusoidal waveforms and is connected to the linear vibrator (loudspeaker). The core of the vibrator then acts as an actuator that pushes the Perspex rod further inwards and draws it outwards in a cyclic motion such that the latex sheet undergoes a forced series of cyclic tension and compression. Air supply is regulated by an air compressor, which can be varied from a few bars to 15 bars. The air is directed through a 3 meter long soft rubber tube fitted into the steel flange at the bottom of the encased box as shown in the Figure 4 below. Finally, a portable stroboscope is placed at a distance of approximately 10cm away from the observation hole as indicated in Figure 4. The stroboscope generates a series of rapidly flashing lights at frequencies prescribed by a dial control to match the frequency of the vocal fold membrane vibration.

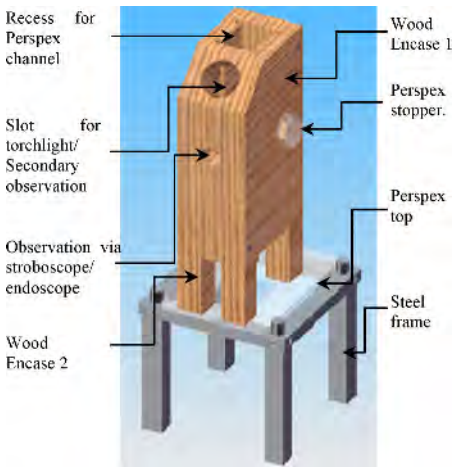

Figure 2: Wooden Encase with Perspex Top Stand

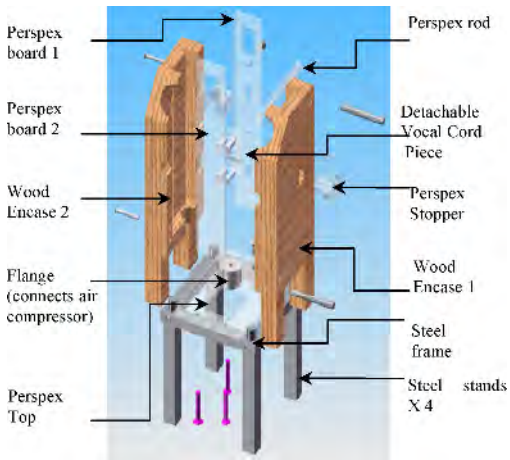

Figure 3: Exploded View of Hemilarynx Model

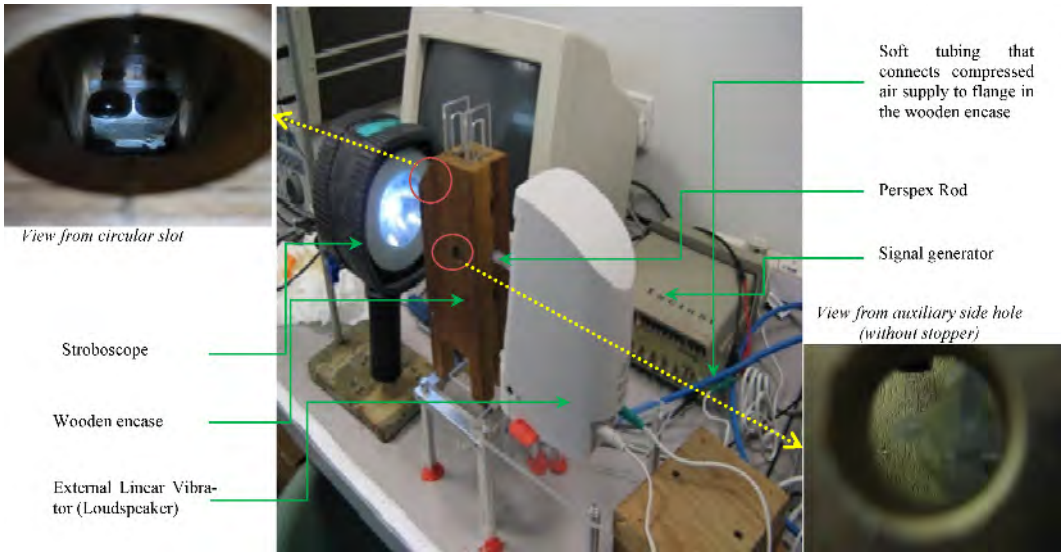

Figure 4: Complete experimental setup with in- experiment views of mock vocal cord with prototype of novel wound closure device during forced vibration and airflow conditions.

III. Results

Experiments are conducted with air supply at constant gauge pressure of 1.5 bars, with low phonation frequencies of 40Hz, 60Hz and 80Hz each with durations of 30 mins [5]. Vibration frequencies of the vocal fold pieces are tallied and validated with stroboscope flash emissions readings.

Observation via the circular slot is conducted at time points of 10 and 30 minutes for all 3 sets of frequencies tested to observe retention of the prototype wound closure device and the tearing of the film at large displacements and high frequencies. Results of the experiment are given in Table 1 below.

Table 1 Ex-vivo experimental trials on stability of novel wound closure device in a hemilarynx model.

Actuator Frequency (Hz)	Stroboscope Frequency (Hz)	Retention of selected prototype on film		Tearing of film observed
		10 (mins)	30 (mins)	30 (mins)
40	40.1	Yes	Yes	No
60	60.3	Yes	Yes	No
80	80.2	Yes	Yes	No

Neither tearing of the polyurethane film nor dislodgment of the selected prototype is observed within a timeframe of 30 minutes for frequencies of 40Hz, 60Hz and 80Hz respectively.

IV. Discussion

Through the ex- vivo experimental setup of the hemilarynx, we are able to validate the dynamic anchoring capabilities of the selected prototype wound closure device, under low frequencies of phonation of 40Hz – 80Hz, characterized by large displacements of the vocal cords. Similarly, the hemilarynx setup is very easily customized to cater for ex-vivo experimentation on other prospective prototype designs of the novel wound closure devices, as well as that involving microsutures and surgical glue. The results of such experimentation with the hemilarynx model will give a good indication of the respective mechanical stability of these materials and devices under vocal cord vibration and subglottal airflow conditions. It will serve to validate and complement other forms of mechanical analysis for epithelial wound closure in microlaryngeal surgery.

The mechanical hemilarynx has several drawbacks compared with an actual human larynx. A single layer polyurethane film is only sufficient to generate compressive stresses along a small area of contact interface with the selected prototype. On the other hand, compressive stresses will act throughout the embedded ends of the selected prototype in an actual larynx due to the presence of the deeper layers of the lamina propria and vocal ligament in a human vocal fold. Viscous and adhesive effects of vocal fold tissue will present shear stresses on the novel wound closure device when it is implanted in a human larynx environment.

In addition, it is difficult to achieve good simulation of subglottal airflow around the vocal fold piece and the wound closure device due to the presence of guiding screws in the Perspex flow channel. Nevertheless, this is not deemed as a major limitation as pressures exerted by vocal cord muscles during phonation far dominate over subglottal airflow pressures [8].

V. Conclusion

The experimental hemilarynx setup is a highly versatile and customizable. It offers direct simulation of vibration of the vocal cords and has been designed to facilitate mechanical means of surgical experimentation on the vocal cords. Most importantly, it has demonstrated good applicability in the evaluation of novel epithelial wound closure devices.

Virtual Total Knee Replacement System Based on VTK

Hui Ding, Tianzhu Liang, Guangzhi Wang, Wenbo Liu

Department of Biomedical Engineering, Tsinghua University, Beijing, China

Abstract — **In this paper we present a surgery planning software of total knee replacement (TKR). It was established initially based on the open source package - Visualization Toolkit (VTK). The main innovative feature of this surgery planning system is that it could help the surgeon to choose correct size, orientation and position of the prosthetic components, in order to restore the correct alignment of the mechanical axis of the lower limb. To simulate the multiple degrees of freedom of the embedded prosthesis in operation, such as introversion-extroversion, exterior-interior rotation, flexion-extension, and translations along anatomical axes, in total knee replacement procedure, the appropriate human-machine interactive technology and alignment restrictions were designed to help the operator to perform the virtual cutting and virtual assembly manipulation. Moreover, the clinical commonly used quantitative index contradistinction was provided to assist the doctor to determine the spatial relation of the implantable prosthetic components in 3D space. The function design of the software system was evaluated by the virtual motion analysis of the knee flexion, which obtained a good effect. The process diagram and detailed treatments of virtual operation was provided in this paper. The software of surgery planning plays important roles in preoperative lectotype of the prosthesis and alignment procedure of bone resection and assembly operation.**

Keywords — **Total Knee Replacement, Visualization Toolkit (VTK), Surgery Planning.**

I. Introduction

Total knee replacement (TKR) is a surgical operation in which a surgeon removes a patient's damaged knee joint surface and replaces it with artificial components to restore the disabled knee functions. The purpose of the TKR surgery is to correct the axial alignment of the lower extremity, maintain the joint stability, relieve the pain in the joints and thus restore the whole function of the knee joint.

In order to ensure the good postoperative function of the knee joint, the bone resection position and the placement of the prosthetic components have to be controlled precisely within three dimensional spaces. Therefore, the preoperative planning software of total knee replacement was receiving more and more attention. At present, many institutions have successfully developed total knee replacement surgery planning system [1-3]. Using the planning software, surgeons can virtually simulate the surgical procedures with computer. The system allows them to determine important surgical parameters such as the amount and angle of resection and choose the best artificial knee joint for patient before real operation [1].

As the key procedure to success restore the knee function are the correct selections of prosthesis and put it to the correct location relative to the femur and tibia in TKR surgery. The most import feature of the simulation system is the appropriate human machine interface which provides all kinds of changeable characteristic of the spatial position of the prosthesis in the 3D space. The export of the quantificational indices of operation planning systems provides a significant basis for the establishment of the operation planning.

This paper introduces a TKR planning software which was developed based on Visualization Toolkit (VTK). The preoperative computer tomographic (CT) images of the patient were used to reconstruct 3D bone models. The 3D models of prosthetic components were obtained from 3D laser scan. The appropriate human-machine interactive technology was used to manipulate the 3D model of bones and prosthetic components. Through the simulation of knee flexion of the lower limb models after virtual total knee replacement, the surgeon could observe and evaluate the assembly result from different view point, which help the surgeons to decide the appropriate position of the bone resection and place the embedded prosthesis to desired position. This simulation system is dedicated to assist the surgeon in the preoperative determination of accurate location of the osteotomy, selection of prosthetic implants, as well as the 3D positioning of the implants.

II. Materials and methods

A. *Description of the TKR Planning system*

The basic steps of computer-assisted preoperative planning consist in seven steps: (1) Construct the three dimensional models of limb (femur and tibia) and prosthetic components. The 3D model of lower limbs was constructed from CT images of lower limbs and the 3D model of prosthetic components was from three dimensional laser scan; (2) Identify the limb mechanical axis; (3) Determine the spatial position of prosthetic models in 3D space with re-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1028–1031, 2009
www.springerlink.com

spect to the bones; (4) Pre-assembly of bones and prosthetic components; (5) Quantitatively determine the appropriate bone resection positions and directions; (6) Virtual Cutting; (7) Educe quantitative indicators and save the key index and assembled model.

A block diagram of the planning procedure is illustrated in Fig. 1. The TKA planning system was developed based on the open source platform of Visualization Toolkit (VTK) and development platform of Visual Studio 2005.

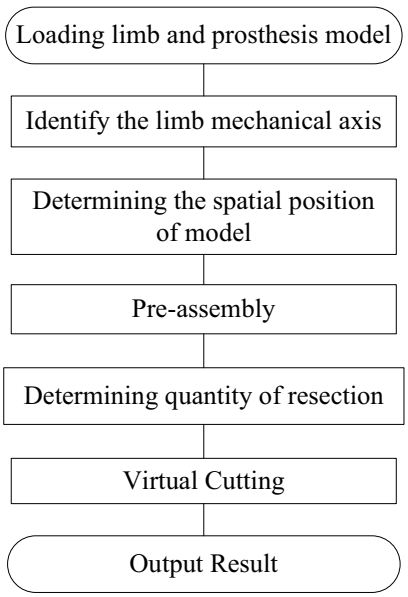

Fig. 1 A block diagram of the TKR planning system

B. Materials

1. Three dimension model of lower limb: The 3D bone models were constructed from computed tomography (CT) scan. Lower limb CT scan was performed with 1mm slice space and image resolution of 512*512. The corresponding pixel size is 0.782*0.782 mm. Slices covers the range from the proximal end to of femur to the distal end of tibia.

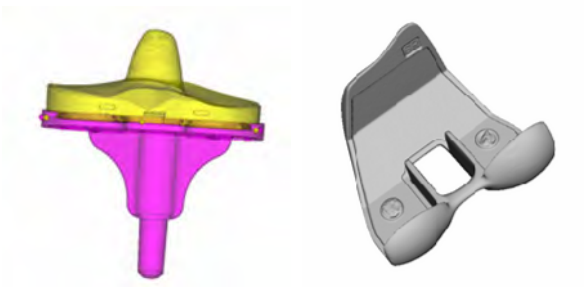

Fig. 2 Three dimension model of the prosthetic components

2. Three dimension model of the prosthetic component: The 3-D prosthetic component models was constructed from three-dimensional laser surface scans, which reverse-engineered the articular surfaces into point clouds with associated point normals. The sampling resolution of the laser scanner used was about 0.5 mm. A 3-D surface model of the prosthetic component is shown in Fig. 2.

C. Realization of the Virtual TKR System

1. Mechanical axis Selection: Osteotomy and prosthesis assembly is based on the mechanical axis of the lower limbs. As a result, lower limb mechanical axes determination is essential in the virtual TKR system. We select the femoral mechanical axis, FMA, from the center of the femoral head to the center of the intercondylar notch of femur, and select the tibial mechanical axis, TMA, from the center of the tibial plateau to the center of the ankle joint.

2. Determining the spatial position of model: Total knee replacement is an extremely "position sensitive" surgical operation [1]. The restoration of correct alignments of lower limb mechanical axes demands precisely positioning manipulation of prosthetic components of femur and tibia in relative with the bones in 3D space. Thus the assembly of tibia and femur prosthetic components may involve multiple degrees of freedom misalignments, such as introversion-extroversion, external-internal rotations, flexion- extension, and translations in all directions.

When we construct the 3D model, each component had its own coordinate system (three orthogonal axes). If we could define the mechanical axes and the flexion axis of the femur and tibia precisely, then the model can be transferred to any desired 3D position with rigid body transformations.

In distal femoral replacement, the bone-cutting of the thighbone basically included the section of distal femoral condyle, the anterior and posterior femoral condyle, and the anterior and posterior bevel of the femoral condyle.

Three steps were designed to determine the position of the thighbone prosthesis. The first step is to choose the anatomical landmarks to determine the mechanical axes of femur and the axis of joint flexion-extension. We palpate a set of points in the surface of femoral head to calculate the center of the femoral head, and pick up the intercondylar notch of femur with the 3D model. Thus the femoral mechanical axis, FMA, from the center of the femoral head to the center of the intercondylar notch was determined. Then we palpate the anterior and posterior femoral condyles to determine the flexion-extension axis of femur.

The second step was to determine the section location of distal femoral condyle. The primal section plane always perpendicular to the femoral mechanical axis and can be adjusted in the direction of proximal-distal. A reference

plane was generated to help the visual inspection of the resection position.

After the initial section plane of distal femoral condyle was determined, the third step could be performed. The flexion-extension axis of femur and the reference plane were used to restrict the flexion-extension of the femoral prosthesis. The cutting planes of anterior and posterior femoral condyle were set parallel to the flexion-extension axis and perpendicular to the reference plane. Moreover, he the cutting planes of anterior and posterior bevel were set parallel to the flexion-extension axis and keep a specific angle to the reference plane. According to the known sizes and angles of the prosthesis, those cutting planes of anterior and posterior femoral condyle can be determined.

The selected landmarks and generated reference plane are show in Fig. 3 and Fig. 4.

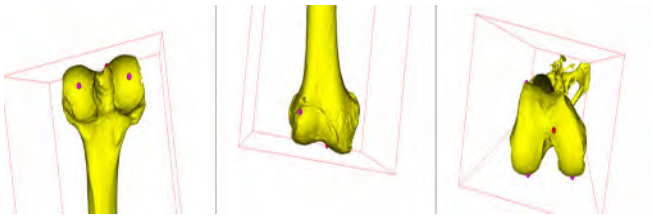

Fig. 3 The palpate of anterior, interior and exterior posterior femoral condyle

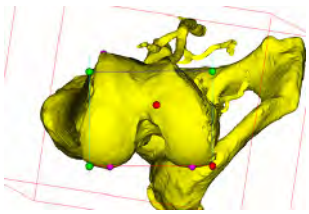

Fig. 4 Reference planes for determine the section of anterior and posterior femoral condyle.

For the tibia, we select the tibial mechanical axis, TMA, from the center of the tibial plateau to the center of the ankle joint. The sagittal plan of tibia was determined by the tibial plateau center, the astragal center and the landmarks interior 1/3 part of the tibial tubercle. With those selection, the restrictions to the tibial prosthesis was applied.

3. Pre-assembly: The pre-assembly of the femur and tibia prosthesis were processed by a sequence of alignments. In the first step, the direction of the prosthetic axis was aligned with the mechanical axis of the thighbone model, and the prosthesis could be moved proximally and distally. Then the inner and outer diameter of the prosthesis was aligned with the thighbone model along the flexion-extension axis. In the third step, through the projection of the center of the femoral condyle notch, the projection of sagittal plane was drawn on the reference plane, and the prosthesis was aligned to make the center of the prosthesis located in this vertical line, with the posterior cutting surface of the thighbone aligning with the posterior cutting line on the reference plane. The similar alignments were performed with the tibial bone and prosthesis.

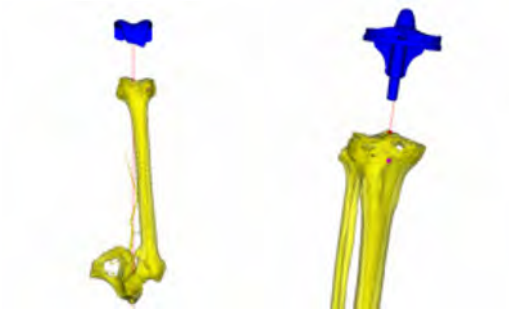

Fig. 5 Pre-assembly of femur and tibia prostheses

4. Determining of the Bone-cutting Quantity: In the operation planning system, the bone-cutting quantity of the distal femoral condyle was calculated by the cross point of the bone-cutting plane of the distal femoral condyle and the thighbone axis. Because the thighbone prosthesis was restricted to move along the mechanical axis of femur, the relative position of the center of prosthesis had no change during the movement. Therefore, the cutting quantity of the distal femur could be determined easily.

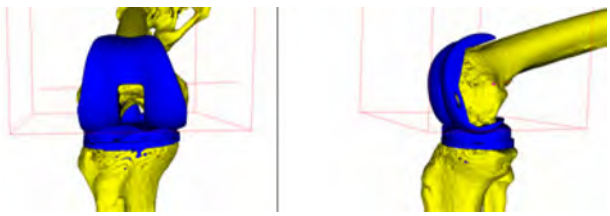
In usual cases, if the tibial plateau was perpendicular to the mechanical axis of the tibia, the thighbone prosthesis was in the external rotation position with an angle of 3°. Then bone-cutting quantity of the interior femoral condyle of posterior was longer than that of the exterior femoral condyle of posterior for 2 to 3mm. The cutting quantity of the tibial plateau referred to the distance from the centers of the tibial plateau to the cutting plan of femur. As the mechanical axis of the tibia always past through the centers of the tibial plateau and the bone-cutting surface, the distance between the two centers could be calculated directly as the bone-cutting quantity of the tibial plateau.

5. Virtual resection: The cutting surface of the virtual cutting was realized with the implicit function in the VTK. In the single plane cutting, the implicit function of the virtual cutting was set as the corresponding cutting surface function. However, the virtual cutting of multi-plane was needed in the femur resection, which made it necessary to process the regions of all the cutting surfaces with the "And" operation, and the implicit function of the result

region was set as the implicit function of the virtual cutting to obtain the effect of simultaneous multi-plane cutting.

6. Quantitative indicators of output and save model after assembly: Before the pre-assembly, the models of prosthesis were not in the same coordinate system with the bone models. Therefore, the methods of normal align, rotating align and pan align were selected to complete the alignments between the prostheses, the femur and tibia. The alignments result in accurate assembly of all prosthetic components and bones in the same coordinate system.

D. Virtual motion analysis



The simulation result of the prosthesis replacement was analyzed initially through the virtual inspection of surgeon. The models can be manipulated to perform rotations along the flexion-extension axis. Fig. 6 illustrated the virtual knee flexion with the 0°, 45° and 75° respectively.

(a) virtual knee flexion with the 0°

(b) Virtual knee flexion with the 45°

(c) Virtual knee flexion with the 75°

Fig. 6 Virtual knee flexion

III. Result and Discussion

This paper mainly dealt with combining the computer simulation technique with the conventional surgery operation process to establish a knee operation planning system. It made full use of the available data obtaining technology including the CT scanning and the laser tridimensional scanning to realize the 3D expression of the virtual objects, and the VTK interaction technology to realize the man-machine interaction.

In present study, we use 3D CT image with 1mm slice distance which generate a good 3D model of the whole femur and tibia. In actual use, the CT scan could be performed only with the hip, knee and ankle joints to build the axes of lower limb, which reduce the number of images.

The article provides a full set of virtual surgery process procedure, it helps the pre-operative prosthesis selection, osteotomy planning, and other assembly simulation to improve the accurate of the surgery.

Further tests will focus on the improvement of simulation procedure and the human-machine interactive. The accuracy of the system will be evaluated and improved through calibration.

Abstract — **A shoulder-elbow rehabilitation robot has been developed as clinical treatments to facilitate motor learning and accelerate recovery of motor functions for stroke patients. However, the connection between motor learning and muscle activation patterns for stroke patients remained unknown. This study was tried to fulfill the gap by examining the muscle coordination and motor learning strategies of normal subjects while they interacted with the rehabilitation robot. A Hill-type biomechanical model based on twelve shoulder and elbow muscles was hence constructed for the upper-limb to simulate the interaction. Two normal subjects were recruited to perform upper limb circular tracking movements, clockwise and counterclockwise, on transverse plane at shoulder level in a designed force field generated by the rehabilitation robot. From the inverse dynamics analysis, the interaction was analyzed and the patterns of muscle activation were calculated. EMG signals of eight upper limb muscles were also measured for model validation and muscle coordination observation. The principle component analysis (PCA) was performed to distinguish different groups of muscle co-activation. Results showed that the constructed biomechanical model may be used as a tool for evaluating effects of treatment and be utilized as a blueprint for the design of the training protocol for the stroke patients.**

Keywords — **stroke, rehabilitation, biomechanical model, motor control, optimization.**

I. Introduction

Rehabilitation program is the main stay of treatments for patients suffering from trauma, stroke or spinal cord injury. Conventionally, these programs rely heavily on the experience and manual manipulation by the therapists on the patients' affected limbs. Since the number of patients is large and the treatment is time-consuming, it is a great advance if robots can assist in performing treatments. Recently there have been many researches working on how to use robots in assisting patients in rehabilitation [1-4].

Although many positive outcomes are reported for robot-aided treatment, clinical assessments currently used for stroke patients are based on subjective evaluation of physicians with assessment indices, such as modified Ashworth scale, Brunnstrom's stage and Fugle-Meyer's score, etc. It is hard to describe the individual characteristics of stroke patients with those assessment indices. Hence, there is a need of studies of connection between motor learning and muscle activation patterns for stroke patients. To fulfill the gap, the goal of this research was tried to construct a biomechanical model of the upper limb such that the muscle activations can be estimated for both normal subjects and stroke patients. A better understanding of the motor control and the recovery mechanism of stroke patients during treatments are then provided to physicians. Furthermore, customized treatments for stroke patients may be designed by using the analyses to facilitate the rehabilitation training.

II. Materials and Methods

In our previous studies, a robot was developed for neuro-rehabilitation of the upper extremity [5]. The robot was designed to perform two-dimensional motion on the transverse plane and was able to provide a desired resistive or assistive force to the subjects. Upper limb circular tracking movements, clockwise and counterclockwise, on transverse plane at shoulder level were hence performed in a designed force field.

EMG signals were measured by eight surface electrodes (Delsys, Inc.) from following muscles: pectoralis major (PEC), deltoid (DEL), biceps (BIC), triceps (TRIC), pronator teres (PTm), supinator (SUP), flexor digitorum superficialis (FDS), extensor digitorum (ED). The signals were amplified with a gain of 1000 V/V and band-passed of 20 Hz to 450 Hz and sampled at 2.0 kHz/channel. Signals were processed by full-wave rectification and linear envelope. Smoothed EMG signals were derived after normalizing the signals with the EMG of the isometric contraction and passing the signals through an adaptive filter (cutoff frequency 0.25~2.5Hz) [6].

A Hill-type biomechanical model which includes twelve muscles around shoulder and elbow joints was constructed for the upper-limb to simulate the interaction between subjects and the rehabilitation robot. These muscles includes

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1032–1036, 2009
www.springerlink.com

deltoid anterior (DA), deltoid middle (DM), deltoid posterior (DP), teres major (TM), pectoralis major (PM), triceps brachii (TB), biceps brachii (BB), anconeus (ANC), brachialis (BRA), brachioradialis (BRD), pronator teres (PT), and extensor carpi radialis (ECRL). The free body diagram of this model is shown in Fig. 1. According to Fig. 1(c), the dynamic equations of the upper are described as

$$\vec{F}_1 + \vec{F}_2 = m_1\vec{a}_1, \tag{1}$$

$$\vec{L}_1 \times \vec{F}_2 + \vec{\tau}_1 + \vec{\tau}_2 = \vec{L}_{g1} \times m_1\vec{a}_1 + I_1\vec{\alpha}_1. \tag{2}$$

Likewise, the dynamic equations of the forearm as illustrated in Fig. 1(b) are given by

$$\vec{R} + \vec{F}_2 = m_2\vec{a}_2, \tag{3}$$

$$\vec{L}_2 \times \vec{R} + \vec{\tau}_2 = \vec{L}_{g2} \times m_2\vec{a}_2 + I_2\vec{\alpha}_2, \tag{4}$$

where the subscripts 1 and 2 represent the shoulder and elbow, respectively. R is the resistive force imposed at the subject's wrist by the robot. F expresses the force. L is the segment length of the arm. L_g represents the length from the center of the mass to the proximal end. The torque is given by τ. m describes the mass. The acceleration and angular acceleration are symbolized by a and α, respectively. I stands for the moment of inertia.

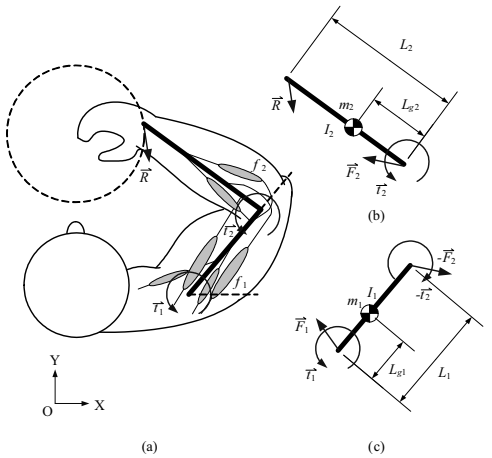

Fig. 1 Free body diagram of the upper-limb biomechanical model

With the measurement data and the muscle-skeleton parameters from the anthropometry, the required forces and torques at the shoulder and elbow for the arm's movements can then be solved by applying the inverse analysis (Fig. 2). In order to solve the load sharing problem for each muscle forces, a nonlinear optimization problem was formulated as in [7, 8]

$$\min J = \sum_{j=1}^{12}\left(\frac{f_j}{PCSA_j}\right)^2 \tag{5}$$

Subject to

$$\sum_{j=1}^{n}\left(\vec{d}_j \times \vec{f}_j\right) + \vec{\tau}_1 = 0, \tag{6}$$

$$\sum_{j=1}^{m}\left(\vec{d}_j \times \vec{f}_j\right) + \vec{\tau}_2 = 0, \tag{7}$$

$$f_j \geq 0, \tag{8}$$

$$f_j - F_{oj} \leq 0, \tag{9}$$

where f_j, d_j, and $PCSA_j$ are the muscle force, moment arm and physiologic cross-sectional area of the muscle j, respectively. n is the muscle number around the shoulder and m is the muscle number around the elbow. F_{oj} represents the optimal muscle force of the muscle j.

With incorporation with the curves of the muscle force-length properties and force-velocity properties, muscle activations were computed by equation below

$$A_j = \frac{f_j}{f_{oj} f_{LT} f_{FV}}, \tag{10}$$

where A_j is the muscle activation of the muscle j, and f_{oj} is the isometric force of the j muscle. The force-length and the force-velocity factors are represented as f_{LT} and f_{FV}, respectively.

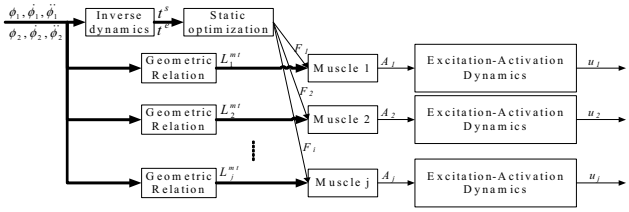

Fig. 2 Inverse analysis of the human-robot interaction

In order to gain a more perspective realization of the co-activation between muscles during a tracking movement, the principle component analysis (PCA) was applied [9]. The purpose of the PCA is to reduce the dimensionality of dependent variables to several orthogonal components. Hence, the data covariance matrix of the calculated muscle activations was formed and then decomposed by computing the corresponding eigenvectors and the eigenvalues. According to the eigenvalues, the number of principle components (PCs) is choose to retain most of the major informa-

tion hidden in data such that different groups of muscles co-activation were distinguished.

III. Results and Discussions

An example of the calculated muscle activations was shown in Fig. 3 for a normal subject tracking in the CW direction. Fig. 4 showed the muscle activations of a tracking cycle in both CW and CCW direction for a normal subject. In this figure, the left and right side plots indicated results in the CW and CCW tracking direction, respectively. From top to bottom, the first plot showed wrist's trajectories in X axis (solid line) and Y axis (dashed line); the second plot showed the angles of shoulder (solid line) and elbow (dashed line). All muscle activations were presented in plots from third to seventh. The muscle activation of TB, BRA, ECRL, TM, and DP were expressed in solid lines; dashed lines are used to showed that of BB, BRD, PT, PM and DM. As for the ANC and DA, dotted lines were used. From this figure, one can find that in the CW direction TB was first activated from 0% to 45% of the cycle and followed by the BB from 35% to 70% and then TB from 70% to 100% again. On the other hand, for the CCW direction, BB was first activated from 0% to 45% and followed by TB from 41% to 95% and then BB from 95% to 100% to complete the cycle. PM and DA were activated at the same time since they are both the prime mover for the horizontal flexion at the shoulder joint. In the constructed model, all muscles were assumed to be mono-articular except the biceps and the triceps which were modeled as bi-articular such that agonist muscles and antagonist muscles can not be activated simultaneously. In contrast, biceps and triceps may have temporary co-activation due to the continuity and correlation of the movements as seen in Fig. 4.

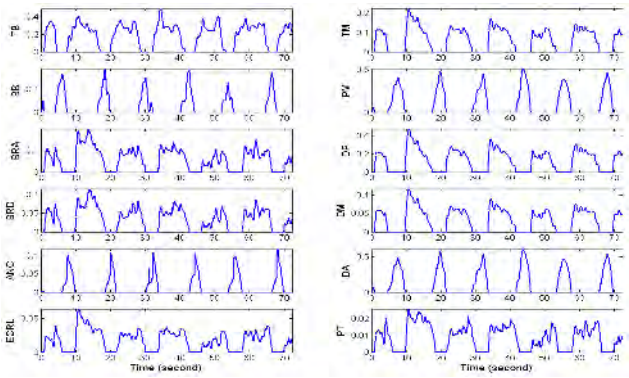

Fig. 3 Example of the calculated muscle activations

The comparisons with measured EMGs for the muscle activations were shown in Fig. 5 for direction CW as an example. The measured EMGs were presented in dotted lines, and the computed muscle activations were shown in solid lines for TB, BB, PM, and DM. The dashed and dashed-dotted lines illustrated muscle activations of DA and DP, respectively. The muscle activation patterns obtained from the biomechanical model were consistent with the EMG signals. However, only one measured EMG signal for the deltoid muscle can be acquired but there are there heads of deltoid muscles constructed in the model. As a result, the estimated muscle activations may provide more detail information than the EMG can offer. The corresponding correlation analysis between the computed muscle and activations and the measured EMGs were shown in the Table 1. The ill-correlation of the PM muscle may result from the noise-contamination of the EMG measurements or the surface electrode may not be placed correctly. For the CCW direction, the calculated muscle activation of DM indicated a short period of activation which may explain the ill-correlation with the measured EMG signals.

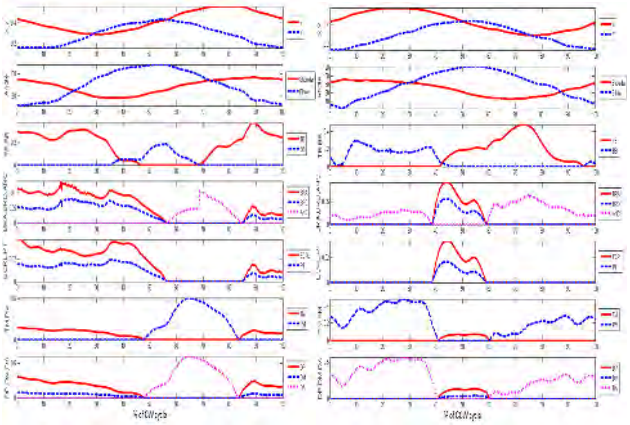

Fig. 4 Muscle activations of a tracking cycle: CW (left), CCW (right)

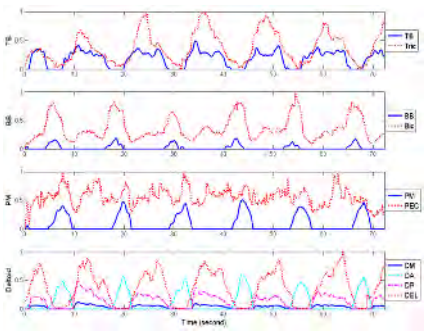

Fig. 5 Comparisons between EMG measurements and calculated muscle activations for a normal subject in the CW direction

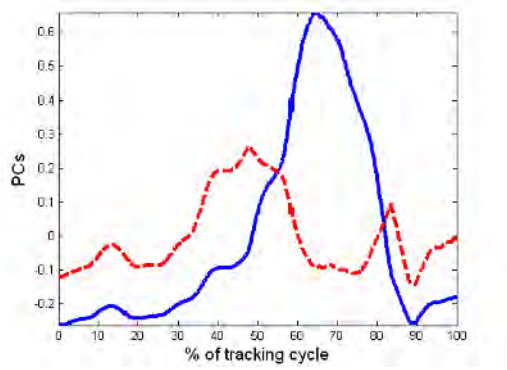

Fig. 6 Values of PC1(solid) and PC2 (dashed) in the CW direction

Fig. 6 showed the results obtained from the PCA analysis for a tracking cycle in the direction CW as an example. Since the first and the second principle component (PC1, PC2) explain 70% and 10% of the data variance, respectively, the analysis is therefore focus on the examination of the PC1 (solid line) and PC2 (dashed line). The coefficients of PC1 and PC2 were indicated in the Table 2. From the plot and the table, one can see that the values of PC1 were positive from around 50% to 82% of cycle and mainly contributed from PM and DA. From 35% to 60% of cycle, the values of PC2 were positive due to the contribution of BB. As for the rest of the tracking cycle, both PC1 and PC2 presented negative values which may be explained by TB and DP. Fig. 7 showed the calculated muscle activation patterns of one cycle for a stroke patient in the CW (left plots) and CCW (right plots) directions while performing circular tracking movements. Observe that the stroke patient performed in-coordinative TB and BB activation for the CW tracking cycle and the secondary movers such as BRA, BRD, ECRL and PT were activated at the early stage of the tracking cycle. Same situation can also be found in the CCW direction. Furthermore, the stroke patient's TB was first activated in the CCW direction. Also, DP and DM were activated in the 0~30% of the cycle, which remained silent for the norm subjects.

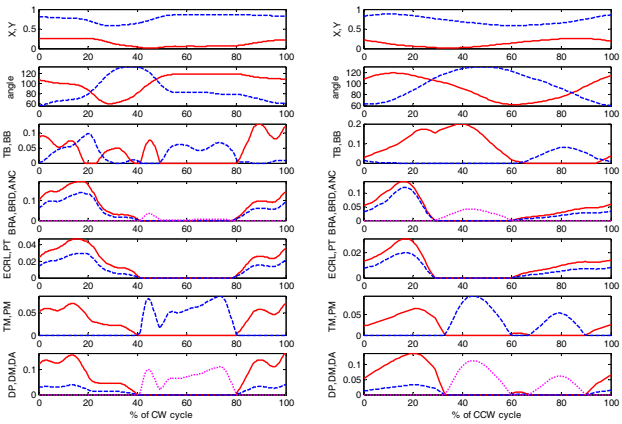

Fig. 7 Muscle activations of a stroke patient in circular tracking movements (left CW, right CCW)

IV. Conclusions

With the help of the biomechanical model, the pattern of the muscle activation of the upper-limb of stroke patients can be estimated. The information may be utilized as a blueprint for the design of the training protocol. In future, time course variation of these muscle activations may provide an assessment tool for the stroke patients during robot-aided rehabilitation.

Using Virtual Markers to Explore Kinematics of Articular Bearing Surfaces of Knee Joints

Guangzhi Wang[1], Zhonglin Zhu[1], Hui Ding[1], Xiao Dang[1], Jing Tang[2] and Yixin Zhou[2]

[1]Department of Biomedical Engineering, Tsinghua University, Beijing 100084, China
[2]Beijing Ji Shui Tan hospital, the 4th Medical College of Peking University, Beijing, China

Abstract — **This paper proposed a method of using virtual markers to track the movement of the articular bearing surfaces of femur, tibia and patella simultaneously. With this method, the femur, tibia and patella were treated as three rigid body connected by soft tissue and thus the articular surface moves with corresponding bone in three dimensional (3D) space. The contact kinematics of articular bearing surface can be figured out by track the position and orientation of bones during knee flexion. To perform this method, three sets of tracking marker were attached tightly to femur, tibia and patella to track the 3D motion of lower limb. The articular bearing surfaces of knee joint were digitized to create three groups of registered virtual markers associated to the tracking markers of each bone, respectively. During knee flexion, 3D movement of femur, tibia and patella were tracked by capture the motion of tracking markers. Then the 3D coordinate of each virtual marker was calculated using the registration information of virtual markers. Thus, the trajectory of virtual markers could be tracked during knee flexion which indicates the real kinematics of bearing surfaces of knee joint. Three fresh-frozen lower limbs were tested before and after total knee replacement operation using this technique. The test results show that this method could be used to explore the contact condition of articular bearing surfaces accurately.**

Keywords — **total knee arthroplasty, kinematics, articular surfaces, motion tracking, virtual marker.**

I. Introduction

It is known that the geometry of the articular can affect the location of the contact point during knee motion and ultimately affect the trajectory of the leg. For the total knee arthroplasty (TKA), the position and orientation of the prosthesis components can significantly affect the pattern of knee motion. Surgical implantation strategies, such as placement and sloping of the components, can have dramatic effects on gait. Moreover, the geometry, position and orientation of the prosthesis components affect the mechanics of knee joint which is correlated with the reliability of the TKA. So that, an accurate knowledge of *in vivo* kinematics of the human knee is important in order to improve the treatment of knee pathologies. Knee kinematics had been measured extensively in cadavers and in living subjects [1, 2]. However, direct measurement of contact kinematics of articular bearing surfaces remains technical challenge in biomedical engineering. Previous studies have used various technologies to measure kinematics in human subjects, including video, computerized tomography (CT) and magnetic resonance imaging (MRI) techniques. In recent years, image based 3D model and 2D fluoroscopic image measurements were widely used in the study [3, 4] . Some recent studies have implemented 3D models generated from CT and MRI scans to estimate the motion of the contact points of the femur on the tibial plateau using the bony geometry of the femur and tibia [2, 5]. However, it is hard to obtain the geometry and acquire the motion of the bones simultaneously with the image techniques during knee flexion to quantify tibiofemoral contact in consecutive joint angles.

The object of this study was to quantify the contact kinematics between the tibial and femoral cartilage and/or implanted components during consecutively knee flexion. We use a new methodology to track the movement of virtual markers located on the articular bearing surfaces of femur, tibia and patella simultaneously. Thus the tibiofemoral articular contact of different legs can be compared using the model obtained by digitizing the bony surface geometries of knee joints or using the computer model of artificial knee joint components. The kinematics of articular bearing surfaces before and after the total knee replacement can be compared using this technology.

II. Materials and methods

A. Materials

The three fresh-frozen knee joints specimens (total-femur to midtibia) were used to perform the test. All specimens were anatomically normal, with no varus or valgus deformities. The institutional review board approved the study.

Before the test, three metal screws were inserted into the patella, tibia, and femur. A small X-shaped traceable frame with a marker on each of the four arms was fixed to the metal screw tightly to capture the movement of bones in six degrees of freedom (DOF).

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1037–1041, 2009
www.springerlink.com

The specimens were tested before and after implanted with different designed prosthesis such as Simith-nephnew GENESIS II patella preserving and high flexion insert replacement by the same surgeon. Ligament balancing was performed with the femoral and tibial components in their neutral positions.

B. Experiment Setup

1) Weightbearing apparatus: A custom-built Oxford-type weightbearing rig (Fig. 1) actively loaded the knee by moving the femur head to produce continuous flexion and extension to simulate deep knee bends before and post TKA operation. The quadriceps muscles were loaded by dead weights via thin wires which pulling the rope attached to each individual muscle head of the quadriceps. The load was intended to mimic the passive resistance of the quadriceps tendon and to ensure that the patella remained in contact with the femur. The simulated ankle joint allowed rotations about three orthogonal axes and no translations. The simulated hip joint allowed vertical translation, rotation in coronal plane and flexion resulting in one rotational and two translational degrees of freedom. Therefore, the knee retained its full six degrees of freedom.

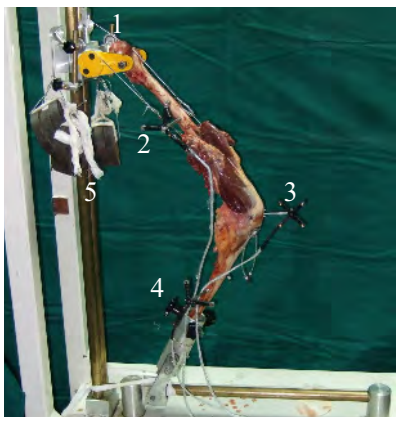

Fig. 1. Weightbearing flexion rig and motion tracking markers. (1) Hip joint, (2) traceable frame fixed to femur, (3) traceable frame fixed to patella, (4) traceable frame fixed to tibia, (5) dead weights.

2) Measurement Devices: To determine the tibiofemoral and patellofemoral tracking characteristics throughout knee flexion and extension, we firmly attached X-shaped traceable frame of marker arrays, each with four infrared-emitting diodes (IREDs) on each of the four arms, to the femur, tibia and patella using metal screws. The three-dimensional position and orientation of bones were tracked with an Optotrak Certus^{TM} optoelectronic camera system (Northern Digital, Waterloo, Canada) via the traceable frames. The root-mean-square (RMS) accuracy for each IRED was 0.1 mm in the plane of flexion and 0.15 mm perpendicular to the plane of flexion. The weight of the patellar tracking frame and associated cable was less than 15g. The effect of this on the kinematics would therefore be easily offset by the quadriceps load.

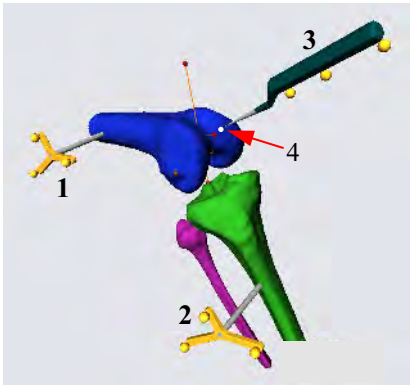

Fig. 2. Traceable frame and digitizer probe for selection of virtual markers. (1) femur tracking frame, (2) tibia tracking frame, (3) digitizer probe, (4) virtual marker.

C. Traceable Markers and Virtual Markers

While the small traceable frame tightly fixed to bones (Fig. 2), 6 DOF movement of each bone can be captured by the Optotrak Certus^{TM} motion capture system. Each bone was regarded as a rigid body moving in 3D space. Thus, any specific point located in the bone will move with the rigid body (bone) and the trajectory of this point in 3D space can be calculated by resolve the rotation and translation of the rigid body. Therefore this specific point can be tracked as if it is a virtual traceable marker. If we define a group of virtual markers on each of the articular bearing surfaces, the 3D movements of articular surface of each bone can be tracked to explore the contact kinematics of bones with consecutively flexion and extension of the knee. A digitizer probe with 3 IRED markers (Fig. 2) was used to digitize the articular bearing surface of femur, tibia and patella. The tip of digitizer probe was calibrated with accuracy of 0.1mm (RMS) before it can be used. The virtual markers located in the articular bearing surface of each bone were obtained by moves the tip of digitizer probe in front of the cartilage while record the 3D location of probe tip and the traceable frame mounted on each bone simultaneously with Optotrak Certus^{TM} system. Then the recorded 3D location of virtual markers with respect to the traceable frame of corresponding bone can be transferred to world coordinate system to analysis the relative motion of the bones.

D. 3D model of articular surfaces of knee joints

For the accurate modeling of the bones, a set of point palpation was performed to sample the coordinates of the articular bearing surfaces of the femur, tibia and patella. Thus, the articular geometries can be represented as point clouds and the 3D surface models could be generated by orderly connect the points to produce mesh grid.

For model the implanted components, we obtained the articular geometries using a three-dimensional laser scanner, which reverse-engineered the articular surfaces into point clouds. The sampling resolution of the laser scanner used was about 0.5 mm.

E. Experiment procedure

Before the TKA procedure, the specimens were set up to the weightbearing rig. Three traceable frames were tightly fixed to the femur, tibia and patella to track the motion of bones. Then, the knee was opened to perform the virtual marker palpation procedure of the articular surfaces using digitizer probe. More than 300 points were obtained for each articular surface.

After suture of the knee, flexion and extension test were performed with the weightbearing rig. 3D movements of the femur, tibia and patella were measured via the traceable frames and recorded at 25 Hz by the Optotrak Certus system during the consecutively knee flexion and extension. Six trials were repeated for each specimen.

After the normal knee flexion test, the TKA procedure was performed by the same surgeon. During the TKA procedure, register points were selected to sample the location of the prosthesis components relative to the traceable frames which was used to register the 3D prosthesis model as the virtual markers. And then, the specimens were tested with the weightbearing rig and Optotrak Certus^{TM} 3D motion tracking system again.

F. Data Processing

1) Coordinate Transformation: When we test the knee, the Optotrak Certus system records the translation vector and rotation matrix of each traceable frame individually. To identify the kinematics of the articular surface, the relative 3D movements of virtual markers need to be resolved. First of all, the virtual markers were defined by digitizing the articular surface with in the traceable frame coordinate system of each bone. So that the 3D coordinates rigid-body transformation is needed to transfer the locations of virtual markers from the frame coordinate system to the world coordinate system. With the rotation matrix $\boldsymbol{R}$ and translation vector $\boldsymbol{T}$ of each traceable frame recorded by the Optotrak Certus system, the coordinate of each virtual marker $\boldsymbol{P_{fi}}$ in traceable frame coordinate system can be transferred to $\boldsymbol{P_{wi}}$ in world coordinate system by equation:

$$P_{wi} = R \cdot P_{fi} + T \tag{1}$$

where, $\boldsymbol{R}$ is an orthogonal rotation matrix and $\boldsymbol{T}$ is displacement vector which indicate the location of the traceable frame in world coordinate system.

2) Re-orientation Process: With the weightbearing rig all the bones moved simultaneously throughout the knee flexion and extension. To represents the kinematics of articular bearing surface of knee joint, the relative movement of tibiofemoral and patellofemoral joint are desired. In this study, relative movements were calculated using a custom-written Matlab program. The kinematics of the joints were determined from the traceable markers and represented as Cardan angles as described by Tupling and Pierrynowski [6]. Translations and rotations of the patella and tibia relative to the femur were calculated from the measured 6D data of the traceable frame.

3) Registration of 3D model and virtual markers: Because the number of virtual markers sampled with digitizer probe is limited, the generated mesh grid is sparse. We obtained the articular geometries from three-dimensional laser scans, which reverse-engineered the articular surfaces into point clouds with higher resolution and generate fine 3D model of the surface. We registered the 3D model of joint components with the virtual markers and transferred the 3D model to the position determined by virtual makers in each joint flexion angle to improve the accuracy of kinematics analysis of the articular surfaces.

4) Kinematics of the 3D Model of Articular Surfaces: In order to compare the kinematics of articular bearing surface at different knee positions and across different subjects, the registered 3D model of bones or implanted components were used to characterize the roll and gliding motion of components in three-dimensional space. By put the motion of 3D model together, the roll and gliding character and contact area of the articular bearing surfaces during knee flexion can be observed.

III. Results

A. Virtual markers and 3D Model of articular surface:

Fig. 3 (left column) depicts samples of virtual markers (point cloud) of the surface of a femoral component obtained by digitizer and 3D laser scanner respectively. The corresponding 3D model of femoral component is recon-

structed by orderly connect the points to construct mesh grid and calculate the associated normals of the surface. The bottom right model was obtained by multiple passes of 3D laser scan.

B. Kinematics of articular bearing surface:

After we obtain the 3D model of articular bearing surface and record the motion of femur, tibia and patella, the kinematics of articular bearing surfaces can by analyzed. The translations and rotations of the patella and tibia relative to the femur were calculated from the measured movement of traceable frame in three-dimensional space.

Fig. 4 illustrates the articular bearing surface of femoral condyle and tibia plateau of two joint flexion angles. The left figure indicates the both side of the femoral condyles balanced contact tibia plateau and the right figure indicates that with more joint flexion the lateral side of femoral condyle is not contact tibia plateau.

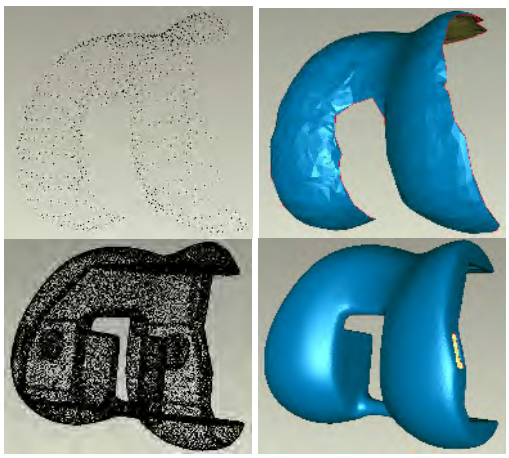

Fig. 3. Point cloud and corresponding 3D surface model. Left column are the virtual markers digitized using 3D probe and point cloud obtained via 3D laser scanner, right column illustrate the corresponding 3D surface model.

Fig. 5 is another example of 3D kinematics analysis of the articular bearing surface. Three surface models were obtained from the virtual markers of femur, tibia and patella joint surfaces using 3D digitizer. The left figure illustrate that in the beginning of knee flexion the patella contacts the femoral condyles in both side. In the middle figure, the patella contacts femoral condyles only in lateral side. The right subplot indicates that with highly knee flexion the patella sink to the deep trochlear groove of the femur and not contact the formal condyles any more.

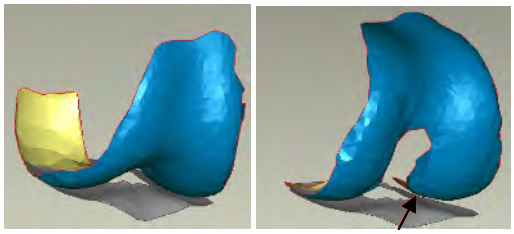

Fig. 4. Contact analysis of articular bearing surface of femoral condyle and tibia plateau in two joint flexion angles.

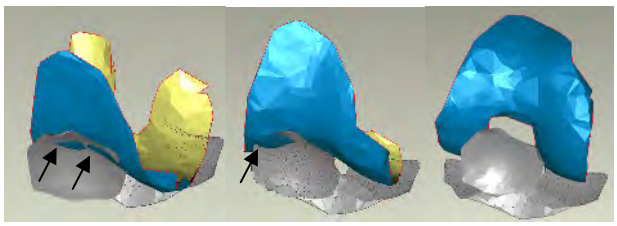

Fig. 5. Contact analysis of articular surface of femoral condyle, tibia plateau and patella with three joint flexion angles.

IV. Discussion and Conclusions

Using virtual marker tracking technique, we tracked the contact kinematics of articular bearing surfaces of femur, tibia and patella simultaneously. Three-dimensional joint kinematics and contact locations were determined with consecutive joint angles. This method is potentially useful in the accurate measurement of joint kinematics. The contact kinematics of tibiofemoral articular with different prosthesis component design can be compared by register the model to the moving virtual markers in consecutive joint angles. The kinematics of articular bearing surfaces before and after the total knee replacement can be compared using this technology.

The accuracy of our method highly depends on the representation of the articular geometry. The virtual marker tracking technique can be used with the CT-based bone model surfaces, and MR-based articular cartilage model surfaces.

Simultaneous Recording of Physiological Parameters in Video-EEG Laboratory in Clinical and Research Settings

R. Bridzik, V. Novák, M. Penhaker

Video-EEG/Sleep laboratory, Clinic of Child Neurology, University Hospital Ostrava, Czech Republic
VSB – Technical University of Ostrava, FEECS, Ostrava, Czech Republic

Abstract — **The possibility of a flexible connection of various diagnostic equipment and seeking for correlations between recordings of different physiological functions is a powerful tool of diagnostics. There are many well-established interconnections, such as video-EEG or video-PSG. However, in some cases we need a combination of parameters "tailored" to the individual patient. Finding solutions for the patient is an interesting competence of the biomedical engineer/EEG technician.**

Keywords — **Video-EEG, pH-metry, device connection, biosignal processing**

I. Introduction

Simultaneous recording of several physiological parameters is often used in diagnostics of many diseases in video-EEG laboratory. Some combinations are fixed – for example the polysomnography comprises recording of EEG, EOG, EMG, respiratory effort, airflow and SpO2.

Many patients need an individualized combination of physiological parameters according to the diagnostic situation. For example, sometimes the correlation between the sleep stage and the moment of urination (wet time) is needed; sometimes the question should be the correlation between respiratory parameters and reflux of the gastric content to the esophagus (detected by esophageal pH-metry).

In case of these individualized combinations of physiological parameters there are some possibilities of quick and flexible approach:

II. Flexible approach

A. Functional addition through the video

This is a very simple, but flexible and fast way. When combining the external measurement with video-EEG equipment, there is a possibility to record the analogue output of the external device on the video. This simple approach is useful especially when the moment of some event should be recorded – for example the LED on urination detector is blinking, when the patient wets. The accuracy is influenced by the resolution and frame-rate of the video.

B. Software association of recordings off-line

It means subsequent combination of digital recordings after the end of measurement. This solution is applicable when the accuracy requirement is about 1 second. It is necessary to compare the internal time clocks of both equipments before and after the measurement. Possible difference should be compensated by linear interpolation. Biological check of synchrony is useful, too. The data format for the measurement interchange depends on the software of the auxiliary device – it should be binary, simple ASCII, European data format (used for EEG/PSG data transfer), or the XML format are the best choice in our opinion.

1) One of the simplest data format appropriate for the data interchange is the ASCII. The data in simple ASCII file are not structured, so it is rather complicated to read and analyze this data (lack of standardization).

2) The XML is a very flexible data format[3]. It has the advantage of a much better possibility to structure the data. The fact that this data format is supported by MS-Excel, web browser etc. is another advantage of the XML. The XML DOM Interface is an ActiveX object supporting the browsing of the XML data by any application using the XML modules[2].

3) The European data format is a widely used data standard[1,4]. Many laboratories use it for EEG data sharing. Unfortunately, it was developed predominantly for the EEG and is not so flexible as the XML.

4) The binary format of the physiological function recording is simple and structured, but with high variability, and there is often a problem with the lack of documentation.

C. Hardware combination of devices

Hardware interconnection is possible in case of analogue output of the secondary device (which should be connected to auxiliary data channel of EEG/PSG machine).

Case report: We have evaluated a case of 3-month-old boy with paroxysmal apnea and convulsions. The EEG and sleep EEG was without epileptic spikes and sharp waves.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1042–1043, 2009
www.springerlink.com

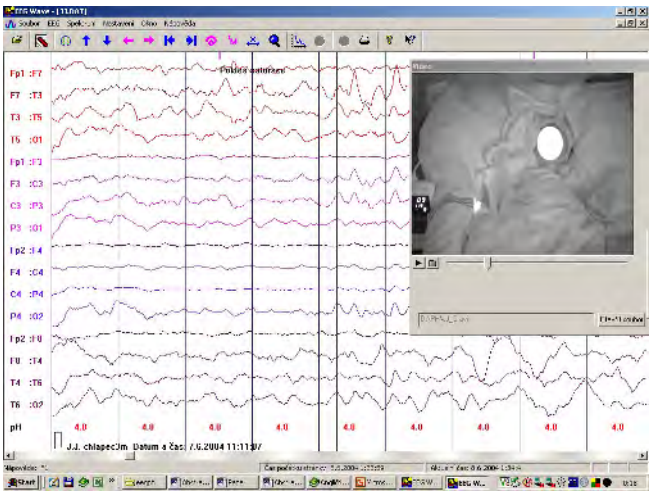

Fig. 1 Combination of 3 devices EEG, SpO2 (in the video-channel) and esophageal pH associated off-line.

The anti-epileptic drugs were ineffective. Because of symptoms of possible gastro-esophageal reflux, we decided to perform a complex recording of several physiological parameters: the video, EEG, ECG, SpO2 and esophageal pH-metry. We had no measurement device for SpO2 with digital output at that time, so we used the analogue output in the video-channel. The data from pH meter were associated after the end of the recording.

The correlation found episodes of the gastro-esophageal reflux with the drop in the peripheral hemoglobin saturation. The diagnosis of the gastro-esophageal reflux disease, not the epilepsy, was established. The child was treated for the reflux and administration of antiepileptic drugs was stopped.

The patient is currently doing well.

III. Conclusions

There are several physiological parameters useful for the correlation in the video-EEG or polysomnographic laboratory. We recommend combining e.g. the pH-metry with the video-EEG. In some cases, it is useful to interconnect the bicycle-ergometer with the detectors of the EEG and cardiologic parameters (ECG, SpO2). In children with nocturnal wetting, the correlation should be between the EEG (sleep stage) and the urination probe. The physician makes the clinical decision, but the engineer provides the technical solution.

In our opinion, the best choice for data interchange between the different equipment in one laboratory and even for the data sharing between laboratories is the XML format[3]. We have developed an XML parser for the biomedical data in the C++ language.

Abstract — **Intra-Body Communication (IBC) is an interesting and emerging communication methodology in recent years. Beneficial from conductive property of human body, IBC treats human body as transmission medium for sending/receiving electrical signal. As a result, interconnected cable and electromagnetic interference can be greatly reduced for devices communicated within human body. These advantages are significant for home health care system, which abundant of interconnected cables are needed. Furthermore, IBC technology also provides an alternative solution to communicate with implanted devices.**

Currently, pioneer researchers have proposed two general methods for realization of IBC, namely: "Capacitive coupling technique" and "Galvanic coupling/Waveguide type technique". Among the methodologies, the Galvanic technique requires neither return path nor common reference. This feature enables the technology attractive for networking biomedical devices on human body and draws much attention from recent studies. Thus, in this work, a preliminary 3D model of electromagnetic (EM) technique is developed in order to provide insight for electric signal distribution within human body. The development of a mathematical model also facilitates future researches in the aspect of communication theory of IBC, such as: optimizing carrier frequency, identifying channel characteristics, developing suitable modulation/demodulation technique, and etc.

In this paper, a mathematical model, which employs a homogeneous cylinder in analogous to a human limb, is obtained by solving the Laplace Equation analytically. The proposed model is simple and preliminary, yet it encourages further development of better model in the next phase and lays a foundation for future research and development of Intra-Body Communication.

Keywords — **Intra-Body Communication, Body Area Network, Galvanic coupling type/Waveguide type technique.**

I. Introduction

Home health care system and long term physiologic parameters monitoring system are important for chronic disease patients and elderly. They could provide patient and paramedic instant health information and generate alert while emergence. As a result, the research and development of these systems are attracting much attention from researchers. Currently, one of the main research directions is to develop versatile, intelligent, accurate, and convenient system, because it can elevate the performance for the users.

Intra-Body Communication (IBC) is a new communication technique, which employs human body as transmission medium for electrical signal. This is a special type of communication methodology and treats human tissue as a "cable" for electrical signals transmission. The merits of this technique are successful removal of connection cable, reduction of possible electromagnetic radiation, and less probably to be interference by external noise. These features are attracting much interest in the aspect of Body Area Network (BAN); especially, IBC works and relies on the human body. It also can improve home health care system and long term monitoring system, as abundant cables create problems for this kind of system. Thus, these features and advantages motivate the development and advance the research of IBC.

In this article, the authors attempt to present a mathematical model for IBC. In this model, a human limb is generalized as a 5-cm radius homogeneous cylinder with 30-cm long. After applying the quasi-static conditions, the governing equation has been reduced to Laplace Equation and a mathematical model for IBC can be obtained. The proposed model is simple and preliminary, yet it encourages further development of better model in the next phase and lays a foundation for future research and development of IBC.

II. Background

IBC was first introduced by T.G. Zimmerman in 1995[1]. They employed the electrostatic coupling technique to demonstrate the feasibility of the idea and built the first prototype system. The design consisted of a transmitter and a receiver, which had electrodes attached to the human body as depicted in Figure 1. The electric field of the transmitter is induced by the electrodes, coupled to the human body and flowed towards the ground, and then the electrodes of the receiver detected the electric field flowing through the human body with respect to the ground. Normally, only a few potion of electric field flowed to other parts of the body

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1044–1048, 2009
www.springerlink.com

and detected by the receiver eventually. Thus, the sensitivity of the receiver should be high enough in order to have better and reliable performance.

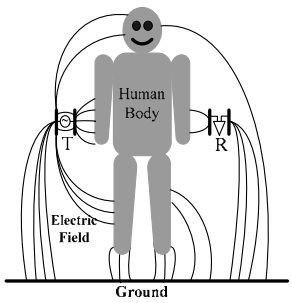

Figure 1 Electrostatic coupling technique

Since the development of the prototype IBC system by Zimmerman, several interesting applications, such as: heart rate and oxygen saturation sensors[2], sensors[3, 4], modeling[5, 6] and various communication techniques: On/Off Keying(OOK)[5], Differential Binary Phase Shift Keying (BPSK), Frequency Shift Keying (FSK)[2, 7, 8] etc. have been employed for improving the performance and stability of IBC.

The Galvanic coupling/Waveguide type technique[9-13] is an alternative configuration for implementation of IBC. As shown in Figure 2, electrodes of the transmitter are attached to one end of the human body while electrodes of the receiver are attached to another end. When electrical signals are applied to the electrodes of the transmitter, the signal will propagate along the human body in analogue to electromagnetic wave propagate along a waveguide. The electrodes of the receiver, which attached on the other end of the body, detect and convert the information from the transmitter. Unlike the electrostatic coupling technique, the electrical signal propagated via ionic fluid and thus, less dependent on the surrounding environment. Since the technique is relative new, the research of galvanic coupling technology mainly focused on application – especially biomedical application. Although the achieved data rate of Galvanic coupling type technique is low, independent of the earth ground and current propagation within human tissue are more attractive than the electrostatic coupling technique. Based on these reasons, the research direction of the authors is focused on the Galvanic coupling type IBC.

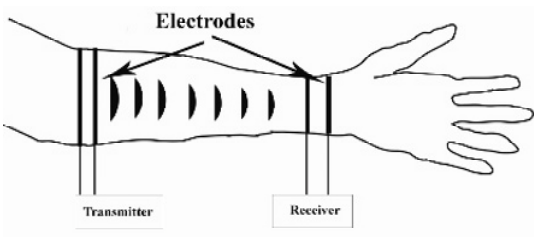

Figure 2 Waveguide type technique

III. Mathemtical model

Since the first report of IBC appeared in 1995, Galvanic coupling technique received much attention from researchers and engineers. During the period, various prototypes and experiments have been built and conducted. Other than demonstrated the feasibility of the method and developed application for IBC, one of the main research goals is to investigate the electrical properties of IBC. Currently, various researchers will employ different carrier frequency, coupling amplitude, encoding scheme, electrode location, and etc. The reasons behind of this phenomenon would be quite complicated; however, lack of good understanding of IBC propagation mechanism may be an explanation. Based on this observation, the authors attempt to develop a model in order to give insight about the electrical and communication properties of Galvanic coupling type IBC.

As the initial attempt of modeling IBC, a human limb is selected and ring-type electrodes are attached to either bands (at $z=z_1$ & z_2) as shown in Figure 2. The irregular geometry of human limb is difficult to be described by mathematics, so, a h=30-cm long homogeneous cylindrical muscle with a=5-cm in radius would be studied instead (as depicted in Figure 3). Then, applying the Maxwell Equations for the simplified problem to study the mechanism of IBC and find out the mathematical model for the problem.

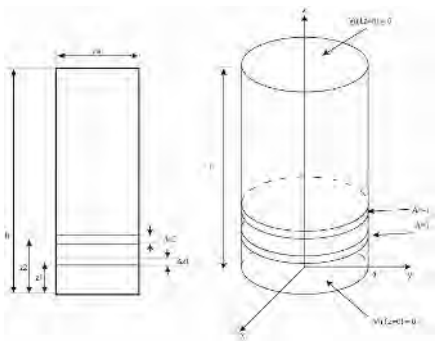

Figure 3 Simplified model with ring electrodes

Additionally, as the material of the IBC problem is biological tissue and is operating at low frequency[9-11], the quasi-static approximation may be used. The quasi-static approximation states that "if the dimension of the studied problem is less than 1 meter and satisfies Eq. (1), the capacitive effect can be neglected" [14, 15].

$$\frac{\omega\epsilon_0\epsilon_r}{\sigma} \ll 1 \tag{1}$$

In Eq. (1), ε_r and σ represent the relative permittivity and conductivity of the tissue and ω denotes the operating angular frequency. In Table 1, the quasi-static approximation with muscle's electrical characteristics[16] is listed.

Table 1 Quasi-static condition

	10kHz	100kHz
Conductivity σ	3.4e-1	3.9e-1
Relative Permittivity ε_r	3.0e4	8.0e3
$\frac{\omega\epsilon_0\epsilon_r}{\sigma}$	≈0.049	≈0.114

From Table 1, for the operating frequency less than 100kHz, the quasi-static could be applied and according to the prior research, the operation frequency of waveguide type technique is typically less than 100kHz[9, 11]. Thus, the governing equation becomes Laplace Equation and, the formulation of the IBC problem can be written as:

$$\nabla^2 V = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial V}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2 V}{\partial \phi^2} + \frac{\partial^2 V}{\partial z^2} = 0 \tag{2}$$

with general side-excited case:

$$\begin{aligned} &V(r,\phi,z=0)=0 \\ &V(r,\phi,z=h)=0 \\ &\frac{\partial V}{\partial r}(r=a,\phi,z)=\frac{J(z)}{\sigma} \end{aligned} \tag{3}$$

where the ring type injected current signal is defined as:

$$J(z)=\begin{cases} J_1 = 1mA/m^2 & z1-\frac{\Delta z1}{2} \le z \le z1+\frac{\Delta z1}{2} \\ J_2 = -1mA/m^2 & z2-\frac{\Delta z2}{2} \le z \le z2+\frac{\Delta z2}{2} \\ 0 & elsewhere \end{cases} \tag{4}$$

By solving the above formulation, an analytical solution for voltage distribution within the cylinder can be obtained.

$$V(r,\phi,z)=\sum_{m'=1}^{\infty} A_{m'} I_0\left(\frac{m'\pi}{h}r\right) sin\left(\frac{m'\pi}{h}z\right) \tag{5}$$

where

$$A_{m'}=\frac{2}{\left[I_0\left(\frac{m'\pi}{h}r\right)\right]'_{r=a}h}\int_0^h J(z)sin\left(\frac{m'\pi z}{h}\right)dz \tag{6}$$

and, I_o represents the modified Bessel function of the first kind of order 0.

With Eq. (5) and Eq. (6), the potential on the surface and within the human limb could be found spatially. From Figure 4, the plot of electrical signal inside the human limb is shown (X-Z sectional view at y=0 of the voltage distribution). Due to the electrode configuration employed in this case, the expected or calculated voltage induced by the electrodes is symmetry with respect to z-axis and the voltage on the same level of z-axis at the surface of the human limb is equal. This suggests that the electrodes of the receiver should not be placed on the same level of z-axis for this parallel ring type electrode case.

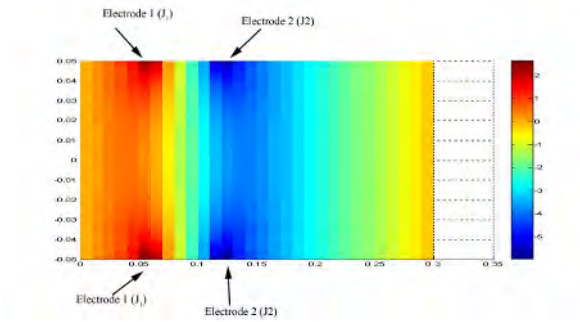

Figure 4 X-Z sectional view (at y=0) of the voltage distribution of the cylinder

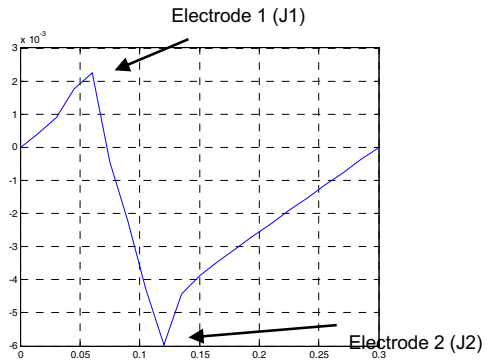

Figure 5 Voltage distribution on the surface of human limb along z-axis

On the other hand, from Figure 5, if electrodes are placed in the direction of z-axis, the voltage difference between electrodes of the receiver will be high (e.g. if the electrodes of receiver located at z=0.2cm and z=0.25cm, the voltage difference would be around 1mV). Thus, according to the mathematical model derived by this paper, the electrodes of the received of IBC would be better placing across z-axis.

IV. Summary

Intra-Body Communication (IBC) is an interesting and emerging communication methodology in these years. Beneficial from conductive property of human body, IBC treats human body as transmission medium for sending electrical signal.

In this paper, a mathematical model, which employs a homogeneous cylinder in analogous to a human limb, is obtained by solving the IBC problem analytically. Through applying the quasi-static approximation, the Maxwell Equation can be simplified to Laplace Equation and the obtained an analytical solution for the voltage distribution can be obtained in certain symmetrical cases. The obtained model reveals the propagation mechanism of the ring type electrodes in human limb and suggests the insight of the configuration of the electrodes placement of the receiver.

The proposed model is simple and preliminary, yet it provides a foundation for analysis and future development of IBC. The obtained model encourages further development of better model in the next phase and lays a foundation for future research and development of Intra-Body Communication.

Abstract — **Diabetes is a group of metabolic diseases affecting more than 200 mln people worldwide, which is characterized by elevated blood glucose level. Diabetes causes a number of late complications among which diabetic foot syndrome (DFS) is one of the most dramatic as a major cause of the lower limb amputations. In IBBE PAS the TeleDiaFoS system aimed at monitoring of DFS treatment was developed. In the system, the Central Clinical Server is accessed by the Patient's Module using a wireless internet connection to send the wound pictures, the blood glucose (BG) readings and the blood pressure (BP) values. Clinical verification of the TeleDiaFoS system has been organized as a randomized 90-days trial with the study and the control groups consisting of 10 type 2 diabetic patients, each. Currently, the evaluation of the first patient treated with multi-injection insulin delivery and antibiotic – dalacin therapies has been terminated. Home telecare therapy led to 12-fold reduction of the wound surface (from 356 mm^2 to 29 mm^2). During the whole 90-days period BP was controlled efficiently, however, acceptable BG level has not been maintained. In conclusion, application of the system leads to more effective realization of the DFS therapy and has a positive impact on the patient's comfort.**

Keywords — **Diabetes mellitus, diabetic foot syndrome, telemedicine, wound healing, foot scanner**

I. Introduction

Diabetes mellitus is listed among the most serious and dangerous chronic conditions such as heart disease and stroke (cardiovascular diseases), cancer, asthma and chronic obstructive pulmonary disease that cause 30 mln deaths all over the world each year. The number of diabetic patients has already exceeded 200 mln and it will reach 330 mln cases by the year 2030 according to the predictions.

The International Diabetes Federation and the WHO describe the dramatic increase of the number of cases of diabetes that is occurring throughout the world today as "the most challenging health problem of the 21st century" [1]. Diabetes is characterized by high blood glucose level (hyperglycemia) that impairs the function of the body's proteins leading to a number of late complications related to the microangiopathy, the macroangiopathy and the neuropathy. Among these complications the diabetic foot syndrome (DFS) that is caused by neuropathy, angiopathy or both is one of the most dramatic. DSF is manifested in the form of ulcers, which are unhealing open sores or wounds that most often are located on the sole of the foot. If left untreated these foot ulcers can become infected and may lead to amputation. It is estimated that DSF is a direct cause of more than 50% of all lower limb amputations in the world.

Diabetes has been an incurable disease, so far. Therefore, patients with diabetes require life-long instantaneous monitoring and treatment aimed not only at controlling of the blood glucose level but also at screening for, diagnosing and taking care of the late complications of diabetes. Telemonitoring and telecare have been used to serve these purposes starting from the early 90-ies. First home telecare systems were applied during insulin therapy of diabetic patients for the remote monitoring of the patient's metabolic state, the life-style and the course of the treatment. These systems contributed to an improvement of: the reliability of the data collected and reported by the patients, frequency of the check-ups of the data performed by the physician and different measures of the outcome of the treatment [2-4]. Later, telemedicine usage has spread on screening, monitoring and treating of the late complications of diabetes such as the diabetic retinopathy, the cardiovascular disorders and the DFS. In the last few years, several video consultation services for the DFS patients have been reported, basing on the use of the modern mobile phones integrated with the digital cameras [5-8].

In the first part of the manuscript the design and implementation of the TeleDiaFoS home telecare system developed by the authors is presented. In the second part, a clinical trial validating the feasibility of the system is described and the results of the first clinical application of the TeleDiaFoS system are shown.

II. TeleDiaFoS system

The TeleDiaFoS consists of: the Central Clinical Server (CCS), the Diabetologist's Workstation, the Podiatrist's

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1049–1052, 2009
www.springerlink.com

Workstation and a set of the Patient's Modules (PM). The structure of the system is presented in Figure 1.

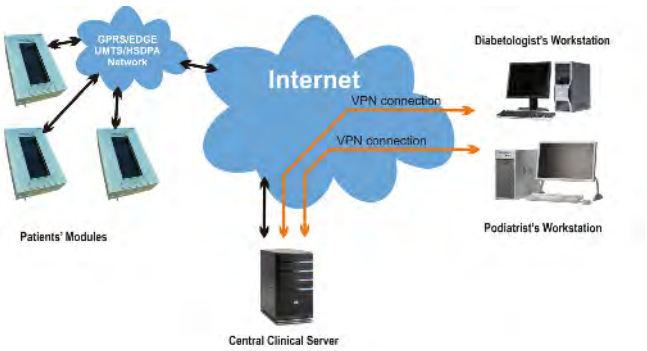

Fig. 1 Structure of the TeleDiaFoS system

The main database of the system is located in CCS. This database [9] contains 5 modules:

- *Patient's Registration,* which groups the standard patient's data like name, address, and telephone number.
- *Examinations*, which collects the data related to the patient's general state, diabetes treatment and diabetic foot examination (vibration sensing test, pressure and temperature sensing test, ankle-brachial index, pedobarographic examination, images from scintillation camera, angio-CT, USG, RTG). In this module there are also results of the tissue evaporative water loss (TEWL) measurements, pH and temperature of the skin and the images of the foot ulcers taken with an optical scanner during routine check-ups in the foot care clinic.
- *Telemedical Data*, which gathers the data sent by the patient using the homecare PM, i.e. blood glucose concentration, arterial blood pressure, heart rate and images of the foot wounds.
- *Graphical Presentation*, which makes it possible to annotate the schematic pictures of the patient's feet by means of marking the location and size of the ulcers and other changes on the foot like tinea pedis, gangrene, pseudomonas aeruginosa and keratosis (see Figure 2). It is also possible to erase parts of the foot image, which corresponds to the amputated parts of the patient's foot. Additionally, the physiological parameters being monitored, i.e. the blood glucose concentration, the arterial blood pressure and the heart rate can be displayed on the time graphs.
- *Options,* which enables to synchronize the database, change the optical scanner, and display short information about the TeleDiaFoS database.

The data can be either entered manually or can be uploaded automatically from the PM, which is a homecare device (see Figure 3).

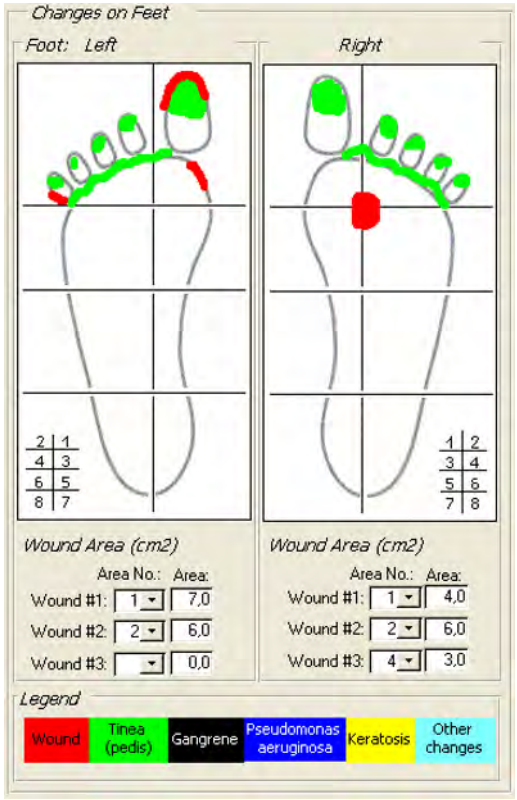

Fig. 2 Exemplary drawing of feet state.
Wounds and tinea pedis are present on both feet.

PM is operated by a patient using a simple two-buttons remote controller. There are four LEDs located on the front panel of PM which signals the current state of the device. The following operations can be performed:

- taking pictures of the sole of the patient's foot with a built-in foot scanner,
- downloading the blood glucose data, the blood pressure recordings and the heart rate values from memory of the external meters connected to PM,
- switching PM on and off.

The Accu-Chek Active glucometer (Roche, Germany) and BP 3BU1-4 blood pressure meter (Taiwan) were selected devices to gather the patients' data. PM is able to communicate with glucometer and to download the data stored in its internal memory using the infrared interface (IrDA). The communication with the blood pressure meter is possible via the RS232 port.

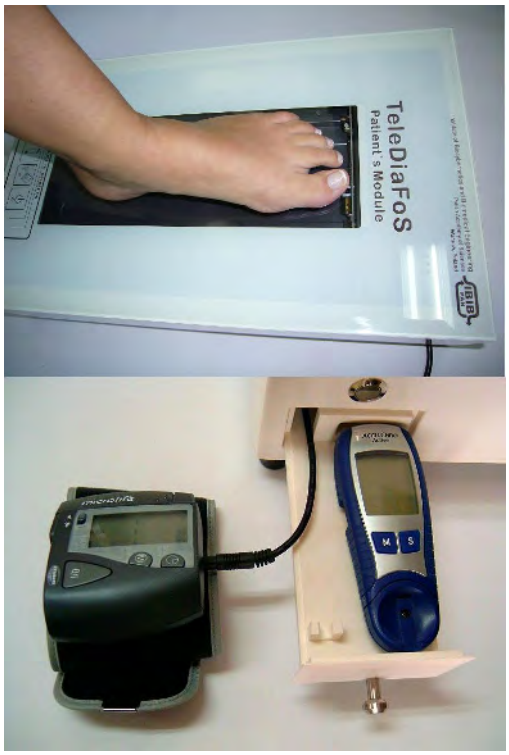

Fig. 3 Patient's module with a foot prepared for scanning (upper picture); glucometer and blood pressure meter connected to PM (lower picture)

It is possible to send the pictures of the foot being scanned together with the blood glucose readings and the blood pressure values being downloaded from the above-mentioned meters to the CCS. The PM is connected to the Internet using the built-in wireless modem, which operates in HSDPA/UMTS/EDGE/GPRS modes. The modem software selects automatically the highest data transfer speed available in the network of the internet provider.

The foot image files and the files containing the data downloaded from the external meters are transferred to the CCS automatically using the ftp protocol. At the server site specialized software service decodes the data and inserts them into the TeleDiaFoS database.

Physicians can access the patients' data using the workstations with locally replicated copies of the main database. The data on the local workstations are synchronized with the data stored in the main database through the virtual private network (VPN).

Proper operation of all building blocks of the TeleDiaFoS and the technical feasibility of the automatic teletransmission of the data from PM were confirmed during extensive laboratory tests. The initial tests in real homecare conditions were performed afterwards with one patient over a period of 32 days. The patient sent 6 pictures of the foot and 6 times was sending the data from measuring devices. No technical problems during the homecare test were identified. The patient has not reported any problems related to the management of PM.

III. Clinical Verification of the TeleDiaFoS

Clinical verification of the TeleDiaFoS system has been organized as a randomized 90-days trial. The study protocol has been approved by the Local Ethical Committee. The target of 10 type 2 diabetic patients in the study group and in the control group has been set. Each patient has to sign the informed consent for participation. The inclusion criteria comprise the ability and willingness of the patient to perform everyday self-monitoring (i.e. blood glucose and blood pressure testing) and control (i.e. insulin injections), age between 45 and 65 years, neuropathic DFS with an ulcer located on the sole of one foot, ankle-brachial index greater than 0.7. Patients are excluded from the study in the case of the proliferative retinopathy and / or maculopathy that require active treatment, kidney dysfunction (creatinine > 2 mg/dL), cardiac insufficiency, cardiac infarction within the last 3 months before the study and mental impairment. The study protocol includes 3 clinical visits at the beginning of the study, after one month and at the end of the study. During the first visit each patient is trained to be able to use the glucometer, the blood pressure meter and to control the PM.

Currently, the treatment of the first patient from the study group (66 years old male with a 9-years history of diabetes, treated with multi-injection insulin delivery and antibiotic – dalacin therapies) has been terminated.

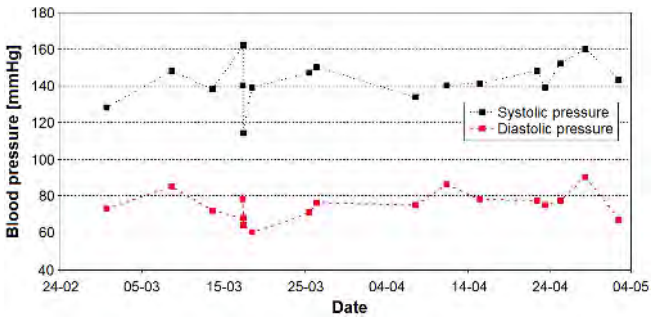

Fig. 4 Blood pressure of the diabetic patient with DFS treated using the TeleDiaFoS

During the monitoring period 13 transmissions of the data were performed (in average once per week). Most of the time blood pressure was controlled satisfactory (see Figure 4). However, acceptable glycemic control has not been maintained (see Figure 5). Despite this, the treatment that

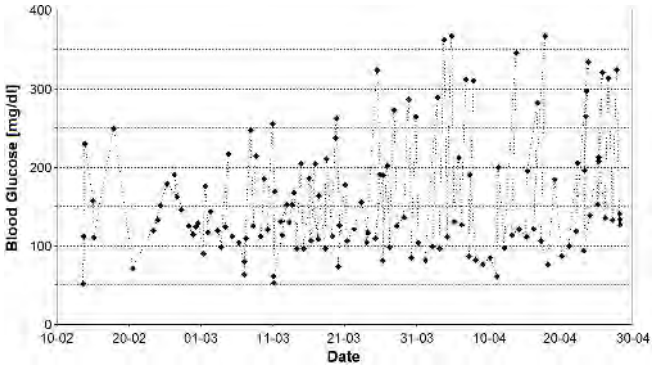

Fig. 5 Blood glucose concentration of the diabetic patient with DFS treated using TeleDiaFoS

Fig. 6 Exemplary pictures of the foot wound sent by the patient at the beginning of the study period (left), 23 days later (in the middle) and at the end of the study (right)

was supported by an application of the TeleDiaFoS system led to more than 12-fold reduction of the wound surface, i.e. from open wound with a surface of 356 mm^2 to minimal change of the skin area measuring 29 mm^2 (see Figure 6).

IV. Conclusions

The TeleDiaFoS system takes the advantage of the wireless telematic technology which enables the physician to monitor and analyze patients' data remotely. Application of the system leads to more effective realization of the DFS therapy and has a positive impact on the patient's comfort eliminating the inconvenience related to regular visits in the outpatient clinic.

In-vitro Evaluation Method to Measure the Radial Force of Various Stents

Y. Okamoto[1], T. Tanaka[1], H. Kobashi[1], K. Iwasaki[2], M. Umezu[1]

Abstract — **Endovascular treatments of stenosis in carotid artery often utilize a self-expanding stent. There are a variety of stents commercially available. The radial force of a stent is a key parameter to characterize its mechanical property, but there is no reliable evaluation to standardize the force measurement. In measuring the radial force accurately, the stent deformation has to be uniform for the whole structure so as to ensure the force balance. Here we aim to develop such a measuring system of stent radial force, and compare the results with those obtained by conventional techniques.**

A developed device consisted of a tubular stent holder and a load measuring system. The Precise, Protege and Easy Wall stents with a diameter (D) of 10 mm were placed by a delivery system. Radial forces were measured with D = 8, 6, 5, and 4 mm at a temperature of 37 degrees. Maintaining the circular shape of stents was found to influence substantially the magnitude of radial force. The value increased about 80 % at maximum for those measured by conventional techniques. These data show that the radial force has to be uniformly applied in a circumferential direction. Also, the Easy Wall stent showed a distinct tendency in contrast to the Precise and Protege stent. The Easy Wall stent was found to be placed with eliminating the axial variation of mesh geometries.

These results indicate that the radial force measurements of stents have to ensure the uniform mesh geometry in both the axial and circumferential direction. It was concluded that our device can ensure the reliable measurement of stent radial forces.

Keywords **— Stent, Radial force, Self-expanding stent, Mechanical property**

I. Introduction

Endovascular treatments of stenosis using a stent are a common procedure. There are indeed a variety of stents available in market. In clinical practice, however, selection criteria of stents are often obscure, and are determined empirically by surgeons. In order to establish a selection guideline of stents, it is mandatory to understand mechanical properties of stents, such as radial force, and characterize them among a variety of stents in a standardized condition. In doing so, a reliable in vitro evaluation methodology has to be established.

A measurement of stent radial force, such as seen in literatures [1-4], often utilizes a film-type jig to hold a stent tested [1] [2](Fig. 1). In our laboratory, we previously used a comb-type jig (Fig.2). However, these conventional systems have some disadvantages. First, stents tended to show varying patterns of the cross-section in the axial direction according to loading applied. Second, the uniformity of the stent mesh was no longer maintained, resulting in varying mesh intervals locally. Particularly, the large deformation with the irregular mesh was often detected at the edge. In order to solve these problems, we aim to develop a new system for measuring a stent radial force. Here we compare the data with those obtained by our previous measurement system in order to establish a reliable methodology of stent radial force measurement.

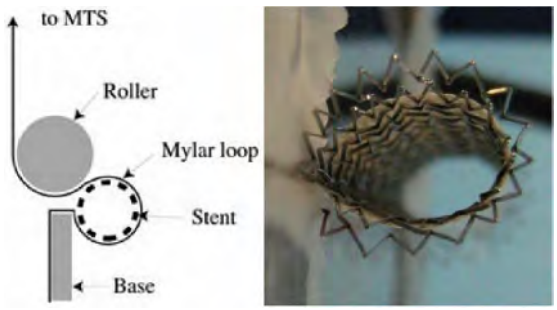

Fig.1 Schema and photograph of film-type jig

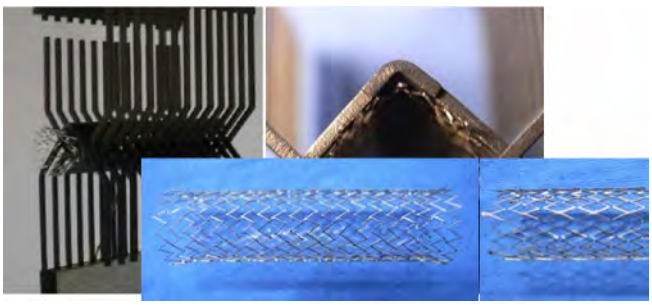

Fig.2 Photograph of comb-type jig

www.springerlink.com

II. Material and Method

Fig.3 shows a schema of a newly developed device for measuring a stent radial force. It consisted of a U-shaped stent holder and a load measuring system. A pair of stent holders constituted a tubular geometry, in which a stent is placed by a delivery system.

Fig.4 shows a photograph of a stent delivered. As shown in the figure, the cross-section of a stent remained circular, and there is no marked variation of mesh-to-mesh pitches in the axial direction.

Conventionally, the cross-sectional shape of the stent in response to loading applied depends on the geometry of a jig (Fig.2). Also, the edge of the stent tends to be locally deformed. These drawbacks were improved in our current measuring system.

The stent tested comprised three commercially available ones, namely the Precise, Protege and Easy Wall stents with a diameter (D) of 10 mm, as shown in Table. 1. These stents varied in mesh geometry, and the Precise and Protege stents had a similar zigzag shape fabricated by laser cutting of a tubular Nitinol, while the Easy Wall stent was a wire-braided type. Experiments were conducted at a temperature of 37 degrees. Radial forces were measured with D = 8, 6, 5, and 4 mm for three stents, respectively.

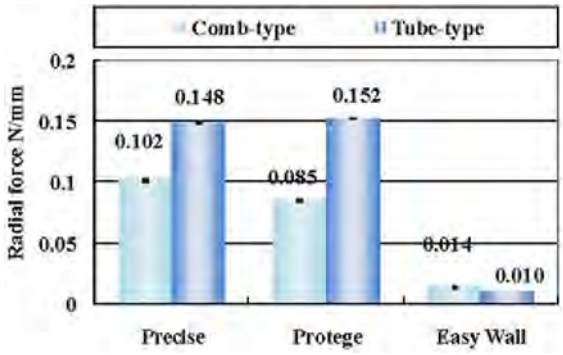

Fig.5 Comparison of radial force between comb-type and tube-type jigs at a diameter of 8 mm
(Left: Precise, Centre: Protégé, Right: Easy Wall)

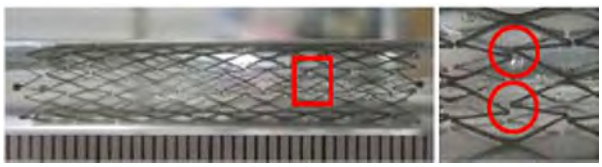

Fig.6 Photograph of irregularities on mesh of the Protege stent (D=8mm)

III. Results and Discussion

Fig.5 compares the results obtained by a comb-type and tube-type jig for the Precise, Protege and Easy Wall stent at a diameter of 8 mm. In the Precise and Protege stents, radial force measured showed 45 %, and 79 % higher for the tube-type jig than those of a comb-type jig. On the other hand, the Easy Wall stent showed an opposite tendency, where the tube-type jig showed 29 % lower value. In the case of the Precise and Protege stent, the elimination of clearance within a jig using the tube-type one elevated the magnitude of the radial force. The comb-type jig had the clearance at the corner, where the stents were deformed locally.

As a result, the zigzag stent segment did not shrink in the circumferential direction, resulting in the lower value of radial force. On the other hand, the Easy Wall stent had a diamond-shaped segment, which released the radial force in the axial direction. This stent structure substantially reduced the radial force. In the comb-type jig, the Easy Wall stent received the counter force due to the mechanical contact at the edge, whereas the tube-type jig had the same cross-sectional shape along with the axis. These results indicate that the present tube-type jig system enables to measure the radial force of stents in a reliable manner.

Also, we used a delivery system to insert a stent inside a jig. Then, we found an interesting phenomenon for the Protege stent. In releasing a stent out of the delivery system, the Precise and Easy Wall stent did not show any mesh irregularities. However, the Protege stent showed a local

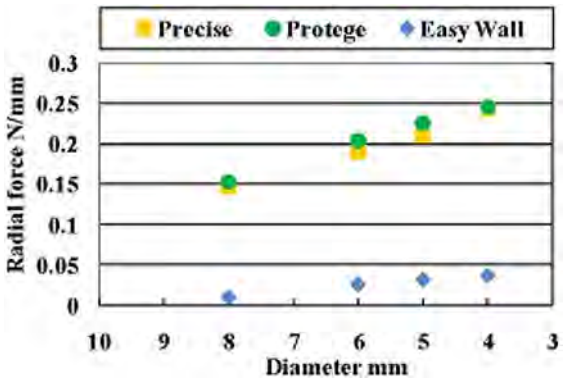

Fig.7 Characteristics of a radial force

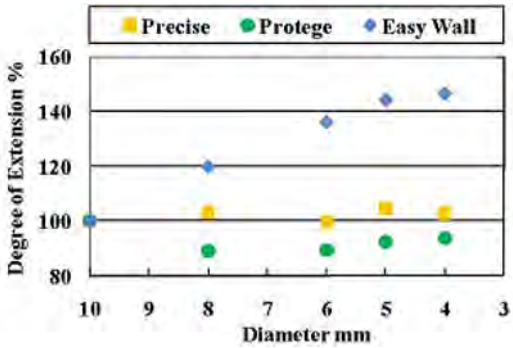

Fig.8 Extensional rate of the stent longitudinal length during radial force measurements

mesh deviation during release as shown in Fig.6. This phenomenon attributes to the mesh design, and the use of a delivery system in testing stent radial force was found to be important.

Fig.7 characterizes a radial force measurement at a diameter of 8, 6, 5, 4 mm for the Precise, Protege and Easy Wall stents. Also, Fig.8 shows the degree of extension of the longitudinal length of stents. By comparing those two figures, there is an interesting trend of stent radial force. In Fig.7, it can be observed that the Easy Wall stent did not even show a marked elevation of radial force under maximum compression. This was caused by the axial extension as shown by Fig.8. Indeed, the axial extension of the Precise and Protege stent did not vary substantially, which in turn led to increase the radial force linearly for the loading applied.

IV. Conclusions

We demonstrated that the present system enabled to measure stent radial force more accurately than previous ones. Also, it was found that the radial force was substan-

tially affected by the mesh structure. These data may provide a useful knowledge to assess the radial force in clinical practice and to establish the selection guideline of stents in endovascular treatments.

Motivating Children with Attention Deficiency Disorder Using Certain Behavior Modification Strategies

Huang Qunfang Jacklyn[1], S. Ravichandran[2]

[1]Student, Singapore Management University, Singapore
[2]Faculty, Temasek Engineering School, Temasek Polytechnic, Singapore

Abstract — **Attention-Deficit Hyperactivity Disorder (ADHD) is a neurobehavioral developmental disorder and its manifestation during childhood are characterized by a persistent pattern of inattention and/or hyperactivity. ADHD is currently considered a persistent and chronic condition for which no medical cure is available, although medication and therapy can treat symptoms. Children with such mental retardation more often exhibit behavior problems than children without disabilities. Teaching these students is more challenging and is considered as one of the most important functions of special education. Though a common behavior modification strategy is not always useful in dealing with neurobehavioral development, it may be more appropriate to design strategies based on the cognitive ability of the subject undergoing treatment. This paper summarizes the knowledge gained by the authors on designing specific cognitive strategy to deal with children in the age group (8 – 12 year). The strategy discussed in this paper is mostly focused on educating children with attention deficit disorder than treating hyperactivity as hyperactivity is mostly managed by the used of medication. The behavior modification strategy suggested is based on the fact that children within the age group have strong interest in specific activities involving audiovisual stimulus. The strategy aims in motivating the children to learn a specific act such as learning subjects like mathematics. The protocol basically motivates the children to focus and concentrate on solving a problem in order to be rewarded with audiovisual stimulus which are of interest to them. Though it may be beyond the scope of this paper to provide a comprehensive picture on the neuro-cognitive modifications associated with this behavior modification strategy, it provides a realistic picture on the changes reflecting the improvements in the cognitive aspects of the subject.**

Keywords — **ADHD, Behavior modification, Cognitive strategy**

I. Introduction

Attention-Deficit/Hyperactivity Disorder (ADHD) is typically first diagnosed in childhood, with symptoms persisting into adolescence and adulthood [1]. ADHD is characterized by inattention, impulsivity, and hyperactivity. It has recently been estimated to affect 3.5% of school-aged children worldwide and is said to be one of the most common psychiatric disorders of youth [2, 3]. Children with these problems are often unpopular and lack reciprocal friendships, but are not always aware of their own unpopularity [4]. Though these symptoms tend to decline with age, at least 50% of children with ADHD still experience impairing symptoms in adulthood [5]. Despite the vast literature supporting the efficacy of stimulant medication in the treatment of attention-deficit/hyperactivity disorder (ADHD), several limitations of pharmacological treatments highlight the clear need for effective alternative psychosocial treatments. There are also evidences on interventions involving both the school and parents training which have resulted in classifying these as "empirically validated treatments" [6].

II. Definition of ADHD

Most studies on ADHD attribute reasons/explanations on how they affect the cognitive processes of subjects [7, 8, 9]. However the field has not been able to develop an evidence-based intervention based on cognitive-behavioural principles [10]. Indeed, part of the challenge has been the changing conceptualization of the etiology and behavioural profile of ADHD [11]. Based on the pattern of symptoms present, the Diagnostic and Statistical Manual (DSM-IV) distinguishes three subtypes, namely, the inattentive, the hyperactive/impulsive, and the combined subtype [12]. The latter is by far the most common. Children with the inattentive ADHD subtype suffer from rejection by peers. Their social behaviour is of a more subdued nature [4]. Children with ADHD display chronic and pervasive difficulties with inattention, hyperactivity, and impulsivity that result in profound impairments in academic and social functioning across multiple settings (typically, at home, in school, and with peers). Some children with ADHD, despite having difficulties in performing tasks at school, have a healthy social life, while others appear to be unable to connect with peers and other people in a normal way [4].

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1057–1060, 2009
www.springerlink.com

III. Neurophychological aspects of ADHD

Explanations on the neuropsychological aspects of ADHD as per available literature imply that the disorder has a pathological basis in descending cortical control systems such as the prefrontal cortex and frontostriatal networks [13].The literature also states that, the prefrontal cortex is believed to bias subsidiary processing implemented by posterior cortical and subcortical regions in accordance with current goals. One of the mechanisms by which the prefrontal cortex is believed to exert its coordinating effects is via the suppression or gating of neural signalling irrelevant to current behaviour or goal [14, 15].

IV. Assessment of ADHD

The use of "Disruptive Behaviour Rating Scale" to obtain parent and teacher ratings of the 18 symptoms of *DSM-IV* ADHD has been reported as a qualitative yard stick to categorize subjects under various types depending on the manifested symptoms [16]. Children were categorized as ADHD only if symptoms were present prior to age seven and if these symptoms caused significant functional impairment. Individuals with six or more symptoms of inattention but fewer than six symptoms of hyperactivity-impulsivity were identified as Predominantly Inattentive Type, participants with six or more symptoms of hyperactivity-impulsivity but fewer than six symptoms of inattention were categorized as Predominantly Hyperactive/Impulsive Type, and individuals with six or more symptoms on both dimensions were coded as Combined Type [17].

V. Changing conceptualization of ADHD

The changing conceptualization of ADHD necessitates the field to constantly evaluate the adequacy of treatment approaches, and the working theory of ADHD has an important impact on treatment approaches. It has been reported that the sensory integration therapy, for use with children with ADHD involves compensatory strategies, such as altering or avoiding certain stimulus characteristics of the physical environment. This therapy is based on the assumption that ADHD is an "input" problem, and that sensory and motor input is processed and interpreted in faulty ways which result in inappropriate responses to sensory stimuli [18]. In ADHD cases, we are dealing more with cognitive deficiencies as opposed to distortions [19].

VI. Treatments currently being practiced

Treatment of ADHD is currently managed through various methods such as pharmacological intervention, behaviour interventions, cognitive behaviour treatment, neural-based intervention. Each treatment has its own merits and demerits and quite often a combination of two interventions is sought by the clinicians in treating ADHD children. We intend not to elaborate on the merits and demerits of each intervention in this paper, but would provide a brief insight into each intervention and focus more on the behaviour intervention and strategies beneficial in motivating children to develop attention for solving problems in education.

A. Pharmacology

Though it is beyond the scope of this paper to discuss the various medications available for ADHD children, developments in the pharmacological management of ADHD mean that there is now a much greater choice of approved medications these days. However, there are limitations to an exclusively pharmacological approach in the treatment of ADHD. These include the limited effects of stimulant medication on problems such as academic achievement and peer relationships, the fact that up to 30% of children do not show a clear beneficial response to stimulants. It is reported that the long term side effects of taking stimulants has been a limiting factor in the used of these medication as children suffer side effects such as insomnia and appetite suppression. [6].

B. Behaviour Interventions

It is seen that the inattentive, hyperactive, and impulsive behaviors that characterize ADHD often contribute to impairment in the parent–child relationship and increased stress among parents of children with the disorder [20, 21]. It follows that one evidence-based component of comprehensive treatment for ADHD involves working directly with parents to modify their parenting behaviours in order to increase positive outcomes with their children [22]. Effectively modifying poor parenting practices is of utmost importance, as poor parenting is one of the more robust predictors of negative long-term outcomes in children with behaviour problems [23]. Parents are taught to identify and manipulate the antecedents and consequences of child behaviour, target and monitor problematic behaviours, reward pro-social behaviour through praise, positive attention, and tangible rewards, and decrease unwanted behaviour through planned ignoring, time out, and other non-physical discipline techniques.

In classroom behaviour management, teachers are instructed regarding the use of specific behavioural techniques, which includes giving praises, planning ignorance etc. Behavioural goals are set at a level that is challenging, yet attainable, and are made increasingly more difficult until the child's behaviour is within developmentally normative levels based on the principle of shaping. Behaviourally based classroom interventions appear to be a very effective means of behaviour change in children with ADHD in the school setting. However, as cooperation of school professionals is necessary for these interventions, some of these challenges exist as with home behavioural programs [6].

C. Cognitive-behavioral Treatments

It has been reported by researchers that studies conducted on cognitive-behavioural approaches which include training in self-instructions, problem-solving, self reinforcement, and self-redirection have helped children to cope with errors. Children were taught a five-step process of problem-solving, including defining the problem, setting a goal, generating problem-solving strategies, choosing a solution, and evaluating the outcome with self-reinforcement. These concepts were reinforced through the use of modelling and role-playing exercises, instructional training, homework, and behavioral techniques, such as social reinforcement and a token system. As observed from the studies, there was a significant decrease in child activity level following CBT than controls [24].

D. Neural-based Interventions

Neurofeedback, based on electroencephalogram biofeedback, is sometimes used as one of the intervention in the management of ADHD children. The theoretical basis of neurofeedback describe ADHD as a disorder of neural regulation and under arousal, and it is assumed under this approach that these neural deficiencies are amenable to change using behavioural methods [25]. Some refer this intervention as a relatively unresearched treatment, and the research that has been conducted has reportedly been inconsistent and problematic. It is believed that this is due to methodological problems such as confounded treatments, inconsistent use of dependent measures, and a lack of clinically meaningful dependent measures [18, 26].

E. Combined behavioural-pharmacological interventions

It has been reported that Medication Management was as effective as Combined Treatment in reducing ADHD symptoms, with no clear incremental benefit of behaviour therapy noted [6]. Also, it is believed that combined treatment may allow for lower doses of medication to be used in conjunction with behaviour management in the home and school settings, resulting in increased satisfaction with treatment [27, 28].

VII. Strategies to improve attention span

The current behaviour modification strategies are based on identifying and manipulating the antecedents and consequences of child behaviour, target and monitor problematic behaviours, reward through praise, positive attention, and tangible rewards. Our focus was more on those subjects who have attention deficit yet who were willing to cooperate with assistances for learning. This group of people has been identified with certain interests in audio-visual stimulus and hence were willing to participate in solving problems leading to positive attention.

VIII. Treatment protocol

Our treatment protocol relies on some of the audio-visual animations which can be played using an available audio-visual system. As it is possible to play a variety of animated audio-visual animations which are of considered fascination by the children, it serves as a reward for every positive step taken by those who cooperate on solving problems, thereby prompting better attention.

IX. Conclusion

Treatment of ADHD is currently managed through various methods such as pharmacological intervention, behaviour interventions, cognitive behaviour treatment, neural-based intervention. Each method has its own merits and demerits and quite often a combination of two interventions is sought by the clinicians in treating ADHD children. No single strategy in the management of ADHD children has been advocated by the clinicians in the past and the success of each strategy depends on the cooperation extended by the subjects in a given setup. The current strategy based on behaviour modification is very attractive due to the fact that it does not relay on pharmacological intervention. However any strategy has its own limitations and in this behaviour modification strategy, the success purely depends on the ability of the subjects to be motivated in learning for rewards given for every positive step in improving their attention span. It is also worth noting that if the reward falls short of the subject’s expectation, it may results in poor attention span of the subjects under this treatment protocol.

Regeneration of Speech in Voice-Loss Patients

H.R. Sharifzadeh[1], I.V. McLoughlin[1] and F. Ahmadi[1]

[1]School of Computer Engineering, Nanyang Technological University, Singapore

Abstract — **This paper considers regeneration of natural sounding speech from whisper-speech, produced by patients with vocal tract lesions affecting the glottis. Such reconstruction is important for both total and partial laryngectomy patients to improve on the monotonous robotized sound typical of electrolarynx devices.**

Reconstruction of speech from whispers has been demonstrated previously, however the resulting speech does not exhibit particularly high intelligibility, and more importantly, sounds un-natural. It is the conjecture of the authors that limited pitch variations in the reconstructed speech contributes most to that lack of naturalness.

In this paper, a method for pitch contour variation in reconstructed speech is presented. This method extracts voice factors which are important to 'naturalness' from the whispered signal and applies these to the reconstructed speech. The method is based upon our previous published work which implemented an analysis-by-synthesis approach to voice reconstruction using a modified CELP codec.

Keywords — **Rehabilitation, Laryngectomy, Speech, Whispers, CELP codec**

I. Introduction

The speech production process starts with lung exhalation passing a taut glottis to create a varying pitch signal which resonates through the vocal tract, nasal cavity and out through the mouth. Within the vocal, oral and nasal cavities, the vellum, tongue, and lip positions play crucial roles in shaping speech sounds; these are referred to collectively as vocal tract modulators [1].

Total laryngectomy patients will have lost their glottis and also the control to pass lung exhalation through the vocal tract in many cases. Partial laryngectomy patients, by contrast, may still retain the power of controlled lung exhalation through the vocal tract. Despite the loss of the glottis including vocal folds, both classes of patients retain the power of vocal tract modulation and therefore by controlling lung exhalation, they have the ability to whisper [2]; in other words, they maintain most of the speech production apparatus.

In normally phonated speech, pitch itself is known to be the major source of important tonal information, alongside the lower formants [3]. Since there is no fundamental pitch present in whispers, other parameters contribute more heavily to perceived tonal variation. These include duration, amplitude, and formant location/bandwidth (whisper-speech formants are both wider and upward shifted compared to normal speech, as it is described in section 2). Although the contribution of amplitude to pitch variation has been studied by others such as [4], neither duration nor formant location have been used for tone reconstruction. The new technique presented in section 4 describes an algorithm which combines the use of formant information, along with amplitude, to estimate pitch contour variations in vowels.

The approach discussed in this paper utilizes a code excited linear prediction (CELP) codec and is based upon our previous published work in [5]. In a standard CELP codec, speech is generated by filtering an excitation signal in which the excitation sequence is selected from a codebook of zero-mean Gaussian sequences and then is shaped by an LTP filter to convey the pitch information of the speech [6]. For the purpose of speech reconstruction from whispers, we need to modify the standard CELP codec which details are described in section 3.

Section 2 outlines whispered speech features regarding formant information in vowels and also in terms of their acoustic and spectral characteristics while section 3 explains the modified CELP codec customized for our purpose of natural speech regeneration. Section 4 discusses our proposed method for pitch contour variation in reconstructed speech and finally section 5 concludes the paper.

II. Acoustic and Spectral Features of Whispered Speech

Whispered speech can be categorized into two different classes: soft whispers and stage whispers [7]. Soft whispers which are also referred to as quiet whisper are produced in certain circumstances to reduce perceptibility, such as whispering into someone's ear in the library and usually used in a relaxed, comfortable, low effort manner [8]. Stage whispers, on the other hand, are a combined kind of whisper one would use if the listener is some distance away from the speaker [7]. In other words, stage whisper is actually a whispery voice in phonetic terms, which is a type of phonation that involves vocal fold vibration [9].

Within this paper, we will concentrate on soft whispers which are produced without vocal fold vibration and not

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1065–1068, 2009
www.springerlink.com

only are more commonly used in daily life but also are the same type of whispers produced by laryngectomy patients.

As mentioned, essential physical features of whispered speech include the absence of vocal cord vibrations which leads to the absence of fundamental frequency and consequent harmonic relationships [10]. This is the most significant acoustic characteristic of whispers. By considering a source filter model [11], exhalation can be identified as the source of excitation in whispered speech and the shape of the pharynx is adjusted so that the vocal cords do not vibrate [12]. Thus, turbulent aperiodic airflow is the only source of sound for whispers, and it is a strong, rich, and hushing sound [13].

Regarding spectral characteristics, whispered speech sounds do have peaks in their spectra with roughly the same frequencies as those for normally phonated speech sounds [14]. These formants occur within a flatter power frequency distribution, and there are no harmonics in the spectra corresponding to the fundamental frequency [10].

Whispered vowels differ from normally voiced vowels. All formant frequencies (including the important first three formants) tend to be higher [15], particularly the first formant which shows the greatest difference between two kinds of speech. Lehiste in [15] reported that F1 is approximately 200-250 Hz higher, whereas F2 and F3 are approximately 100-150 Hz higher in whispered vowels.

Furthermore, unlike phonated vowels where the amplitude of each higher formant is less than for lower formants, whispered vowels usually have second formants that are as intense as first formants. These differences mainly in first formant frequency and amplitude are thought to be due to the alteration in the shape of the more posterior areas of the vocal tract including the vocal cords which are held rigid. Although these changes in acoustics are significant, there is only reported to be a small reduction, of 10 percent or less, in the accuracy of vowel identification for whispered speech [16].

As mentioned, since excitation in whisper mode speech is the turbulent flow created by the exhaled air passing through the open glottis, the resulting signal is completely noise excited [12, 16]. One of the consequences of a glottal opening is an acoustic coupling to the subglottal airways. The subglottal system has a series of resonances, which can be defined as the natural frequencies with a closed glottis. The average values of the first three of these natural frequencies have been estimated to be about 700, 1650, and 2350 Hz for an adult female and 600, 1550, and 2200 Hz for an adult male, but there are of course substantial individual differences [17]. Analysis shows that the effect of these subglottal resonances is to introduce additional pole-zero pairs into the vocal tract transfer function from the glottal source to the mouth output. The most obvious acoustic manifestation of these pole-zero pairs is the appearance of additional peaks or prominences in the output spectrum. The influence of zeros can also be seen sometimes as minima in the spectrum [18].

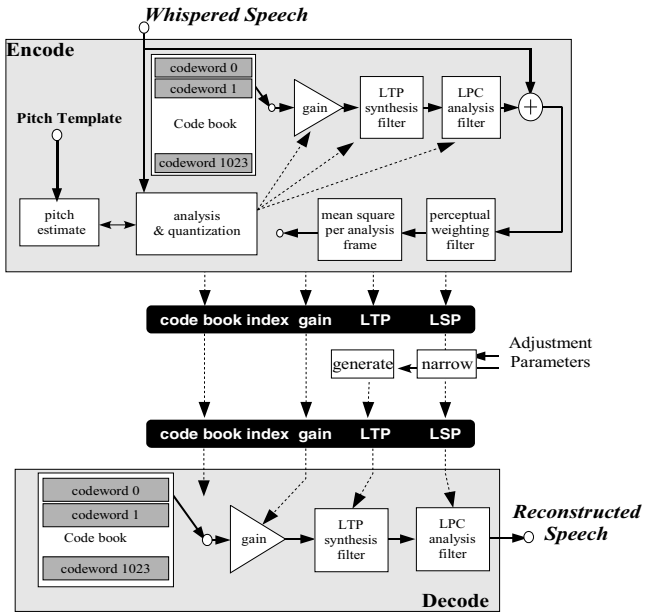

Fig. 1 A block diagram of a modified CELP codec used for speech reconstruction

III. Modified CELP Codec

As described in section 1, the approach used in this project utilizes a code excited linear prediction (CELP) codec in which the excitation sequence is selected from a codebook of zero-mean Gaussian sequences and then is shaped by an LTP filter to convey the pitch information of the speech.

Figure 1 shows a block diagram of the CELP codec as implemented in this paper, with the modifications for whisper-speech reconstruction identified. In comparison with the standard CELP codec, we have added a "pitch template" corresponding to the "pitch estimate" unit while "adjustment parameters" in this model are used to generate pitch factors as well as to apply necessary LSP modifications. The pitch estimate method is described within section 4 while LSP modifications, required for preparing the whispered speech signal to insert pitch into it, is described in the following.

For this research, a 12^{th} order linear prediction analysis is performed on the waveform, which is sampled at 8 kHz. A

frame duration of 20 ms is used for the vocal tract analysis (160 samples) and a 5 ms sub frame duration (40 ms) for determining the pitch excitation.

In the CELP codec, as well as many other low bit-rate coders, linear prediction coefficients are transformed into line spectral pairs (LSPs) [19]. LSPs describe the two resonance states of an interconnected tube model of the human vocal tract. These conditions are those that describe the modelled vocal tract being either fully open or fully closed at the glottis respectively. In reality, the human glottis is opened and closed rapidly during speech and thus the actual resonances occur somewhere between the two extreme conditions. The LSP representation, hence, has a significant physical basis [20]. However, this rationale is not necessarily true for whispered speech (since the glottis does not vibrate), and thus we need to make some adjustments to the model.

In figure 2, the linear prediction spectrum obtained from analyzing a typical segment of a vowel in whispered speech (/a/) is plotted and dashed lines drawn at the LSP frequencies derived from the linear prediction parameters are overlaid on it.

As discussed in [21], spectral peaks are generally bracketed by LSP line pairs, with degree of closeness being dependent upon the sharpness of the spectral peak, and its amplitude. However, as previously discussed in section 2, whispered speech has few significant peaks in the spectrum which implies wider distances between LSP lines. Hence to emphasize formants, it is necessary to narrow the LSP lines corresponding to likely formants, i.e. the 2 or 3 narrowest of them.

Since altering the frequency of lines may lead to formation of unintentional peaks by narrowing the gap between two irrelevant pairs, it is important to choose the pair of lines corresponding to likely formants. As mentioned, this might be done by choosing the three narrowest LSP pairs which works well when the signal has fine peaks (see our previous paper in [5]), but in case of the expansion of formant bandwidths (common in whispered speech), which leads to the increase of distance between the corresponding LSPs, the choice of the 3 narrowest LSPs may not identify the three correct formant locations, particularly for a vowel. The narrowing procedure is, hence, strengthened with the formant position indication based upon the classic approach of finding phases of the poles of vocal tract transfer function. As a matter of fact, the improved algorithm will narrow the LSP pairs which are corresponding to each of the three formants (regardless of the fact they are the narrowest LSP pairs or not). Figure 3 shows the result of LSP narrowing algorithm as described above for the same frame in figure 2.

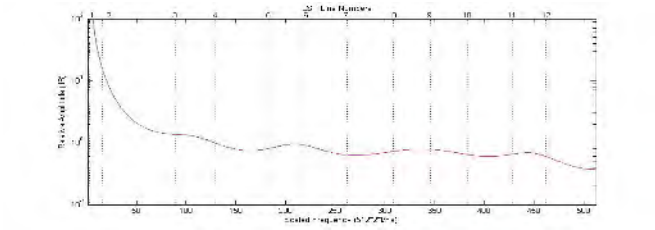

Fig. 2 Plot of LPC spectrum with LSPs overlaid for a whispered vowel /a/

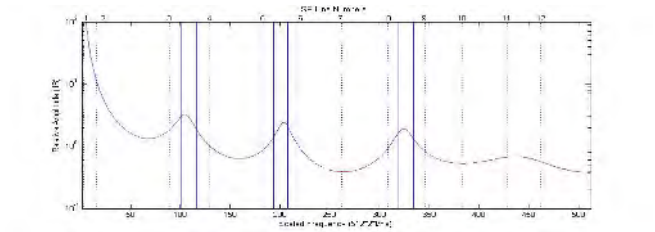

Fig. 3 Reconstructed LPC spectrum after applying improved LSP narrowing procedure for the whispered frame illustrated in figure 2

IV. Pitch Contour Variation Method

The pitch estimation algorithm discussed in this paper is based upon our recent work in [5] in which parameters are extracted from normally phonated speech and is tried to regenerate the excitation based on these parameters using CELP excitation synthesis method, but for improving the method to gain more natural synthesized speech, a novel approach for pitch estimation in terms of formant locations and amplitudes is proposed in this section. (Further details regarding the approach basics and the corresponding LTP filter parameters used in the CELP codec can be found through [5].)

By performing several alteration steps, a whispered vowel segment is converted to a normally phonated segment in a CELP based regeneration method. These steps are mostly being accomplished between the encoding and decoding modules of the CELP codec. As mentioned in section 4, the procedure is commenced by smoothing the LSP parameters to stabilize the formant locations of each segment. The formant bandwidths are also decreased to intensify formant amplitudes. The resulting formants are then shifted down to match the formant locations of normally phonated vowels.

As described in [5], long term predictor delay, *P,* has the main role in pitch determination in the CELP codec. Pitch contour variation, hence, can be achieved by variation of this parameter which, in our proposed method, is based on formant frequencies and amplitude according to (1) as follows:

$$P(n) = \begin{cases} P_{n-1} + \bar{P} + \alpha(\theta_n - \bar{\theta}) + \lambda h + S & h > 0 \\ P_{n-1} + \bar{P} + \alpha(\theta_n - \bar{\theta}) & h < 0 \end{cases} \quad (1)$$

in which n represents the number of current speech frame, h shows the instant amount of $\Delta F1_n \Delta F2_n$ which calculates the covariance of the first and second formants, S is the average value of formants in L previous frames which is calculated based on (2), α and λ are the factors to be set for generating the most natural voice and θ is the gain value in the CELP codec.

$$S = \frac{\sum_{i=n-L}^{n-1} F1_i + F2_i}{2} \quad (2)$$

Figure 4 illustrates the regenerated pitch contours of two samples of whispered vowel /a/ based on (1). Figure 5 demonstrates F1, F2, and pitch contour of a whispered and corresponding reconstructed vowel.

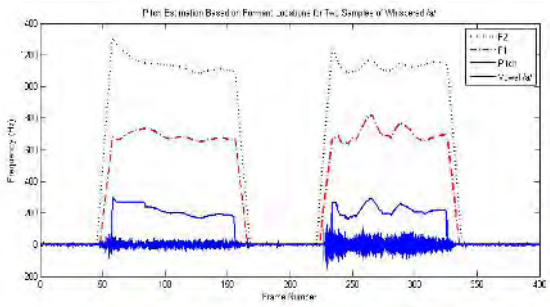

Fig. 4 Pitch estimation based on the first 2 formants of whispered vowel /a/

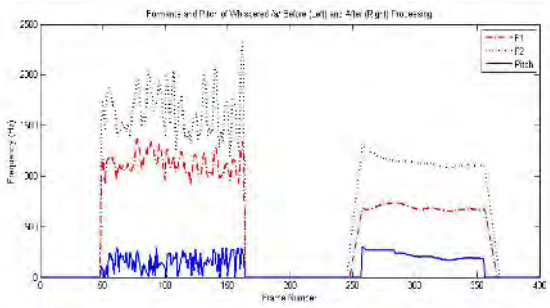

Fig. 5 Formants and pitch values for whispered vowel /a/ before and after enhancement

V. Conclusion

A method for real time synthesis of normal speech from whispers through an analysis-by-synthesis CELP codec with concentration on natural pitch generation in vowels has been proposed. By extraction of voice factors including formant location and amplitude, this method tried to regenerate natural pitch contours particularly in vowels.

By consideration of formant locations as well as amplitudes, a formula for generating pitch parameters in CELP codec was proposed. The results of the current work could highly contribute to natural speech regeneration for voice-loss patients.

Human Gait Analysis using Wearable Sensors of Acceleration and Angular Velocity

R. Takeda[1], S. Tadano[1], M. Todoh[1] and S. Yoshinari[2]

[1]Division of Human Mechanical Systems and Design, Graduate School of Engineering, Hokkaido University, Sapporo, Japan
[2]Human Engineering Section, Product Technology Department, Hokkaido Industrial Research Institute, Sapporo, Japan

Abstract — **This work proposes a method for measuring human gait posture using wearable sensors. The sensor used consist of a tri-axial acceleration sensor and three gyro sensors aligned on three axes. These are worn on the abdomen and the lower limb segments (both thighs, both shanks and both feet) to measure acceleration and angular velocity during walking. Three dimensional positions of each lower limb joint are calculated from segment lengths and joint angles. Segment lengths are calculated by physical measurement and joint angles can be estimated mechanically from the gravitational acceleration along the anterior axis of the segments. However, the acceleration data during walking includes three major components; translational acceleration, gravitational acceleration and external noise. Therefore, an optimization analysis was represented to separate only the gravitational acceleration from the acceleration data. Because the cyclic patterns of acceleration data can be found during constant walking, a FFT analysis was applied to obtain some characteristic frequencies. A pattern of gravitational acceleration was assumed using some parts of these characteristic frequencies. Every joint position was calculated from the pattern under the condition of physiological motion range of each joint. An optimized pattern of the gravitational acceleration was selected as a solution of an inverse problem. Three healthy volunteers walking straight for 20 seconds on a flat floor were measured. For comparison reflective markers were also placed on the volunteers for camera recordings. As a result, the characteristic three-dimensional walking of each volunteer could be expressed using a stick figure model. The trajectories of the knee joint in the horizontal plane were checked by images on PC. Therefore, this method provides important quantitive information for gait diagnosis.**

Keywords — **gait analysis, wearable sensor system, gravitational acceleration.**

I. Introduction

Gait analysis is an important clinical tool for diagnosing patients with walking disabilities. Currently, the main method for gait analysis is done by tracking a patient's movement through camera-based analysis systems, like the Vicon motion analysis system (Vicon Motion Systems, Inc.). Camera-based systems can provide three-dimensional position of body segments, but use of these systems is generally indoors in laboratories.

An alternate method for measuring human motion is by wearing small acceleration sensors on the body [1]. Wearable sensor systems are useful because it allows measurements outside the laboratories [2] [3]. However, wearable acceleration sensors can not provide position data directly. Therefore, many works in the past using wearable sensors systems have been limited to monitoring gait events [4] or comparing raw acceleration data [5].

A popular method for measuring three-dimensional position from acceleration is by double integrating the acceleration data. However integrating acceleration data accumulates error causing drift. Instead of integrating acceleration data, this work will use the gravitational acceleration measured by a wearable sensors system to calculate tilt angle of body segments. A optimization analysis was developed to estimate the gravitational acceleration included in acceleration data. This analysis used cyclic patterns of acceleration data during constant walking and physiological motion range of each joint to estimate only the gravitational acceleration. Gaits of three healthy volunteers were measured and the acceleration data of every lower limb segment was measured simultaneously. As a result three-dimensional walking established in this method could be visualized by using a stick figure model.

II. Method

A. Sensor System

A sensor system consisting of a tri-axial acceleration sensor (H34C, Hitachi Metals, Ltd.) and three single axis gyro sensors (ENC-03M, muRata Manufacturing Co., Ltd.) was used for this investigation. The axes of both acceleration and gyro sensors were orthogonally aligned. The sensor system also contained a data logger that simultaneously recorded the 3 axis acceleration and 3 axis angular velocity data for a maximum of 150 seconds at a sampling rate of 100Hz. Sensors were placed on seven segments (abdomen (AB), left and right thigh (LT, RT), left and right shank (LS, RS), left and right foot (LF, RF)) as shown in Fig. 1.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1069–1072, 2009
www.springerlink.com

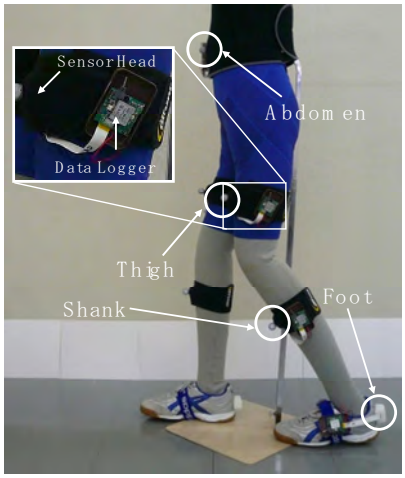

Fig. 1 Sensor attachment location. Sensors are attached to the abdomen (AB), both thighs (LT, RT), both shanks (LS, RS), both feet (LF, RF).

B. Acceleration and Gyro Sensor Measurement

The three-dimensional position of lower body joints can be calculated from orientation and length of each body segment. We presumed that the orientation of the segment is equal to the orientation of the attached acceleration sensor.

$$\theta^{\alpha} = \sin^{-1}\left(\frac{a_x^{\alpha}}{g}\right) \quad (1)$$

Here, a_i^{α} is the acceleration measured along x axis direction of segment α (LT, RT, LS, RS, LF, RF). During static state the gravitational acceleration is the only acceleration for a_i^{α}, therefore the orientation angle θ^{α} is the orientation against the direction of gravity. Gyro sensors were used to measure the horizontal rotation of the abdomen. Rotation θ^{AB} can be calculated by integrating the angular velocity ω, measured from the gyro sensor placed on the abdomen.

$$\theta^{AB} = \int \omega \, dt \quad (2)$$

C. Gravitational Acceleration Estimation

Data collected by the acceleration sensors during gait has three major components: translational acceleration, gravitational acceleration, and external noise [6]. Therefore a method was developed to separate out the gravitational acceleration to obtain segment orientation using Eq. 1.

The thin line in Fig. 2 shows the raw data taken from the anterior axis of an acceleration sensor of the RS. Noise is removed from this data by using cyclic acceleration patterns during gait. Cyclic patterns have been reported in the movement of body segments during constant walking [7] [8]. Fast Fourier transformation was applied to the acceleration data to investigate the frequencies of these cyclic patterns. The frequency analysis results are shown in Fig. 3. Peaks at certain frequencies were found. The first peak is the same frequency as the gait frequency and defined as the primary GF (gait frequency). This work focused on the first three frequencies in Fig. 3, the primary GF, secondary GF, and tertiary GF. The acceleration data of these GFs were extracted from the original acceleration data using low-pass and band-pass filters. As shown in Fig. 2, the composite data coincides with the original acceleration data with the noise removed. Since the heavy line in Fig. 2 still contains both gravitational acceleration and translational acceleration, wave decomposition was performed.

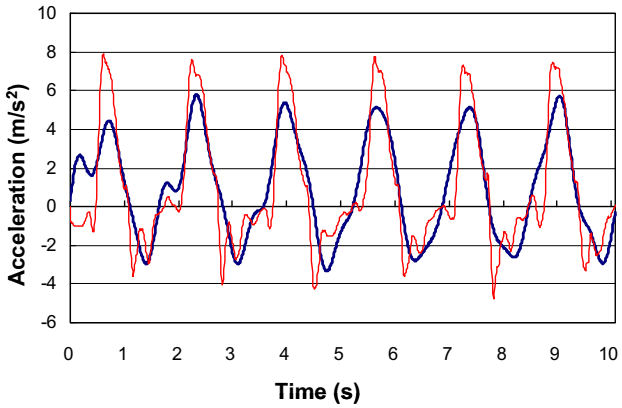

Fig. 2 Anterior axial acceleration data of right shank. Thin line represents raw acceleration data and Heavy line represents composite data of primary, secondary and tertiary GFs.

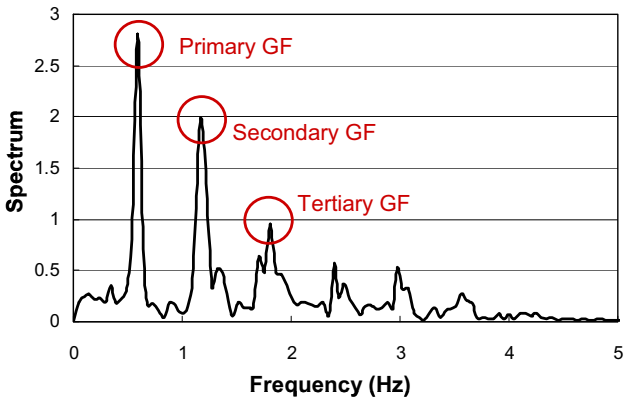

Fig. 3 Frequency analysis of anterior axial acceleration during constant gait. The primary, secondary and tertiary frequencies are circled in red.

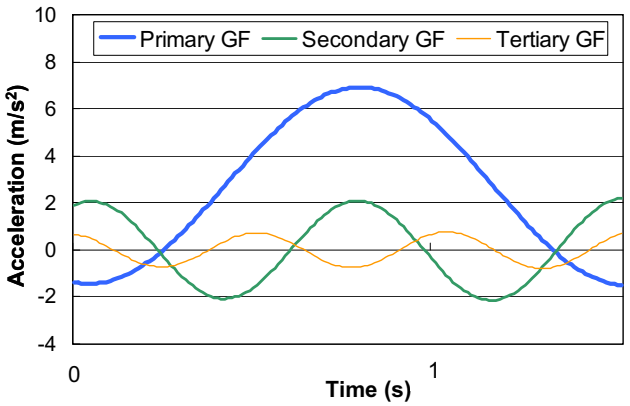

Fig. 4 The extracted primary, secondary and tertiary GF acceleration data. One primary GF cycle is equal to two secondary GF cycles and three tertiary GF cycles.

Wave decomposition divided the secondary and tertiary acceleration data into peaks and valleys. Since one primary GF cycle is equal to two secondary GF cycles and three tertiary GF cycles, the secondary was divided into 4 peaks and valleys and the tertiary GF was divided into 6 peaks and valleys, with 0 as the threshold. The gravitational acceleration was assumed to be a combination of these peaks and valleys.

There are $2^4 = 16$ combination for the secondary GF, and $2^6 = 64$ combinations for the tertiary GF, giving a total of $16 \times 64 = 1024$ combinations for each sensor. In this work, normal walking was assumed to be bilaterally-symmetric, meaning that right and left leg acceleration combinations are the same. Therefore, the total number of combinations was limited to 16,777,216 (1024 for the foot × 1024 for the shank × 16 for the thigh).

An optimization algorithm was developed to establish the gravitational acceleration within the 16,777,216 combinations. First, one combination is considered and the orientation of each body segment is calculated using Eq. (1), then the ankle, knee and hip joint positions can be calculated from the tilt angle and length of segments. Next, the range of motion of flexion-extension of the hip and knee and plantar flexion-dorsal extension for the ankle were checked (hip: -20°to 90°, knee: 0° to 120°, ankle: -30° to 50°). Afterwards, the ankle and hip position during heel contact was checked to remove any combinations that showed inadequate posture.

Within the combinations that fulfilled the conditions above, one combination with the least amount of vertical position error for the left and right ankle during heel contact was taken as the gravitational acceleration. Using the selected gravitational acceleration a stick figure model was created to visually confirm the lower limb posture.

D. Experiment Process

Three volunteers, 2 male and 1 female, participated in the experiment. None of the volunteers had any past history of disabilities or injuries. Along with sensors reflective markers are placed on the volunteers for analysis with video camera. In addition lower body measurements of each volunteer were taken.

Volunteers were asked to walk a flat straight corridor; the gait velocity was at the discretion of the volunteers. To avoid errors caused by attachment, measurements of each sensor were measured before and after trials.

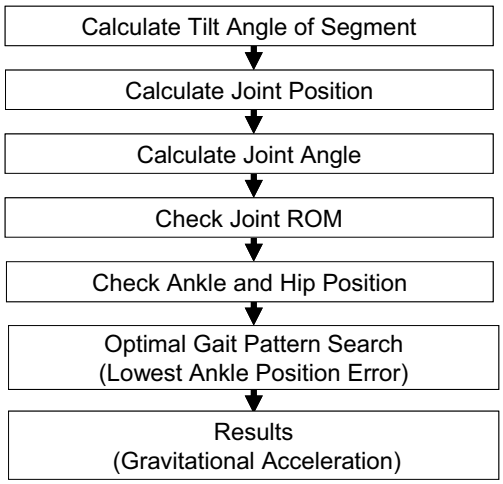

Fig. 5 Gravitational acceleration estimation algorithm. Combination created from primary, secondary and tertiary GF are used to estimate optimal gravitational acceleration.

III. Results and Discussions

Figure 6 and 7 are a comparison of the calculated hip and knee joint angles with this method and the angles determined using camera images. The horizontal axis represents percent in a gait cycle and vertical axis represents joint angle in degrees. There are differences in the swing phase for the hip joint, but the maximum and minimum peak values and joint angles during heel contact were similar. In the knee joint angle results shown in Fig. 7, the peak flexion angle was 10 degrees different.

The differences in the results may be caused by several reasons. Since the acceleration data are larger at the end segments of the limb some frequencies containing high amplitude acceleration data at the shank or foot could have been excluded by the low-pass and band-pass filters. These high frequencies could be the reason why there were differences in the peak flexion angles in the knee joint but not so much in the hip joint.

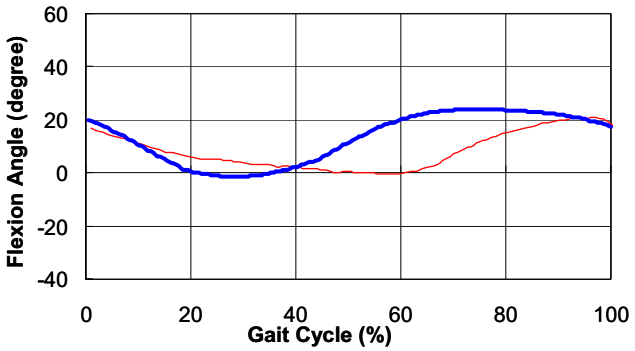

Fig. 6 Hip joint flexion angle comparison. Thin line represents joint angles measures by camera and heavy line represents those of this method.

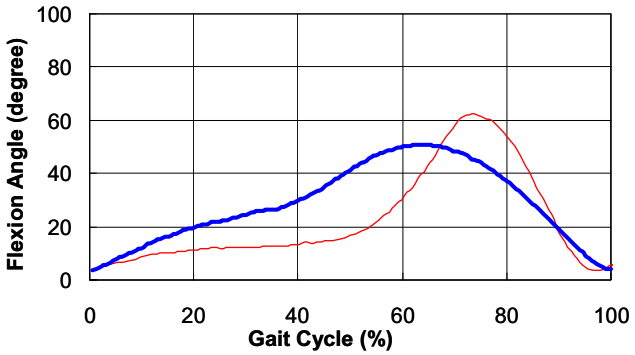

Fig. 7 Knee joint flexion angle comparison. Thin line represents joint angles measures by camera and heavy line represents those of this method.

Another reason is because the gravitational acceleration estimated by this method was optimized for heel contact, and the pattern may not have been optimal for the swing phase, where the maximum knee flexing occurs.

A Stick figure representation of a volunteer using this method is shown in Fig. 8.

IV. Conclusions

This work showed that the acceleration patterns during gait can be used to estimate lower body posture. We developed an optimization analysis that estimated the gravitational acceleration. The estimated gravitational acceleration was used to calculate the orientation of each body segment and gait of the subjects could be visually confirmed by stick figure model.

However, there are some limitations to this work. Because this method uses the cyclic acceleration pattern, this can only target constant movements such as gait, running and climbing of stairs.

Fig. 8 .Stick figure lower limb representation of a subject during gait.

Future works will be to improve estimation of gravitational acceleration with consideration for swing phase. In addition, conduct experiments on patients with lower limb disabilities to verify effectiveness for gait diagnosis.

Abstract — **In this paper, we present a segmentation method for ultrasound images acquired serially for intra-operative data acquisition in computer assisted total hip athroplasty application. To extract the bone surface from ultrasound image, we propose a method based on model deformable (snake) with integration of local intensity variable around the evolved contour. We also proposed an adaptive additional force calculated from image gradient vector flow in narrow band around the contour. In this serial image segmentation, we utilized the segmentation result of previous image as an input of next image segmentation. Finally, we perform a post treatment of the final contour to select exclusively the real points on the bone surface. This point selection is based on intensity criteria, so that we only keep the points having strong intensity amongst the points on the final contour. Validated on a fresh cadaver and a health subject, we found that the precision of this method is applicable for the input of registration method in computer assisted orthopedic surgery. Despite of its possibility to be applied in off line manner, the needed time calculation is acceptable for intra-operative application.**

Keywords — **ultrasound images, segmentation, model deformable, gradient vector flow, computer assisted surgery.**

I. Introduction

Image guided surgery proposes intra-operative navigation for the surgeons in performing minimally invasive surgery. Using this navigation, some medical interventions that considered as too dangerous before, it becomes a daily routine in operating room nowadays. Computer assisted surgery also proposes better result of surgical procedure, shorten post-operative recovery needed times and lower overall cost motivated the emergence of computer assisted surgery. Using this approach, surgeon can design a pre-operative planning based on available images acquired pre-operatively. This planning is then integrated to the operating room by performing a registration between intra-operative images data with the preoperative ones. This registration process determines the spatial relationship between pre-operative and intra- operative datasets.

The needed intra-operative data are usually obtained by sliding a three dimensional pointer on the anatomical part using. This method is fast, easy, and accurate; but it has twofold important drawbacks: *invasive*; acquisition area is *limited* in the exposed anatomical part and cause additional pain. In the other hand, the lack of dataset in some areas may affect the registration accuracy.

For orthopedic application, CT scan is commonly used as pre-operative data and implanted fiducially markers, optically tracked sensor data, or localized X ray data as intra-operative ones. Since past few years, ultrasound images have also been used as intra-operative modality because of its non-invasive, inexpensive, and real-time character. But due to the poor image quality (speckle, delayed echoes, reverberation…), ultrasound images are very difficult to analyze in order to obtain an accurate segmentation result.

Besides of segmentation result quality, to achieve accurate registration result, sufficient amounts of intra-operative data are also required. The more data are utilized for registration, the more accurate registration result can be obtained. These additional data sets can be gathered from a set of serial ultrasound images in the interested area. However, the complexity of ultrasound images analysis will significantly increase the needed intra-operative time. This intra-operative additional time is critical to reduce the blood loss and infection risk. Thus, we need a fast serial ultrasound image segmentation algorithm applicable in surgical intervention and require minimum user interactions.

This paper focuses on an automatic bone surface detection method applied for serial ultrasound images acquired intra-operatively. The proposed method based on a deformable model (snake), with an additional force derived from the gradient vector flow. These serial segmentation results of such images are then applied as an input for a registration processes for orthopedic surgery, especially total hip athroplasty for our case.

II. Method

To extract the bone surface from ultrasound images, we follow the expert reasoning described in [1,2]. As shown in figure 1, bony structures can be characterized by a strong intensity change from a bright pixel group to a global dark

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1073–1076, 2009
www.springerlink.com

area below, because bones high absorption rate generates an acoustic shadow behind. The segmentation method should produce a smooth contour, because discontinuities are normally not present on the bone. Some artifacts might be generated below the bone structure when ultrasound probe position is close to the bone surface during acquisition.

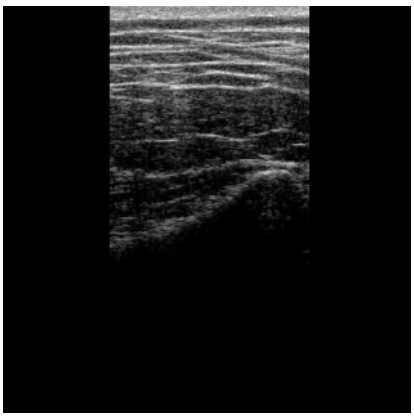

Figure 1: Ultrasound image of iliac.

Considering all that, we applied a method based on open active contour represented as a set of discrete points, initialized as a simple contour placed near to the bone surface. This contour is then evolved until meets the bone surface.

A. Model deformable

We propose previously in [1, 2], an automatic bone surface detection method for single ultrasound images based on deformable model. The method also includes region based energy for detecting the image local contrast; and intensity based posteriori point selection to select only the real bone.

Model deformable: The active contours are generally modeled as the sum of *internal energy*, that imposes the regularity of the curve; and *external energy* that attracts the contour toward the image significant features. The segmentation process is then achieved by minimization of the following total energy function [3]:

$$E(s) = \underbrace{\int_{\Omega}(\alpha|v'(s)|^2 + \beta|v''(s)|^2)ds}_{InternalEnergy} + \underbrace{\int_{\Omega}P((v))ds}_{ExternalEnergy} \quad (1)$$

$v'(s)$ and $v''(s)$ represent the derivative of the model, and $P(v)$ is an image potential associated with the image force.

We proposed an open contour active model with two free extremities to make it move easily. From the given initial contour, the model is evolved to find the minimum energy. The minimization process is estimated via finite elements method. For each step in time discretization, the evolved snake contour is updated using this equation:

$$V_t = (\tau A + I)^{-1} + (V_{t-1} + P(V_{t-1})) \quad (2)$$

where V_t is evolved contour at discretized time step t, A and I are pentadiagonal matrices express the contour rigidity and identity matrix respectively.

Implementing this snake using that numerical scheme, bring us to linear system, so we have to solve a pentadiagonal banded symmetric positive system. We can compute the solution using a LU decomposition of $(\tau A + I)$ need to be computed only once.

Regional energy integration: in classical snake, $P(v)$ is defined as negative of gradient image to stop the evolution in the image border. In our case in bone detection from ultrasound images, we need to integrate the local intensity variation, so that the contour detects only a group of bright-to-dark intensity variation, and not in the opposite contrast. The final contour should be placed about in the middle of the bright intensity stripe.

To handle this local image intensity change automatically, we propose to integrate the regional energy around the evolving contour. We defined this term as difference of mean intensity between the regions above (V_{up}), below (V_{down}) and at the considered location (V_{middle}) as illustrated at figure 2. So, it can be formulated as follows:

$$Dif(v_i) = 2 \times V_{middle} - V_{down} - V_{up} \quad (3)$$

if the difference is negative a penalization is applied.

$$E_{regional} \begin{cases} k & \text{if } Dif(v_i) < 0 \\ Dif(v_i) & \text{otherwise} \end{cases} \quad (4)$$

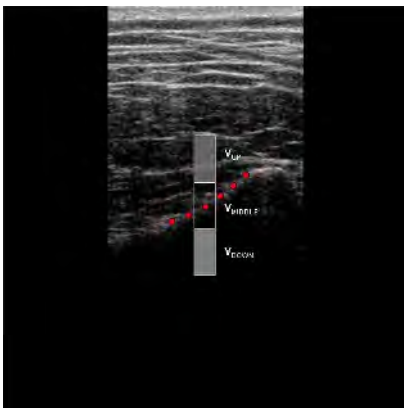

Figure 2: Regional energy definition.

The final external energy is then incorporated to the contour actives as the multiplication result between this region-based measurement and the original gradient term.

$$E'_{regional} = E_{regional} \times E_{external} \quad (5)$$

B. Gradient Vector Flow (GFV)

In order to simplify the snake initialization and avoid local minimum solution, in previous implementation we followed Cohen [4] who proposed an additional force in the contour normal direction. This force pushes the contour evolved upward since the initial contour is placed below the edge to be detected from ultrasound image.

In the context of serial images segmentation, we propose to use the segmentation result of the previous image as the initial contour of next image segmentation process. It is possible because the bone positions in two consecutive ultrasound images are normally not so distance. This approach will accelerate the overall segmentation method, since contour active requires only some amount of iterations to find the bone surface. Unfortunately, this initialization technique might give false segmentation result when the initial contour from previous image placed above the desired bone surface. In such position, the contour active will never find the correct result situated below, because the additional force push always upward.

To overcome this drawback, we proposed an adaptive additional force that capable of pulling the evolved contour toward the edge, even its position is above. This additional force is derived from image *Gradient Vector Flow* (GVF) [5, 6] as an energy that regularizes the potential gradient in order to improve active contours facing the weak image intensity and boundary concavities. GFV improves active contour to converge to long, thin boundary indentations and extend the capture range. In our context, this force is integrated to pull the contours toward the edge to be detected where ever its position is.

This method replaces the external force term $P(v)$ with a gradient vector field, $gvf(I)$, derived from the equilibrium state of this partial differential equation:

$$gvf_t = g(|\nabla f|)\left|\nabla^2 gvf\right| - h(|\nabla f|)(gvf - \nabla f) \quad (5)$$

The first term in that equation is referred to as *smoothing term* since it produces a smoothly varying vector field. The second term $(gvf - \nabla f)$ is referred to as the *data term*, since it encourages the vector field $gvf(I)$ to be close to ∇f. The weight functions *g(.)* and *h(.)* are applied to the both of smoothing and data terms. We propose the following weight functions:

$$g(|\nabla f|) = e^{-\frac{|\nabla f|}{K}}$$

$$h(|\nabla f|) = 1 - e^{-\frac{|\nabla f|}{K}}$$

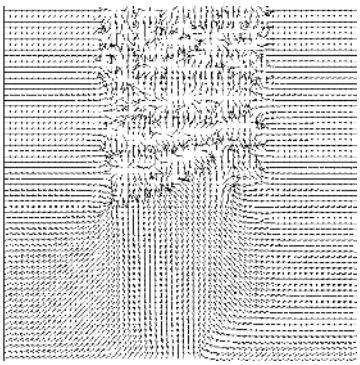

Figure 3: Gradient Vector Flow of the image in figure 1.

Using these weight functions, GVF field will conform to the distance map gradient near the relevant features, but vary smoothly away from them. The constant K determines the extent of the field smoothness and the conformity gradient. This additional force gives the desired edge a capability to pull the contour active downward when it is situated above, without loss its capability to push the contour upward in the other situation.

GVF calculation is a time and memory consuming process. To reduce the needed computation time and memory for computing of this force, we proposed to calculate only in the narrow band area around the evolved contour. We expect that the initial contour (comes from previous segmentation) is situated in this defined narrow band. This is the often the case in the images acquired serially, due to the similarity of two consecutives images of this type.

C. Posteriori selection.

Since the active contour initialization goes from one side to the other of the image, and considering that the real bone contour does not always do so, we need to perform a posterior point selection procedure. Amongst all points on the final contour, only those statistically having high enough intensity are retained.

D. Implementation issue

To integrate both of two methods effectively, but at the same time respect the operating room time constraints, we perform this segmentation in offline manner instantaneously after the images acquisition. For the first images, the addi-

tional force is fixed like a balloon force in vertical direction. When it reaches the convergence, we start the segmentation process using the previous contour as initialization and images energy and GVF calculation in the range of 15 pixels around the contour. For each images, we evolved the snake in fixed number iteration without convergence detection. In our experiences, 70 iterations are sufficient to put the contour in the desired edge.

Once all of the images have been segmented, we perform a posteriori selection to detect the real points on the bone surface.

III. Validation

To perform the validation of segmentation method quantitatively, we utilize an approach presented by Chalana [7] that compares the difference between the manual segmentation and automatic one. Measured as *Mean Sum of Distance* (MSD), the method calculates the mean of closest points in two compared curves as error measurement. The method was validated on three fresh cadavers and two healthy subjects (25 images for each) by comparing the result of automatic segmentation results with the manual ones. The images were acquired in the hip bone area, as we are interested particularly to apply the method for hip athroplasty application. The result this validation is presented in table 1.

Table 1 MSD between automatic and manual segmentation (in mm)

Subject	MSD	Max
Cadaver iliac wing (3 set)	0.46±0.39	1.34
Cadaver symphis (3 set)	0.57±0.43	0.82
Cadaver ischium (3 set)	0.85±0.54	1.40
Cadavre knee (3 sets)	0.53±0.30	0.81
Healthy iliac wing (2 set)	0.56±0.89	1.34
Healthy symphis (2 set)	0.63±0.22	0.90

From that table, we can see that almost of the segmentation result on the total hip surgery acquisition areas is acceptable as the input of computer assisted surgery. On ischium, this error is rather big due to its poor images quality on this anatomical area. Although the method is not intended to perform a real time bone contour extraction, but in average it needs less than 1 second giving the final results for each image.

Despite of its capability to describe the segmentation error precisely, MSD also prone to the segmentation error performed manually that utilized as gold standard. Furthermore, in serial images there are a big amount of images to be analyzed, thus manual segmentation might then becomes a hard, tedious and labor intensive task for the operators. The other error source might also comes from the inter- and intra-operator variation during segmentation. Further work, we plan to investigate this variability for validating the segmentation method.

IV. Conclusions

We presented this paper that focused on segmentation method applied on ultrasound images acquired serially for computer assisted orthopedic surgery. The segmentation result is then utilized as enhanced input of geometric based registration between CT scan and ultrasound image for total hip athroplasty. The method extract the bone surface from ultrasound image based on model deformable (snake) with integration of local intensity variation information around the evolved contour. We also proposed an adaptive additional force calculated from image gradient vector flow in narrow band around the contour. In this serial image segmentation, we consecutively utilize the segmentation result of previous image as the input of next image segmentation. And finally, we perform a post-treatment on the final contour to select exclusively the real points situated on the bone surface. This point selection is based on point's intensity criteria, so that, we only keep the points having strong intensity amongst the points on the final contour.

Validated using some different object, we found that the precision of this method is acceptable and quite fast for real clinical application in computer assisted surgery.

Bone Segmentation Based On Local Structure Descriptor Driven Active Contour

A. Alfiansyah[1,2], K.H. Ng[1] and R. Lamsudin[3]

[1]Faculty of Industrial Engineering, Islamic Indonesian University, Indonesia
[2]Department of Radiology, University of Malaya, Malaysia
[3]Faculty of Medicine Islamic Indonesian University, Indonesia

Abstract — **In this paper we present a method to segment the bony structures from CT scan data using active contour guided by image local descriptor derived from 3D Hessian matrix that encodes important local shape information. Eigen-values decomposition of 3D Hessian matrix measures the maximum changes in the normal vector (gradient vector) of the underlying intensity iso-surface in a small neighborhood. Thus, the eigen-values of the Hessian matrix can be explored to locally describe whether the underlying iso-surface behaves a form like a sheet, a tube, and a blob. Inspired by this fact, we propose a novel filtering method capable in estimating the sheet-ness measure that enhances the bony structures in the image but capable to remove the noise. We choose a segmentation method based on geometric active contour for the reason of its robustness against noises often presence in images, and also its capability to automatically handle the topological change. To incorporate this Hessian based local structure descriptor, we utilized the sheet-ness measure to drive the surface evolution in geodesic contour active toward the sheet like structure, lower for tube like region and zero for the others. We do not define the tube-like elimination term, as the curved end of the bone structure have a behavior that is both sheet-like and tube like. The contour active is implemented by following the surface evolution using level-set implementation in a narrow band area around the evolved surface to make the computation faster and more efficient.**

Keywords — **CT scan image, segmentation, model deformable, Hessian filter, local descriptor.**

I. Introduction

Segmenting the bony structure from Computer Tomography Scanner (CT scanner) images plays the roles important in computer assisted surgery, not only for reconstructing three dimension model in intra operative navigation, but also for pre-operative surgical planning. Methodologically this segmentation method is also important for feature based registration, where CT scan is commonly utilized as pre-operative data. In almost conventional technique, the segmentation of such data type is done using a method based on application of threshold value of the bony anatomy in CT scan. To enhance the result, this method is then followed by large connected component detection or sometimes a manual post-processing. This segmentation of bone using thresholding approach is a fairly successful procedure, since the CT values for bone are higher than that of surrounding soft tissues.

Although the CT value for bone is well-known (as Hounsfield value) and can be considered as constant for each images acquisition thanks to image modality pre-calibration, a discrimination based on these values does not always work well in practice for all areas of anatomical bone at all different condition of patient. In orthopedic surgery, it is often that the CT scan images are polluted by the noises comes from metallic object implanted to the patient before. Furthermore, some different anatomical bones are often situated near each other, that make the segmentation gives the false result.

This paper, we present a segmentation algorithm to be applied in bony anatomical extraction using contour active geodesic. To enhance such deformable model, we applied a local descriptor based on second-order local shape operator. Such local descriptor is useful to determine the anatomical bone structures, as they have a specific geometrical form that near to the sheet and tube. Our proposed filter is also capable to reduce the presence of the noise in the image by detecting the other local structure different from that in the anatomical bone.

The remaining of this paper is organized as follows: Section 2 introduces the proposed method that includes the local structure descriptor based on image's Hessian filter and brief theory of geodesic active contour. The filter method and model deformable integration strategies as well as our numerical implementation scheme are also detailed in this section. Section 3 presents the experimental results of the application of the method. And finally, Section 4 concludes this paper.

II. Method

A. Local structure descriptor

One of the common approaches to analyze the local behavior of an image I by consider its Taylor expansion in the neighborhood of a point x_0

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1077–1081, 2009
www.springerlink.com

$$I(x_0 + \Delta x) \approx I(x_0) + \Delta x^T \nabla I(x_0) + \Delta x^T H(x_0) + \ldots$$

where ∇I is the gradient vector and H denotes the Hessian matrix.

Both the gradient and the Hessian matrix are usually used separately. The gradient vector is widely used as a normal to an implicitly defined iso-surface and its magnitude provides edge detector information, while the Hessian matrix encodes the shape information description of how the normal to iso-surface changes. We want to take the profits of this local shape information by defining a Hessian matrix based image filter. This Hessian based filter is a voxel based filter, meaning that each voxel is calculated for a filter response. In 3D image I , this second order derivative of the intensity values to form a Hessian matrix for each voxel can be calculated as:

$$H = \nabla^2 I = \begin{bmatrix} I_{xx} & I_{xy} & I_{xz} \\ I_{yx} & I_{yy} & I_{yz} \\ I_{zx} & I_{zy} & I_{zz} \end{bmatrix} \quad (1)$$

Then, from this Hessian matrix we can compute the three eigenvalues ($|\lambda_1| \geq |\lambda_2| \geq |\lambda_3|$) that each of them encodes the local shape information. This eigenvalue decomposition measures the maximum changes in the normal vector (gradient vector) of the underlying intensity iso-surface in a small neighborhood.

Some previous works are interested particularly on eigenvalues and eigenvectors exploitation of the Hessian matrix based analysis. Sato [1] and Frangi [2] independently employed these eigenvalues to design a filter for vessel enhancement in 3D medical digital images. Later then, Sato *et al.* [3] generalized their previously introduced concept to enhance tubular, blob, and sheet–like anatomical structures. The relationship between different combinations of the eigenvalues of Hessian matrix and their corresponding possible 3D local structure can be observed at Table 1.

Table 1 Eigenvalue decomposition from Hessian matrix to determine the the local structure description ($|\lambda_1| \geq |\lambda_2| \geq |\lambda_3|$)

Eigenvalues	Likeness local structure
$\lvert\lambda_1\rvert \approx \lvert\lambda_2\rvert \approx 0;\ \lvert\lambda_3\rvert >> 0$	Sheet-like
$\lvert\lambda_1\rvert \approx 0;\ \lvert\lambda_2\rvert \approx \lvert\lambda_3\rvert >> 0$	Tube-like
$\lvert\lambda_1\rvert \approx \lvert\lambda_2\rvert \approx \lvert\lambda_3\rvert >> 0$	Blob-like
$\lvert\lambda_1\rvert \approx \lvert\lambda_2\rvert \approx \lvert\lambda_3\rvert \approx 0$	Noises-like

For our application, we are particularly interested to apply this local descriptor in segmenting the bony structure, in which propose a sheet-ness measure that enhances bone structures and then use it to guide a deformable model that stops at bone boundaries on the image. Thus at every voxel, we determine whether the underlying iso-intensity surface behaves like a sheet. In this case, we know that the eigenvectors corresponding to the null eigenvalues span the plane of the plate structure and the other eigenvector is perpendicular to it.

To determine such structures, we define firstly three ratios, R_{sheet}, R_{blob}, R_{noise}, that describe the structure likeness of an iso-surface to the some geometry form to differentiate the sheet-like structures from others. They are defined as:

$$\begin{aligned} R_{sheet} &= \left(|\lambda_1| + |\lambda_2|\right) / |\lambda_3| \\ R_{blob} &= \left|\left(2|\lambda_3| - |\lambda_2| - |\lambda_1|\right)\right| / |2 \cdot \lambda_3| \\ R_{noise} &= \sqrt{\lambda_1^{\,2} + \lambda_2^{\,2} + \lambda_3^{\,2}} \end{aligned} \quad (2)$$

We utilize these three ratios to determine a score measures the structure sheet-ness to decide whether a structure should be kept during segmentation, as it have a sheet-like structure, or be removed because it is considered as having the blob-like and noise structures. The structure sheet-ness S can be calculated follows:

$$S = \begin{cases} 0 & \text{if } \lambda_3 > 0, \\ \exp\left(-\dfrac{R_{sheet}^{\,2}}{2\alpha^2}\right) & \\ \left(1 - \exp\left(-\dfrac{R_{blob}^{\,2}}{2\beta^2}\right)\right) & otherwise \\ \left(1 - \exp\left(-\dfrac{R_{noise}^{\,2}}{2\gamma^2}\right)\right) & \end{cases} \quad (3)$$

Each term of the equation 2 has a different function that depends on the characteristics of Table 2.

Table 2 Properties of ratios defined from the Hessian eigenvalue for different local structure form in image.

Ratio	Sheet	Tube	Blob	Noise
R_{sheet},	0	1	1	Undefined
R_{blob}	1	1	0	Undefined
R_{noise}	λ_3	$\sqrt{2\lambda_3}$	$\sqrt{3\lambda_3}$	0

Each term in equation (3) correspond to a filtering process that enhance specific geometric structure, but remove the others. Each of them is:

- $\exp\left(-\frac{R_{sheet}^{\ 2}}{2\alpha^2}\right)$ corresponds to a sheet structure enhancement term, that will be maximum value in the sheet like structure, but minimum for others.
- $\left(1-\exp\left(-\frac{R_{blob}^{\ 2}}{2\beta^2}\right)\right)$ is a term to remove the blob and noise structure, because it having zero value for both, but high value for sheet.
- $\left(1-\exp\left(-\frac{R_{noise}^{\ 2}}{2\gamma^2}\right)\right)$ is background and noise reduction term that high only in the present of structure.

Using our defined term, we do not define a tube elimination term, thus this structure will be kept during segmentation. We decided to design our filtering method like that because sometimes the curved ends of bony structures have a behavior that is both tube-like and sheet-like. Thus, to accommodate this form, the sheet-ness measure is designed to be maximum for sheet-like voxels, lower for tube-like regions, and zero for other structures.

The advantage of this approach is that after the sheet-ness computation, we have a confidence score denotes the sheet-like at each voxel, and in addition, for high score locations, we can estimate the thickness of the sheet as well as the normal vector to the plane.

B. Contour Active Geodesic

Firstly motivated in majority part by the classical parametric snakes introduced by Kass *et al.* [4], at nowadays, the deformable model is widely utilized for segmentation in many computer vision applications. This method was elaborated extensively by so much research in medical image analysis and computer vision, and then the corresponding literature is very rich. We are specifically interested to a type of this deformable model known as contour active geodesic, which has been extended from the original model to naturally handle changes in topology due to the splitting and merging of contours during evolution. We begin by describing the active contour itself, and then, we will integrate local descriptor later as we move forward.

Let $C(p,t)$ be a family of closed curves where t parameterizes the family and p the given curve, where $0 \le p \le 1$. We assume that $C(0,t) = C(1,t)$ and similarly for the first derivatives for closed curves.

The curve length functional can be defined as:

$$L(t) = \int_0^1 \left\| \frac{\partial C}{\partial p} \right\| dp \tag{4}$$

By taking the first variation of the length functional, we obtain a curve shortening flow, in the sense that the Euclidean curve length shrinks as quickly as possible when the curve evolves:

$$\frac{\partial C}{\partial p} = \kappa \vec{N} \tag{5}$$

where κ is the local curvature of the contour, and $\vec{N}$ is the inward unit normal. The detailed this derivation can be found in [5].

For the intrinsic property of being closed, the curve under the evolution of the curve shortening flow (5) will continue to shrink until it vanishes. By adding a constant ν, which we will refer to as the “inflation term", the curve tends to grow and counteracts the effect of the curvature term when ν is negative [6]:

$$\frac{\partial C}{\partial p} = (\kappa + \nu)\vec{N} \tag{6}$$

The image influence can be introduced to the above framework by changing the ordinary Euclidean arc-length function along the curve C given by:

$$\partial s = \left\| \frac{\partial C}{\partial p} \right\| \partial p \tag{7}$$

to a geodesic arc length

$$\partial s_\phi = \phi \cdot \partial s = \phi \cdot \left\| \frac{\partial C}{\partial p} \right\| \partial p \tag{8}$$

by multiplying a conformal factor ϕ, where $\phi = \phi(x,y)$ is a positive differentiable function that is defined based on the given image $I(x,y)$.

We now take the first variation of the following geodesic curve length function:

$$L_\phi(t) = \phi \int_0^1 \left\| \frac{\partial C}{\partial p} \right\| dp \tag{9}$$

and reach a new evolution equation combining both the internal property of the contour and the external image force:

$$\frac{\partial C}{\partial t} = \phi \kappa N - \nabla \phi \tag{10}$$

As in equation (6), we also add an inflation term to this curve evolution model:

$$\frac{\partial C}{\partial t} = \phi(\kappa + \nu)N - \nabla\phi \tag{11}$$

More details of the geodesic active contours explication can be found in the work of Caselles *et al.* [7,8], Kichenassamy *et al.* [6], and Yezzi *et al.* [9].

C. Integration scheme

The generic numerical implementation of geodesic active contour using level set formulation [10, 11] of Equation 11 is (that now become standard):

$$\frac{\partial \psi}{\partial t} = \phi\left(div\left(\frac{\nabla\psi}{|\nabla\psi|}\right) + \nu \right)\cdot|\nabla\psi| + \nabla\phi\cdot\nabla\psi \tag{12}$$

where ψ is the level set function, usually initialized as a signed distance function to be updated in each time step, and $div\left(\frac{\nabla\psi}{|\nabla\psi|}\right)$ essentially the curvature κ of the level sets of ψ. Classically, ϕ is usually associated to a decreased function of gradient intensity having near to 0 value on the region with high gradient, but it will be 1 in the region with constant intensity variation. This value is applied to stop the implicit active contour from evolving at image boundaries or salient features.

To incorporate the Hessian filter into model deformable, we modified ϕ so that it depends not only to the image gradient, but also to the sheet-ness measurement defined previously. Thus for each voxel in equation 12, ϕ function should be redefined as:

$$\phi = S \cdot e^{\left(\frac{\nabla I}{K}\right)^2} \tag{12}$$

where S and ∇I denotes the sheet-ness measure calculated from equation 3 and image gradient respectively.

D. Implementation issue

To make the computation efficient, the proposed contour active is implemented using the zero level set of a signed distance function in the narrow band around the evolved contour. The derivative term $\nabla\psi$ is calculated using central different method as $\nabla\psi$ is relatively smooth. For $\nabla\phi$, we applied a second-order essentially non-oscillatory scheme to capture the image gradient that sometimes sharp.

The method is initialized using a surface issued from image binarisation by applying the threshold value of the bony anatomy in CT scan. This result is then enhanced using large connected component to remove the remaining speckle in the binary volume.

III. Experiences

At this moment the validation is performed qualitatively. In evaluating the segmentation results, we have particularly focused on CT scan hip bone image for our application in computer assisted total hip athroplasty. We utilized two CT scan image with different conditions: a clear and noise polluted CT scan images.

For our application context, the method segments the CT scan image much better than conventional binary segmentation of bones; in which sometimes missing the segmentation and incapable in removing the remaining noise issued by metallic object in CT scan data for the patient with implanted prothese due to their previous surgery.

IV. Conclusions

We proposed a segmentation method which combines the capability of Hessian filter in detecting specific local structure in images to drive a geodesic contour active in segmenting structures having sheet-like form. We introduced a generalization of sheet-ness measurement derived from the Hessian shape operator property that robust enough facing the noise present in image. This sheet-ness operator is directly integrated to the image energy in geodesic contour active.

In current work, we are not only validating the method with different CT image data set but also better integrating this Hessian filter to the deformable by taking into account the direction of the sheet-ness measure and its normal vectors.

Abstract — **Risk prevention and alarm are crucial for home care of aged people who live alone. In this paper, an acoustically-analytic approach is proposed to extract behavioral patterns for modeling and monitoring living activities. An experimental environment was established for collecting sound tracking data of behaviors from daily activities. Each sound tracking data was transcribed to the corresponding sound event sequences by caregivers and psychologists. A living activities mining algorithm is applied to extract meaningful sequences of sound event as behavioral patterns. Then K-means algorithm is adopted to classify events into several fuzzy clusters relating to living activities for modeling behaviors in daily activities. An experimental database consists of 150 sound tracking data was established by collecting three guided behaviors included rolled out of bed to drink water, go to the toilet and watch the fish jar from 5 subjects in two weeks. 476 meaningful sequences of sound events were explored and clustered into 32 quasi-activities. These quasi-activities were further concluded into 5 kinds of behavioral patterns for modeling living activities. The preliminary result shows the potential for modeling and proactively detecting abnormal behaviors or changes of the aged.**

Keywords — **Aged people, Living Activities, behaviorism**

I. Introduction

Advancement of medical technologies and living quality extend global human life. According to the official report from United Nations, the percentage of aged people population has reached to 7% in 2004, and it will arrive to 21% in 2050 in official estimation [1]. Due to the aging society, aged people's care and its related services are getting common recently. Consequently, concerns of aged people's safety and life quality are more important. For issue of improving aged care and aged people's life quality, apply well-developed information communication technology (ICT) into aged people care service is the tendency.

Monitoring living activities of the aged people can prevent accidents and increase safety in their daily lives [2, 3, 4]. Currently, most common approaches to monitor the safety of aged persons are via wireless networks [5, 6]. Patients wear portable wireless sensors for monitoring their daily safety. If any abnormal conditions such as dizzy, heart attack or falling down occur, the information will be reported to healthcare staffs or nursing stations for providing first aid or further assistances. However, this approach will not work if the patients do not want to wear portable wireless sensors.

In this research, an acoustically-analytic approach is proposed to extract behavioral patterns for modeling and monitoring living activities. A living activities mining algorithm, which utilizes an event matching algorithm and K-means algorithm [7], is proposed to process the sequences of sound events to explore living activity models Discovered living activity models provide references about living models and behavioral prediction of aged people. These behavior models also can assist caregivers at home or care centers to prevent accidents of the aged people effectively and increase their quality and satisfaction.

II. Materials and methods

Humans' behaviors express their inner thoughts and desires. Through monitoring and observing daily actions of humans, the personal behavior model can be concluded and effective to predict the future behaviors.

According to behaviorism from Edwin Ray Guthrie [8], Human has a tendency to duplicate the successful movements. This process is called canalization [9] which is key factor for human to form a habit. When human comes across the same issue daily, he/she defers to the custom movement to respond and carry out the same issue. Behaviors in human life will produce sounds; these sounds will be appropriate sources for behavior mining due to the issue of privacy. For example, people will feel humiliated and their privacies are violated if they are monitored in video while they are taking a shower or toileting.

In this research, an approach of behaviors mining via sound data was proposed. Figure 1 shows the framework of

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1082–1085, 2009
www.springerlink.com

this research. It consists of three phases, which are development of sound tracking data collecting pilot environment, tagging sound tracking data to sequences of sound event and living activities mining and behavior model exploring algorithms.

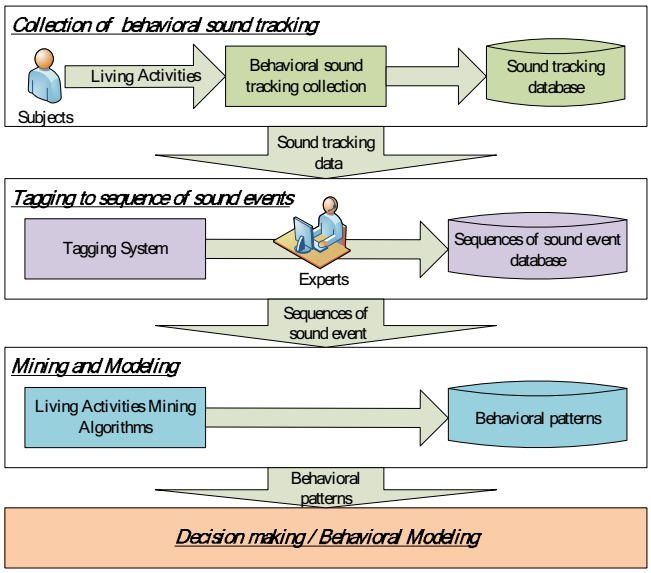

Fig. 1 Research framework of the proposed system for mining and modeling the aged people's behaviors

A. Collection of behavioral sound tracking

A sound tracking data collecting environment was established to simulate real bedroom, lavatory and kitchen of aged peoples' daily living environment. Figure 2 illustrates the sound tracking data collection environment. Five Omni-directional capacitance microphones with -65dB +- 3dB sensitivity at 1000Hz and frequency response range 50 ~ 18000 Hz are set up in proper positions to clearly record sound data of aged people. The sound data was recorded in wave format with 8 kHz sample rate and 8 bits resolution. Real-time sound tracking data is sent to the data center by the network, which is build up in the ceilings. Figure 3 illustrates the network deployment of sound data collection environment. Network protocol in this environment is control area network (CAN) 2.0 with sample rate 1 megabps [10]. Sound data captured by omni-directional capacitance microphones and transfer to data server via Ethernet for database establishment. In this research, the sound tracking data collected from three habits of daily life was recorded in the environment for further processing in the second phase.

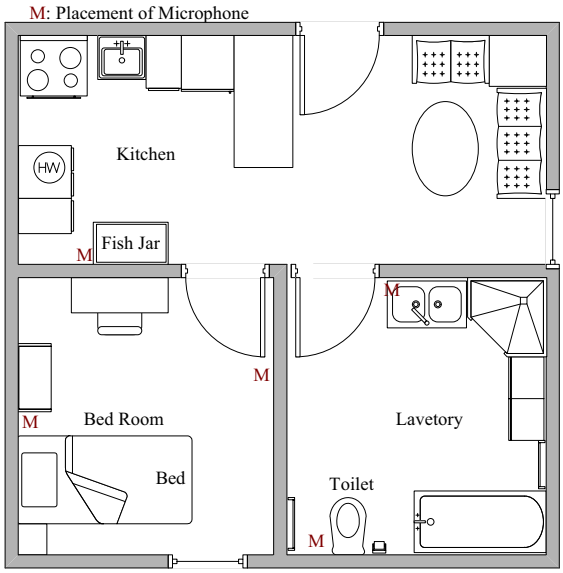

Fig. 2 Sound tracking data collection environment

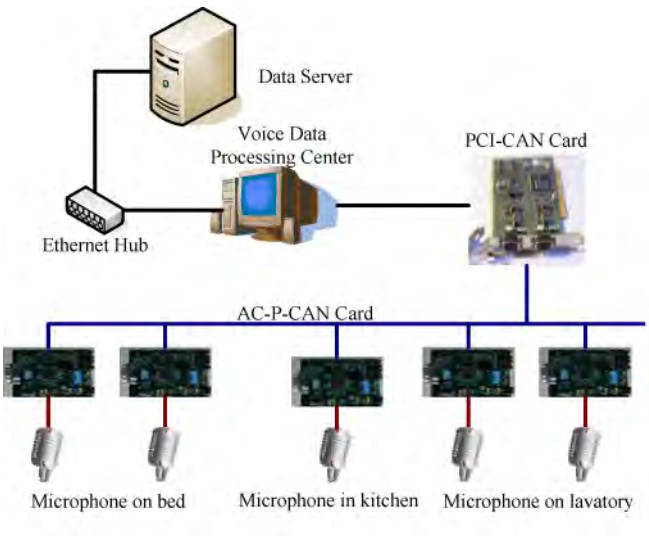

Fig. 3 CAN Network deployment for sound tracking data collection

B. Sound tracking data tagging process

In the phase, sound tracking data which was collected from the phase A was been analyzed according to two different habits of daily life and tagged into the corresponding sequences of sound events. The experts such as caregivers and psychologists of behavior were invited to tag the sequences of sound events with possible activities according

to the behavior conditions of the subjects manually. Figure 4 shows the tagging system interface. Those tagged sound event sequences provide information about subjects' daily behaviors.

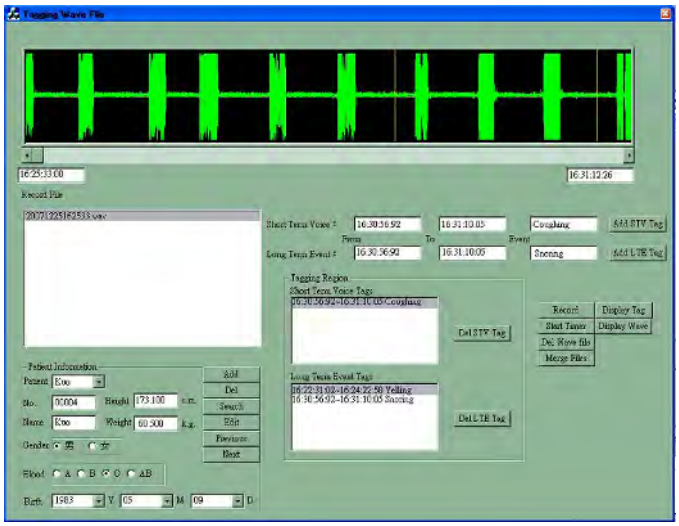

Fig. 4 Sound data tagging system interface

C. Mining and Modeling Process

For the issue of canalization, individual living activities will be reduplicated in the daily life. In this phase, a living activities mining algorithm, which utilizes a event matching algorithm and K-means algorithm[11], is proposed to explore sequences of sound event that are representative of daily activities and classify those sound event sequences to several categories according to the similarities.

The steps of living activities mining algorithm is:

Step 1: Apply the event matching algorithm to explore meaningful behavioral patterns B_1~B_M from sound event sequences S_1~S_N, mutually which are trivial sound segments tagged from phase B.

Step 2: Set length constrain for filtering behavioral patterns from step 1 to form B_1~B_O.

Step 3: Calculate the probability of each behavioral pattern by

$$prob(B_i) = \frac{N(B_i)}{C_2^N}$$

Then set constrain of probability to over 0.05 for filtering behavioral patterns from step 2 to B_1~B_P.

Step 4: Apply K-means algorithm to classify behavioral patterns from step 3 to M categories according to the similarities of behavioral patterns.

Each category discovered from the above algorithm represents a behavioral model. An example of event matching mining string exploring algorithm can be described as:

Assumed there are three data blocks:

Data block 1: ABABC
Data block 2: ABAAC
Data block 3: CCBAC

The probability of each behavioral pattern discovered from above data blocks is shown as following.

$$prob(ABA) = 0.333$$
$$prob(BA) = 0.667$$

With proposed algorithm and set the length constrain is 2, data segment ABA and BA will be explored to represent a meaningful behavioral patterns.

III. Results and Discussion

In the experiment, five subjects who are over sixty years old were brought into the sound data collecting environment to collect the testing database. They were guided by the working staffs with the two instructed behaviors of drinking water and toileting in the way of instruct-to-action. 150 sound tracking data was recorded and tagged into sequences of sound event by the caregivers and psychologists of behavior for different behaviors. 11,175 sequences of sound event were tagged totally. After processed living activities mining algorithm, 476 meaningful sequences of sound event were explored. Those sequences of sound event were processed by the living activities extraction algorithm to conclude behavioral models. The experimental result is shown in Table 1.

Table 1 Expected and experimental classified results

Expected Result	Experimental Result
Drinking water	Drinking water on bed
	Drinking water in kitchen
Watching fish jar	Watching fish jar in kitchen
Toileting	Washed hands after finished
	Finished with lavatory door closed
	Finished with lavatory door open

Figure 5 shows a state diagram example for one of the selected behavioral model of daily activities - toileting, which includes the states of door-opening, flushing, and door-closing. These states would be executed in sequence if no specialized condition happened. However, different

outcome of action and sound would result from different conditions. State transfer diagram could be used for modeling human action and exploring action changing and accidents.

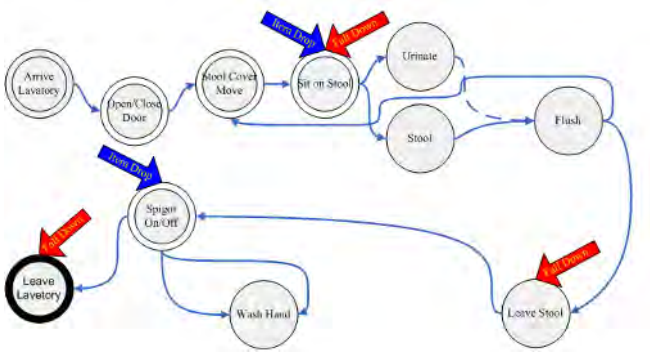

Fig. 5 A state diagram example for daily activities - toileting

In this research, three expected behavioral models of living activity should be explored, but there were six different sound traces found in the experiment. This is because that the subjects have the action variation in their daily lives. Although the subjects were guided by the same instructions, they would act for different actions which represented different sound event sequences. These six different experimental results were further analyzed and found that they actually could be concluded into three kinds of behaviors as shown in Table 1. Those results gave us a great encouragement that the proposed algorithm is feasible to explore living activities correctly.

IV. Conclusions

In this research, an acoustically-analytic approach is proposed to extract behavioral patterns for modeling and monitoring living activities of aged people. A sound tracking data collecting environment was established to simulate real bedroom, lavatory and kitchen of aged peoples' daily living environment. The sound data was analyzed by two different habits of daily lives and tagged into the corresponding sequences of sound events by experts. Then living activities extraction algorithm was adopted to analyze the sequences of the sound events to explore living activities. These living activities were further induced into individual behavior models, which can be applied to alarm abnormal and dangerous conditions in aged care. The experimental result shows the proposed living activities mining algorithm could explore living activity models correctly and effectively. This result also shows the aged people's behavior detection system via sound traces is feasible. In the future, the proposed algorithm needs more sound data with no limitation for providing more effective and reliable activity modeling.

Abstract — **Because of the rapid aging population in Taiwan and the trend of fewer children, people are looking into technical solutions for continuous/intermittent monitoring of vital signs in the home setting environment and the interactions between family members. In this study, we have designed and implemented a home medical gateway system to connect the home-care side and the health informatics side. The home-care part provides five vital signs monitoring and on-line feedback message. Users are allowed to browse their records and read the received health information (e.g. physical checkup, health education, preventive inoculation…etc.) on the Flash based interface. This study also evaluated the practicability of the home gateway system. The number of interviewees is twenty. The analysis results show the positive user feedback of the system, and have high potential to promote the quality of patient's life. An example case of obstructed sleep apnea (OSA) patient has been studied with this system. The result shows that the gateway system can help the OSA patient to monitor and improve their sleep quality.**

I. Introduction

Being the fastest aging nation in the world, Taiwan is now facing challenges of changing society structure, house hold style, and national expanses on health care. According to the definition of population structure of the United Nations, the Aging Population Society is that over 7% of total population is exceeding 65 years old. The Extra-aging Population Society is that over 20% of total population is exceeding 65 years old. In terms of the population statistic in Taiwan in 2008, the populace of older over 65 years is 2.34 million, which is 10.21% of total population. This already exceeded the threshold of the Aging Population Society [1]. It is inevitable to development Smart Medical Home to decrease the expenditure of medical service price.

For those who live in the cities and urban areas, we normally can access the health care facilities quite efficiently. It would thus require more emphasis on the quality of long term health care, especially for the home care sector of whole social care system. In view of the possible causes of deteriorating life quality can be simply age related or as complicated as disease related, the development of "Smart Medical Home" will have to cover deep thoughts of both humanity and medical needs [2-4]. These include possible disabilities caused by losses of sensory and motor functions, pains and discomforts caused by physical and metabolic changes, and psychological stresses due to self awareness and lack of knowledge about the health status and possible progresses.

Since 1990, there are more and more researches and development focus on the new technologies which could apply in the home care service [5-7]. There are also many researches focus on the cost and social impact with the home care service, but the real evaluation still lack [8,9].

This study focuses on the design and planning of a smart medical home gateway system which provide convenient home health care services. This study integrated several medical care services in the gateway system, including the biosignal record and monitor, physiology check records, health and hygiene education, and social welfare information. The health care services are designed for the chronic patients, elder and parents. The user could manage their families' and their self's health, and get health information and welfare from public resource more conveniently. In order to evaluate the practicability of the home gateway system, this study investigated and analyzed the user feedback by paper survey.

II. Method

A. Architecture of the home gateway system

This study focuses on the design and planning of a smart medical home gateway system which provide convenient home health care services. The assignment of the home gateway system is transmitting the biosignal to the server, information exchanging with hospital and social welfare canter, and a health manager interface for the user. The architecture of the smart medical home gateway system is shown in figure 1. The biosignal would transmit to server through the home gateway way. The home gateway also

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1086–1089, 2009
www.springerlink.com

provides the function of security monitor, which will send the emergency massage for the user. Moreover, the home gateway system transmits the health information from public resource and display on the user interface which was made in this study.

The server in this smart medical home gateway system was developed by MySQL Database. MySQL database could edit and modify through Microsoft Access conveniently. The interface was designed and made by Flash in this study. The user could use all function in the user interface through a touch screen.

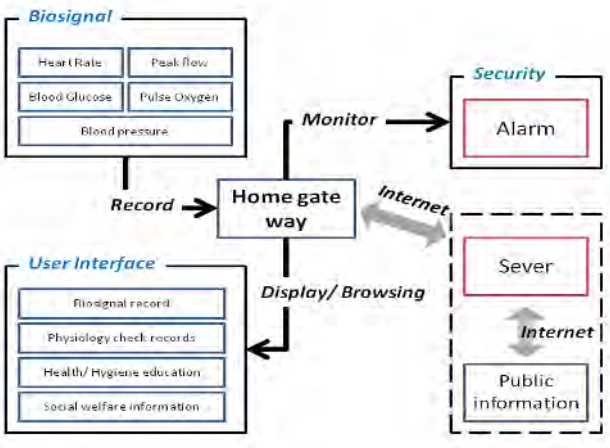

Fig. 1 The architecture of the home gateway system

B. Biological signal measurement

The biosignal measurement items involved in this home gateway system are shown in table 1, which including blood pressure, blood glucose, heart rate, pulse oxygen (SpO_2) and peak flow. All of the biosignal were collected by wearable devices which have wireless transmission function. The wireless technology used in this study is Bluetooth. Blood pressure and blood glucose could be measured by 2-in-1 device which made by Tibac technology Inc. The measured results could be sent and record in the server through home gateway after per measurement. Heart rate and SpO_2 are also measured by 2-in-1 device which was made in this study. Heart rate, pulse and SpO_2 value are real-time transmitted to the home gateway system and be monitored for emergency. Peak flow meter was designed for asthma patients controlling and monitoring their asthma condition. The principal measure theory of peak flow meter is heat lose on the sensor surface. The peak flow curve and calibrated value were transmitted to home gateway by Bluetooth after per measurement automatically.

In this system, user could choose the biosignal device following up the physicians' indication. The safe range of each biosignal should be sat to suit for personal health condition.

Table 1 The characters of medical devices

Item	Biosignal	Safe range	Transmission rate
Blood pressure monitor	Blood pressure	S: 85~95 mmHg D:120~140 mmHg	1dataset after measurement
Blood glucose monitor	Blood glucose	<140 mg/dl	1 dataset after measurement
Heart rate monitor	ECG or Pulse	50 ~ 110 beat/min	1024 data points/ sec
Pulse oximeter	Pulse	95 ~ 100 %	1024 data points/ sec
Peak flow meter	Respiratory flow	-	1 dataset after measurement

C. Evaluation

In order to evaluate the practicability of the home gateway system, this study investigated and analyzed the user feedback by paper survey. The survey questions are shown in table 2. The theme of questions are separated into three parts, these are the feedback of device operation, the interface and the acceptability conception. There are 20 interviewees in this study. The interviewees would finish the survey after experience the home gateway system. In order to let interviewees realize and respond the questions quickly, all question are positive item. The feedback score is 1 to 5, and the middle point score is 3. If user's feedback score higher 3 means it has positive feedback. The survey results were analyzed by T-test. The analysis software is SPSS.

Table 2 User Feedback Survey items

No.	Question
	Device Operation
1	Ease to use
2	Benefit for personal health care
3	Suitable for home use
4	Suitable for elder
	Friendly Interface
5	Simple and clear information display
6	Ease to use
	Health Homecare Conception
7	Match further needs
8	High potential in the market
9	Reduce medical cost
10	Promote the quality of health life

III. Results and Discussion

The health care services in this home gateway system have three categories, those are physiology signal real-time monitor, health record and health related information. This study designed a "health manager interface" which provides a friendly interface allow user browsing the health record and health related information conveniently. The interface was designed and made by Flash. The design concept of this interface is simple and instinctive operation. The information shown in the interface including the physiology measurement record, personal physiology check and health service record, hygiene education, and children electronic protective inoculation record. The health manager interface is shown in figure 2. Each family member has their own physiology measurement record and personal physiology check. The safe range of each biosignal would suit for the personal physiology condition. This interface also allow user appointing next physiology check through the system.

There are 20 interviewees in this study. The career and background of interviewees are all related to the "home care service" subject. There are 45% of interviewees are the industrial research and development workers, 45% of interviewees are the savant, another 10% are unsigned. The analysis results of the survey are shown in figure 3. SMEAN(VAR00001) to SMEAN(VAR00010) are the number code of questions which are list in table 2. Column "Sig. (2-tailed)" shows the T-test result and expresses significant difference with mean (under 95% confidence intervals). In other words, the results show the positive feedback of all questions. Interviewees are of the opinion that the operation of the interface is simple and instinctive for elder, the home care service is helpful for manager the personal health, and the information communication service is clear and convenient. Question 7 (match further needs) and 8 (High potential in the market) have highest score.

An application case of the smart medical home gateway system is the home care of obstructive sleep apnea (OSA) patient. The physiology real-time monitor and health record services were used in this study. This physiology real-time monitor applied in this application case is SpO_2 monitor. In 2000 Vázquez et al utilized the oximeter to estimate the apnea hyperpnoea index (AHI), which has potential to monitor the physiological condition of OSA patient [10]. Figure 4 shows the SpO_2 monitor result of an OSA patient during sleeping. This clinical measured data were obtained from Apex Medical Corporation. Dark black line is breath (refer to left scale) flow which was measured by resistance belt, and grey line is SpO_2 concentration curve (refer to right scale) which was measured by pulse oximeter. After the OSA patient decreased the breath frequency (or no breath), the SpO_2 concentration start to decrease. Low SpO_2 concen-

tration stimulates the patient breathing. In this application case, the home gateway system could record the frequency of low SpO_2 concentration during sleeping and providing a reference to medical treatment. If low SpO_2 concentration continues a long time, the system will trigger the alarm to notify other families to check the condition. For the future integration of mechanical ventilator, physician could adjust the treatment level through the gateway system. The OSA patient also could track the covering by themselves through the gateway system. The physiology real-time monitor and health record services could provide positive feedback control for the treatment.

IV. Conclusion

During the processing of this study, we have several discussion meeting and requirement interview with related social welfare centers. We have modified the detail of the smart medical home gateway system clearly. The smart medical home gateway system already provides the services of biosignal record and monitor, physiology check records, health and hygiene education, and social welfare information. The preliminary test shows that the system could monitor the OSA patient's sleeping quality and providing references for treatment. This study also evaluated the practicability of the hardware and software of this system. The result shows the positive user feedback of the system, and has high potential to promote the quality of patient's life.

Abstract — **Position control in joint space is a basic problem in robot control where the goal is to make the manipulator joint track a desired trajectory. A number of globally asymptotically stable position control algorithms are available in the literature. Among them, an application of intelligent fuzzy PID controller to position control of robot system is studied in this paper. The robot system used is the laparoscopic surgery robot of the National Cancer Center, Korea. The intelligent fuzzy control algorithms consist of rule-based fuzzy PID and learning fuzzy schemes. The results of the experiments for the rule-based fuzzy PID controller and the learning fuzzy controller are compared with results using conventional PID controller. Various performance indices like the RMS error, IAE, ISE and etc. are used for comparison. It is observed that the learning fuzzy controller gives the best performance. Further refinement of the proposed algorithm for the control performance enhancement is under way.**

Keywords — **Fuzzy PID Control, Position Control, Learning Control, Rule-based Fuzzy PID control, Real-time OS, Laparoscopic surgery, Surgical robot, Telesurgery.**

I. Introduction

The conventional linear PID controllers are still the majority of the regulators used in industrial control systems because of their simple structure and robust performance in a wide range of operating conditions. However, the linear PID controllers using fixed gain coefficients are limited in the control techniques when they are applied to the nonlinear or time variant systems with delay. In particular, in case of the medical robot systems such as laparoscopic surgery robot, the precision control of the surgical tool is required to perform accurate surgical task. When conventional PID controller is used in the control of the multi-DOF (degree-of-freedom) manipulator with nonlinearity, large time delays, strong coupling, and with fixed PID gain parameters, it is difficult to fully satisfy performance requirement of tracking the target in real-time and precisely. In order to systemically tune parameters of conventional PID controller, many research have been done [1][2].

In this paper, we applied methods of the rule-based fuzzy PID controller and the learning fuzzy PID controller. Also, this control algorithm is compared with a linear PID controller and rule-based fuzzy PID controller.

II. System Configuration of Laparoscopic Surgery Robot

A laparoscopic surgery robot is composed of a surgery robot (master robot) and a control robot (slave robot) that telesurgery operation is available through a controlling laparoscope and surgical instrument in an abdominal cavity(Fig. 1). A surgical instrument in a slave robot is inserted in trocar that penetrates an abdominal skin and a muscle layer, and then is operated. A surgical instrument that is inserted to trocar does five drives of such operation as a pitch axis operation, yaw axis operation, rotation axis operation, translation axis operation and actuation axis operation. A master robot must realize 5 degrees of freedom corresponds to equally these, and each joint structure in the proposed system designed to be corresponded one to one by the same structure as a structure of slave robot [3].

III. Controller Design

A. Rule-based fuzzy PID controller design

A generally rule-based fuzzy PID controller is a control method of creating a control signal with summing a proportional, integral and derivative signal about an inference input of tracking error and change of error(Fig. 3). In the initially of a system, a control gain coefficient of PID controller is tuned by a rule-based fuzzy PID controller. However, a proportional gain coefficient is retuned by a newly created control rule by the learning controller. Then, an integral and derivative gain coefficient corresponding it is retuned by the ***Ziegler-Nichols*** tuning method [4].

Two input variables(error($e(n)$) and change of error($\Delta e(n)$) of fuzzy PID controller are defined as:

$$E(n) = Pcmd(n) - Presp(n), \quad \Delta e(n) = e(n) - e(n-1) \qquad (1)$$

where, n is an event, P_{cmd} is a transferred control input value from master, and P_{resp} is a feedbacked response value from each robot axis of slave.

A control input value transmitted from the master composed to transmits a normalized fuzzy section value to the slave as a section of a universal set [-1, 1], and then this value was directly used as a fuzzy input value of fuzzy PID controller. An output value was directly performed to normalizing work by size conversion to a section of a universal set.

The fuzzy control rules were the most performed by **IF-Then** rules in ***Mamdani*** controller. Because the input variables are individually designed for seven input membership function, total 49 of fuzzy rules can be made.

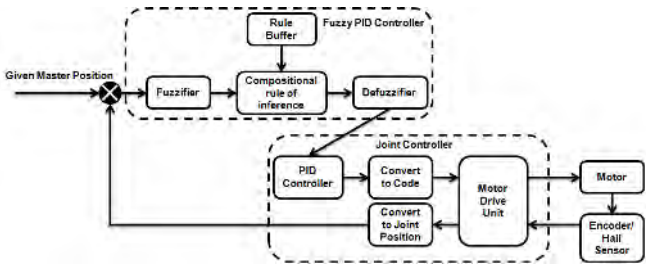

Fig. 3 Structure of a linear PID controller

PM	PB	PM	PM	PS	PS	ZO	PS
PB	PB	PB	PM	PM	PS	PS	ZO

This paper applied the simplified reasoning method by ***Mizumoto*** that is classified as one of the linear reasoning methods in product-sum-gravity method [5].

B. PID control gain coefficient

In this paper, the rule-based fuzzy produces readjustment values for the proportional PID gains only. The corresponding values of the fuzzified integral gain coefficient and the fuzzified derivative gain coefficient are calculated using Ziegler-Nichols method. In the deffuzifier block the fuzzy signal KP_I, is outputted and is added to the proportional gain coefficient K_P in the PID gains block to readjust the values.

$$KP(After\text{-}Apps) = KP(Before\text{-}Apps) - KPI \cdot KCP \qquad (2)$$

where, I is the sampling instant, $K_{P(After\text{-}Apps)}$ is the proportional PID gain after the application of the rule-based fuzzy PID controller. $K_{P(Before\text{-}Apps)}$ is the proportional PID gain before the readjustments. K_{CP} is the descaling factor coefficient for the proportional PID gains.

The integral and derivative gain coefficients are calculated using the ***Ziegler-Nichols*** method from the readjusted proportional gain coefficient.

C. Learning fuzzy PID controller design

The learning fuzzy PID controller is in effect the rule-based fuzzy PID controller with an addition of the rule creation and modification (figure 8). The rule creation and modification are composed of the linguistic rule table, the fuzzified past K_P buffer and the rule reinforcement [6][7].

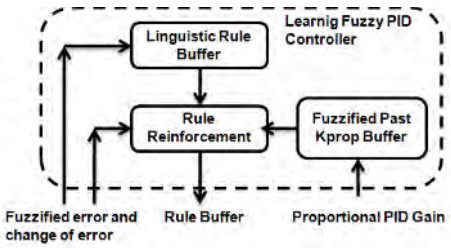
Table 2 Comparative table of performance criteria about step response

Controller	RMS Error	Steady State Error	Settling Time	Maximum Overshoot	Delay Time	Rise Time	Fall Time	IAE	ISE	ITAE	ITSE
PID	0.032085	0.100439	0.316	0.93	0.1	0.108	0.156	6.19462	0.462212	5.599202	0.414848
Rule-Based Fuzzy PID	0.023906	0.100231	0.264	0.22	0.068	0.068	0.116	3.62758	0.256601	3.011748	0.199133
Learning Fuzzy PID	0.019042	0.100173	0.24	0.17	0.052	0.056	0.072	2.30881	0.1628	1.599909	0.106816

In the proposed learning fuzzy PID controller, the present control result is decided to have a cause in the past n samples of manipulated quantity and then this controller tunes the rules using in the past n sample before the present sample. By the values of $K_{Prop}(I\text{-}N)$ and K_{PC}, the new control rules is created in the rule reinforcement block, and these rules are applied to the rule buffer of rule-based fuzzy PID controller.

$$K_{Prop}(I) = K_{Prop}(I\text{-}N) + K_{PC} \tag{3}$$

where, $K_{Prop}(I\text{-}N)$ is the proportional PID gain from the fuzzified past K_{Prop} buffer block, N is number of past samples before the present samples and I is sampling instant. K_{PC} is a value of gain correction.



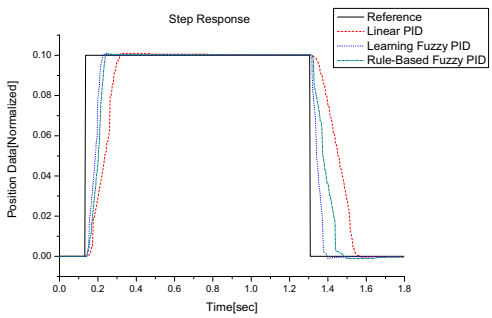


Fig. 4 Learning fuzzy control algorithm

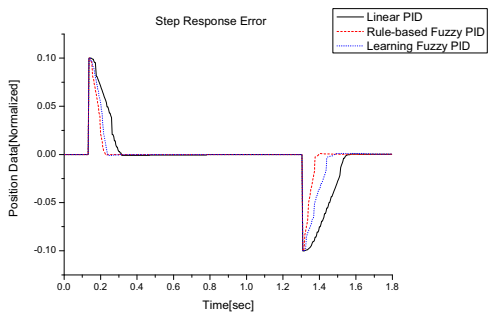
Number of samples in the present system are defined the number in conjunction with the delay time and set up 6.



IV. Experimental Comparative Analysis

For the comparative testing the reliability and stability of the fuzzy PID controllers and a linear PID controller, a trial performance test is performed by applying the controller in the slave robot of the surgery robot system. Also, we are compared control performance through the test results. In the 5 axis of a slave robot, a translation axis that the surgical instruments are really set up have each different weight through the kinds of surgical instruments and the types of operation are various. Through these test, we compared to the control performance due to the various performance parameters such as RMS error, steady state error, settling time, maximum overshoot, delay time, rising time, IAE, ISE, ITAE, ITSE and etc..

Fig. 5 is the test result of the position tracking performance of the translation axis about the unit input of slave robot with step position command of master robot. A position tracking of translation axis of slave robot through a rapid change of translation axis of master robot verified a possibility about more fast tracking in the learning fuzzy PID controller. For numerical evaluating the system's response and comparing with the controllers, the various performance criteria were used. In Table 2, we summarized the values.

(a) Tracking result

(b) Positioning error

Fig. 5 Result of the position tracking performance of the translation joint with step position command

V. Conclusions

In this paper, the rule-based fuzzy PID controller and the learning fuzzy PID controller are both applied to a laparoscopic surgery robot, currently developing. The learning fuzzy PID controller is realized through the design of fuzzy rules and membership functions. Through the experiments applying to translation axis of a laparoscopic surgery robot prototype, currently developing, the learning fuzzy PID controller was compared with conventional PID controller and typical rule-based fuzzy PID controller and was proved to have better performance through the comparative analysis. Also, through all types of experiments under load and dynamic condition similar to surgery, a tracking performance of the system confirmed that is a suitable level. Accordingly, we will be going to process not only the experiments about the translation axis but also the experiments of the other axis. The complementary measures for the various additional function and the improved accommodation and stability are necessary hereafter, and the related developments are now under way.

Abstract — **The purpose of this study is to investigate the influence of the ultrasound peak pressure and sonication duration on blood-brain barrier (BBB) disruption, and also seek for the optimized sonication parameter to introduce BBB-opening with minimal hemorrhagic damage. Twelve SD rats were sonicated. During sonication, the 309 kHz focused ultrasound was employed to deliver burst-mode low-pressure ultrasound to animal brains in the presence of microbubbles to introduce local and temporal BBB disruption. Different ultrasonic peak pressures and sonication durations were tested, and the BBB-disruption and accompanied hemorrhage were confirmed by brain section and histological examinations. Our results showed that the peak pressure is the major factor to generate BBB disruption, where as the sonication duration can be utilized to moderately regulate the accompanied hemorrhagic damage. We also found that the low-pressure long-duration ultrasound exposure may be beneficiary to reduce hemorrhage than high-pressure short-duration mode.**

Keywords — **Focused ultrasound, blood-brain barrier, histology**

I. Introduction

The blood-brain barrier (BBB) is a specialized structure of blood vessel walls that limits the free transportation and diffusion of molecules from the vasculature to the surrounding neurons. Many methods have been developed to enhance the BBB permeability to assist the penetration through the tight junction for therapeutic purpose, but most of the existing approach all induce a systemic BBB disruption, and was also fail to achieve the targeting drug delivery to a specific brain region.

High-intensity focused-ultrasound (HIFU) was first developed a half century ago, and has been shown with the potential to increase BBB permeability[1,2]. Recently, Hynynen et al showed that the BBB can be selectively disrupted with a reduced ultrasound energy exposure, which minimized the parenchyma damage with the use of low-power burst mode HIFU sonications under the presence of Optison® (GE Healthcare, Milwaukee, WI, USA), an ultrasound contrast agent to enhance the BBB-disruption effects[3,4].

Although the burst mode was already used during the HIFU sonication to lower the damage of surrounding tissue, hemorrhage still can be observed and becomes the major adverse effect of this approach. Intracerebral hemorrhage may be hazardous when intending to use this approach to locally deliver therapeutic molecules into brain. Therefore, exploring the safety ultrasound exposure only disrupts BBB but not causing any hemorrhage becomes a major task to make this treatment modality more promising. Therefore, the optimization of the sonication becomes essential in order to make this approach more secure.

On the optimization of delivered acoustic parameters into brain, current literatures reports that operating frequency, burst-tone ultrasonic wave output, and the concentration and administration of ultrasound microbubbles are all relevant. At the ultrasound burst-tone wave deliver design, most of the reports emphasize on the effect of peak acoustic pressure, and the role of sonication duration on BBB disruption was regards to be only play a secondary but not a major role and are rarely investigated.

In this study, therefore, we aim to investigate the sonication parameter take into account the pressure and the sonication time in order to optimize the quality of focused ultrasound induced BBB disruption. A 400-kHx focused ultrasound was selected in this examination based on its good skull-bone penetration capability. The accompanied tissue damages were evaluated by histological approach.

II. Methods

A. Animal preparation

Adult male Sprague-Dawley rats (300–350 g) were purchased from the National Laboratory Animal Breeding and Research Center (Nan-Kang, Taipei, Taiwan). The experiments conducted in this study were approved by the Institutional Animal Care and Use Committee of Chang Gung University and adhered to the experimental animal care guideline.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1094–1097, 2009
www.springerlink.com

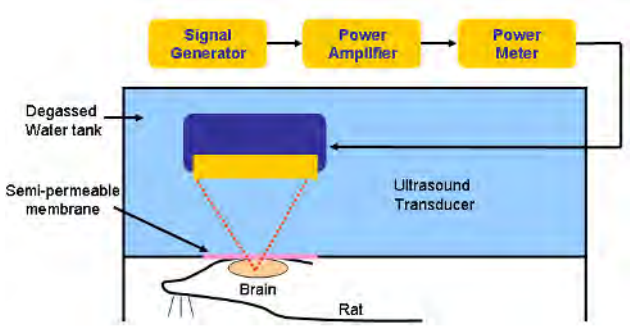

Fig. 1 Experimental setup

In the preparation of the experiments, animals were anesthetized using Chlorohydrate (300 mg/kg) through IP injection. Craniotomy was performed before the ultrasound sonication to reduce distortion of the ultrasound focal beam. A cranial window of approximately 7×7 mm2 was opened with a high-speed drill and a PE-50 catheter was placed in the jugular vein. The skull defects were covered with saline-soaked gauze to prevent dehydration and infection during the process.

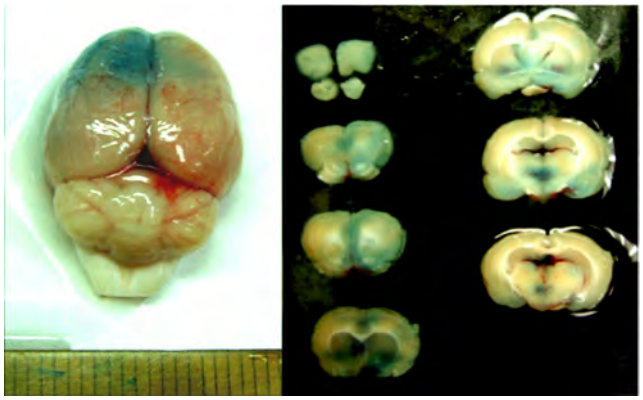
B. Ultrasound Sonication

Figure 1 shows our experimental setup. The ultrasonic focal beam was generated by a 1-3 Piezocomposite focused ultrasound transducer (Imasonics, France. Diameter = 60 mm, Curvature radius = 80 mm, Frequency = 400 kHz, electric-to-acoustic efficiency = 40%). An arbitary-function generator (33220A, Agilent, USA) was used to generate the driving signal that was fed to a radio-frequency power amplifier (100A250A, Amplifier Research, USA) and the energy of signal delivered to the transducer was monitored by a power meter (Model 4421, Bird, USA). Another acrylic water tank was used for animal experiment, which had a window of approximately 4×4 cm^2 at its bottom that was sealed with a thin film to allow the entry of ultrasound energy. The animal was placed directly under the water tank with its head tightly attached to the thin-film window. The animals were prepared for the experiment as described above and placed below the water tank as figure 1.

Micro-bubbles also presented during the HIFU treatment to enhance the efficiency of BBB opening. SonoVue® (Bracco, Milan, Italy. SF_6 coated with mean diameter = 2.0-5.0 μm) was injected through the catheter 10 seconds prior to the sonications. (Each bolus injection contains 10 μl).)

On the acoustic parameter design, the pressure of 0.3,0.4,0.56 MPa and the sonication duration of 15, 30, 60, 90, 120, 150, and 180s were employed respectively. The burst length were fixed at 1%, and the pulse-repetition frequency were fixed to 1 Hz.

C. Pathologic Examinations



Animals were sacrificed about 3-4 hours after HIFU sonication. The brains were immediately removed and frozen in an OCT compound (Tissue-Tek®, SAKURA, USA). The tissues were sectioned using a Microtome (Model 3050S, Leica, German). The slices were preserved and stained with hematoxylin and eosin (H&E). The results were classified into 4 categories as figure 2, it depends on level of hemorrhage and cell damage. The neuronal cell damage and hemorrhage were evaluated quantitatively by four different grades. The grade 0 was defined as neither tissue damages nor erythrocyte extravasations were observed after sonication. In grade 1, a few small extravagated erythrocytes were occasionally observed, but H&E staining showed neither neuronal loss nor cell structure changed. In grade 2, there is continuous and extensive hemorrhage, accompanying neuronal loss, or apoptotic cell death. Grade 3 was the most severe damage in tissue, it has observed neuronal cell necrotic death besides grade 2.

Besides of HE staining, the terminal deoxynucleotidyl transferase biotin-dUTP nick-end labeling (TUNEL) staining from selected slides on the neighboring sections of the H&E plane were used to detect the apoptotic neurons. The histology evaluations were performed by personnel blinded to the ultrasound parameters but was informed of the specific sonication brain side.

The neuronal cell damage and hemorrhage were evaluated quantitatively by four different grades. The level 0 was defined as neither tissue damages nor erythrocyte extravasations were observed after sonication. In level 1, a few small extravagated erythrocytes were occasionally observed, but H&E staining showed neither neuronal loss nor cell structure changed. In level 2, there is continuous and extensive hemorrhage, accompanying neuronal loss, or apoptotic cell death. Level 3 was the most severe damage in tissue; it has observed neuronal necrotic or apoptotic cell death.

III. Results

First we demonstrate the histological examination of the tissue been sonicated by focused ultrasound. Figure 2 demonstrates a typical brain section after the focused ultrasound exposure (peak pressure = 0.3MPa, sonication duration = 60s). Brain tissue stained by the blue dye was caused by the dye leakage into the parenchyma. From the observation of the brain sections, it shows that the focal energy can be well steered and well penetrate the unilateral brain.

(a) (b)

Fig. 2 Typical example showing the animal brain section after undergo the focused ultrasound exposure. (a) Outlook appearance; (b) Brain tissue sections.

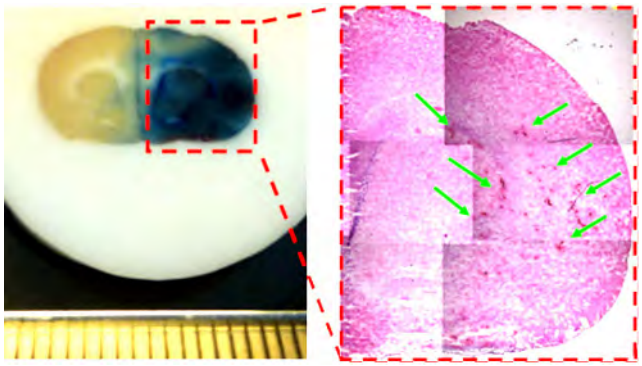


Fig. 3 HE stain examination at the sonication region

Figure 3 demonstrate typical HE stained section showing that intracerebral hemorrhage could be induced when excessive ultrasonic energy were delivered (0.3MPa, 150s). In the BBB disruptive region, there are a number of micro hemorrhage region was be detected (pointed by green arrows).

Figure 4 further demonstrate that the apoptotic cell detection by using TUNEL staining. No apoptotic cell was found when a lower parameter was delivered (0.3MPa, 15s) as shown in Fig. 4(a). When the sonication energy increased (0.3MPa, 150s), apoptotic cells can be stained in brown color (pointed by arrows) as shown in Fig. 4(b). This shows that even under the same peak pressure, the variation of sonication duration can also induced a variety of tissue damage.

Next we analyze the focused ultrasound induced brain damage in a parametric way by testing the sonication parameter with varied peak pressure and sonication time. A series of sound pressure ranging from 0.3 to 0.56 were employed, and the sonication duration ranged from 15 to 180s.

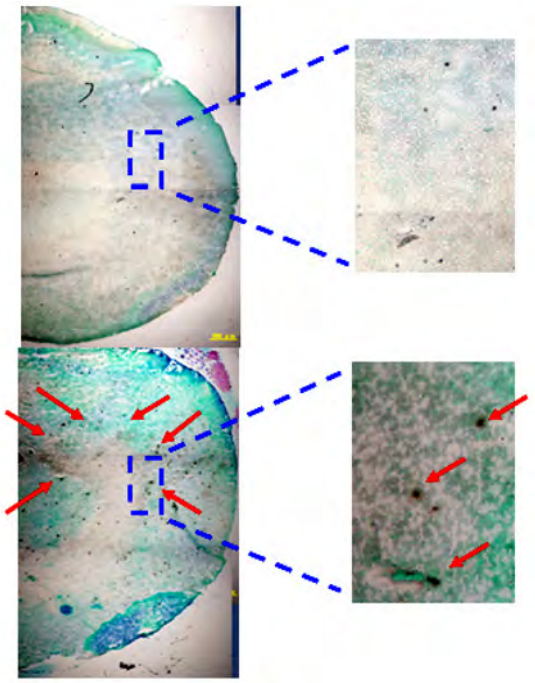

Fig. 4 TUNEL stain examination at the sonication region.

Figure 5 shows the brain tissue damage level after examine the sonicated brain sections both in HE and TUNEL (. The threshold of BBB disruption under the operating frequency was characterized to be (60s, 0.3 MPa), (30s, 0.4 MPa), and (15s, 0.56 MPa). Figure 6 demonstrate the similar information as Fig. 5 but only 0.3 and 0.56 MPa sonication were shown. When analyzing the data from Figs. 5 and 6 together, it can be observed that as the sonication duration decreased, the required peak pressure seems to be higher. On the other hand, when higher pressure was employed, tissue damage were more apparent and the damage level was characterized to be increased accordingly.

From the point view of exposure ultrasonic energy, the delivered power of two cases listed in Fig. 6 were 2 W and 10 W respectively. For example, 0.3 MPa/ 75s (the data were not present but should be located at the range between 60s and 90s cases) and 0.56 MPa/ 0.56 MPa and 15s contains identical exposure energy (power × time) but the higher pressure one contributes to a severer tissue damage.

When looking into the brain tissue section in detail (see Fig. 7), 0.3 MPa/ 60s can well disrupt the BBB region with and only take a few portion of active area been damaged (i.e., intracerebral hemorrhage); on the other hand, for high pressure sonication (0.56 MPa/ 15s), The focused ultrasound induced intracerebral hemorrhage covering all the BBB disruptive region (In some cases, the hemorrhagic areas was larger than the BBB-disruptive area). This sup-

ports that under the same standard of energy exposure, the combination of low pressure/ long sonication time would be superior than high pressure /short sonication time in inducing BBB disruption and at the same time reduce the hemorrhage as could as possible.

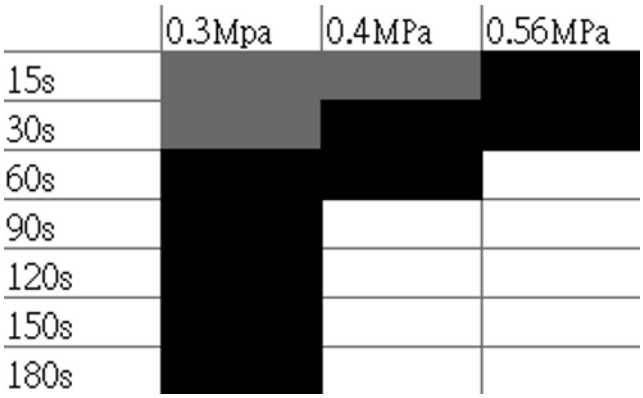

Fig. 5 BBB disruption threshold investigated under different acoustic pressures and sonication times. Gray = no BBB disruption was found; black = BBB disruption was detected.

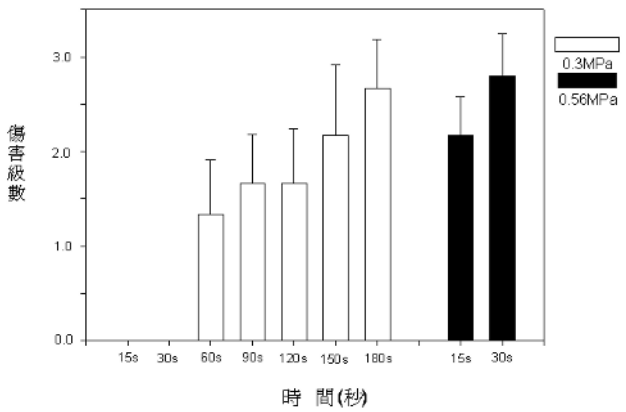

Fig. 6 Histological analysis under different sonication

IV. Conclusions

In this paper, we have successfully analyzed a more comprehensive sonication protocols study that includes not only the major factor, peak pressure, but also one of the important factors, sonication time. We have proposed to reach the requirement of BBB disruption and at the mean time reduce the brain damage, a combination of low-pressure long sonication time may be better. This approach could be benefiting the focused ultrasound brain drug delivery from the view point of increasing the safety of this technology. The future study will include a more precise and comprehensive parameters investigation to further optimize the focused ultrasound energy delivery for brain drug delivery.

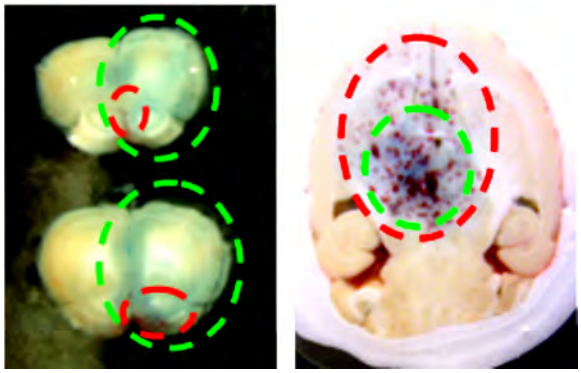

Fig. 7 Brain tissue damage when sonicating with the energy at (a) 0.3 MPa, 60s and (b) 0.56 MPa, 15s. Red regions represents the BBB disruptive region and the green region represents the hemorrhagic occurrence coverage.

Abstract — **For safe and effective home healthcare, a network system monitoring one's vital signs and evaluating one's health conditions is highly desirable. In our laboratory, we have developed a vital sensing system for home healthcare. The purpose of this study is to design and implement a prototype web-based healthcare management system (WBHMS) to make effective use of the data that are measured by the vital sensing system.**

In system design, we adopted a platform-independent web-based system for its easy use. Then we considered security and privacy because the personal data were handled via the Internet. Moreover, we considered that the users were able to check not only the data from the vital sensing system but also the analyzed report as feedback.

From the above design specifications, we implemented a prototype WBHMS. This WBHMS consisted of a web server with Apache, an application server with Tomcat, a database server with PostgreSQL, and a web application with JAVA technologies. This web application had a data viewer function, an analysis function, and a feedback function. The data viewer function provided graphs of physiological data, which were body temperature, blood pressure, pulse wave (PW), and electrocardiograph (ECG), measured by the vital sensing system. The analysis function estimated parts of the users' health conditions by two indexes. One was pulse wave velocity reflecting arteriosclerosis and was calculated from both PW at the tips of one's finger and ECG. The other was an index reflecting autonomic nervous activity and was estimated based on power spectrum analysis of RR interval of ECG. The feedback function provided advice based on both the measurement data and the results of the analysis function.

Through performance tests, we have confirmed that the prototype WBHMS has the ability to make effective use of the measurement physiological data for home healthcare.

Keywords — **Home healthcare, Web-based healthcare management system, Data viewer function, Analysis function, Feedback function,**

I. Introduction

Disease such as stroke, heart disease, and cancer are generally related closely to lifestyle [1-3]. Therefore, it is essential for people to improve their daily lifestyle to prevent and reduce the diseases. To realize the improvement, we think it most desirable that people can easily know their health conditions and can obtain adequate advice based on evidence from their physiological data.

In our laboratory, we have developed a vital sensing system which can measure users' physiological data easily in order to improve home healthcare [4]. This vital sensing system mainly consisted of two sensor units and data viewer software. These sensor units are called "smart telecom unit" and can measure blood pressure, electrocardiograph, pulse wave, and body temperature. Moreover, these sensor units had a Bluetooth module in order to transmit wirelessly the above data to a personal computer with the data viewer software. Users can check the data by using the software.

Although this vital sensing system can measure one's physiological data and display the data, it is essential to develop a data management system in order to make effective use of the data.

The purpose of this study is to design and implement a prototype WBHMS to make effective use of the data that are measured by the vital sensing system.

A vital sensing network composed of a vital sensing system and a WBHMS is shown in Figure 1.

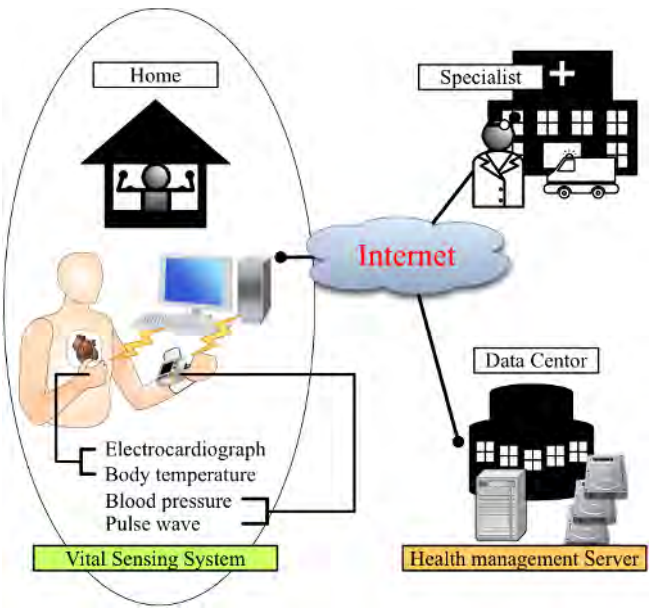

Fig. 1 Architecture of a vital sensing network composed of a vital sensing system and a web-based healthcare management system

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1098–1101, 2009
www.springerlink.com

Since we develop a prototype WBHMS which enables users to share the data with specialist via the Internet and supports the specialist giving advice based on both the data and the analysis report of the data, the WBHMS would contribute to improve the users' daily lifestyle.

II. Design of healthcare management system

We adopted a platform-independent web-based system for its easy usage and effective utilization of our vital sensing system. Therefore, we considered security and privacy because the personal data were handled via the Internet. Moreover, we considered that the users were able to check not only the data from the vital sensing system but also the analyzed report as feedback.

A. Privacy and security for web-based healthcare management system

There are various envisioned security threats such as the leakage or falsification of private information and virus attacks on a WBHMS. In each case, the fundamental security attributes of the information, namely integrity (prevention of unauthorized modification), availability (prevention of unauthorized withholding), and confidentiality (prevention of unauthorized disclosure) must be protected [5]. The most important security threats are shown as follows:

- Central information server attacks: Personal data are stored in a data server, and can be accessed over the Internet by remote users. Even though such systems are useful for users, they put the confidentiality and integrity of stored data at risk. The related security incidents are unauthorized access, technical failure of the server system, denial of service, and the threat of computer viruses.

- Communication lines monitoring and tampering: Since data have personal information, we may detect unauthorized access to the data, which is compromising the confidentiality of the data, by monitoring communication lines. The related security incidents are the infiltration and falsification of communication data.

- Authorization problems among diverse environments: Users have access to the WBHMS from a remote site. Ensuring that only authorized persons can access the personal data becomes increasingly difficult and complex. The related security incidents are masquerading user identity, unauthorized use of an application and password theft.

B. Functions of web-based healthcare management system

Our vital sensing system can measure the users' physiological data and show the data to users. However, for the people that don't have correct knowledge about the disease or are indifferent about their health would hardly utilize the system. Therefore, considering such a situation, we decided to design the three following functions:

1. Data viewer function: This function enables users to check their physiological data not only from their home but also from everywhere via Internet every day. They also can review own past records easily. Moreover, since specialist can confirm users' long-term condition via the Internet, the specialist gives some proper advice about users' health to the users.

2. Analysis function: This function estimates invisible physiological condition from the data measured with the vital sensing system. Moreover, it is expected that this function would support diagnosis by specialist.

3. Feedback function: The advice by the specialist is useful for the users. This function enables the specialist to give proper advice according to each user. Moreover, the users don't have to go to the hospital frequency in order to consult their health with the specialist. This function is also convenient for users who have no time to go to the hospital.

III. Implementation of a prototype web-based healthcare management system

We constructed a prototype WBHMS based on the design specifications in Section 2. The configuration of this system is shown in Figure 2.

This system was composed of a broadband router, three server computers, and open source software installed in these computers. The broadband router allowed only Hypertext Transfer Protocol Security (HTTPS) as communication protocol to go through. The HTTPS encrypts the information dealt between server and client for security. Apache for web server, Tomcat for application server, and PostgreSQL for database server were installed on the server computers (OS: Fedora6, CPU: AMD Opteron 2350, Memory: 2 GB). Moreover, a web application composed of Java Server Pages and Servlet was deployed on the application server. In the database server, redundant arrays of inexpensive disk (RAID) and disk backup were carried out in order to prevent disk failure. The latest software update and setting for security were executed after all the required software was installed.

The home users and specialist can easily access this system via the Internet wherever and whenever they want.

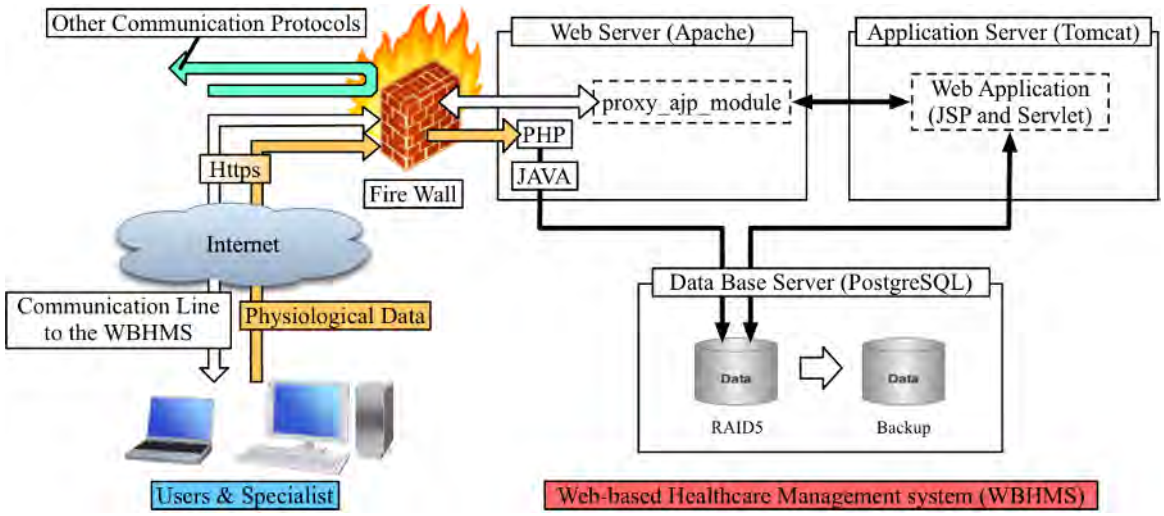

Fig. 2 Configuration of the prototype web-based healthcare management system

IV. Web Application with Java Technologies

The web application was deployed on the application server. When users access the web server, the users' request is transferred to the application server via the web server. This web application was developed by JAVA technologies and provide available service according to the users' requests. The users utilize this web application system on the web browser without the install of any special software. This web application supplied three functions composed of data viewer, feedback, and analysis.

A. Data viewer function

Sample screenshots of the data viewer function are shown in Figure 3. This data viewer function provided graphs of physiological data, which were body temperature, blood pressure, pulse wave (PW), and electrocardiograph (ECG), measured by the vital sensing system. This viewer function also provided the graphs of monthly data and the graphs of daily data. These graphs were generated by JFreeChart, which is one graph generation library, on the web application.

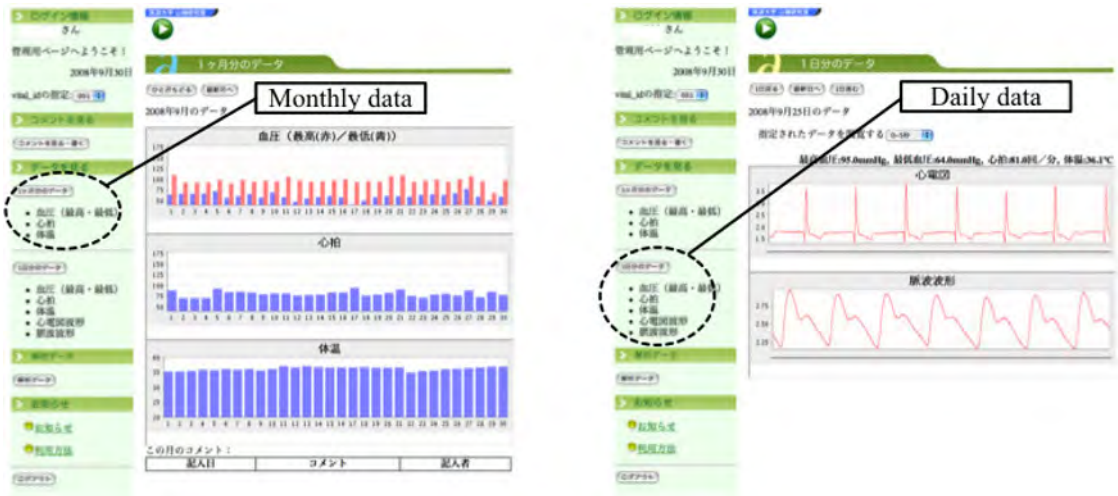

Fig. 3 Sample screenshots of measurement data shown in the data viewer function

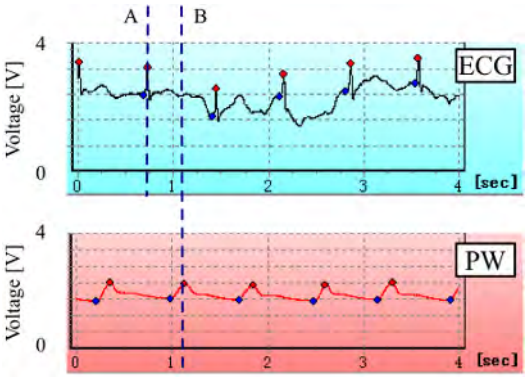

Fig. 4 Sample screenshots of the analysis function

Fig. 5 A sample screenshot of feedback function

B. Analysis function

Sample screenshots of the analysis function were partly shown in Figure 4. This analysis function estimated parts of the users' health conditions by two indexes.

One was pulse wave velocity (PWV) reflecting arteriosclerosis. We calculated the PWV from both ECG at the tips of one's finger and PW as follows:

1. Peak points of both ECG and PW were detected as both point A and point B in Figure 4.
2. The time difference from point A and point B was calculated.
3. Body length was divided by the time difference. Then, PWV was calculated.

The other was an index reflecting autonomic nervous activity and was estimated from two power spectrum frequency components (0.04 to 0.15 Hz and 0.15 to 0.4 Hz) of RR interval of ECG.

C. Feedback function

A sample screenshot of the feedback function is shown in Figure 5. The feedback function provided advice based on both the measurement data and the results of the analysis function. If specialist gives some advice to users at regular intervals, this advice would supports improvement in user's lifestyle.

V. Conclusion

In this study, we have designed and implemented the prototype WBHMS in order to make effective use of the data measured by the vital sensing system.

We have operated this WBHMS for more than 6 months through basic performance tests. We confirmed that this system has the ability to make effective use of the measurement physiological data for home healthcare.

At present, we assume our vital sensing system is used at user's home. However, there are a few people who don't have the Internet environment or even personal computers. Therefore, we are planning to introduce this system to public establishment such as community center. This would promote not only home healthcare but also community health.

[2]Sekioka Clinic, Minami–Ise, Japan

Abstract — **We propose a novel technique to track the motion of the left ventricular myocardium on a sequence of transthoracic two–dimensional echocardiogram. Although the proposed method is generally based on the traditional correlation based motion tracking, the tracking accuracy and stability are improved by the introduction of new objective function. In our method, the objective function is defined from the model where multiple Regions of Interest (ROIs) are connected to each other with elastic links. The elastic links reflect both elastic and shape properties of myocardium. The proposed method is implemented and evaluated using ten clinical subjects. The experimental results show that the tracking accuracy of the proposed method is higher than that of the conventional method.**

Keywords — **echocardiogram, motion tracking of myocardium, connected multiple ROIs**

I. Introduction

The echocardiogram is an essential tool for diagnosis and treatment of cardiovascular diseases. The use of echocardiograms for clinical diagnosis serves clinicians and doctors with multifold advantages including noninvasiveness of diagnosis and real–time imaging. Recent technical innovations of ultrasonic diagnosis equipment reclaim their new availabilities in clinics. These novel modalities require clinicians or doctors to track a specific tissue of myocardium by hand to keep their focus on a relevant tissue to evaluate. Manual tracking not only be tedious and time consuming but also leads subjective diagnosis and significant variability within clinicians. Therefore, an automated, computer–based objective tracking of myocardium is necessary for quantitative diagnosis.

Several approaches have been proposed to quantify the motion of myocardium from two dimensional (2–D) echocardiograms[1, 2, 3, 4]. The quantified velocity or motion itself is not of direct use for the diagnosis. In order to track the relevant regions of myocardium, we must define a region of interest (ROI) that typically corresponds to the myocardium and track the ROI in time by using the quantified velocity field.

In the tracking stage, the displacement of ROI is estimated from quantified tissue velocity and then it is accumulated on the position of ROI. In this context, the error of estimated displacement is also accumulated, hence it sometimes corrupts the tracking. The incorrect estimation of displacement occurs frequently due to the low quality of echocardiogram degraded by image noise such as speckle. Furthermore, the error causes that a tissue tracked by a ROI is not equivalent between consequent image frames. Once the error deflects the ROI form original tissue displacement, it is quite difficult to correct this disagreement between original tissue and tracking ROI.

We propose a novel algorithm to track motion of relevant regions in myocardium from high spacial resolution 2–D echocardiograms. These high resolution echocardiograms are generated from the ultrasonic radio frequency (RF) signals not using any low–pass filters. The proposed algorithm employs a modified version of the correlation method where ROIs are connected each other by elastic links. The conventional cross–correlation approach proposed for estimation of velocity field in images employs an objective function which measures the similarity of speckle patterns in two images. Instead of this objective function, we use an objective function in which we add terms evaluating the spacial relationship of ROIs.

The paper is organized as follows. We describe the motion tracking algorithm in Section II. In Section III, availability of the proposed method is evaluated using clinical echocardiograms. And finally, we conclude the paper in Section IV.

II. Myocardial motion tracking

We describe here how to estimate the velocity field and how to track the motion of relevant regions in echocardiograms by the proposed method.

A. High spacial resolution echocardiograms

An ultrasonic radio frequency (RF) signal captures the motion of left ventricular myocardium for one heartbeat. The signal is digitized with high spatial resolution and input to a PC. The one heartbeat length ultrasonic signal is separated into N frames corresponding to the frame rate of echo-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1102–1106, 2009
www.springerlink.com

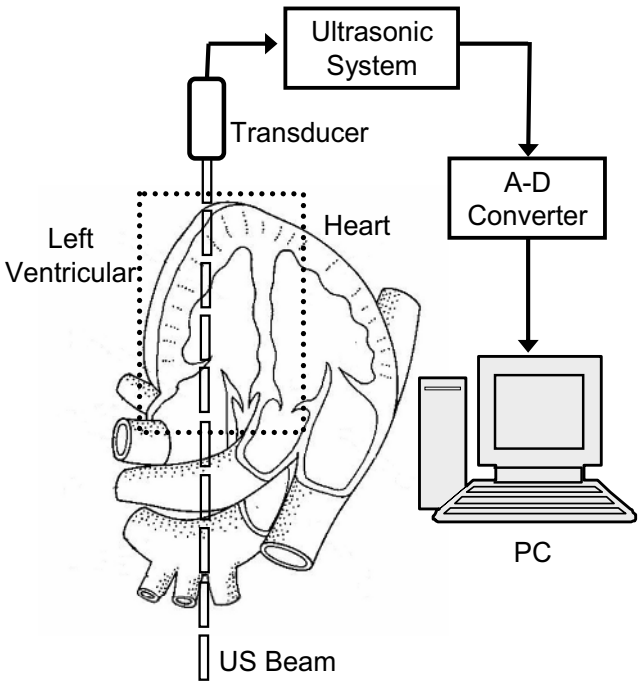

Fig. 1 Diagram of ultrasonic system for data acquisition

cardio-gram. The RF signal in each frame consists of L scan-lines. Same as in the diagnosis equipment, these scan-lines are aligned pertinent to the direction of themselves in the frame buffer and interpolated to derive the echocardio-gram. Creating images from acquired RF signal instead of using echocardiogram generated by diagnosis equipment allows us to control the spacial resolution of the resultant images. This means that we are able to obtain echocardio-grams with intended resolution.

Fig.1 illustrates the block diagram of the data acquisition process.

B. Image representation

We handle the echocardiogram derived above as a high–resolution gray-scale raster image. We show here some definitions and representation related to images used in the following contents.

Let $p = (p_x, p_y)$ and $f(p,i) = f(p_x, p_y, i)$ denote the pixel at (p_x, p_y) and the pixel value corresponding the pixel p. An echocardiogram of i-th frame is represented as a grayscale image, which is a vector where a pixel value is an element,

$$F_i = (f(p,i) \mid p \in R_{ALL}), \tag{1}$$

where $R_{ALL} = ([1, W], [1, H])$ denotes the region containing entire image surface. We denote a rectangular sub region of which p is the center and w and h are the width and height as,

$$R(p,w,h) = \left(\left[p_x - \frac{w}{2}, p_x + \frac{w}{2} \right], \left[p_y - \frac{h}{2}, p_y + \frac{h}{2} \right] \right). \tag{2}$$

A sub–image cropped by the subregion $R(p,w,h)$ from the entire image F_i is represented by,

$$\begin{aligned} f_i(R(p,w,h)) &= (F_i \mid R(p,w,h)) \\ &= (f(p,i) \mid p \in R(p,w,h)). \end{aligned} \tag{3}$$

The parallel translation of a pixel is defined as an add operation for vectors,

$$\begin{aligned} p' &= p + q \\ &= (p_x, p_y) + (q_x, q_y) \\ &= (p_x + q_x, p_y + q_y), \end{aligned} \tag{4}$$

then, the distance between two pixels p and q is obtained by,

$$\begin{aligned} d(p,q) &= \|p - q\| \\ &= \sqrt{(p_x - q_x)^2 + (p_y - q_y)^2}. \end{aligned} \tag{5}$$

And the angle of the line segment connecting p and q is defined as,

$$\theta(p,q) = \tan^{-1}\left(\frac{p_y - q_y}{p_x - q_y} \right) \tag{6}$$

C. Connected Multiple ROIs

In the motion tracking method, we should fist define an objective function to optimize. A well–defined objective function is required to give a good evaluation for displace-ment between two images and be robust for image noise. Our former research[5] shows that an objective function based on the residual instead of the cross– correlation de-rives good performance for the myocardial motion tracking in echocardiograms.

The basic idea of the method in [5] is that elastic links which connect adjacent ROIs can reduce tracking errors due to velocity estimation error. Fig. 2 shows that the model of this idea. The connecting multiple ROIs increase the com-plexity of objective function.

Let $P = \{p_1, p_2, \cdots, p_n\}$ and $Q = \{q_1, q_2, \cdots, q_n\}$ represent a set of tracking point on the i-th frame and i + 1-th frame respectively. The objective function for P and Q is defined as,

$$h(P,Q) = \sum_{j=0}^{n} \left\{ \gamma(p_j, q_j) + \frac{k}{2}(L(p_j) - L(q_j))^2 \right\}, \tag{7}$$

$$L(p_j) = \begin{cases} d(p_{j+1}, p_j), & 1 \le j \le n-1 \\ d(p_0, p_j), & j = n \end{cases}, \tag{8}$$

where $L(p_j)$ denotes a distance between the i-th and i + 1-th tracking points. The parameter k reflects the elastic property of myocardium and controls change of distance between tracking points. A large k constrains tracking points not to change the distance between each other.

The objective function in (7) is based on the assumption where the elastic property of myocardium is homogeneous. This assumption sometimes results tracking errors in [5]. In order to adopt this assumption on the real property of myocardim, we modify (7) by introducing heterogeneous elastic parameters.

$$h'(P,Q) = \sum_{j=0}^{n} \left\{ \gamma(p_j, q_j) + \frac{k_j}{2} \left(\frac{L(p_j) - L(q_j)}{L(p_j)} \right)^2 \right\}. \tag{9}$$

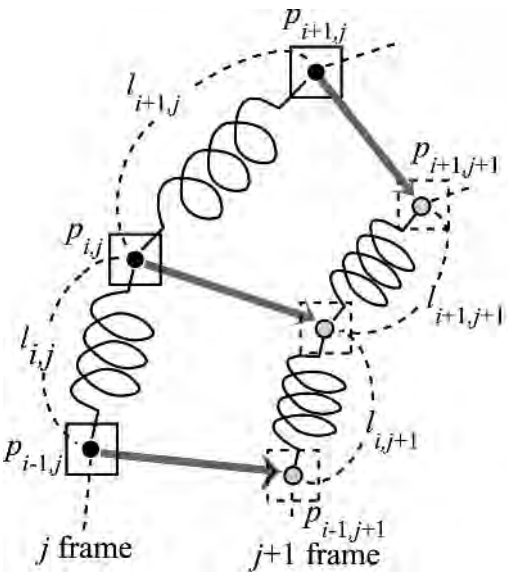

Fig. 2 Model of the objective function in the proposed method

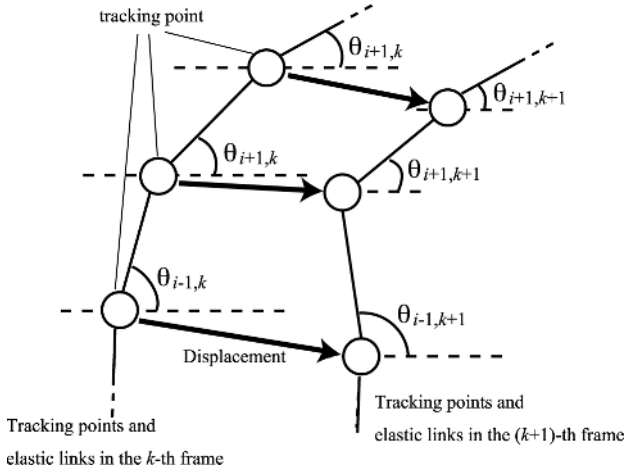

Fig. 3 Shape–constraint elastic link model

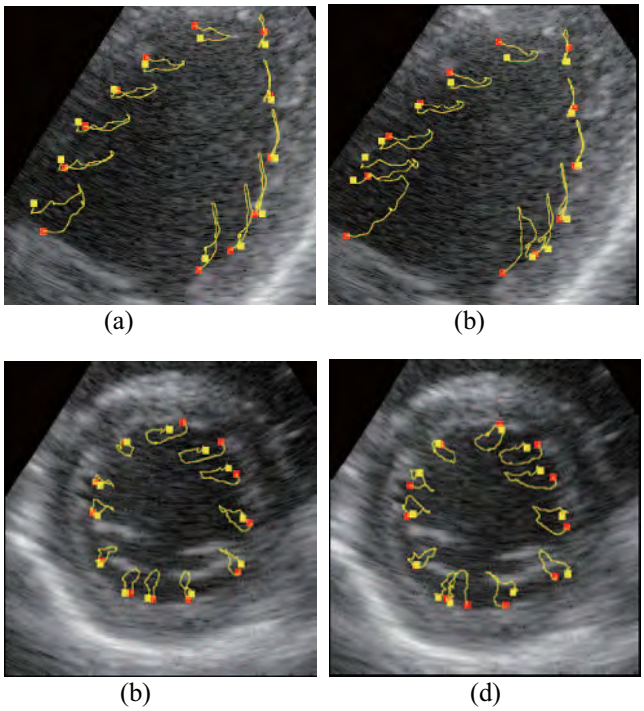
The each parameter k_j in $K = \{k_1, k_2, \cdots, k_n\}$ reflects the elastic property of link corresponding to the tracking point. The proposed method minimizes the (9) by using a dynamic programming approach.

D. Shape–Constraint Elastic Link Model

The motion property of myocardium in the long–axis B–mode scan is different from that in the short–axis scan. For instance, in the long–axis the shape of left ventricular endocardium does not changed while the cavity of left ventricle does, during systole and diastole cycle. Motivated by this property, we introduce the shape–constraint elastic link model (SCEL) into the objective function of motion tracking.

The basic concept of SCEL model is illustrated by Fig.3. The model considers the angle of each elastic link not only the length of them. The model constraints the angle change between two consequent frames. The objective function considering the SCEL model is expressed as,



$$h''(P,Q) = \sum_{j=0}^{n} \left\{ \gamma(p_j, q_j) + \frac{k_j}{2} \left(\frac{L(p_j) - L(q_j)}{L(p_j)} \right)^2 + v_j (\theta(q_{j+1}, q_j) - \theta(p_{j+1}, p_j))^2 \right\}. \tag{10}$$

Where, the angle change between frames, $\theta(q_{j+1}, q_j) - \theta(p_{j+1}, p_j)$, are calculated by equation (6).v_j is weighting factors which control the importance of shape–constraint in the objective function. At this point, we defined the weighting factors experimentally. For minimi-

zation of the objective function (10), we can also employ dynamic–programming approach.

E. Determination of weighting factors k_j and v_j

To track myocardial motion accurately using SCEL, we have to determine a suitable combination of weighting factors k_j and v_j . These parameters control the level of importance of the image correlation, distance change between tracking ROIs and angle consistency in the objectivefunction (10).

(a) (b)

(b) (d)

Fig. 4 Examples of tracking result by the proposed and the conventional methods. (a),(c) and (b),(d) are results by the proposed and conventional methods respectively.

The determination of the weighting factors is quite important; however it is almost impossible to determine a suitable combination of factors to a particular echocardiogram. From this reason, we determine the value of factors employing the following exploratory experiment. At first, three sequences of echocardiogram are selected randomly for the exploratory experiment. The myocardial motion contained in the three sequences is tracked by manual. Next, a range of kj and vj is defined within that the values do not corrupts the motion tracking.

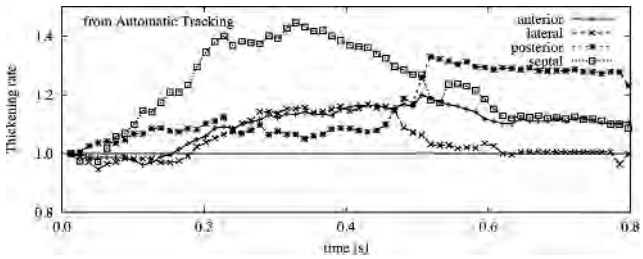


Fig. 5 An example of myocardial wall thickening assessment using motion tracking result

III. Experiments and Results

We use ultrasonic diagnosis equipment (Hitach–medical EUB–6500) to acquire ultrasonic RF signals. The signals capture the motion of left ventricular myocardium in short– and long–axis view. Ultrasonic data from ten normal subjects are used for verification of the proposed method. High spacial resolution echocardiograms are created from the RF signals. Initial tracking points are defined by manually on the first frame.

Fig. 4 illustrates the examples of tracking result. In the figure, (a),(c) and (b),(d) show the result by the proposed method (10)and the conventional CMR one (9) respectively. Since we use one heart beat length signals, the tracking points is expected to return at the position of initial ones. From these results, it is obvious that the proposed method is able to track the myocardial motion more reliable than the conventional one.

Fig.5 shows an example of application of the proposed result. This figure illustrates change of myocardial thickening during one heart cycle. The myocardial thickening of four myocardial region, anterior, lateral, posterior and septum, are calculated using the motion tracking result by the proposed method.

Conclusions

In this paper, we propose a new modality to track the myocardial motion from 2–D echocardiogram. The experimental results with clinical subjects show that the performance of the proposed method is empirically superior to the conventional methods.

Further study topics include (1) further improvement of tracking accuracy, (2) define an effective procedure to define the elastic parameters kj and vj in (10) and (3) detailed performance evaluation with enough number of clinical data.

Assessment of Foot Drop Surgery in Leprosy Subjects Using Frequency Domain Analysis of Foot Pressure Distribution Images

Bhavesh Parmar

Ramrao Adik Institute of Technology, Navi Mumbai, India

Abstract — **Foot problems in leprosy subjects are of major concern. Quantitative assessment of corrective foot drops surgery in detecting effectiveness of recovery after surgery overtime having prime importance. This paper quantifies and distinguishes between the foot pressure images of leprotic subject for preoperative as well as different duration of post-operative and of normal foot. Detailed analysis is performed on walking foot pressure distribution image in the frequency domain. Power ratio (PR) (ratio of power in higher spatial frequency components to the total power in the power spectrum) is used to distinguish between the foot pressure image pattern in preoperative and postoperative over different time duration. Statistical Analysis involving calculation of 'p' using Welch ANOVA test followed by post Dunnett's test and Kruskal-Wallis test has been carried out on mean PR to understand the progress of recovery after surgery from preoperative state and with normal state in all the foot sole areas. It is observed that the postoperative stages are the one with increase sensitive feet and decrease PR. These results could help in early detection of recovery and/or defect of surgery, and thereby help orthopedic surgeons for early corrective action for preserving or restoring normal foot function.**

Keywords — **Foot drop surgery, Foot pressure images, Frequency domain Image Analysis, Leprosy, Power ratio.**

I. Introduction

Leprosy, a disease as old as mankind, has been a public health problem to many developing countries. Leprosy has always and everywhere been regarded as a special disease. It has stimulated studies in various fields, such as pathology, histology, immunology and rehabilitation. Of them rehabilitation of the victims has assumed prime importance as its focus is on prevention of further advancement of deformities. This paper aims to understand the pressure distribution patterns under the foot-soles of leprotic subjects at different stages of curing of leprotic disorder with different time duration after surgery with new foot pressure parameter PR (ratio of power in higher spatial frequency components to the total power in the power spectrum of the foot pressure image) developed by Prabhu et al., 2001[1]. This work could help the orthopedic surgeons in detecting the effectiveness of surgery with time duration after correction of leprotic feet and thereby in taking early corrective action for curing of the feet disorders of the disease as well as the functional rehabilitation of the leprosy feet, in time.

Section II describes the foot pressure measurement system used for acquiring the data and image processing methodology. Section III describes the frequency domain analysis of walking foot pressure images. In section IV results with analysis is been discussed. At last conclusions with the scope for the future extension are discussed in section VI.

II. Foot pressure measurement system

The Foot pressure measurement system involves the use of an optical pedobarograph developed earlier [2] in the Biomedical Engineering laboratory, IIT, Madras.

Standing foot pressure measurements gives only a fraction of the potential information regarding the functionality of the foot. More valuable information would result from the dynamic distribution of pressures and loads, particularly since many abnormalities of the foot only reveal themselves in dynamic (walking) measurements while remaining hidden on a fairly detailed static (standing) analysis [3].

The size of the individual footprint is varying and these foot print images are divided into ten standard regions as per the method indicated in Patil et al [4]. Now each plantar area is obtained manually, from the corresponding frames of distinct phase of walking cycle, i.e., area 1 and 2 from heel–strike; area 4 from mid–stance and area 5 to 10 from push–off phases of walking cycle.

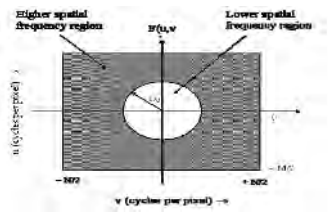

Figure 1 The Fourier spectrum, *F(u,v)* of an image showing the higher and lower spatial frequency regions.

$$LFP = \left\{ \sum_{D(u,v)=0}^{D_0} |F(u,v)|^2 \right\} - |F(0,0)|^2 \quad (1)$$

$$HFP = TP - LFP \quad (2)$$

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1107–1111, 2009
www.springerlink.com

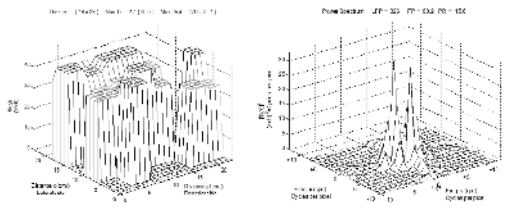
$$PR = \left(\frac{HFP}{TP} \right) \text{ x } 100 \quad (3)$$

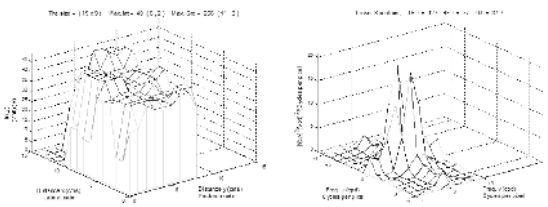
Frequency domain analyses of these images corresponding to all the plantar areas are performed, and the PR (ratio of high frequency power to the total power in an image) is calculated using equations (1-3).

III. Frequency domain analysis.

The frequency domain analysis, of walking foot pressure light intensity images, is done for 12 leprotic subjects. Comparisons of PR values are made between normal and leprotic subjects pre and post corrective foot drop surgery.

A. Results





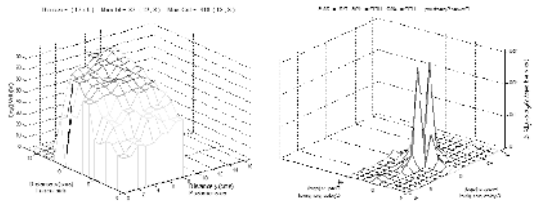


Figure 2 (a) The walking foot pressure image intensity (spatial) distributions; the directions of x and y axes are from medial to lateral and posterior to anterior side and (b) power spectrum after deleting the DC component, in area 2 for a normal subject, respectively.

(a) (b)

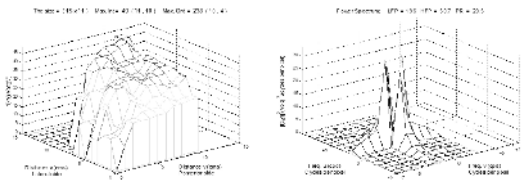

Figure 3 (a) The walking foot pressure image intensity (spatial) distributions; the directions of x and y axes are from medial to lateral and posterior to anterior side, respectively, and (b) the power spectrum (after deleting the DC component), in area 2 of the left foot for a leprotic subject before corrective foot drop surgery.

Figures 2(a) and 3(a) show the spatial variation of intensity distribution in area 2 (lateral heel) for a normal and leprotic subject (with foot drop and claw toes) before the corrective foot drop surgery. It is observed that the spatial intensity variation distribution for a leprotic foot is not uniform (Figure 3a) compared to that of a normal foot (Figure. 2a). The power spectrum of these intensity distributions are shown in Figures 2(b) and 3(b), respectively. The power spectrum of foot pressure image intensity for a leprotic foot before corrective surgery (Figure 3b) shows higher relative value of high spatial frequency power in the total power spectrum distribution compared to that of a normal foot (Figure 2b), giving rise to higher value of PR (37.7) in that area of the foot for the leprotic subject before the surgery.

(a) (b)

Figure 4 (a) The walking foot pressure image intensity (spatial) distributions; the directions of x and y axes are from medial to lateral and posterior to anterior side, respectively, (b) the power spectrum after deleting the DC component, in area 2 of the left foot for the same subject, (as in Fig 3) after corrective foot drop surgery (41-60 days after correction).

(a) (b)

Figure 5 (a) The walking foot pressure image intensity (spatial) distributions; the directions of x and y axes are from medial to lateral and posterior to anterior side, respectively, and (b) the power spectrum after deleting the DC component, in area 2 of the left foot for the same subject) (as in Figs. 3 and 4) after corrective foot drop surgery (above 210 days after correction).

Similarly the spatial variation of intensity distribution in area 2 (lateral heel) for the same leprosy subject after corrective surgery (41-60 days duration after surgery and 210 days after surgery) are shown in Figures 4(a) and 5(a), respectively. The corresponding power spectrums are shown in Figures 4(b) and 5(b), respectively. It is observed, from Figures 4(a) and 5(a), that the foot pressure spatial intensity distribution is becoming nearly uniform, giving rise to lower relative value of high spatial frequency power in the total power spectrum compared to the corresponding value before corrective foot drop surgery, thus decreasing the value of PR (28.5 and 20.5, respectively) towards normalization.

B. Analysis of Results

The Figures 6 and 7 show summary of variations of values of PR in different foot sole areas for two typical leprotic

subjects before and after different durations of the foot drop corrective surgery in comparison with normal subjects. It is observed from the Figures, that the PR values are very high prior to surgery in heel, first and second metatarsal head and second to fifth toes. The high values of PR observed in the heel area could be due to the foot drop and in the mid foot areas due to lateral shift of walking pattern observed in foot drop subjects. The high values of PR in second to fifth toes could be due to claw toes exerting high pressure distributions. There is general recovery (after foot drop surgery) in the heel to fore foot regions, as shown in decrease of average PR values in all foot areas (fig. 6) from 28-30 (before surgery) to 18-22 as the recovery process takes from 40-60 days to 210 days. The values in the second to fifth toes did not reduced due to non correction of claw toes in all the leprotic subjects. From comparison of both the Figures 6 and 7, it is observed that the recovery pattern is different in both the subject. In Fig. 6 the recovery is faster than the Fig 7, form that we can say that the recovery of foot sole parameter may also depend on the type of corrective surgery.

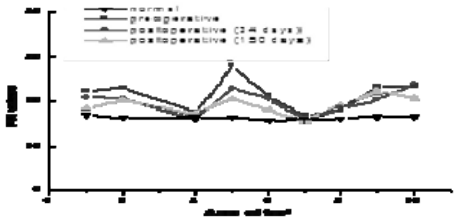

Figure 6 Variations of mean values of PR in the different areas of the foot sole for leprosy subjects before and after the foot drop correction with varying recovery time.

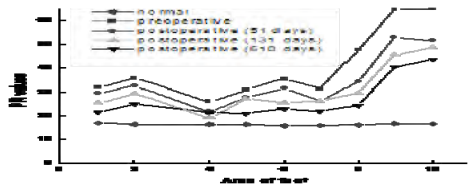

Figure 7 Variations of mean values of PR in the different areas of the foot sole for leprosy subjects before and after the foot drop correction with varying recovery time.

The mean PR values, for all leprosy subjects in preoperative and postoperative stage of corrective surgery-with different time durations of recovery compared to corresponding normal feet, are shown in first group for all the specified foot sole areas.

The above Figure 8 shows summary of variations of mean values of PR in different foot sole areas for all the leprosy subjects before and after different durations of the foot drop corrective surgery in comparison with normal subjects. It is observed that the PR values are very high prior to surgery in heel, second metatarsal head and second to fifth toes. The high values of PR felt in the heel area in mid-stance phase, could be due to the foot drop and in the lateral mid foot area due to lateral shift of walking pattern observed in foot drop subjects. The high values of PR in second to fifth toes could be due to claw toes exerting high pressure distributions. There is gradual recovery (after foot drop surgery) in the heel to fore foot regions, as shown decrease of average PR values in all foot areas from 30-35 to 20-22 as the recovery process takes from 40-60 days to 210 days. The values of PR after 210 days being very nearly equal to normal subject values. The values in the second to fifth toes did not reduce due to non correction of claw toes in all the leprotic subjects.

C. Statistical Analysis

A statistical study was carried out on PR values obtained from the foot image data of normal and leprosy subjects

Table 1 Values of mean difference and significance level (p) for different group taking normal as a control group for all foot sole areas.

Group	Areas of foot								
	1	2	4	5	6	7	8	9	10
Preoperative	-16.955**	-16.939**	-9.119**	-14.885**	-23.899**	-10.175**	-14.25**	-31.136**	-28.595**
Postoperative (40-60 days)	-10.471*	-9.785**	2.189§	-11.403**	-16.022**	-10.158**	-9.864**	-25.071**	-25.645**
Postoperative (90-110 days)	-2.885§	1.220§	1.465§	-5.357§	-7.976§	-4.939§	-6.284§	-21.750+	-22.250+
Postoperative (111-150 days)	-10.747§	3.179*	0.647§	-6.319§	-9.763§	-6.244*	-7.903*	-20.520+	-19.150+
Postoperative (>210 days)	-6.876§	2.184§	1.718§	-6.912§	-8.124§	-3.928§	-6.437§	-24.100+	-25.833+

** Very significant ($0.001<p<0.01$), * significant ($0.01<p<0.05$), § not significant ($p > 0.05$), + Dunn's test could not performed due to small sample size.

(before and after the corrective foot drop surgery). To know the difference of mean values of PR in all the standard foot sole areas, comparisons were made between different groups. If the data is parametric, it will be tested by Welch ANOVA test followed by Dunnett's C test. For non-parametric data relevant Kruskal-Wallis test has been performed followed by Dunn's test.

Normal group is found to be significantly different ($0.001<p<0.01$) from preoperative group and ($0.01<p<0.05$) postoperative group for40-60 days after surgical correction of foot drop. Table 1 shows the details of these tests and respective level of significance (p) and mean differences for all groups belonging to different foot sole areas.

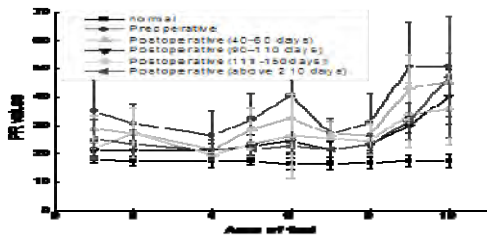

Figure 8 Mean values of PR in the different areas of the foot sole for normal and all the leprosy subjects before and after the foot drop correction. The bars indicate the standard deviations in every foot sole areas.

IV. Discussion

It is observed that the percentage of power in higher spatial frequency components, is more in the foot pressure images corresponding to before the corrective foot drop surgery for the leprotic feet than those of the images of the normal feet in all the corresponding foot sole areas, giving rise to higher value of PR. This may be due to the non uniform variations of the spatial intensity in the foot pressure image of the leprotic feet (Figure 3a) as compared to a more smoother intensity distributions, in a normal feet (Figure 2a). Variation of the spatial intensity reduces to nearly uniform after the corrective foot drop surgery of the leprotic surgery in their recovery period (Fig. 4a and 5a). It is also observed that when the duration of recovery period for the corrective surgery increases, the power ratio also decreases, tending to near normal value. From comparison of the recovery pattern in different subjects, it is observed that the recovery is faster (Fig. 6) in some of the subjects than other (Fig 7). There is gradual recovery in the heel to fore foot regions, as shown by decrease of average PR values in all foot areas from abnormal to nearly normal (Fig. 8) as the recovery period increases. The values of PR after 210 days are found to be very nearly equal to normal subject values.

Statistical results shows that the mean values of the parameter PR, for all leprotic subjects before corrective foot drop surgery, compared to the corresponding values of PR of normal feet are found to be significantly higher with 'p' values < 0.001 for all the areas of the foot sole.

V. Conclusions

Walking foot pressure patterns of normal and leprotic subjects before and after the foot drop correction have been analyzed in frequency domain to understand the change taking place in the pressure distribution patterns under the foot-soles of leprotic subjects before and after undergoing corrective foot drop surgery. The foot pressure parameter PR shows the difference between its values before and after corrective foot drop surgery and hence help to detect the effectiveness of the corrective foot drop surgery.

It is observed that the relative values of higher spatial frequency power in the total power spectrum of foot pressure is more, in the images of leprotic subjects before corrective foot drop surgery and in initial stage of recovery after corrective surgery, than those of the images of the normal feet in all the foot sole areas, giving rise to higher value of PR. This may be due to the non uniform variations in spatial intensity of foot pressure image in the leprotic feet as compared to a smoother intensity distribution, in normal feet. Variation of the spatial intensity of foot pressure image reduces nearly to uniform level in the later stage of recovery after the corrective foot drop surgery. It is also observed that when the progress of recovery, for the corrective surgery increases the power ratio PR also decreases towards normal values, showing the degree of recovery from foot drop. After the corrective foot drop surgery with different durations of recovery, the mean values of the parameter PR reduces nearly to normal value for all leprotic subjects, in all foot sole areas except toe areas.

The different durations of recovery processes observed after foot drop corrective surgery, may help the orthopedic surgeons to assess, quantitatively, the procedures used by them in selecting the insertion points, quality, lengths and tension used for the Tibialis Posterior tendon transfer in foot drop corrective surgery.

Abstract — **Telemedicine plays a more and more important role in supporting doctors and taking care of people's daily health. Recently, the 3G mobile phone progressed rapidly. It is possible to use the 3G mobile phone for telemedicine. In this paper, new functions are developed for ICU/CCU Remote Patient Monitoring System using a 3G mobile phone and the system was evaluated.**

This system consists of three parts: Patients Monitoring System, Remote Information Server which are built in the hospital and Java-enable 3 G mobile phones. Patients Monitoring System consists of bedside monitors in ICU/CCU and central monitors installed in the place where medical staffs gather. Commonly, several patients' information which was measured with bedside monitor can be stored in the database of central monitor. Remote Information Server plays an important part. It can extract specific data from central monitor and send it to the 3G mobile phone. Via the Internet and 3G mobile network, the Java application on the 3G mobile phone receives the data and displays the visual information on the screen of the mobile phone to the doctor. Even from the outside of the hospital, by using this system the doctor can monitor the vital biosignals of patients in ICU/CCU, such as ECG, SpO2, RESP, and so on. The doctors can monitor graph trend data as well as real-time data, list rend data and patient information. Graph trend application is useful to watch the past of change of the patient. This application took about 23 seconds till the doctor displayed graph trend data. However, this delay time was decreased for 8 seconds by compressing data with algorisms.

The proposed system can provide high level patient monitoring to doctors and do a powerful supporting to save patient's lives when doctors are outside the hospital.

Keywords — **telemedicine, 3G mobile phone, java, ICU/CCU**

I. Introduction

In late years, with the spread of the Internet and the development of the mobile technology, we can get information anywhere anytime. This progress affects the field of medical care and the study of the telemedicine using a mobile phone is reported much in the world. In North America and Europe, there is the reports that they collects the measurement data in the server via Bluetooth equipped with a PDA and a mobile phone [3][4]. In Japan, with TV phone, the system knowing the state of patient are reported [2]. In this way, the studies of telemedicine are performed actively in the world.

The mobile phone is expected as a platform for the ubiquitous society in Japan. The total number of the subscribers of mobile phone (including PHS) is more than 104 million. The big market is mainly shared by three carrier companies. More than 53 million users belong to NTT docomo Inc., 30 million users belong to KDDI Corporation, and 19 million users belong to SoftBank Corporation [7]. The diffusion rate is more than 84%. From this data, it may be said that each person in Japan has a mobile phone in hand.

Nowadays, mobile phone has become more than a tool only for talking with other people. Multi-functions, such as Internet browser, one-segment broadcasting, Java application, Camera, Bluetooth/infrared connection, GPS, multitasking and so on make it more and more powerful and indispensable. Furthermore, third-generation(3G) mobile communication networks combine standardized streaming with a range of unique services to provide high-quality Internet contents. Packet communication via WCDMA networks provided by NTT docomo and SoftBank can reach 144kbps when high speed moving, 384kbps when walking while 2Mbps when being stillness (downlink speed) as that via CDMA 2000 provided by KDDI can reach the limit of 2.4mbps(down link speed). Therefore, the mobile phone is possible to transfer large amount of data, such as photos, movies and application.

For the medical scene, the doctor contacts medical staffs with a mobile phone routinely. When a patient had an accident, and there is a doctor outside a hospital, the medical staff in the hospital telephones the mobile phone of the doctor and tells it about the situation. The method to know the condition of the patient then is only conversation with the partner of telephone.

we started the development of the ICU/CCU Remote Patient Monitoring System which supported a doctor by adding visual information. We improve utility more by adding a new function to a current system.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1112–1115, 2009
www.springerlink.com

II. Method

A. System architecture

The overview of ICU/CCU Remote Patient Monitoring System is shown in Fig. 1. This system consists of three parts: Patient Monitoring System, Remote Information Server which are built in the hospital and Java-enable 3G mobile phones. Patient Monitoring System consists of bedside monitors in ICU/CCU and central monitors installed in the place where medical staffs gather. Commonly, several patients' information which was measured with bedside monitor can be stored in the database of central monitor. Remote Information Server plays an important part. It can extract specific data from central monitor and send it to the 3G mobile phone. Via the Internet and 3G mobile network, the java application on the 3G mobile phone to the doctor. Even from the outside of the hospital, by using this system the doctor can monitor the vital biosignals of patients in ICU/CCU, such as ECG, SpO2, RESP, and so on.

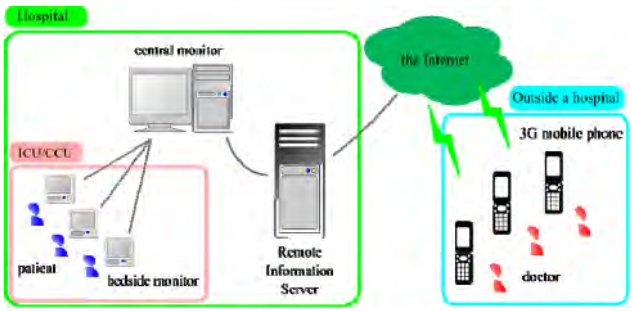

Fig. 1 The system architecture

The model of bedside monitor is DS-7100, and central monitor is DS-5700. They are both provided by Fukuda Denshi Co., Ltd. The bedside monitor can measure ECG, RESP, IBP, NIBP, TEMP, SpO2 and EtCO2. The central monitor memories 96-hour waveform and simultaneously monitors up to 16 patients. The connection is up to bedsides and 16 patients [5][6].

Remote Information Server is Apache web server on a SUSE Linux operating system. This server is running the PHP Hypertext Preprocessor (PHP) application.

We use mobile phone F901iC released by NTT docomo Inc., which is biggest mobile communication carrier in Japan. The java application we made uses jiglet application which jig.jp company offers [8]. This application can work on in not only NTT docomo's i-mode platform but also ezweb platform of KDDI Corporation and S! platform of SoftBank Corporation. In other words, it can be used on all the mobile phones in Japan, no matter which carrier company they are belong to.

B. Protocol and Data Format

Session between the application of mobile phone and Remote Information Server is transited by HTTP communication. If doctors want to check some information, they can get necessary information by appointing a specific parameter in URL of PHP application.

Data format is based on XML (Extensive Markup Language). The mobile phone analyzes the tag of the data which received from Remote Information Server and extracts necessary data. This data format can acquire necessary data just to appoint a tag, but depends on the quality of performance of the mobile phone in processing time.

For example, the format of the URL used to get the data needed is as http://xxx.server.xxx/realtime.php?time=xxx&pati=0&data=ECG1&type=HR&length=10&scale=6. And the received data is shown as following: <time>xxx</time><id>0</id><name>ECG1</name><type>HR</type><meas>60</meas>. The time of the data received is "xxx", the patient ID is "0", the name of the waveform is "ECG1", type of the measurement is "HR", and the number of HR is "60".

III. Results

A. Examples of Monitoring Application

There are four functions in the Remote Patient Monitorig application. They are real-time waveform monitoring, list trend Monitoring, patient information checking and graph Trend Monitoring.

Fig.2 shows three monitoring application: Real-time monitoring, List trend monitoring and Patient information

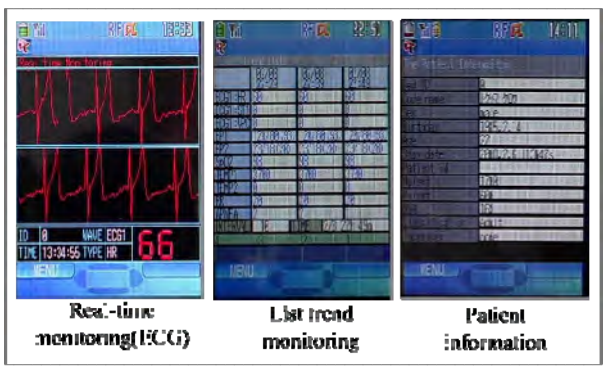

Fig. 2 Monitoring application

checking. Real-time Monitoring shows the real-time waveform of ECG, SpO2, RESP and so on. The bottom of the screen also shows the basic information of the waveform, the time shown on the bed side monitor and the average value. Fig. 2 shows "HR=66". List trend monitoring shows the patient's numeric data of the last 4 days. Doctors can check several value of the patient in the hospital. Patient information displays the basic information of the patient. This information displayed in this function on the mobile phone corresponds to the data registered with the bedside monitor.

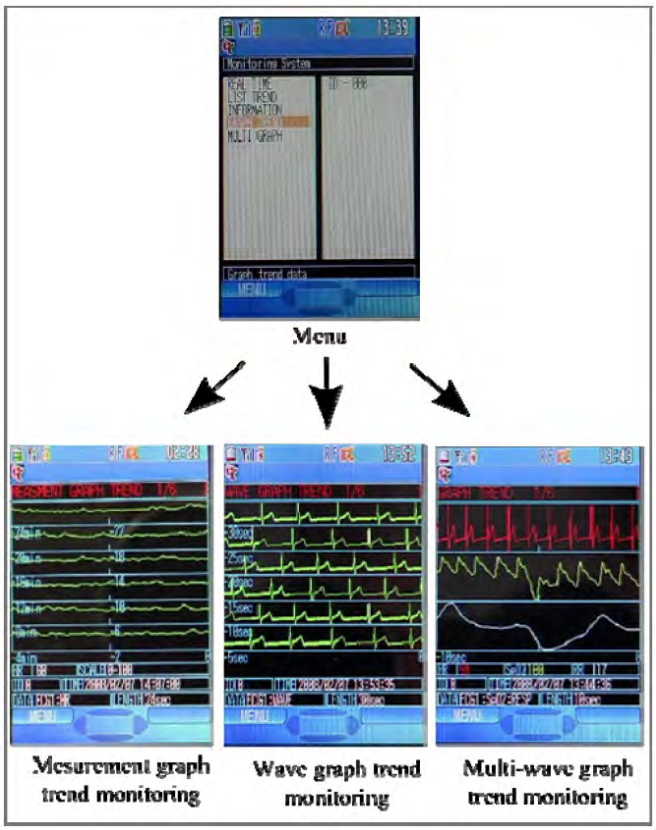

Fig. 3 Graph trend application

There are three modes in graph trend application, as shown in Fig. 3. The first is measurement graph trend monitoring mode that can display measurement data for 24 minutes to the screen on the mobile phone. The second is wave graph trend monitoring mode that can display wave data for 30 seconds to the screen. The last is the multi-graph trend fashion that can display three wave patterns at a time.

B. System Evaluation

Table 1 shows received data size and delay time before acquiring some information with FOMA F901iC.

Table 1 Size of data and delay time

Item	HTTP + PHP processing time[s]	Mobile phone processing time [s]	Size of data[Kbyte]
To get real-time waveform at the beginning	0.42	4.29	1.30
To get list trend data	0.52	6.50	3.24
To get the patient's information	0.27	3.47	0.196
To get the wave graph trend data	1.44	37.3	51.7
To get the multi – wave graph trend data	0.66	23.3	26.3
To get the measurement graph trend data	0.43	7.88	5.07

As is showed in Table 1, the time used for transferring is related to the size of data. And processing time that HTTP communication and PHP application is negligible compared with the processing time of the mobile phone. The processing time of mobile phone costs the most of delay time. Wave graph trend data and multi-wave graph trend data acquiring the waveform of the long time is big size of data and it take much time till mobile phone is displayed it. Therefore we compressed it to reduce delay time.

C. Compression Algorisms

A simple method to reduce the size of data is to decrease sampling rate of the original data. However, this method isn't adequate method for a complicated wave pattern such as the ECG. ECG wave appears in turn a wave that changes suddenly (Q-wave, R-wave, S-wave) and a wave that changes slowly (P-wave, T-wave). If Sampling rate is matched with Q,R and S-wave, it is redundant that P and T-wave do a sample of wave in this sampling rate. Therefore, with the following method, we compressed it.

1. Original data is made the resolution that match with the width and height of the screen of the mobile phone.
2. It is similar to the data by a straight line, and the point that is necessary for drawing is chosen.
3. The chosen data are drawn on the screen of mobile phone as the waveform.

Table 2 Data size and delay time after having compressed

Item	Delay time [s]	Size of data [Kbyte]
To get the wave graph trend data	12	15
To get the multi-wave graph trend	8. 5	8. 30

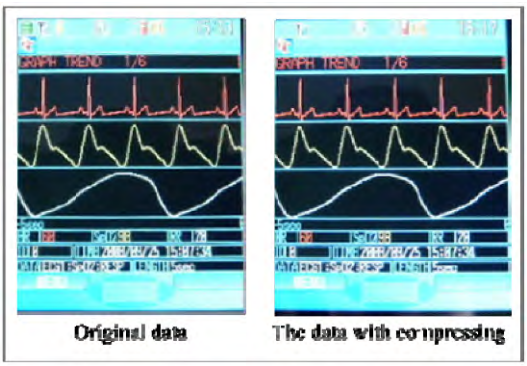

Fig. 4 Comparison with original data and the compressed data

As is showed in Table 2, size of wave graph trend data and size of multi-wave graph trend data was decreased for about 15 Kbyte and 8.30 Kbyte each by compressing data with algorisms. And each delay time was able to decrease. As is showed in Fig. 4, it is said that compressing waveform is almost not different from original waveform. Delay time was able to be decrease, but it cannot be yet said that it is displayed smoothly. Therefore, more attention should be put on the improvement of the performance of the application, including adopting new compressing algorithms and so on.

IV. Conclusion

In this paper, new function “graph trend application” and compressing algorithms are introduced to the Remote Monitoring System for ICU/CCU by a 3G mobile phone to make the system more useful and quickly. The proposed system can provide high level patient monitoring to doctors and do a powerful supporting to save patient’s lives when doctors are outside the hospital.

Abstract — **The point of this study is on the development of wireless patient monitoring system that can monitor heart rates in real time environments. The entire system consists of a portable photoplethysmography device, a healthcare server and a Smartphone for healthcare information reports. The portable device collects heart rate information from the patients and sends the data to home healthcare server. This device is designed to be easily worn and have low power consumption. The role of the healthcare server is to analyze the collected biomedical signals. The result of the analysis is displayed on the Smartphone through the CDMA networks. The application program on Smartphone gives the healthcare information to patients and doctors. This system would be useful for patients who have chronic heart disease.**

Keywords — **Heart Rate, Photoplethysmography (PPG), Smartphone, Personalized Comment Service, Telemedicine**

I. Introduction

The recent progress in personal healthcare device such as blood pressure monitor, electrocardiogram (ECG) monitor, pulse oximeter and blood sugar monitor has made ubiquitous healthcare easier. Now, there are lots of devices which are portable and easy-to-use in that field. It has been developed with multiple functions not only real time monitoring but also doing signal analysis and signal transfer to doctors using wireless communication technology. It means that patient can receive healthcare services such as prevention, diagnosis and prognosis management at any time and in any place [1] with the help of small personalized monitoring devices. Furthermore, it could be performed without visiting hospital regularly.

However, people may feel the lack of personalized healthcare comment service contents, in spite of efforts to develop of various personal healthcare devices for health monitoring under ubiquitous healthcare management environment.

We propose a heart rate (HR) monitoring system model that aims to easily measure of HR, and to provide personalized comment service in daily life. This system integrates Smartphone into giving meaningful information and Bluetooth™ technology, CDMA (Code Division Multiple Access) network for healthcare data transferring. In this paper, the Smartphone based monitoring system has been preliminary evaluated. This system is focused on enhancing the quality of healthcare service for people who do not visit their physicians on a regular basis in medical interpreting aspects.

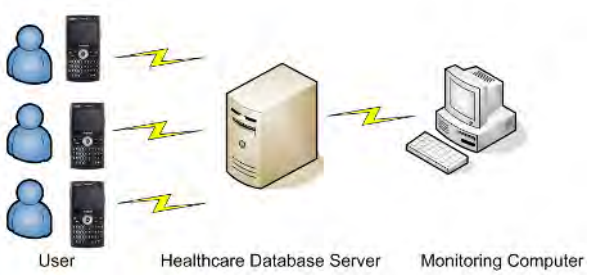

Fig. 1 Proposed scenario using Smartphone

II. System Design and Implementation

The aim of this study is to design and implement a mobile system can monitoring heart rate. This Smartphone based system provides general healthcare comment of heart rate. It not only provides healthcare comment to user but also send the physical data of user to physician for review and consultation. Fig. 1 shows the architecture of the proposed application in this study. The heart rate caring system consists of three parts which include a heart rate measurement module to acquire the user's physiological data, and a Smartphone based mobile unit for data review with programmed physician's comment and healthcare database server for data recording and backup.

A. Heart Rate Measurement Module Description

ECG is widely used as one of the most simple and effective methods of continuously monitoring the heart for telehealthcare and conventional medical care [2]. Although it has been used widely for heart rate monitoring however, it has some uncomfortable aspect when people without have sufficient medical knowledge use this device. For instance, at least 3 electrodes will be required for heart rate measure-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1116–1119, 2009
www.springerlink.com

ment [3] and user has to know the proper placement of each electrode.

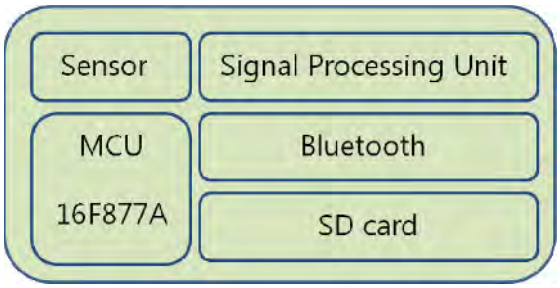

Fig. 2 The Scheme of PPG module

In contrast to ECG, photoplethysmography (PPG) is a simple and low cost optical technique that can be used to detect blood volume changes in the microvascular bed of tissue [4]. The most recognized wave form feature is the peripheral pulse, and it is synchronized with each heartbeat [5]. According to recent research, the component of PPG pulse is synchronous with the beating heart. The pulse rate based on finger photoplethysmography always agreed with the heart rate based on the ECG [6]. Therefore the pulse of PPG can be a source of heart rate information.

In accordance to previous study result, the analog circuitry of the HR measurement module was designed based on the photoplethysmography and a CHUNJIIN oxygen sensor (CJ002R, finger probe type) was used to measure the PPG signals. This module consists of an analog circuit for photoplethysmography, secure digital (SD) memory module (SD-COM-RTC, ELPOT Co.) for raw data storage, serial communication module and Bluetooth™ module (FB155BC, Firmtech Co.) for data transmission.

The main control unit of this module is an 8-bit microcontroller, PIC16F877A, which has 10-bit multi-channel Analog-to-Digital converter. It digitizes the signals with a sampling frequency of 200Hz for heart rate estimation. The heart rate measurement module transmits the estimated HR data to the Smartphone through Bluetooth™. Fig. 2 illustrates the heart rate measurement unit.

B. Mobile Healthcare Module Description

The Smartphone (Samsung, SPH-M6200) was used as the user's heart rate data review device. Basically, this user terminal device performs HR data analysis. It transmits data of biomedical signal between Smartphone and healthcare data server by CDMA network. We developed an application program in C#. In the proposed design, it adapted for client-server architecture, with Smartphone unit serving as the client end and the healthcare server unit serving as the server end. Through this architecture, doctor could review the HR data of multi users. In this system, Smartphone works as a HR information provider, so the users can review their daily physiological data to get a personalized description and prescription by programmed classification.

C. Diagnosis of Heart Rate Status by Rule Based Algorithm

Rule based algorithms were applied to this system for determine the heart status of the user. Through this method, we could offer the descriptions and prescriptions of heart rate case-by-case. The rule based algorithm was verified by the medical doctor in Wonju College of Medicine, Yonsei University. A classification program, developed by Microsoft Visual Studio™ 2005 (Microsoft, USA), was installed on the Smartphone and healthcare database server to provide heart rate review result respectively.

The automatically provided description and prescription is dependent on user's present and past data. Consequently, collecting and reconstructing data of heart rate is essential. The information of heart rate status is generated by the following series.

1. Current Heart Rate State Classification

The classification of current heart rate status was reorganized according to '2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care [7]' and clinical experiences. We suggested HR state to emergency, alert, abnormal, normal1 (slow) and normal2 (fast). Fig. 3 shows the classification of heart rate present status.

2. Classification of Heart Rate Up and Down State

This part represents the comparison between present state of HR and their mean value during first week in the previous month. It has three classification of up, same, and down. Fig. 4 shows the classification of up and down status.

3. Variation Steps in Classification of Heart Rate Up and Down State

The step variation of up and down is defined as the step difference between present data during the period of seven days in the previous month. There are in total of eight steps in this part. Fig. 5 shows the step variations in heart rate status.

4. Heart Rate Status Information Provider

Almost of available HR status and the possibility were checked by physicians. The information is assigned according to the available HR status. Provided information consist of two parts. The first part is the objective explanation of the present HR data, and the second part is the medical

doctor's suggestion or comment on each one of the different HR data state combinations.

5. Selected Examples of Description and Prescription

- Your current heart beat is extremely slow. You have bradycardia.
- It is hard to maintain the blood pressure when the heart beat is 40 or lower because the amount of blood pumped out of the heart decreases significantly. You need to get test as soon as possible.
- Heart beat is affected by autonomic nerve, so it constantly changes according to our bodily conditions.
- Heart beat of 50 or lower could result from temporary rest, other medicines, and heart diseases. If there are no evident symptoms, no special treatments are required. However, if you have breathing problems, vertigo, emesis, nausea, chest pain, then a checkup is needed.

D. Healthcare Database Server

The healthcare data includes personal information, heart rate. It was collected at Smartphone first and then sent to healthcare database server at hospital. The respective data from each user's Smartphone are sent through TCP/IP communication or CDMA network. The physician in charge could get their patient form this server. This, though a simple application program, could allow them review the healthcare data.

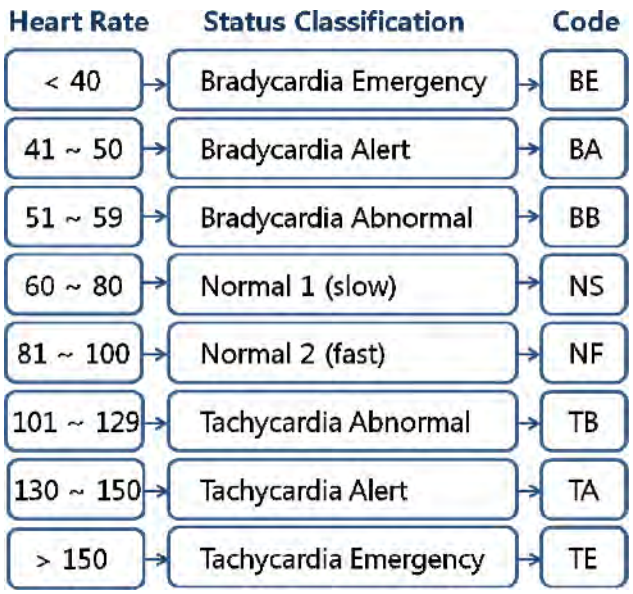

Fig. 3 Classification of heart rate present status

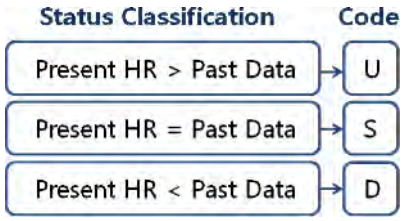

Fig. 4 Classification of up and down status

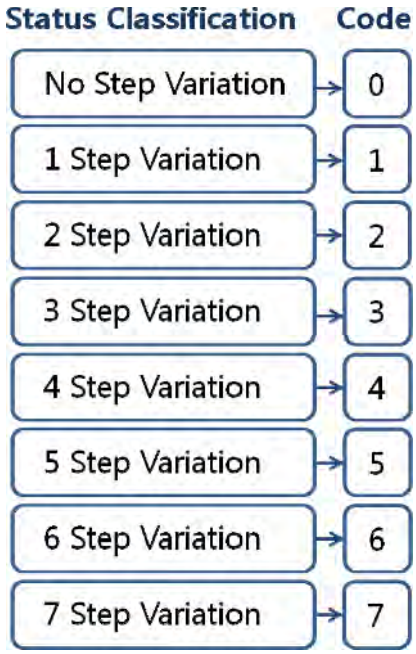

Fig. 5 Step variations in heart rate status

III. Conclusions and Discussion

In this preliminary study, we proposed a heart rate caring service for user using Smartphone. In these days Smartphones are reasonably priced and are becoming increasingly popular with powerful functions on it, not to mention its large storage space. Thus, a Smartphone based telemedicine system without doctor is cost effective solution in a range of medical applications [8]. It is a suitable for daily self-checking user's health parameters.

Knowing the physical change of oneself while they live is very important. It prevents and allows for an early treatment strategy that makes the health management systematic and stable.

This proposed system has two major advantages. Firstly, it offers a chance to review of heart rate changes to general user in medical interpreting aspect. Secondly, it provides

personalized comment of heart rate to user based on case-by-case analysis.

ACKNOWLEDGMENT

This study was supported by a grant from the Korea Health 21 R&D Project, Ministry of Health & Welfare, and Republic of Korea (A020602). The authors would like to thank Mr. Kim Oh Hyun and Ms. Park Mi Jung in Wonju Christian Hospital, Wonju, and Republic of Korea for their help in medical consultation. The authors would also like to thank Mr. Uh Soo Yong for help in research assistance.

Abstract — **This study aims to investigate the effect of music on human central nervous system fatigue during his various activities. In general, fatigue is viewed as an unavoidable and negative consequence of physical activity, since the outcome almost exclusively results in reduced performance and function. Fatigue can occur in two basic mechanisms, central and peripheral fatigue. Even though peripheral fatigue plays a role in reducing the efficiency of performance, here in this study our interest is central fatigue. For simplicity in investigation, we executed the study with jogging, using EEG as a tool to quantify the parameter.**

Eleven male volunteers with a mean age of 22.45 years (range 18 – 24 years) and mean weight of 70.45 Kg (range 52 to 92 Kg) participated in the study. EEG signals were acquired while an individual undergo jogging on a treadmill until individuals feel tired. Experiment was divided into two set: in first experiment individuals used to jog without hearing music and during second experiment they were jogging with music. The data was preprocessed and ANOVA tests were performed to determine the relation between the mental fatigue during absence of music and the presence of music. The results is evident that, hearing music while jogging significantly decreases the mental fatigue and thus the overall duration of jogging has been elongated

Keywords — **Electroencephalogram, Cognitive fatigue, Jogging, Effect of music, Stochastic analysis**

I. Introduction

Walking and jogging is a form of trotting or running at a slow or leisurely pace. The main intention is to increase fitness with less stress than actually running, instead of competition. Jogging is an excellent means of improving cardiovascular health, bone density, and physical fitness. In contrast, in endurance performances for hours or even minutes without any break, an incline in performance will occur. The sustained muscular contractions externally associated will not being able to maintain certain force, lead to physiological fatigue, tremor or pain, localized in the specific muscle. This is called muscular fatigue [1].

Fatigue can occur in two basic mechanisms, central and peripheral [2]. In central fatigue, proximal motor neurons of the brain and spinal chord are involved. However in peripheral fatigue motor units of peripheral nerves, motor endplates and muscle fibers are affected [3]. In this study, central fatigue plays a key role and central fatigue is defined as, the failure to sustain concentration tasks and physical activity as opposed to external stimulation [4], which exists in the absence of any clinically detectable motor weakness or dementia.

Today advancement in technology people got habituated to hear music during almost all activity in their day to day life. Does really music play a predominant role for effective work? We have chosen jogging a one of the activity for such analysis, since it plays major role in fitness and rehabilitation centre.

Often music claim to and is believed to have favorable psychological and physiological effects on human beings and other animals [5]. Such effect of music on human central nervous system can be quantitatively studied using Electroencephalography (EEG).

EEG is the measurement of electrical activity of the brain. The resulting collection of traces is known as an electroencephalogram [6]. The frontal and the temporal lobes of the brain are involved in the motion and hearing activity respectively; so, we aim to study the activity of brain in these regions.

To the author's best knowledge there is a little data pertaining to the effect of music on CNS while jogging. This study aims to; examine whether music helps in reducing the mental fatigue while jogging and thus helping the person to jog for a much longer period time than there normal duration.

II. Methodology

A. Subjects

Eleven male volunteers with a mean age of 22.45 years (range 18 – 24 years) and mean weight of 70.45 Kg (range

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1120–1123, 2009
www.springerlink.com

52 to 92 Kg) participated in the study. Subjects were chosen randomly to include a right mixture of persons who are not much involved in jogging or other physical activities and athletes to whom jogging is part of their daily life. All the subjects were healthy during the time of conducting the experiment.

B. Protocol

It was observed during the experiment that the people who do not get involved in much of physical activities get tired very fast when compared to the athletes. However, since we are interested in studying the effect of music on the brain while jogging, we consider a well mixed population.

Subjects were instructed not to participate in any heavy training or physical activity 24 hours prior to their clinical assessment or testing day. They were informed not to apply hair oil before the EEG experiment. They were asked to jog on a Treadmill model –720T for a time period of 15 minutes with an average speed of 6kmph through out the experiment. The EEG signals were recorded two times for each subject. First time when subjects were not listening to music and the second time when were subjects listening to music while jogging. Music digitized at CD quality was played using Nokia N73 MP3 player at an identical intensity for all subjects. The choice of music is decided by the subject itself. Few subjects selected Bollywood music and few selected rock music based on their interest.

The EEG signals were recorded from five surface electrodes (F3, F4, T3, T4 and Cz) placed according to the standard 10-20 system of electrode placement configuration using a battery-powered, MITSAR-20 EEG amplifier instrument. A plastic mesh is placed on the subject's scalp to identify the positions of signal electrodes and then the electrodes were pasted on the required positions. In addition to the proposed positions 2 electrodes (A1, A2) one to each ear and one neutral is also connected. The EEG gel is used to paste the electrodes which act as an excellent conductor.

The EEG is activity is captured by WINEEG software using sampling rate of 250 Hz and gain of 3000 EEGs were acquired at identical hours of the day for all subjects. This time of the day was chosen, based on the results of a campus-wide survey, to coincide with the hours of maximum physical activity. All experimental data were recorded at the Rehabilitation Bioengineering Group (RBG) laboratory, IIT Madras.

C. Analysis

EEG raw data were contaminated with noise, which had to be eliminated through a pre-processing procedure. Generally, the raw signals of the EEG larger than 50–70 μV were treated as artifact. Under this assumption, the artifacts were removed through Independent Component Analysis (ICA) with the help of WINEEG software.

The pre-processed data were separated into θ (4–8 Hz), α (8–13 Hz), and β (13–22 Hz) bands with the help of MATLAB. The δ (0.5–4 Hz) band was not included in our analysis. The powers of alpha, beta and theta are calculated at time intervals 30–50 sec, 4 min–4min 20 sec, 8 min–8min 20 sec, 11 min–11min 20 sec and 14 min–14min 20 sec.

$$P_{\alpha} = 100 \times \frac{\text{Power Range 8-13Hz}}{\text{Total Spectral Power}}$$

Using these powers the overall increasing or decreasing slopes with respect to time were calculated using a linear fit. The presence of music, position of the electrode and subjects were the other variables in calculating the slope of these powers additional to the wave form (α, β, θ) itself being a variable.

D. Statistical Analysis

The results obtained are further analyzed statistically using the N-way ANOVA toolbox in MATLAB to find whether there is any significance difference in these powers with respect to the presence of music.

III. Result

Sample power spectrum of EEG acquired from the five different electrodes before and after pre processing is shown in figure 1 and 2

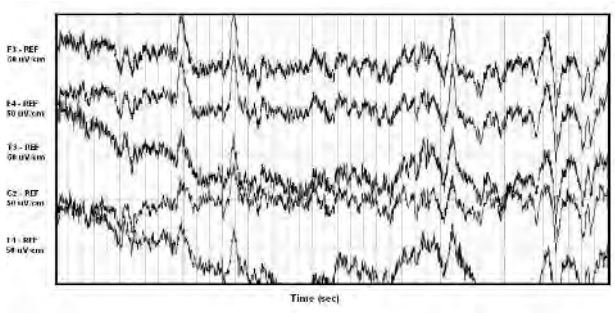

Figure 1 Raw EEG data of the 5 electrodes in the order F3, F4 T3, Cz, T4 with respect to time.

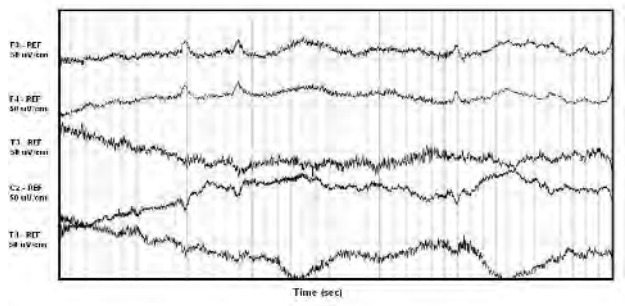

Figure 2 EEG data of the electrodes after the removal of artifacts using the Independent Component Analysis

A sample of the linear fit of the Power of α vs. Time is shown in the Figure 3.

Table 1 shows the statistical analysis of the data using n-way ANOVA.

IV. Discussion

Music has been believed to have favorable physiological and psychological effects such as reducing stress, increasing the degree of calm *etc*. Many studies [7–9], have been conducted in the past to verify the validity of music while performing various physical activities mostly followed an approach in which the brain activity was not studied. However it was evident from their research that music definitely has a positive effect and enhances the performing of the activity. In our experiment, we considered the study of the EEG activity of the brain which also revealed that music definitely has a significant affect on the brain while jogging.

Previous studies used analysis of subjective information. Rauscher *et.al*. [10] used various spatio-temporal cognition tasks. Steel *et.al*. [11] tested the performance of subjects on backward digit span. Bridgette *et. al*. [12] used a mathematical test. Stratton [13] used the stress perceived while waiting as an indicator. In our study, the notable difference is that the analysis was quantitative and used well developed statistical techniques. While processing the signals obtained, the signals are filtered to remove any out-of-band noise and artifacts, further decomposition of the signals into independent components or the application of other noise cancellation methods were not undertaken since the study was looking for differences between correlated pair-wise samples of activities before and during exposure to music. In addition to analysis, we also targeted an activity in which much of the physical motion of the subject is involved as physical fatigue of the subject is also related to the brain activity.

The Multivariate analysis of variance (MANOVA) result infers that, there is a significant ($p < 0.0168$) difference between EEG waves (alpha, beta and theta) with subjects. With-in subject, our result infers that there is significant ($p<0.0369$) different between with and with out music. An existence of the trend can be observed for the music*wave interaction effect with a significance of $0.081 < 0.1$. MANOVA result shows that significant difference we seen in EEG rhythms (alpha, beta and theta), subject with and without music during jogging.

V. Conclusion

This study helps us to understand the effect of music on the brain while jogging. From the results, it is evident that

music definitely has a significant effect on the human brain while jogging; however our study does not reveal whether listening to music has a decrease or increases the mental fatigue. Therefore a further study can be conducted to find out whether music really decreases the mental fatigue and thus helping the person to jog for a much longer period of time.

ACKNOWLEDGMENT

The authors wish to thank all the members of Rehabilitation Bioengineering Group (RBG) at IIT Madras and the volunteers who participated in this study.

System for Conformity Assessment of Electrocardiographs

M.C. Silva[1], L.A.P. Gusmão[2], C.R. Hall Barbosa[1] and E. Costa Monteiro[1]

[1]Post Graduation Program in Metrology, Pontifícia Universidade Católica do Rio de Janeiro, Brazil
[2]Electrical Engineering Department, Pontifícia Universidade Católica do Rio de Janeiro, Brazil

Abstract — **Safety and performance assessment are essential for most medical devices. In some countries they are mandatory at least prior to the launch of the equipment in the market. Aiming at contributing with the assurance of the metrological reliability of analog and digital electrocardiographs (ECGs), this work presents the development of a system for ECG conformity assessment according to IEC 60601-2-51 and OIML R90 standards. The proposed system has been calibrated with traceability to SI units and is structured in two subsystems: evaluation of electrical safety and evaluation of performance. The first subsystem performs grounding tests, leakage current tests and insulation tests, and is based on commercial equipment. The second subsystem evaluates the metrological characteristics of ECGs and is composed by software in LabVIEW, a digital-to-analog converter and three signal conditioners. The system has been evaluated using two digital ECGs in use in a public hospital of Rio de Janeiro. The tests performed indicate that the system complies with the requirements of IEC 60601-2-51. It has been observed a maximum error on the standard signals lower than 1% during the calibration of the equipment that integrates the performance evaluation subsystem. The non-conformities observed during the system validation by means of ECG essays were probably due to the high noise level present in the hospital environment, being necessary the continuous use of digital filters. Also, limitations on the system concerning common-mode rejection ratio, temperature drift and reticulate of time and amplitude have been observed and solutions are being studied.**

Keywords — **Metrology, Electrocardiograph, Metrological Reliability, Conformity Assessment, Biometrology.**

I. Introduction

The measuring instruments used for biomedical application need metrological evaluation in order to guarantee their reliability concerning safety and performance [1].

The International Organization of Legal Metrology (OIML) elaborates international recommendations for measuring instruments as a base for the metrological regulation used by a specific National Metrology Institution (NMI). Concerning health, there are about 13 OIML metrological recommendations, being three of them already adopted by the Brazilian NMI.

Despite the fact that (pre-sales) type approval and (post-sales) periodic verifications are routinely used in legal metrology for the metrological control of measuring instruments, medical electrical equipment are usually only required to go through type approval. Type approval for medical electrical equipment (MEE) usually involves compliance with the IEC 60601 standard series, containing prescriptions of safety and performance for MEE.

Particularly, for electrocardiographs (ECGs), although existing a specific international metrological recommendation from OIML (R-90 for analog ECGs)[2], it has not been adopted as a metrological regulation by the Brazilian NMI. By means of the study of the R-90 and of the IEC 60601-2-51 Standard [3, 4], containing the particular requirements for safety and essential performance of recording and analyzing single channel and multichannel electrocardiographs, the present work has developed a preliminary system for ECG conformity assessment, aiming to contribute with the elaboration of a specific metrological regulation for ECGs [5].

II. Materials and Methods

The IEC 60601-2-51 standard classifies electrocardiographs as recording ECGs and analyzing ECGs. The recording ECGs are divided into analog and digital without automated measurement. The analyzing ECGs are digital devices with automated measurement of electrocardiograms, including or not the automated signal interpretation.

IEC 60601-2-51 divides the performance evaluation in two kinds of tests:

Accuracy of operating data (section 50): this test aims at evaluating the reliability of analyzing ECGs measurements.

Protection against hazardous output (section 51): this test evaluates the essential characteristics of all kinds of ECGs.

The system presently developed contains qualitative and quantitative analysis and has been divided in two subsystems: electrical safety and performance evaluations.

The *electrical safety evaluation subsystem* evaluates the protection against electric shock hazard (IEC 60601-1). In order to perform these tests, a commercial equipment has been used (601 Pro Series$_{XL}$ International Safety Analyzer).

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1124–1127, 2009
www.springerlink.com

By means of this equipment, grounding, leakage current and insulation tests have been performed.

The performance evaluation subsystem evaluates metrological characteristics of ECG. It comprises software in LabView, a digital-to-analog converter and three signal conditioners. This subsystem evaluates ECGs according to section 50 and 51 of IEC 60601-2-51.

Since the procedures and conditioners used for the correspondent tests of section 50 and 51 are very different, this subsystem has been divided in two parts: *part 1- evaluation of operating data accuracy* and *part 2 - evaluation of protection against hazardous output.*

The part 1 of the performance evaluation subsystem *(operating data accuracy)* includes:

Database: It provides the characteristics of the signals to be generated by the software ECG/MPD. It is based on the database adopted by the IEC 60601-2-51 standard and includes signals to cover sub-sections 51.107 and 51.109;

Software ECG/MPD: This software has been developed in LabView and is used to simulate the ECG recordings and signals, in order to cover sub-sections 51.107 and 51.109;

D/A converter: Converts digital signals to be used by the analog ECG conditioner.

ECG conditioner: Conditioner circuit that attenuates and adjusts the analog signals to be directly connected to the patient cable.

The part 2 of the performance evaluation subsystem (*protection against hazardous output*) comprises qualitative and quantitative evaluations. For the quantitative tests it was developed an equipment including 5 parts:

Signal Generator Software: developed in LabView, it generates sinusoidal, triangular, square and pulse signals.

D/A converter: the same used for the part 1 of the performance subsystem;

MPD/Signal Generator conditioner: it simulates the signals of the *Software Signal Generator* and is used together with the ECG/MPD software to simulate signals to cover sub-sections 51.107 and 51.109;

E-P Conditioner: it simulates the electrode-skin impedances, in order to evaluate noise and common mode rejection ratio;

Mains Voltage Noise Simulator: Simulates the noise due to the mains voltage that is superimposed to the heart's electrical potential and the capacitive impedance between the patient and the ground terminal.

In order to perform the preliminary evaluation of the developed system for conformity assessment of ECGs, measurements have been done in two recording ECGs (brands A and B) in use in a public hospital of Rio de Janeiro. Since the test of *operating data accuracy* described in the section 50 of IEC 60601-2-51 applies only to analyzing ECGs, procedures have been developed for the accuracy evaluation of the amplitude of recording ECGs using the IEC database and the amplitude specification indicated in the OIML R-90 recommendation [2].

Table 1 shows the sensitivity-setting, database and leads used to perform the ECG evaluation.

The maximum permissible limits used for conformity assessment were the ones specified in the IEC 60601-2-51 standard (±25 μV for reference values lower than or equal to 500 μV, or more than 5% or ± 40 μV – the highest – for reference values above 500 μV).

Table 1 Sensitivity-setting, Database and Leads used during accuracy evaluation of the amplitude of ECG

Sensitivity-setting (mm/mV)	Database	Leads
20	CAL05000 CAL10000	I, aVL V1, V2
10	CAL10000 CAL20000	II, aVF V3, V4
5	CAL20000 CAL40000	aVR, V5 V6, aVL

During the ECGs evaluation, the gains used in LabView were related to the attenuation values adjusted at the moment of measurement (Fig.1).

In order to guarantee the metrological reliability of the developed system and the results obtained with both ECGs, the system has been calibrated with traceability to SI, at the Metrology Laboratory of the Electronics Material Depot of the Air Force at Rio de Janeiro (PAME-RJ). This calibration has been performed in the ECG Conditioner and in the MPD/Signal Generator Conditioner [5].

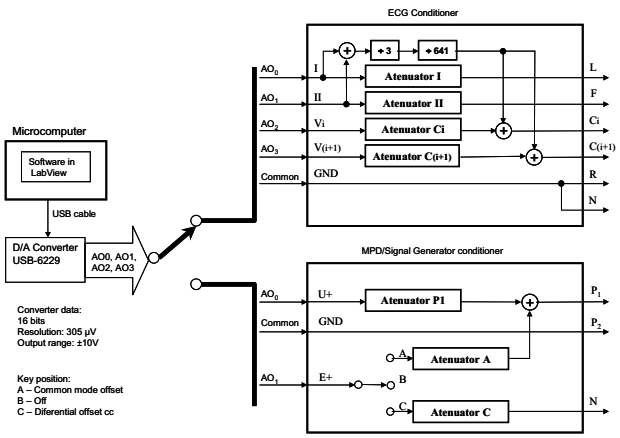

Fig. 1 Block diagram of the calibrated system

In Figure 1 are shown the 6 outputs of ECG Conditioner to be connected to the ECG being evaluated. In this conditioner, each electrode has a connection previously established, except for the chest electrodes. In this last case the evaluation is performed in pairs: C1 and C2, or C3 and C4, or C5 and C6. In the case of the *MPD/Signal Generator Conditioner*, the evaluation is performed between two electrodes or a set of electrodes, whose connections change as a function of the test described in section 51 of the Standard.

During the calibration of the developed system, the level of attenuation was measured in each attenuator

III. Results

By means of the study of the IEC 60601-2-51 standard, the best positions to measure the attenuation level and to perform the calibration of the *ECG conditioner* and of the *MPD/Signal Generator Conditioner* were identified and are presented in Table 2.

Table 2 Attenuation levels measured for the attenuators of Fig. 1.

Attenuator	Attenuation level during ECG evaluation	Measured attenuation level	Error (%)
I	650	650.8	-0.12
II	650	653.4	-0.52
C_i	650	650.7	-0.11
$C_{(i+1)}$	650	652.2	-0.34
P_1	1001	1008	-0.69
A	28	28.23	-0.81
C	28	28.65	-2.27

Since the error between the attenuation level used during the ECGs evaluation and during calibration was lower than 1% for attenuators I, II, C_i, $C_{(i+1)}$ e P_1, this error has been disregarded in order to facilitate the analysis of results.

The ranges used to perform the ECG conditioner calibration were between 100 µV and 5000 µV and between -100 µV and -5000 µV. The maximum values of error and uncertainty [6, 7] are presented in Table 3. The smallest uncertainty observed in the conditioner outputs was 0.40µV.

Table 3 Values obtained during calibration of the ECG Conditioner

Output	Largest Error		Largest Uncertainty	
	RV (µV)	Error (%)	RV (µV)	$U_{95,45\%}$ (µV)
L	-100	-0.64	-4000	±0.52

RV – Reference value; $U_{95,45\%}$ - Expanded uncertainty for a 95.45% level of confidence

Both ECGs evaluated were compliant to electrical safety requirements according to the IEC 60601-1 standard.

By evaluating the amplitude accuracy, it has been observed that the ECG of brand A presented better results with the digital filters turned off, and the one of brand B using the digital filters (Table 5). Nevertheless, both ECGs presented non-conformities for the sensitivity setting of 5mm/mV.

Since the IEC 60601-2-51 standard does not define anything about the use of digital filters during measurements of protection against hazardous output, in all of these tests the result analysis had to be performed with these filters turned on and off. In general, the recordings presented a high noise level, hindering the evaluation that proceeded with a sequential introduction of filters until achieving an adequate signal to noise ratio (Table 6).

Table 5 Non-conformities identified in the ECGs for the sensitivity-setting of 5 mm/mV during amplitude accuracy evaluation

Brand	Amplitude (µV)	Database	Derivation	Error (µV)

IV. Discussion

The measurements performed in two ECGs using the system developed for conformity assessment have shown non-compliances with the performance standard requirements for both equipments.

Concerning the accuracy of amplitude evaluation, the results indicate non-compliances that might have been caused by limitations such as: high noise level in the measurement environment; the necessity of the use of filters during tests, which can generate an error in the measurement of the ECG output signals.

In order to make a complete performance analysis of the ECGs it has been necessary to complement the IEC 60601-2-51 requirements and technical guide with the OIML R-90 recommendation. The latter is directed to a single type of recording ECG (the analog ECG) but the detailed information of this recommendation has been used for accuracy evaluation of the amplitude and in some tests of protection against hazardous output.

V. Conclusions

The system developed for conformity assessment of ECGs complies with the requests of IEC 60601-2-51 for the evaluation of recording ECGs, and partially, of analyzing ECGs. The observed limitations concerning the common-mode rejection ratio, temperature drift and reticulate of time and amplitude have been characterized and solutions are being studied.

After solving the detected limitations and increasing the number of outputs of the D/A board to eight outputs, the system will be able to perform all essays of IEC 60601-2-51, making it possible to evaluate all types of ECG.

Abstract — **This article proposed a computer-aided engineering process that is to fabricate a prosthetic socket using rapid prototyping technology. Moreover, since current RP machines use a layer-based process to manufacture products, this result in RP products liable to break along layers once bending moment is applied. To prevent RP prosthetic socket from breaking, this study proposes wrapping a layer of unsaturated polyester resin (UPR) around the prosthetic socket to reinforce its strength. Factors affecting the strength of the resin-reinforced RP socket include thickness and forming orientation of the preliminary RP socket, thickness of the UPR layer, and type of material used to make the preliminary RP socket. This study employed Taguchi experimental design method to design a series of test specimens for use by the 3-point bending test. Based on analysis of the results of the bending strength test, the design parameters for a resin-reinforced transtibial socket of appropriate strength can be determined. The preliminary RP socket for a specific transtibial amputee is fabricated using an FDM machine and then wrapped with a reinforcing layer of UPR.**

To confirm the applicability of the resin-reinforced socket developed in this study, the measurement of interface pressures between the residual limb and the socket was implemented. Analysis of the result of this measurement would assist a prosthetist to realize the distribution of interface pressures at the pressure-tolerant (PT) and pressure-relief (PR) areas of the residual limb while the resin-reinforced RP socket is being worn. The result of this study demonstrates that by integrating a CAD system, reverse engineering and RP technologies, a qualified resin-reinforced RP socket can be fabricated that meets the requirements of a transtibial amputee. The quality uncertainty of sockets can be improved if the proposed socket and the corresponding production procedure are adopted to replace the traditional manual method of fabrication.

Keywords — **Prosthetic socket, Transtibial amputee, Rapid prototyping, Resin reinforcement.**

I. Introduction

Introducing the contemporary technologies involving rapid prototyping (RP) and CAD systems provides an alternative means to overcome the shortcomings of the conventional process of fabricating prosthetic sockets. Since the emergence of rapid prototyping technology, a variety of prosthetic sockets have been designed and fabricated using various types of RP machines that include stereolithography (SLA), selective laser sintering (SLS), fused deposition modeling (FDM), and droplet/binding [1,2]. Although RP technology has been employed to develop prosthetic sockets for almost two decades, no RP prosthetic socket provided by prosthesis industry has really ever been used in daily life. That is because any object fabricated by current layer-based RP machines is liable to break along the forming layer. Therefore, a method of wrapping a carbon fiber layer was proposed to reinforce the strength of RP sockets [3]. Fuh et al. [4] also suggested that coating a reinforced layer on the RP socket would improve its strength.

A project aimed to develop a plaster-free process (Fig. 1) that employed the contemporary technologies including a scanner, CAD systems together with RP machines [5]. That

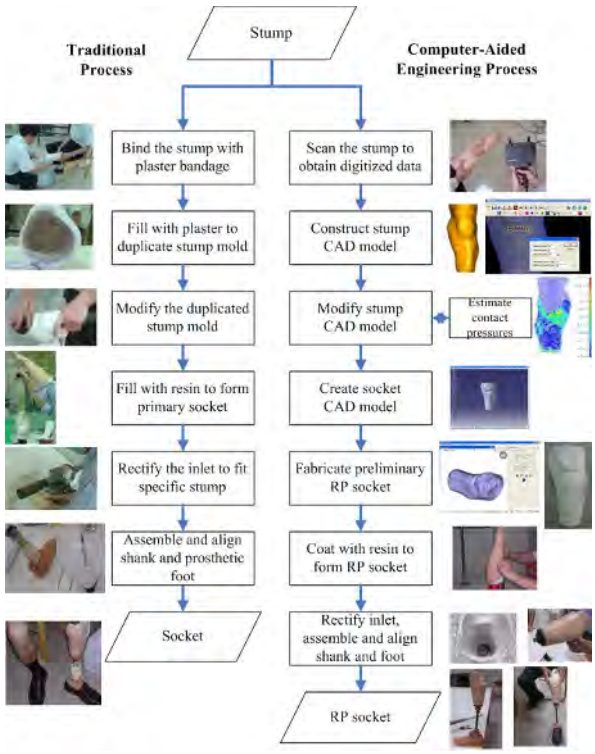

Fig. 1 Comparison between traditional and computer-aided approaches

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1128–1131, 2009
www.springerlink.com

project concluded that prosthetic sockets fabricated by RP machine are liable to break along forming layer during the implementation of testing RP prosthetic socket. To prevent RP prosthetic socket from breaking, wrapping a layer of unsaturated polyester resin (UPR, a widely adopted material in conventional socket manufacturing process) around the prosthetic socket to reinforce its strength is then proposed. This idea also raised the problem of determination of factors affecting the strength of the resin-reinforced RP socket. The bending strength of this proposed socket might need to be validated by a testing process such as the three-point testing method. An experiment reported in this paper is to determine the appropriate parameters including RP material, thickness of the RP layer, forming orientation of the preliminary RP socket, thickness of the UPR layer coating for building resin-reinforced RP prosthetic sockets of proper flexural strength.

II. METHOD

A. Three-point bending test and Taguchi experiment method

To confirm the parameters that affect the strength of RP socket a series of bending strength tests are implemented. We apply the Taguchi method to data analysis of the bending test in order to find out the best parameters of the RP prosthetic socket, including thickness of the RP layer, thickness of the UPR layer, the RP material and RP fabricating orientation, and the relationship illustration is shown in Fig. 2. Based on the ASTM D790 [6], a standard method for testing the flexural properties of reinforced plastics, the specification of a testing specimen is designed and an MTS universal tensile testing system is used (Fig. 3). To simplify the experiment, the Taguchi method [7] helps to compare all the parameters.

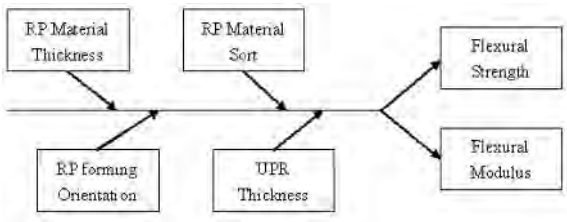

Fig. 2 The relationship of the parameters

Based on the expertise of a prosthetist and RP techniques, the level values of the parameters are determined as follows: RP materials selected in this study including ABS, PC and gypsum; the thickness of specimen made by RP machine designated as 1.5 mm, 2.0 mm and 2.5 mm; the thickness of

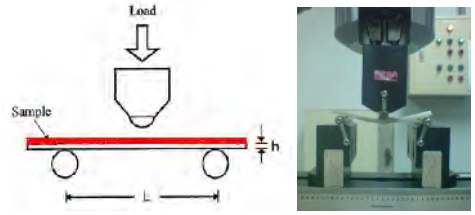

Fig. 3 The layout and a MTS machine used for three-point bending test

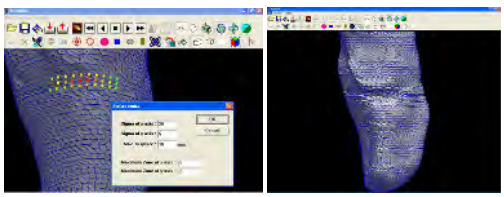
UPR layer coated onto RP specimen 2.0 mm, 2.25 mm and 2.5 mm; the forming orientation of RP specimen. Taguchi method provided the appropriate orthogonal array (L_9 in this study) is selected to carry the reasonable number of experiments. According to the calculation values of the flexural strength and flexural modulus from the MTS testing data, the ratio of signal and noise can be estimated the best performance parameters as shown in Table 1.

Table 1 Best collocation of the prosthetic socket fabricated by FDM and 3D printing

RP type	FDM	3D printing
RP Thickness	1.50 mm	2.00 mm
UPR Thickness	2.50 mm	2.50 mm
RP Material	ABS	Gypsum
Forming orientation	Horizontal	Lie down



The results shown in Table 1 are then used to design socket, two kinds of sockets will be fabricated. The first one is fabricated by FDM, and the other is fabricated by 3D-printer.

B. Design and fabrication of a resin-reinforced socket

Based on the principles of designing a prosthetic socket to achieve the criteria of a qualified prosthesis in terms of comfort, sufficient strength, and good performance, the sensitive (or pressure-relief, PR) areas on a residual limb should not bear too much load either at standing or during the stance phase of the prosthesis. The weight should be supported on pressure-tolerant (PT) areas while the amputee is walking and standing. The PR areas are moved outward and PT areas indented inward according to the expertise of the prosthetist so that the interface pressures between stump and socket can be properly distributed. The shape modification will be proceeded iteratively until biomechanical assessment of the interface pressures on all PT/PR areas meets the load-bearing ability of the amputee. The modified stump shape (Fig. 4) will then be used to design a socket for the specific amputee. With the parameters illustrated in Table 1

to achieve better flexural strength and flexural modulus, the designed socket model with a thickness of 1.5 mm (Fig. 5a) is then acquired and its data in STL format transferred to an FDM machine. A preliminary RP socket with ABS material is fabricated as shown in Fig. 5b.

To reinforce the bending strength of a socket made by RP, covering the preliminary RP socket with six layers of cotton socks, the liquid UPR mixed with hardener was then filled and uniformly squeezed by hand around the socket to allow UPR to infiltrate into the socks' fiber layers (Fig. 5c). The thickness of the resin-reinforced layer is approximate 2.5 mm according to the three-point test specimen. The proximal brim of that resin-reinforced socket is manually trimmed to fit the shape of the stump (Fig. 6).

(a) (b)

Fig. 4 Shape modification during socket design

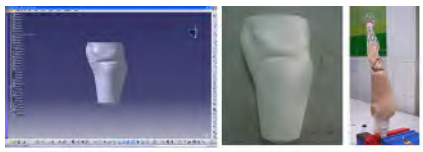


Fig. 5 A socket CAD model, its preliminary RP socket and infiltration of the resin-layer

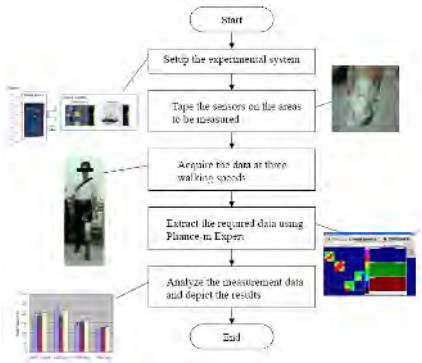
Fig. 6 Trimming the proximal brim, assembling components and fitting the stump

C. Measurement of interface pressures and results

To verify the applicability of resin-reinforced RP socket fabricated by following the procedure proposed as shown in Fig. 1, interface pressures between socket and stump were measured using socket sensors (Fig. 7). A male volunteer (whose residual limb is the stump used in this study) weighing 60kg with a left below-knee amputation was selected in this experiment. A Pliance mobile system® [8] was employed to measure the local pressure distribution at the residual limb and socket interface. The procedure of the measurement for interface pressures is shown in Fig. 7. Due to the preliminary RP socket made of gypsum was brittle and avoiding its rough surface harm to stump, the layer of gypsum was removed. That means the preliminary RP socket fabricated by using a 3D printing machine was used as mold for producing a UPR socket. The measurement results (Fig. 8) showed that the interface pressures either on main PT areas or PR areas have similar distribution.



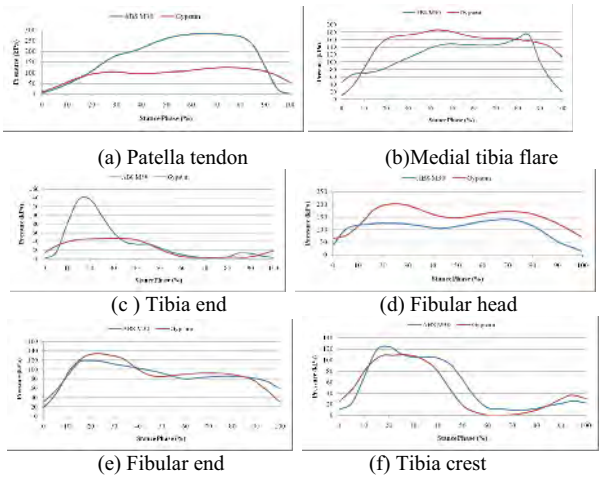


Fig. 7 Procedure for the measurement of interface pressures

(a) Patella tendon (b)Medial tibia flare

(c) Tibia end (d) Fibular head

(e) Fibular end (f) Tibia crest

Fig. 8 The interface pressures measured on some PT/PR areas

III. Conclusions

Using the Taguchi experimental design method and ASTM three-point bending test standard, the parameters that influence the flexural strength of the RP prosthetic

socket coated with a UPR layer could be determined. Based on the better parameters, including thickness of the RP layer, thickness of the UPR layer, the RP material and RP fabricating orientation, the resin-reinforced RP prosthetic sockets fabricated by FDM and 3D-printer RP machines can be normally used by volunteer amputee for walking and implementing the interface pressure measurement.

Two RP-based sockets have been designed and fabricated based on the computer-aided process proposed in this study. This process reduced the quality uncertainty and labor intensity, and also the level of discomfort experienced by the amputee, which are pitfalls of the conventional manual method. An assistant interface used in the proposed process also helps to shorten training time for prosthetists and to modify pressure-tolerant and pressure-relief areas more precisely.

Although the resin-reinforced RP prosthetic socket proposed in this study has primarily shown the applicability for the specific amputee, a long period of trial should be conducted for a durability test. Furthermore, investigation on the trial use of more subjects is needed for testing effectiveness of using this socket type.

A New Phototherapy Apparatus Designed for the Curing of Neonatal Jaundice

C.B. Tzeng[1], T.S. Wey[1], M.S. Young[2]

[1]Department of Electronic Engineering, Kun Shan University, Tainan, Taiwan, R.O.C.
[2]Department of Electrical Engineering, National Cheng Kung University, Tainan, Taiwan, R.O.C.

Abstract — **In this paper, we propose the prototype of a new phototherapy apparatus that ensures a safe and effective therapy against neonatal jaundice. It use the high power LED (with the wavelength within a specified range) as the light source and allows the medical care personnel to adjust the light intensity and the place of the body to be irradiated according to the symptom and jaundice index. The light intensity of each module is adjustable separately at each therapy stage to treat the patient in an orderly way. The current status of the therapy can be monitored by the medical care personnel on the monitor to make appropriate adjustments.**

According to the test and the measurement of the photocharacteristics, the 100% luminance of this system is 2.5 times the luminance of a blue lamp and its wavelength is fixed at 460nm. Therefore, this proposed LED phototherapy apparatus is better than others.

Keywords — **Neonatal Jaundice, Phototherapy, High power LED, Luminance, Light intensity**

I. Introduction

About 80% to 90% new born babies suffer from the "neonatal hyper-bilirubinemia", also known as the "neonatal jaundice", because the liver function of neonates has not been completely developed and, thus, the bilirubin in the blood can not been excreted naturally, resulting in yellow skin and eyes. More than 60% of the neonates and more than 80% of the premature babies suffer from this disease.

The neonatal jaundice may disappear gradually within two weeks and no side effects will be left. This is the so-called physiologic jaundice. If the symptom does not disappear within two weeks, it is reasonable to suspect the occurrence of "pathologic jaundice" that might be brought about by other factors. Excessive bilirubin will damage brain cells and may lead to cerebral palsy or even death. [1-6]

The normal serum bilirubin value of a newborn baby is between 0.2mg/dl and 1.4mg/dl. When it exceeds 5mg/dl, jaundice appears in the skin, fingernail or sclera. The symptom of hyper-bilirubinemia appears when the serum bilirubin value is between 15mg/dl and 20mg/dl. A newborn baby is diagnosed with kernicterus when the serum bilirubin value is higher than 20mg/dl. [2, 4, 5]

Depending on the severity of the disease, the treatment by medicine, phototherapy, and blood exchange are usually used to cure jaundice, among which the phototherapy is the most commonly used approach. It irradiates the skin of the patient with a special light to decompose the bilirubin structure and excrete it through organs. The phototherapy apparatus commonly used by many hospitals at the present, use a timer to control the duration of the therapy and the light source (such as fluorescent lamp) with fixed luminance. With this type of apparatus, the duration of therapy is controlled manually or through a timer, without the possibility to adjust the light intensity and the time of the irradiation cycle depending on the symptom. Therefore, newborn babies may be hurt by excessive light intensity at the initial stage. This and other factors affect the efficacy of phototherapy.[6-10]

After analyzing the disadvantages and problems of current phototherapy apparatus, we propose a "design of phototherapy apparatus with multiple operation modes and automatic light adjustment mechanism" for medical personnel as an alternative. The new design features customized light intensity, adjustable therapy duration, and periodical change of the light intensity that can effectively minimize the side effect of phototherapy. [11-14]

Normally in phototherapy, the apparatus uses a high-voltage fluorescent lamp as the light source. This design not only brings potential hazard to the medical personnel and the treated newborn baby, but also brings about direct or indirect injury to newborn babies who fail to adapt to the apparatus. [15-17] The main objective of this study is to make improvement of the following designs:

1. Replacement of the traditional fluorescent lamp with LED

The high-power blue LED with a wavelength between 460nm and 475nm (medical literature reviews suggest the best wavelength for treatment of jaundice is between 425nm and 475nm) is used for this new design. [6, 7, 9, 14] Instead of the high voltage for traditional fluorescent lamps, low voltage is used to control the irradiation of the LED.

2. Adjustable irradiation intensity

Irradiation of the LED is controlled with a pulse width modulation (PWM), so that the medical care personnel can adjust the intensity of the irradiation depending on the symptom of the disease.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1132–1135, 2009
www.springerlink.com

3. Pre-set irradiation time to avoid carelessness and mistakes

The time of irradiation can be set via the human-machine interface to disable the machine at the end of the therapy to reduce the cost of human resources.

4. Selectable irradiation intensity for each module place

The modular design allows the user to set the intensity and time of irradiation for each module via the human-machine interface.

Accordingly, this phototherapy apparatus provides more functions for medical care personnel, such as customized light intensity, duration of the irradiation, and periodical adjustment of the light intensity, to reduce the side effects of phototherapy.

II. System Design

To remove the disadvantages of traditional phototherapy apparatus, the system suggested in this study provides the following basic functions: (1) the high-power LED is used to replace the traditional fluorescent lamp; (2) intensity of the irradiation is adjustable depending on the symptom; (3) the irradiation time can be set in advance to reduce the need for manpower; (4) the volume to be irradiated is selectable; and (5) the easy-to-use human machine interface.

The structure of the system is shown in Fig. 1. It comprises a human machine interface (running on PC), a control system (Embedded microcomputer ARM 7), an irradiating module (Embedded MCU, constructed by Toshiba MCU chip TMP87C202), and a power supply (POWER).

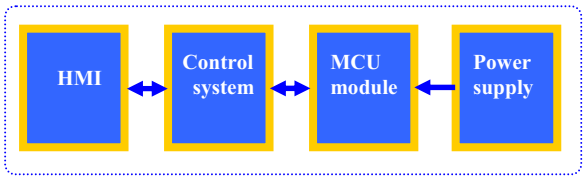

Fig. 1 Block diagram of this proposed system.

The control system (Embedded microcomputer ARM 7) is the core of the system for status display (showing the connection between the PC and embedded MCU), command transmission (transmitting commands to the controlled node for execution of specified actions), reading data (reading the signal detected at the controlled node and its status), manual control (implementing manual control without connection to the PC), and communication interface (providing a communication interface between the PC and embedded MCU).

The picture of this proposed apparatus is shown in Fig. 2.

Fig. 2 Photo of a LED Jaundice Phototherapy Device, designed by our research team in Kun Shan University.

A. Measurement Results of the Proposed Phototherapy System

The Japanese TOPCON spectroradiometer (Model SR-3) is used for measurement of the exposure and spectrum. The TOPCON SR-3 is a spectrum measurement instrument to measure the FPD and visible light source, as well as the luminance and hue of a single point. It has a resolution up to 1nm and is suitable for the laboratory that needs highly-accurate and highly-precise analysis of visible light spectrums. It is installed with standard software applications for easy analysis and storage of the measured data. The SR-3 instrument can display 2D color drawings; it can also measure extremely small light dots through using a close-up lens. TOPCON SR-3 can measure the luminance value up to 0.1 cd/m^2.

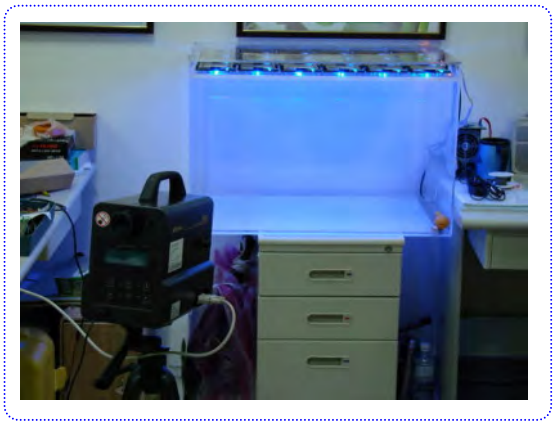

Fig. 3 Measuring instrument.

Fig. 3 shows the simulated phototherapy environment and a spectroradiometer is used to measure the data. The CS-900 measurement software is used for collection of measured data. Excel software is used for comparison of the

measurement results. The items to be measured include (1) background measurement (without a doll) with light pollution (with the fluorescent lamp on); (2) background measurement (without a doll) without light pollution (with the fluorescent lamp off); (3) simulated measurement (with a doll) and with light pollution (with the fluorescent lamp on); and (4) simulated measurement (with a doll) without light pollution (with the fluorescent lamp off). 11 luminance values are applied to each measurement item. They are 0%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, 100%.

III. Conclusions

A. Comparison with the Current Phototherapy Apparatuses

To prove the advantages of this system that current phototherapy apparatuses do not provide, we use the SR-3 spectroradiometer to measure the three phototherapy apparatuses, including the ones using the blue or white fluorescent lamps, for the intensity of their wavelength. The measurement results are shown in Fig. 4. The blue fluorescent lamp /max. luminance is at the wavelength 435nm/intensity 0.003683107 (top diagram), the white fluorescent lamp /max. luminance is at the wavelength 435nm/intensity 0.002954492 (middle diagram), and the blue LED/max. luminance is at the wavelength 460nm/intensity0.009041377 (bottom diagram).

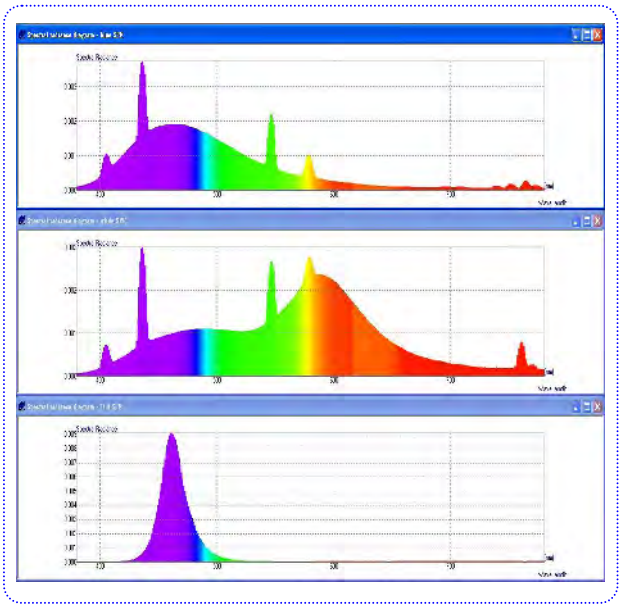

Fig. 4 Intensity of different phototherapy apparatus.

The Excel data is shown in Fig. 5. These three apparatuses meet the requirements for treatment of neonatal jaundice with the wavelength within the optimal photo range (425~475nm). However, the color gamut of the visible light of the white fluorescent lamp is too wide and the intensity of the blue fluorescent lamp is only 40% of the LED. The 100% luminance of this system is 2.5 times the luminance of a blue lamp. Its wavelength is about 460mm. The design of this proposed LED phototherapy apparatus is better than the traditional systems.

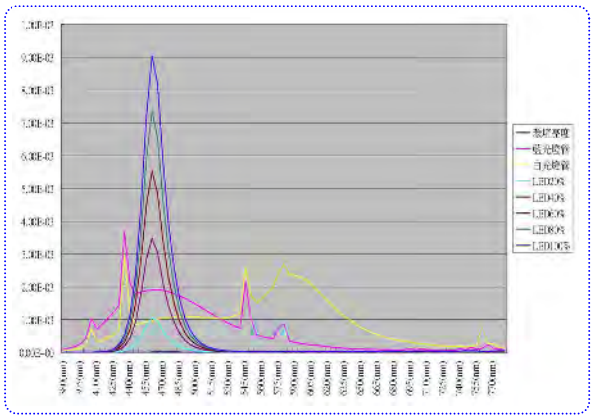

Fig. 5 Intensity comparison of different phototherapy apparatus.

B. Advantages and Development of the Proposed System

As the measurement result of TOPCON SR-3 shows, the wavelength of this system is within the range of 460~475nm, as indicated on the specifications of high-power LED. As these figures shown, this phototherapy system has a wavelength that is within the ideal range of the wavelength required for the treatment of neonatal jaundice (about 425~475nm).

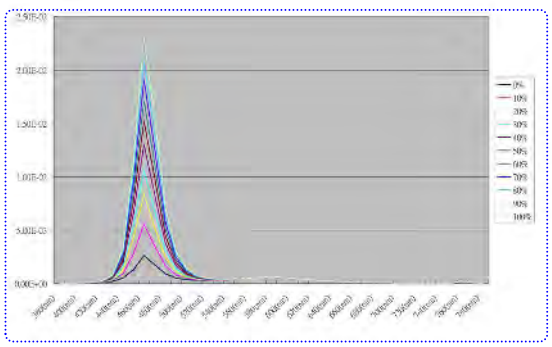

Fig. 6 Comparison of background and luminance with light pollution.

After importing SR-3 data in the Excel, comparison is made using a fold-line chart for each luminance from 0% to 100% at an interval of 10%. As shown in Fig. 6, the intensity of the irradiation is adjusted via the human-machine interface and the exposure rises accordingly, indicating that the system can provide the performance as expected.

The "auto therapy control panel" of the human-machine interface allows the setting of the treatment time, intensity, and module block to be used for the treatment. The medical care personnel can adjust the intensity, time and affected area of the irradiation depending on the symptom and jaundice index of the patient. They can view the treatment and adjust it at any time.

Scientists have found that LED of different colors has different efficacies for human bodies. For example, the red/blue light: relief of inflammation, anti-allergy, anti-acne, treatment of sinusitis; ultraviolet: disinfection. The most popular IPL therapy also applies LEDs.

Accordingly, this system is applicable to other fields only by replacing the blue LED of the modular photo board with the LED of other wavelength. In addition to treatment of neonatal jaundice, this system can be applicable to the daily life of us in many different areas.

Abstract — **In this paper, we promote effectiveness, by using light simulation software, which we are able to simulate the propagation of the light, and we design a baby dummy (which it's sizes are close to a real baby), where we can measure the effectiveness of the light over the skin surface.**

With this method we show the results of an actual device and also propose a new design to use as an example for improving the effectiveness. Using this software we can get better results and hoping developers use this method for exchanging the phototherapy device performance, which babies patients are the ones who have the benefits.

Keywords — **Jaundice, Bilirubin, Phototherapy, Simulation software, Device performance.**

I. Introduction

The aim of phototherapy is to curtail rising serum bilirubin and prevent its toxic accumulation in the brain, where it can cause the serious, permanent neurological complication known as kernicterus. Phototherapy has greatly reduced the need for exchange transfusion to treat hyperbilirubinemia. Phototherapy is used in 2 main ways: prophylactically and therapeutically.

The photoisomerization of bilirubin begins almost instantaneously when the skin is exposed to light. Unlike unconjugated bilirubin, the photoproducts of these processes are not neurotoxic. Therefore, when faced with a severely hyperbilirubinemic infant, it is important to begin phototherapy without delay.

The normal serum bilirubin value of a newborn baby is between 0.2 mg/dl and 1.4 mg/dl. When it exceeds 5 mg/dl, jaundice appears in the skin, fingernail or sclera. The symptom of hyperbilirubinemia appears when the serum bilirubin value is between 15 mg/dl and 20 mg/dl. A newborn baby is diagnosed with kernicterus when the serum bilirubin value is higher than 20 mg/dl.

The most effective light sources for degrading bilirubin are those that emit light in a relatively narrow wavelength range of 458 nm. At these wavelengths, light penetrates the skin well and is maximally absorbed by bilirubin.

Irradiance is the light intensity, or number of photons, delivered per square centimeter of exposed body surface. The delivered irradiance determines the effectiveness of phototherapy; the higher the irradiance, the faster the decline in serum bilirubin level. Spectral irradiance, quantities as $\mu W/cm^2/nm$, largely depends on the design of the light source. It can be measured with a spectral radiometer sensitive to the effective wavelength of light. Intensive phototherapy requires a spectral irradiance of 30 $\mu W/cm^2/nm$, delivered over as much of the body surface as possible.

The gallium nitride LED is a recent innovation in phototherapy. These devices provide high irradiance in the blue to blue-green spectrum without excessive heat generation. Light-emitting diode units are efficient, long-lasting, and cost-effective. The latest models incorporate amber LEDs to counteract the blue hue effect that can irritate caregivers.

LED have shown that are more efficient both in energy consumption than ordinary fluorescent lamps; but above else deliver more energy in the skin for breaking up the bilirubin (Yun-Sil Chang and Jong-Hee, 2005).

We will study further more about the principle of an LED phototherapy unit, which this project really appreciated Kun Shan University's LED phototherapy unit. (Fig. 1 shown)

Fig. 1 Photo of a LED Jaundice Phototherapy Device, designed by our research team in Kun Shan University.

II. Research methodr

So as promoting the efficiency for a jaundice treatment, we will focus in 2 parts of effectiveness :

(1) Energy saving : we can predict with the software, the amount of irradiance in the baby's skin. This means that if we had a light source of 6W light power, we can set a

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1136–1139, 2009
www.springerlink.com

minimum of power so the light is above the minimum the bilirubin breaks (> 30 μw/cm^2).

(2) Expose at maximum the skin's surface : we are going to be able to see how much of the skin surface we will cover with the light, so this means, if more skin is covered, a better treatment we will provide to the patient. For this study work, we will study the behavior of an actual device, from Kun Shan University, Department of Electronic Engineering.

Using Trace Pro simulation software, requires these steps to perform a study in it *:*

(1) Creating a Solid Model : Here in the first step, we create the 3D model of the light source (LED) and later we create the "Dummy Baby" which is a dummy with actual sizes from a new born baby, so we can simulate the light behavior in a planar surface and with the dummy.

(2) Defining Properties : This step is very important, where we define the physical properties of each part of the LED, planar surface and "Dummy baby".

(3) Applying Properties: This step is a continue from previous one, we select different types of properties as well we set the light source and its properties (5W, 458nm, 30000 rays, radiometric measurement).

(4) Ray Tracing: we finally trace the rays, the computer works, to get our simulation results.

(5) Analysis: finally, when we get the results, we can analyze all we need to study.

First study: Planar surface

We first begin with studying the behavior of the light, with just a planar surface, this surface have skin properties (Tissue, Epidermis).

Second study: with "Dummy baby"

We already know how the jaundice phototherapy device behaves, but just with a plane surface, which we can wonder: "It works the same with a baby inside the phototherapy device ?"

This section, we construct without software what I called Dummy baby, which is a design, not real baby, but is a body which have the basic properties: (1)Extremities (legs: 170mm long, 57mm radius; arms: 145mm long, 15mm radius), (2)Head (62 mm radius), (3)Thorax (chest, waist and shoulders all average: 360 mm radius).

This is not all, how about the measurements; well we get them from babies' average sizes for all these basic properties. So finally, designing our Dummy baby, so for final design, to study the behavior of the jaundice phototherapy device.

Result and discussion

Starting with a full power LED in Fig. 2 and Table 1, (Fig. 2(a) 5W LED), we can see the power absorbed is too high, with an average of 367.51 μW/cm^2, which means the required amount of light power (over 30 μW/cm^2) is surpassed by more than ten times! This means we can still lower the light power by ten and still have good results with the jaundice phototherapy device. So for conclusion, we waste energy with full power LED.

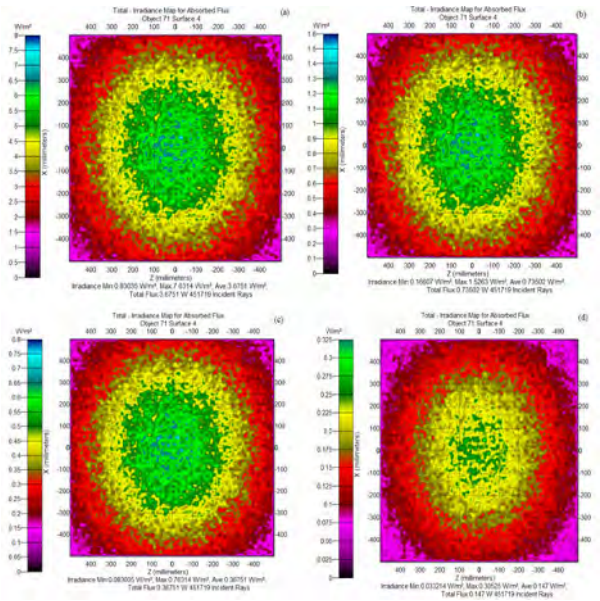

Fig. 2 Results of study of a planar surface without any customized LED pattern, results on Table 1; (a) 5W, (b) 1W, (c) 0.5W, (d) 0.2W.

With 1W we drastically reduce the LED power by 80% (Fig. 2(b) 1W LED), also is very good to see that all surface is over the minimum (over 30 μW/cm^2), average of 73.502 μW/cm^2, so this part we still have good results with the baby patient jaundice and also the device won't consume a lots of power (reduce from 175W to 35W) which becomes efficient. But we can still see many parts of the surface above the 100 μW/cm^2, so we still going to reduce the power, so we can save even more energy!

With Fig. 2(c), for 0.5W LED power, we again reduce the power to 50%, having as result an average of 36.751 μW/cm^2, clearly above of the minimum power we need to have the phototherapy device to do its job. But also we can see that the area can do the job, is only concentrate in the center and the borders remain under the minimum, which makes this light pattern inefficient.

For Fig. 2(d), with 0.2W LED power, an average of 14.7 μW/cm^2, this power is not enough for the objective of the

jaundice device, just only in the middle we can see have power over the minimum required.

So from these figures (Fig. 2 (a), (b), (c) and (d)) we can appreciate, the best light pattern is for 1W, which is low power and almost cover all surface above the minimum required.

Table 1 Results of study, without any customized LED pattern

Figure (Fig. 2)	**Total LED power**	%LED power	Irradiance Over 30μW/cm^2	**Average Irradiance Power**
5W(Fig.a)	**175W**	100%	100%	**367.51 μW/cm^2**
1W(Fig.b)	**35W**	20%	92%	**73.502 μW/cm^2**
0.5W(Fig.c)	**17.5W**	10%	60%	**36.751 μW/cm^2**
0.2W(Fig.d)	**7W**	4%	4%	**14.7 μW/cm^2**

Then, we customize 3 different LED light power pattern to increase energy saving by reducing LED power and having same great results. On Figure 3 and Table 2, we compare the best LED uniform light pattern (1W) with two customized light pattern.

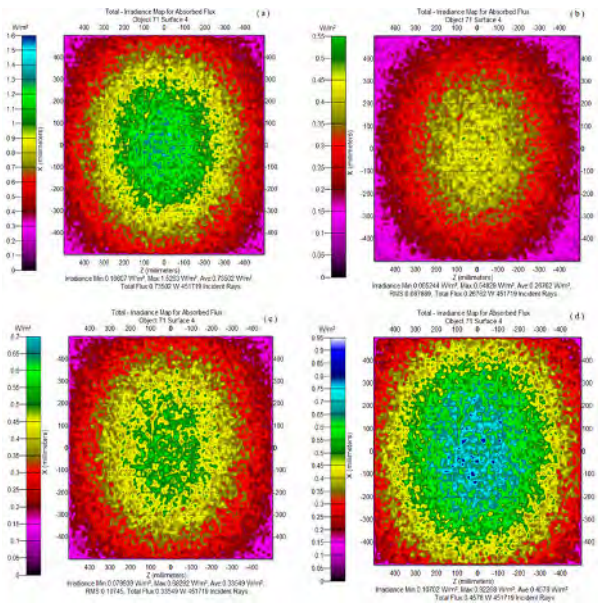

Fig. 3 Results for planar surface with a customized LED pattern, results on Table 5; (a) 1W, (b) light pattern # 1, (c) light pattern # 2, (d) light pattern # 3.

First, we know 1W is very efficient, delivers good amount power over the surface (73.502 μW/cm^2, of average), but also we know many parts of the surface, special in the middle, where the amount of power still high and I change the light pattern to change the values around the surface.

The first LED customized light pattern (Light pattern #1), we put an out ring of 0.5W, which we know in the borders the irradiance goes down and in the middle goes a power of 0.2W. We choose this pattern, because we want to try to get the minimum LED possible power pattern. So we know before, 0.2W in the middle we will have barely enough power to get it over the minimum required (over 30 μW/cm^2), and for the edges, we increase the power to 0.5W. In the Fig. 3(b), we see we get an irradiance barely surpass the minimum required, but also we can see we still get a ring of irradiance power bellow the minimum required. So for this reason we create the custom patter number two.

Custom pattern number two, in the corner's LED and the out-middle LED we increased the power to 1W, this way we intend to increase the outer irradiance ring that was below with the minimum irradiance power required. So as final result, with the light custom pattern # 2, we have good irradiance, which the average is 33.549 μW/cm^2, which is good to break the bilirubin and covers most of the plane surface and we don't need to much power (1W light patterns requires 35W total LED power, custom LED # 2 requires just 17W LED power to do the same job) so this means we will have the same results with less power.

Then, last pattern # 3, I increase the power for the outer LEDs to 1W (Light pattern # 3), so finally we can get the same amount of coverage (92% of surface is greater than 30 μW/cm^2) as if we put the all LED to 1W, so finally we can get same coverage and average over 30 μW/cm^2 but with much less power.

Table 2 Results for planar surface with customized light pattern

Figure (Fig. 3)	**Total LED power**	%LED power	Irradiance Over 30μW/cm^2	**Average Irradiance Power**
1W(Fig.a)	**35W**	20%	92%	**73.502 μW/cm^2**
Light pattern #1 (Fig.b)	**13W**	7.42%	30%	**26.762 μW/cm^2**
Light pattern #2 (Fig.c)	**17W**	9.7%	76%	**33.549 μW/cm^2**
Light pattern #3 (Fig.d)	**23W**	13.14 %	92%	**45.78 μW/cm^2**

III. Conclusions

For conclusion, with our project, we want to state that our main goal is to promote the light simulation software in the steps of designing a neonatal jaundice phototherapy apparatus, this way we can improve the device's performance.

Energy Saving and Performance

With an energy saving program, we can get a cheaper device, which will be able to do the main goal of the jaundice phototherapy device (bilirubin breaking) with less energy, as for the designers with this they can reduce cost on:

- Have less light sources, but with great performance.
- Use a reliable light sources, we can be able to use cheap LED as light sources, omitting expensive ones, if can do good performance.
- Reduce manufacturing cost, by placing less light sources if with less LED we can have a great performance.

Enhance the phototherapy

Enhancing the phototherapy, as we know, the most skin we can cover with the minimum light irradiance power, the most effective therapy we will get, by reducing the timing the baby patient will stay for therapy and this way the hospital or clinic can reduce cost for energy, less hours and the number of times the equipment can be used in a period of time.

As for final statement, we hope developers really can see the importance of simulation software in the design steps, as we prove we can have better results from saving energy and performance enhance.

As for recommendations, to improve the reliable of the results from the simulation software, we will need to pay attention to the following issues:

(1) Close communication between the Jaundice phototherapy device designers and the light source manufactures. This because important information we can't see in the data sheet, that we will need! (For example: the range of working wavelengths, the loss power by heat and noise, etc). So this way we can reduce the errors on the final result we get from the light simulation software.

(2) When designing a better baby model (if it uses) remember the software cares and we get the result just one surface at time. This means we need to construct a irradiance map (total surfaces together) to have a good analysis.

ACKNOWLEDGMENT

The authors wish to acknowledge the International Cooperation and Development Fund (Taiwan ICDF) for the financial support provided during this study. In addition, the authors wish to acknowledge the National Science Council for the support of researched project NSC96-2622-E-168-005-CC3.

Abstract — **Despite of wide use of surface electromyography (EMG) recorded during dynamic exercises; the reproducibility of sEMG variables has not been fully established in cycling exercise. As an extension of our previous study, this study aims to examine, muscle fatigue of bicyclist and aerobic-cyclist on biceps brachii medial, trapezius medial, latissimus dorsi medial, and erector spinae muscles within low back pain (LBP) group using bilateral surface EMG (sEMG).**

Five male volunteers with LBP were chosen and sEMG was recorded bilaterally from selected muscle groups for 30 minutes of ride of each subject. The collected sEMG signals were filtered using Butterworth filter with a pass band of 20–400 Hz and stop band of 47–49 Hz. Statistical tests were performed to determine the difference in fatigue, using MPF difference. No significant result was found for aerobic–cyclist. Whereas, in case of bicyclists in LBP group showed a significantly fatigue in biceps brachii medial, right trapezius medial and erector spinae.

From the results, it is evident that LBP can worsen significantly by cycling than aerobic cycling; for subjects who have previous injury to lower back. These inferences could be used when deciding fitness and rehabilitation regimes.

Keywords — **Surface Electromyography, Low Back Pain, Bicycling, muscle fatigue, repetitive motion disorder.**

I. Introduction

This paper is an extension of our previous study; muscle fatigue analysis for bicycle and aerobic cycle riders [1, 2]. Cycling serves both, as a mode of transportation and as training equipment in fitness and rehabilitation. Cycling utilizes a reciprocating vertical motion similar to walking, hence cycling plays equivalent important in fitness and rehabilitation centres. As there is little data pertaining to the development of LBP and shoulder pain in cyclists, this study aims to examine whether difference in muscle activity existed between aerobic–cyclists and bicyclist of LBP using sEMG. Our previous study on road cyclist infers that, there is a higher muscle fatigue in the back muscles of LBP group when compared to non LBP group of bicycle riders. However for aerobic–cyclist there was no significant result found.

sEMG has been used to display muscle activation patterns and is extensively employed to interpret both dysfunction and functional muscle recruitment patterns related to cycling activity [3]. The sustained muscular contractions externally associated with not being able to maintain a certain force, lead to physiological fatigue, tremor or pain, localized in the specific muscle. This is called muscular fatigue [4], associated with a compression of the power spectral density (PSD) of the sEMG towards lower frequency [5], measured by MF computed from the sEMG PSD.

The spectral analysis of the sEMG was widely used to detect and quantify the electrical manifestations of muscle fatigue [6]. It was well known that during a sustained muscle contraction, the power spectrum of the sEMG is scaled toward the lower frequency end. At this time, the spectral scaling is most reliable sign of localized muscle fatigue; and some researchers rely on it for studying the variations of the excitability of the membrane of muscle fatigue during sustained contractions.

In our study, we concentrate on peripheral muscle fatigue. The development of muscle fatigue during exercise is associated with a decrement in their performance. Mechanisms of muscle fatigue depend on the exercise conditions and the subject's level of physical fitness. The decrements in skeletal muscle power output are also related to neural drive reductions and may also lead to muscle fatigue in prolonged exercise [1]. In general, fatigue is viewed as an unavoidable and negative consequence of physical activity.

In summary, one could infer that bicycling can induce higher muscle fatigue in individuals with LBP than aerobic–cycling. As a support of our result, we have performed a 10 point visual-analogue scaling test.

II. Methodology

A. Subjects:

Five male volunteers with a mean age of 26.20 years (range 23 – 29 years) and mean weight of 60.17 Kg (range

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1140–1143, 2009
www.springerlink.com

45 to 68 Kg) participated in the study. LBP group had a history of low back pain (1 year < LBP > 3 years).

B. Protocol

Subjects were instructed not to participate in any heavy training or physical activity 24 hours prior to their clinical assessment or testing day. All activities were explained to the subject before the experiment. Subjects rode their own road bicycles on outdoor within the institute campus and were instructed to sit and keep a posture of their comfort. They were also instructed to cover a distance of 6 km in 15 minutes. While riding, cyclists were exposed to vibration and force during which several muscles will be activated. On the other hand, aerobic–cycling experiment was done as indoor experiment for 30 minutes and data were collected at initial and after 30 minutes of aerobic cycling. Indoor experiment and outdoor experiment were carried on different day, so that they do not have influence on each other. In our study, we considered the biceps brachii medial (BBM), trapezius medial (TM), latissimus dorsi medial (LDM), and erector spinae (ES) muscle group, bilaterally. Signals from these groups of muscles were collected using EMG. (Delsys, Inc., USA).

Before placement of the electrode, the site was shaved, abraded with sandpaper, and cleaned with ethanol to avoid impedance mismatch and movement artifact. Ag/AgCl differential electrode was adhered to the skin along the muscle fiber orientation. Care was taken to place electrodes on the midline of muscle belly, between the myotendonous junction and the nearest innervation zone. Detection surface was oriented perpendicularly to the length of muscle fibers.

Bagnoli-8^{TM} machine with an amplifier gain setting of 1000 was used to acquire the myolectric signal. Customized program was written in LabVIEW^{TM}, National Instruments, Inc. This was used to sample sEMG at the rate of 1000 Hz. Each subject was asked to exert MVC and the sEMG were recorded for 10 seconds, before cycling. sEMG was also collected at three intervals for all the subjects as they underwent psychophysical tests to determine MVC. The three intervals were, a) before cycling, b) after 15 minutes of cycling, and c) after 30 minutes of cycling. All experimental data were recorded at the Rehabilitation Bioengineering Group (RBG) laboratory, IIT Madras

C. Analysis

Raw sEMG signals were filtered using eighth-order Butterworth filter with a pass band of 20–400 Hz. A second order notch filter with a band stop of 47–49 Hz was used to eliminate AC line interference. Filtered signals were normalized with respect to mean, and then full–wave rectified. sEMG signals were analyzed in frequency domain using power spectrum. The power spectrum of the sEMG has been reported to change under influence of muscle fatigue [7]. As muscle fatigues, there is a concomitant change in the power spectrum of sEMG signals; there is an increase in the amplitude of the lower frequency band and a relative decrease in higher frequency band. Decrease in mean power frequency (MPF) from sEMG profiles is a recognized method of determining fatigue in an isometric muscle action [8]. However the methods employed to calculate MPF and the groups of muscles selected vary with requirement. In this study, hamming–windowed algorithm was applied on rectified sEMG signals and MPF was extracted from the power spectrum. Fatigue difference was calculated using MPF. These were used to determine the level of muscle fatigue.

$$\text{MPF difference} = (\text{MPF}_{\text{after}} - \text{MPF}_{\text{before}}) \quad [1]$$

D. Statistical Analysis

Skewness test performed on the features extracted from sEMG signals showed that they were not normally distributed. Hence a non-parametric test, Mann–Whitney 'U' test, was used to determine the significant difference in EMG activation between bicycle riders and aerobic–cycle riders, before and after 30 minutes of cycling.

III. Result

Sample power spectrum of EMG acquired from erector spinae muscle of LBP subjects is shown in Figure 1.

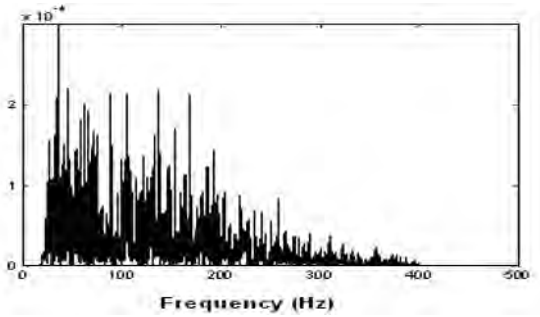

Figure 1 Power spectrum of erector spinae of LBP group

MPF difference was able to significantly differentiate ($p<0.05$) EMG activity in right trapezius medial and erector spinae muscles of LBP group than control group of bicyclist from the same muscle groups. Table 1 shows the compari-

son of MPF difference on right and left Biceps Brachi medial of LBP group.

Table 2 shows the Comparison of MPF difference on Right Trapezius Medial and Right Erector Spinae for LBP group of bicyclist and aerobic – cyclist.

Visual Analogue Scale Result: LBP subjects were admitted based on entry criteria and their severity of LBP was quantified after 30 minutes of cycling using a 10 point visual-analogue scale.

The result of 10 point visual-analogue scale, infers that LBP groups of aerobic cyclist have a mean of 6.20 (±0.49), while bicyclist have a mean of 7.80 (±0. 86).

Result infers that there is a significant difference existed between the aerobic –cyclist and bicyclist.

IV. Discussion

This study demonstrates the difference in muscle activity of LBP individuals who uses aerobic and road cycle for fitness, using a statistical test. Still to our surprise, we found that there were no differences between LBP and control group; during a dynamic exercise on an aerobic cycle. It also states that there were no significant fatigue occurred for LBP groups of bicyclist and aerobic–cyclist; during a dynamic exercise on an aerobic cycle. LBP subjects, with a previous history of existence of back pain for a period of 1 to 3 years only, were chosen for this study. Subjects were instructed to use similar models of bicycles.

Limitation of this pilot study was the duration; the experiment duration was determined after the initial screening test made on sample subject. Screening test infers that, subjects were not able to maintain the speed after 30 minutes of cycling. As a result of this, our experiment duration was fixed as 30 minutes.

A few previous studies have examined the changes in lower extremity muscle activities during cycling in indoor environments and lower extremity only [9 –11, 3]. In our study, we consider the back muscle and upper extremity; also compare the rode bicycle riders and aerobic–cyclist.

Chaffin, DB *et al.* (1978), reported isometric strength testing provides information which can be used to predict occupational injuries associated with dynamic lifting tasks. Hunter *et al* (2001) reported that MVC produce highest levels of EMG and therefore will be more effective in describing maximal muscle recruitment activity. They suggest that MVC can be used as a normalization procedure for dynamic cycling activity. Therefore, during this study, a psychophysical test for dynamic lifting task was performed to determine MVC of the required muscles for each subject.

Hunter *et al* (2001) also demonstrated that MVC produced greater MPF activity, which indicates a higher rate of motor units firing or recruitment of a greater number of motor units. As generally reported, MPF decreases as muscle fatigue progresses. Although central and peripheral factors are responsible, the main factor contributing to the MPF shift towards lower values may be peripheral, i.e. a slowing of the muscle action potential conduction velocity. In our study, MPF of LBP group shows a steady decrease when compared to control group.

Hoeven *et al* (1993) performed linear regression analysis on sEMG. Our study used MPF difference to significantly differentiate the fatigue of muscle before and after 30 minutes of cycling. In the literature, gender difference in muscle fiber compositions are still discussed controversially. Most authors found no statistically significant differences between genders [12]. Hence this study had only male participants.

V. Conclusions

This study helps us to understand the consequences of cycling. From the results, it is evident that there is no significant result was found for aerobic–cyclist. Whereas, in case of bicyclists in LBP group showed a significantly fa-

tigue in biceps brachii medial, right trapezius medial and erector spinae than those in the control group. From the results, it is evident that LBP can worsen significantly by cycling than aerobic cycling; for subjects who have previous injury to lower back.

These inferences should be used when deciding the use of bicycle as an option in fitness and rehabilitation, instead of walking for LBP individuals.

ACKNOWLEDGMENT

The authors wish to thank all the members of Rehabilitation Bioengineering Group (RBG) at IIT Madras and the volunteers who participated in this study.

Abstract — **A 3D surface model of human anatomy is widely used in medical imaging software to increase visualization of volumetric data in 3D. In the first part of the paper, we present a process for fast 3D surface reconstruction with high quality from large volumetric data. The subsampling technique is used to support large volumetric data. After constructing the contours, we apply the smoothing technique to smooth out the polygon mesh. Specifically, in this study, we focus on the subsampling and smoothing parameters that affect the quality of the 3D surface model and the efficiency of the computation time. In addition to 3D surface reconstruction, 3D surface clipping is also useful for visualization because it allows one to see detail structures inside the surface model. In the second part of the paper, we propose another process to perform 3D surface clipping on volumetric data. Clipping along an arbitrary plane requires the position and orientation of that clipping plane. Since, with clipping only, the corresponding clipped surface produces empty holes, a texture mapping technique is used to cover the holes by placing the cut image data of that clipping plane on top of the clipped surface. Our proposed processes in this paper are based on the Visualization Toolkit (VTK) library.**

Keywords — **3D Surface Modeling, Surface Clipping and Visualization Toolkit (VTK)**

I. Introduction

3D Surface Modeling is one of volumetric data representations. It is represented in a form of polygon meshes, which consist of a large number of vertexes and normal vectors. These vertexes and normal vectors can be exported into a graphic file format without the original volumetric data for constructing a physical model. This is an advantage of 3D surface model because the physical model is useful in some applications. For example, it is used for printing a surgical guide in dental implantology by a rapid prototyping machine. Another good advantage of 3D surface modeling is an ability to view an interested section by a clipping method. This paper is divided into two parts: a 3D surface modeling or reconstructing process and a 3D surface model clipping method. In addition, all processes are developed and based on the Visualization Toolkit (VTK) [1] library, which is an open source library for computer graphics, image processing and visualization.

In the first part, a 3D surface reconstruction process is proposed to solve a problem of reconstruction from large volumetric data. This problem is usually solved by high efficient hardware. For example, John G. Torborg [2] applied a parallel processing technique to provide floating point computation, which handled complex models, and preserved basic operations, such as transforming and clipping. Although these algorithms are effective, they will be difficult to implement in practical if the resources of hardware, such as random access memory (RAM) and computer processing unit (CPU), are limited. Consequently, we proposed a process for reducing resources requirement and reconstructing a 3D surface model by basic algorithms. The proposed process uses subsampling technique to reduce the resolution of volumetric image data. This technique helps reducing memory and computation time usages. The proposed process applies the Marching Cubes algorithm [3] to extract contours from volumetric data. Furthermore, it uses polygon decimating to reduce memory for handling poly data, and polygon smoothing is applied to adjust the quality of a 3D surface model.

In the second part, 3D surface clipping method is proposed. This method requires a clipping plane for defining a clipped location, and we use texture mapping technique for covering empty holes at a cut surface after clipping a 3D surface model.

This paper is organized as follows. The next section discusses a concept of the Marching Cubes and describes the proposed process for reconstructing 3D surface model. Then, a concept of clipping and the 3D surface clipping method are explained. We will show the experimental results of the proposed processes. Finally, the conclusion is discussed in the last section.

II. Marching cubes algorithm and 3D surface reconstruction

Marching Cubes is a popular algorithm for extracting a contour from volumetric image data, and the contour is constructed by matching between voxel and cube patterns.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1144–1148, 2009
www.springerlink.com

These patterns are generated from the consideration of edges and vertexes in each cube, and they can be summarized into 15 patterns [3], which are shown in Figure 1. Each vertex is considered to turn on when its weight is higher than the defined threshold. In addition, the position of contour that passes through each edge is defined by linear interpolation between two vertexes.

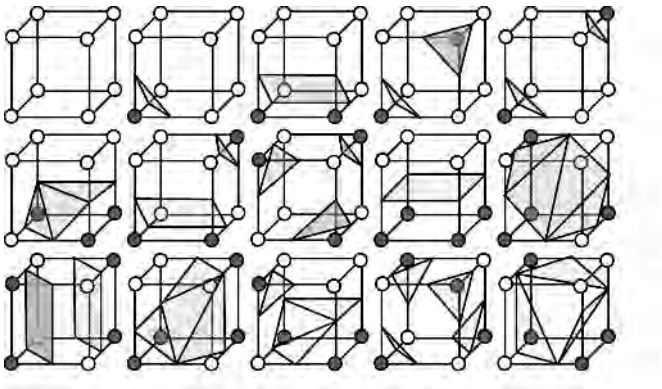

Fig. 1 The 15 patterns of Marching Cubes Algorithm

The Marching Cubes algorithm is supported by the vtkMarchingCubes class in the VTK library. The input of this class is vtkDataObject that is a general representation of visualization data, such as volumetric image data, and its output is vtkPolyData that is the data set of vertexes, lines, polygons, and triangle strips. Therefore, we should adjust and improve the image data before applying the vtkMarchingCubes class. Moreover, the quality of polygon mesh can be improved after reconstructing. Specifically, the proposed process for reconstructing a 3D surface can be divided into six steps as shown in Figure 2.

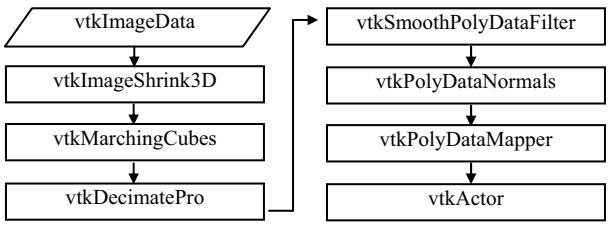

Fig. 2 The 3D Surface Reconstruction Process

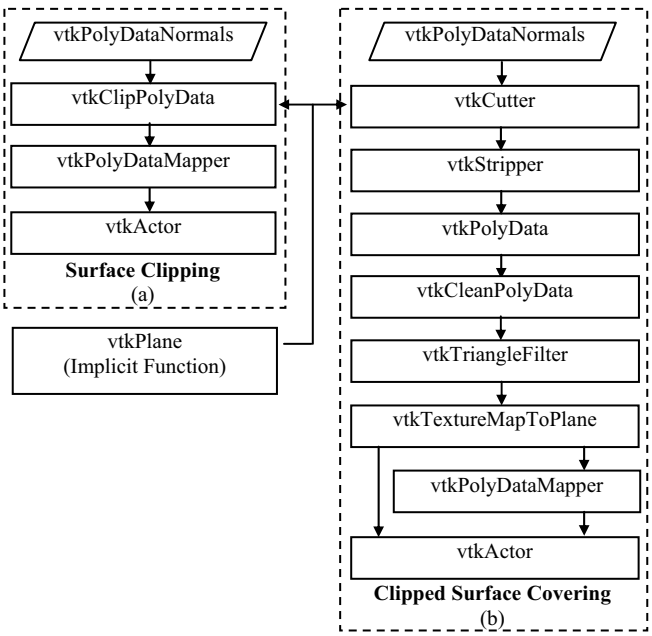
The first step starts by applying the subsampling techniqued that is supported by the vtkImageShrink3D class. We use the subsampling technique to reduce the effect of large volumetric data. In the next step, vtkMarchingCubes class is selected to reconstruct the contour or polygon mesh. Hence, we apply the mesh decimation for reducing the number of the triangle mesh, and it is served by the vtkDecimatePro class. This step helps us to reduce memory usage for interacting with the polygon mesh. In the next step, the polygon mesh is smoothed by the vtkSmoothPolyDataFilter class that uses Laplacian smoothing. Then, the vtkPolyDataNormals class is applied to calculate the normal vector of the polygon mesh, and the vtkPolyDataMapper class is applied to map poly data into basic graphic data by the setMapper method of the vtkActor class. The vtkActor is an object format that is allowed to add in the vtkRenderer for display.

III. 3D SURFACE CLIPPING

Surface clipping is a basic operation for dividing the polygon mesh from one piece into two pieces. The divided pieces are based on the implicit function, which divides all points into negative scalar values on one side and positive scalar values on the other side. This operation is served as the vtkClipPolyData class. In addition, the points that make the implicit function to be zero are defined as the cut edge. This operation is called cutting, and it is supported by the vtkCutter class. When 3D performs surface clipping, the empty holes may exist. One approach to covering these holes is by replacing with an image at the clipped-plane position. This enables one to see the detail at cut surface.



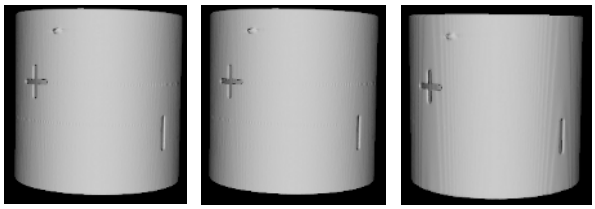


Fig. 3 The 3D Surface Clipping Method: (a) Surface Clipping Process and (b) Clipped Surface Covering

The proposed 3D surface clipping method can be divided into two parts as shown in Figure 3. In the first part, 3D surface clipping is performed by the vtkClipPolyData class, which includes the implicit function of a plane. The position and orientation of the corresponding plane must be defined for clipping. In addition, we use the output of the vtkPolyDataNormals class as an input of the vtkClipPolyData class. Then, the output of vtkClipPolyData is prepared for display by the vtkPolyDataMapper and the vtkActor classes. In the second part, the cut surface is covered by finding the cut edge of 3D surface using the vtkCutter class. The output of this class is poly data; however, it does not contain any points and lines data. Thus, the vtkStripper class is needed for reconstructing points and lines. After that the vtkPolyData class can be applied to create poly data through the SetPoints and SetPolys methods. The result of this step requires the vtkCleanPolyData class for removing unused points and merging duplicated points. The vtkTriangleFilter class is applied to convert the poly data into triangle polygons. These triangle polygons are used as an input to the vtkTextureMapToPlane class for generating texture coordinates by mapping points to a plane. Finally, the output of vtkTextureMaptoPlane class is applied to vtkPolyDataMapper for converting poly data into basic graphic data. To set the texture of actor, we use the SetTexture method of the vtkActor class.

IV. Experiment and Result

A. 3D Surface reconstruction experiment

In this section, we tested on the cone beam CT data of a cylinder phantom. These data contain 324 axial slices. Each slice consists of 400x400 pixels, and the data spacing is 0.4 mm. The proposed process was tested on Java environment, and based on Pentium D CPU 2.80 GHz, 504 MB of RAM, and Intel(R) 82865G Graphics controller. In addition, this study defined the threshold value for reconstructing from 200 to 31692 Hounsfield units (HU) to extract the cylinder and metal areas. We defined the reduction factor (r) of the vtkDecimatePro class to be 0.1, and studied the effect of the computation time on three parameters: the subsampling factors of vtkImageShrink3D class, and the number of iterations (n) and the relaxation factor (σ) of vtkSmoothPolyDataFilter class. The reduction factor is used to reduce the data set. If the reduction factor is set to 0.6, the data set will be reduced 60 percents. The subsampling factors (δ) are defined in three dimensions as x: y: z axes. The number of iterations and the relaxation factor for smoothing polygon mesh will be set to a high value if we want more smoothing. However, we cannot set them too large because the polygon mesh may distort excessively. The effect of these parameters on computation time usages can be shown on the Tables 1-3. Figure 4 shows that the quality of a 3D suface model was not reduced when we little adjusted the reduction factor of the vtkDecimatePro class and smoothing parameters of the vtkSmoothPolyDataFilter as shown in Figure 4(b). However, when we increased the subsampling factors, the quality of the 3D surface model was reduced as appeared in Figure 4 (c).

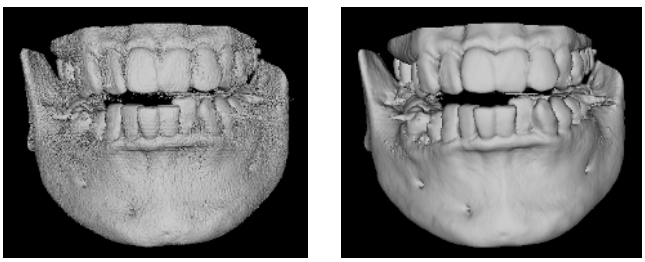
(a) (b) (c)

Fig. 4 Examples of the quality of the 3D surface model:
(a) δ = 1:1:1(400x400x324), r = 0, n = 1, σ = 0, Time = 33.11 s,
(b) δ = 1:1:1(400x400x324), r = 0.2, n = 3, σ = 0.3, Time = 29.20 s, and
(c) δ = 2:2:2(200x200x162), r = 0.2, n = 3, σ = 0.3, Time 6.65 s.

Table 1 Computation time usages when varying the subsampling factors. (n = 1, σ = 0.01)

Subsampling Factors	Time (s)	Subsampling Factors	Time (s)	Subsampling Factors	Time (s)
1 : 1 : 1 (400x400x324)	33.11	1 : 1 : 2 (400x400x162)	16.30	1 : 2 : 2 (400x200x162)	8.74
2 : 1 : 1 (200x400x324)	23.12	2 : 2 : 1 (200x200x324)	12.05	2 : 2 : 2 (200x200x162)	6.54
1 : 2 : 1 (400x200x324)	21.35	2 : 1 : 2 (200x400x162)	8.86		

Table 2 Computation time usages when varying the number of iterations for smoothing. (δ = 1:1:1 (400x400x324), σ = 0.01)



Number of Iteration	Time (s)	Number of Iteration	Time (s)	Number of Iteration	Time (s)
1	33.11	7	33.36	50	38.33
3	35.00	10	31.23	70	40.67
5	36.57	30	35.20		

Table 3 Computation time usages when varying the relaxation factor. (δ = 1:1:1 (400x400x324), n = 1)

Relaxation Factor	Time (s)	Relaxation Factor	Time (s)	Relaxation Factor	Time (s)
0.01	33.11	0.07	26.35	0.5	28.37
0.03	27.29	0.1	25.80	0.7	25.19
0.05	26.24	0.3	25.86	1.00	25.62

Table 1 shows that the time usages of subsampled reconstruction are about two times less than the non-subsampling case when subsampling by two in one direction. With subsampling by a factor of two in two directions, the computation time was about three times faster than the non-subsampling case. Likewise, the time usage of subsampling by a factor of two in all directions was about five times less than the non-subsampling case. Table 2 shows that the computation time usages are increased slightly when we defined the number of iterations to be a large value. The difference of the computation time when varying the relaxation factor in Table 3 is inexplicit.

In addition, we applied the proposed process to reconstruct a 3D surface from another CT volumetric data. It was acquired from Hitachi CB MercuRay CT scanner. These data contain 300 axial slices with the image size of 512x512 pixels, and data spacing of 0.2 mm. We defined the threshold boundary as 200 to 2000 HU, and the 3D surface results are shown in Figure 5. In addition, Table 4 shows the computation time when we adjusted some reconstruction parameters.

(a) (b)

Fig. 5 Examples of the 3D surface model: (a) δ = 1:1:1 (512x512x300), r = 0, n = 1, σ = 0, Time = 67.54 s, (b) δ = 2:2:2 (256x256x150), r = 0.2, n = 3, σ = 0.3, Time = 28.65 s.

Table 4 Computation time usages with different reconstruction parameters.

Subsampling Factors	Reduction Factor of Decimation	Number of Iteration	Relaxation Factor	Time (s)
1 : 1 : 1 (512x512x300)	0.0	1	0.0	67.54
1 : 1 : 1	0.2	3	0.3	96.98
1 : 1 : 1	0.3	3	0.3	106.36
1 : 1 : 1	0.2	5	0.3	106.85
1 : 1 : 1	0.2	5	0.5	106.03
2 : 2 : 2 (256x256x150)	0.2	3	0.3	28.65

Figure 5 (b) shows that the quality of the 3D surface barely differs from the 3D surface reconstructed with the original size (Figure 5 (a)), although we subsampled by two in all directions. In contrast, the computation time of the subsampling case is about two times less than the non-subsampling case. Table 4 shows that the computation time increases when the number of iterations for smoothing is increased, whereas the reduction factor of decimation and the relaxation factor have a little effect on computation time usages.

B. 3D Surface Clipping Result

In this section, we used the 3D surface model acquired from a Hitachi CB MecuRay CT scanner to study the clipping method. We used the subsampling factors of two in all directions. The reduction factor of decimation was 0.2, the number of iterations for smoothing was 3, and the relaxation was 0.3. The results in Figure 6 show that the proposed method can cover the holes that occur on the cut surface.

(a) (b)

Fig. 6 Examples of the 3D Surface Clipping when defining the position and the normal vectors of the clipping plane: (a) position was 0, 0, and 29.79, and normal vector was 0, 0, and 1 (b) position was 44.6, 102.4, and 0, and normal vector was -0.9, -0.3, and 0.

V. Discussion and Conclusion

In this research, we propose a process for reconstructing a 3D surface model from large volumetric image data, and a method for clipping a 3D surface model. All steps are based on the pipeline of VTK. The first experiment shows that the subsampling factors are the main parameters to reduce the computation time while the reduction factor of polygon decimation, the number of iterations for smoothing, and the relaxation factor have little effect. In contrast, the number of iterations will be significant if the polygon mesh has a large size. However, the quality of 3D surface may reduce when increasing the subsampling factors. The second experiment shows that the proposed method achieves the clipping of the 3D surface model without holes at the cut surface. With the proposed processes, reconstructing and clipping the 3D surface model can be implemented on the limited resource.

Acknowledgment

Abstract — **Background: Warm-up before exercise could increase blood flow of whole body, increase muscles and skin temperature, prevent injury within exercise. Passive warm-up can increase temperature of muscles as active warm-up do, but it won't cause the muscle fatigue. To use heat packs or to apply ultrasound is the way for passive warm-up. Purpose: To determine the effects of two different modalities of passive warm-up and exercise without warm-up on exercise performance and recovery on muscle damage. Methods: Eight volunteers were participated in this study (age =23.88±5.06 y/o), and all of them were involved into three groups as control group (CON), heat packing group (HP) and ultrasound group (USD). CON never received any warm-up protocol before eccentric exercise, HP received 15 minutes of superficial heat with electrical heat pack before exercise, and USD received 7 minutes of deep heat with ultrasound diathermy before exercise. Each subject processed 30 repeated bouts of eccentric exercise with 80% MVC level. Serum CK, MVC, ROM and CIR were measured before, immediately after exercise and at 2nd, 4th, 7th, and 10th days post-exercise. Results: When measuring serum CK and CIR, there were no significant difference between CON, HP and USD (p>0. 05). When measuring ROM and MVC, there were significant difference between CON, HP and USD (p<0. 05). Conclusion: USD and HP have better muscle strength and performance than CON. According to the recovery procedure, USD took lesser damage on muscles than HP and CON. USD had lesser swelling then HP and CON in recovery stage after exercise.**

Keywords — **Passive warm-up, Muscle damage, Ultrasound**

I. Introduction

Sports injuries are common problems in clinic, especially for muscle damage. [1-7] The clinical features of muscle damage include increased activation of creatine kinase (CK), muscle dysfunction, decreased muscle power, muscle fatigue, decreased range of motion of involved joint, muscle swelling and delayed onset muscle sorenessoccured.[8,9] Many evidences revealed that adequate warm up before exercise, not only decreased muscle damage occurred but also elevated skin and body temperature through increased whole blood volume in athletes, and improve exercise performance .[10-14] There are two types of warm up. Active warm up and passive warm up. Active warm up means use sub maximal intensity before exercise to elevate deep muscle temperature, such as jogging, yoga, swimming. And passive warm up means elevate muscle and core temperature by external modality, without cause energy diminish, such as hot pack, bath or massage. [11,13,15] So it is interesting to discuss that passive warm up could increase blood flow in major muscle group and prevent energy consumption. Hot pack and ultrasound are common heat modalities in clinics, but few studies investigate the recovery effect when apply in muscle damage. The goals of our study are to compare the effect of different heat modality in recovery after muscle damage. And we use swelling of joints, range of motion of joint, muscle swelling and creatine kinase (CK) in blood as indirected makers after eccentric exercise.[16-23]

II. Method

There are 8 physical educational college students involved the study. The mean age was 23.88±5.06. All of them need to accept 3 different intervention, which included control group(CON), ultrasound intervention before eccentric exercise(USD), and hot pack apply before eccentric exercise(HP). The interval between each session was 18 days to make sure total recovery.[24,25] All of the subjects were examined the upper arm circumference of nondominant side(CIR),we measured 4 cm and 8 cm above elbow joint (CIR-4,CIR-8), and maximal voluntary isometric contraction (MVIC) of biceps, active range of motion(AROM) of elbow joint, and blood sample analysis before test. The eccentric exercise mode included that subjects eccentric elbow flexor with 80% load of maximal voluntary isometric contraction of biceps, and repeat 30 times. The contraction time of each eccentric exercise was 5 seconds and the rest interval between each contraction was 45 seconds. [26] Subjects were examined the upper arm circumference of nondominant side, MVIC of biceps, AROM of elbow joint immediately after eccentric exercise, repeat the above measurements and CK analysis on 2nd,4th,7th,10th day after exercise to examined the recovery state after muscle damage.

III. Result

CK. There were no significant difference between 3 groups at each time (p>0.05)(fig.1), and all the groups showed elevation the concentration of CK after 2nd day post exercise, and peak on 4th day then gradually recovery. CK on 4th day post exercise had significant difference from pre-test in CON and HP groups, but not revealed in USD group.

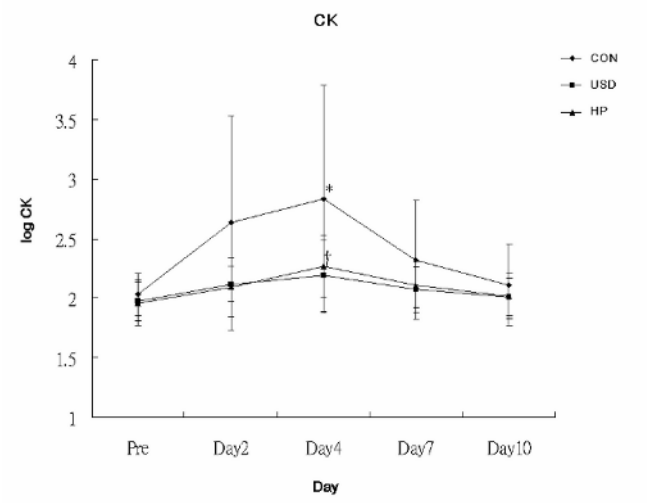

Fig. 1 CK response to eccentric exercise in CON, HP and USD groups. * means significant difference compared with pre-test in CON group ($p < 0.05$), † means significant difference compared with pre-test in HP group ($p < 0.05$)

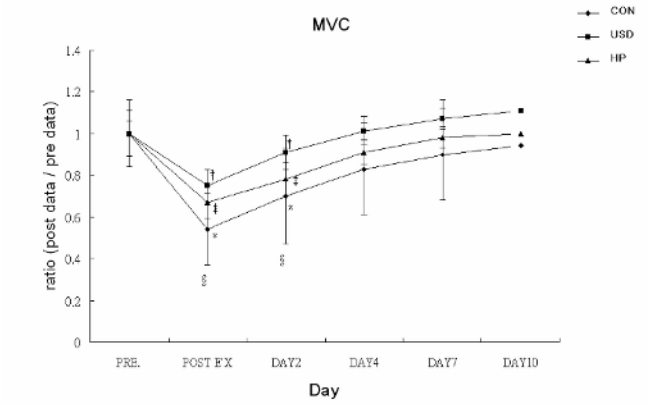

Fig. 2 MVIC response to eccentric exercise in CON, HP and USD groups. * means significant difference compared with pre-test in CON group ($p < 0.05$),† means significant difference compared with pre-test in USD group ($p < 0.05$),‡ means significant difference compared with pre-test in HP group ($p < 0.05$),§means significant difference between CON and USD group ($p < 0.05$).

MVIC. It sowed significant less MVIC post exercise in 3 groups ($p < 0.05$) (fig.2), especially in CON group, and less in USD group. It recovered after 2nd day post exercise, but had significant difference from pre-test. The MVIC of USD showed significant higher than CON group at post exercise immediately and 2nd day after exercise.

ROM of elbow joint. All the groups showed significant decrease after eccentric exercise ($p < 0.05$) (fig.3), especially the CON group. USD and HP groups showed significant decrease after eccentric exercise only on 2nd day post exercise. There were significant difference between USD and the other two groups on 2nd,4th,7th,10th day.

CIR. There were no significant difference between CON, USD and HP group at each measurement in upper arm proximal part, and all the groups showed significant increase after eccentric exercise even on 2nd day post-exercise. Only CON group had significant swelling persist on 4th day post-exercise (fig.4). In the distal part, it revealed significant swelling on 4th day post-exercise in CON and HP groups (fig.5).

IV. Discussion

USD showed significant effect in decrease muscle damage and improve muscle recovery. In our study, CK data revealed that USD applied before exercise could decrease muscle damage, but there were no significant difference between all three groups. We hypothesized that the reason was due to insufficient work load. Some studies used the mode of 100% MVIC and repeat for 12 times could lead muscle damage, [25,29] but 80% MVIC and repeat for 30 times in our study didn't show the result. Further study is needed to make sure how intensive eccentric exercise program will induce muscle damage. USD and HP groups showed better recovery after eccentric exercise, and it means that passive warm up before exercise could less muscle damage from exercise. Though some authors compared the effect of microwave with coldpack, and found no difference between each other. The effect of hot mechanism before exercise still be doubted.[17,29,30] More study could focus on local blood flow change after passive warm up and find the link between temperature and muscle damage. In our study we found that there were no difference persist in three conditions, and it was different from other studies. The reason may be due to insufficient precise tool to exam. The Dopplar ultrasound maybe need to consider to detail detect microchange in cross section of muscle fiber in future study.[31,32]

V. Conclusion

USD and HP have better effect than CON. According to the recovery procedure, USD took lesser damage and swelling than HP and CON in recovery stage after exercise.

Capacitive Interfaces for Navigation of Electric Powered Wheelchairs

K. Kaneswaran and K. Arshak

Department of Computer and Electronic Engineering, University of Limerick, Limerick, Ireland

Abstract — **This paper presents the design of capacitive interfaces, developed on standard printed-circuit boards, which allow persons with muscular weakness the ability to navigate an electric powered wheelchair by small finger movements. The goal was to develop a high-quality and reliable capacitive-sensor interface that was easy to use, met ergonomic requirements and reduced the mobility requirements needed by that of a standard joystick user. Usability and acceptability criteria were also considered. An Assistive Device Platform was also developed to allow the sensors to interface to a wheelchair platform. The sensors were connected to the platform through an I^2C connection. The platform can also accommodate for other sensors such as accelerometers and switch interfaces requiring digital interfaces such as SPI, parallel and serial connections thus accommodating for a wider range of motor disabilities. The platform has been tested by able and non-able bodied users.**

Keywords — **Assistive Technology Device, Electric Powered Wheelchair, Capacitive Sensors, Joystick, Electric field sensing.**

I. Introduction

The successful integration of capacitive touch sensors into everyday consumer products, e.g. mobile phones, has led to improved user interfaces and aesthetic look of the products. Although these new intuitive interfaces have been designed for a mass portable device market their non mechanical nature may have more relevant use in Assistive Technology Devices (ATD).

As a standard, a power wheelchair system is normally supplied with a master joystick. For persons with severe immobility and conditions which limit range of movement the use of a joystick to control navigation of a powered wheelchair may not be possible. In this case a secondary joystick is provided and usually consists of a sip-and-puff, chin or a head control device. However, a clinical survey in 2000 [1] of 200 practicing clinicians in the U.S presented that 40% of patients who used the secondary joysticks found steering and maneuvering tasks difficult or impossible. The paper outlined the requirement for more "independent mobility controllers"; controllers which allow even the most severely immobile person the ability to navigate a powered wheelchair. The Assistive Device Platform (ADP) together with the use of capacitive sensors is designed to alleviate some of the problems associated with the use of secondary joysticks by making them easier to use, non mechanical in nature and aesthetically more pleasing. The current state of the art device, the VIC-CCD [1], uses a mixture of capacitive technology and infrared sensing. The problems found with infrared sensing is that strong sunlight can affect the CCD elements. This problem is rectified by using capacitive based touch pads. This paper outlines the design of the ADP for use with printed circuit board (PCB) based capacitive sensors and their application to Assistive Technology Devices (ADT).

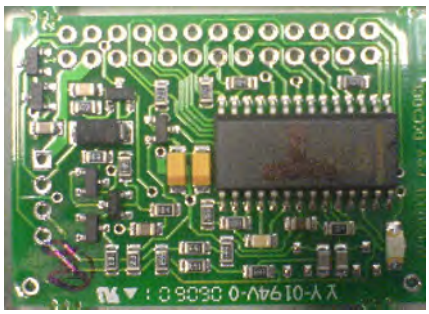
II. Assistive device platform design

A. Microcontroller and Wheelchair interface

The ADP is based around the ADuC842 microprocessor [3], which boasts a plethora of peripheral support allowing us to interface a wide range of sensors to the system. Some of the common on-chip interfaces are UART, $I^2C^{©}$, SPI I/O, an 8 channel 12 bit 420 kSPS ADC, two 12 bit DAC's, two PWM sigma delta DAC's, three 8-bit bi-directional digital ports and one 8-bit digital input port.The microcontroller is an optimized 8052 core offering up to 20 MIPS peak performance. Three different memory options are available offering up to 62 kBytes of nonvolatile Flash/EE program memory. Four kBytes of nonvolatile Flash/EE data memory, 256 bytes RAM, and 2 kBytes of extended RAM are also integrated on-chip. The on chip data retention allows code to run from internal memory without the need for an external memory IC reducing board size and power consumption. A unique feature of the ADuC842 is that it allows both the I^2C and SPI bus access simultaneously. The Analog Device range of Capacitive Sensing IC's gives the option of I^2C or SPI interface. This makes the system more versatile as the code can be included for both interface types allowing several devices to be run simultaneously.

A main component of the Assistive Device Platform is the General Purpose SLIO Board (GPSB), figure 1. This is an interface board which allows us to connect to the Wheelchair controller unit on almost all Dynamic Ltd controller powered wheelchairs. The GPSB allows the designer to control the wheelchair by use of four analog channels two of which are direction channels and two mirror channels.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1153–1157, 2009
www.springerlink.com



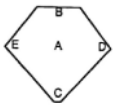


Figure 1: General Purpose SLIO Board (GPSB).

The four channels must be used in a dual decode format with all voltages with respect to half rail for correct interface. Table 1 outlines the dual decode voltage specification. The voltage speed mirrors are used for error control, when a change in voltage occurs on the directional channel a corresponding voltage change occurs on the mirror channel. The mirror voltage changes in proportion by 5 - 10% of the direction value voltage. The voltage speed mirror value never exceeds ±.17 of the half rail voltage value.

Table 1: Voltage Specifications Dual Decode.

	Stick Position		V_{DIR}	V_{SPD}	V_{DIR}	V_{SPD}
	A	0°	0	±.05	0	±.05
	B	17.5°	1.3	±.06	0	±.16
	C	-20°	-1.5	±.16	0	±.16
	D	20°	0	±.17	1.5	±.17
	E	20°	0	±.17	-1.5	±.16

All voltages are with respect to mid rail.

Under fault conditions, for example due to a short on the directional or speed mirror channels, the GPSB will detect a direction channel and mirror channel mismatch and issue a speed mirror fault to the DX© Controller stopping the wheelchair motor system. However the wheelchair will operate without the use of the speed mirror channels. If the speed mirror channels are not used they should be tied to the mid-rail voltage as with the current assistive device platform.

The ADuC842 has two 12 bit DACs and two PWM sigma delta DAC's. The first two DAC's are used to control the motion of the wheelchair; the second two DAC's can be used to generate the speed mirror faults but are not implemented in the current design. The output of the DAC's are buffered through op-amps and connected to a resistor network before connection to the GPSB. The resistor network reduces the current input and gain of the signal to the GPSB keeping the output range of a dual decode joystick between .05v and 4.5 volts. This is the recommended connection method for any dual decode joystick.

Power is supplied to the ADP by the GPSB which has the ability to supply a 20mA regulated or 200mA unregulated source for the remote joystick design. The ADP uses a 5v regulator connected to the SB+D output of the GPSB to supply power for the microprocessor, serial output port interface circuitry and capacitive IC's. The diagram in figure 2 depicts the typical configuration of the master and secondary joysticks for DX© controlled wheelchairs.

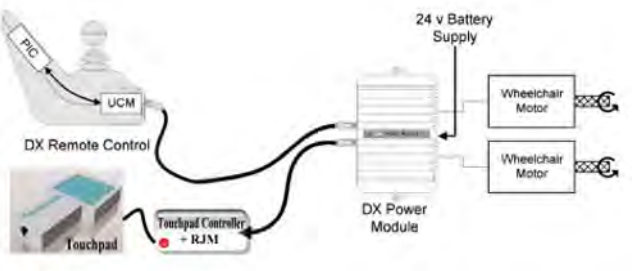

Figure 2: Prototype System.

B. Capacitive based sensors for touch control

Three touchpad designs were developed for use with the ADP and were based around the new range of Analog Devices Capacitive to Digital IC's. The AD7142 [3] was chosen for our first design but later upgraded to the AD7147 [4]. The main difference between the two is that the AD7142 required a transmit electrode to create an electric field that the receiver electrodes could detect. The AD7147 however used a single electrode to create transmit and sense the electric field. This simplified board design and reduced the pin count and size of the IC.

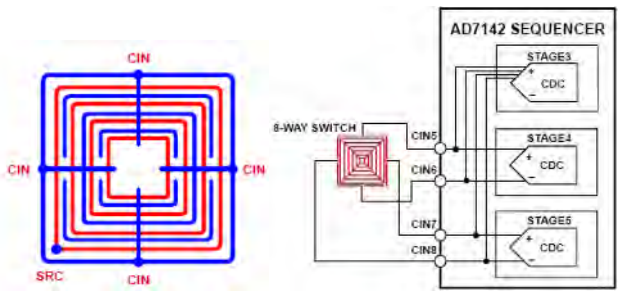

Figure 3: 8-way Switch and connections.

Figure 3 shows the use of the AD7142 to create a simple 8 point switch. It requires the use of 4 sensors each pair connected differentially, this way there can never be a false touch as the response of the system can only be from two of the sensors. This sensor type can have dimensions ranging

from 8 mm square up to 15 mm square, and requires four inputs to the AD7142. The 8-way switch gives eight positional outputs: north, south, east and west, as well as the diagonal positions: northeast, southeast, southwest, and northwest. Users move their finger in a gliding motion around the 8-way switch to change the output position. The 8-way switch is constructed from four virtual 'buttons' that are routed in an intertwined fashion. The top and bottom buttons are connected internally in the AD7142 to a CDC (Capacitance to Digital Converter) as a differential pair, as is the left and right buttons. The connections for the 8-way switch are shown in Figure 3. The 8-way switch also requires an activation measurement; this measurement detects if the 8-way switch is active before determining the direction of movement. The measurement requires a connection to the sequencer of the AD7142, as shown in Figure 3, Stage 3. The inputs from all four elements of the 8-way switch sensor sum together at the positive CDC input to determine if the sensor is active. When the user activates the 8-way switch in any direction, status bits in the status registers are set. The ADP can read back data from the AD7142 to determine which status bits are set. Four status bits on the AD7142 are used to determine all eight positions from the 8-way switch. To make the sensor interface mimic a proportional joystick the values of stage 4 and stage 5 CDC outputs are scaled accordingly and limited to the maximum input range of the Wheelchair interface hardware. The sensor board was connected to the ADP using I^2C connections.

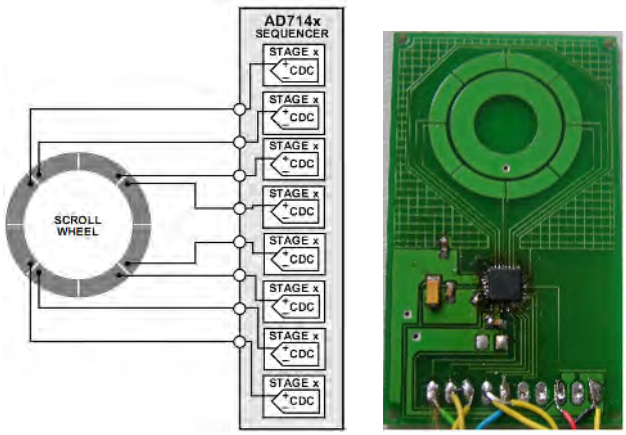

Figure 4: Scroll wheel connections and prototype PCB.

The second design the AD7142 as a scroll-wheel device much like that of the IPod. This required that 8 segments were connected to the AD7142 inputs and internally to 8 positive CDC inputs as shown in Figure 4. An algorithm supplied by Analog Devices was used to determine the finger position on the pad. The algorithm read 8 stages from the CDC sequencer and used these values to determine whether the persons finger was scrolling, the position on the scroll wheel, whether there were one or two fingers being used, and gave a switch output if the finger was stationary in either up, down, left or right positions. The algorithm results were found by reading the status of a 16 bit register, table 2, containing the positional information. The switch output was used to drive the wheelchair while the scroll status was used to change the profiles on the DX Controller. The sensor board was connected to the ADP using I^2C connections.

Table 2: Status Register for Scroll-wheel

Status Bits 15 - 8							Position 8 bits		
Activation	Tapping	Go up	Go Down	Touch Error	Touch Error	Not used	Bit7	<->	Bit0

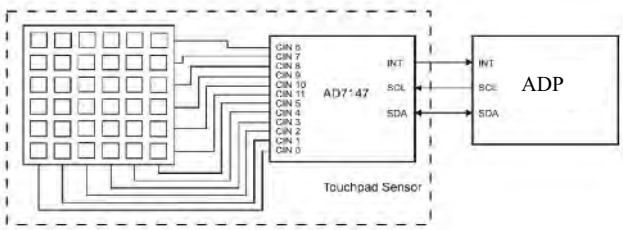

Figure 5: Touchpad connections.

The final sensor interface design was a 23mm x 23mm touchpad. The AD7147 IC was used as it was smaller, required less external components and used single electrode sensors to detect electric field disturbances. Fig 5 shows the connections for the touchpad, while figure 6 shows the actual touchpad used for testing. The touchpad requires 12 connections, 6 for the x-axis and 6 for the y axis, each con-

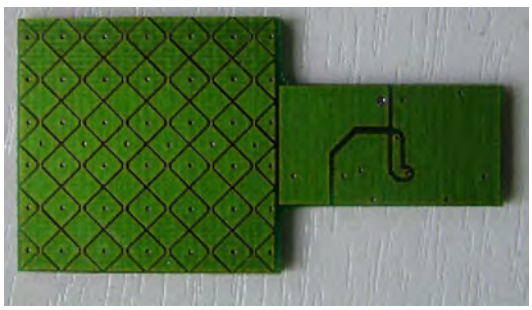

Figure 6: 23mm x 23mm Touchpad PCB design.

nected to a positive input of the CDC per stage using a total of 12 stages. After the ADP reads the 12 stages from the AD7147 the algorithm produces four 16 bit registers containing positional and status information

The status of the register can is decoded using Table 3.The extra functionality is exploited by using the tap function to increase and decrease the profile number of the DX© Controller. A tap in the upper quadrant raises the profile number while a tap in the lower quadrant decreases the profile number.

Table 3: Status Registers for 23mm x 23mm touchpad.

Bit	Register 0	Register 1	Register 2	Register 3
15	Active	Active	Not used	Not used
14	Tap	Tap	Not used	Not used
13	Go Left	Go Up	Not used	Not used
12	Go Right	Go Down	Not used	Not used
11	2 Fingers	2 Fingers	Not used	Not used
10	Large finger	Large finger	Not used	Not used
9	Touch error	Touch error	Not used	Not used
8	Touch error	Touch error	Not used	Not used
7	8 bit position	8 bit position	8 bit position	8 bit position
↓	↓	↓	↓	↓
0	Range 0 -199	Range 0 -199	Range 0 -127	Range 0-127

C. DAC Output.

The DAC outputs on the ADuC842 control the motor on the wheelchair by sending voltages to the GPSB in proportion to the movement of the user's finger across each of the touch pad designs. The range that the GPSB will accept before issuing a fault is between .05v and 4.5v. The DAC output can be set to either 8 or 12 bit. By using 8 bit we can reduce the number of calculations needed to scale the final voltage output and also issue an update to DAC in one write operation.

III. Experiment

For each sensor a user was seated in an Invacare Cruiser Plus wheelchair with the ADP connected as a secondary joystick. The DX© Controller was reprogrammed to accept the secondary joystick on the three lower profiles each programmed to control the motors at different proportions to full speed. Profile one allowed a maximum speed of 40% of the max value, profile 2 was set to 50% while profile 3 was set to 60%. The user was then asked to navigate the electric powered wheelchair using the three different profiles around a room full of obstacles such as bollards, tables and chairs.

IV. Results

Through general discussion and visual inspection it was clear to see that the users found it easier to drive the wheelchair with the proportional systems, 8 way switch and touchpad. The users found that there was no necessity for the scroll-wheel on the second design unless they were in need of controlling an environmental unit or detailed menu system much like it was designed for in MP3 players. The size and shape of these touch controllers in general were a major improvement over the VIC-CCD controller as users found it bulky and cumbersome affecting their mental attitudes and willing to accept it as an assistive device. All users were successfully able to change from profile to profile on each design. Some found the touchpad design to be more responsive than a commercial joystick with respect to obstacle avoidance as the smaller finger movements could be completed quicker than a wrist movement when pushing a joystick.

Furthermore, the ability to attach a small metal rod to any moveable part of the body meant the wheelchair could be controlled by any moveable limb expanding the range of users who can avail of this device. The touchpad design was also controlled by use of the tongue.

V. Conclusion

This paper demonstrates how technology already available can be used to improve accessibility and independence for persons with severe immobility. The paper outlines several designs than can be used to control navigation of an electric powered wheelchair. However, further testing is scheduled before the ADP platform and capacitive sensors can be used to control a wheelchair system on a day to day basis.

Health Care and Medical Implanted Communications Service

K. Yekeh Yazdandoost and R. Kohno

Medical ICT Institute, National Institute of Information and Communications Technology, Yokosuka, Japan

Abstract — **The medicine day by day and more and more is associated with and reliant upon concepts and advances of electronics and electromagnetics. Numerous medical devices are implanted in the body for medical use. Tissue implanted devices are of great interest for wireless medical applications due to the promising of different clinical usage to promote a patient independence. It can be used in hospitals, health care facilities and home to transmit patient measurement data, such as pulse and respiration rates to a nearby receiver, permitting greater patient mobility and increased comfort. As this service permits to remote monitoring of several patients simultaneously it could also potentially decrease health care costs. Advancement in radio frequency communications and miniaturization of bioelectronics are supporting medical implant applications. This paper discusses the issues related to health care via Medical Implanted Communications Service (MICS) and presents guidelines for addressing these issues.**

Keywords — **Implant medical device, in-body radio communications, electromagnetic wave, thermal effect, security and privacy.**

I. Introduction

The use of implantable wireless communication device is growing at a remarkable rate for human medical and clinical applications such as cardiac pacemaker, blood glucose sensing, pain management and epileptic seizures, because the Medical Implant Communications Service (MICS) is replacing inductive communication for radio frequency implanted device. Therefore everybody can benefits of the best healthcare service irrespective of their geographic location.

Implantable medical devices have a history of great success in the treatment of many diseases, such as heart diseases and neurological disorders. Pacemakers are the oldest and most successful example of implantable medical device. Today's aging population is driving wide scale demand for more advanced healthcare treatments, including wireless implant devices that can deliver ongoing and cost effective monitoring of a patient's condition.

Using MICS, a healthcare provider can set up a wireless link between an implanted device and a base station, allowing physicians to establish high-speed, easy-to-use, reliable, short-range access to the patient health data in real-time. Innovation in wireless communications aligned with the MICS band of frequencies is fueling the growth. The frequency band for MICS operations is 402-405 MHz [1], [2].

From a regulatory viewpoint, the establishment of the MICS band began in the mid 1990s when Medtronic petitioned the Federal Communication Commission (FCC) to allocate spectrum dedicated to medical implant use. After gaining wider industry support, the 402–405 MHz MICS band was recommended for allocation by International Telecommunication Union Radiocommunication Sector Recommendation (ITU-R) SA1346 in 1998. The FCC established the band in 1999, and similar standards followed in Europe. The common standards will eventually allow patients with implantable devices to obtain care worldwide.

Recognizing the level of international support for the use of MICS, international travel of patients fitted with MICS devices should not pose any problem.

The IEEE 802.15 WPAN Task Group 6 (TG6) was formed with the charter of drafting a standard for Body Area Network (BAN) [3]. There are more than 25 companies, including R&D centers and universities from around the world. According to the IEEE 802.15.TG6 group, there is a need for a communication standard optimized for low-power devices and operation on, in or around the human body to serve a variety of applications including medical, consumer electronics and personal entertainment. What is unique in this wireless standard is the presence of a body, which impacts the radio frequency channel model.

The growing complexity of implant devices has led to the need to transfer greater amounts of data during a communications session; the use of MICS devices with bandwidth up to 300 KHz can support these and future development. A typical communications distance for a MICS device is intended to be around 2 meters, allowing greater patient mobility during communications sessions.

Implanted medical devices are usually driven by two primary requirements. First, it must consume very little power so that they can last on battery power for a long period of time. Second, Implanted medical devicess must often be added to other low-cost, small-sized components such as sensors. This consideration requires that MICS radios be low cost, have a simple design.

The design of implanted medical devices is challenged by the following basic requirements:

- Low power consumption

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1158–1161, 2009
www.springerlink.com

- Form factor
- Thermal effect
- Antenna and body loss
- Reasonable data rate
- High reliability
- Security

The above challenges are more crucial when to know that, between 1990 and 2002, over 2.6 million pacemakers and implantable cardioverter defibrillators were implanted in patients in the United States [4].

II. Wireless communications

The use of implanted medical devices is not without many significant challenges, particularly, the increasing of propagation losses in biological tissue. Therefore, to ensure the efficient performance of body implanted wireless communication the channel model need to be characterized and modeled for reliable communication system with respect to environment and antenna.

An important step in the development of a wireless MICS is the characterization of the electromagnetic wave propagation from devices that are inside the human body. The complexity of the human tissues structure and body shape make it difficult to drive a simple path loss model for MICS. As the antennas for MICS applications are placed inside the body, the MICS channel model needs to take into account the influence of the body on the radio propagation.

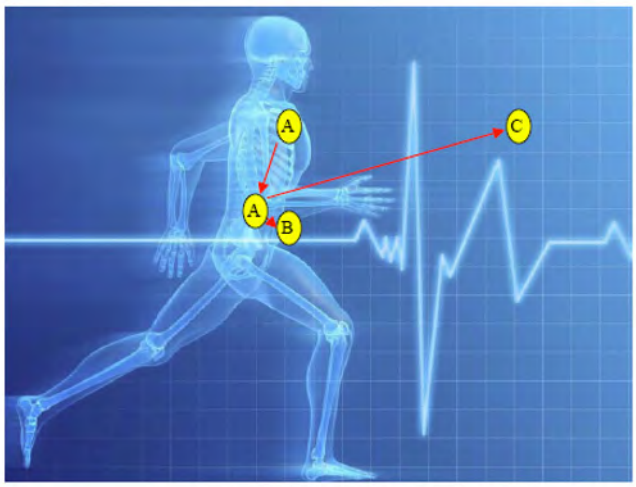

Fig. 1 Possible communication links for medical implanted devices

For wireless communication inside the human body, the tissue medium acts as a channel through which the information is sent as electromagnetic radio frequency waves. A propagation model is necessary to determine the losses involved in the form of absorption of electromagnetic wave power by the tissue. Absorption of electromagnetic waves by the tissues, which consists of mostly water, accounts for a major portion of the propagation loss.

Fig. 1 shows possible communication links for medical implanted communications service; implanted device to the implanted device (A to A), implanted device to the body surface (A to B), and implanted device to 2 meters a way from the body (A to C).

Indeed, the need for small sized antennas and RF front ends with compromising performance has emerged as a key driver in implanted medical wireless devices.

III. Body tissues and radio frequency

Understanding the human body's effect on RF wave propagation is complicated by the fact that the body consists of components that each offer different degrees, and in some cases different types, of RF interaction. The liquid nature of most body structures gives a degree of RF attenuation, whereas, the skeletal structure introduces wave diffraction and refraction at certain frequencies.

The human body is not an ideal medium for radio frequency wave transmitting. It is partially conductive and consists of materials of different dielectric constants, thickness, and characteristic impedance. Therefore depending on the frequency of operation, the human body can lead to high losses caused by power absorption, central frequency shift, and radiation pattern destruction. The absorption effects vary in magnitude with both frequency of applied field and the characteristics of the tissue, which is largely based on water and ionic content. It is very difficult to determine the absorption of electromagnetic power radiated from an implanted source by the human body. Although quite a few investigation has been done to determine the effect of human body on radiated field [5], [6], and almost all of these studies have been based on external sources.

When the wavelength of a signal is significantly larger than the cross-section of the human body being penetrated, there is very little effect of human body on the signal. These wavelengths occur at frequencies below 4 MHz. Above 4 MHz the absorption of RF energy increases and the human body may be considered to be essentially dense until roughly 1 GHz when the dielectric properties of the human body begin to introduce a scattering effect on the RF signal.

Table 1 shows the electrical properties of muscle, fat, and skin at frequency of 403.5 MHz [7]-[9]. Where ε is the

dielectric constant, σ is the conductivity, δ is the penetration depth.

Table 1 Electrical properties of the body tissues at 403.5 MHz

Tissue	ε	σ[S/m]	δ[m]
Muscle	57.1	0.7972	0.0525
Fat	5.5783	0.0411	0.3085
Skin	46.7060	0.6895	0.0551

IV. Thermal effects

The heating effect of microwave destroys living tissue when the temperature of the tissue exceeds 43^o C. Accordingly; exposure to intense microwaves in excess of 20 mW/cm2 of body surface is harmful.

For the safety reason of human body to the radiation, in-body radiation is restricted to certain level. There is a relatively extensive body of published literature concerning the biological effects of RF radiation. The FCC regulations limit the Maximum Permissible Exposure (MPE) to non-ionizing radiation based on the amount of temperature rise that will occur. The regulation limits the temperature rise to 1 degree of Celsius. This limit is being determined by the specific heat of the tissue. The IEEE C95.1 [10] defines that the body exposure to radiation from implanted medical device is considered as partial body exposure in an uncontrolled environment. In such a case, the general provisions of the standard should not be violated, which is whole-body averaged SAR during localized exposure. The limits for partial body exposure are specified in terms of maximum limits on the Specific Absorption Rate (SAR). The average SAR over the whole body is to be lower than 0.08 W/Kg and the spatial peak value of the average SAR over any 1 g of tissue (define as a tissue volume in the shape of cube) is to be less than 1.6 W/Kg. The spatial peak SAR shall not exceed 4 W/Kg over any 10 g of tissue in wrists, ankle, hands and feet. The relationship between radiation and SAR is given by

$$SAR = \frac{\sigma |E|^2}{\rho} \quad (W / Kg) \tag{1}$$

where σ is the electrical conductivity of the tissue, E is the induced electric field, and ρ is the density of tissue. Experiments show exposure to an SAR of 8 W/Kg in any gram of tissue in the head or torso for 15 min may have a significant risk of tissue damage [11].

V. Low power consumption

For a long-term implantable device, minimizing the device power consumption is the most critical requirement. For an implant device with a desired battery life of seven to 10 years, every joule of energy must be carefully conserved. Power consumption determines the life of the implant as well as the battery size. The battery can be the largest component in a medical device where a minimal device size is another critical requirement.

Energy is largely consumed during data transmission. The transceiver's output power amplifier must be capable of broadcasting data relatively quickly over a reasonable distance. The smaller the transmission range and the slower the data can be sent, the lower the power consumption. Furthermore, the tiny antennas used in an implanted device are inefficient, requiring a further boost in power. And, as noted earlier, the human body is a good attenuator of an electromagnetic signal.

Fortunately, implant transmissions are usually infrequent, so MICS-band transceivers squeeze power savings by turning off as many circuits as possible. An obvious approach to saving power is to keep the power-hungry transmitter circuits powered off when not required. Most radio circuits are designed to operate in a receive mode when not transmitting, both because the radio is constantly looking for an asynchronous transmit request and because the receiver circuits generally consume less power.

A more effective technique is to periodically power-down the receiver circuits to conserve additional power. The trick is to periodically wake the receiver up to check for an asynchronous transmit request. The power-up timing must be done quickly enough to catch the transmitted message with just enough time left to acquire the portion of the message containing the information.

VI. Security and privacy risk

Wireless technology gives many benefits but these may come with unanticipated risks. The patient's private medical information stored on pacemakers or implantable cardiac defibrillators could be extracted and their devices reprogrammed without the patient's authorization or knowledge.

Security typically involves protecting data and protecting the network from pinching or destruction. Protecting data ensures that it arrives at the destination as it was transmitted and that no other entity was able to receive and decode the data. Protecting the network ensures that external attacks do not adversely affect network performance [12].

Implantable medical device such as pacemakers and implantable cardiac defibrillators can save lives and greatly

improve a patient's quality of life. But, as these devices begin to interoperate in vivo and to use wireless communications with out side the body, the need to address security and patient privacy.

There has never been a reported case of a patient with an implantable cardiac defibrillator or pacemaker being targeted by hackers.

When considering implantable medical device security and privacy, it is important to draw distinctions between classes of devices that have different physical properties and healthcare goals.

The range of applications supported by MICS technology is quite wide, from patient condition monitoring to control of body functions. Likewise, the degree to which the patient will need security and protection of privacy will also vary.

VII. Conclusions

The use of implantable devices in the treatment of a number of chronic diseases and disorders including pain management is growing at a remarkable rate. Advances in low-power semiconductor design and manufacturing processes are enabling longer battery life. Innovations in wireless communications aligned with the Medical Implant Communication Service band of frequencies are fueling the growth. Furthermore, clinical research continues to identify new indications for implantable devices, applications that will benefit from the ever-improving sensor electronics that will optimize patient therapy in real-time. Finally, physicians are recognizing the advantages of implantable devices over traditional methods of treatment. There are a number of problems that could surely benefit from MICS, such as; deafness, blindness, paralysis, Parkinson's disease, and epilepsy. Indeed, the medical implant communications service is going to make a significant impact on health care in the coming next few years.

MultiAgent System for a Medical Application over Web Technology: A Working Experience

A. Aguilera, E. Herrera and A. Subero

Faculty of Sciences and Technology, University of Carabobo, Valencia, Venezuela

Abstract — **At present, many medical applications are limited to storing basic information concerning patients, such as, their medical history, diagnostic issued by specialists, reviews, etc. But the medical work is not easy when considering complex cases involving different experts and require a high degree of coordination and cooperation. Traditionally communication between experts takes place across consultations involving large amounts of resources (money, time, etc.). MultiAgent Systems (MAS) are a branch of artificial intelligence distributed to adequately address problems of coordination and communication (among others) where several decision-making agents are involved. The objective of this work is the design and implementation of MAS that allows coordinate the workflow of a medical center. We have implemented a management tool for medical records and requests for medical services based on Web technology. The application made available to doctors all the information necessary for carrying out timely diagnosis, through electronic medical records. Regarding the tasks of coordination mentioned: assigning tasks to doctors, requests for reviews, delivering results, among others, using technologies such as text messaging, e-mail messages and on-line. To design agents and their roles, tasks and plans using the "Software Agent Architecture Pattern" the which is based on a set of classes organized for the encoding software components with agents that are integrated into Web applications, in addition to use as MAS commonKADS Methodology development of MAS. Currently have an application robust and stable. It is worth mentioning that this approach used specifically in the medical field is extended to other areas that require coordination distributed.**

Keywords — **MultiAgent Systems, Web technology, MAS-commonKADS, Medical Application.**

I. Introduction

Agent-based systems technology has recently generated plenty of research work because it has been considered as a new paradigm for conceptualizing, designing, and implementing software systems. It is particularly attractive for software development that operates in distributed and open environments. Central to the design and effective operation of such MAS is a core set of issues and research questions that have been studied over the years by the distributed artificial intelligent community [19]. An intelligent MAS includes a number of software agents interacting to each other to solve a problem. Various agents are responsible for planning different tasks. These tasks should be coordinated to solve complex problems [10, 11, 13].

Particularly in health care environments, agents have the potential to assist in a wide range of activities [16]. They can keep the autonomy of the collaborating participants, integrate dissimilar operating environments, and coordinate distributed data, such as patient's records filed in different hospitals (private and public) or in different medical departments, and other organizations involved in health care systems such as insurance companies and government organizations. The agents at a MAS may run associated with different locations, such as the departments of a medical center [15] or the file of a single person included in a health care program from a certain community [3]. The autonomy of each agent in a MAS keeps the independent views of each modeled actor. For example, each agency involved in the provision of health care to a community, such as social workers, health care professionals and/or emergency services may have different private policies determining their relationship between their individual decisions and other agents [3]. Agents can also handle the complexity of solutions through decomposition, modelling and organization of relationships among components; improve patient management through distributed patient scheduling using cooperating intelligent agents; provide remote care monitoring and information for such groups as the elderly and chronically ill; undertake hospital patient monitoring; supply diagnosis decision-support; improve medical training and education in distance-learning tutoring systems [20]; gather, compile and organise medical knowledge available on the Internet [2,23]; and enable intelligent human-computer interfaces to adapt medical data and users requirements and visualise medical data [9,10,11,21]; medical decision making [14], medical e-learning [5]; medical workflow [6,7] .

II. Medical case study

Physicians treat different diagnostic cases, and some of them are considered obvious (classical cases). This happens because the nature of the illness under study is simple or

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1162–1165, 2009
www.springerlink.com

because the physician's experience is significant. There are other less obvious cases for which it is not easy to establish a satisfactory diagnosis directly (complex cases). There are many reasons for this: (1) a number of available judgment elements may not be enough, (b) the illness has not evolved enough for certain signs to appear; and/or (3) an incidental nonschematized cause may appear. The diagnosis in these cases can then involve great difficulties and require a complex procedure [1]. This procedure can implement several clinical maneuvers (exploration of various organs or systems, complementary tests, and sometimes, a further patient observation) which are repeated several times [17].

In the daily practice, the care of a particular patient is often shared by several different clinicians who are located in a variety of physically distributed health care settings [11]. In addition to this interorganizational coordination, there is also a need to ensure that the activities within an organization are effectively and coherently managed. In a hospital, for instance, health care typically involves execution of interrelated tasks by medical doctors, nurses, pharmacists, laboratory analysts, and resource management departments. Shared care is a situation where in which clinicians (GPs and specialists) jointly treat the same patient. Patients requiring shared care are, for example, patients undergoing chronic disorders, such as diabetes mellitus, obstructive pulmonary diseases, and/or cardiological diseases [24]. They may also be, or patients who receive palliative care at home or patients with a multisystemic pathology where physiopathology and etiology are necessary to examine the results of several diagnostic procedures. A clinical case illustrating this type of work is shown in fig. 1 (A more detailed explanation is found in [18]). In this case, we can observe the interaction among a GP, a radiologist and a pathologist.

The provision of medical care typically involves a number of individuals, located in a number of different institutions, whose decisions and actions need to be coordinated if care is to be effective. In doing so, shared care requires structured coordination of medical activities, where physicians know the kind of guidelines or protocols will follow and where physicians trust each other's actions and interventions. When different providers are involved in a patient's care without proper coordination, care process may not be meaningfully integrated; a patient receiving such a care under such conditions may be subject to two conditions: unjustified interventions and/or justified actions not performed. To provide an adequate software support for such a coordinated health care management it was decided to adopt an agent-based approach [1].

Clinical case

A 40 year-old male patient, non-smoker, without any obvious particular antecedents in his past medical history. He attended his GP with a non-productive cough of a three-month evolution . His physical tests normal. GP recommended him a palliative treatment and some laboratory and paraclinical tests (Postero-anterior chest x-ray).

x-ray result : circumscribed 2-3 cm nodule located in the right upper lobe of the lung with the presence of interior calcifications of non-specified type. Heart and rest of study without obvious modifications. Scanner recommended.

CAT Lung scanner: It indicates a 2 x 3 cm mass with non-epimacular aspect located in the right upper lobe of the lung with non-specified calcifications. There is no affectation of Mediastinum lymphatic ganglia. There are no other masses in the thorax.

Pulmonary biopsy: macro and microscopic analysis of post-operative piece.

Diagnosis: ENDOBRONCHIAL HAMARTHOMA.

The patient left the hospital and considering the benign origin of the pathology, the doctor recommended an annual check up with his general practitioner.

Fig. 1. A clinical case

III. Design and Implementation of the System

We defined system architecture with a three-level structure [1]: the collaborator level or users (human agents), computer systems agents (software agents) and the data level (databases and knowledge bases). For design and develop of system, we follow the procedure showed in Fig. 2. We used a model-view-controller and a web agent pattern [4] to our design. The first task consists in identifying and defining model elements. Then, these elements are coded and tested individually. Finally, system functionality is checked and validation tests are executed with the real user.

At design level, we have used a pattern architecture based in the model-view-controller (MVC) to our web application. For the agent design, we have used an experimental framework called WAF [4]. This framework has been used successful in the developing of several theses in the University of Carabobo- Venezuela with web technology. In this framework, each agent has its own directory (following Tomcat's structure), and each agent is also structured in directories according to WAF. Each directory (environment,

behavior, resource and communication) contains the implementation of Java classes. The communication among agents is made by message passing thanks to javax.mail library and to the implementation of a blackboard.

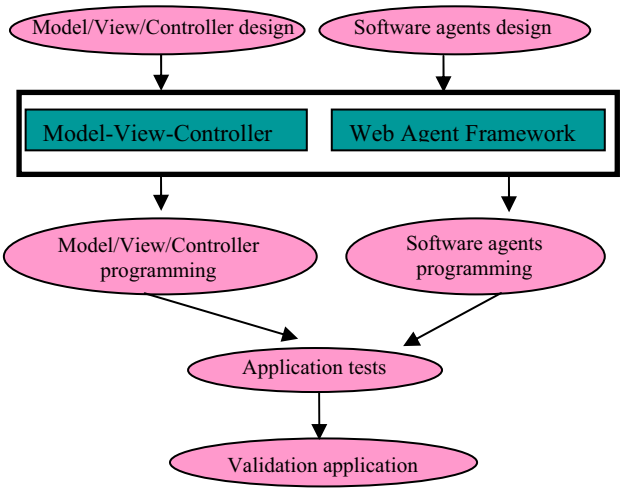

Fig. 2. Procedure of design and develop system

The aim of our web application is to facilitate data exchange and communication among the medical specialists in medical solving problems. This system offers the specialists adequate interfaces for storage and updating of medical histories; it also allows us the dynamic construction of our medical case base. At the level of construction, the system was conceived to allow an easy incorporation of software agents. These agents have the objective to coordinate medical work, control medical doctors' workload, control appointments, and so on. The idea is to provide to the users a working and portable tool easy to install and integrate with other applications.

At develop level, we used a client-server communication model based on Sun Microsystems technology. This model is the base of high level views of JAVA™: servlets and JavaServer Pages (JSPs). In the context of our application, JSPs constitute the views of application according to model MVC; they allow communication with users; servlets constitute the models and one special servlet is the controller. JSPs and servlets are coded in XHTML and Java respectively. TOMCAT server is our web server and PostgreSQL is our database system. In the agent's case, each one constitutes a thread program by extending the Thread class in Java. Each agent runs as an independent process on the server side [8].

IV. System validation

The system is conceived as a web application. The system validation is based on user and functionality tests. The web application is composed of a number of services, most of which a user can interact with through the use of a web accessible graphical user interface.

a. User validation

The validation approach is based on expert inspection and user tests. The aim of the user tests is to verify the user behavior in front of the system. The user has to test different services and use them in the daily work.

Test plan :

1. Selection of functionalities to be tested by users.
2. Construction of a questionnaire with functionalities and query evaluation.
3. Selection of a complex case with medical aid.
4. Request of medical specialists concerned with the medical case.
5. Random selection of other specialist physicians.
6. Gathering of information from specialists.
7. Analysis of result.

The services of the system to be tested are:

• User access and security of the system.

• Updating patient data: personal data, familiar data, past history.

• Updating case data: consultations, establishment of actual clinical context.

• Management of patients.

Test Results: We worked on a real case in the «Enrique Tejera » hospital, Venezuela (Valencia). 5 physicians were asked. Additional functionalities by specialty were required. In general, our application is successful and each of the services defined for the system can be successfully completed. The main difficulty is related to specialist availability.

b. Usability test

The aim of this test is to evaluate the quality of the interface with computer specialists.

Test plan:

1. Selection of instruments from ISO/IEC 9126 norm [12].
2. Preparation of questionnaires.
3. Random selection of computer specialists.
4. Request from computer specialists.
5. Information gathering from physician specialists.
6. Analysis of result.

Test Instrument: Some basic principles of usability from ISO/IEC 9126 standard [12]. P10 - Principles of dialogue, P11 - Usability of system, P12 – Visual display of information, P13 - Guidance to users, P14 - Dialogues menu styles,

P15 - Dialogues for process control languages, P16 - Dialogues by direct handling, P17 - Dialogues for the filling of forms.

Test results: 3 expert users have been inquired. Improvements are necessary on the following aspects: User feedback; Possibilities of interface personalization; Presentation of windows; Information on the state of the system; Reduction of errors.

V. Conclusions

Multi-agent systems have shown their effectiveness to develope distributed systems on different areas. We used this approach to address the medical knowledge acquisition problem. A web application has been developed for distributed management of patients having critical disorders. Preliminary evaluation of this application shows that in real-life clinical application settings the procedure followed in building dynamically knowledge bases is effective. Internet is a technology that makes applications highly portable and accessible. The method followed in this development can easily integrate with other existing applications.

Collaborative Radiological Diagnosis over the Internet

A. Aguilera, M. Barmaksoz, M. Ordoñez and A. Subero

Department of Computer Science, Faculty of Science and Technology, University of Carabobo, Valencia, Venezuela

Abstract — **Nowadays in many cities, there is a high concentration of general and specialized physicians working in areas of highest population density. Additionally, the large number of patients who come from rural medical centers to hospitals and others medical centers is increasing. For this reason, it is necessary to create, as an alternative, mobile care centers, in order to reduce the patients in the main hospital centers. The objective of this is to develop a collaborative web application to assist the radiological medical diagnosis at distance. This application combines the web, the case based and the collaborative technologies. The application design was made with XP methodology including own elements of the Case Based Reasoning (CBR) and Computer supported Cooperative Work (CSCW). In the specification phase, we used interviews with experts and non-experts users. At the implementation level, case bases and collaborative tools have been developed to help the medical inter-consultations. We built a practical implementation of system with all these elements. This application offers to radiologists: an online help, a case base with cases solved in the past and collaborative tools. Thus, we offer the possibility of inter-consultations with others radiologists using chat, audio, video and pointers. The fuzzy similarity function was used to querying and to adapting the case base. All these functionalities have been integrated in the same application to user's comfort and use facilities. In this way, the radiologist diagnoses efficiently and with more precision. Our application was validated by the user and functionality tests and the network performance tests to obtain: average transfer rate and latency with several possibilities of communication. The user's acceptation is good and the network tests give us the better platform to implantation.**

Keywords — **Radiological Diagnostic, Collaborative Work, Case Based Reasoning, Web Medical Application.**

I. Introduction

With the introduction of high speed networks, high-resolution computers and connectivity to internet and advanced techniques on images processing, the changing phase of the health care is creating a demand of support tools of effective decisions. All of this, to help to the medical practitioners with the overload of information when they is providing high-quality patient care with effective costs. These tools not only must demonstrate a behavior based on knowledge to assist in the resolution of the medical problem but that also they must provide intelligent, intuitive and interactive interfaces that allow the users to execute their tasks effective and efficiently. Additionally with the initiation of the radiology departments in these technological aspects, the development of viable computer systems comes to be incrementally important. Medical diagnostic imaging instrument and electronic networks have resulted in accumulation and online availability of large collections of digital medical images. The radiological diagnosis is subjective by nature. The computational systems make efforts for improving the precision / fidelity in the diagnosis and the consistency of the diagnostic final decision and the resulting reproducibility in the image interpretation. It is necessary to design an appropriately defined and organized notation that enables to the clinicians to externalize, reflect on and share diagnostic knowledge. The specialty of radiology, in common with most of medicine, is gradually developing a more systematic approach to training, replacing the traditional mixture of ad hoc apprenticeship and formal lectures with a combination of structured tuition and case-based experimental learning.

Artificial Intelligence has been applied in numerous applications in the domain of health sciences. In the late 1980's, followed by ground laying work done by Koton [9], and Bareiss [3], Case-Based Reasoning (CBR) appeared as an interesting alternative for building medical AI applications, and then it has been used in the field. Case-Based Reasoning (CBR) is a recognized and well established method for building medical systems. Many works have been developed [1], [5], [7], [13] etc. The intention of these works is a) to help medical students improve their knowledge by solving practice cases and b) to help in the construction of medical knowledge base systems to support of medical decision making.

Consultation between radiologists and referring physicians is part of routine medical practice. These collaborative acts are important both for clinical decision-making concerning diagnosis and treatment, and for the training of student and novice physicians. In medical domain, there are many works related to collaborative technology (groupware), the most of them are oriented to Computer Support Collaborative Work (CSCW). These systems are able to support the collaborative multi-expert acts with the technical infrastructure [4], [6], [12], etc. Others works are oriented to the workflow systems like [2], [8], [10], etc.

The aim of our work is to carry out the implementation of a collaborative application for radiological diagnostic aid.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1166–1170, 2009
www.springerlink.com

This application integrates a case-based reasoning mechanism and some techniques computer support collaborative work. The case based reasoning give us to selecting a case similar to the actual case. The CSCW techniques give us the possibility of real time interconsultations between specialists using text messaging, video conferencing and an electronic whiteboard.

II. Radiological diagnostic process

Once the imaging procedure has been performed, the radiologist analyzes the images to identify pertinent features and integrates the imaging findings and their clinical context to determine the diagnosis or a set of diagnostic possibilities. Then, the radiologist communicates the results of the procedure to the referring physician, and may offer recommendations about further investigation. Each of these steps requires informed decision making. Some times, the radiologists have doubts about to a diagnosis. In this case, he/she can a) to querying the academic medical knowledge and b) to ask another radiologist about this diagnosis.

In general, the radiological diagnostic process can be resumed in the following steps (Fig. 1) [11]:

1. Patient evaluation and imaging study selection. Initiated by the referring physician, this process can benefit from access to clinical guidelines, consultation, and decision support.
2. Request for examination. The information tasks involve communication and require provision of appropriate definition of the problem and clinical information.
3. Performance of the examination. This involves adaptation to the problem and patient- specific requirements as well as modification based on intermediate findings, post processing, and analysis of image data for presentation and interpretation.
4. Identification of findings. The tasks are both perceptual and cognitive and include use of decision aids and education resources.
5. Interpretation of patterns and formation of diagnostic assessment. Interpretation requires integration of findings, other patient-specific information, and general knowledge.
6. Communication of results and recommendations. The tasks are those of creating a narrative report, direct contact, an image review and consultation.
7. Improving process. The radiological process requires continual monitoring and control, research database development, process and outcomes analysis, and cost-effectiveness evaluation.
8. Education and training. Information needs are for methods of carrying out all of the processes involves in

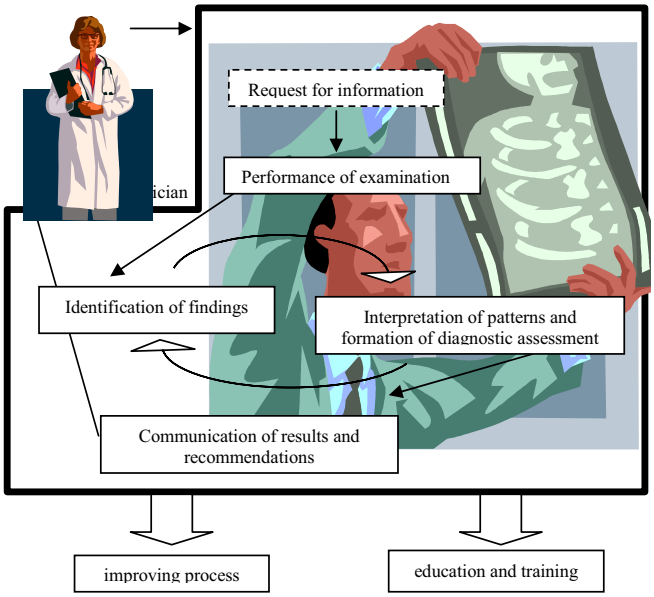

Fig. 1 Diagnostic Process

radiological practice as well as for the knowledge to support them.

Information is the sine qua non of decision making. In radiology, such information includes clinical data (presenting symptoms, signs, laboratory data, results of prior imaging studies) and clinical knowledge (general facts about diseases, how to choose imaging studies, how to perform and interpret radiological examinations). Radiologists also must consider the risks, benefits, and costs of the available actions, and the desirability, or “utility,” of each potential outcome of the decision, both from the perspective of society and that of the individual patient. Computer systems can aid radiologists in these tasks by providing patient-specific information, recalling general medical knowledge, and integrating such information to recommend a course of action. First, decision making requires accurate and ample patient-specific clinical data. Unfortunately, radiologists often lack information (patient-specific clinical data.) to determine if the requested procedure is appropriate, to perform the procedure safely, and to interpret the results accurately. Second, physicians must draw upon a large, rapidly growing body of medical knowledge. Organizing, storing, and retrieving this knowledge is a daunting task. Third, optimal decision making requires an understanding of the “utility” — that is, the relative value — of all possible outcomes of the available plans. Utility can include consideration of costs, mortality, morbidity, and the patient’s preferences. The utility of diagnostic tests such as radiological procedures reflects their potential informative ness and their

role in the overall management of the patient's illness. Decision making is a process, not a single action. For example, to resolve a question raised by an imaging finding, additional imaging procedures may be needed. Or, if a particular imaging finding is present, one may need to re-analyze the image for additional features to confirm or refute a diagnostic hypothesis. A radiologist may need to seek additional clinical information, either from the patient's records or by further examination of the patient. Thus, it is crucial to integrate the various aspects of the decision-making process, whether computer-aided or not, and to integrate knowledge of imaging procedures, findings and diagnoses with pertinent patient-specific information. In diagnostic radiology, a decision aid is required when interpretation demands specialist expertise, when many images are generated or when interpretation is especially difficult.

III. Collaborative radiological application

The application is called SICADIR (System for Collaborative Support Radiological Diagnostics). This is design over Internet with the advantage of increased its availability. The main goal considered in the system design was to build a tool which facilitates the processes of interaction between specialists and the support of physicians' knowledge based in experiences. The design of the architecture includes the following subsystems:

1) Database management subsystem. This is responsible for the maintenance of databases (insertion and deletion of data): patient history and images (Fig. 2). Also, it controls update and query processes. The medical information of patients and the cases are structured in an entity relationship model.

Entities: CASE (id_case, title, problem, solution, sex, age); IMAGE (id_case, image)]; SIMILARITY (id_case similarity, age); HISTORY (id_patient, firstname, secondname, sex, age, instruction_level, civil_state, address, telephone, year, month, day, country, state); USERS (login, password, names, email)

Relationships: SEARCH (login, id_case); HAVE (id_case1, id_case2); CREA (login, id_patient); HAVE2 (id_case1, id_case2)

2) Case base management subsystem. The medical knowledge representation is done with a case base, where the knowledge provided by the medical practice/experience is reflected through a wide repository of cases. This subsystem provides retrieve, adaptation, verification and learning processes for the case base. We retrieved all cases which satisfy certain parameters. These parameters include the patient's medical condition (signs and symptoms) and her/his age. We use an evaluation function to find the best neighbor (if any) that match the case of entry. This function does a search across the case base to show cases with a certain similarity with the actual case. Other element considered is a range of -3, +3 at the age of the patient. The appropriate indexes were built to identify the case in the case base.

3) CSCW subsystem. This contains the basic tools to support of collaborative work: chat, videoconference, common blackboard, facilities to share applications and files. These tools are integrated in a single application being able to access to her at the moment that is desired.

The flow through the system can be illustrated with this short example: a general physician seeing a patient with pulmonary distress could access selective clinical data, x-rays, etc. searching for clinical and therapeutic guidelines, and also patient-oriented educational resources correlated to this problem, from the information resources contained in the system or in the web. When the physician is faced with taking a clinical decision, he/she can request assistance from the system using the user interface. This interface then communicates with the support decision-making subsystem which will assist the decision-making process. This subsystem will try to give answers to the requirement accessing the present knowledge in the system by means of the case base. If this knowledge is not sufficient to fulfill the user's requirements, this subsystem will establish a collaborative session with other physicians. In order to do this, the processes contained in the CSCW subsystem will be activated Fig. 3.

Application implementation

For the implementation of SICADIR, we used the Web Server Apache and the application was developed in PHP with the database manager MySQL. For the CSCW, we used the NetMeeting application which is a client of multipoint videoconference VoIP. It is included in many versions of Microsoft Windows (from Windows 95 OSR2 to Windows XP). It utilizes the H.323 protocol to make the conferences, and it is interoperable with clients based on OpenH323 like Ekiga, as well as Internet Locator Service (ILS) like reflector. Also, it uses a soft modified version of protocol ITU T.120 for the electronic blackboard, the sharing of applications, the remote desktop sharing (RDS) and the transferences of files. The secondary electronic blackboard in NetMeeting 2.1 (and later) uses the H.324 protocol.

Test phase

Following the eXtreme Programming methodology, we have applied the unitary tests (using scripts of tests) to verify the soundness and consistence of each one of the functionalities in the application. Also, a general test of the system was made in order to verify its stability and capacity of answer in the context of the requirements. On the other

hand, a heuristic evaluation of the Web site associated to application SICADIR was made, with the purpose of verifying the fulfillment of the basic principles of usability. Also, the user and acceptability tests were applied to verify if the different functionalities from the application are offered to the user of safe way, reliable and friendly. We asked the radiologist in the "Enrique Tejera-Venezuela" hospital about our application. They have accepted our system and they have given a feedback including recommendations to improve it.

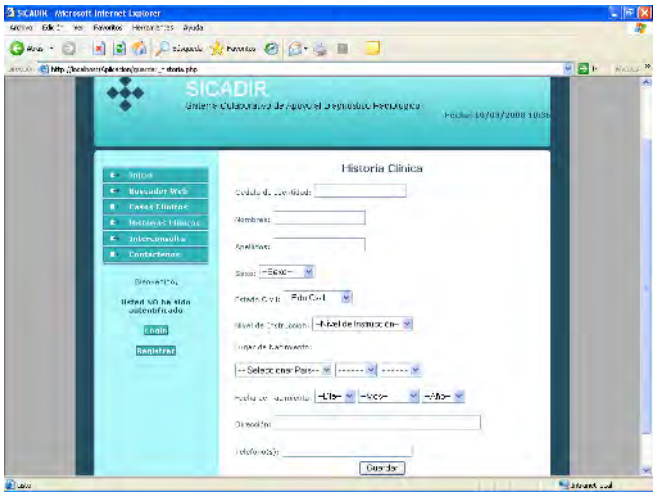

Fig. 2 Patient interface

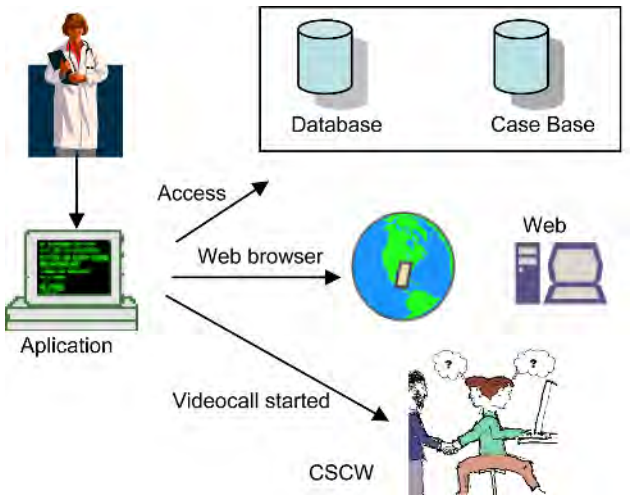

Fig. 3 The flow through the system

IV. Conclusions

A web application for a support to medical decision making in radiological diagnosis has been presented. This application includes three important elements: the database management, the case base management and the CSCW tools. Several tests have been done and we have the good results. Several technologies have to be combined to get to the new medical challenges. The internet is field which offer many advantages for developing of more accessible application. The security and confidentiality of data remain to explore and to implement.

Abstract — **This device will be capable of working as a wrist and finger exerciser to aid stroke patient recovery. This assistive device will be linked via an appropriate wireless protocol to a PC game engine. It is envisaged that this link via interacting with the game will trigger visual stimuli neurons that will accelerate recovery of patients. The many challenges in conceptualizing of the abovementioned device are addressed by the use of "smart materials" or "muscle wires" and ultra compact power sources. It is hoped that the presentation of the paper will create a greater awareness on the recent quantum improvements in materials technology and design. The portability of the device will enable ease of use for patients at home, a speedy and measurable recovery and freeing the rehabilitation resources of orthopedic departments.**

Keywords — **muscle wire, rehabilitative engineering, passive hand motion, strokes.**

I. Introduction

Handflex aims to work as an assistive device for stroke patients and aids the recovery of the finger and wrist mobility. Stroke is the paralysis of the muscles in the body. We will focus on hemiplegic and embolic stroke. There are several causes that lead to the occurrence of these two incidents. One of the causes is the formation of blood clots or the breakage of blood vessels leading to the disruption of blood flow. The other is the paralysis in the muscles due to injury to the brain's motor centers.

This device will assist patients by providing passive motion to each finger of the hand. The stimuli, administered within a systematic program, we proposed will realize demonstrable recovery. Muscle wires are embedded into a glove. The heat generated when an electric current is present would cause flexion and extension of the muscle wires. The movement of the muscle wires generate passive motions which will enables rehabilitation process. It is hoped that computer gaming sessions requiring psychomotor will encourage neural activity between the hand and brain via visual stimulus will further speed up the healing process.

II. Anatomy of hand

The human hand is very unusual in human anatomy. The hand is required to be flexible in order to position the fingers and the thumb. It must have adequate strength to provide for normal hand functions. In addition, hand must also be coordinated to perform fine precision motor tasks.

The human hand consists of several different structures. The most important structures of the hand are the bones & joints, ligaments & tendons, muscles, nerves and the blood vessels. In this report, we will only focus on the bone, joints and muscles.

A. Bones and joints

The human hand consists of 27 bone segments that are connected together to each other through the joints. In the wrist, there contains 8 small bones which are called the carpals. Further in to the palm, the carpals are connected to the metacarpals. Besides this, there are also small bone shafts known as phalanges that will line up to form each finger and thumb. These are shown in the Figure 1 below.

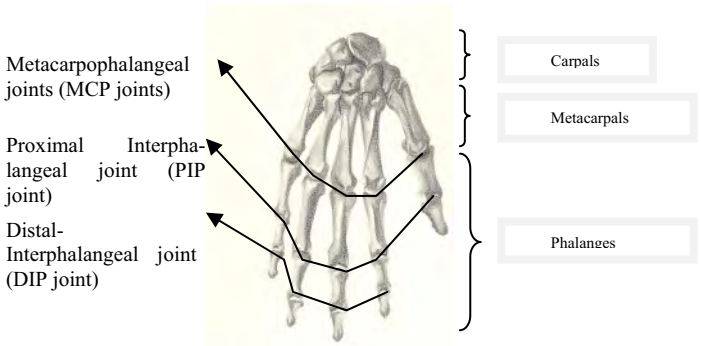

Figure 1 Bone structures on the hand

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1171–1174, 2009
www.springerlink.com

The carpal bones of the human hand are generally arranged in 2 rows namely the proximal[1] and the distal [2]rows. The distal carpals will articulate with the 5 metacarpals.

The 5 metacarpals will also articulate with the proximal phalanges, and the proximal phalanges will join up with the middle phalanges which will then articulate with the end-sections of the fingers which are known as distal phalanges. However, the thumb is an exception as it lacks a middle phalange.

The main knuckle joints are formed by the connections of the phalanges to the metacarpals. These joints are called the metacarpophalangeal joints (MCP joints). As for the 2 joints that connect the 3 phalanges in each finger are called the interphalangeal joints (IP joints).The one closest to the MCP joint is called the proximal IP joint (PIP joint) and the joint that is nearer to the end of the finger is called the distal IP joint (DIP joint) [1]. However for the thumb, it only has 1 interphalangeal joint between the 2 thumb phalanges [1]. The types of joints that have been mentioned above are shown in Figure 1.

B. Hand Muscles

There several different types of muscles in the hand that assists the hand to articulate. The muscles in the hand are separated in to 2 main portions. The 2 main portions are the intrinsic [3] muscles and the extrinsic [4] muscles. Under the intrinsic muscle, this can be further classified in to the dorsal and the volar muscle [2]. The extrinsic muscles, can be further classified in to the extensors and the flexors muscle groups.

In the dorsal intrinsic muscle group, there are the dorsal interossei and the abductor digiti minimi muscles [2]. In asimilarly way the volar intrinsic muscle group, there are 2 layers which are the superficial layer and a deep layer. The superficial layer consists of the lumbricals, flexor digiti minimi and the thenar muscles [2]. The volar extrinsic deep consists of the palmar interossei and the opponens digiti minimi. Next, the extrinsic extensors are divided into the muscles whose primary action is on the wrist extension and the muscles whose primary action is at the digits. However, we will only focus on those muscles whose primary action is at the digits. The muscles whose primary action is at the digits are the abductor pollicus longus, extensor pollicus brevis, extensor pollicus longus, extensor indicis, extensor digiti minimi and the extensor digitorium [2].

The extrinsic flexors muscles are arranged in 3 layers. They are the superficial muscles, intermediate muscles and deep muscles. The primary effect of these 3 layers of muscle is at the wrist, digits and the palm. The types of muscles at these 3 layers are the flexor carpi radialis, Palmaris longus, flexor carpi ulnaris, flexor digitorum superficialis, flexor pollicus longus and the flexor digitorium profundus [2].

III. Causes of paralysis in body parts

In this section, we will discuss the conditions that have caused certain parts of the body to become paralysed. The 2 conditions are Hemiplegia and the Embolic Stroke.

Hemiplegia refers to paralysis or abnormal movements on one side of a person, either the right or left.

Hemiplegia affects people differently but the most obvious result is a varying degree of weakness and lack of control in one side of the body. It will also cause specific learning difficulties such as dyslexia [5] , perceptual and concentration problems [4]. There are several different causes of Hemiplegia. One of the most common causes will be stroke. Stroke occurs either when a blood clot forms and obstructs normal blood flow or when a blood vessel breaks, cutting off or disrupting blood flow [5].

Embolic stroke occurs when a blood clot or other particle form in a blood vessel away from the brain is swept through the bloodstream to lodge in narrower brain arteries [6].

A blood clot is called an embolus. This is caused by irregular beating in the heart's 2 upper chambers. This abnormal heart rhythm can lead to poor blood flow and the formation of a blood clot [6]. Paralysis of the muscle thus occurs.

IV. Muscles wires

Muscle wires[6]are thin strands of a special nickel-titanium alloy that actually shorten in length when electrically powered. They are easy to use, and they can lift thousands of times their own weight. The direct linear motion of muscle wires offers the type of motion that is very similar to that of a human muscle.

A. Properties

The bending ability [8] of the muscle wires is determined by the wire's diameter (Figure 2). Therefore, the minimum bend radius is the smallest bend that the muscle wire can make without being damaged.

[1] Nearer to the body
[2] Further from the body
[3] Originate at wrist and hand structures
[4] Origins are located proximal to the wrist
[5] Impaired ability to learned to read
[6] Muscle wire is also referred by its trade name Flexinol

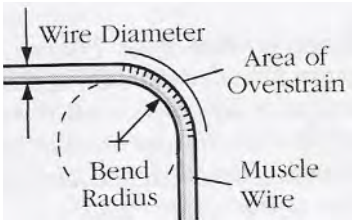

Figure 2 Minimum bend radius[7]

The electrical properties [8] of the muscle wires follow the basic equations derived from Ohm's law. The three equations are:

$$V = I \times R^{8}$$

$$W = I \times V^{9}$$

$$W = I^{2} \times R^{10}$$

When an electrical current [8] is passed through the muscle wires, the resistance in the wire causes it to dissipate part of the current as heat. As the result, the temperature of the wire increases. As it reaches a level that is high enough, the wire will undergo shape memory effect phase. The activation and relaxation temperature of the muscle wires is dependent on the formulation of the alloy. There are two types of alloys; namely the low temperature alloy and high temperature alloy.

The speed at which muscle wires can contract and relax depends on several factors. This includes the circuit that drives the wires, the surrounding condition, and the wires formulation. However, the total time for contract and relax action of the wire depends on the composition, the electrical power applied, and the local cooling conditions. To reiterate, local cooling conditions are important to shorten the relaxation speed. Therefore, the more quickly the muscle wires can be cooled, the faster its cycle time.

Muscle wires exhibit two types of microstructure for heating and cooling respectively. During heating, muscle wires contracts. During full contraction, microstructure formed is harder austenite phase. When wire cools, it changes to martensite phase. Thus, the wires relax and lengthen to its original length. The change in microstructure provides the muscle wires with unique shape memory effect.

[7] Figure from Muscle Wires Project Book[8]
[8] Voltage (in volts) equals current (in amperes) times resistance (in ohms)
[9] Power (in watts) equals current (in amperes) times voltage (in volts)
[10] Power (in watts) equals current (in amperes) squared times resistance (in ohms)

B. Shape memory effect

The shape memory effect for muscle wires is the ability of the wires to recover to its original shape. Upon heating, wire will undergo plastic deformation resulting in contracting and bending of the wire (Figure 3).

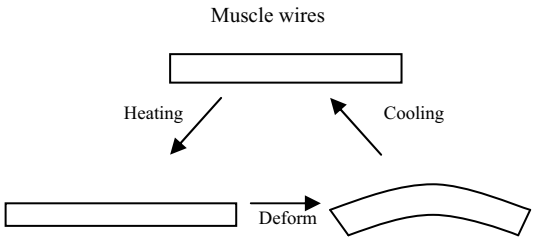

Figure 3 Shape memory effect

V. Muscle hand

The muscle hand consists of muscle wires embedded on the casing of the wearable glove (Figure 4). The purpose of this design is to provide movement to the phalanges and protect the user's hand from the heat produced during the process of contraction. This design is based on the fundamental movements of the hand. The glove concentrates mostly on the flexion and extension of the DIP joint, PIP joint and, the thumb MCP and IP joint.

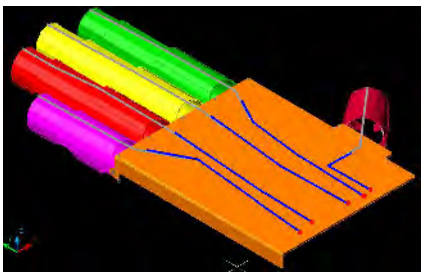

Figure 4 Muscle hand

The designed 'V-shape joint system' comes close to duplicating the functionality of the hand (Figure 5). The V-shape joint is located between the two fingers of the wearable glove. It is capable of providing a wide range of motions such as abduction and adduction for the fingers. Hence, this provides a firm and flexible support for ease of movement. This design will not hinder the natural movement of the phalanges.

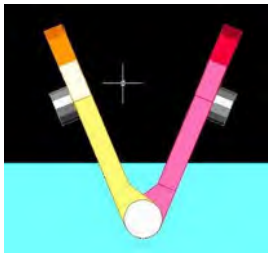

Figure 5 Joint system

The hinge joint segment system is located at the joints of the fingers (Figure 6). It enables the glove to replicate the natural joints. This promotes flexion and extension of the fingers. In addition, it serves as a guide while the muscle wire acts as the movement generator for the injured phalanges. This would allow natural movements to the phalanges.

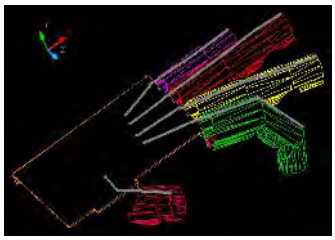

Figure 6 Segment system

The limitations posed by the use of the muscle wire are the heat produced, calling for the need to protect the hand from this heating effect. Also any additional detailed movement to the phalanges requires a very complex layout of muscle wires. In basic finger movements such as extension and flexion two muscle wires are used to move a phalange.

VI. Discussion

While designing the wearable glove type robotic "muscle hand" prototype, our groups faces several problems. One of the stumbling blocks was the difficulty in purchasing muscle wires. All the muscle wires suppliers are from overseas. The only way of getting the wires is through internet purchases. While purchasing the muscle wires, we face some difficulties.

Next, there is also an absence of information on how to embed muscle wires into the designed prototype. The first prototype was fabricated by 'trial and error'. Since then, we have improved on our designs to enable different sequence of finger movement.

The activation start temperature of the muscle wires poses many challenges in the design. In addition, insulation conditions surrounding the muscle wires can greatly affect the performance. Quicker the wires cools, faster it relaxes and reverts to its initial length thus the shorter the cycle time. Therefore, the cooling method used is critical to effectively operate the muscle hand.

The areas we have yet to research and focus on will be the nature of the recovery process from the stroke to a point where the patient can confidently independent. There is also an absent of information on how to establish our device to stimulate re-growth and restore the brain cell functions.

VII. Conclusion

Muscle wire is the best candidate for our "muscle hand". However, problems of heat generation and rapid cooling required, poses challenges for a ventilated version of the muscle hand.

Finally, it is hoped that this project will heighten attention and interest in this domain of rehabilitate engineering. The inclusion of game based activity will further enhance our horizon to achieve our desired goals.

Acknowledgments

As a group, we would like to thank Mr Gribson Chan of St. Luke's Hospital for initiating this project and keeping us on track in our research. We would also like to thank Dr Boey Siek Yeng and Dr Ong Fook Rhu from the Singapore Polytechnic's School of Mechanical and Manufacturing Engineering for their invaluable assistance and support in throughout this project. Not forgetting thanking Singapore Polytechnic for being able to fund the project and participate in this conference.

Treatment Response Monitoring and Prognosis Establishment through an Intelligent Information System

C. Plaisanu[1], C. Stefan[1]

[1]SC IPA SA, Bucharest, Romania

Abstract — **Numerous medical statistics confirm the extremely high incidence of genital area neoplasia. Although the incidence of this type of cancer is growing, currently, in the oncology field, negative aspects such as ignorance, diagnosis fear and lack of sanitary education are still dominant. This article presents a framework for developing a decisional system for monitoring treatment response at genital area cancer patients as well as the assessment of their life expectancy and prognosis. The decisional system is being developed by an undergoing national research project - NEOSIM - and will be implemented at The Oncology Institute of Bucharest.**

Keywords — **genital neoplasia, decisional system, data acquisition, prognosis**

I. Introduction

In Romania, at the present time, there is no virtual system for research, diagnosis and medical prognosis in oncology. This article would present the main objectives and achievements of an undergoing national research project, characterised by an important degree of originality and novelty and implemented in a main Romanian oncology institute.

The fundamental idea of this project is to elaborate an intelligent informational system for monitoring, treatment modification and prognosis elaboration, in order to assist oncology experts in supervising their patients.

It is of great importance to mention that, in the oncology area, the effect of treatment generates the possible extension of a patient's lifespan. It other words, it would be essential to forecast the most probable life expectancy, taking into account all the changes in clinical and paraclinical parameters and, also the prescribed treatment.

This research also includes the monitoring and analysis of some tumoral markers that are considered to be more accurate in prognosis establishment, an innovative approach regarding disease evolution (for example the level of telomerase, enzyme involved in DNA replication).

II. Description of system architecture

In order to achieve the proposed main objectives, it would be necessary to design and implement a virtual information platform, based on a decision support system. This intelligent informational system will have five main components; a brief presentation of these components will be made as follows.

A. Oncological Warehouse Module

This module is actually a medical knowledge database. It has the role of storing relevant medical information, obtained from oncology specialists and experts, but also from other medical sources. As it name suggests, this module contains a large amount of medical data, such as: patient general information, clinical and paraclinical parameters, genic expression category parameters (telomerase), imagistic data, facts, rules, solving methods, heuristics, complete information about genital area neoplasia, clinical studies, etc.

B. System Reasoning Core Module

This module is an application that holds the control knowledge and represents an inference engine. In order to obtain the required information regarding the evolutional state of the disease and the efficiency of the treatment, the medical database would be exploited with the purpose of reasoning generation. Through this module, the oncology clinician will obtain additional information for treatment adjustment and prognosis forecasting.

C. The Dialogue Interface

This interface also called NEOSIM Façade, will allow communication of oncology specialists within the advising steps. It would also make possible the on-line access of medical experts to the knowledge base. Together with Medical Knowledge Spring module, it also has the role of adding and updating information into the system.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1175–1178, 2009
www.springerlink.com

D. Medical Knowledge Spring

This module would permit the knowledge acquiring. Therefore, oncology specialists would be able to insert medical data in a form recognized by the system and, also, to update the complex medical data base;

E. The Knowledge Interpreter

This knowledge interpreting and explicative module has the purpose to explain to the medical personnel, the information level of the intelligent system, the reasoning processes and the results obtained from advising sessions among oncology specialists. This module will also display the results obtained from the evaluation of changes suffered by analyzed parameters, the solution for treatment adjustment and prognosis;

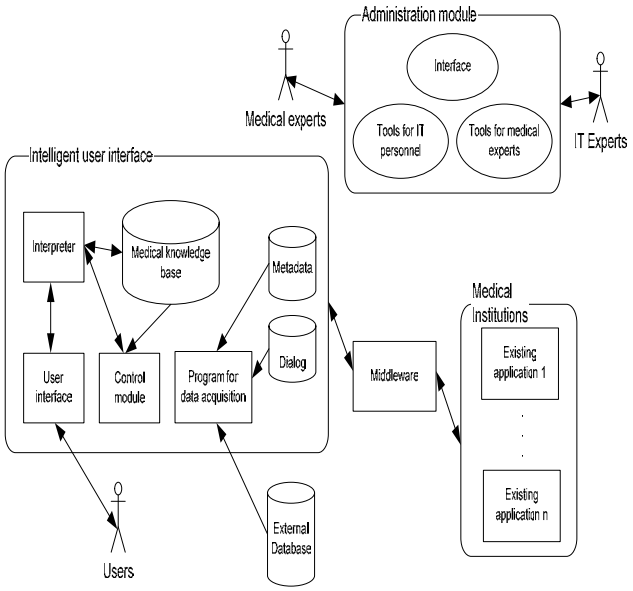

Fig. 1 System architecture and main user groups

The intelligent system also contains a module that ensures the interoperability with existing information systems from the medical institutions where it would be implemented. Medical and IT experts will have access to a management module in order to assure the proper functioning of the platform.

The latest technologies for medical information management will be used for the design of the intelligent information system. In order to increase safety and integrity of data it is necessary to use technologies like semantic web and ontologies.

The system will also be based on open standards like web services (SOAP, UDDI, WSDL) or XML to ensure interoperability and integration of various applications and information systems that exist or will be developed in the future. [1]

III. Presentation of main user groups

The intelligent system contains three categories of user groups: medical experts specialized in the oncology domain, the IT experts that supervise the proper technological functioning of the system and the general users that are oncology doctors or resident doctors involved in health-management of cancer patients [2].

A. Medical experts

In order for the system to contain all the medical information that are necessary, medical experts will access the intelligent system in the purpose of creating descriptive models that will define the main characteristics of different types of genital area neoplasia and, also, the parameters and investigations necessary for evaluating such pathologies. Furthermore, there will be defined sets of parameters and features (clinical and paraclinical parameters, imagistic aspects, parameters in the genic expression category) whose utility will be materialized in elaborating the decision to modify the treatment and the prognosis.

B. General users

The general users are the oncology field doctors that are practically involved in clinical supervision of cancer patients. They would establish a dialogue with the system in order to optimize their clinical decision. In the medical practice, and especially in the oncology field, it is essential to know whether the prescribed treatment is working or not, the main problem being the large quantity of variables that a doctor has to deal with. In this regard, the intelligent system would manage properly this situation, helping the doctor to optimize his decision or to obtain additional information. The system also facilitates the dialogue and the advising among the oncology specialists through the elaboration of a virtual community.

C. IT experts

The IT experts have an important role in the system their purpose being the continuous monitoring and management, in real time, of the execution environment from the technical-functional point of view.

IV. System objectives

The main objective of this intelligent informational system is to improve the treatment and life expectancy of patients diagnosed with genital area cancers. This is realized by monitoring and properly analyzing the disease evolution based on the evaluation of treatment response and health changes reflected by medical imagistic aspects and clinical and paraclinic parameters.

A. Main medical objectives

The most important medical aspect is considered to be the prognosis establishment through a complex analysis of tumoral markers variability from the diagnosis moment and over the treatment period. There are two types of genital area neoplasia that are most common nowadays, uterine and ovarian cancers, and an accurate modality of prognosis prediction would by the tracking of high sensitivity tumoral markers such as CA 125, SCC, CEA and TPA [3].

These markers can indicate the primary tumor at the moment of diagnosis and, if the administrated treatment hasn't been efficient, they can indicate a recidivating tumor. In addition to these markers, the Bucharest Oncology Institute research team is also conducting an innovative study of gene expression category markers such as DNA- replication enzyme telomerase. About this enzyme it is known that it becomes active in the evolution of cancer and if it's found very early, it becomes a marker for diagnosis. Telomerase can tell if the disease is very advanced and also can establish the prognosis of the patient [4], [5].

The intelligent system would manage a large amount of data regarding tumoral markers variations and would correlate them to the clinical status and life expectancy of the patient.

B. General objectives

This project consists of numerous and complex activities, combining fundamental research, application research and support activities, all involving four main Romanian institutes- one University, an important Oncology Institute and two IT Institutes. There are six phases of the research project, all the objectives accomplished through them being presented above [6].

Phase 1: Creation of conceptual models for medical decision and computerized models for medical data - clinical parameters, tumoral markers and gene expression parameters and imagistic aspects.

Phase 2: Design of system architecture, object orientated models for specifying system's functions, specifications for realization of an identification model of the main characteristics genital area cancers, a specific model for monitoring gene expression category parameters and a project presentation site.

Phase 3: Database and data knowledge structure design, specification of the intelligent monitoring, treatment change and diagnostic elaboration system, (inference engine, dialog interface, knowledge acquisition module, explicative and interpretative module) and also software specifications for information system module component (administrative module, middleware, virtual community).

Phase 4: Elaboration of programs for information system component modules (administration modules, middleware to existing system connection application, application for elaborating a virtual community) and the programs and algorithms for the intelligent monitoring, treatment change and diagnostic elaboration system (medical knowledge base, inference engine, dialog interface, knowledge acquisition module, explicative and interpretative module).

Phase 5: Scientifically research is conducted in order to realize the testing methodology, the functional testing of algorithms, data bases and intelligent system's component modules. There is also realized the evaluation methodology and intermediary evaluation report of activity.

Phase 6: This phase refers to demonstrations, scientific communications and articles. There will also be a manual for presentation and utility of the project. The phase ends with the final evaluation report.

V. Implementation of the system

The main outcome of this systems implementation is essential for the patient: it would made possible for the oncology doctor to answer the most common question that the suffering patients have – has the administrated treatment been efficient and, what is the life expectancy from the moment of the diagnosis ? In other words, one of the main effects that the system would have is to ensure the patient that all the variables in his health status are complete and correct monitored therefore, his life quality and prognosis would be improved.

The system assures a high level of certitude in prognosis assessment due to computerized analysis of a large quantity of data regarding complex genetic parameters and tumoral markers.

The most important aspect regarding this systems implementation concerns the social area. It would improve the life quality and life expectancy of genital area neoplasia patients and reduce medical errors by access to relevant medical data.

The system would also generate a continuous professional forming of medical specialists based on scientific

knowledge and on the best practice and would be an important education and research support in the medical field.

In the technical area, the project intends to use the most recent informational technologies low cost, meaning the web services, the ontology, the semantic web, advanced programming languages, which respect the newest development tendencies of the informational society and in which the information access is not restricted by temporal or geographic barriers.

Regarding the financial aspect, the project would generate savings throw the growth of efficacy of the clinical decision process, by reducing the number of hours spent for diagnosis and treatment and there for also reducing the financial costs.

VI. Conclusion

This project would create a complex virtual journal of disease evolution in which there will be included concrete data on the respective patient but, also, medical analysis, imagistic aspects as well as values of some clinical parameters, tumoral and genetic markers.

In the medical world, the research aims at discovering new methods for prognosis assessment and treatment response evaluation. In the field of oncology an element of special interest is represented by life expectancy and prognosis. In this way, the project brings an innovative element: monitoring the evolutional state of the disease by tracking and analysing the levels of some tumoral markers and gene expression category markers.

Regarding the medical practice, the system offers the oncology doctor a sufficient and complete data volume about the patient, the reduction of the work volume with the help of modern informatics and telecommunication techniques, the increase of the analysis speed of the medical information based on a virtual interpretation system of medical data, as well as the improvement of the patient's life quality.

Abstract — **Here we describe a personal training simulator that improves manual dexterity required for the anastomotic technique of Coronary Artery Bypass Grafting (CABG). The simulator-based surgical training is termed "DRY Lab". The system evaluates surgical skill hydrodynamically as well as visually. This report focuses on the effects of regular DRY Lab for an inexperienced surgeon.**

A cardiac surgeon with no experience in CABG volunteered for the DRY Lab. The model of a coronary artery consisted of a three-layered silicone rubber tube. To ensure its suitability for suturing, the tearing strength of the tube was 0.14N. In the course of training, the surgeon made 62 anastomosis in 80 days. During this time, we recorded the number of sutures, operation time, and hydrodynamics of the anastomosis made early and late in the training sessions. Hydrodynamic testing measured the pressure difference due to suturing in steady flows. At a flow rate of 100ml/min, the Reynolds number was 350.

On the period of the training, the mean number of sutures was 16.9 ± 2.5. Thereafter, it decreased gradually, converging to 14.0 ± 0.0 on the last day. This indicated that the surgeon eventually established own particular design of an anastomosis throughout the trainings. Pressure loss of the anastomosed model in the final training was 65.8% lower than that in the initial training. The difference appeared to be due to the stenosed effective orifice area of the anastomosis.

In sum, the findings suggest that quantitative assessment of simulator-based surgical training is an effective way to improve anastomotic technique in CABG.

Keywords — **Surgical Training, Skill Assessment, Self Training, Pressure loss, Coronary Artery Bypass Grafting**

I. Introduction

Surgeons need a large volume of high-quality experience to improve or maintain their skill. It was reported that patients undergoing selected cardiovascular or cancer procedures can significantly reduce their risk of operative death by selecting a high-volume hospital [1]. Especially in a field of cardiac surgery, the operators' individual techniques are important to reduce the mortality [2] [3]. However, the situation has been more difficult to provide enough operating cases for trainee cardiac surgeons. The number of CABG cases was 20,095 for 2,937 registered cardiac surgeons in Japan [4]. "WET Lab" was adopted as a surgical training method that experts instruct trainees on defrosted porcine hearts. Although the WET Lab has advantages such that enable to avoid malpractice and good fidelity of the organs, it is high-cost for instructors, organizers and trainees.

Our group proposes the "DRY Lab" stage, before the WET Lab stage to brush up fundamental surgical techniques by their own using simulators. It is demanded by both experts and trainees that the simulators must include quantitative assessment functions to keep the motivation. Ideally, the quantitative assessment can be done instantly while the training. We have developed coronary artery model named "YOUCAN" and beating heart simulator "BEAT". Then the first trial of the quantitative assessment was done with original mock circulatory simulator. The anastomotic technique of an expert and inexperienced trainee cardiac surgeon was hydrodynamically assessed by selected parameter of an energy loss [5][6]. This Report focuses on the short-term effects of regular DRY Lab training on an inexperienced surgeon.

II. Method

A. DRYLAB training

A cardiac surgeon who inexperienced CABG clinical cases volunteeered for the regular DRY Lab training. The trainee made 62 anastomosis in 80days. Fig.1 shows the models of vessels consisted of three-layered silicone rubber tube. To ensure its suitability for for suturing, tearing strength was measured. Fig.2 shows measurement apparutus for the measurement. The coronary artery model and defrosted porcine coronary were tested. The specimens were sized to square shape (5mm × 5mm) by a scalpel. The

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1179–1182, 2009
www.springerlink.com

specimens were sutured by surgical strings (PROLENE 8-0, ETHICON). Tensile testing mashined recorded the load where the model was torn by strings. The value of tearing-strrength were obtained as 0.14N (model) and 0.27N (pig).

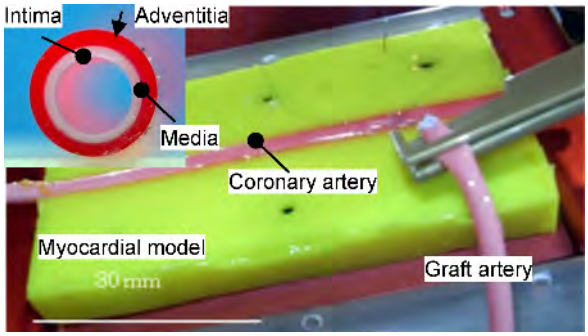

Fig. 1 Silicone tubular models of coronary artery and graft artery: "YOUCAN"

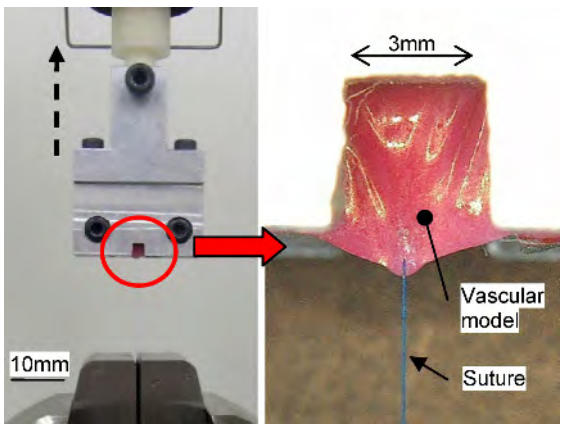

Fig. 2 Measurement of the tearing strength

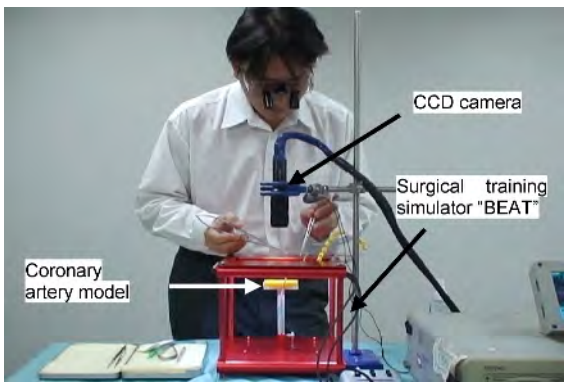

Fig. 3 Training apparatus; coronary artery model has been mounted on the "BEAT".

The tearing strength of the model was adjusted about half of poricin artery. Because it was reported that porcine coronary artery has three times of elasticity compared to human coronary artery [7]. Fig.3 shows apparatus for the DRY Lab training. The coronary artery model was mounted on the BEAT. Although the BEAT could simulate myocardial pulsatile motion, the trainings were done under off-beating condition to study the training effects within initial phase. We recorded the number of stitches and time to complete an anastomosys with a CCD camera (VH-6300, KEYENCE, 0.9 Mpixel). The trainee was received feedback consultations with assessment reports at the beginning of each trainings.

B. Hydrodynamic assessment of an anastomotic technique

Fig.4 shows an experimental apparatus to assess an anastomotic technique hydrodynamically. This open-circuit was designed to simplify the assessment procedure. A manometer was installed at inlet and outlet of the test section. The pressure difference was measured under steady flow condition where flow rate of 100ml /min and the Reynolds number of 350 (simulated coronary circulatory flow at the peak). Anastomosed models were selected from early and late in training sessions.

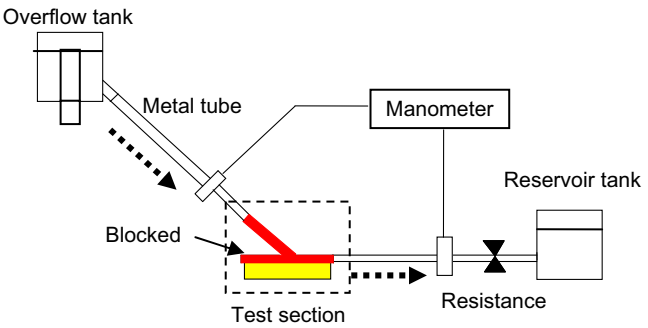

Fig. 4 In-vitro mock circulatory simulator for hydrodynamic assessment of the anastomosed models.

C. Analysis of surgical operation in clinical cases

Clinical operations of on-pump CABG that operated by a registered cardiac surgeon, a cardiac fellow and a resident was recorded by digital video camera (at UPMC Passavant hospital, Pittsburgh, USA in 2008). The number of experienced case was >10,000, >700 and 0 cases, respectively. Total time and rhythm was calculated from the visual records. Then, it was examined that characteristics of the DRY Lab training comparing to surgical operation in a clinical case.

III. Results and Discussion

Fig. 5 shows changes anastomotic design during the DRY Lab trainings. On the first day, number of stitches to make an anastomosis was counted as 16.9 ± 2.5 (mean ± S.D.). Thereafter, it has decreased gradually then converged to 14.0 ± 0.0 on the last day. This results indicated that there exists two phases during the training. The earlier is the trial phase that understanding and solving the technical problems (see fig.5 A). The later can be understood as fixing phase to fix the established technique (see fig.5 B). It was suggested that continuous feedback is needed for a trainee especially in an initial stage.

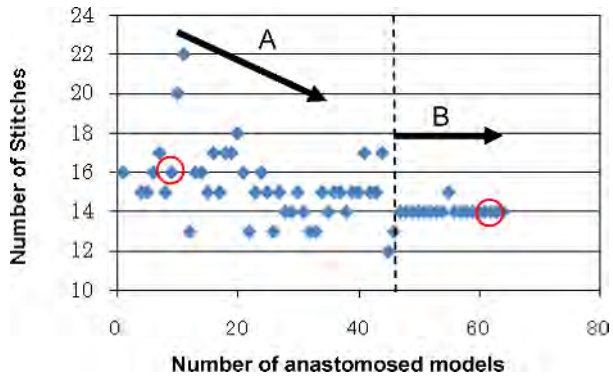

Fig. 5 Changes of anastomotic design were observed during the DRY Lab training. (A: trial phase, considering suitable design for an anastomosis, B: fixing phase after the design was established)

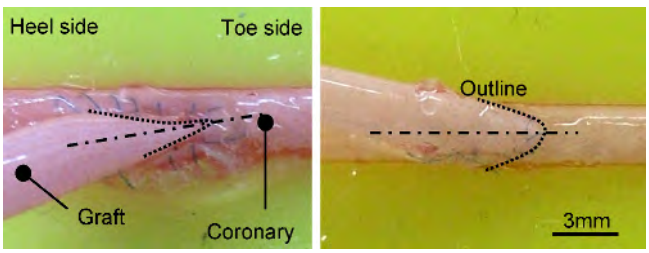

Fig. 6 Outcomes of anastomosed models (left: the first day, right: the last day)

Next, we selected the best model based on a comment of the trainee from the first and the last day. Fig. 6 shows the comparative visual inspection. Initial model was observed as more likely collapsed rather than the later model as shown with dotted line in Fig.6. Irregular stitches may be caused of stenosis. Graft artery of the initial model was more twisted compared to the later model. The orientation of stitches in later model was found as close to a shape of an eclipse.

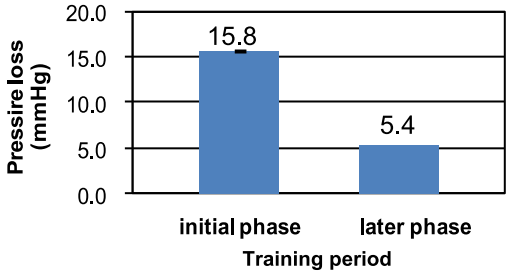

Fig. 7 Comparison of pressure loss of anastomosed models (the initial vs. the end of the training)

Fig. 7 shows the result of hydrodynamic assessment anastomosed models. The values of pressure loss in the initial and the later day model were 15.8 ± 0.1 mmHg and 5.4 ± 0.0 mmHg, respectively. The mean flow rate in each condition was 28.0 g/min and 27.8 g/min. The pressure loss of later training was 65.8% lower than the initial. Then energy loss was calculated by equation (1), using following parameters: pressure gradient ΔP and flow rate $Q_{in.}$

$$E_{loss} = \oint (\Delta P \cdot Q_{in}) dt \quad (1)$$

The energy loss of the initial and the later models were 0.98 ± 0.01 mJ and 0.34 ± 0.00 mJ, respectively. The energy loss of later model was less than 65.7% lower than the initial model. The difference appeared to be due to stenosed effective orifice area of the anastomosis. This result could indicate following two thoughts. (a) An anastomotic technique of a trainee surgeon has been significantly improved, (b) measurement of pressure difference is effective method to distinguish the phase of a trainee. It still needs further studies to establish the evaluation index for an anastomotic technique.

Table 1 shows timing data for an anastomosis, which was obtained by image analysis of the on-pump CABG operation. Fig. 8 shows a time chart to finish one anastomosis. It was found that total time of the experienced group (expert and fellow) was clearly lower than resident and the DRY Lab trainee. It was also clarified the DRY Lab trainee took more time to do parachuting technique compared with the resident. It can be thought that the silicone vascular models were fragile. Therefore it has taken more time for parachuting to avoid tearing the coronary artery model. Further improvements of the models were expected. The total time of DRY Lab trainee without parachuting time was 8.3 min. it was lower than the time of the resident. Fig. 9 shows time for each single suture to make one anastomosis. The value of standard deviation of the time for respective stitches can be understood as a rhythm of suturing during an anastomosis. This value of the DRY Lab trainee was higher as 65.5 (s) comparing to that expert and fellow were 6.9 (s) and 9.7 (s), respectively.

Table 1 Comparison of the time for anastomosis

	Total time (min)	Rhythm: time of respective stitches (sec) (mean ± S.D.)
Expert	4.8	16.0 ± 6.9
Fellow	5.9	19.2 ± 9.7
Resident	14.6	62.4 ± 31.6
DRY Lab	16.0	68.6 ± 65.5
DRY Lab (except parachuting time)	8.3	52.1 ± 22.7

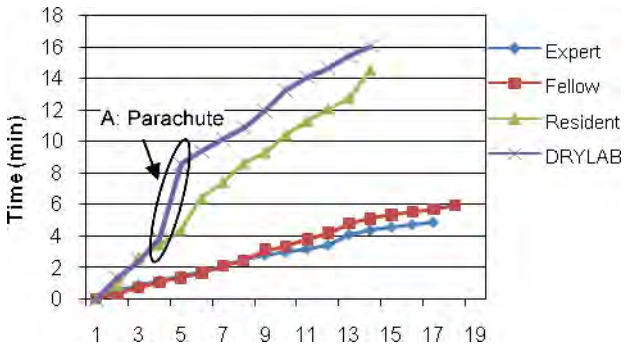

Fig. 8 Time chart to finish one anastomosis (clinical case vs. DRY Lab, A: time for parachute)

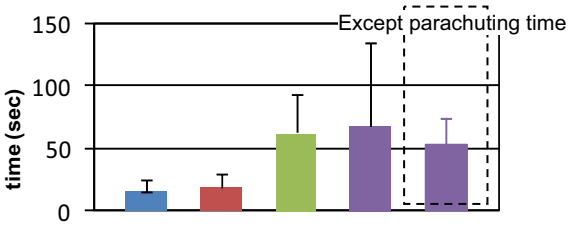

Fig. 9 Quantification of a suturing rhythm during an anastomosis (clinical cases vs. DRY Lab

IV. Conclusions

In this study, the DRY Lab, a simulator-based surgical training, has been proposed as a new approach to overcome the recent severe situation to train the cardiac surgeons. 62 anastomosis have been made by a trainee cardiac surgeon within 80 days. A hydrodynamic assessment of an anastomotic technique has been suggested by using mock circuit. It has been confirmed that measurement of pressure loss is effective to distinguish the learning phase of the trainee. An anastomotic technique also has been quantified by timing the respective sutures during a clinical operation. In sum, the findings suggest that quantitative assessment of simulator-based surgical training is an effective way to improve anastomotic technique in CABG.

Abstract — **The Seldinger technique is a well-established medical procedure to insert an indwelling device into blood vessel. Although the method is widely performed, various adverse effects due to the procedure have been reported. In order to improve safety, some hospitals originally compiled important reminders based on their experiences in an operation manual. The aim of our research is to provide evidences supporting failure behaviors with a mock system to promote awareness in clinical practice. This paper presents results of a newly developed test method to evaluate the possibility of perforation while inserting the dilator to the cervical vein after the guidewire placement.**

A tensile tester (AGI-250kN, Shimadzu Corp.) equipped with a load cell (SLBL-50N, Shimadzu Corp.) was utilized to measure the insertion force of a dilator to vein. The porcine vein was prepared to be aligned with 15mm and to be cut opened to expose the medial wall, and it was mounted on a custom-made device. A guidewire and a dilator were vertically suspended from the upper side of the tensile tester. During the dilator was approaching down to the vein through the guidewire at the constant velocity, the insertion force was measured and the tissue surface was observed simultaneously. The perforation force was examined in relation to the insertion angle from 15degrees to 60degrees.

While veins were pressed only by a guidewire, perforation was not identified at all degrees. After inserting a dilator, veins were torn at 45degrees and at 60degrees more than 10N. It was suggested that vessel wall could be thinner and be torn by multiple insertion. It is concluded that the usage situation of a guidewire and a dilator was assessed objectively and the angle-load relationship was quantified. The test would be helpful to propose safe approach for patients.

Keywords — **Risk assessment, Central venous catheter, Perforation, Guidewire, Dilator.**

I. Introduction

Central venous catheters are routinely utilized to measure hemodynamic values, to deliver medications, and to offer nutrition. The catheter skill is required of doctors as basic procedure. However, central veins are located in deep except the external jugular. Doctors should search the inserting position blindly.

In order to approach a central vein, there are several methods: 1) catheter over the needle (conventional), 2) catheter over the guidewire (recently popular), 3) catheter through the needle or the catheter thorough cannula (less popular). Among them, the Seldinger technique (above 2) is a well-established medical procedure that allows catheters to be placed in the vein through a guidewire path.

Although the method is widely performed, various adverse effects due to the procedure have been reported[1-4]. The major complications are arterial puncture, bleeding, cardiac arrhythmias, etc. They have the following possible causes: 1) patient, 2) operator, 3) technique characteristics, 4) equipment available.

Many researchers have studied about the rate of catheter-related complications with respect to each factor. In order to improve safety, some hospitals originally compiled important reminders based on their experiences in an operation manual. Moreover, some doctors recommend using the ultrasonography to target the vein accurately by supporting visual information.

The aim of our research is to provide evidences supporting failure behaviors with a mock system to promote awareness in clinical practice. This paper presents results of a newly developed test method to evaluate the possibility of perforation while inserting the dilator to the cervical vein after the guidewire placement.

II. Materials and Methods

A. Seldinger technique

The system is designed for Seldinger technique. The technique is pursued as follows.

1. Insert the guidewire through the needle tube into the vessel
2. Remove the needle with indwelling the guidewire in the vessel
3. Pass a dilator through the guidewire into the vessel and expand the puncture hole with the dilator
4. Insert the central venous catheter via the guidewire and advance to the desired position

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1183–1186, 2009
www.springerlink.com

This testing method fulfills the condition as expressed above in 4.

B. Test apparatus

To examine the acceptable load for central vein while using the guidewire and the dilator under clinical situations, a mock system was developed. It was composed of a tensile tester and a vein-fixation jig. As shown in Fig.1, a load-cell (SLBL-50N, Shimadzu Corp.) was equipped on the top of the tensile tester (AGI-250kN, Shimadzu Corp.). Also, the vein-fixation jig was attached below the tester.

The porcine vein was prepared to be aligned with 15mm and to be cut opened to expose the medial wall as shown in Fig.2. And, it was mounted on a custom-made device with tucking the vein as shown in Fig.3.

A testing guidewire was passed through the dilator, and the dilator was chucked to the top of the tensile tester. Then, the guidewire was suspended from the ceiling and lay the part of it on the vein. During testing, veins were moistured with saline.

C. Test process

C-1. Perforation force: Measure the loading force with varying the angle θ that is formed between the vein and the dilator.

1. Adjust the jig to set the angle (θ=15, 30, 45, 60 [degrees]) between the vein and the dilator.
2. Advance the head of the dilator to about 10mm from the vein as a default position.
3. Measure the loading force with 20Hz sampling rate, while shifting the dilator downward in a vertical direction by 500mm/min until perforating the vein or moving 20mm from default position.
4. Repeat 1-3 by varying θ. The angle is registered as θ_p, if the vein starts to be perforated.

C-2. Slip angle (θ_s): Identify the angle θ when the guidewire is slipped away with no perforation.

1. Adjust the jig to set the angle ($\theta=\theta_p$-15, θ_p-7.5, θ_p [degrees]) between the vein and the dilator. The angle θ is set to the perforation angle θ_p+7.5degrees.
2. Advance the head of the dilator to about 10mm from the vein as a default position.
3. Measure the loading force with 20Hz sampling rate, while shifting the dilator downward in a vertical direction by 500mm/min until perforating the vein or moving 20mm from default position.
5. Repeat 1-3 by varying θ. The maximum loading force is registered as F_s, and also the angle is as θ_s, if the vein remains not to be perforated.

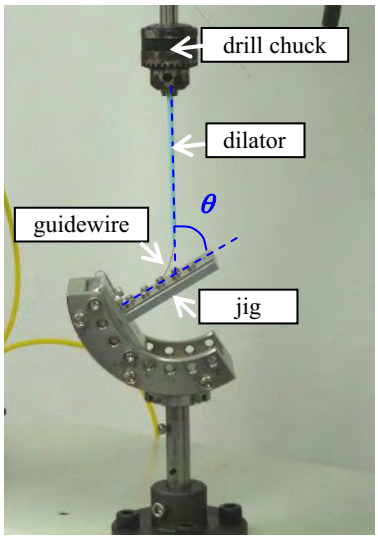

Fig. 1 Test apparatus

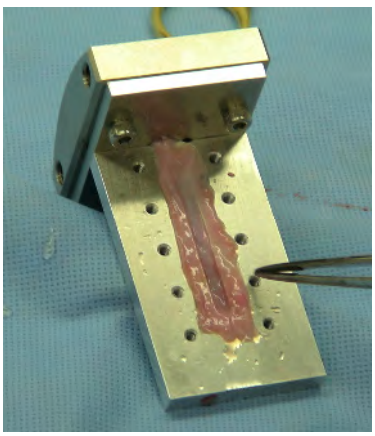

Fig. 2 Porcine vein

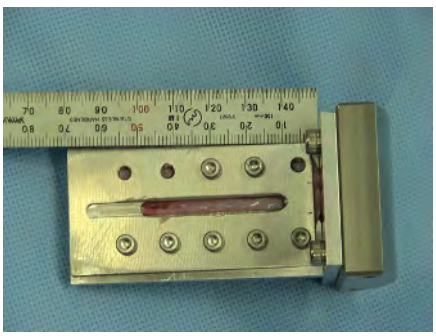

Fig. 3 Attachment jig

D. Experiment

The testing methods were applied for the porcine cervical vein. The details are as follows.

(a) θ=15 degrees, 4 trials (*C-1*)
(b) θ=30 degrees: 5 trials (*C-1*), 1 trials (*C-2*)
(c) θ=45 degrees: 4 trials (*C-1*), 2 trials (*C-2*)
(d) θ=60 degrees: 1 trials (*C-1*)
(e) $\theta=\theta_s$ degrees: 1 trials (*C-2*)

III. Results

A. Perforation force and slip angle

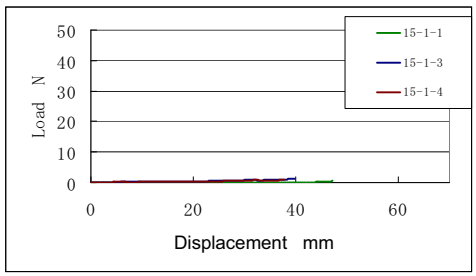
While veins were pressed only by a guidewire, perforation was not identified at all degrees. After inserting a dilator, veins were torn at 45degrees and at 60degrees more than 10N.

Fig.4 (a)-(d) show the loading force to the displacement of the dilator while changing the angle by 15degrees. Fig.4 (e) shows at the angle of 37.5degrees that was determined as the angle between 30degrees and 45degrees.

(a) θ=15 degrees
- Vein perforation was not observed.
- Dilator was just slipping over vein.

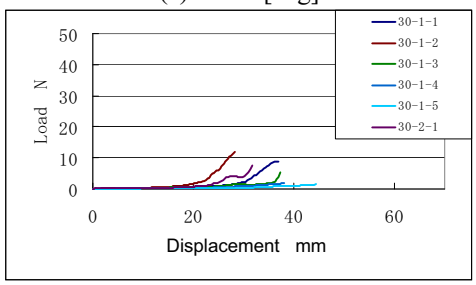
(b) θ=30 degrees
- Vein perforation was not observed.
- Dilator was slipping over vein, and deformed to follow the shape of vein.

(c) θ=45 degrees
- Vein was stretched thin, and perforated.
- Vein was started to be split over 10N.



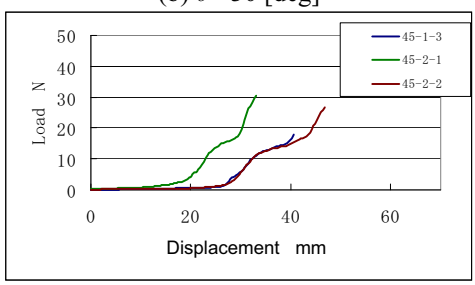
(d) θ=60 degrees
- Vein perforation was observed at 30N.
- Vein was perforated due to pushing the head of the dilator.

(e) θ=37.5 degrees
- Vein perforation was not observed.

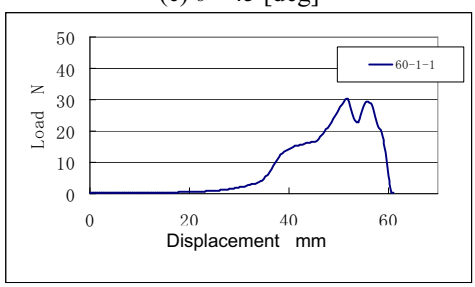


B. Relationships between loading force and angle

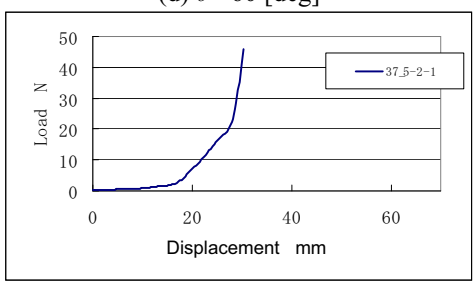
Table 1 and Fig.5 show the results of perforation force to insertion angle for all cases. At 45degrees, for three trials, vein was started to be split at 10.9±1.4N. For the other three trials, veins tore loose from the jig. At 60degrees, vein was entirely perforated at 30.4N. At 37.5degrees, perforation was not observed at more than 45N.



In Fig.5, measurement value was indicated in round, and average value was marked in asterisk.



(a) θ =15 [deg]



(b) θ =30 [deg]

(c) θ =45 [deg]

(d) θ =60 [deg]

(e) θ =37.5 [deg]

Fig. 4 Loading force to displacement of the dilator

Table 1 Perforation force to insertion angle

θ [deg]	Num. of trials	Num. of data obtainable	Num. of perforation	Perforation force Av.±Dev.[N]
15	4	3	0	N.A.
30	6	4	0	N.A.
45	6	6	3	10.9±1.4
60	1	1	1	30.4
37.5	1	1	0	N.A.

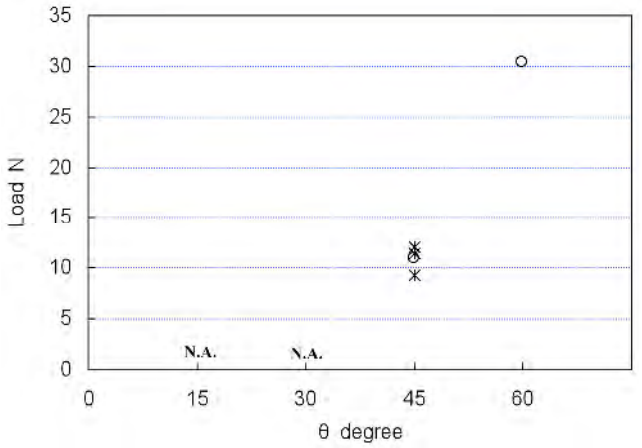


Fig. 5 Perforation force to insertion angle

IV. Discussion

During the insertion, dilator proceeded in 5 steps as follows: 1) dilator was slipping over the vein, 2) dilator was bending to fit the guidewire path, 3) dilator was pushing onto the vein, 4) dilator was bending to fit the guidewire path (same as 2), 5) guidewire was kinked by dilator and vein perforation was identified.

As shown in Fig.5-(d), after guidewire kinking, the loading force was decreased drastically. It was caused by vein perforation. Fig.5-(c) shows that no force-decreasing point was identified, but vein was stretch to thin and perforated. Fig.5-(e) shows that there were neither force-decreasing point nor perforation. Thus, the pushing force to the vein would make vascularized tissue be thinner and be destroyed.

As described in the conventional manual[5], this experiment exhibited the insertion angle was suitable at 30degrees to 45degrees. Under the general operation, 10N as inserting force is larger than anticipated. However, caution should be exercised in multiple insertions of the guidewire and the dilator.

V. Conclusion

It is concluded that this newly-developed evaluation method was achieved as follows: 1) the usage situation of a guidewire and a dilator was assessed objectively. 2) The angle-load relationship was quantified. The test would be helpful to propose safe approach for patients.

The Assessment Of Severely Disabled People To Verify Their Competence To Drive A Motor Vehicle With Evidence Based Protocols

Peter J. Roake

European Mobility Group, Hemel Hempstead, England

Abstract — **Objectives. The demographics of the disabled and aging populations who are demanding to maintain their independence and mobility are testing the driver licensing authorities to ensure that physical and cognitive difficulties are measured to an acceptable standard.**

The highways are becoming more congested with an ever increasing population which is likely to continue for many years to come. It is therefore important to ensure that the disabled and elderly populations are accurately assessed of their competence to drive for the safety of all.

Assessment procedures which take account of the client's limitations, innovative adaptations to vehicles and the latest range of vehicles available should result in a solution which satisfies the national regulations and the aspirations of disabled and elderly people.

Methods. In North America, Europe and Scandinavia this task is being carried out by a team of professionals such as Occupational Therapists, Clinicians and Engineers. Assessment centres are being developed throughout these countries working to national and local standards utilising part time and voluntary staff in an effort to keep costs down.

The need for evidence based assessment reports is becoming an essential requirement to justify the costs of funding an adapted vehicle, especially if a drive from the wheelchair solution is deemed necessary.

Results. It is clear that a common approach to assessment methods is required and new EU initiatives are being developed such as PORTARE and CAPI projects (Refer: Fit to Drive International Congress in Prague June 19th – 20th 2008) which will result in an EU handbook of Driving Assessment and Protocols for adapting vehicles.

Discussion. Will it be possible for countries who take their population demographics seriously to participate in these EU initiatives and benefit from the research to ensure that their disabled and aging people will be able to drive safely on the road?

Keywords — **Disability, Assessment, Driving, Simulator, Wheelchair**

I. Introduction

Advances in medical provision have resulted in an ever increasing aging population throughout most developing countries, coupled with the expectations of the disabled community to maintain their mobility is leading to extra ordinary demands on driver licensing authorities to decide on driving entitlement.

In the USA and E.U./Scandinavian countries the decision on the ability of a person to drive after acquiring a disability is taken by a doctor using guidelines developed over a period of time reflecting agreed standards of safety for the territory concerned.

These guidelines are not consistent [1] throughout these countries making it difficult to extend these guidelines to the developing world, however they can provide a good platform to start from if standard regulations do not exist.

However certain common sense rules apply which govern items such as visual and cognitive ability being two of the most written about subjects when considering testing for the driving ability of the elderly and disabled and are readily referenced.

It is anticipated that the aging and disabled populations will continue to expand in line with the technological advances in the vehicle adaptation field such that more people will expect to maintain their mobility and independence.

In many countries including Australia rules/laws exist to ensure people who reach a certain age have to retake their national driving test [2] the results of which are not always conclusive as many older drivers adapt their method of driving to compensate for infirmity.

It is important to have in place a recognised method of performance measurement/test that can determine their ongoing mobility with regard to driving a motor vehicle. This can consist of a theory test combined with a practical road test reflecting the latest demands on drivers. Some elderly people may find this discrimative and be reluctant to subject themselves to a driving test of this sort, especially as some may be only using their vehicles for short journeys. This was the case for the group of disabled people in the U.K. who were given a special three wheeled vehicle funded by the U.K. government.

This group rarely completed more than 1000 miles per year and when they were eventually transferred into specially adapted standard cars it was found that their average annual mileage more than quadrupled as they became familiar with the benefits of driving the modern car albeit no additional driving test was thought necessary further high-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1187–1190, 2009
www.springerlink.com

lighting the possible need for additional driver testing when changing from one type of driving system to another.

A. Static simulator

This method of assessment is usually carried out in a semi clinical environment utilising simulators or test rigs with a video screen or some method of stimulus to impart a dynamic element into the evaluation experience. Some of these simulators include the sound of a car's engine, ability to change gear and vibration to make the test more realistic.

Other methods rely on visual stimulus using a variety of light patterns to test the cognitive ability with regard to decision making accuracy.

These types of clinical tests are usually carried out indoors and can be regarded as a "sorting process" prior to road testing however the value of utilising the static simulator is that severe cognitive difficulties can be identified without endangering the disabled person or driving examiner which could be the outcome when road testing.

Borderline cases will need to be subjected to a live road test in an effort to extend their cognitive ability to recognise instructions given by the driving examiner and observing road signs in an all encompassing driving test which takes into consideration visual acuity and the ability to remember items such as road signs. In some countries this process is videoed to provide evidence of the performance of the road test.

B. Disability examples.

When an individual acquires a disability from a road traffic accident, medical negligence or other source a significant element of their recovery/rehabilitation is awareness of their mobility prospects.

These disabilities can include Tetraplegia, Hemiplegia, Polio, Muscular Dystrophy and Thalidomide being just a small sample of catastrophic impairments that can inhibit mobility. Some of these disabilities can result in it being necessary to drive a vehicle from an electric wheelchair where the following considerations should be made.

C. Driving from an electric wheelchair.

People presenting in an electric wheelchair at the assessment centre are some of the most difficult to assess as the integrity and crash worthiness of the wheelchair needs to be considered along with the everyday special needs of the disabled person. This reduces the selection of wheelchairs considerably to ensure compatibility of the wheelchair with a suitable vehicle and wheelchair tie down system.

A wheelchair assessment including a driver option can result in an expensive solution which may need the support of external or third party funding agencies as these specialised wheelchairs can cost up to (Euro) €20,000.

In the USA and E.U./Scandinavian countries drive from the wheelchair has been available for over 20 years utilising large electric wheelchairs and van derived vehicles with automatic transmission such as the Dodge Day Van, Mercedes Sprinter, Ford Transit Van, VW Caravelle and Chrysler Voyager Entervan which have entry possibilities through either the side or rear doors. In E.U. countries there has been a trend towards the smaller van derivatives such as the Renault Kangoo and VW Caddy types with automatic transmission and usually entry into the vehicle through the rear doors as the demand for this type of solution is increasing in line with the demographics outlined earlier.

Crash testing of wheelchairs and wheelchair tie downs to National Standards are now mandatory in these territories which provide a sense of security and confidence for users, funding agencies and insurance companies.

D. Driving criteria.

The criteria for safe driving is no different for a disabled person to that of an able bodied person and in most countries where drive from the wheelchair has been legislated the demands of being able to operate the primary and secondary controls are no different.

Servo systems have been developed to compensate for reduced ability to enable severely disabled people to drive safely and pass the standard driving test. Part of the assessment process is to determine the essential demands of the driving test and the approval of a doctor and/or oculist is essential in this process where cognitive and visual acuity has been tested and approved.

The hands on driving of the vehicle needs to be established so that the appropriate servo systems can be prescribed.

E. The Steering system.

In the case of high lesion tetraplegia, with a cervical break at, say C5/6, where loss of muscle tone, ligament control and nerve responses may have been compromised it may be necessary to determine work effort, range of movement and speed of movement of the hands and arms to determine a satisfactory steering solution.

The results of which can range from a reduction of the steering efforts and fitting a special quad grip device to the

steering wheel rim to fitting a joystick steering device in lieu of the steering wheel.

The assessment process needs to test these parameters at least 20 times, to inflict a measure of fatigue and record the results in a clinical format which can be stored on a computer to be included in the assessment report.

F. Braking and accelerator.

These two features are considered together as it is necessary to determine the minimum time taken to effect an emergency stop from a designated speed. A typical emergency stop reaction time could be measured from a speed of 48k/h to a point in time when all road wheels are locked up (i.e. sufficient brake load to stop the vehicle in the designated stopping distance), (say 100Nm), in the quickest possible time.

This stopping distance has no particular international standard however a nominal figure of 0.75 seconds is generally accepted as a satisfactory stopping time to pass a driving test.

For most high lesion tertraplegics this can only be achieved by adding servo assisted brake and accelerator systems into the vehicle such as Electronic Brake and Gas device (E.B.G.).

The assessment process should include access to a static simulator or test rig which is wheelchair compliant and enables the individual to attempt this via a joystick control or hand control which is directly connected to transducers which can undertake both force and time measurements which are then processed by a computer to provide a direct read out of the resulting performance.

Stimulus can be by light or sound or both with a minimum number of 20 tests once the person has become familiar with the tasks involved [3].

G. Fatigue Allowance.

It is necessary to determine the fatigue boundary of the person being assessed so that an accurate conclusion of their capabilities is made. This can involve repeating the steering and emergency stop reaction tests until the work effort and or reaction times deteriorate to an unacceptable level or beyond the technology available to adapt the vehicle.

This will be seen on the output graphs and be useful to include in the conclusions of the assessment report. It is important for the assessor to be able to recommend a driving solution which is able to extend a disabled persons range of mobility bearing in mind that most journeys consist of two directions i.e. going out and getting back.

Budgetary constraints can sometimes result in inadequate driving controls be prescribed which have great demands on the driver and result in fatigue which can lead to a loss of confidence in attempting the journey resulting to false economy and frustration for all concerned.

H. Servo Systems Development

Devices for interfacing with the vehicles primary and secondary controls are always under development to support the competitive nature of the vehicle adaptation industry. This type of development engineering is an ongoing feature of the automotive industry with the release of "concept cars" which sometimes include electronic joystick devices to operate steering, braking and accelerator along with infra red or wireless systems to interface with vehicle electronic systems such as Multiplex and Can Bus electronic systems.

Research and development by the automotive industry is not always directed at the less able and more targeted at improving sales, however it is clear that in recent years the development of on board computers and much improved vehicle electronic systems that a considerable spin off has benefited the disabled driver such as digital signals monitoring and controlling most of the vehicles primary and secondary systems. Specialist adaptation companies throughout the E.U. and Scandinavia have been spearheading the interface devices to enable the severely disabled to regain a measure of independence and mobility.

With the co operation of the industry as a whole the new interface devices are able to comply with stringent type approval demands of the Vehicle Construction and Use Regulations both in the USA and E.U./Scandinavian countries.

I. Disabled Driver Statistics.

The most severe of disabilities such as those mentioned earlier which represent the smallest population but reflect the highest cost due to the low volume and high technical content whereby a drive from the wheelchair solution for a high lesion tertraplegics could cost in the region of (Euro) €120.000. These levels of cost are regularly reflected in litigation cases or supported by governmental/charitable funding activities.

The vast majority of special needs mobility funding will be required to support people with lesser disability but also life threatening conditions such as Hemiplegia (stroke) where relatively simple vehicle adaptations will be required (e.g. left foot accelerator pedal or simple hand controls for operating the brake and accelerator) which subject to assessment may be all that is required.

There is a need for ongoing assessment of people who have progressive disabilities such as Multiple Sclerosis (M.S.), Muscular Dystrophy (M.D.) and Motor Neurone Disease (M.N.D.) where the condition can deteriorate to a point where safe driving can be compromised e.g. in some M.S. cases the ability to positively transfer the right foot from the accelerator pedal to the brake pedal to stop the car become difficult to achieve. However if hand controls are used which are operable within the peripheral vision of the driver then the confidence to stop the car is regained and generally the overall emergency stop time is reduced to an acceptable level.

The responsibility for reassessment is not clear in many countries and in some territories relies on the integrity of the driver to report his/her condition to the authorities and determine a solution for continuance of driving or alternatively stop driving altogether.

J. European Initiatives.

There are two projects being conducted by professional bodies in the E.U. to self regulate the assessment process (PORTARE) and the vehicle adaptation process (CAPI) in an effort to standardise these activities across all countries of the E.U. and Scandinavia.

The outcomes will be a set of standards and quality procedures which should be available for publication during 2009/10. This work will enable developing countries that recognise the importance of making mobility for all a priority in their governmental strategies to put into practise at a beneficial budget.

II. Conclusions.

The assessment of older drivers is complicated by various changes associated with the aging process, including cognitive, morbidity and differences in individuals to adjust to impairments and road testing may be the most appropriate method of reviewing driving competence [4].

However when assessing the severely disabled (who may be confined to a wheelchair) competences to drive a motor vehicle there are many facets to consider such as the suitability of the wheelchair, effects of gravitational forces and the type of servo systems that are required to meet the national driving regulations. It is clear that in the western countries that driving regulations exist according to the territory and not necessarily on U.S. or E.U. wide basis.

There is massive scope to standardise the methods of assessment throughout the world to ensure that severely disabled people are not excluded from being able to extend their mobility as far as possible.

The work of the E.U. POTARE and CAPI groups are an attempt to meet these criteria and countries who are considering an inclusive legislation for their elderly and disabled drivers could benefit from this research.

An agreed set of standards/rules need to be developed with the possibility of flexing them to meet with local conditions may provide a framework to base the research on.

This research should include the vast amount of literature available for assessing the cognitive and sensory perception that may affect driving [5] amongst others whose literature contribution has provided a set of international data to compare with including [6]

In addition to the development of international standards for assessment methods there is a need to set out standards for vehicle adaptation methods which take into account the design, crash worthiness and national standards such ISO, Construction and Use regulations for motor vehicles and the criteria set out by testing authorities such as German TUV organisation (short for Technischer Überwachungs-Verein, Technical Monitoring Association in English) and in the USA Society of Automotive Engineers (SAE).

This research will benefit developing countries that will be looking for agreed standards that encompass good working practices coupled to high quality engineering at a cost that is affordable.

Acknowledgment.

This research was supported by the European Mobility Group and the UK Forum of Assessment Centres. The author also wishes to acknowledge the support of the SIM University in Singapore and industry partners: Steering Developments Ltd in the UK and the University of Greenwich in London.

Abstract — **In the first part of this paper, the *E'* (storage modulus) and *E''* (loss modulus) values of six cylindrical specimens of Silastic® Q7-4780 medical grade silicone (suitable as a 90 day implant material), immersed in containers with physiological saline solution at 37°C, were measured using dynamic mechanical analysis. The results were compared with previous published data of a medical grade silicone, suitable as a 29 day implant material. The moduli of Q7-4780 were frequency-dependent as expected and were not significantly different from the shorter-term implant material. In the second part of this paper, the *E'* and *E''* values of Elast-Eon™ 3, a polyurethane with poly(dimethylsiloxane) (PDMS) and poly(hexamethylamine oxide) (PHMO) segments, were measured before and after accelerated aging in an oven at 70°C for 38 days. The moduli of six cylindrical specimens of Nagor® medium hardness medical grade silicone were also investigated using the same aging conditions. The results showed, that both the *E'* and *E''* of the Elast-Eon™3 were affected by accelerated aging. However the properties of Nagor® silicone were not affected.**

I. Introduction

Rheumatoid arthritis and osteoarthritis can destroy the natural metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints in the hand [1, 2]. As a result, patients will experience pain and loss of function of the hand [3, 4]. In many cases, the best option available to restore the function of the hand is to replace the destroyed joint with an artificial joint [4, 5, 6].

One of the most popular artificial joints used is the one-piece silicone joint developed by Alfred B. Swanson in the 1960s [5]. Since the development of the Swanson joint (Wright Medical Technology, Arlington, TN 38002, USA), other designs have been produced, such as the soft skeletal hand implants (Small Bone Innovations, Inc, Morrisville, PA 19067, USA) and the NeuFlex finger joint (DePuy Orthopaedics, Inc, Warsaw, IN 46581, USA) [6].

Silicones are used because they are biocompatible, durable, flexible and allow the necessary range of movements. However, the joints fracture prematurely *in vivo* [6]. The highest fracture rate reported is 82% by Kay et al. [7].

Silicones are viscoelastic i.e. their properties are time (or frequency) and temperature-dependent [8]. It has been suggested by Mahomed *et al*. [9] that there is the possibility that the behaviour of the silicone joint may be frequency-dependent.

Mahomed *et al*. [9] investigated the viscoelastic properties of 3 medical grade silicones intended for 29-day implantation (short-term). During the tests, the silicones were immersed in physiological saline solution at 37°C. The properties were measured using dynamic mechanical analysis (DMA) over a frequency range, *f*, of 0.02–100 Hz. It was concluded that the viscoelastic properties of these silicones depended on frequency and appeared to be undergoing the onset of a transition from the rubbery to the glassy state at above about 0.3 Hz. As a result, above about 0.3 Hz, the three silicones grades used in their study could experience a reduced life-time and dissipate more energy through fractures [9].

Apart from the short-term silicone, silicones intended for 90-day implantation (medium-term) are also available from the supplier (Dow Corning Limited, Allesley, Coventry, UK) for research. It is not known whether the implantation time will affect the viscoelastic properties of the material. The aim of the first part of this paper is to investigate this possibility using the same experimental procedure as Mahomed *et al*. [9].

More recently, another viscoelastic material, Elast-Eon™ has been suggested as a possible substitute for silicone in the implants [10]. Elast-Eon™ is a polyurethane elastomer with poly(dimethylsiloxane) and poly(hexamethylamine oxide) segments [11].

The properties of materials such as Elast-Eon™ that are suitable to be implanted in the body should not deteriorate while *in vivo*. It is possible to subject the materials to elevated temperatures, known as "accelerated aging", to determine whether deterioration is likely to occur [12, 13]. It is not known whether accelerated aging will affect the modulus of the material. However, the properties of polyurethane has been reported to degrade as a result of accelerated aging [14, 15, 16], but not those of poly(dimethylsiloxane) [14, 17].

The aim of the second part of this paper is to compare the effect of accelerated aging on the modulus of Elast-Eon™ and of Nagor® medical grade silicone; a poly(dimethylsiloxane).

www.springerlink.com

II. Theory

The modulus of a viscoelastic material is represented by a complex number [8].

$$E^* = E' + iE'' \quad (1)$$

Where E' is the storage modulus (elastic) and E'' the loss modulus (viscous).

Aging of a material can be accelerated by a factor of

$$f = 2^{\Delta T/10} \quad (2)$$

by increasing the temperature by an increment ΔT [12, 13]. For example, if a material is maintained at 70°C for 38 days, this is the same as aging it for 38 × 2(70-37)/10 = 380 days, i.e. aging for ≈ 13 months, at 37°C [12, 13].

III. Materials and Methods

The experiments were performed on a Silastic® Q7-4780 Silastic® silicone (medium-term implant material from Dow Corning Ltd, Coventry, UK). The material was supplied in two parts, Part A and B. A Schwabenthan Berlin two-roll-mill (Engelmann & Buckham Ltd, Alton, Hampshire, GU34 1HH, UK) was used to mix the parts together. Ten cylindrical specimens (29 mm in diameter and 13 mm thick), were pressed into a mould and cured in exactly the same way as described previously [9]. Since these silicones are intended to be implanted for a maximum of 90 days, they were kept in physiological saline solution (9.5 g L^{-1} NaCl in water) at 37°C for 90 days to simulate *in vivo* conditions before undergoing compression tests.

Nagor® medium hardness medical grade silicone was supplied as a cured 17 mm thick carving block with dimensions (70 x 20 mm) from (Nagor Limited, Isle of Man, IM99 1AX, British Isles). The original carving block was cut into six cylindrical silicone specimens (15 mm diameter, 6 mm thickness).

The Elast-Eon™ 3 was supplied by the manufacturer (AorTech Biomaterials Pty Ltd, Frenchs Forest, Australia) as a cured cylinder of material. The original cylinder was cut into six cylindrical specimens (diameter 5 mm, thickness 2.2 ± 0.2 mm).

Six specimens of the Nagor® and Elast-Eon™ 3 cylinders were immersed in containers with physiological saline solution and put into a Carbolite natural convection laboratory oven (Carbolite, Hope Valley, S33 6RB, UK) at 70°C for 38 days. This is the same as aging them for ≈ 13 months at 37°C.

Each sample was immersed in physiological saline at 37°C and subjected to sinusoidal cyclic compression tests under a static load of 40 N in the frequency range 0.02-100 Hz, using a BOSE ElectroForce 3200® Series testing machine (BOSE Corporation, ElectroForce Systems Group, Minnesota, USA) [9]. The peak for the sinusoidal cyclic load was ± 5 N. All tests were controlled using the BOSE WinTest DMA software.

IV. Results

The results for Silastic®, in Fig. 1, show that E' is fairly constant, at ≈ 7 MPa, at loading frequencies below 0.3 Hz (log$f$ value of -0.5). Above this, E' increases, eventually attaining a value of about 13 MPa. E'' also shows similar frequency-dependent behavior. Therefore, the medium-term implant material (silicone Grade Q7-4780) appears to undergo a glass transition above ≈ 0.3 Hz. Below this frequency it behaves like a rubber and above it, it starts to behave more like a glass.

Results for Elast-Eon™ 3, in Fig. 2, show that both E' and E'' of Elast-Eon™ increased with frequency i.e. showed frequency-dependent behavior. The moduli also increased after accelerated aging. The upper and lower 95% confidence intervals (shown as error bars) did not overlap throughout the frequency range, i.e. accelerated aging had a significant effect. The appearance of the specimens changed after accelerated aging. Before aging, they were transparent with a slight yellow coloration, but after aging, they became darker and more opaque.

Fig 3. shows that for the Nagor® silicone both the E' and E'' increased with frequency i.e. showed frequency-dependent behavior. The E' increased slightly but not significantly after accelerated aging i.e. the confidence intervals (shown as error bars) overlapped thought the frequency range.

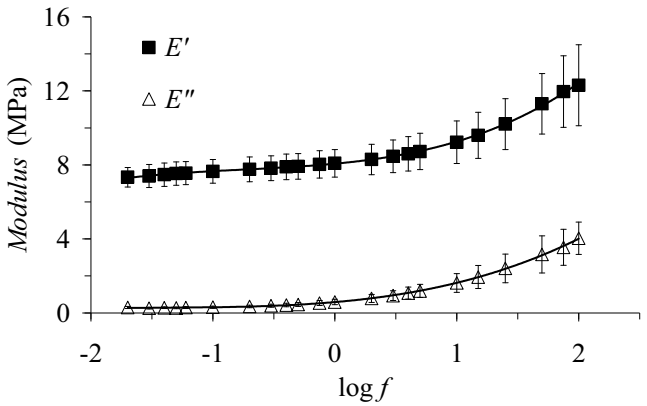

Fig. 1 E' and E'' of Silastic® Q7-4780 plotted against $\log_{10}$ of frequency

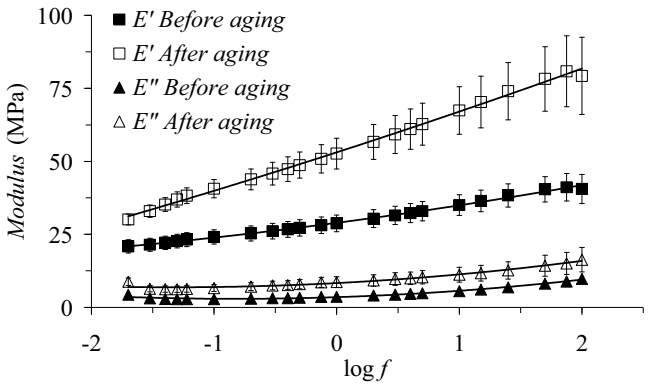

Fig. 2 *E'* and *E''* of Elast-Eon™ 3 plotted against $\log_{10}$ of frequency

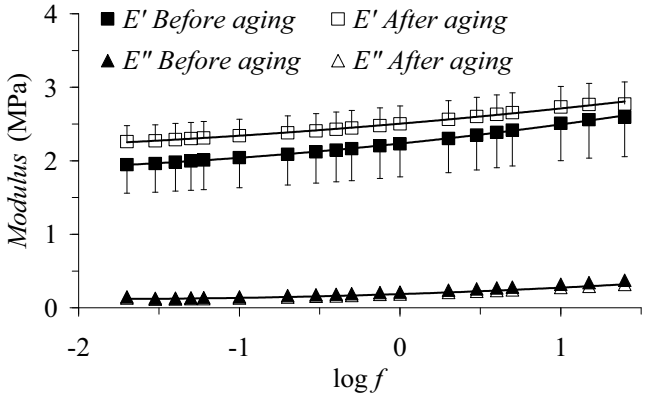

Fig. 3 *E'* and *E''* of Nagor® silicone plotted against $\log_{10}$ of frequency

V. Discussion

When the results in Fig.1 were compared with published data [9] from a short-term implant material (silicone Grade C6-180) using 95% confidence intervals, the confidence intervals throughout the frequency range overlapped, i.e. implantation time had no significant effect on *E'* and *E''* values. The frequency-dependent behavior of Silastic® Q7-4780 is consistent with the previous studies by Mahomed *et al*. [9] and Murata *et al*. [18].

Accelerated aging (70°C for 38 days) significantly affected the viscoelastic properties of Elast-Eon™ 3. As no previous study has investigated this, it is not possible to compare this result with other studies. However, Elast-Eon™ is a derivative of polyurethane and previous studies [14, 15, 16] have suggested the polyurethanes will degrade as a result of accelerated aging. It is recommended that before Elast-Eon™ 3 is used as a substitute for silicone in finger and wrist implants, further studies are required to determine its effectiveness as an implant material. In particular it would be interesting to age Elast-Eon™ at 37°C for a year and measure its properties before and after aging.

The viscoelastic properties of Nagor® medium hardness medical grade silicone were not affected by accelerated aging (70°C for 38 days). This result is consistent with previous studies [14, 17].

VI. Conclusions

- *E'* and *E''* of Silastic® Q7-4780 are frequency-dependent.
- The *E'* and *E''* of Silastic® Q7-4780 is not significantly different ($p < 0.05$) when compared with Grade C6-180 investigated by Mahomed et al [9]. Implantation time does not affect the properties.
- *E'* and *E''* of Elast-Eon™ 3 and Nagor® medium hardness medical grade silicone are frequency-dependent, before and after accelerated aging has occurred.
- *E'* and *E''* of Elast-Eon™ 3 increased after accelerated aging (at 70°C for 38 days) and were significant different ($p < 0.05$) when compared to the moduli before aging. After accelerated aging, the colour of Elast-Eon™ 3 darkens and the opacity increases.
- *E'* of Nagor® medium hardness medical grade silicone increased slightly but not significantly after accelerated aging.

Synergic Combination of Collagen Matrix with Knitted Silk Scaffold Regenerated Ligament with More Native Microstructure in Rabbit Model

Xiao Chen[1], Zi Yin[1], Yi-Ying Qi[1], Lin-Lin Wang[1], Hong-Wei Ouyang[1,2 *]

[1] Ccenter for stem cells and issue Engineering, School of Medicine, Zhejiang University; China
[2] Department of Orthopaedic Surgery, Sir Run Run Shaw Hospital, School of Medicine, Zhejiang University; China

Abstract — **A number of researches on ligament and tendon tissue engineering scaffold have been carried out. However, a scaffold which simultaneously possesses optimal strength, porous structure and biocompatible microenvironment is yet to be developed. This study aims to design a new practical ligament scaffold by synergic incorporation of silk material, knitting structure and collagen matrix.**

Physical properties and biocompatibility of the knitted silk-collagen sponge scaffolds were evaluated in vitro and in mice model. Their efficacy for in situ ligament tissue engineering was investigated in New Zealand White rabbit model with a 6-mm gap defect of the medial collateral ligament (MCL). The histology, microstructure, biochemical composition, matrix genes expression and strength of the ligament repair of different groups were evaluated at 2, 4 and 12 weeks.

In vitro data show that cells on collagen matrix expressed higher collagen I and decorin genes at 3 and 5 days than that on silk substrate. The study in mice model demonstrated that silk scaffold caused little inflammatory reaction after subcutaneous implantation, the strength of scaffolds decreased to 25.9% of original value at 3 month and increased to 33.5% at 6 month. In the MCL repair study, silk-collagen treated MCLs had more connective bands of collagen matrix formed and more collagen deposition compare to those in silk treated MCLs at 2 ,4 and 12 weeks. Moreover, silk-collagen treated MCLs possessed better mechanical property, larger diameter of collagen fibrils and stronger scaffold-ligament interface healing at 12weeks.

These results proved that the knitted silk-collagen sponge scaffold possessed optimal internal space, biocompatible environment and mechanical strength. It could improve the structure and function of ligament repair by regulating ligament matrix genes expression and collagen fibril assembly. The findings suggested that knitted silk-collagen sponge scaffold is a promising candidate scaffold for practical ligament and tendon tissue engineering.

Keywords — **ligament, tissue engineering, knitted silk scaffold, collagen matrix**

I. Introduction

Ligaments and tendons are frequently damaged during sports and other rigorous activities [1,2]. Significant dysfunction and disability can result from suboptimal healing of ligament injuries. At present, the therapeutic options to treat tendon and ligament injuries include autografts, allografts, xenografts and prosthetic devices However, no ideal replacement have been able to adequately restore function for the long term [1,2]. Clearly, more advantageous alternative grafts are yet to be developed.

Recent advances in biomaterials provide the possibility of developing biodegradable grafts for ligament and tendon tissue engineering and reconstruction. However no scaffold that simultaneously possesses optimal strength, a porous structure and a biocompatible microenvironment has not been developed [3]. This study aimed to design a new practical ligament scaffold by the synergistic incorporation of silk fibers, a knitted structure, and a collagen matrix, in which silk fibers provided mechanical strength, the knitted structure provided internal connective space, and a collagen matrix initially occupied the internal space of the knitted scaffold for neo-ligament tissue ingrowth as well as the capacity to modulate neo-ligament regeneration by regulating matrix gene expression and the assembly of collagen fibrils. This study was conducted to assess: 1) the effect of collagen and silk on ligament matrix gene expression; 2) the degradation and biocompatibility of a knitted silk scaffold in a mouse model; and 3) the effect of a knitted silk+collagen scaffold on in situ ligament repair in a rabbit model.

II. Materials and Methods

The warp knitted scaffold was fabricated using 12 yarns (1 filament/yarn) of silk fibers on a knitting machine. Plain knitted silk scaffolds were manufactured with 21 stitches per centimeter. The pore size was approximate 1 × 1 mm. Then the knitted scaffolds were processed to extract sericin. The sericin-extracted knitted silk mesh was moderately stretched and immersed in an acidic collagen solution and frozen at -80°C for 12 h. It was then freeze-dried under a vacuum for 24 h to allow the formation of collagen microsponges. Then the scaffolds were crosslinked by dehydrothermal treatment. All subsequent analyses were carried out to evaluate these hybrid scaffolds.

Rabbit BMSCs (3.5×10^4 cells/cm^2) were seeded on silk, collagen films and normal plates. Cells were cultured in

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1195–1198, 2009
www.springerlink.com

DMEM supplemented with 10% FBS and harvested after 3 or 5 days for analysis of gene expression. Medium was exchanged after 3 days.

Sericin-free and 1% collagen-modified knitted silk were used. Fifteen ICR mice weighing 20-25 g were anesthetized with 10% chloral hydrate. A 1-cm dorsal midline skin incision was made on the back of each mouse and two subcutaneous pockets were created by dissection. Implants were inserted into each pocket individually, taking care to prevent any contact between them. Specimens were harvested at15 or 60 days histological evaluation and 30，60days for mechanical evaluation.

Animal model: In twenty skeletally mature female New Zealand White rabbits., a MCL gap defect was e was created according to the method used by Musahl *et al* [4]. In brief, from a medial incision, a piece of the MCL midsubstance, 6 mm in length, was transected and removed. In the right leg, a hybrid scaffold (10×4×1 mm) was then secured on top of the gap using a non-resorbable suture (6-0 nylon) at each of the four corners (n =14). Silk was sutured in the left leg for control. In the remaining animals (n = 6), right MCLs were not cut and a gap injury was surgically created in the left leg and remained untreated. In all animals, the tension on the repaired tendon was returned to approximately normal. The wound was then irrigated and fascia and skin were closed. Post-operatively, animals were allowed free cage activity. Specimens were harvested at 2, 4 and 12 weeks for histological, Masson trichrome staining, collagen content, matrix genes expression and strength of the ligament analysis. At 12 weeks, two randomly-selected rabbits in each group were used for transmission electron microscopy (TEM) and about 1000 collagen fibrils were measured to assess the collagen fibril diameter. The interface healing between engineered ligament and host tissue was also examined.

III. Results

A. Morphological characterization, in vivo degradation and cytotoxicity of scaffold

SEM observation of the silk+collagen hybrid scaffold demonstrated that collagen microsponge was formed in the interstices of the knitted silk scaffold (Fig. 1 B).Histology results (Fig. 1 C-E) showed that tissue ingrowth by fibroblasts between the fibers of the scaffolds with little vascularization was observed at 15 and 60 days after subcutaneous implantation. A few inflammatory cells were found around silk fibers.

The knitted silk scaffold exhibited a 19.6% (p <0:05) decrease in ultimate tensile strength (from 46.5 ± 9.2 to 37.4 ±3.8 N) as an effect of sericin removal when compared with the raw fibers and retained 25.9% of its original tensile strength at 3 months, and 33.5% at 6 months.

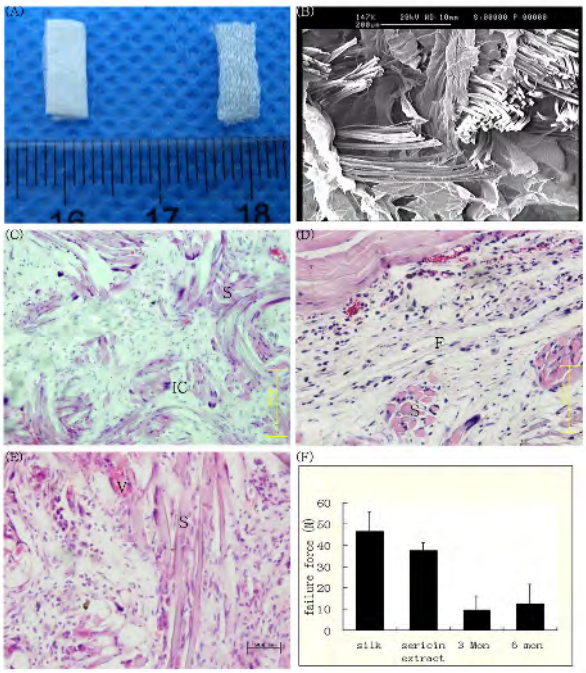

Fig. 1. Characterization of scaffold: The gross (A) and SEM images (B) show combined silk scaffolds showing collagen sponge formed in the knitted silk scaffold . Cellular response of sericin-free silk scaffolds (C,D) and hybrid scaffold (E) to subcutaneously implanted at 15 (C), 60 days (D, E), post-surgery. F. The changes in the mechanical stress of knitted silk scaffold after sericn extraction and subcutaneously implanted at 3 months and 6 months. S indicates silk scaffold in all forms; F indicates .broblasts with capsulation; IC indicates in.ammation cells; V indicates vascular formation. Scale bars 200 um (B,C), 100 um,(D) and 50 um(E).

B. BMSC response on collagen and silk film

At both 3 and 5 days, the mean level of collagen I and decorin expression after cell seeding on the collagen film was elevated (Fig. 2). A decrease of collagen III was found in the silk film specimen, at 3 days. At 5 days, the mean levels of collagen III were similar in the three groups.

C. Results of MCL repair

The defects in MCLs treated with hybrid scaffold (14/14), silk scaffold (13/14) and those without treatment (3/6) showed good attachment of the scaffold to the proximal and distal ends of ligament. The volume of spacefilling fibrous tissue and enveloping soft tissue increased at hybrid scaffold treated groups. The CSAs of both treatment groups (silk+collagen-treated group: 6.4 ± 0.9 mm2 and silk-treated

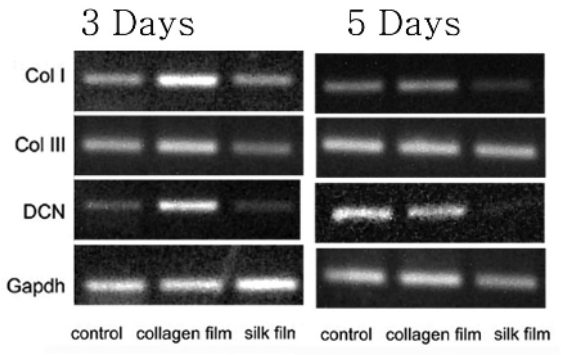

Fig. 2. RT-PCR analysis of collagen I, collagen III and decorin gene expressions of MSCs seeded ion collagen and silk films at 3 and 5 days. Col I: collagen I, Col III: collagen III, DCN: decorin.

group: 4.2 ± 1.0 mm2) were nearly twice as large as that of normal MCLs (2.4 ± 0.1 mm^2) ($p < 0.05$).

The histology and Masson trichrome staing of silk+collagen treated groups showed that more collagen fibers with a larger number of cells exhibiting spindle-shaped morphology along the axis of tensile load were formed in the silk+collagen group than in the silk-treated group at 2 and 4 weeks (Fig. 3). At 12 weeks, all the regenerated tissues showed organized bundles of highly crimped fibers. However, more collagen bands were ingrowth into the scaffold at cross section and the interface of one (out of 3) silk+collagen-treated ligament was interspersed with adi pose connective tissue, while 2/3 silk-treated ligaments had similar adipose tissues (data not show).

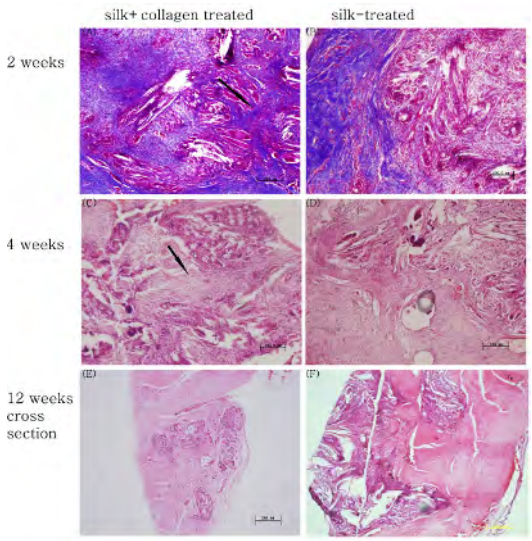

Fig. 3. Repaired MCLs at 2, 4 and 12 weeks. Scale bars 100 um (A-D), 200 um(E, F).

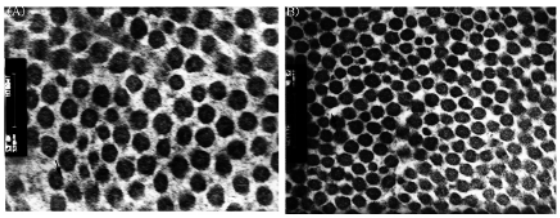

Fig. 4. Ultrastructure of the repaired MCLs 12 weeks. A. silk–collagen-treated MCLs, B.the silk-treated MCLs. Magnification 73 000X.

Both the silk+collagen-treated and silk-treated MCLs had much smaller collagen fibrils than native ligament, but the diameters were larger in the silk+collagen-treated group (65.8 ± 11.8 nm *vs.* 51.2 ± 9.8 nm)(Fig. 4). All samples from silk-treated ligaments had lower collagen content than silk+collagen-treated MCLs. At 4 and 12 weeks, the collagen I expression of silk+collagen-treated MCLs was higher at 4weeks and lower at 12 weeks compare to silk-treated MCLs. The mean level of decorin expression in silk-treated MCLs was elevated at 4 and 12 weeks (data not show).

Mechanical character of repaired MCL: In terms of the failure model, all normal (6/6), silk+collagen-treated (5/5), and half of the silk-treated MCLs (3/5) failed by tibial avulsion. Two specimens of silk-treated MCLs failed at the scaffold-ligament interface, and the remaining one broke in the midsubstance. These results were in accord with the histology results and indicated that normal ligament and silk+collagen-repaired ligament were stronger than the MCL insertion at the tibia. The stiffness of the MCLs in the treated groups was similar (24.3±2.9N/mm vs. 21.7±8.4 N/mm, respectively, $p > 0:05$). The ultimate load of the MCL for the Silk-collagen treated group was 31% higher than that of silk-treated groups, although the difference was not found to be significant ($p > 0.05$) .It may due to the relative small sample size(n=5).The energy absorbed at failure for the silk-collagen -treated group was 90% higher than that of the silk-treated group, the $P>0.05$ may due to the small number of the samples. Both were significantly less than that for the normal (147± 97 Nmm, $p < 0:05$).

IV. Discussion

The results of the study showed that that the addition of collagen matrix led to the formation of larger collagen fibrils in MCL repair by regulating matrix gene expression and the assembly of endogenous collagen fibrils. It highlighted the important role of biomaterials in modulating ligament regeneration processes. Although the collagen fibril diameters in the MCL repair were still smaller than those in native ligaments, the average diameters of fibrils in

the silk+collagen-treated MCLs were significantly larger than in the silk-treated MCLs at 12 weeks, and this was consistently related to the better histology and mechanical properties of the silk+collagen-treated MCLs.

To understand the mechanisms by which collagen and silk regulates the assembly of collagen fibrils in MCL repair, we tested ligament matrix gene expression effected by the silk and collagen both in vitro and in vivo. Cells on collagen had higher matrix gene expression compare to those on silk. The different expression levels of different matrix genes caused by the collagen and silk may be one of the reasons for the change in fibril diameter. Previous studies reported that decorin decreases collagen fibril diameter both in vitro and in vivo [5]. In the in situ MCL repair study, the lower expression of collagen I and the higher expression of decorin may cause the smaller collagen fibers in silk-treated MCLs.

The present work showed that knitted scaffold has much internal connective space to allow large bands of collagen fibers with proper orientation and crimp pattern to form within the scaffold. However, the internal space decreases when the knitted scaffolds are put under heavy physical loading. In order to utilize the excellent biocompatibility of collagen matrix while preserving the internal space of the knitted silk scaffold, collagen sponge was chosen to fill the pores of the scaffold. The histology showed that the space filled by collagen sponge facilitated cell infiltration and connective tissue formation in the scaffold, at 2 weeks and 4 weeks after operation. The mechanical strength of the silk+collagen treated MCLs were also stronger than the silk treated MCLs.

Moreover, it is worthy of note that healing at the scaffold-ligament interface was improved by the hybrid collagen+silk scaffold. This may be explained by the fact that silk+collagen-treated MCLs synthesize more collagen ($P < 0.05$). It indicated that the structural/functional unit of the MCL was improved by enhancing neoligament tissue formation as well as interface healing between neoligament and native ligament.

Silks are naturally occurring protein polymers that have an excellent strength that have mechanical characters similar to the human ACL [3]. Our data showed that the knitted sericin-free silk and silk+collagen scaffolds were biocompatible and retained 25.6% of their tensile strength after 3 months implanted subcutaneously in mice. The tensile strength increased to 33.5% after 6 months which may be due to the ingrowth of new tissue. The knitted silk scaffold-treated MCLs reached 50% of normal failure force; this is higher than the peak force in vivo [2]. These data demonstrate the strong potential for knitted silk scaffolds in ligament regeneration.

V. Conclusions

In conclusion, this study highlight the important biological roles of biomaterials in ligament regeneration and the concept of an "internal-space-preservation" scaffold for the reconstruction of tissues which need to resist heavy physical loading. The knitted silk-collagen sponge scaffold, which possessed optimal internal space, a biocompatible environment, and mechanical strength, is a promising candidate for practical ligament and tendon tissue engineering.

Abstract — **In this study, we prepared BG filler powder containing some ions such as copper or zinc via sol gel method and their loading onto chitosan polymeric matrix for improving their bioactivities as well as their effect onto microorganisms such as Staphylococcus aureus bacteria were studied. The produced biocomposites characterized using X-ray diffraction (XRD), Fourier transformer infrared spectra (FT-IR), Thermogravimetric (TGA) analyses and Scanning electron microscope. Bioactivity behavior carried out in simulated body fluid (SBF) at 37 ºC and pH 7.4 for the biocomposites to verify the formation of apatite layer onto their surface. The results proved the presence of integration and homogeneity between BG and chitosan polymeric matrix. The results showed that BG/chitosan composite containing zinc ions had high ability effect onto Staphylococcus aureus compared to other composites. The in-vitro study confirmed the formation of apatite layer onto the surface of chitosan polymeric matrix and its composites with BG proving the vital role of chitosan to precipitate the ions of calcium and phosphate onto the composite surface. The conclusion show that BG/chitosan composite had ability to induce the bone-like apatite layer and anti-bacterial properties especially those containing zinc ions. Therefore, these biocomposites are promising to use as bone grafting, in tissue engineering as scaffolds and antibacterial applications.**

Keywords — **Sol-gel, chitosan, Antibacterial, In-vitro, Biocomposites**

I. Introduction

The formation of the hydroxyl-carbonate apatite (HCA) layer on the surface of bioactive glasses (BG) performed and a hydrated silica gel layer formed during the reactions [1]. Recently, the ionic products of BG dissolution exert a genetic control over the osteoblast cell cycle and the rapid expression of genes that regulate osteogenesis and the production of growth factors [2]. BG knows for their bone regeneration ability [3]. Certain bioactive glasses show to exert an antibacterial effect when challenged with bacteria [4]. Bioglass exerts an antibacterial effect on certain oral bacteria, possibly by virtue of the alkaline nature of its surface reactions. This may reduce bacterial colonization of its surface in vivo [5]. There are two types of antibacterial material containing either organic or inorganic substances such as chitosan [6] or silver, copper, and zinc [7]. Several interesting biological properties have reported for chitosan such as wound healing, immunological activity and antibacterial effects [8-10]. An interesting advance in technology has been to trap silver or zinc ions within inorganic ceramics and to apply these compounds to various materials as long lasting antimicrobial treatments [11]. The antimicrobial and anti -inflammatotory potency of these materials originate from the release of the Zn, Cu, Ag ions which react with proteins by combining the SH groups and leads to the inactivation of such proteins [12]. The zinc component results in the formation of a fibrous collagen capsule around the zinc polycarboxylate cement in vivo, which compromises the strength of the intermediate region between the bone and the cement [13]. In this study, we prepared the preparation of new composites from chitosan and BG containing cupper or zinc elements. The prepared composites characterized by XRD, TGA, FT-IR and SEM. These composite samples were soaked in SBF for different times. In addition, their bioactivities were characterized measurement of calcium and phosphorus, FT-IR, and SEM.

II. Materials and Methods

A. Materials

The polymer material used in this study was chitosan (High molecular weight and Brookfield viscosity: 800,000 cps) and 2-hydroxyethylmethacrylate (HEMA) were purchased from (Aldrich). Cerric ammonium nitrate initiator (CAN) was provided from (BDH, England). The starting materials used in this method to prepare (BG) were $Ca(NO_3)_2$ $4H_2O$ (Merk), triethylphosphate (Merk), tetraethylorthosilicate (Merk) and Sodium hydroxide.

B. Methods

B.1a. Preparation of BG filler

The bioactive glass material (BG) (45S5) was prepared in weight percentage: 45: SiO_2, 24.5: Na_2O, 24.5: CaO and 6: P_2O_5 using sol-gel method according to Li et al. [14]. Briefly, preparation of BG powder using sol-gel method was carried out via addition of $Ca(NO_3)_2$ $4H_2O$,

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1199–1203, 2009
www.springerlink.com

triethylphosphate, tetraethylorthosilicate and NaOH to de-ionized water at 25°C in the presence of nitric acid. After mixing, the resulting sol was aged at 60°C and dried at 130°C. The dried gel stabilized at 450°C, ground and sieved up to 50 μm. Other two types of glasses BG-Zn and BG-Cu were prepared by addition of tetraethylorthosilicate, $Ca(NO_3)_2$ $4H_2O$, triethylphosphate and $ZnNO_3$ or Cu $(NO_3)_2$ to deionized water at 25°C in the presence of nitric acid. The mix composition, expressed in weight % was as follows: 60% SiO_2; 26% CaO; 4% P_2O_5; and 10% of either ZnO or 10% of CuO. After mixing, the resulting sol was aged at 60°C and dried at 130°C. The dried gel stabilized at 450°C, ground and sieved below 50 μm.

B.1b. Preparation of BG/polymeric composite samples

Fixed weight (1.5 g) filler powder dispersed, well mixed with the copolymer mixture after 2.5 h from copolymerization process from the previous experiment and kept at 40 °C in water bath for 30 min to complete the copolymerization process in the presence of the filler. The BG/grafted chitosan composites left overnight at room temperature and then the mixture was washed with hot ethanol with stirring for 2 h to remove the homopolymer. The composite mixture filtered, collected and dried at 60°C overnight. The grafting yield of the grafted chitosan in the presence of BG filler powder calculated according to the following equation:

$$\text{The grafting yield} = (W_f\text{-}Wi/\ W_i) \times 100$$

Where: W_f is the weight of grafted chitosan in the presence of 1 g of filler and Wi is the weight of original chitosan. The produced BG/grafted chitosan composites denoted as BG composite. The same experiment was repeated with BG-Cu filler (1.5 g) to produce BG-Cu/ grafted chitosan composite that denoted as BG-Cu composite and repeated with BG-Zn filler (1.5 g) to produce BG-Zn/grafted chitosan composite that was denoted as BG-Zn composite.

B.2. Characterization

The thermal properties of the starting fillers and their composites were evaluated by thermogravimetric analysis (TGA) using a Perkin–Elmer, 7 series thermal analyzer at a heating rate of 10°C/min. The phase analysis of samples examined by X-Ray diffractometer (Diana Corporation, USA) equipped with CoK_α radiation. The FT-IR spectra measured using KBr pellets made from a mixture of powder for each sample and assessed from 400 to 4000 cm^{-1} using a Nexus 670, Nicloet FT-IR spectrometer, USA. SEM micrographs of the composites were also studied using SEM Model Philips XL 30, with accelerating voltage 30K.V. and magnification 10x up to 400.000x.

B.3. Bacterial test

The test microorganism was Staphylococcus aureus. Antibacterial test has carried out as follows: 40 ml of the agar medium inoculated with 200 micro liter of the test microorganism prepared inoculums and poured in 15 cm diameter Petri dish and solidified. After placing the disks of the tested materials on the surface of the solidified agar and let it to diffuse in the medium, the plates incubated at 37°C for 24 hours. The observation of the Halo zones carried out to assess the antimicrobial activity.

B.4. Bioactivity test

In order to study the bioactivity, the samples were soaked in SBF, proposed by Kokubo et al. [16] at the body temperature (37°C) and pH = 7.4 for several periods. After the immersion periods, the solutions were analyzed by spectrophotometer (Shimadzu, Japan) using biochemical kits (Techo Diagonstic, USA) to detect the total calcium ions $(Ca)^{2+}$ at λ= 570 nm and phosphate ions (PO_4^{3-}) concentrations at λ= 675 nm.

III. Results and Disccussion

A. The grafting yield (G) and thermo-gravimetric analysis (TGA)

The G of the BG-Cu composite recorded the maximum value (1390) compared to BG composite (1057) and BG-Zn composite (1097), respectively. This result is due to the presence of Cu doped with BG resulted in the enhancement of the affinity of BG-Cu filler particles to the co-polymeric matrix compared to other composites. The TGA results show that the destruction of three BG/ BG-Cu/ BG-Zn composites started at 168, 159 and 104°C and ended at 470, 557 and 557°C, respectively. The total weight loss of the three composites were 28.18, 46.13 and 38.35%, respectively, as a result of the release of all CO_2, NH_3 gases and water molecules [15] (Fig.1). The attached copolymer onto the filler particles was calculated by subtracting the weight loss of BG filler powder from the total weight loss of the prepared composite, whereas, the weight loss of BG filler recorded 3.78% due to the release of absorbed water proving its stability. Therefore, the order of the attached layer of copolymer onto the surface of BG particles was mentioned as follows: BG-Cu composite> BG-Zn composite >BG composite (42.35> 34.57> 24.30%, respectively). It noted that BG powder containing 10% copper oxide as in BG-Cu composite had high affinity to the copolymer compared to other composites and this result is coincided with the grafting data.

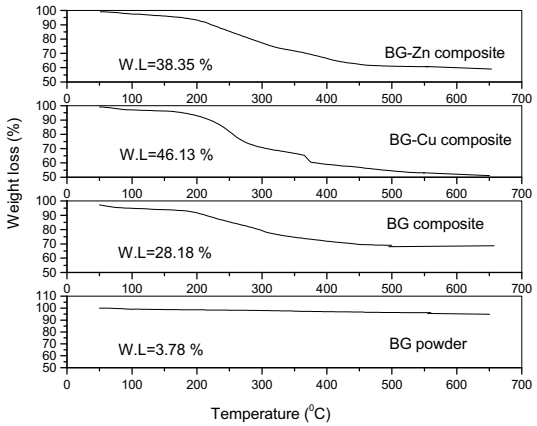

Fig. 1 TGA analysis of the BG composites compared to BG filler powder

B. Characterization of composites

B.1. Phase analysis

The XRD patterns of BG filler, copolymer, BG powder and their composites shown in Fig.2. In case of copolymer, there is a broad hump in the range of 2θ (12–25)° attributing to the structure of chitosan polymer (Card No.39-1894) as a result of interaction between HEMA monomer onto chitosan polymer (Fig.2a) For BG filler powder, the amorphous nature characterizing BG structure appears as a broad peak in the range of 2θ (30–40°). This broad peak which appears in the BG spectrum is still persisted in three BG composites with the disappearance of copolymer peak proving the effect of the filler particles onto the polymer sites as well as the amorphous nature of the copolymer matrix [17] (Fig.2b, c and d).

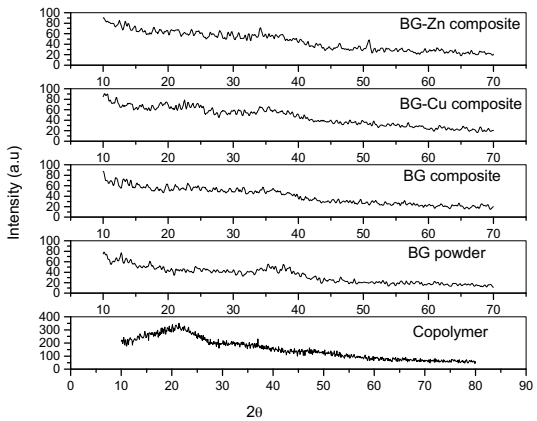

Fig. 2 XRD patterns of the prepared samples

B.2.FT-IR analysis

The FT-IR spectra of copolymer, BG filler and their composites show in Fig.3. After the loading of the BG filler powder onto the co-polymeric matrix,for the three composites, the optical density (O.D) of polymer bands were reduced compared to original copolymer proving effect of BG particles onto these sites especially as in BG and BG-Zn composites. Also, the O.D of phosphate and/or Si-O-Si at 1060 cm^{-1} and OH at 3450 cm^{-1} appearing into the spectra of the three composites were reduced compared to original BG filler denoting effect of coating onto these site bands especially as in BG-Cu composite (Fig.3). This result is coincided with the grafting and TGA results.

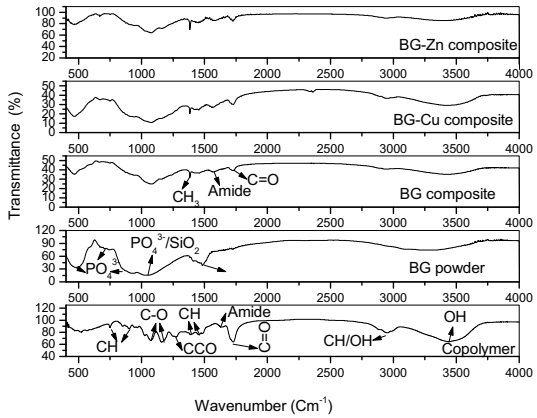

Fig. 3 FT-IR spectra of the prepared samples

C. Bacterial effect

The effect of the prepared composites onto bacteria (Staphylococcus aureus bacteria) show that the inhibition zone was 1.1, 2.05 and 2.2 cm for BG/, BG-Cu/ and BG-Zn/ composites, respectively (Fig.4). This result proves that the BG-Zn composite or BG-Cu/composites releases Zn or Cu ions which react with proteins in the micro-organism via the combination of SH groups resulting in the inactivation of proteins.

Fig. 4 Effect of the prepared composites on bacteria (Staphylococcus aureus) as in a) BG composite, b) BG-Cu/composite and c) BG-Zn/composite

D. Bioactivity behavior

D.1. In vitro test

D.1a. Total calcium ions (Ca^{++})

Concentration of Ca^{++} ions recorded higher values at all periods for three composites than control especially BG-Zn composite proving release of Ca^{++} ions from the composite surface into the media (Fig.5). This result proves that the presence of chitosan polymeric matrix containing BG particles leads to acceleration of the release of Ca^{++} ions from the surface especially for BG-Zn composite.

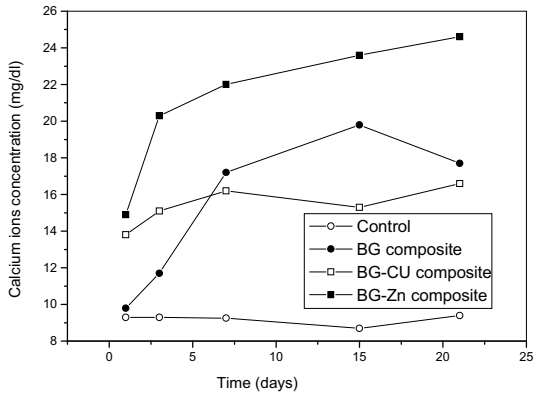

Fig. 5 Concentration of calcium ions in SBF post-immersion of three composites for different periods compared to control

D.1b. Phosphate ions (PO_4^{3-})

Concentration of PO_4^{3-} ions post-immersion for all tested composites recorded lower values than control especially BG and BG-Cu composites at all periods proving mineralization of PO_4^{3-} ions onto the composite surface and the interaction between phosphate ions in SBF and amino groups of chitosan into the composite (Fig.6). This result confirms that the presence of copolymer matrix containing BG or BG-Cu fillers enhanced the deposition process of phosphate ions.

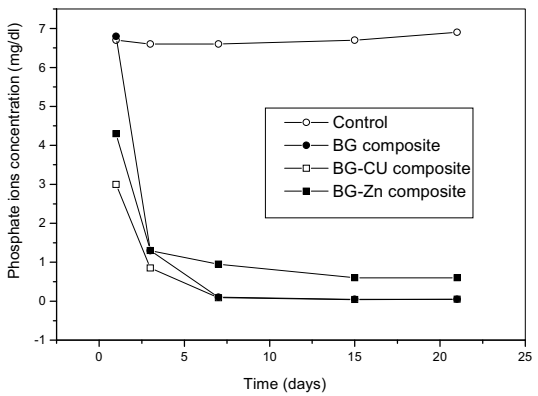

Fig. 6 Concentration of phosphate ions in SBF post-immersion of three composites for different periods compared to control

D.2. Solid Characterization

D.2a FT-IR analysis

Fig.7 shows that the O.D of OH at 2950 and 3450 cm^{-1} and phosphate groups at 470 and 1070 cm^{-1} into the spectra of three composites are enhanced post-immersion after 21 days compared to pre-immersion (Fig.3) proving mineralization of phosphate ions onto the surface. For BG composite, new bands appeared at 805, 880 and 1440 cm^{-1} that are assigned to carbonate group's post-immersion proving formation of carbonated apatite layer. For BG-Cu composite, new bands appeared such as phosphate band at 910 cm^{-1} and carbonate groups at 1400-1470 cm^{-1} denoting formation of carbonated apatite layer. For BG-Zn composite, new band appeared for carbonate group at 1460 cm^{-1} denoting formation of carbonated apatite layer. Additionally, it noted that the three composites had ability to form the carbonated apatite layer onto their surfaces.

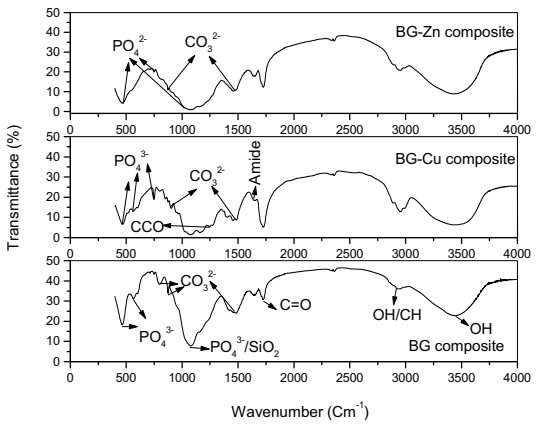

Fig. 7 FT-IR patterns of BG, BG-Cu and BG-Zn composites post-immersion for 21 days in SBF

D.2b. Microstructure of composites

For BG composite, pre-immersion (Fig.8a), SEM shows the appearance of smooth surface containing BG particles that are connected to each other and coated proving high homogeneity, while post-immersion (Fig.8b), SEM shows abundance of spherical shapes with some clusters having small particles indicating nucleation of apatite layer.

For BG-CU composite, pre-immersion (Fig.8c), SEM shows the presence of smooth surface containing some pores having irregular shapes proving coating and integration. Post-immersion (Fig.8d), SEM shows the presence of larger spherical shapes appearing onto the

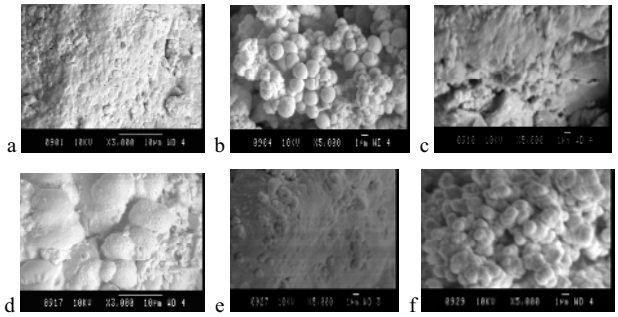

Fig. 8 SEM of BG composite a) pre- and b) post-immersion, BG-Cu composite c) pre- and d) post-immersion and BG-Zn composite e) pre- and f) post-immersion for 21 days in SBF

composite surface compared to post-immersion of BG composite indicating the role of Cu additive into the BG composite on the shape of the formed apatite layer. For BG-Zn composite, pre-immersion (Fig.8e), SEM shows the presence of smooth surface containing BG-Zn particles. Post-immersion (Fig.8f), SEM indicates the appearance of spherical particles which accumulated and connected to each other onto the surface proving high nucleation of a bone-like apatite layer.

IV. Conclusion

The results prove the presence of integration and homogeneity between BG and chitosan polymeric matrix. The data prove that BG/chitosan composite containing zinc ions had high ability effect onto Staphylococcus aureus compared to other composites. The in-vitro study confirmed the formation of apatite layer onto the surface of BG chitosan composites proving the vital role of chitosan to precipitate the ions of calcium and phosphate onto the surface. The results show that BG/chitosan composite had ability to induce the bone-like apatite layer and anti-bacterial effect especially those containing zinc ions in their structure. Therefore, these biocomposites are promising to be used as bone grafting, in tissue engineering as scaffolds and antibacterial applications.

Abstract — **Rapid prototyping of real products, which are customized to the needs of individual patients, became very successful in the field of biomaterials recently. But meanwhile the production is increasing, demands for the newly developed materials and new approaches became more and more important. In this respect multi-material functionally graded sintering has been introduced into production of materials. Certain combinations of materials with different mechanical properties tend to be promising in the field of bio-implants production as well as the Rapid prototyping methods such as Selective Laser Sintering (SLS) and 3D printing (3DP). In this study a possibility of application of functionally graded metal structures was evaluated. The two materials, CoCr alloy and Ti6Al4V alloy, were joined together by multi-material sintering procedure. Both materials are known to be used in orthopedics because of their excellent biocompatibility. In this case the testing samples were made as graded structures, having CoCr alloy on one end and Ti6Al4V alloy on the other end. Different sintering temperatures were applied. The obtained samples were tested in terms of biocompatibility where the manufacturing conditions, especially the sintering temperature, and surface structure were taken into account. The used cells were Balb/c Mouse Fibroblasts and the viability was assessed by MMT test. Samples were further examined for influence on PBMC (Peripheral Blood Mononuclear Cells) by Flow Cytometry analysis (FACS).**

Keywords — **functionally graded, biomaterial, rapid prototyping**

I. Introduction

The implantation of integrated biomedical devices to the human body provides challenges to the engineering materials science and technology. Because the production has rising tendency, new materials and innovated approaches are still required [1]. In this respect multi-material functionally graded sintering has been introduced into production.

In the multi-material functionally graded implants the mechanical, physical and chemical properties change from one side of the product to the other. Biomaterials with excellent osseointegration and low Young's modulus on one side of the implant and other materials with perfect mechanical properties such as hardness, abrasion resistance etc. on the other side, are advantageous for various bio-applications. For example, the disadvantage of joint requirements in bioimplants can thus be eliminated and the risk of screw connections or corrosion of welding avoided [2]. These appliances can also present contrasting adhesive requirements over very short distances along the same structure [3]. The additional requirements such as simplicity of manufacture, low cost production and individual demands such as design which can differ from patient to patient should be met as well [1].

Fundamental materials which are recommended especially for joint and bone implants and can withstand complex operating conditions are pure Ti, Ti-6Al-4V alloy and Co-28Cr-5Mo alloy [4, 5]. Especially titanium and its alloys currently constitute the most favored implant materials for joint replacement [6]. Moreover the powder metallurgy is involved in improving the bone-implant contact by making the implant structure porous and thus friendlier to bone cell anchorage [7]. In comparison to other metallic implant materials, titanium is characterized by a high biocompatibility, a good workability and corrosion resistance with suitable mechanical properties (low Young's modulus - high strength) [1]. Ti and Ti-6Al-4V alloy also perform a highly inert behavior while they develop a very sable oxide layer when exposed to air or to aqueous media [8]. Among all implant materials, Co-Cr-Mo alloys demonstrate the most useful balance in strength, fatigue and wear along with resistance to corrosion. Powder Metallurgy (P/M) route offers additional advantages [9]. It has been shown, that the extent of bone growth in implants where powder metallurgy was used was markedly greater, attributed to the microstructure of these implants [10].

There are numerous manufacturing processes employed nowadays in the Powder Metallurgy (P/M) field. The most promising ones are Selective Laser Sintering (SLS), Three-Dimensional Printing (3DP) or Metal Printing Process (MPP). These processes build components ready for use directly from metal powders using layer manufacturing principles. By changing the powder in the powder reservoir form layer to layer, graded materials can be thus produced [11].

II. Materials and methods

A. Materials

Ti6Al4V and CoCr alloys were supplied in a powder form by Arcam AB. The powder was produced by a gas atomization process and particle sizes laid within a size range from 10 to 70 μm. Multi-material functionally graded samples of CoCr alloy and Ti6Al4V alloy were manufactured by the MPP. They consisted of one part of CoCr and one part of Ti6Al4V, see Fig. 1. These were built in the shape of disks (30mm diameter, 3mm thickness) by the successive application of 10 to11 pattern layers of CoCr and Ti6Al4V on a foundation of pure Ti6Al4V powder, consolidated at various temperatures as derived in Fig. 1. For comparison, one sample of pure CoCr alloy and one of pure Ti6Al4V alloy where also manufactured by a similar procedure. The consolidation took place in a protective atmosphere of 95% Ar and 5% H, while the compaction pressure during consolidation was set to 170 MPa.

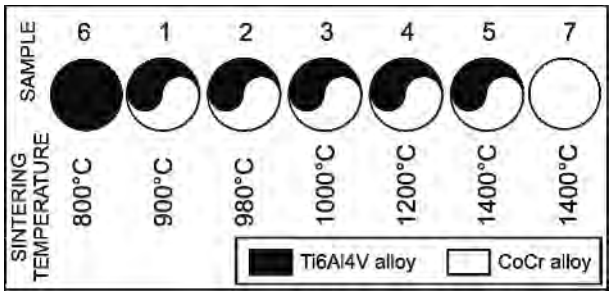

Fig. 1 Layout of testing samples

B. Mechanical Properties

Hardness was measured with the help of Brinell test, where the hardened steel ball-shape indenter was used. The diameter of indenter was 2.5mm and the applied load was 612.9N for 10 seconds. Specimens were measured at Ti6Al4V part and CoCr part three times to determine an average value.

Contact Angle was measured by Surface Energy Evaluation System. The samples were ultrasonic cleaned in ethanol bath and dried with agitated air. The sessile drop technique was used to measure the water contact angle using the See System software. The contact angle was measured three times on each part of the samples.

Surface topography was evaluated using the JEOL JSM 5410 Scanning Electron Microscope. Images were taken to show the most realistic information about the surface topography of the samples.

C. Biocompatibility

Viability: The Balb/c Mouse Fibroblast cell line was used in this study. For the precise evaluation of number of live cells the MTT test was used. The cytotoxicity level (see Table 1) was evaluated on the basis of cells viability in culture with presence of tested material extraction compared with control culture without presence of any cytotoxic material.

Table 1 Evaluation of cytotoxicity level

Viability	Cytotoxicity evaluation	Cytotoxicity level
>80%	Non-toxic	0
80-60%	Slightly toxic	1
60-40%	Moderately toxic	2
<40%	Highly toxic	3

In-vitro cultivation with PBMC: Isolated leukocytes were cultivated with the selected samples on 24-well cultivation plate for 18 hours in H-MEMd cultivation medium. $5x10^5$ cells from each specimen were then stained with Hoechst 33258 five minutes prior to measurement for exclusion of dead and damaged cells. Samples were measured on BD LSRII flow cytometer. Data were evaluated by TreeStar FlowJo software.

III. Results

A. Mechanical Properties

Hardness results are shown in Fig. 2. It can be seen, that the hardness of both materials increases with increasing sintering temperature. The hardness of CoCr alloy is generally higher than hardness of Ti6Al4V.

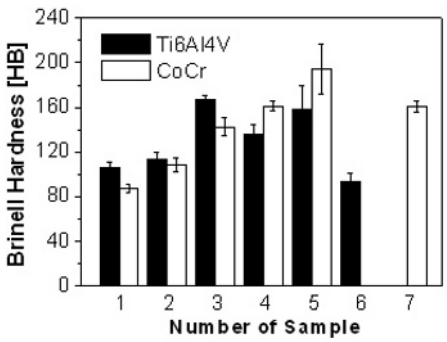

Fig. 2 Brinnel hardness results

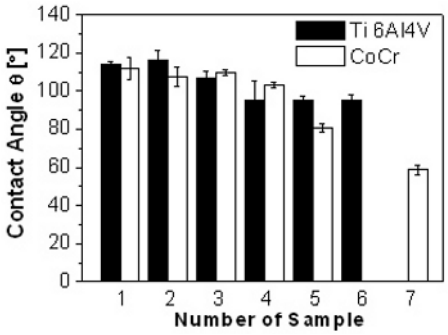

Fig. 3 Contact angle results

Contact angle results are shown in Fig. 3. The contact angle decreases with increasing sintering temperature. This applies for both materials, but the contact angle of Ti6Al4V is generally smaller than that of CoCr alloy.

Surface topography results are shown in Fig. 4a-g. The porous structure can be seen within all samples, but the best consolidation can be seen within the sample number 5 (Fig. 4e), where the interface between the two materials is also most visible.

B. Biocompatibility

Viability for different dilutions was evaluated and the results are shown in Table 2. The most favorable multi material sample is number. Numbers 4 and 5 exhibited high toxicity only in the presence of 100% extract; with the 50% extract they were non-toxic. The most adverse reaction can be seen within sample number 1. Sample number 6 proved the great biocompatibility of Ti6Al4V alloy.

In-vitro cultivation with PBMC results are shown in Fig. 5. The percentage of live cells after 18 hours incubation with presence of the samples was evaluated by FACS analysis of each of the samples. Also the micrographs of cells reaction are shown in Fig. 6a-h. For comparison, a control sample without presence of any of the materials was included into the results (Fig. 6h).

Table 2 Cytotoxicity levels for different extract dilutions

	Cytotoxicity Level			
Sample	100% extract	50% extract	25% extract	10% extract
1	3	3	3	0
2	3	1	0	0
3	0	0	0	0
4	3	0	0	0
5	3	0	0	0
6	0	0	0	0
7	2	0	0	0

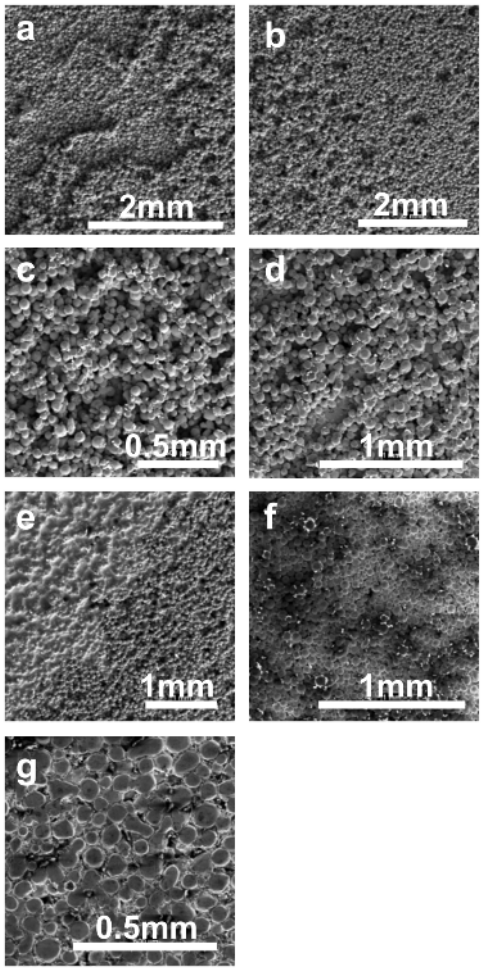

Fig. 4 SEM image of sample surface - interface between CoCr and Ti6Al4V alloy: (a) sample no.1, (b) sample no.2, (c) sample no.3, (d) sample no.4, (e) sample no.5, (f) sample no.6, (g) sample no.7

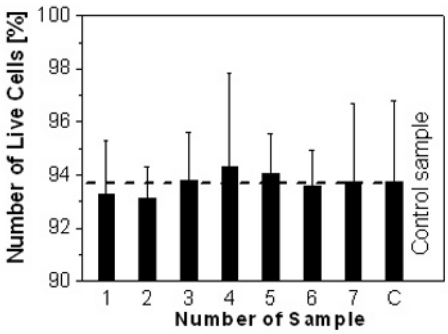

Fig. 5 Percentage of live cells within each sample obtained by FACS

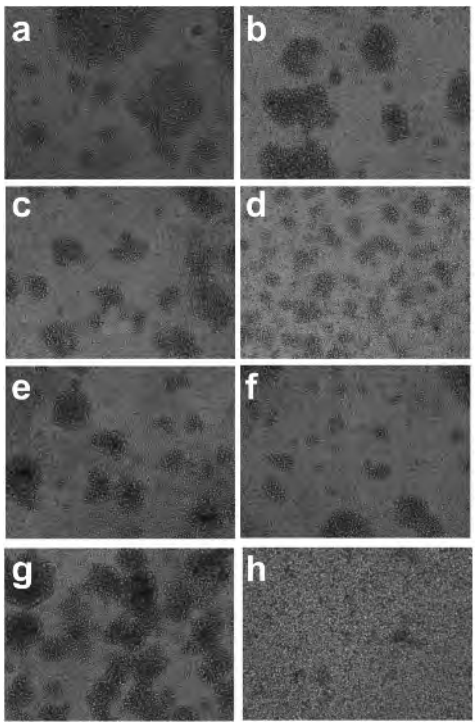

Fig. 6 Images of PBMC proliferation (magnification 10x): (a) sample no.1, (b) sample no.2, (c) sample no.3, (d) sample no.4, (e) sample no.5, (f) sample no.6, (g) sample no.7, (h) control sample

From the Fig. 5 and 6 it can be concluded, that the presence of samples has negligible influence on the cell behavior. No significant mortality or proliferation of cells has been reported by the FACS analysis. Only the micrographs show a slight agglomeration of PBMC.

IV. Discussion

Increase in hardness with increasing sintering temperature is favorable for further wear resistance properties.

As well as the decrease of the contact angle with increasing sintering temperature, which promises better cell anchorage and proliferation and better access of cell nutrients.

The functionally graded samples sintered at lower temperatures did not reach full density during consolidation but had a remaining porous structure. This condition was however improved with increased temperature. The higher was the temperature the better was the consolidation of particles, which promises better mechanical properties in general. It is also likely that further improvement would come with an increase in compaction pressure.

Also the viability of Balb/c cells was better within those samples, where the particles were consolidated more compactly. Nevertheless more detailed study in terms of biocompatibility would be required in order to state this type of material as fully applicable in bioimplant manufacturing.

Damage or proliferation of PBMC was negligible in relation to the control sample. Even though there was significant agglomeration of cells in presence of samples, materials are not likely to cause a strong immune reaction.

V. Conclusions

In this study a possibility of application of functionally graded metallic materials was studied. From the obtained results it can be stated that such combination of materials is likely to be applicable in the field of bioimplants. Samples where the higher temperatures of sintering were applied are recommended for further testing in order to meet high requirements on mechanical properties and biocompatibility.

Abstract — **Polymeric microspheres are versatile tissue engineering scaffold, suitable for simultaneous drug delivery and surface modification. They are small units that can be individually tailored for different cell types and purposes, then assembled with various compositions and shapes. In addition, they provide a 3D environment for cell-cell and cell-material interactions. Poly(3-hydroxyburate-co-3-hydroxyvalerate) (PHBV, 8% PHV content), a biodegradable and biocompatible microbial polyester, was used to fabricate microspheres using an oil-in-water emulsion solvent evaporation technique. As PHBV is biodegradable, the eventual construct will consist of only natural tissues, avoiding chronic complications. The versatility of microspheres is useful in neural therapies which require several cell types and various biomolecular signals to overcome inflammation, glial scarring, and inhibitory signals, as well as to promote repair and regeneration. Due to cell source limitations, neuronal expansion might have to be carried out on the microspheres to yield enough neurons for therapies. Also, a key requirement for engineered neural tissue would be its functional integration into host tissue. Thus, the suitability of PHBV microspheres as neural tissue engineering scaffolds was investigated using neuro2a neuroblastoma cells as a model for proliferating neurons and primary mouse fetal cortical neurons as a model for functioning neurons. Scanning electron microscope (SEM) imaging, and confocal laser scanning microscopy were used to observe morphologies of cells cultured on PHBV microspheres. Also, DNA Quantification and cell viability assay (MTT assay) were carried out. Neuro2a cultures on PHBV microspheres showed a growth trend comparable to that in 2D culture plate controls, in both assays. Also, through immunoflourescence staining for beta-III tubulin, primary neurons were found to extend neurites on PHBV microspheres. The results showed that PHBV microspheres are suitable scaffolds for neural tissue engineering, as they support the neural cells' adhesion, growth, proliferation and differentiation.**

Keywords — **Neural Tissue Engineering, Polymeric microspheres, Poly(3-hydroxyburate-co-3-hydroxyvalerate)**

I. Introduction

Cell replacement, drug delivery, and cell delivery therapies are being developed for neurodegenerative diseases and traumatic injuries to the nervous systems. Some challenges for an effective therapy include avoiding further inflammation, providing neuroprotection, stimulating tissue regeneration, overcoming inhibitory cues, and promoting functional recovery [1, 2, 3, 4].

Polymeric microspheres have been widely used for drug delivery. Their sizes, surface morphology and drug delivery profiles can be controlled [5, 6, 7]. Being small, they can also be injected into the defect site via less invasive surgical methods [8, 9]. Furthermore, microspheres made from biodegradable polymers, such as PLGA and PHBV, would disappear from the implant site thus avoiding long term complications.

PHBV is a polyhydroxyalkanoate produced by microorganisms for energy storage. It has been produced commercially and in large quantities from engineered microorganisms, and is considered a renewable resource [10, 11]. Furthermore, PHBV was found to be biodegradable [12] and biocompatible [13]. Thus, PHBV has potential as an environmentally-friendly material for tissue-engineering scaffolds in the form of microspheres. However, PHBV does not seem to be among the biomaterials studied for use in neural tissue engineering [14].

For PHBV microspheres to be useful neural tissue engineering scaffolds, they would have to support neural proliferation due to cell source limitations [15], and maturation of the cells to provide function [16]. In this work, neural proliferation was studied using neuro2a neuroblastoma cell line, and neuronal maturation was investigated using mouse fetal cortical neurons.

II. Materials and methods

A. Materials

Poly(3-hydroxyburate-co-3-hydroxyvalerate) (PHBV, 8% PHV) was purchased from Sigma-Aldrich. Chloroform and Poly (vinyl alcohol) (PVA, Mw 6000) were acquired from Fluka (Steinheim, Germany) and Polysciences (Warrington, PA, USA) respectively. Neuro2a cells were a gift from Associate Professor Too Heng Phon (National Univer-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1208–1212, 2009
www.springerlink.com

sity of Singapore/Biochemistry, Singapore). C57/BL6 mice were obtained from Animal Holding Unit (AHU, National University of Singapore). All medium components were purchased from Invitrogen. All other chemicals were purchased from Sigma-Aldrich unless otherwise stated.

B. Microsphere fabrication

Poly(3-hydroxyburate-co-3-hydroxyvalerate) (PHBV) microspheres were fabricated using the water-in-oil-in-water (w/o/w) double emulsion solvent evaporation technique [17]. 0.6 g PHBV was dissolved in 12 ml chloroform at 60 °C to form the oil phase, while 0.15 g poly(vinyl alcohol) (PVA) was dissolved in 300 ml phosphate buffer saline (PBS) to form the water phase. The first water-in-oil emulsion was formed by sonicating (SONICS Vibra-Cell™, Boston, Massachusetts, USA) a mixture of 1 ml water phase in the oil phase. The second water-in-oil-in-water emulsion was obtained by adding the first emulsion into the remaining water phase and stirring the mixture at 300 rpm using a mechanical stirrer (RW20, Ika Labortechnik, Staufen, Germany) for 4.5 hours. This final mixture was maintained at 37°C using a water bath on a magnetic hotplate stirrer (Cimarec2, Barnstead/Thermolyne, Iowa, USA). The formed microspheres were collected and wash 5 times with deionised water, then freezedried (Alpha 1-4, Martin Christ, GmbH, Germany) for 36 hours.

C. Scanning Electron Microscope imaging of microspheres

The microspheres were characterized by measuring their sizes and imaging their surface morphology using a scanning electron microscope (SEM) (JSM-5600VL, JEOL, Tokyo, Japan). Freezedried microspheres were mounted onto brass stubs using carbon tape. The microspheres were then coated with platinum using a sputter coater (JFC-1300, JEOL, Tokyo, Japan). The coated samples were viewed under the SEM and patches of microspheres were captured to provide sample sizes of no less than 100 microspheres per fabricated batch. Representative images of the spheres' surface morphology were taken at various magnifications. The diameters of the microspheres were measured from the SEM images using the software Smile View.

D. Neuro2a cell culture

The neuro2a cells were cultured in Hyclone hi-glucose DMEM with 10 % fetal bovine serum and 1% penicillin-streptomycin added. The medium was changed at 50% every 24 hours.

E. Mouse fetal cortical neuron culture

Primary cortical neurons were harvested from E16 embryos (mouse C57/BL6) and cultured in Neurobasal medium supplemented with B27 and L-Glutamine.

F. Cell Seeding

Before seeding, microspheres were treated by overnight soaking in medium (uncoated microspheres) or 0.01w/v% poly-L-lysine solution (PLL-coated microspheres) at room temperature. Glass coverslips were also soaked overnight in PLL. 5 mg of treated microspheres were placed into each well of 24-well plates. Neuro2a cells were seeded onto the microspheres at 3 X 10^4 cells per well. Cortical neurons were seeded at 5 X 10^5 cells under similar conditions. In addition, cortical neurons were seeded onto PLL-treated coverslips at 1.5 X 10^5 cells per well.

G. MTT assay

The assay is based on the transformation of yellow water-soluble tetrazolium (MTT) salt, by viable cells' mitochondrial succinic dehydrogenases, to water-insoluble purple formazan crystals of which quantity is proportional to the number of viable cells [18]. Medium from culture wells was replaced with serum-free medium and MTT chemical at 9:1 ratio. The cultures were then incubated for 3 hours at 37˚C. Following this, the solution was removed and 500µl of DMSO was added into each well to dissolve the formed purple crystals. The resulting solutions were transferred into 96-well plates, and measured for absorbance (560 nm) with reference wavelength (620 nm) using a microplate reader (Tecan GENios, Switzerland).

H. Total DNA quantification

The assay measures cell numbers by quantifying the amount of DNA using Hoechst 33258 [19]. Cultures were washed twice with PBS and the cells lysed in ultrapure water through 3 freeze-thaw cycles. The cell lysates were mixed with 1 µg/ml Hoechst 33258 in 10mM TrisHCl (pH 7.4), 1mM EDTA and 0.2M Nacl fluorescence assay buffer, then incubated in the dark for 30 minutes. The fluorescence was read at 465 nm using a microplate reader with excitation at 360 nm.

I. Immunoflourescence staining

Immunoflourescence staining was carried out to label various biomolecules and structures in the cells. Cultures

were fixed with 4% paraformaldehyde for 20 minutes, then washed once with PBS, twice with 100mM NH_4Cl in PBS, and once more with PBS. Following this, permeabilisation of the cells was carried out for 15 minutes in 0.1 w/v % saponin in PBS. Primary antibodies were diluted 150 times in blocking buffer consisting of 5% fetal bovine serum and 2 % bovine serum albumin in PBS. The saponin was removed from the culture samples and the samples were incubated in this primary antibody solution for 1 hour. After the incubation, samples were washed 3 times with PBS, and incubated for 1 hour in secondary antibody solution consisting of fluorophore-conjugated secondary antibodies diluted 150 times in blocking buffer. Finally, the samples were washed 4 times in PBS, placed onto glass coverslips, and viewed under Laser Scanning Confocal Microscopes:

- TCS SPE, Leica Microsystems GmbH. Wetzlar, Germany
- Axiophot microscope, Carl Zeiss Inc., Thornwood, NY, USA
- C1 system, Nikon Singapore, Singapore)

J. Statistical analysis

All data is presented as mean ± standard deviation of 3 replications.

III. Results

A. Microsphere characterization

Table 1 shows the size distribution of the 4 microsphere batches fabricated for this study. Figure 1 shows a representative SEM image of microspheres from the 4 batches fabricated. The microspheres are generally spherical, and have similar surfaces with nano-sized features and pores.

Table 1: Microsphere sizes

Batch	a	b	c	d
Mean diameter	189.2	209.9	218.4	203.2
Standard deviation	37.9	48.7	55.3	77
Sample size	145	138	139	152

Figure 1: SEM image of microsphere morphology

B. Growth curve of neuro2a model

Figure 2 shows the growth curves of neuro2a cultures on uncoated, and PLL-coated microspheres, in comparison to tissue culture plate well. The growth curves were measured through the MTT (a) and TDQ (b) assays. Both sets of growth curves show comparable cell growth and proliferation on the 3D microspheres compared to standard 2D culture wells up to 9 days in vitro.

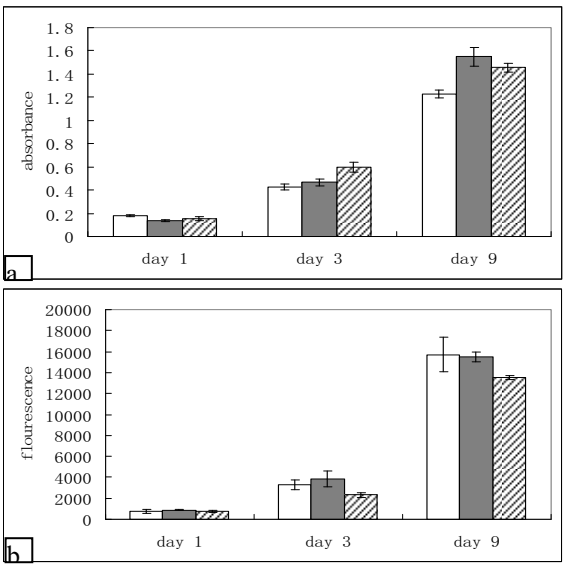

Figure 2: MTT results of neuro2a cultures on uncoated ■, and PLL-coated ▨ microspheres, in comparison to tissue culture plate well □.

C. Primary neuron differentiation on PHBV microspheres

Figure 3 shows neurite extension from mouse fetal cortical neurons as verified by beta-III tubulin staining. The cortical neurons were cultured for 3 days on PLL-coated microspheres. They were stained with Hoechst (blue) for nuclei, and anti-beta-III-tubulin (red) for neurites.

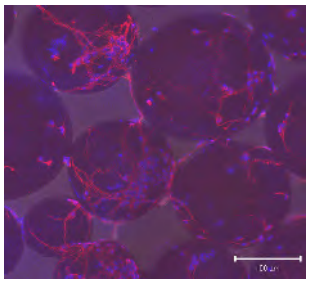

Figure 3: CLSM image of primary neurons on microspheres

IV. Discussion

Due to cell shortages, neuron populations would have to be expanded in vitro to yield enough cells for tissue engineering applications and research [15]. Thus, it is important for scaffolds to support neuronal proliferation. Neuro2a is a neuroblastoma cell line and was used as a model for neuronal proliferation in this study. Neuro2a proliferated on PHBV microspheres at a rate comparable to standard 2D cultures (figure 2). As neuro2a is a neuron-like, the results suggest that neuronal cells such as Neural Stem Cells and Neural Progenitor Cells can proliferate on PHBV microspheres too.

One final aim of neural tissue engineering is to restore function. Thus, scaffold should support neuronal differentiation essential for functional development and restoration. Neuronal differentiation involves formation of cellular structures which include neurites at early stages of maturation. Due to their innate capacity for differentiation, primary mouse fetal cortical neurons were chosen for investigating neuronal differentiation on PHBV microspheres.

Antibodies to beta-III-tubulin were used to stain for neurites. Beta-III-tubulin is found in the microtubules of neurites [20]. Thus, beta-III-tubulin's presence (figure 3) suggests that neurons were extending neurites which could be or could develop into axons and dendrites, and form functional networks on PHBV microspheres.

V. Conclusions

PHBV microspheres have been shown to support neuronal proliferation and differentiation. Thus, PHBV microspheres have potential as neural tissue engineering scaffold.

Acknowledgment

The first author would like to thank Ms Chen Yanan for her mentorship and help in harvesting the primary neurons.

Abstract — **Recently, researchers have challenged to create three-dimensional (3-D) tissues with tissue engineering technology in order to establish in vitro models and new therapy for damaged organ. We have developed cell-sheet based tissue engineering and successfully fabricated pulsatile 3-D myocardial tissues both in vivo and in vitro by layering cardiac cell sheets. However, in vitro scaling up of 3-D cell-dense tissues is limited due to lack of blood vessels supplying oxygen and nutrition and removing waste molecules. In this study, we have developed novel bioreactor culturing layered cell sheets on collagen-based microchannels and examined cell behavior between tissues and channels. Rat cardiac cells including endothelial cells were cultured on temperature responsible culture dishes for 4 days. By lowering temperature, confluent cardiac cells were harvested as an intact cell sheet and two cardiac cell sheets are layered. Collagen-based microchannels were engineered by gelling collagen around parallel stainless wires and extracting the wires. The double-layer cell sheets were put on the microchannels and the constructs were connected to the novel perfusion bioreactor. After 5 days of cultivation, the tissue sections were stained with Hematoxylin-Eosin and endothelial cell specific Isolectin B4. HE staining demonstrated that layered cell sheets tightly connected onto the collagen microchannels. The microchannels maintained their patency during culture period. The cardiac cells migrated into collagen gel and the number of migration increased flow-rate dependently. At higher flow-rate, some cardiac cells reached to microchannels and covered over their inner surface. Isolectin B4 staining showed endothelial cells formed networks within the cell sheets and also played as migrating cells. We have successfully fabricated 3-D tissues with perfused microchannels and tissue-originated cells migrated and communicated with the microchannels. These results showed new insights regarding in vitro vascular formation and indicated the possibility for fabricating vascularized 3-D tissues.**

Keywords — **Tissue engineering, Cell sheet, Bioreactor, 3-D myocyte tissues, Vascular formation**

I. Introduction

For end stage heart failure, cardiac transplantation is the most effective treatment, but transplantation is limited by sever shortage of donors. Therefore myocardial tissue engineering to supplement impaired heart tissue is expected alternatively, and has been investigated by various researchers [1]. The conventional approach of tissue engineering is to construct 3-D tissues by using biodegradable scaffolds as alternatives for ECM. In contrast to using biodegradable scaffolds, our group has developed a novel method to fabricate tissues by layering cell sheets. The layered cell sheets were connected tightly, and electrical communications were established between the layered cell sheets [2], layered cell sheets macroscopically beat like heart both in vitro and in vivo [3]. This method has high potential to fabricate functional cell-dense myocyte tissues. However, in the reconstruction of cell-dense myocardial tissue, hypoxia and nutrient insufficiency and waste accumulation limit the final size of viable constructs.

In this study, we developed novel perfusion bioreactor to fabricate 3-D tissues with collagen-based microchannels to overcome those limitations during tissue culture. Cell migration and communicate with the microchannels were examined.

II. Materials and Method

A. Preparation of neonatal rat cardiac cell sheets

Neonatal rat myocytes were isolated from ventricles of 1-day-old rat (CLEA Japan Inc, Tokyo, Japan) as previously described procedures [4]. Briefly, ventricles were minced and digested in Ca^{2+} -Mg^{2+} -free Hanks' balanced salt solution (Sigma, St. Louis, Mo) with 200U/mL collagenase (Class II, Worthington Biochemical, freehold, NJ) at 37°C for 4 cycles of 10 min. Isolated myocytes were cultured in medium with 6% fetal bovine serum, 40% medium 199, 1% penicillin-streptomycin solution, and 54% balanced salt solution containing 166mM NaCl, 1.0mM NaH_2PO_4, 0.8mM $MgSO_4$, 26.2mM $NaHCO_3$, 0.9mM $CaCl_2$, and 5mM glucose. The cell suspensions were seeded at a density of 2.4×10^6 cells/dish on UpCell dish (φ35mm, Type-E, CellSeed Inc, Tokyo, Japan) . The dishes were incubated in 5% CO2 atmosphere for 4 days at 37°C. To detach confluent cell as a cell sheet, culture dishes were incubated in another CO2 incubator set at 20°C for 1 hour.

www.springerlink.com

B. Creation of collagen-based microchannels

The stainless wires (φ300μm) were inserted into the holes (φ400μm) of the acrylic frame made from Rapid Prototyping (EDEN, Objet Geometries Ltd, Israel) (Fig. 1B). Neutralized liquid collagen was poured into the acrylic frame surrounding the stainless wires set at parallel position (Fig. 1C). To make collagen harden, the collagen was incubated for 30 minutes at 37°C. After collagen gelling, extracting of the wires yielded 300-μm-diameter channels in the collagen gel (Fig. 1D). Neutralized collagen solution consisted of 10% decuple-concentrated cardiac cell culture medium described above, 10% balanced solution containing 10mM Hepes (Sigma, St. Louis, Mo), 15mM $NaHCO_3$, and 80% collagen Type1 (IAC-05, KOKEN Co. LTD, Tokyo, Japan). At the same time as collagen gelling, the double-layer cell sheets were put on the collagen based-microchannels for attachment. The distance from microchannels to cell sheets was approximately 600μm.

C. Assembly of bioreactor

The collagen-based microchannels with cardiac cell sheets were cultured statically at 37°C for 24 hours to make collagen gel stabilized. To perfuse the microchannels, the acrylic frame was connected to the connector of the microsiring pump (KDS270, KD Scientific, USA). All bioreactor devices were putted in the culture box (As one, Tokyo, Japan) maintained at 37°C by the fan heater (Sankei, Tokyo, Japan) and supplied with mixed gas (5% CO_2, 95% Air). The perfusion rate was set to 0.3mL/min, 0.5mL/min, and 0.7mL/min. During the experiment, the performance of bioreactor was observed by the monitoring system (Power Lab, AD Instruments, NZ). The pH and oxygen of culture media were measured by the optic chemical sensors (Presens, Regensburg, Germany) and the inlet pressure of channels was measured by a disposable pressure transducer (Truwave, Edwards Lifesciences, CA., USA) (Fig. 2).

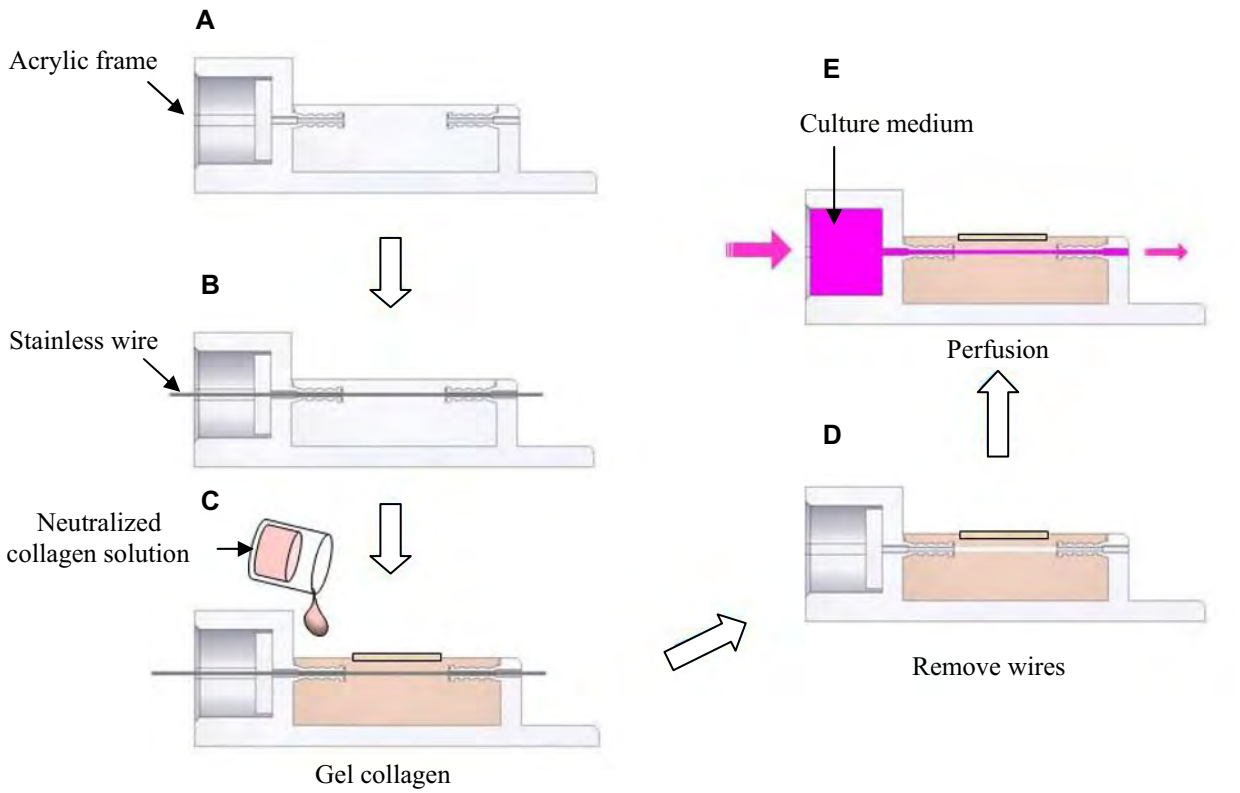

Fig. 1. Schematic diagram of fabricating collagen-based microchannels. The Acrylic frame served as a gel holding device (A). The stainless wires (φ300μm) were inserted into the holes (φ400μm) of the acrylic frame (B). Neutralized liquid collagen gel was poured into the device surrounding the stainless wires putted in parallel position. At the same time as collagen gelling, the double-layer cell sheets were put on the collagen based-microchannels (C). After collagen gelling, extracting of the wires yielded 300-μm-diameter channels in collagen gel (D). After 24hours, culture medium was perfused through the microchannels (E).

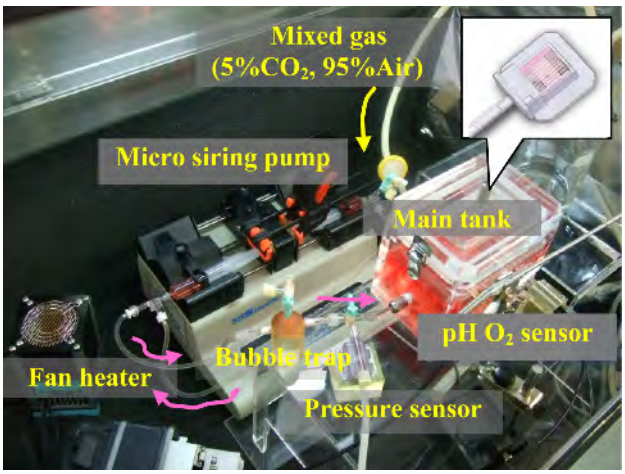

Fig. 2. The perfusion bioreactor was set in the stainless box. In this box, temperature was kept at 37°C.

D. Histological analysis

After perfusion culture, the construct was fixed in 4% paraformaldehyde (Wako Pure Chemicals, Osaka, Japan) and routinely processed into 10-μm-tick paraffin-embedded sections. Hematoxylin and eosin and Azan staining were performed by conventional methods. Fluorescence cells were labeled with Griffonia Simplicifolia Lectin I Isolectin B4 (Vector Laboratories inc, Burlingame, USA), and selected slides were nuclear-stained with 1:500 dilution of Hoechst 33342.

III. Result

During our experiments, the constant flow was realized in the bioreactor system (Fig. 3A-C). The flow within collagen-based microchannels was checked by black ink immediately prior to the fixation. No medium leakage was observed from the microchannels. After perfusion culture for 5days, the HE staining demonstrated that the inner diameter of the collagen-based microchannels did not change at any flow.

In the first place, the distance between cell sheets and the microchannels set at approximately 600μm and the media flow was changed. At flow-rate of 0.3mL/min, the cell migration form the cell sheets was not observed (Fig. 3D). However, at the rate of 0.5mL/min, the cardiac cells migrated into the collagen gel, the distance of migration was approximately 100μm, and the cells just above each microchannel tended to migrate more (Fig. 3E). In the case of 0.7mL/min, the cardiac cells migrated into the

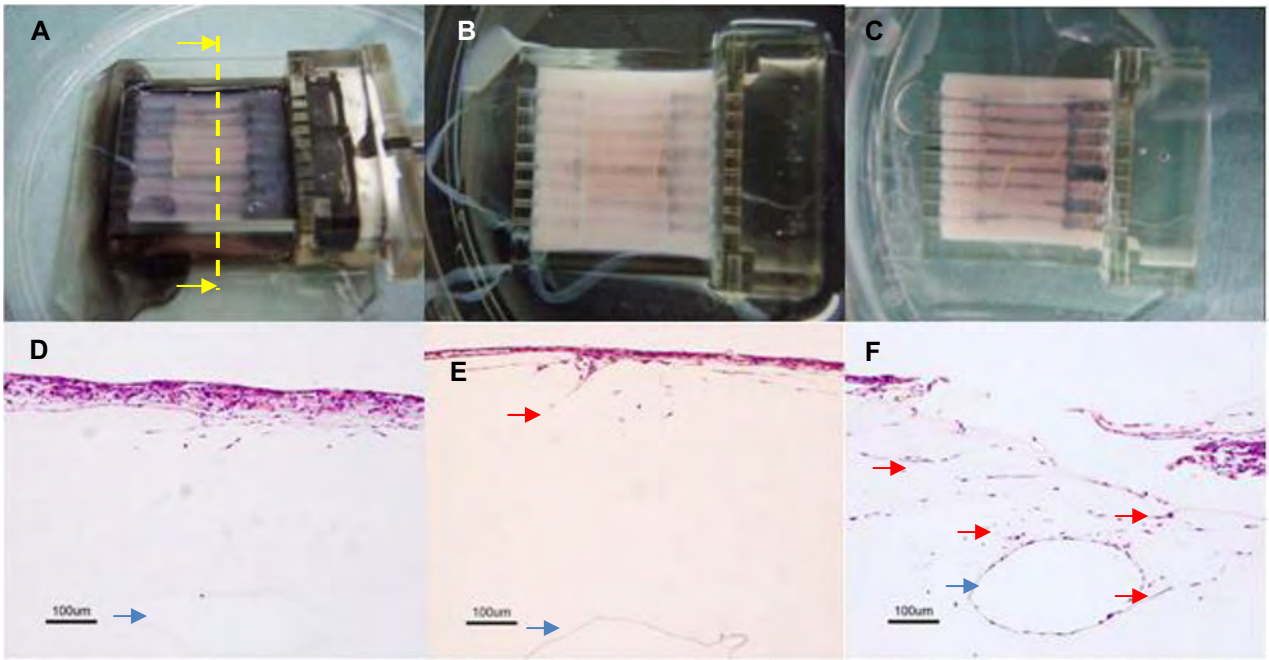

Fig. 3. Collagen-based microchannels after perfused culture. The microchannels were media flowed with 0.3mL/min flow rate. The yellow arrows indicate cross section of HE strain slide (A). 0.5mL/min flow rate (B). In case of 0.7mL/min, the layered cell sheet detach from the collagen gel (C). Demonstration of the morphology with hematoxylin and eosin stain of A (D), in the case of B (E), and C (F). The blue arrows indicate microchannels, and the red arrows indicate migration cells.

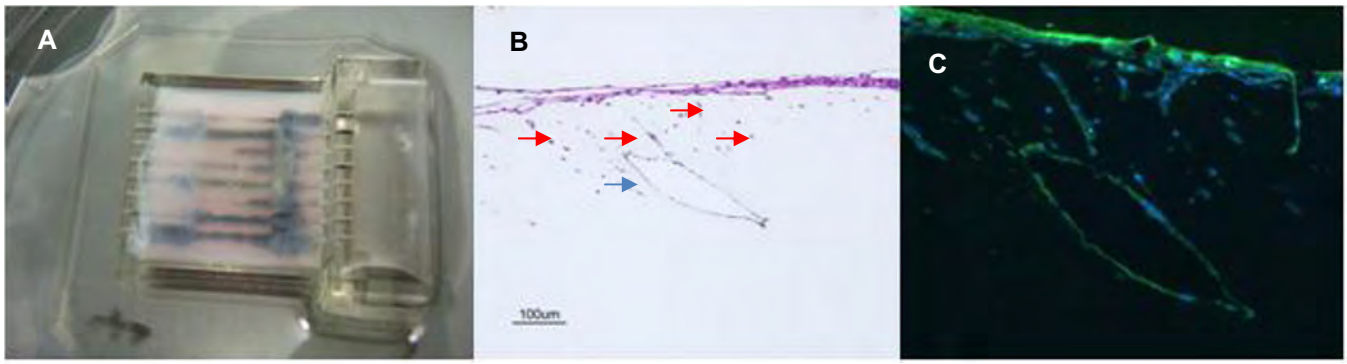

Fig.4. Novel collagen-based microchannels (A). To accelerate the bridge between cell sheets and microchannels without cell sheet delamination, the distance between them was made shorter to approximately 200μm and flow rate was fixed at 0.5mL/min. In result, the cardiac cells migrated and communicated with microchannels. Further more migrating cells covered over the inner surface (B). Isolectin B4 staining showed those migrating cells included endothelial cells (C).

microchannels more deeply and reached to the microchannels (Fig. 3F). However, the higher flow rate caused greater media permeation through collagen gel and the cell sheets finally detached from the gel, (Fig. 3C). Over 0.7mL/min flow-rate, cell sheets detached from the first.

To accelerate the bridge between cell sheets and microchannels without cell sheet delamination (Fig. 4A), the distance between them was made shorter to approximately 200μm and flow rate was fixed at 0.5mL/min. In result, the cardiac cells migrated and communicated with microchannels. Further more migrating cells covered over the inner surface (Fig. 4B). Isolectin B4 staining showed those migrating cells included endothelial cells (Fig. 4C).

IV. Conclusions

We have successfully fabricated cardiac tissues with perfused microchannels and tissue-originated cardiac cells migrated and communicated with the microchannels, and covered over their inner surface. Endothelial cells also contributed to 3-D tissue reconstruct. These results showed new insights regarding in vitro vascular formation and indicated the possibility of fabricating vascularized cardiac tissues.

Abstract — **Plasma treatment is a technique that can be used to modify the surface of materials. It has been widely used in applications such as surface cleaning, activation, etching, and coating. In this work, pulse inductively coupled plasma (PICP) device is introduced for treatment of crosslinked gelatin film. The effects of plasma on the properties of gelatin film were investigated. Type A gelatin film crosslinked by dehydrothermal (DHT) was treated by N_2 plasma. PICP device produces plasma by discharging large electrical current around a cylindrical quartz tube. The operating pressure of N_2 was 5 Pa and the number of pulse applied was varied from 1 to 10 pulses. The surface properties of crosslinked gelatin were characterized by water contact angle and atomic force microscopy (AFM). The preliminary results showed that, the water contact angle of crosslinked gelatin treated by N_2 plasma were decreased compared to untreated crosslinked gelatin film. This implied that, N_2 plasma could introduce hydrophilic groups onto the surface of crosslinked gelatin. The result from AFM revealed that, enhanced surface roughness of crosslinked gelatin film when much number of pulses applied. *In vitro* test using L929 mouse fibroblast revealed that, the number of cells adhere and proliferate on plasma-treated samples was higher than that on untreated samples. The results implied that PICP has a high potential to modify the surface of gelatin for greater cell affinity.**

I. Introduction

One of significant challenges for tissue engineering is to design and fabricate suitable scaffolds from biodegradable materials favorable to cell adhesion, growth, proliferation and differentiation [1]. Commonly, cell attachment and growth are considered as two important factors of cell affinity because they will directly influence cell capacity to proliferate and differentiate [2]. Surface characteristics of material such as hydrophilicity/hygrophobicity, charge property and surface roughness greatly influence cell attachment and growth on the material [3].

Gelatin is a protein biopolymer derived from partial hydrolysis of native collagens, the most abundant structural proteins found in skin, tendon, cartilage and bone of animal. Due to a wealth of merits such as biological origin, nonimmunogenicity, biodegradability, biocompatibility, and commercial availability at relatively low cost, gelatin has been widely used in pharmaceutical and medical fields. Recently, Ratanavaraporn [4] has reported that gelatin could be used to partly replace collagen in scaffold fabrication without losing great biological properties of collagen. Since gelatin is water soluble, dehydrothermal crosslinking was employed to prevent its solubility so that it could be used in tissue culture. However, crosslinked gelatin exhibited hydrophobicity property which was not favorable to cells adhesion [5].

Many approaches have been developed to improve cell affinity of hydrophobic polymers, including surface and bulk modification. Surface modification can be performed by combining some functional groups that are biologically active onto surface of the materials. Surface coating is a simple and general approach for surface modification, but bioactive molecules usually are not able to spread well on the hydrophobic substrate, and thus the surface is unstable [5]

Plasma treatment is a method that can be employed to modify the surface of material since reactive groups or chains can be easily introduced onto the surface of material. Cold plasma such as radio frequency (RF) generated plasma has been reported to modify surface of biomaterials such as poly (lactide-co-glycolide) (PLGA) [5]. However, this plasma generating process is continuous, therefore the controls of heat accumulation and plasma exposures are difficult. Pulse inductively coupled plasma (PICP) method, on the other hand, eliminates heat accumulation problem as well as producing higher energy plasma. PICP device generates plasma by applying large electrical discharge around cylindrical quartz tube. The plasma produced provides high energy ions and electrons that they can be used to modify material surface [6,7]. PICP is discontinuous therefore the plasma exposure can be relatively easy to control.

In this study, PICP was introduced to enhance cell affinity of crosslinked gelatin film. The plasma-treated gelatin was then characterized by water contact angles measurement and atomic force microscopy (AFM). The cell affinity of plasma-treated gelatin was evaluated and compared with that of untreated gelatin using mouse L929 fibroblast as a model cell *in vitro*.

www.springerlink.com

II. Materials and methods

Type A Gelatin from porcine skin was obtained from Nitta Gelatin, Japan. Dulbecco's modified Eagle's medium (DMEM) and trypsin/EDTA from Sigma Aldrich Chemical Co. were used as received.

A. Preparation of crosslinked gelatin film

Type A Gelatin was dissolved in deionized water to achieve 10% w/w solution. The solution was cast into a teflon mould. After solvent evaporation at room temperature, the film was removed from the mould and crosslinked by dehydrothermal treatment (DHT) at 140°C for 48 hr to obtain crosslinked gelatin (GA-DHT).

B. Plasma treatment

The plasma treatment was done by PICP device using nitrogen gas. Crosslinked gelatin film with a diameter of 14 mm was placed inside a cylindrical quartz tube. The tube was evacuated to less than 2 Pa before filling with nitrogen gas. After the pressure was stabilized at 5 Pa, glow discharge plasma was produced by electrical discharge from a network of electrical energy storage that was charge to a potential of 20 kV. A single pulse discharge and a multiple pulse discharge, in this case up to 10 pulses, were applied to the samples and were coded as GA-DHT-1 and GA-DHT-10, respectively.

C. Characterization of plasma treated gelatin

Determination of water contact angle: Contact angles of crosslinked gelatin films were investigated at room temperature using a Contact Angle Meter Model CAM-PLUS MICCRO equipped with an optical microscope from TANTEC INC. Deionized water was used as liquid media. The contact angle of the samples was averaged from 5 measurements.

Surface topography: Surface topography of the samples was examined by Atomic Force Microscopy (AFM) in contact method. Three-dimensional images and surface topography parameter data were acquired using Nanoscope image-processing software.

D. In vitro cell culture

Plasma treated crosslinked gelatin and untreated crosslinked gelatin were placed into 24-well tissue culture plates and sterilized in 70% (v/v) ethanol for 30 min. To remove ethanol, the samples were rinsed with phosphate-bufferd saline (PBS). L929 mouse fibroblast cells were seeded at a density of $2x10^4$ cells per well in DMEM containing 10% fetal bovine serum and incubated at 37°C in 5% CO_2 incubator. After cultured for 6, 24 and 72 hr, the culture media was replaced with 3-(4,5-dimethylthiazolyl)-2,5-diphenyltetra zolium bromide (MTT) (0.5 mg/ml) and incubated for 30 min to establish cell viability. Dimethylsulfoxide (DMSO) was used to elute complex crystals and the absorbance of solution was measured at 570 nm using a spectrophotometer. The same treatment of the films without cells was used as control. All data were expressed as mean ± standard deviation (n=3).

III. Results and discussion

Water contact angles of untreated and plasma-treated crosslinked gelatin film were shown in Fig. 1. It could be seen that water contact angle of plasma-treated crosslinked gelatin film was lower than that of untreated samples. The water contact angle of plasma-treated crosslinked gelatin film was decreased with increasing a number of pulses applied. This could be due to the introduction of hydrophilic groups by nitrogen plasma onto the surface of crosslinked gelatin [8].

The surface topography of crosslinked gelatin films before and after nitrogen plasma treatment was investigated by AFM. The three-dimensional images of AFM were shown in Fig. 2 and the quantitative data of surface roughness parameters were presented in Table 1. The surface of the untreated crosslinked gelatin was smooth (Fig. 2a) and the value of mean surface roughness (Ra) was 0.603 nm. However, after treated by plasma for 1 pulse, the sample surface became obviously rough and irregular (Fig. 2b).

Table 1 Surface parameter of crosslinked gelatin film before and after plasma treatment

Surface parameter	Treated and untreated gelatin		
	GA-DHT	GA-DHT-1	GA-DHT-10
Ra (nm)	0.603	0.628	0.787

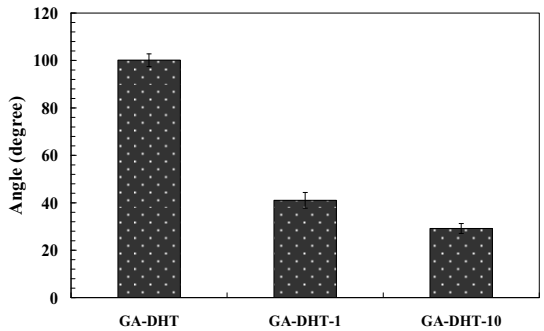

Fig. 1 Water contact angle of untreated and plasma-treated gelatin films

The mean surface roughness was increased to 0.628 nm. When further increasing the nitrogen plasma pulses applied to 10 pulses, the roughness of the gelatin film was remarkably enhanced (Fig. 2c). These results revealed that, enhanced surface roughness of crosslinked gelatin film could be obtained by increasing the number of pulses applied.

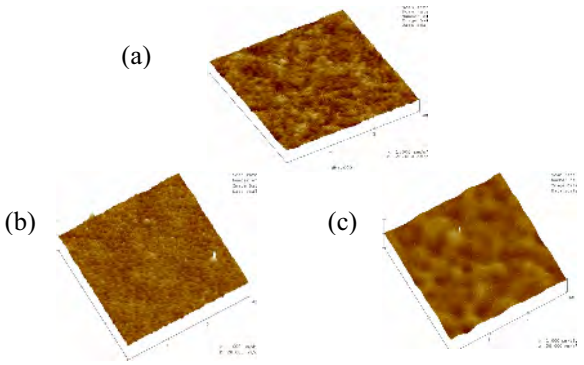

Fig. 2 AFM images of crosslinked gelatin films before and after plasma treatment: (a) untreated; (b) treated with 1 pulse; (c) treated with 10 pulses

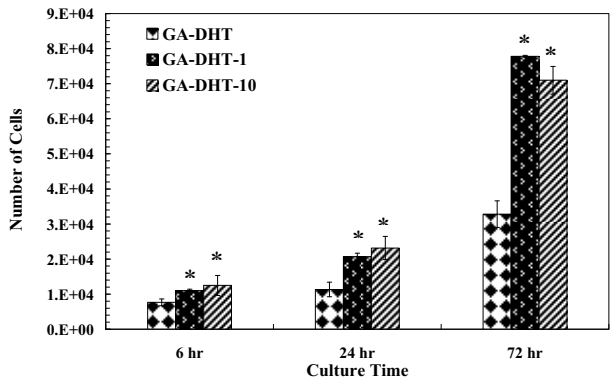

Fig. 3 Number of L929 cells on plasma-treated and untreated crosslinked gelatin film after 6, 24 and 72 hr culture. * represented a significant difference at P<0.05 relative to GA-DHT.

The results on *in vitro* L929 cell attachment and proliferation on plasma-treated and untreated crosslinked gelatin film were shown in Fig. 3. It was notice that the number of adhere cells (after 6 hr of culture) and proliferated cells (after 24 and 72 hr of culture) on PICP-treated gelatins was significantly higher than that on untreated samples. This implied that, increasing in the hydrophilic property and surface roughness of PICP-treated crosslinked gelatin can improve cell adhesion and proliferation.

IV. Conclusions

In this study, PICP was introduced to treat the surface of crosslinked gelatin film. It was found that hydrophilicity and surface roughness of PICP-treated gelatin was promoted in comparison to untreated samples. From *in vitro* L929 cell culture, it was shown that cells could adhere and proliferate on PICP-treated samples greater than that on untreated samples. The results implied that PICP method has potential to modify the surface of crosslinked gelatin for tissue engineering application.

Dosimetry of ^{32}P Radiocolloid for Radiotherapy of Brain Cyst

M. Sadeghi[1,2,*], E. Karimi[2]

[1] Agricultural & Medical & Industrial Research School, P.O. Box 31485/498, Karaj, Iran
[2] Faculty of Engineering, Research and Science Campus, Islamic Azad University, Tehran, Iran

Abstract — **In the radionuclide treatment of some forms of brain tumors such as craniopharyngiomas, the selection of the appropriate radionuclide for therapy is a key element in treatment planning. The aim of present study was to study the influence of ^{32}P in the radionuclide therapy of cranio-pharyngioma cysts by considering to its dose rate to sites of the diseased tissues. Dosimetry calculations were performed by utilizing the MCNP4C radiation transport code. Analytical dosimetry was additionally performed using the Loevinger formula in MATLAB software for ^{32}P. Each result was compared under identical conditions. The needed activity for injection according to the cyst volume was also obtained in the case of ^{32}P. At the range of 200-300 Gy dose, changes of activity was studied too. Increasing desired dose for therapy results in growth of essential activity for treatment.**

Keywords — **MCNP4C, MATLAB, Craniopharyngioma, Loevinger, Dosimetry**

I. Introduction

Intracavitary radionuclide instillation offers an alternative method for delivering to a focal area in a brain relatively larger radiation dose rate in comparison to external radiation therapy.

Craniopharyngioma is a cyst that develops in the area of the brain called the hypothalamus that is close to the pituitary gland. It is usually found in children [1] or young adults and accounts for around 10% of all brain cysts in young people. It can however be diagnosed at any age. Craniopharyngiomas are nearly always benign but can cause symptoms once they press upon neighboring structure of the brain [2]. Consequently they are often quite large when they are detected and may range in size from 2.5 to 10 cm in diameter [3].

Chromic phosphate (^{32}P) suspension is supplied as a sterile, nonpyrogenic aqueous suspension in a 30% dextrose solution with 2% benzyl alcohol added as preservative. According to this fact that ^{32}P is a beta emitter with half-life 14.2 days, it is used in the form of colloid to treatment craniopharyngioma cyst. The maximum energy of beta spectrum ^{32}P is about 1.71 MeV with average energy o.695 MeV.

Various simulations have been done in the case of brachytherapy using PENELOPE code by Sánchez-Reyes et al [4] etc. The cyst and its surrounding medium were simulated by Rojas et al [5] using PENELOPE code. In this work the dosimetry of the cyst for ^{32}P were done based on the Loevinger and Berger formula and the MCNP4C radiation transport code. Calculation and simulation were done by assuming volume spherical distribution of the radiocolloid [5].

II. Material and methods

A. Loevinger analytic formulas

Loevinger's formula is one of the useful formula calculated dose rates in the case of cyst therapy using beta emitter radionuclide. The basic equation was suggested for a beta emitter point source in uniform medium [6], but by calculating for a spherical volume distribution following formula obtains [5]:

Which the normalization constant B is evaluated by forcing all emitted energy to be absorbed in a very large sphere, and

$$D_{\beta}(x) = A\left\{\begin{array}{l}\frac{\pi Bt}{2x}\left(t\left[12x-11t+4(t-R)\exp(\frac{t+R-x}{t})\right]+3R^2+2Rx-5x^2+2(R^2-x^2)\ln(\frac{t}{x-R})\right)\theta(R+t-x)+\\ 2\frac{\pi Bz^2}{x}\exp(\frac{z-R-x}{z})\left[R+z+(R-z)\exp(\frac{2R}{z})\right]\end{array}\right\}\theta(x-R) \quad (1)$$

is given by:

$$B = \frac{1}{4\pi}\rho v^2 \alpha \overline{E}_{\beta}, \quad (2)$$

With

$$\alpha = \left[3c^2-(c^2-1)\exp(1)\right]^{-1} \quad (3)$$

and $\overline{E}_{\beta}$ is the average energy per disintegration.

The formula changes when the dose rate at the inner surface of the wall is desired (means x=R) [5]:

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1220–1223, 2009
www.springerlink.com

$$D_\beta = A\left\{\left(\frac{\pi B t^2}{2R}(4R(3-\exp(\quad))-t(11-4\exp(\quad))\right)+\frac{2\pi B z^2}{x}\times\exp(\frac{z-R-x}{z})\times(R+z+(R-z)\exp(\frac{2R}{z}))\right\} \quad (4)$$

All above equations, the relation between activity and the decay time were used in our analytical calculation for estimating dose rate at any desired distance of the cyst wall. According to volume of the cyst, amount of radiopharmaceutical for injection was calculated too; diameters of the cyst were obtained via MRI images.

The average diameter is approximately 3 cm. The best condition for treatment is achievement 200-300 Gy dose to the interface wall of the cyst [7].

The activity according to desired dose in inner surface of the wall obtains by following formula:

$$A_{inj}=1.355\times10\text{^}(-2)\times D_c\times V_{cyst}\times\rho/(f_1\times f_2\times\bar{E}_\beta\times T_{eff}) \quad (5)$$

A_{inj} is given in μCi and V_{cys} is in cm³. $\bar{E}_\beta$ average energy of radioisotope, T_{eff} effective half-life, ρ density of the cyst (g/cm^3) and D_c is desired dose rate for treatment. Coefficients f_1 defines as the ratio of the dose at radius R from a finite size sphere of radius R to the dose at the center of the cyst [7] and f_2 is equal to 0.455 for cyst with diameter bigger than 1 cm. Activity for 250 Gy dose by using ^{32}P obtain as below:

$$A_{inj} = 75.01\times V_{cyst} \quad (6)$$

(A_{inj} is given in μCi and V_{cys} is in cm³).

By assuming spherical shape for cyst, following formula used for a cyst volume:

The necessary radiocolloid volume was obtained by considering the initially volume and existence activity before injection:

$$V_{inj} = \frac{A_{inj}}{A_o}\times V_o \quad (7)$$

Which V_o is the initially volume of the ^{32}P and A_o is existent activity.

In this work density which used for soft tissue wall was 1.00 g/cm^3 (equal to water) either for inner volume and also the cyst wall.

B. MCNP4C calculation (Monte Carlo N-Particle) [8]

In order to quantify the accuracy of the Loevinger formulas introduced in the preceding section the calculation was done using a full Monte Carlo simulation technique. The cyst was simulated by numerous spherical shells. The $^*F_8$ Tally gives the energy deposition in each point of the cyst in units of MeV. There are four possible source types:

1. Fixed (or general source) source.
2. MCNP generated surface source.
3. Criticality Source.
4. User supplied source.

A particle source has an intensity, energy, direction, shape and temporal characteristics and needs to be positioned somewhere within the phase space of the problem.

The density used in this work is illustrated in Table 1.

Table 1 Composition of different material used in the MCNP4C simulation performed in this paper

	Soft tissue (Rojas, 2003)	Perspex
Density [g/cm^3]	1.0	1.15
H	10.117	8.050
C	11.100	59.98
N	2.600	
O	76.183	31.96

Because of more accurate simulation by MCNP4C code, at the case of soft tissue, density of the inner volume fluid was assumed equal to water. Surrounding medium was simulated by assuming Perspex density.

The condition to compare the result for each radionuclide was created similar: a cyst with radius 1.75 cm and wall thickness 1 mm. The Inner volume of the cyst was layered with a distance of 0.25 mm separating each layer (Fig. 1).

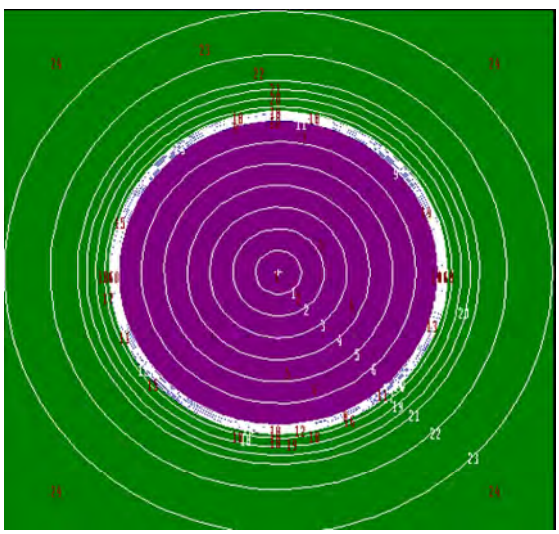

Fig.1 Schematic of the cyst with 1.75 cm radius and 1 mm wall thickness, the distribution of the radiocolloid versus r.

The data were calculated regarding 1 MBq/cm^3 activity concentration of radiocolloid.

^{32}P beta spectrum was inserted according to the intensity of the energy in the range of 0-1.71 MeV.

The spherical deposition of radionuclide can be shown by the following formula:

P=dV/V $P(r) = r \times p$,

$$P(r) = r(\frac{dV}{V}) = r.(\frac{3r^2}{R^3})$$

R: radius of the Cyst

In simulation by MCNP4C code, the spherically distribution of ^{32}P at inner volume of the cyst was indicated by considering above equation (means r^3).

III. Results and Discussion

For a cyst with radius 1.75 cm and wall thickness 1 mm, MCNP4C results and Loevinger's formula calculation consequences were obtained and compared with each other. All the activity concentration of the radiocolloid is 1 MBq/cm^3. Two densities of the wall were used in simulation: soft tissue and compact bone. Inter fluid density considered equal to water for soft tissue wall and same as gel for compact bone wall, the density of surround medium was considered as Perspex density. In analytical calculation based on Loevinger's equation for ^{32}P the mean density was used for compact bone case, and for soft tissue wall was considered as same as simulation.

The parameters which used in computing were:

I. 3 diameter of the cyst in cm
II. Point of interest for Dosimetry in cm
III. Desired dose
IV. Initially volume (the volume which is mentioned on the vial) mL
V. The day passed after production in day
VI. Primary activity (the activity which is mentioned on the vial) in mCi

First estimating dose rate was done based on 250 Gy total dose at inner surface of the cyst wall. In Table 2 MCNP4C results have been mentioned based on 1 MBq/mL concentration activity of ^{32}P.

The results of calculation based on Loevinger's formula at same condition have been compared with MCNP4C data. The results of simulation by MCNP4C code and analytical calculation (MATLAB program) have a good corresponding (Fig. 2). The relative errors were less than 9%.

The contrast between MCNP4C code and MATLAB program results with PENELOPE data for soft tissue [5] according to Table 3 and Figure 3 shows some differences. All the facts were based on 1 MBq/mL concentration ^{32}P. In this work simulation was done based on energy spectrum of ^{32}P.

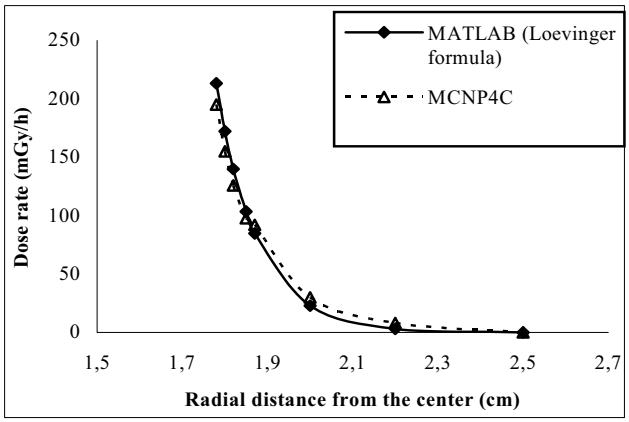

Fig. 2 Comparison between Mon Carlo and MATLAB program data of ^{32}P radionuclide for soft tissue wall

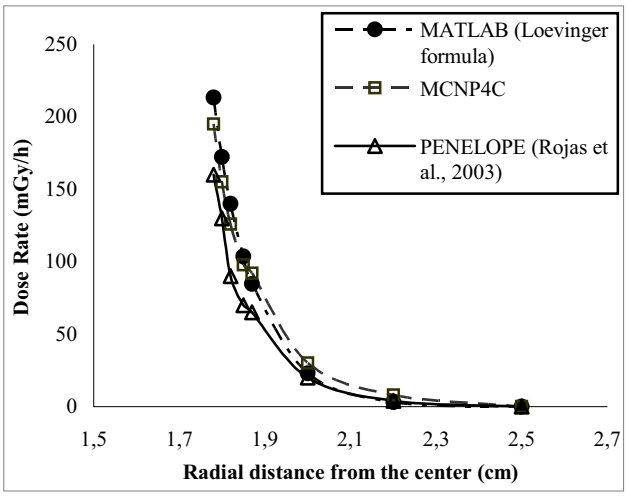

Fig. 3 Comparison between Monte Carlo and MATLAB data with PENELOPE data of ^{32}P radionuclide

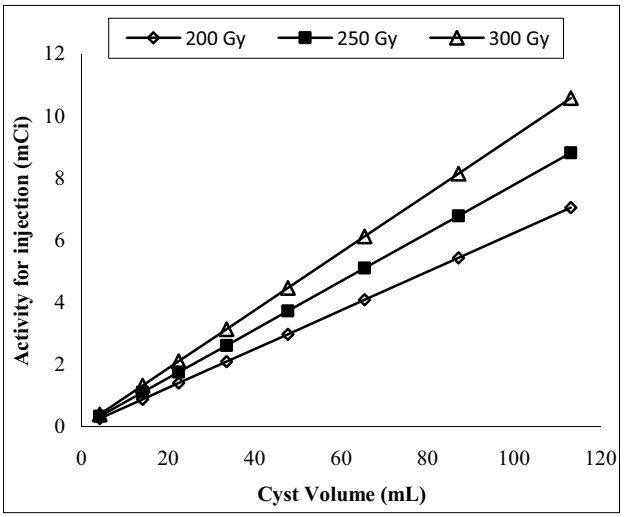

Fig. 4 Differences of needed activity for injection by changing the desired dose for therapy

Three desired doses that have more probable chance in therapy were seen: 200, 250 and 300 Gray and so according to these values, the injection activity for different volume of the cyst was calculated for ^{32}P (Fig. 4). Increasing desired dose causes increasing at necessary injection activity in therapy, also changing in volume of the cyst has direct effect on activity.

IV. Conclusion

In this work, the dosimetry for radiocolloid therapy of cystic craniopharyngiomas was investigated. The ideal assumed in the calculation was a spherical cyst (R=1.75 cm) with 0.1 cm thickness. The cyst and its surrounding medium have been simulated by spherical shells. The results obtained with the analytical expression have been compared with calculations performed with the MCNP4C code for ^{32}P. The calculation shows a nice agreement. In the range of 200-300 Gy for different volume, activity obtained for ^{32}P.

Abstract — **The amphiphilic block copolymers methoxy-poly (ethylene glycol)-poly (ε-caprolactone) (mPEG-PCL) was grafted to 2-hydroxyethyl cellulose (HEC) to produce water-soluble copolymers. Doxorubicin (DOX)-loaded nanoparticles were prepared by dialysis method and the sizes of nanoparticles were determined by dynamic light scattering (DLS) in solution. The size of the nanoparticles was in the range of 197.4 to 340.7 nm. Rhodamine 123 was used to probe the relative P-glycoprotein (P-gp) expression in human breast cancer cell lines MCF-7/WT and MCF-7/ADR. Confocal laser scanning microscopy (CLSM) showed a difference between the fluorescence images of DOX-loaded micelles and free DOX. For a quantitative basis, flow cytometry was done on both cell lines treated with DOX-loaded micelles and free DOX to compare a difference in effect. The amount of DOX-loaded micelles in MCF-7/ADR increased compared to that in the MCF-7/WT cells. This gives insight into how the micellar system developed in this study overcomes the multidrug resistance (MDR) effect.**

Keywords — **methoxy-poly (ethylene glycol), poly (ε-caprolactone), multidrug resistance, P-glycoprotein**

I. Introduction

One of the most common problems encountered in chemotherapy is the lack of specificity in treatment which leads to many unpleasant and detrimental side effects. Furthermore, clinical chemotherapy of breast carcinoma is considered insufficient mainly due to drug resistance. The multidrug resistance (MDR) of breast carcinoma is associated with the expression of P-glycoprotein (P-gp) on the plasma membrane, leading to activation of P-gp efflux which causes a reduction of the intracellular drug concentration [1]. Expression of P-gp confers drug resistance to numerous antitumor agents, including the drug doxorubincin (DOX). High drug accumulation in solid tumors was achieved by prolonged circulation in blood as well as the enhanced permeability and retention effect [2]. To achieve this advantage, drug carriers play a key role. Amphiphilic block copolymeric micelles having nano range of particle size possess the core-shell architecture where the core provides the space for drug loading [3]. We have developed the biodegradable block copolymers as micellar-type carrier. For example, poly (ethylene glycol)-block-poly (ε-carprolactone) (PEG-PCL) in which PEG is hydrophilic segment and PCL is hydrophobic one. This sort of amphiphilic block copolymer can self-assemble in the aqueous solution to form micelles where hydrophobic anti-tumor drug is entrapped. In the present study, we synthesized comb-like copolymer PEG-PCL-graft-cellulose for the application of drug carrier. Then, Rhodamine123 (Rh123) was used to display the efflux pump P-gp in human breast cancer cell lines [4], and the cellular uptake of DOX released from the micelles was performed using flow cytometry. The intracellular distribution of cell-associated DOX was observed under confocal laser scanning microscope.

II. Materials and methods

A. Materials

Monomethoxy-PEG (mPEG, M_W=5000) was purchased from Scientific polymer products. Inc. ε-caprolactone and stannous 2-ethyl hexanoate (SnOct) were purchased from A Johnson Matthey Company. The mPEG was purified by re-crystallization on the dichloromethane/diethyl ether system, and ε-caprolactone was dried using CaH_2 and distilled under reduced pressure. 2-hydroxyethyl cellulose (HEC) was purchased from Aldrich Chem. Co. Inc., USA. DOX in aqueous solution (DOX.HCl, 2 mg/mL) was purchased from the Sigma Chem. Co. Inc., USA.

For cell culture experiments, human breast cancer cell lines, MCF-7/WT (Adriamycin-sensitive cell line) and MCF-7/ADR (Adriamycin-resistant cell line). The medium was composed of DMEM, 10% FBS, 1% antibiotic-antimycotic. Rhodamine123 (Rh123) was purchased from Sigma.

B. Synthesis of mPEG-PCL-g-HEC copolymers

The mPEG-PCL diblock copolymer was synthesized by ring opening polymerization of ε-caprolactone in the presence of mPEG as a macro initiator with SnOct as catalyst at 130°C for 24 h [5, 6]. Carboxylic acid terminated mPEG-PCL (0.35 g) was dissolved in THF and stirred at room temperature for 30 min. Then DCC (0.01 g) and DMAP

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1224–1227, 2009
www.springerlink.com

(0.015 g) were added sequentially. The HEC (4.125 g) was dissolve in DMSO (10 ml) and introduced to the reaction mixture. The resulting mixture was stirred for 12 h at room temperature under nitrogen atmosphere. The THF was removed in a rotary vacuum evaporator. The mixture was dialyzed to remove DMSO then extracted with dichloromethane to eliminate unreacted mPEG-PCL. The product was frozen and lyophilized to give the solid product.

C. Doxorubicin loading in mPEG-PCL-g-HEC

The micelle solution was prepared by direct dissolution of copolymer in aqueous solution, due to good water solubility of mPEG-PCL-*g*-HEC copolymer. Unlike its hydrophobic drug, DOX.HCl is hydrophilic so it was modified with PBS buffer (pH 9.4) prior to dissolution in THF. This was dropped into the aqueous solution of mPEG-PCL-*g*-HEC copolymer in glass vial, which was allowed to stand overnight to remove THF solvent, then was transferred to a dialysis bag and dialyzed against 500 mL of double distilled water using cellulose dialysis membranes (molecular weigh cut off 50,000 Da). The nanosphere solution was centrifuged, then filtered with a syringe filter (pore size 0.45μm) to eliminate unloaded DOX and aggregated particle.

D. Particle size measurements

The mean diameter and size distribution of the micelles were determined by dynamic light scattering (DLS) method. The instrument was operated at fixed angle of 90°, 628 nm and 25°C. Mean and standard deviation of particle sizes were calculated by assuming a lognormal distribution, and the measured intensity autocorrelations function of scattered light was corrected using Stokes-Einstein equation.

E. P-glycolprotein overexpression assay

Both wild-type and adriamycin-resistant MCF-7 cells (cell number = 2×10^5) were incubated in 2ml DMEM media with Rh 123 (0.5μg/ml) for 30mins at 37 °C. Cells were then washed with PBS, and incubated at 37 °C for another 50mins. The cells were washed with cold PBS and harvested with trypsin. Finally Rh123 fluorescence in cell pellets was measured by flow cytometry (FACS200, BD) and fluorescence microscopy.

F. Cellular uptake and distribution of DOX

The cellular uptake experiments were performed using a flow cytometer. The cells were seeded in six-well culture plates (1×10^5 cells per well) and incubated for 24 hours. The cells were then incubated at 37°Cwith free DOX or DOX-loaded polymer micelles (DOX concentration of 10μg/ml). 24 hours later, the DOX uptake by cells was measured in a flow cytometer which detected the fluorescent DOX in the cell [7]. In addition the intracellular distribution of DOX was observed under confocal laser scanning microscope (CLSM) [8]. The cells were seeded in MatTek glass bottom dish and incubated with free DOX and DOX-loaded micelle for 2 hours and 24 hours, respectively. After ward, the cells were washed with cold PBS and then observed under a confocal laser scanning microscope (FluoView FV300, *Olympus*).

III. Results and discussions

A. Particle size of micelles

The hydrodynamic diameters of copolymer micelles were measured with DLS at 25°C. In our experiments, samples were prepared and analyzed in a concentration range of 3.0mg/ml which is above its critical micelle concentration (0.045mg/mL). The DOX-free micelle and DOX-loaded micelles sizes were found to be around 197.4 nm and 231.5 nm, respectively. It was found that the particle size of DOX-loaded micelles was higher than that of DOX-free micelles.

B. P-glycoprotein overexpression of MCF-7/WT and MCF-7/ADR

Since Rh 123 has been considered to be a relatively specific substrate for *mdr 1* gene-encoded efflux pump P-gp, the release of this fluorescent dye from the cells is an indication of the overexpression of the membrane-bound protein. Fig. 1 shows that the adriamycin-resistant cells revealed a significant rhodamine efflux compared with wild-type breast cancer cells. This assay displayed that the cells used in the present study retain its phenotype of P-glycoprotein during the experiment. Fig. 2 shows the histogram of Rh 123 fluorescence for MCF-7/WT and MCF-7/ADR, respectively. The cells without Rh123 treatment were used as a control and showed only the auto-fluorescence of the cells. The MCF-7/WT showed higher fluorescence intensity than MCF-7/ADR. This evidences confirmed the overexpression of P-gp in MCF-7/ADR cells. found in fluorescence microscope image (Fig. 1). There is therefore a need to address the drug resistance found in this cell line.

C. Cellular uptake and distribution of DOX

In order to visualize the cellular uptake of DOX, the distribution of DOX by MCF-7/WT and MCF-7/ADR cells were observed by confocal microscopy. Since DOX emits

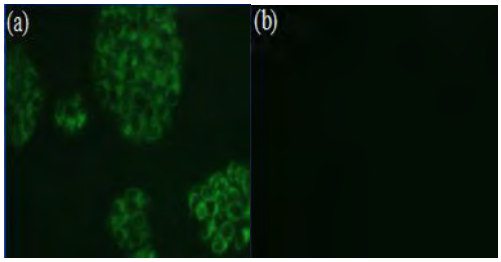

Fig. 1 Fluorescent Rhodamine 123 images of the human breast cancer cell lines. (a) MCF-7/WT (b) MCF-7/ADR

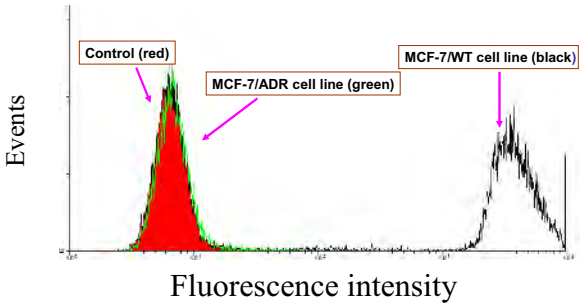

Fig. 2 Flow cytometry histogram profile of Rhodamine 123 efflux for human breast cancer cells.

red fluorescence, its distribution in the cells can be easily observed under CLSM. For free DOX (Fig. 3a and b), the drug was concentrated only in the nuclei but not the cytoplasm [9]. In the case of the micelle formulation, red fluorescence was observed in the cytoplasm, indicating that the large DOX-loaded micelles were internalized by the cells in an endocytotic process. Literature showed that, following cellular uptake, nanoparticles could escape the endo-lysosomal pathway and enter the cytoplasm [10]. After entry into cells, nanoparticles are retained in the cytoplasm for a sustained period of time. When MCF-7/WT cells were exposed to micelles for 24 hours, there was no significant increase in the DOX fluorescence unlike that of cells treated with free DOX. In contrast, with micelle-treated MCF-7/ADR, more intense DOX fluorescence was observed in the cytoplasm after 24 hours. Fig.4 shows the histogram of cell-associated DOX fluorescence for MCF-7ADR and MCF-7/WT cells.

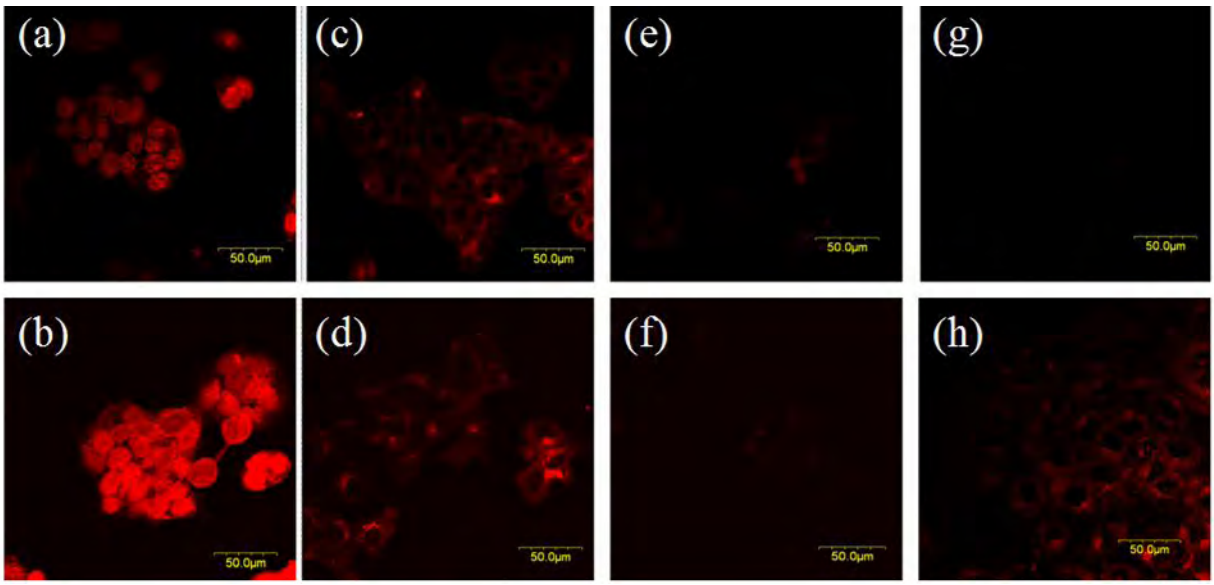

Fig. 3 Confocal images of human breast cancer cell lines treated with different DOX formulations at 10μg/ml concentration. MCF-7/WT cells treated with free DOX for 2h (a) and 24h (b), and with DOX-loaded micelles for 2h (c) and 24h (d). MCF-7/ADR cells treated with free DOX for 2h (e) and 24h (f), and with DOX-loaded micelles for 2h (g) and 24h (h).

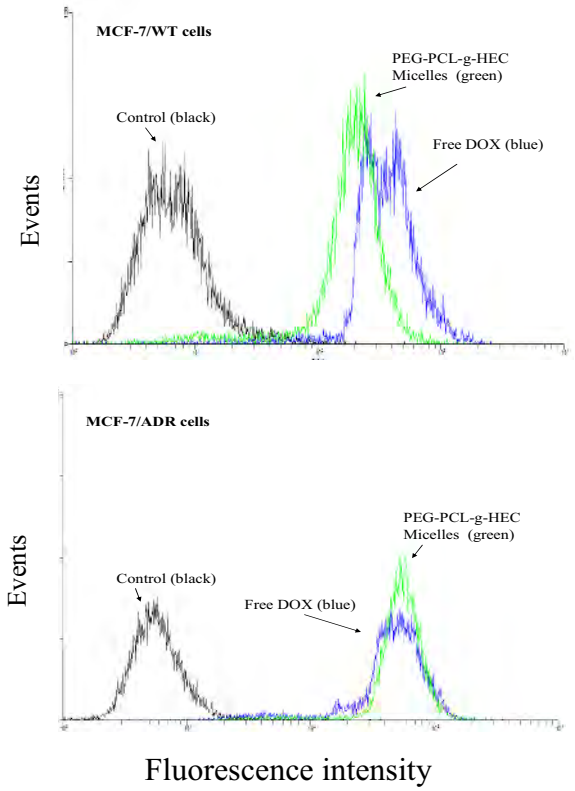

Fig. 4 Flow cytometry histogram profiles of human breast cancer cell lines treated with different DOX formulations at 10μg/ml concentration

For MCF-7/WT cells, the free DOX shows higher fluorescence intensity than DOX-loaded micelles. This indicates that free DOX penetrates the drug-sensitive cell line more efficiently than the DOX-loaded micelles. As for the MCF-7/ADR cells, the cell uptake of DOX-loaded micelles is slightly higher than the free DOX. This result confirms that the cellular uptake of micelles can be enhanced for MDR cells. Hence, the present study suggests that mPEG-PCL-*g*-HEC copolymers may enhance the therapeutic efficacy of DOX in MDR tumor cells.

IV. Conclusions

In this study, the amphiphilic block copolymers methoxy-poly (ethylene glycol)-poly (ε- caprolactone) was grafted to 2-hydroxyethyl cellulose to produce the water-soluble copolymers. The size of the nanoparticles formed by the copolymer was in the range of 197.4 to 340.7 nm. DOX-loaded micelles can accumulate mostly in the cytoplasm while free DOX can diffuse into the nuclei for both MCF-7/WT and MCF-7/ADR. The confocal images further revealed that DOX-loaded micelles entered MCF-7 cells through endocytosis process. The fluorescence intensity of DOX-loaded micelles in MCF-7/ADR cells is higher than that of free DOX. The micellar system of mPEG-PCL-*g*-cellulose was found to be effective to overcome MDR of breast cancer cells. Thus, we expect to carry out in-vivo study in the near future in order to confirm the efficacy of this system to treat breast cancer patients.

Individual 3D Replacements of Skeletal Defects

R. Jirman[1], Z. Horak[2], J. Mazanek[1] and J. Reznicek[2]

[1] Charles University in Prague, 1st Faculty of Medicine/Department of Stomatology, Prague, Czech Republic
[2] Czech Technical University in Prague, Faculty of Mechanical Engineering/Laboratory of Biomechanics, Prague, Czech Republic

Abstract — **In this work several clinical cases of production of individual bone defect replacements will be presented. Special replacements were produced on the basis of 3D geometric models designed from available diagnostic imaging methods (CT and MRI), and their following computer processing. For production of implants by conventional CNC machining were used in clinical practice commonly used biomaterials (titanium, PEEK, UHWMPE), which can be easily machined. The implants were produced for a particular patient individually with millimetre accuracy so that not only fully functional, but also aesthetic defect replacements were achieved**

Keywords — **skeletal defect, individual replacement, defect reconstruction**

I. Introduction

The objective of a skeletal defects reconstruction using individual implants is achievement of comparable function and perfectly natural physiognomy for the patient. There is effort to replace the lost anatomic structures, to renew the disturbed function, and in case of aesthetic surgery, to improve the physiognomy of the patient. At present, the worldwide prosthesis production follows the trend to individualize the prosthesis for a particular patient instead of unified sizes and shapes. Such approach can be applied in various disciplines: neurosurgery, dental surgery, orthopaedics, but also aesthetic surgery [2, 5]. To achieve high-quality osseointegration, it is necessary to ensure optimum conditions for integration of the implant. The success of the reconstruction of the defect using individual implants depends on thorough examination of the patient supplemented with professional diagnostic imaging, proper indication and choice of treatment, and perfect surgery together with prosthetic treatment. Very close cooperation between the surgeon, technician, producer and also the patient is essential not only during the treatment, but also during the patient's convalescence and rehabilitation.

The aim of the project was to devise a fast, accurate and effective method for designing and production of skeletal implants using appropriate commonly used biomaterials, which can be used to replace the defect, and in conclusion, to conduct several clinical studies demonstrating construction of these individual implants together with postoperative RTG verification.

II. Methods and materials

The method of designing and fabrication of individual implants is in data processing and transfer from available diagnostic imaging methods (CT and MRI), and their following transformation to 3-D geometric models. From 3-D models fabricated in this way, it is possible to make a shape reconstruction of the defect with satisfactory accuracy, and subsequently design an individual implant. The model of the defect for planning of the surgery can be made using the rapid prototyping technology (RPT), and the implant itself using the available conventional CNC machining methods (CAD/CEM). For fabrication of individual implants are, with regards to the health and technological possibilities, available metal (titan Ti6Al4V, chirurgic steel) and plastic (PEEK, UHWMPE) materials. The choice of used material must respect the size of the defect, possible force loading and the implantation method.

The geometries of individual prostheses were designed on the basis of the defect models obtained from the CT image files of the individual patients. The models of bone defects were built in the Laboratory of human biomechanics, CTU in Prague, using segmentation of image data executed in the programme Mimics (Materialise). CT images were made on the Siemens Emotion 16 device with resolution 512x512, the size of pixel was 0.682 mm and the distance of individual sections was 1 mm. The following shape adjustments of the individual prostheses were made using the modelling programme Rhinoceros®, and subsequently verified together with the surgeon on a plastic model of the defect on skeletal part created using the Rapid Prototyping technology. The final geometric models of individual augmentations were exported to an STL file, on the basis of which the prosthesis was finally fabricated.

The individual prostheses were fabricated by the DUO CZ engineering company together with companies MEDIN Orthopaedics and ELLA-CS, from plastic materials Chirulen 1020 (UHWMPE polyethylen, MediTech) and PEEK Optima (polyetheretherketone, Invibio), and also from titanium alloy Ti6Al4V ELI, which is commonly used for joint implant prosthesis. The ultimate input for the fabrication was the data file of the individual prosthesis 3-D model. Using the CAD (Computer Aided Design) volume designer, the size and position of the semi-finished product were

determined together with fixing aids enabling effective fixation of the material. The machining programme for the CNC (Computer Numerical Control) device was created in the programme CAM (Computer Aided Manufacturing) generating the NC code using the post-processor, which was then adjusted to the particular machining tool. The final prostheses were fabricated by traditional CNC machining (see. Fig. 1a, 2c, 3b). In the following part, some clinical cases will be presented.

Case 1: Tibia defect

The patient is a 65-year-old man with psoriatric arthritis cured for more than 20 years. He was sent by a regional rheumatologist to an orthopaedic consultation with filling of his right knee, serious dysbalance, especially in the frontal plane, and deepening varus deformity. In the X-ray image, there was evident large destruction of the medial condyle of tibia, which extended over the central line far into the lateral condyle. The depth of the defect from the level of the joint was more than 34 mm. Also symmetric usuration of the distal part of both condyles of the femur. The CT examination with 3-D reconstruction showed the actual size of the defects. While it was possible to cure the defects on femur with standard augmentations, the depth and shape of the defect on tibia made using commonly supplied tibial augmentations impossible. It was possible to solve the situation with a custom-made implant, or a custom-made tibial augmentation adapted on a commonly supplied tibial component. After considering all the conditions, the second option was chosen.

Case 2: Defect of os frontale and os temporale

In 2007, a 33-year-old woman in the 37 week of pregnancy arrived at the Neurosurgery clinic of the 1st Medical Faculty of the Charles University and Central Military Hospital in Prague to be examined for deterioration of mental

a) b) c)

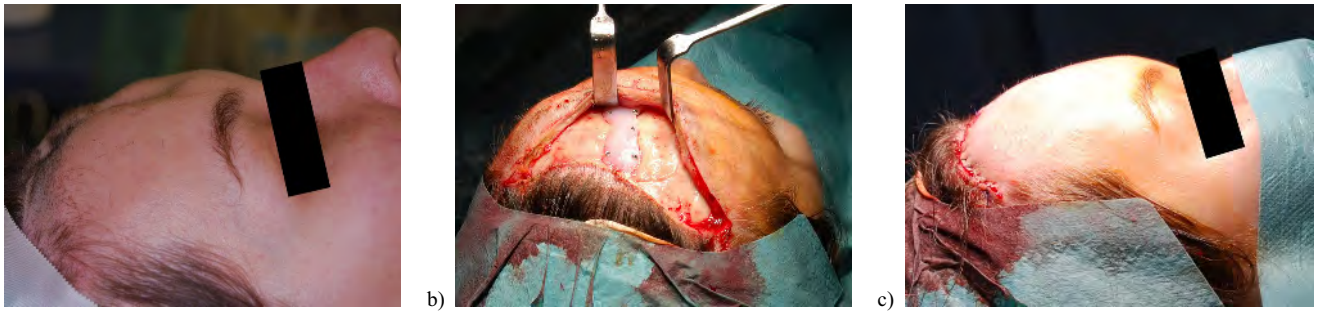

Fig. 3: a) patient with forehead defect, b) fixed implant in the place of the defect, c) patient after the surgery

functions, and symptoms of intracranial hypertension (headaches, vomiting). The imaging method detected a large meningiom on the anterior fossa skull base, size of 76x58x57 mm, with large collateral brain edema. As removing the intracranial tumour is in similar situation usually fatal, due to the vital indication the posterior decompression was performed: the frontal and temporal bones were removed and the dura mater was wide open. After this procedure, the reaction of pupils was immediately adjusted, subsequently after the anti-edema treatment in artificial ventilation the CT finding improved (the brain stem was unblocked), and consciousness was coming back. Only on day 6 after the decompression, it was possible to proceed to the radical resection of the tumour. The anti-edema ventilation regime was still in effect. Two weeks after, a cranial plastic surgery was performed using bone cement, i.e. the large bone defect was modelled from acrylic resin. During healing, there was an inflammatory infiltration of the augmentate, therefore the cement implant was removed, which was the only effective method of solving the situation. Then the inflammation healed. The new implant was fabricated from a block of super-molecular polyethylene Chirulen 1020, and grafted on to the skull using self-tapping titanium screws.

Case 3: Os frontale defect

In 1998, the patient suffered a serious polytrauma as a front-seat passenger, together with fronto-basal injury with defect fracture of the frontal bone in the size of 7x3x2 cm. The patient was repeatedly cured by conventional augmentation procedures using a solid bioceramics replacement covered by resorbable membrane, or using bioactive bone granules separated from the soft tissue by a resorbable membrane Bioguide. Due to the unsatisfactory form and character of the prosthesis, the implant was rejected, which was followed by seamed surrounding tissue. The new individual implant was fabricated from a block of super-molecular polyethylene Chirulen 1020.

III. Discusion and conclusions

Large implants using bone homografts causes problems connected with their integration and resistance to infection; commonly supplied augmentations often do not have satisfactory size or shape. Heavy implants made from bone cement are mechanically and biologically unsatisfactory, and they fail very soon. The way out of these situations are custom-made implants or their components [5]. Replacing large bone defects on tibia is a very difficult task for far-gone knee destructions, and especially during revision surgeries [7].

The main advantage of an individual augmentation, in comparison with commonly supplied modular components, is its optimum shape and the maximum size of the contact surface between the implant and the bone. An individual implant follows exactly the shape of the surface created at the place of the defect, and thus enables even distribution and transfer of loading. The optimum distribution of the loading affects conveniently the structure of the bone tissue, which is loaded evenly on the whole surface, and so there is only minimum reconstruction in the place where the replacement is implanted. The risk of local concentration of loading, which would result in degradation of the bone tissue [6], is reduced considerably. Another indisputable advantage of this approach is minimizing of the bone tissue resection, which is necessary when implanting the standard modular augmentations. The individual augmentation also enables to get over the defects, which might not be possible to treat well using the common augmentations due to their shape or size. The layer of the used bone cement is minimized, and in the future we can predict applying of microporous spray on its contact surface, enabling direct osteointegration.

In case of plastic implants, it is possible to take advantage of their low weight, especially of the skull replacements, but at the same time high degree of their safety in case of a damage (injury, splitting fracture), where the created individual fragments of the ground implant do not form

sharp edges, which might cause deeper injury of the soft tissue (CNS). The chemical structure of these plastic materials enables the surgeon to make fine adjustments (holes, refining the edges) directly in the operating theatre using commonly available millers and drills.

The disadvantage of using the individual augmentation is its higher demand for fabrication, resulting in the higher price. The higher demands for the implant fabrication are especially in the necessity to design a 3-D model of the individual implant and the defect in order to plan the surgery and to check the final set up [3, 8]. The second point is the expenses for preparation of the necessary software, machining time, and the tools for machining the hard material on a special machine tool. Another disadvantage is the necessity of thorough pre-operation planning and a certain latency period between the order for fabrication and the surgery. Standardizing the procedures for taking the measuring data, preparing the software, and the fabrication itself, will allow reducing the period only to several days.

Using of the individually produced augmentation is one of the possibilities how to cure larger bone defects. In case of implants produced in this way, the distribution of the loading on the surface of the neighbouring bone improves. The suitable material for fabrication of these implants is currently commonly used titanium and high molecular polyethylene, but prospectively also PEEK, which is easier to machine, and its mechanical features are closer to the bone tissue. The disadvantage of using individual augmentations is more difficult fabrication, higher price, and high demands for preparation and planning of the surgery.

Brain Gate as an Assistive and Solution Providing Technology for Disabled People

Prof. Shailaja Arjun Patil

Electronics & Telecommunication department, RCPIT, Shirpur Dist: Dhule, Maharashtra, INDIA

Abstract — **A range of applications and products with a combination of nanotechnology, biotechnology, and information technology are under development to directly improve the lives of people with severe injuries or medical conditions. Solutions range from better implants and prosthetics to brain-machine interfaces and they already are in the early stages of development and have working prototypes.**

Nanomedical and bionic products that could directly improve sensory, motoric and other functions cover all aspects of the human body. These visions go far beyond the current implant technologies (bionic ears and limbs, neural and retinal implants, artificial muscles etc) under development.

The best solution we could find for the disabled and elderly people is the use of brain gate. The technology gives the disabled people the opportunity to live a quasi-normal life inspite of being not able to move their body parts. Infact this technology is a boon for physically disabled and elderly people. So, here is a brief introduction of BRAIN GATE.

Keywords — **Basic Principle behind Brain Gate, Need for Brain Gate, Experiment on Human Being, Brain machine interface, Brain gate human neural interface system**

I. Introduction

People who are paralyzed have been given new hope by stem cell research, championed by the late Christopher Reeve P'02. But researchers in neuroscience are looking at other, less controversial ways of restoring independence to people with disabilities.

The Brain Gate System is based on Cyberkinetics' platform technology to sense, transmit, analyze and apply the language of neurons. The System consists of a sensor that is implanted on the motor cortex of the brain and a device that analyzes brain signals.

A. Basic Principle Behind Brain Gate:

The principle of operation behind the Brain Gate System is that with intact brain function, brain signals are generated even though they are not sent to the arms, hands and legs. The signals are interpreted and translated into cursor movements, offering the user an alternate "BrainGate pathway" to control a computer with thought, just as individuals who have the ability to move their hands use a mouse.

B. Need For Brain Gate:

The device was designed to help those who have lost control of their limbs, or other bodily functions, such as patients with amyotrophic lateral sclerosis (ALS) or spinal cord injury. ALS is a degenerative disease in which people eventually lose the ability to perform the most basic movement tasks, including twitching a cheek muscle or blinking an eye. The System consists of a sensor that is implanted on the motor cortex of the brain and a device that analyzes brain signals. So one can easily move a cursor on the computer screen also one can use the robotics arm or any other devices in the case of failure of the limbs.

A team of neuroscientists have successfully implanted a chip into the brain of a quadriplegic man, allowing him to control a computer.

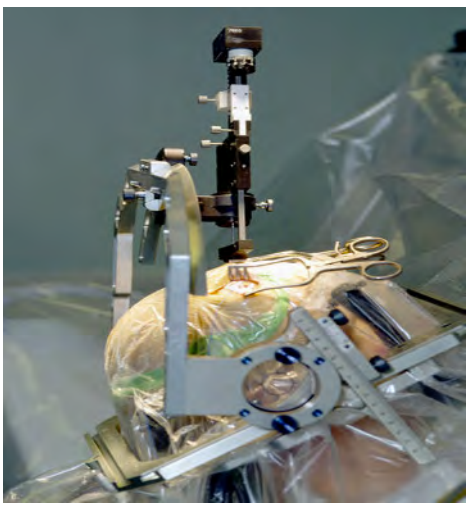

Fig 1. Implantation of brain chip

The chip, called Brain Gate, is being developed by Massachusetts-based Neurotechnology Company Cyberkinetics, following research undertaken at Brown University; Rhode Island.Results of the pilot clinical study will be presented to the Society for Neuroscience annual conference in San Diego, California, on Sunday. Up to five more patients are to be recruited for further research into the safety and potential utility of the device.

C. Experiment On Human Being

SAN FRANCISCO -- Any geek worthy of the moniker has dreamed of connecting his or her brain directly to a computer for blissful freedom from keyboard and mouse. For quadriplegics, that ability would give life a whole new dimension. If people with physical handicaps could control a computer by just thinking, they could also operate light switches, television, even a robotic arm -- something the 160,000 people in the United States who can't move their arms and legs would surely welcome.

Work in that brain-computer interface, or BCI, technology has ramped up considerably in the past five years. More than half of the scientific papers on the topic were published in just the past two years. Also, by connecting their patients' brains directly to a computer, researchers have seen improvement in patients' ability to control a cursor.Cyberkinetics is leading research on BCIs in the private sector. Last year the company enrolled its first patient, Matthew Nagle, in a clinical trial to test its Brain Gate system. From his wheelchair, Nagle can now open e-mail, change TV channels, turn on lights, play video games like Tetris and even move a robotic hand, just by thinking.

The device, which is implanted underneath the skull in the motor cortex, consists of a computer chip that is essentially a 2-mm-by-2-mm array that consists of 100 electrodes. Surgeons attached the electrode array like Velcro to neurons in Nagle's motor cortex, which is located

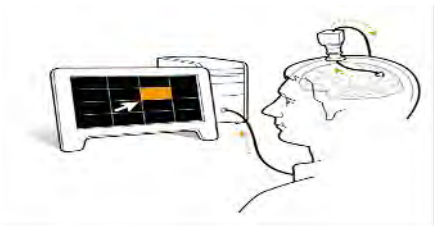

Fig 2.

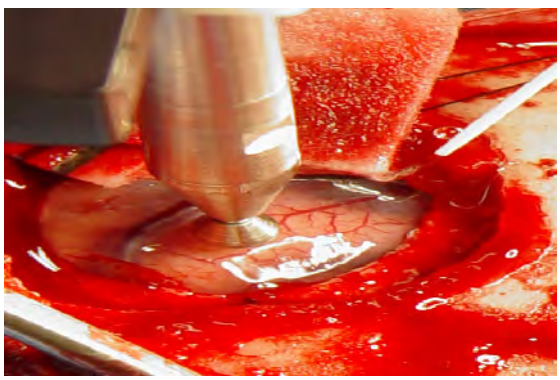

Fig 3. Insertion

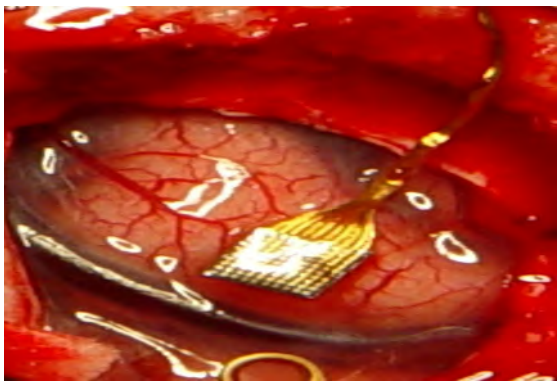

Fig 4. Computer Chip

in the brain just above the right ear. The array is attached by a wire to a plug that protrudes from the top of Nagle's head.

The electrodes transmit information from 50 to 150 neurons through a fiber-optic cable to a device about the size of a VHS tape that digitizes the signals. Another cable runs from the digitizer to a computer that translates the signal.

The Matrix-like device protruding from Nagle's head seems little price to pay for the new abilities he's gained thanks to Brain Gate.

But other researchers are working on simpler, noninvasive BCIs. Jonathan Wolpaw, a professor at the Wadsworth Center in New York, published a paper in December 2004 in the Proceedings of the National Academy of Sciences showing that his noninvasive electroencephalogram, or EEG, cap could pick up brain signals at least as well as Cyberkinetics' invasive technology.

Both patients and their doctors would prefer not to open the skull to implant a BCI, but it's not yet clear whether a BCI sitting outside the head will be as good at picking up brain waves as an implanted device. Experts generally thought the answer was no until Wolpaw published his results.

II. Brain machine interface

Modifying the human body or enhancing our cognitive abilities using technology has been a long-time dream for many people. Nano-bio-info-cogno-synbio (NBICS) is now reaching a critical stage where it could lead to the fulfillment of that dream.

An increasing amount of research tries to link the human brain with machines allowing humans to control their environment through their thoughts. It is said: "Ultimately the technology will be used for people whose spinal cords

Fig 5.

are destroyed in accidents or those handicapped by strokes." Scientists demonstrated in 2002 that human thoughts can be converted into radio waves and used by paralyzed people to create movement. "Scientists in Australia have developed a mind switch that enables people to activate electrical devices (e.g. turn on a radio or open doors) by thinking."

The IDIAP Research Institute (formerly the Institute Dalle Molle d'Intelligence Artificially Perceptive/Dalle Molle Institute for Perceptual Artificial Intelligence) is developing non-invasive brain machine interfaces.

The Institute states in a recent publication: "Brain activity recorded non-invasively is sufficient to control a mobile robot if advanced robotics is used in combination with asynchronous EEG analysis and machine learning techniques. Until now brain-actuated control has mainly relied on implanted electrodes, since EEG-based systems have been considered too slow for controlling rapid and complex sequences of movements. We show that two human subjects successfully moved a robot between several rooms by mental control only, using an EEG-based brain-machine interface that recognized three mental states. Mental control was comparable to manual control on the same task with a performance ratio of 0.74."Many researchers are working on brain machine interfaces.

Cyberkinetics Neurotechnology Systems, Inc. of Fox borough, Massachusetts, received FDA approval to test the "Brain Gate." The company started with people with spinal cord injuries and is now recruiting patients for BrainGate ALS trials, according to deal.com.

Researchers at Duke University Medical Center in Durham, North Carolina, are developing a wireless neuroprosthetic that could potentially be used to control robotic limbs for quadriplegics. Dr. Miguel Nicolelis of the university's Department of Neurobiology has a variety of articles on his webpage. A 14 year-old boy plays space invaders using thoughts alone, as a grid connected to his brain measures his electrocortigraphic activity.

The device was developed by Dr. Eric C. Leuthardt, an assistant professor of neurological surgery at the School of Medicine, and Dr. Daniel Moran, assistant professor of biomedical engineering at Washington University in St. Louis. They connected the patient to a sophisticated computer running a special program known as BCI2000 developed by collaborator Gerwin Schalk at the Wadsworth Center, New York State Department of Health in Albany, which displays a video game linked to an electrocorticographic (ECoG) grid. The primary purpose of the grid was to facilitate treatment for epilepsy.

In Austria, the Graz University of Technology has a brain-computer interface lab. In Japan, Hitachi has joined forces with university researchers. In Finland the Proactive Computing Research Programme (PROACT) is funded by the Academy of Finland and led by Academy Professor Mikko Sams. IST has funded the Presencia project under its Fifth Framework Programme - Future Emerging Technologies Presence Research.

III. BRAINGATE HUMAN NEURAL INTERFACE SYSTEM

Cambridge Consultants' Virtual Helmet can link brain wave patterns to a virtual reality system, allowing the wearer to enter an illusory world of movement. Researchers at Nippon Telegraph & Telephone Corporation in Japan have developed galvanic vestibular stimulation -- a technology that can compel a person to walk along a route in the shape of a giant pretzel, in effect creating remote-controlled humans.

Researchers at Columbia University have combined the processing power of the brain with computer vision to develop a novel device that allows people to search through images ten times faster than they can on their own. The cortically coupled computer vision system -- known as C3 Vision -- turns the brain into an automatic image-identifying machine. The project is funded by the US Defense Advanced Research Projects Agency. The Air Force has long been interested in "alternative control technology" that will allow its pilots to fly planes hands-free.

A ***robotic hand*** controlled by the power of thought alone has been demonstrated by researchers in Japan. It mimics the movements of a person's real hand, based on real-time functional magnetic resonance imaging of brain activity. This is seen as another landmark in the advance towards prosthetics and computers that can be operated by thought alone. The system was developed by Yukiyasu Kamitani and colleagues from ATR

Computational Neuroscience Laboratories in Kyoto, and researchers from the Honda Research Institute in Saitama. Subjects lying inside an MRI scanner were asked to make "rock, paper, scissor" shapes with their right hand. The scanner recorded brain activity and fed data to a connected computer. After a short training period, the computer was able to recognize the brain activity associated with each shape and command the robotic appendage do the same.

A brain-activity interpretation contest organized by the University of Pittsburgh provided entrants with functional MRI scanner data and behavioral reports recorded when four people watched two movies. Competitors were asked to create an algorithm that used the brain activity to predict what viewers were thinking and feeling as the film unfolded.

The crunch test came from a third film. Competing researchers were shown the brain activity only, and had to predict the behavioral data -- what the viewers had reported seeing and feeling during the film on a moment-by-moment basis. The rules are here and the results are here.

Although brain–machine interfaces are often talked about in relation to disabled people, we can expect they will also be used by the non-disabled as a means to control their environment -- especially if the devices are non-invasive and no implants are needed.

To date there has not been much public discussion of the implications of brain machine interfaces, the amount of public R&D funding they receive, and control, distribution and access to these devices.Paralyzed patients dream of the day when they can once again move their limbs. That dream is making its way to becoming a reality, thanks to a neural implant created by John Donoghue and colleagues at Brown University and Cyberkinetics Neurotechnology Systems.

In 2004, Matthew Nagle, who is paralyzed due to a spinal-cord injury, became the first person to test the device, which translated his brain activity into action (see "Implanting Hope," March 2005, and "Brain Chips Give Paralyzed Patients New Powers"). Nagle's experience with the prosthetic was exciting but very preliminary: he could move a cursor on a computer screen and make rough movements with a robotic arm. Now Donoghue and team are pushing ahead with their quest to develop a commercially available product by testing the device in two new patients, one with a neurodegenerative disease and the other suffering the effects of a stroke.

With spinal-cord injuries and some types of stroke and neurodegenerative disease, the information-relay system between the brain and muscles is disrupted. The Cyberkinetics device consists of a tiny chip containing 100 electrodes that record signals from hundreds of neurons in the motor cortex. A computer algorithm then translates this complex pattern of activity into a signal used to control a computer cursor, robotic arm, and, maybe eventually, the patient's own limb.

The researchers have now tested the device in two new patients, one with ALS, a progressive neurodegenerative disease, and the other with brain-stem stroke, a particularly devastating type of stroke that paralyzes the body but leaves the mind intact.

IV. Conclusion

So, this was a brief introduction to brain gate and various applications of brain gate. These are some of the opportunities we can provide to disabled peopled using the brain gate. Though these technologies are in the preliminary stage of their development they are some of the most widely used assistive technologies of the future. With more demand it will become some of the most affordable and house hold assistive technology.

Abstract — **The object of this paper is to investigate the compressive and thermal-compressive fatigue behaviour of four hybrid resin base dental composites. Cylindrical specimens (6mm in length ×3 mm in diameter) were made considering manufacturers' recommendation and stored for 48 hours in distilled water at 37°C. The compressive fracture strength was measured and fatigue tests under frequency of 10 Hz were carried out. For thermal-compressive fatigue test a cyclic flowing cold and hot-water set designed. The compressive strength of the four materials KURARY® Clearfill AP-X (AP-X), 3M ESPE® Supreme, SAREMCO® Extra Low Shrinkage (ELS) and Tetric® Ceram were obtained. Supreme showed the highest compressive fracture strength and thermal compressive strength while ELS was the lowest. The compressive fatigue strengths obtained using staircase method for 100,000 cycles under sinusoidal loading and based on compressive fracture strength, the acquired data were analyzed using ANOVA and Weibull statistics. The results indicate that the Supreme and ELS composites hold the highest and lowest fatigue strengths, respectively. This seems to be caused by the superior matrix properties associated with the different type of fillers alongside the highest ratio of Vol%/ Wt%.**

Keywords — **Dental composites, Thermal compressive fatigue, Compressive fatigue, Fracture Mechanism**

I. Introduction

Light-cured hybrid composites resins are an important group of restorative materials in dentistry and can be used to restore shape and function of anterior and posterior teeth.Since the very first dental resin composites were developed, many efforts to improve their clinical performance have been undertaken. Research on the resin matrix is mainly based on the development of new monomers while studies on the filler content focus on loading, particle size, silanation [1] and on the development of new particles. Such studies are of high importance because the mechanical properties of dental composites depend highly on the concentration and particle size of the filler. The compressive strength and compressive fatigue limit increase with the amount of inorganic fraction while the polymerization shrinkage is said to decrease [1]. Dental composite restorative materials consist of an organic matrix, ceramic fillers, and the interface' between the inorganic fillers and the matrix. Fatigue fractures of resins after years of clinical use were found to be a common failure reason. Braem *et al.* [2] (1994) reported that fatigue is a major factor in determining the life expectancy of resin composite restorations.

Lohbauer *et al*. [3] (2003), evaluating the mechanical properties of contemporary conventional and packable composites under flexural strength and flexural fatigue limits concluded that the fatigue behaviour of the materials does not correlate with initial strength values.

Since the properties of the composites for the restoration of posterior teeth are controversial while clinical and fatigue studies are scarce and also in the oral cavity, prosthetic reconstructions are usually under conditions of thermal variation and loading conditions. Such thermal cycling and cyclic loading may cause fatigue fractures during long-term clinical use, the objective of the present study was to characterize the inorganic fraction and to measure and compare the mechanical properties, compressive strength, compressive fatigue strength and thermal compressive fatigue strength, of four commercially available hybrid composites.

II. Materials and methods

A. Material selection and specimen fabrication

The substances and materials used in this study are presented in Table 1.

Cylindrical specimens, 3 mm in diameter and 6 mm long, were according to the manufacturers' recommendations. The specimens were then stored in distilled water at 35 ± 2°C for 2 days. The quantity of specimens for compressive and fatigue tests were 5 and 15 respectively.

B. Experimental process

The compressive strength tests were carried out under the compressing rate of 0.5 mm/min according to ASTM-D695.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1236–1240, 2009
www.springerlink.com

Table 1: Characteristics of used materials

No	Type	Resin	Filler fraction Vol%/Wt%	Filler type
1*	Micro-hybrid	BIS-GMA UDMA BIS-EMA	59.5/78.5	Zirconia-Silica
2*	Micro-hybrid	BIS-GMA TEGDMA	71/85.5	Barium glass Colloidal silica
3*	Fine particle-hybrid	BIS-GMA UDMA TEGDMA	60.5/78	Barium glass Ytterbium triflorid Ba-Al fluorosilicate
4*	Micro-hybrid	BIS-GMA BIS-EMA	73/82	Barium glass

* 1: Supreme, 2: Clerfil AP-X, 3: Tetric® Ceram, 4: ELS

For the fatigue tests, the mechanical test machine was programmed to operate in force mode, producing 100,000 at a frequency of 10 Hz. During the thermal compressive fatigue testing, the specimens were immersed in cyclic flowing cold (5^0 C) and hot (55^0 C) water with period of 8seconds. The compressive fatigue limit was determined using the "Staircase" method described by Draughn [4] (1979). The initial stress was 60% of the static compression strength mean, calculated for each material.

The specimens were loaded to 100,000 cycles or until specimen fracture. When the specimen resisted to 100,000 cycles, it was tested with a fixed tension increase of 8 MPa of the initial stress. If the specimen failed before reaching 100,000 cycles, it was tested with a load reduction of 8 MPa of the initial stress. Thus, the further values varied (higher or lower), depending on the event of failure or non-failure.

C. Statistical analysis

Mean compressive fatigue strength (CFS) is given by Equation (1) as follows:

$$CFS = x_0 + d\left(\frac{\sum in_i}{n_i} \pm 0.5\right) \quad (1)$$

Where x_0 is the lowest load level considered in the analysis and d is the fixed stress increment. To calculate CFS, data analysis was carried out based on the least frequent event (failures *versus* non-failures). The lowest stress level considered was designated as i=0, the next stage as i=1, and so on until n_i, which was the number of failures or non-failures at a given stress level. According to the assumption of the weakest link, the fracture load of brittle materials would be limited by the longest crack size in the loaded volume. Hence, a distribution of crack lengths resulted in a strength distribution, which was commonly described by Weibull distribution as follows:

$$P_f = 1 - \exp\left[1 - \left(\frac{\sigma_c}{\sigma_0}\right)^m\right] \quad (2)$$

Where σ_0 is the load level at which 63.2% of the specimens failed and m is the Weibull modulus determined by a maximum likelihood approach. P_f is the probability of failure, varying from 0 to 1.

III. Results

A. Compressive fatigue strength

Table 2 presents and figure 1 illustrates the results of mechanical tests.

Table 2: Results of the tests

No	*Compressive Fracture strength (MPa)*	*m*	*CFS (MPa)*

1: Supreme, 2: Clerfil AP-X, 3: Tetric® Ceram and 4: ELS

It could be seen that the fracture strength of Supreme was higher than the others, with Clearfil AP-X and Tetric® Ceram composites ranking as second and third respectively. As for the fracture strengths of ELS, it was lower than the other dental composites. Table 2 also presents the results of the compressive fatigue test obtained *via* staircase method based on Equation (1). The compressive fatigue strength (CFS) of the studied composites (for 100,000 cycles) followed an identical pattern as the fracture strength. Fairly uniform microstructures were revealed during microstructure analysis, hence indicating a proper curing procedure.

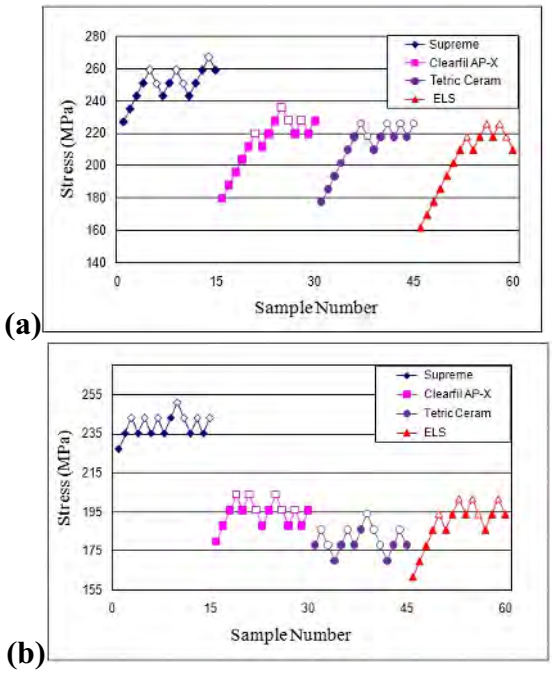

Fig. 1 Comparison of a) fatigue strength, b) thermal fatigue strength, obtained by Staircase method for 15 samples of each composite studied. The non-filled marks are illustrating failed specimens, and filled marks are illustrating non-failed specimens.

B. Thermal compressive fatigue

Table 2 and figure 1 present the results of mean thermal compressive fracture strength, at a fracture probability P_f 63.2%.

The parameter, Decrease of CFS (D.CFS), is the percent of decline of compressive fatigue strength under thermal cycling and is calculated by Equation (3).

$$\text{D.CFS} = \frac{\text{CFS - Thermal CFS}}{\text{CFS}} \times 100 \qquad (3)$$

IV. Discussion

A. Compressive fatigue

To evaluate a material's behaviour related to its reliability on compressive fracture strength, Weibull analysis, together with modulus (m), must be considered. Composites with high compressive fracture strength coupled with high Weibull modulus are better than low compressive fracture strength with low Weibull modulus. In the present study, Supreme and ELS revealed the highest and lowest Weibull module respectively. In other words, fatigue strength result obtained for ELS revealed some dissimilarity in relation to its compressive fracture strength and Weibull modulus. It should be mentioned that in general, high compressive fatigue strength with a low Weibull modulus (m) might be worse than low compressive fracture strength with high Weibull modulus. As seen from Table 2, the compressive strengths of Supreme and ELS composites ranked the highest and lowest respectively. The high compressive strength of Supreme might be attributed to its superior polymer matrix coupled with a favourable filler composition — which was based on a zirconia-silica system. As a result, a very uniform microstructure was obtained. As for the influence of filler volume fraction, previous studies indicated that a chief means of increasing the compressive strength of dental composites was to increase the amount of filler particles . However, results of the present study did not indicate a strong correlation between compressive strength and filler volume fraction.

In a work by Ikejima *et al*. [1], they clearly demonstrated the effects of filler content, filler particle size, and filler silanization on the mechanical properties of dental composites. With the increase of filler volume fraction by up to about 50%, flexural strength, flexural modulus, and shear strength were also increased. However, any further increase in filler volume fraction above 50% did not cause any further increase in flexural strength nor shear strength. On the contrary, there was some evidence that strength started to decline at very high filler levels (>60 Vol %). It should also be noted that the modulus of elasticity continued to increase as more filler particles were incorporated. In the present study, all composites — except Supreme which had a filler volume fraction below 60% and which belonged to the Ultrafine Midway-Filled composites — had a filler volume above 60% and they belonged to the Ultrafine Compact-Filled composites according to the classification of Willems *et al*. [5].

As shown in Fig. 1, Supreme exhibited the highest fatigue strength by virtue of its resin matrix and a zirconia-silica filler type at the highest density. It has been reported that for hybrid composites, increasing the volume fraction of filler particles in a dental composite would heighten the probability of increasing the local energy for crack growth. In other words, an advancing crack would need more energy to move through the particles. In hybrid composites, the direction of crack growth continually changes at it encounters particles. Consequently, the rate of crack growth decreases and more particles are sheared because of higher volume fraction of filler particles.

This thus explained the higher strength in Tetric® Ceram and Clearfil AP-X, which were hybrid composites in comparison to the old composites. As for the ELS composite, its low fatigue resistance under cyclic loading has been confirmed by other similar *in vitro* studies, which

highlighted that 20% of composites filled by microfilled particles failed after two years.

Apart from the type of filler content, the composition of resin matrix also influenced the mechanical properties of composites. With Supreme, the fundamental component was Bis-GMA, but part of the solvent monomer TEGDMA was substituted by UEDMA and Bis-GMA. Asmussen & Peutzfeldt [6] showed that the replacement of Bis-GMA and TEGDMA by UEDMA was instrumental for the increase in both tensile and flexural strengths of the matrix. This could be attributed to the degree of conversion of the polymer matrix or due to the ability of the urethane linkage to form hydrogen bonds in the copolymer, which presumably resulted in restricted sliding of the polymer segments relative to each other.

Asmussen [7] pointed out that composites which utilized a Bis-GMA/TEGDMA blend exhibited a higher degree of conversion when the quantity of TEGDMA was increased. This thus explained the lower strength of ELS (Bis-GMA/Bis-EMA) composites when compared to the other composites in this study which contained TEGDMA.

It is also noteworthy that fatigue cracks may initiate from defects and impurities — especially those located in areas of high stress. As shown in Fig. 2, a primary crack nucleated from a large inclusion located near the specimen edge, causing a fracture at the tip of the Tetric® Ceram composite specimen. Additionally, two secondary cracks which were not nucleated from the inclusion are visible in the picture. The primary crack initiated from a large inclusion had a remarkable effect on fatigue life reduction. For the specimen shown in Fig. 2, it experienced only 1071 cycles under a stress of 225 MPa before fracture. However,

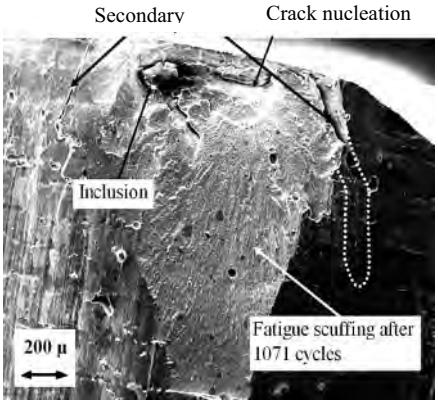

Fig. 2 Fracture surface of Tetric® Ceram composite, illustrating fatigue crack initiation from a large inclusion in the composite and two secondary cracks.

when the fatigue test was repeated under the same stress with a similar Tetric® Ceram composite, a fatigue life of 14320 cycles was obtained (*i.e*., a fatigue life reduction of nearly 90%).

B. Thermal compressive fatigue

Internal stresses due thermal variations can have destructive effects on toughness of the specimen [8]. Thermal shock occurs on the surface of filled or restored area and cause to sudden expansion and contraction on the surface while internal layers remain without any change. Effective factors on thermal expansion coefficient of resin composites contains: amount of filler particles in resin matrix, thermal properties of filler, kind of junction between filler and matrix, matrix composition, amount of polymerization and water absorption. Some efforts have been done with the aim of nomination the degrader factors in composites structures in which the majority have shown water absorption by polymeric matrix as the degrader factor. Presence of water and other liquids cause protuberance and existing of some stresses. Water absorption can has softening effect on the polymeric matrix and also disjoining of filler and matrix. Water also is the author of filler and matrix hydrolysis descending or fracturing the junctions between filler and matrix. Exertion of thermal cycles by water had negative effects on the fatigue limits of all of materials, although, the amount of this descending was not very effective on the fatigue strength of Supreme and ELS. According to the mentioned points these decreasing in fatigue strength can be due to the expansion, contractions and microstructure destruction which is due of water absorption. This weakening intensified for the cases of Clearfil AP-X and Tetric® Ceram. In resin composites there is an inverse relation between the volume percent of filler and thermal expansion coefficient, of course, it is not the only determinant parameter, but can be utilized for the low decreasing of fatigue limit of ELS. Softening of the polymers depends on presence of water, temperature of the polymer and the amount of the difference between it and glassing temperature (T_g). More difference between the polymers temperature and T_g cause more brittleness of them. Whatever this difference is lesser, the polymers become softer. Also in the same reference T_g for Bis-GMA and TEGDMA have been mentioned as 223^0 C and 100-120^0 C respectively. This can strongly justify the more descending of Tetric® Ceram and Clearfil fatigue limits than two other materials under thermal-compressive fatigue tests.

V. Conclusions

The compressive fatigue strength of Supreme and ELS composites posses the highest and lowest fatigue strength, respectively, this is due to superior matrix properties associated with fewer voids in the uniform microstructure seemingly in the wake of the highest ratio (Vol% / Wt %) of different filler particles in Supreme.

Thermal cycling reduced the compressive fatigue limits of the materials' specimens. This matter was due to the secondary stresses in specimen which were existed by expansions and contractions due of the water used for the thermal cycling.

Thermal cycling was more effective on Tetric Ceram' compressive fatigue strength due to the existence of TEGDMA in the composition of the matrix of Tetric Ceram.

Development of Amphotericin B Loaded PLGA Nanoparticles for Effective Treatment of Visceral Leishmaniasis

M. Nahar, D. Mishra, V. Dubey, N.K. Jain*

Pharmaceutics Research Laboratory, Department of Pharmaceutical Sciences, Dr. H. S. Gour University, Sagar 4 70003, India

Abstract — **Aim of present investigation was to develop novel nanoparticulate carrier of Amphotericin B (AmB) for effective treatment of visceral leishmaniasis. PLGA nanoparticles (PNPs) were prepared with emulsion solvent evaporation method. Prepared nanoparticles were characterized for size, polydispersity index (PI), shape, morphology, surface charge, and drug release. *In vitro* antileishmanial potential of AmB loaded PNPs was assessed on GFP transfected parasite (promastigote model, Dd8 strain) and infected macrophages (amastigotes macrophages model) cell line (J774.A1 murine macrophage-like cell line) using FACS and geimsa staining method, respectively and results were compared with marketed liposomal formulation (AmBisome®). The developed PNPs were found to be of nanometric size (168 nm), having low polydispersity index (0.15) and good entrapment efficiency (53.0%). Transmission electron microscopy (TEM) showed that the PNPs were spherical in shape. The zeta potential of AmB loaded PNPs, surface was found to be -46.7 mV. PNPs showed biphasic release characterized by an initial burst followed by controlled release. *In vitro* antileishmanial activity against promastigote model showed about 85% inhibition and with insignificant difference amontgst plain drug, AmBisome® and PNPs. The activity of AmB (1μM) as plain drug, AmBisome® and PNPs against *L. donovani* in intraamstigote macropage model showed percent inhibition 71.77%, 83.03%, 84.06%, respectively. Accordingly, PNPs showed potential antileishmanial activity and is equivalent to marketed AmBisome®. Results suggest that developed novel nanoparticulate carrier could provide controlled, safe, effective and economical delivery of AmB for effective treatment of visceral leishmaniasis as an alternative to lipid based formulations.**

Keywords — **PLGA, nanoparticles, amphotericin B, visceral leishmaniasis**

I. Introduction

Visceral leishmaniasis (kala-azar) is a protozoal infection disseminated by the parasite called *Leishmania donovani,* transmitted by sandfly bite, in which macrophages of the liver, spleen, lymph node and bone marrow are preferentially parasitized and support intracellular replication. Visceral leishmaniaisis maintaining its status as "most neglected disease", occurs in more than in 80 countries in Asia and Africa (*Leishmania donovani*), Southern Europe (*L. infantum*) and South America (*L. chagasi*)[1].

The development of new antiparasitic drugs to market level is a very rare and costly event. The drugs currently in use against leishmaniasis are highly toxic and have serious adverse effects that limit their clinical application. Therefore, parasite- and disease-specific formulations and delivery systems should be explored, enhancing efficiency and reducing side effects of available drugs at relatively low cost. Various polymers have been exploited for formulating the nanoparticualte carrier system but poly (lactic acid) (PLA), poly (glycolic acid) (PGA) and their copolymers poly (lactide-co-glycolide) (PLGA) have been extensively employed because of their biocompatibility, biodegradability, versatile degradation kinetics, FDA approved and commercial available[2,3].

Therefore, in the present investigation, we attempted to develop alternative delivery system i.e. PLGA nanoparticles (PNPs), which may overcome the severe side effects of existing AmB formulations by controlled delivery and provide effective treatment of visceral an alternative to lipid based formulations.

II. Materials and Methods

Amphotericin B was generously gifted by Dabur India Ltd. (Ghaziabad, UP, India). Poly(lactic-co-glycolic) acid (PLGA) with a lactic to glycolicratio of 50:50 (RG502, Mw=12kDa) were received from Boehringer Ingelheim (Ingelheim,Germany), amberlite XAD 16 resin were purchased from Sigma Chemical Co. (St Louis, MO, USA)., Dimethyl sulfoxide (DMSO) and acetonitrile were purchased from Central Drug House (New Delhi, India). All others chemicals were of analytical grade and used as received.

A. Preparation of PNPs

The nanoparticles were prepared by the emulsion solvent evaporation (o/w emulsification) technique [4]. Initially, specified amounts of polymer was dissolved with or without drug in 2 mL of DCM, vortexed and emulsified in 20 mL of a 0.1% sodium cholate solution in a sonicator (Sonics-Vibra Cell, BC-130, Ultra sonic processor, CT, USA) at 20 W output for 1 min. The organic solvent was evaporated at

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1241–1243, 2009
www.springerlink.com

room temperature for 4 h. The nanoparticles were then recovered by centrifugation (33,900 x g, 20min, 4°C; Remi, India), washed twice with water and unentrapped drug removed by using amberlite resin XAD 18 and lyophilized [5].

B. Characterization of PNPs

The particle size, surface charge and PI were determined by using a Malvern Zetasizer (NanoZS, Malvern Instruments Inc., Worcestershire, UK). Particle size and PI of PNPSs were determined by light scattering method based on laser diffraction at angle 135^0. PNPSs surface charge was determined by laser doppler anemometry. Transmission Electron Microscopy (TEM, H7500**,** Hitachi Ltd., Tokyo, Japan) was used for determination of shape and size of PNPs. Dialysis membrane method was used to determine the release of AMB from the nanoparticulate formulations.

C. In vitro intrinsic antileishmanial activity (promastigotes assay)

In vitro antileishmanial screening was performed with 100 µL (10^6 cells per mL) of the parasite suspension (WHO reference strain, *L. donovani* (MHOM/IN/80/Dd8) promastigotes), and plates were incubated at 27°C in an atmosphere of 95% air/5% CO_2 for 1 h prior to addition of formulation. AmB loaded plain and PNPs were added to each well to obtain the final concentration of 0.05, 0.1, 0.2, 0.5 and 1 µM equivalent AmB. Each concentration was screened in triplicate. After a 3-day incubation period at 27°C in the dark and under a 5% CO_2 atmosphere, the viability of promastigotes was checked using FACS by obtaining mean fluorescence intensity of 10,000 counts. Percentage inhibition was calculated considering untreated parasite as control [6].

D. Ex vivo antilieshmanial activity (intramacrophages amastigote model)

Macrophages J774A.1 (10^5 cells/well) in 16-well chamber slides (Nunc, IL, USA) were infected with promastigotes (*L. donovani,* Dd8) at multiplicity of infection of 10:1 (parasites/macrophages) and incubated at 37 ± 1°C in 5% CO_2 for 12 h. Different concentrations of various PNPs formulations in RPMI-1640 medium (Sigma, USA) were added to wells in triplicate and examined for intracellular amastigotes after washing, methanol fixing and Giemsa staining of the slides. At least 100 macrophages nuclei were counted per well for calculating percentage infected macrophages and number of amastigotes per 100 macrophages. The untreated infected macrophages were used as control. Percent parasite inhibition in treated wells was calculated using the following formula [7].

$$\text{Percentage Inhibition} = 100 - \frac{T}{C} \times 100$$

where, T the number of parasites in treated samples/100 macrophages nuclei, and C is the number of parasites in control samples/100 macrophages nuclei. The 50 % inhibitory concentrations (IC_{50}) were determined by using sigmodal regression analysis and expressed in µM ± S.D.

III. Results and Discussion

PNPs were prepared with solvent evaporation method using sodium cholate as surfactant. Sodium cholate is very effective in reducing the size and only low amount remained associated with nanoparticles surface [4]. The unloaded and AmB loaded PNPs were characterized for particle size, shape and surface charge using various techniques (Table 1). TEM photomicrograph reveals the spherical shape of PNPs (Fig.2).

Table 1: Characterization of PLGA nanoparticles

Parameters*	Unloaded PNPs	AMB loaded PNPs
Particle Size	146 ± 26 nm	168 ± 16 nm
Polydispersity index	0.081 ± 0.031	0.152 ± 0.015
Zeta potential	−43.04 ± 1.40 mV	-46.7 ± 0.55mV
% Yield	84.0 ± 1.20	68.50 ± 3.4
Percent drug entrapment (%)	-	53.0 ± 1.5
Drug content (%)	-	2.81 ± 1.1

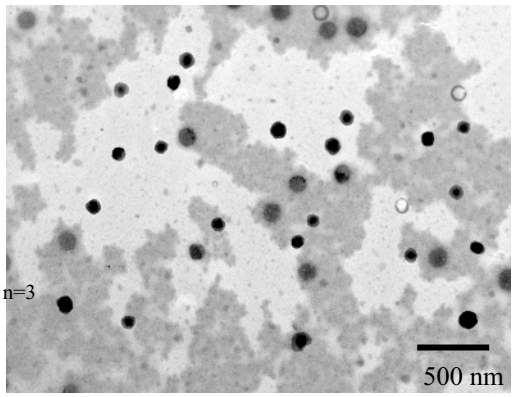

Fig. 1 TEM photo micrograph of PNPs

Drug release from the PLGA nanoparticles prepared by the dialysis method using DMSO was almost complete within 6 days as shown in figure 2.

The profile showed a fast release of the active drug during the first 4 h of incubation. This type of profile is charac-

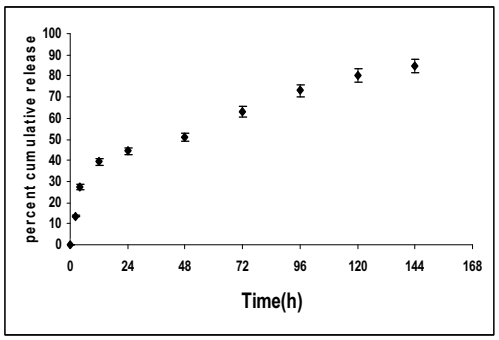

Fig. 2 Percent cumulative release of AmB from PLGA nanoparticles in PBS 7.4 (5% v/v DMSO)

teristic of a burst-release, which suggests that AMB may be in the vicinity of the nanoparticles surface. The fast release is followed by sustained release to 144 h where 86% of entrapped drug is released. The release profile observed with AmB suggested pseudo-zero order release kinetics.

The effect of various concentrations of plain (free) and encapsulated AmB was evaluated against *L. donovani* extracellular promastigote using FACS and the results depicted concentration-dependent inhibition. Maximum percent inhibition obtained with plain AmB, AmBisome®, PNPs (1μM equivalent AmB) were 85.71± 3.69, 87.37± 2.43, and 87.10 ± 2.48, respectively. On the contrary, percent inhibition obtained in amastigote model were 71.77± 1.23 %, 83.03 ±1.32 % and 84.06 ± 1.2 %, with plain AmB, AmBisome®, PNPs (1 μM equivalent AmB), respectively. The result suggests increased activity of PNPs in intramastigote macrophage model that could account for more efficient uptake of particles in comparison to plain (free) drug by macrophages. Moreover, IC_{50} of various formulations and pure drug were calculated in both experimental models (Table 2). The result suggests that a higher IC_{50} was obtained with PNPs while a significantly low value obtained with plain AmB and AmBisome®($p < 0.001$) in extracellular promastigote model. The probable reason for such contrary results is that this parasitic genus has two main forms (promastigotes and amastigotes) with different morphological and biochemical characteristics, including energy metabolism and transport across membranes and their access to therapeutic moiety. The extracellular promastigotes showed a significant higher inhibition with pure AmB and also with AmBisome® and could be ascribed for accessibility of drug to promastigotes and lipidic nature of AmBisome® that can fuse with promastigotes membrane.

Table 2. Antileishmanial activity of various formulations against promastigotes and intracellular amastigotes (IC_{50} values)

Formulations	IC_{50} against promastigotes (μM) by FACS assay*	IC_{50} against intracellular amastigotes (μM) by Geimsa staining method*
AmB	0.091± 0.004	0.21 ± 0.01
AmBisome®	0.082 ± 0.002	0.061 ± 0.02
PNPs	0.079 ± 0.002	0.059 ± 0.03

*Values represent mean ± SD (n = 3)

IV. Conclusion

PLGA nanoparticles were developed, characterized and evaluated for antileishmanial potential. The developed novel nanoparticulate carrier could provide controlled, safe and efficient delivery of AmB for effective treatment of visceral leishmaniasis as an alternative to lipid based formulations.

Swelling, Dissolution and Disintegration of HPMC in Aqueous Media

S.C. Joshi and B. Chen

School of Mechanical & Aerospace Engineering, Nanyang Technological University, Nanyang Avenue, Singapore 639798

Abstract — **This paper contains the work on monitoring the swelling, dissolution, and disintegration processes for hydroxypropyl methylcellulose (HPMC) tablets fabricated under 400, 1000, 2000 kg/cm^2 pressures. The density and porosity of tablets of three grades of HPMC (6, 40, 4000 mPa.s viscosity of 2 wt% aqueous solution at room temperature) were measured to identify the effect of different physical/chemical properties on the swelling and the subsequent processes involved. The process observations were conducted at human body temperature of 37ºC to understand drug release. The cumulative swelling curve showed that particle size and their distribution in HPMC powder, and density and porosity of the formed tablets have influence on the swelling kinetics. The strength and thickness the gelated layer formed during the swelling process influenced by the chemical structure of HPMC ultimately determined the behavior during the swelling, dissolution and disintegration of the HPMC tablets. The possible mechanism leading to these changes was proposed. The detailed kinetic simulation of the integrated process was also discussed, which seemed to follow power-law formulations.**

Keywords — **HPMC, swelling, dissolution, kinetic**

I. Introduction

Nowadays cellulose and its derivates in the form of agglomerates of porous particles are regarded as the most useful filler for direct compression tablets.[1, 2] With improvement in water solubility and affinity, HPMC has been the important vectors in the drug release systems for its high swellability and thermal gelation properties.[3-6]

Among various dosage forms in medicine, tablets still account for 80% of the drug delivery systems administered to human.[7] Physicochemical properties of various grades of HPMC are some of the critical factors that influence swelling, dissolution and disintegration behavior of HPMC tablets in aqueous media.

As a common item in swellable matrix for drug release systems, HPMC tablets had been investigated in various aspects. SEM and NMR were used to monitor the swelling process for HPMC tablets.[8,9] Gel-layer structure was studied by optical imaging.[10] Subsequent dissolution of the gelated layer of the tablets during eroding and moving swelling front was investigated using ultrasound technique.[11] The common mechanism of swellable HPMC was assigned to the glassy-rubbery transition, and swelling kinetics was expressed in power law without consideration to dissolution during swelling.[12] But if the aqueous medium was absorbed into the tablets, the "moving-boundary" would cause heterogeneous swelling of the gelated layer and big deviants from the empirical power relation with time.[13] Most theoretical models did not examine detailed effect of physical and chemical parameters, although these parameters for various HPMC vectors influenced their behavior in aqueous media.[14,15]

The objective of the work was to monitor swelling, dissolution and disintegration process in an aqueous medium for three grades of HPMC tablets formed under 400, 1000, 2000 kg/cm^2 direct compression respectively. Various parameters, like particle size and distribution, density and porosity of the formed tablets, were considered in the process of direct compression formation of tablets and subsequent interaction with aqueous medium. Kinetic studies were derived from the cumulative swelling data of HPMC tablets. The possible mechanism and simulation of the integrated process were discussed.

II. Materials and methods

A. Materials

Different grades of HPMC powders (2 wt% aqueous solution with viscosity as 6, 40-60, 4000 mPa.s at 20 °C), referred as HPMC A, B, and C respectively, were supplied by Sigma. Deionized water was produced from Mill-Q system.

B. Preparation of Tablets

Initially, HPMC A, B, and C powders were dehydrated in vacuum at 60°C. The tablets were prepared using the direct-compression method for 1 minute compression under 400, 1000, 2000 kg/cm^2 pressure at room temperature using Carver Laboratory Press (2518 series). The tablets were stored in the dry box before use.

C. Morphology of HPMC Powder by Scanning Electron Microscopy (SEM)

Pre-dried samples of HPMC powders were mounted on the sample holder using a double-side tape and coated gold.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1244–1247, 2009
www.springerlink.com

The samples were examined wyith a SEM (Leica S360) at different accelerating voltage according to various samples.

D. Density and Porosity of Tablets

The true density of HPMC powder was determined by a pycnometer using nitrogen (Accupyc 1330, Micrometrics). The packed density of tablets was calculated based on the Archimedes Law, and the measurements were repeated three times to minimize errors.

Porosity of the formed tablets was calculated based on equation:

$$\Phi = 1 - \left(\rho_b \Big/ \rho_p \right) \quad (1)$$

Where Φ represents the porosity of tablets, ρ_b and ρ_p represent the density of the formed tablets and the true density of a HPMC powder.

E. Swelling and Dissolution in Deionized Water

Three full-sized tablets of each of HPMC A, B and C were weighed accurately before loading them individually into a porous paper bag soaked in a 50 ml deionized water at 37 °C. The swelling ratios were calculated using equation:

$$\alpha = \frac{w_t - w_{t0}}{w_{t0}} \times 100\% \quad (2)$$

where α represents the swelling ratio, W_t and W_{t0} represent weight of tablets at a certain time and its original weight respectively. The values of α were averaged over three readings for each type of tablet.

III. Results and Discussion

A. Morphology of HPMC Powders

Morphology of three HPMC powder is shown in Figure 1. HPMC A and C showed an irregular rod-like shape with the fibrous appearance, while HPMC B appears oblong in shape. All three types of HPMC powders had a quite broad particle size distribution in the range 20-250 μm.

B. Porosity of HPMC Tablets

With a broad particle size distribution, all three type of HPMC tablets were fabricated under 400, 1000, 2000 kg/cm^2 respectively, and porosity of the formed tablets was shown in Figure 2.

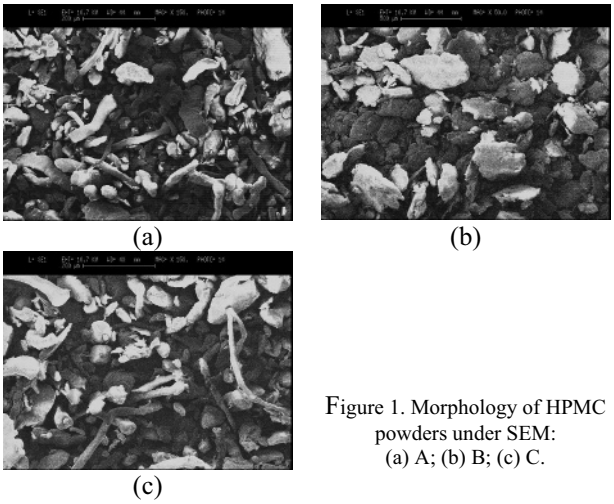

Figure 1. Morphology of HPMC powders under SEM: (a) A; (b) B; (c) C.

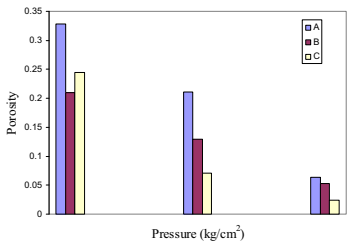

Figure 2. Porosity of tablets of HPMC A, B, and C under various tablets.

With increase in the pressure from 400 to 2000 kg/cm^2, the porosity decreased from 0.3 to ~0.05. Without precisely known average particle size and due to the broad particle size distribution, it was hard to describe relationship between powder size and porosity formed thereof. Nevertheless, the order of porosity of the tablets under the same process pressure indicated that the physical properties of various HPMC powders definitely determined aggregation patterns in the tablet form.

C. Kinetics of Sweeling and Dissoution Process

In general, HPMC tablets, like other swellable matrix would experience different stages when soaked in aqueous media: first, water as plasticizer would penetrate into the tablets to induce a glassy-rubbery transition; then a gel layer would be induced until to the saturation state of water absorption. With further interactions with the aqueous medium, association of the entangle polymer chains in the gelated layer would dismantle leading the structure of the tablets to dissolve and disintegrate.[16] The swelling and dissolution curves for three HPMC tablets are shown in Figure 3.

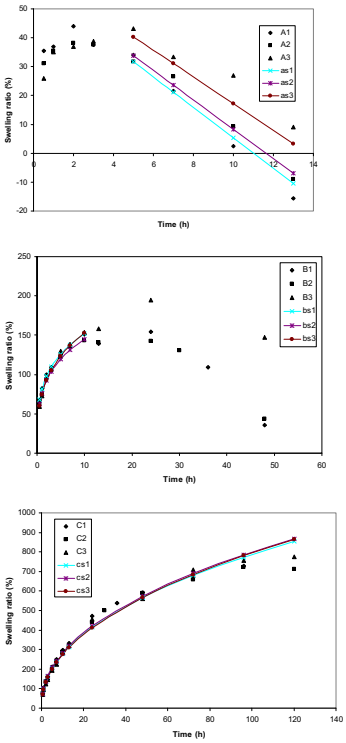

Figure 3. Swelling and simulation curves for tablets of HPMC (a) A; (b) B; (c) C at 400 (1), 1000 (2), 2000(3) kg/cm^2 respectively.

In the case of HPMC A (Fig 3a), tablets formed under the three pressures showed a similar trend. The initial swelling reached its maximum swelling ratio (<40%) in less than 5 h, and the dissolution process dominated after 5h.. The fabrication pressure seemed influencing the swelling process in a limited way with no apparent influence in the dissolution stage. As far as HPMC B tablets were concerned (Fig 3b), the maximum swelling reached around 10 h with a much higher value (>150%), and dissolution rates decreased with the increase in the fabrication pressure. The integrity of the tablets could be kept until a late stage of the whole process. With the highest viscosity of three specimens, HMPC C tablets had the highest swelling ratio (Fig 3c) to almost 800%, and the tablets maintained their integrity during the whole experiment and time scale chosen.

Based on the cumulative swelling curves, simulation results for the process are given in Table 1. For HPMC A, kinetic equations of tablet dissolution at 400, 1000 kg/cm^2 shared a similar trend, while tablets at 2000 kg/cm^2 showed some deviation. For HPMC B specimens, the swelling process obeyed almost the same law, while swelling/dissolution stage showed a reversible trend with the increase in the compression pressure. In the case of HPMC C, the whole process followed a similar trend with the power of the order of 0.45 indicating that the swelling/ dissolution process was a diffusion-control type based on the ideal cylinder geometry.[17]

The rate of the formation, the thickness and the strength of the gelated layer determine the behavior of a swellable hydrophilic matrix. [18] As a type of porous hydrophilic matrix, HPMC tablets would involve three processes when soaked in aqueous media, namely; free water transfusion into the porous tablets, swelling and gelation under water induction of glass-rubbery transition, and dissolution with further water uptake.

Table 1. Summary of simulation results for the process

Material	Swelling time scale in hours (tablet forming pressure in kg/cm^2)	Parameters	
		a	b
HPMC A	5-13 (400)	-5.37	58.12
$\alpha = a*T+b$	5-13 (1000)	-5.09	59.22
	5-13 (2000)	-4.62	63.39
HPMC B	0.5-10 (400)	81.62	0.27
$\alpha = a*T^b$	0.5-10 (1000)	76.04	0.28
	0.5-10 (2000)	74.75	0.31
HPMC C	0.5-120 (400)	99.07	0.45
$\alpha = a*T^b$	0.5-120 (1000)	100.49	0.45
	0.5-120 (2000)	95.68	0.46

α represent swelling ratio, T for the time involved.

As the kinetic-related process of the transfusion of water into the tablets, porosity determined by the particle size and distribution, and the compression pressure, play important roles in the initial swelling process. When the gelated layer formed, the chemical structure of different grade of HPMC chain would be the dominating factor to determine the rate of gelation, and the thickness and strength of the gel layer, thus to decide whether it later affected by dissolution and disintegration process.

Hydrophobic interactions between methyl groups and water were the main driving forces to the spontaneous swelling process and self-aggregation to form gelated layer of different grades of HPMC. The different chain structures and the formed ordered network were determined by the density of methyl groups in the entanglement of polymer chains. As shown in Table 2, HPMC A had the physical cross-linking sites formed by clustering of methyl groups in the swollen state. The formed cluster of physical cross-linking was easy to dismantle, thus shown a dominating dissolution process at the late stage. HPMC B had the lowest substitution ratio of methyl groups, but in a higher molecular weight range (longer polymer chains) resulting in a loosely formed network. HPMC C had the longest polymer chains and the higher ratio of methyl group

substitution. This induced formed network with the highest density of physical cross-linking sites.

Table 2. Specific parameters for different grades of HPMC

HPMC	Viscosity (mPa.s)	% CH_3 content	% HPMC content	M_n
A	6	60-67	7-10	10000
B	40-60	28-30	7-12	22000
C	4000	60-67	7-12	86000

Density of the physical-crosslinking sites determined the strength of gelated layers and subsequently controlled the disintegration behavior of the direct-compressed tablets with time elapsing in aqueous media. As shown in Figure 4, HPMC A had the weakest network that disintegrated into small parts much earlier than HPMC B. HPMC C showed the strongest network and stable shape even after absorbing considerable amount of the aqueous media. Due to the different strength of the gelated layer for various grades, the low viscosity HPMC appeared to be more suitable as a short-time delivery vector or a fast disrupting capsule, while high viscosity HPMC can be used as materials for coating tablets or long-duration delivery vectors.

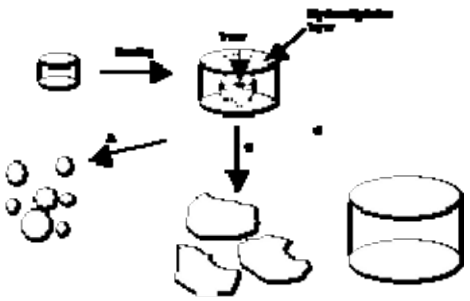

Figure 4. Schematic depicting swelling and dissolution process for tablets with time.

IV. Conclusions

Based on investigated swelling, dissolution and disintegration behaviors of tablets of three different grades of HPMC in aqueous media, physical parameters such as the particle size and distribution and the processing conditions as the pressure and porosity found to have limited influence in the initial swelling stage. The dominating factor that determined the behavior during the whole process was the formation and strength of the gelated layer determined by the chemical structure of the various HPMC. The processes seemed to follow power law formulations.

A Comparative Study of Articular Chondrocytes Metabolism on a Biodegradable Polyesterurethane Scaffold and Alginate in Different Oxygen Tension and pH

S. Karbasi

Medical Physics and Biomedical Engineering Department, School of Medicine, Isfahan University of Medical Science, Isfahan, Iran

Abstract — **There are some different methods in the literatures that used for healing and repairing of cartilage. One of the methods for increasing of regeneration and metabolism in cartilage, is stimulating physicochemical parameters on cell-polymer systems, as cartilage based cells. In this research, two physicochemical parameters, oxygen tension and pH, was changed to measure the lactate production after 1, 2 and 3 days culture and GAG(glycosaminoglycan) production after 3, 7 and 14 days culture of chondrocytes on DegraPol®, as a biodegradable polyurethane scaffold (BPUS), and alginate scaffolds. The results finally were compared on both scaffolds. The results showed that physicochemical parameters like oxygen tension and pH could change cell metabolism. In fact, the physicochemical parameters could affect lactate production and GAG content of chondrocyte cells and it does not depend on the type of scaffold. The best condition of the articular chondrocytes metabolism was for 5% O2 and pH=7.4($p<0.001$). The comparison between BPUS and alginate scaffold is showing that the results are better for alginate beads ($p<0.001$). In fact, hydrophilicity of alginate causes better cell distribution and nutrition than BPUS; because the cells are able to transfer the ions and the products through the medium easily.**

Keywords — **Chondrocyte, physicochemical parameters, DegraPol®, alginate, Tissue engineering**

I. Introduction

Articular cartilage is avascular and communicates with the rest of the body only by limited processes of diffusion of solutes to and from blood vessels in the underlying bone and through contact with the synovial fluid which washes across the articular surface intermittently, propelled by the movement of the joint [1]. Because of the long diffusion pathway involved, provision of glucose and especially oxygen into the cartilage may be particularly critical [2-4].

Even so, oxygen plays a role in chondrocytes physiology which is not well understood. Oxygen concentration may influence inflammation associated with cartilage injury and disease [2]. It is shown that concentrations of dissolved oxygen rang from 45 to 57 mmHg at the cartilage surface to less than 7.6 mmHg in the deep zone, and exteracellular pH ranges from 6.8-7.1[2]. Under these physiological conditions, cartilage has only a small capacity to repair structural damage. In contrast, articular chondrocytes exposed to relatively higher concentrations of dissolved oxygen and extracellular pH actively synthesized extracellular matrix (ECM) when cultured on 3D biodegradable scaffolds [5, 6]. In all of these researches, it is appearing that in similar physicochemical conditions, chondrocyte metabolism is different. It means that the type of scaffold, as the major parameter in tissue engineering, could also affect cell metabolism [7]. One of the 3D substrates that recently are used in articular cartilage tissue engineering is DegraPol® as a biodegradable polyesterurethane scaffold, BPUS [8-10]. BPUS is a new elastic, highly biocompatible and degradable synthesis polymer [8]. It is block copolyester, predominantly based on β-(R)-hydroxy-butyrate and hydroxyl-alkanoate (93% by weight), and linked with TMDI (trimethylhexamethylene diisocyanate) units (7% by weight) [8]. The degradation time can be adjusted between a few weeks and years through the chemical composition of the material. It has low polymer fraction (void volume about 95%) with pore size in about 50-300 μm. Also the elasticity can be varied from highly elastic and expandable from tough to brittle [8-10]. It might be the main reason of using BPUS in articular cartilage tissue engineering. But, we don't find any report about the effect of physicochemical parameters, such as oxygen tension and pH on articular chondrocyte metabolism in BPUS. However, we recently had a comparative study between cell viability of chondrocytes on BPUS and alginate (as a common material for study on chondrocyte metabolism) in different oxygen tension and pH [10]. We have shown that cell viability on alginate beads, in all physicochemical conditions is more than that of BPUS, after 3 days cell culture. We reported that the best conditions for cell viability is 5% oxygen tension and pH=7.4.

The goal of the present study is to investigate the effects of oxygen tension and pH on chondrocytes metabolism for two different scaffold material, BPUS and alginate beads, useful for articular cartilage tissue engineering. This study could answer the reasons of different chondrocyte metabolism on these two scaffolds.

II. Materials and methods

A. Material preparation

The BPUS scaffolds, as round disks were obtained from Zurich University (Institute of polymers). Its dimension was 15 mm in diameter and 1mm in thickness. The pore volume was about 95% and the pore size was about 50-300 μm. The modulus of elasticity was about 40 MPa. The samples were sterile by ethylene oxide method [8-10] and then suspended in distilled water and medium solution over night and then degassed under vacuum.

The alginate solution, as a natural biodegradable polymer, was prepared with the following method [10]. The 1.2% alginate solution was prepared by adding 240 mg alginic acid (Fluka, Biochemica) to 20 mL of 0.9% NaCl and stirring and then was steriled through 0.22 filters.

B. Cell culture method

There were two different methods for cell seeding, depend on the scaffolds. After harvesting of chondrocyte cells from metacarpophangeal joints of 6-9 month-old steers, for BPUS samples, the samples were put into the bottom of a 24 well-plate and then 0.1 mL of cell-medium suspension with 4×10^6 cell/mL concentration was added to the top of the samples for cell attachment [8]. After 2 hours incubation under different physicochemical conditions, the medium (DMEM, 6%v/v FBS, 1%v/v AA) was changed with 2 mL new medium and the plate was put into the incubator again, at the same condition.

For alginate samples; first, the actual amount of alginate solution was added to the pelleted cells to obtain a suspension with 4×10^6 cell/mL of alginate [10]. Then this suspension was mixed thoroughly and transferred to a syringe with 22 G needle and dropped to a sterile 102 mM $CaCl_2$ solution for formation of beads. After dropping all the cell-alginate suspension to the $CaCl_2$ solution, $CaCl_2$ was aspirated and the beads were washed with 0.9% NaCl and DMEM 3-4 times to remove all $CaCl_2$ from the beads.

C. Oxygen tension and pH condition

The experiments was done in three different oxygen tension; 21%, 5% and 1%. Briefly, BPUS and alginate samples was divided to three 6 well-plate. In one row, 2 mL of medium with pH=7.4 and in another row, 2mL of the medium with pH=6.5 was added. Then each 6 well-plate was put into the oxygen chamber. Oxygen was blown in different percents, 21%, 5% and 1%, into the three chambers and finally the chambers were put into the incubator at 37°C and 5 % CO_2. The old medium was replacing with 2 mL of the new medium with the same pH and oxygen, everyday.

D. Determination of lactate production

In this study, after 1, 2 and 3 days culture, for both scaffold and in different oxygen tension and pH, the medium was replaced with 0.5 mL new medium for 4 h [2]. Then the medium (per each sample) was transferred to an eppendorf. 10 *mL* of each medium sample was added to one well of 96 well-plate and 100 *mL* of lactate reagent (Sigma, UK) was added to each well. Finally, the absorbance of each medium sample (in each well) was measured by ELIZA reader (enzyme linked immune absorbent assay) at 540 nm. The standard curve was derived by the same method and the amounts of lactate production were determined for each sample by equation derived from the standard curve.

E. Determination of GAG production

The amount of GAG was measured by DMMB (dimethylmethylene blue, Aldrich) assay in day 3, 7 and 14 of cell culture in different oxygen tension and pH [11]. Briefly, the scaffolds were put separately in papain solution at 60-65°C over night. The papain solution was made with mixing of 20 mM sodium phosphate buffer (pH=6.8), 1 mM EDTA(Sigma, UK), 300 μg papain (Sigma, UK) and 10 mM cysteine-HCl (Sigma, UK). Then, 20 μL of each digested sample were added into a disposable spectrophotometer cuvette. Finally, 1 mL of DMMB was added to each cuvette and absorbance was measured at 595 nm by spectrophotometer. The standard curve was obtained by the same method and the amounts of GAG production for each sample were determined by the equation derived from standard curve. Statistical analysis in all experiments was based on student t-test.

III. Results

A. Lactate production

As shown in figure 1, there is a significant difference between the amounts of lactate production in pH=6.5 and pH=7.4 for BPUS scaffold ($p<0.001$).The results were the same for Alginate.It means that the pH=7.4 is a physiological condition for cell metabolism on both scaffolds. On the other hand, the chondrocytes were producing adenosine triphosphate (ATP) and subsequently, faster cell proliferation. Figures 1 also is showing the increasing lactate production with time in pH= 7.4. In pH=6.5, not only the amount of lactate production is not increasing with time, but also is decreasing for both scaffolds. In general, decreasing pH could reduce the cell volume and reduction of cell volume could change the normal mechanism of transferring

ions like glucose into the cells and reduce lactate production [2-5].

Figure 3 are showing the effect of oxygen tension on lactate production for BPUS scaffold. In this figure, it dose appear that the lactate production in 5% O2 atmosphere is maximum and there is significant difference between these three oxygen tension ($p<0.01$). The results were the same for Alginate. It means that the lactate production is maximized at optimum value of oxygen tension and increased with time. On the other hand, changing of oxygen tension could change cell volume and finally affect the cell metabolism [2-5].

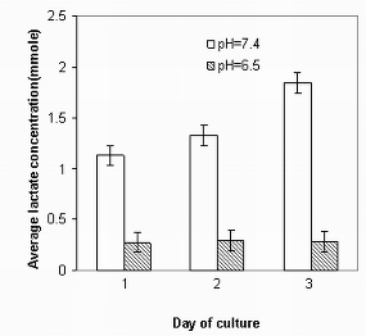

Fig. 1 Effect of pH on lactate production in different days of culture for BPUS (Osm. =380, 21% O_2) (n=9, mean ± SD, P<0.001)

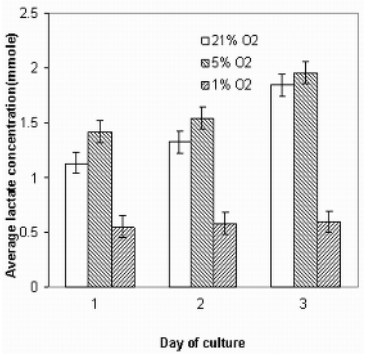

Fig. 2 Effect of oxygen tension on lactate production in different days of culture for BPUS (Osm. =380, pH=7.4) (n=9, mean ± SD, P<0.01)

B. GAG production

The results repeatedly showed here that the highest GAG production is in pH=7.4 and 5% oxygen tension. Figure 3 is showing that GAG production is increasing with time significantly for BPUS scaffold in pH=7.4($p<0.01$). The results were the same for Alginate.

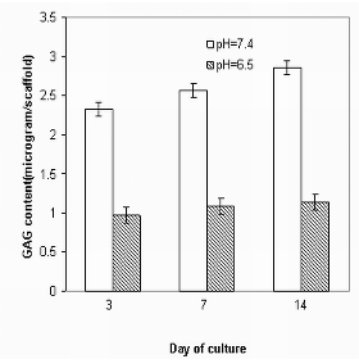

Fig. 3 Effect of pH on GAG production in different days of cell culture for BPUS (Osm. =380, 21%O2) (n=9, mean ± SD, p<0.01)

It is also appear in figure 4 that the amount of GAG production for BPUS scaffold is increased significantly with increasing the time of cell culture at 5% oxygen tension, as Alginate beads($p<0.05$). These results generally shown that the changing of pH and oxygen tension could change cell volume and finally affect the cell metabolism for both scaffolds.

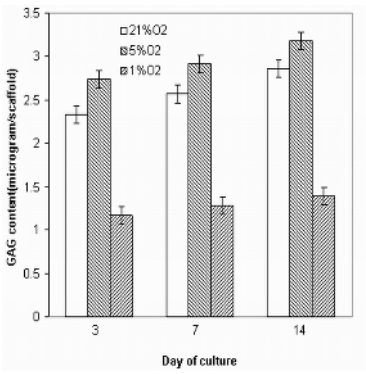

Fig. 4 Effect of oxygen tension on GAG production in different days of cell culture for BPUS (Osm. =380, pH=7.4) (n=9, mean ± SD, p<0.05)

IV. Discussion

The cell–polymer system can be used to identify and control various biochemical and physical factors that are expected to influence cell function and tissue growth [12]. In this study, the comparison between BPUS and alginate scaffold is showing that the results are better for alginate beads. It is shown in figure 5 that average lactate production in constant pH, oxygen tension and Osmolarity, is higher for alginate scaffold ($p<0.001$).

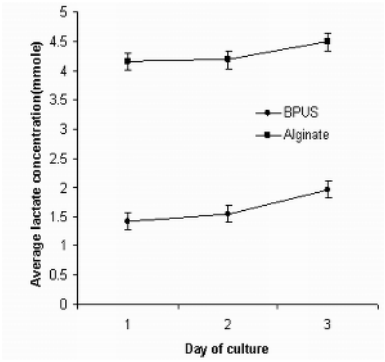

Fig. 5 Comparison between average lactate production for BPUS and Alginate in different days of cell culture (Osm. =380, pH=7.4, 5%O2) (n=9, mean ± SD, p<0.001)

This is also the same for GAG production (p<0.001) (figure 6).

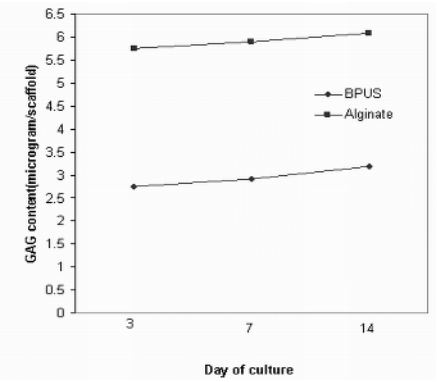

Fig. 6 Comparison between GAG production for BPUS and Alginate in different days of cell culture (Osm. =380, pH=7.4, 5%O2) (n=9, mean ± SD, p<0.001)

It seems likely that there are some factors in alginate that cause these differences. One of these factors is high hydrophilicity of alginate. This property causes good cell distribution and nutrition; because the cells are able to transfer the ions and the products through the medium easily [10]. But, BPUS is not hydrophilic. It has some interconnected porosity that can help cell nutrition and cell metabolism. In static culture, cell seeding is just putting the cells on top of the scaffold. Therefore, in rigid scaffolds like BPUS, cells can not distribute inside the bulk of the scaffold. Also, some of the cells can go through the pores, slowly; but because of the situation in the static culture, medium content can not reach the diffused cells and the cells will die. Therefore, in rigid scaffolds like BPUS that are not hydrophilic and just have some porosity, the best way for increasing the cell metabolism is to find a method for nutrition of the cells in entire part of the scaffold. One of these methods is perfusion culture. Perfusion culture is a method for perfusing the cells through the scaffold [12]. It seems that this method could improve the results for BPUS, significantly.

V. Conclusion

In rigid scaffolds like BPUS that are not hydrophilic and just have some porosity, the best way for increasing the cell metabolism is to find a method for nutrition of the cells in entire part of the scaffold. One of these methods is perfusion culture. It seems that this method could improve the results for BPUS, significantly.

Effect of Cryopreservation on the Biomechanical Properties of the Intervertebral Discs

S.K.L. Lam, S.C.W. Chan, V.Y.L. Leung, W.W. Lu, K.M.C. Cheung and K.D.K. Luk

Department of Orthopedics and Traumatology, The University of Hong Kong, Hong Kong SAR

Abstract — **Intervertebral Disc (IVD) allograft transplantation is presented to be a practical treatment of severe Degenerative Disc Disease (DDD). Limited availability of fresh allograft tissues necessitate the establishment of tissue banking for long-term storage. However, the effects of the cryopreservants on the mechanical properties of the IVD remains unknown. We hypothesize that the appropriate use of cryopreservants can preserve the mechanical properties of the IVD. In this study porcine discs were cryopreserved in different cryopreservative agent (CPA) concentration following a stepwise freezing protocol. After four weeks of storage in liquid nitrogen, dynamic viscoelastic properties of the IVDs were tested using uniaxial compression at different frequencies. Compared to fresh IVDs, no significant differences were found in the elastic modulus (E'), viscous modulus (E") and loss tangent (E"/E') in the discs cryopreserved with 0-20% CPA. However, cryopreservation at 20% CPA mixture resulted in lower E'and E". Our data suggest properly cryopreserved IVD is able to maintain both elastic and viscous characteristics and distribute loads as of a normal IVD.**

Keywords — **Degenerative Disc Disease, Intervertebral Disc, Allograft, Cryopreservation, dynamic viscoelastic**

I. Introduction

Total disc replacement by intervertebral disc (IVD) allograft transplantation has been reported as a possible treatment for severe Degenerative Disc Disease (DDD) [1-3]. Recent clinical trial indicates that IVD allografts are able to preserve motion and stability of the spinal segment [3]. However, limited availability of fresh allograft tissues and the need for size matching during transplantation necessitate the establishment of cryopreserved IVD tissue bank. To date, little is known about the effects of cryopreservants (CPA) on the mechanical properties of the IVD although the mix effects of freezing on the IVD have been previously reported [4-5]. Bass et al. (1997) reported that frozen storage of porcine intervertebral discs alters the compressive creep behaviour and that the frozen disc do not represent fresh behaviour. However, in another study, no significant alteration in the creep response of human lumbar disc were found following frozen storage [5]. Since frozen storage may have some effects on the behaviour of the disc, it is hypothezied that the appropriate use of cryopreservant is required to maintain the integrity of IVD matrix and hence preserve the mechanical properties of the IVD during disc cryopreservation. The objective of this study is to test if cryopreservation with or without CPA can affect the dynamic viscoelastic properties of the IVD.

II. Method

Porcine lumbar IVDs of diameter 22-25mm were randomly assigned to undergo a stepwise freezing protocol using 0% CPA, 10% CPA, or 20% CPA (5 samples each) and stored in liquid nitrogen at -196°C. After 4 weeks of storage the IVDs were fast-thawed at 37°C in a saline bath. All specimens were radiographed by Faxitron (Faxitron X-Ray Corporation, Wheeling, IL) and the lateral and anteroposterior widths of the discs were measured from the radiographs using Image Pro Plus (Media Cybernetics, Inc., Bethesda, MD), and disc cross-sectional area was computed as an ellipse using the formula $\Pi/4 \times d1 \times d2$, where d1 and d2 were the lateral and anteroposterior widths.

Non-destructive uniaxial compression testing was performed using MTS 858 Bionix Testing Machine (MTS System Inc., Minneapolis, MN). The samples were placed on a porous puck inside a 37°C saline bath and then another porous puck, connected to the loading shaft, was loaded onto the samples. A basal compressive load of 10N was applied so as to maintain contact between the puck and the samples during the unloading cycle of the test. Dynamic viscoelastic properties of the IVDs were tested by uniaxial compression as previously described [6] using 6 frequencies of loading (0.05Hz, 0.1Hz, 0.2Hz, 0.5Hz, 1Hz and 2Hz) with 10% strain amplitude. Each frequency test was performed using one cycle of sinusoidal strain followed by 3-minute recovery. The complex modulus $|E^*|$ was determined by $|E^*|=\sigma/\varepsilon$, where stress σ = force (F) / cross-sectional area (A), strain ε = change in disc height (ΔDH) / disc height (DH) [6]. The elastic modulus E' was determined by $E'=|E^*|\cos\delta$, the viscous modulus by $E''=|E^*|\sin\delta$, and the loss tangent by $\tan\delta=E''/E'$.

One-way ANOVA followed by LSD post-hoc test was used to evaluate the statistical difference with $p < 0.05$ considered as significant.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1252–1254, 2009
www.springerlink.com

III. Results

The elastic modulus (E'), viscous modulus (E") and loss tangent (E"/E') of the fresh control and different treatment groups over the range of testing frequencies are presented in Figure 1.

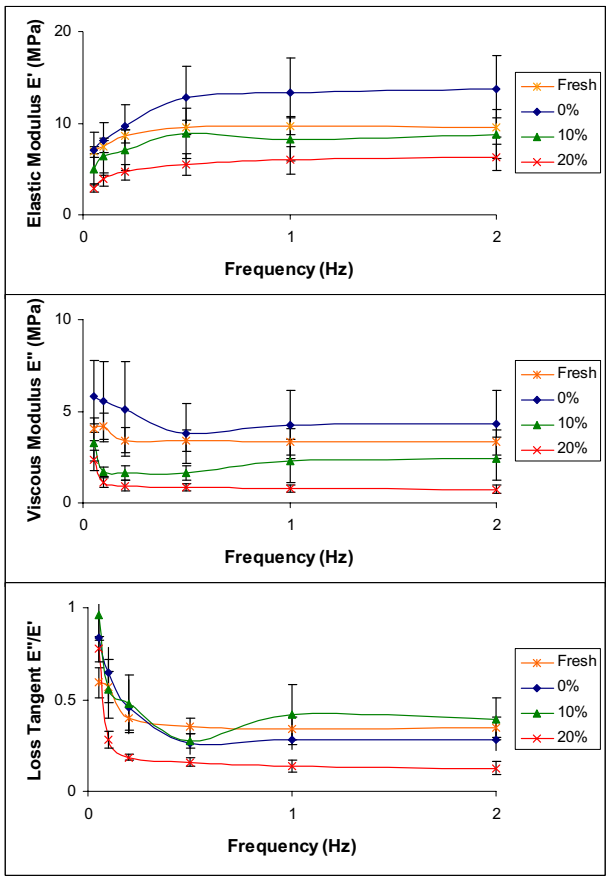

Figure 1: Effects of cryopreservation with or without CPA on the elastic modulus (E'), the viscous modulus (E") and the loss tangent (E"/E') of porcine IVD (Mean±SEM).

The 0% CPA group had the highest E'and E" properties at all frequencies among all the groups, while, the 20% CPA group recorded the lowest E', E" and E"/E' properties at all frequencies out of all the treated groups. Relative to fresh IVD, cryopreservating the IVD 0% CPA resulted in higher E' and E", whilst, IVD cyropreserved with 10% CPA retained the closest E'and E" properties to fresh IVD and IVD cryopreserved with 20% CPA resulted in lower E, E", and E"/E'. No significant differences were found in the E', E" and E"/E' between the fresh control group and the treatment groups.

IV. Discussion

Higher values of apparent modulus attained in the 0% CPA group suggests freezing without CPA have a detrimental effect to the elastic properties of IVD and that the use of CPA can affect the mechanical performance of the IVD during freezing. The full extent of the effects of CPA on the cryopreservation of the disc has yet to be studied.

The use of CPA could be a vital component to cryopreservation of the discs as suggested by other groups [2, 4]. The use of appropriate CPA and freeze-thaw protocol can prevent cell death associated with freezing and reduce ice crystal formation and nuclear expansion which can reduce the potential disruption of the annulus [4, 5]. Although the differences between groups were not significantly, however, the use of CPA in cryopreservation of the IVD can affect other parameters such as cell viability which was not tested in this study. We postulate that the maintenance of mechanical properties of the cryopreserved IVD is related to the preservation of IVD structure due to attenuation of extracellular ice crystal formation with the use of cryopreservants and stepwise freezing protocol.

V. Conclusions

This study demonstrated that the cryopreservation with CPA would not affect the dynamic viscoelastic properties of the IVD. Preservation of the dynamic viscoelastic properties in the IVD allograft would facilitate the kinematics and distribute loads of the spine following the IVD allograft transplantation.

A Serum Free Medium that Conserves The Chondrogenic Phenotype of *In Vitro* Expanded Chondrocytes

Saey Tuan Barnabas Ho[1,2], Zheng Yang[1,3], Hoi Po James Hui[1], Kah Weng Steve Oh[4], Boon Hwa Andre Choo[4] and Eng Hin Lee[1]

Abstract — **Objective: The success of autologous chondrocyte implantation hinges on several factors. One of which is that sufficient chondrocytes with a conserved phenotype is required for the procedure. This proves to be a challenge with conventional cell culturing which is dependent on animal serum. The authors propose a serum free media that not just enhance cell growth but also preserve the chondrogenic phenotype during expansion.**

Design: Chondrocytes were harvested from human articular cartilage biopsies and cultured either in serum supplemented media or in the serum free formulation. To promote cell attachment, collagen or fibronectin coating was coupled to the use of the serum free media. During expansion, cell attachment and proliferation were evaluated, while key chondrogenic markers were assessed in the later redifferentiation phase.

Results: Promising results were observed with superior long term proliferation as compared to the FBS supplemented cultures. When these cells were redifferentiated, aggrecan and collagen II were expressed especially so for the cells cultured on collagen coated surfaces under serum free conditions. These cartilage ECM molecules were either reduced or absent in the FBS group. The serum free formulation also lowered collagen X gene expression which was indicative of a reduced likelihood of the cells undergoing hypertrophy.

Conclusion: The work represents one of the first attempts in the in *in vitro* expansion of human chondrocytes independent of serum or its derivatives. The findings indicate that serum free media on collagen and fibronectin substrates supported higher cell proliferation and better chondrogenic phenotype compared to serum supplemented media.

Keywords — **Serum free, Chondrocytes and Autologous chondrocyte implantation**

I. Introduction

Functionally viable chondrocytes in sufficient quantity is crucial for the success of autologous chondrocyte implantation. This is difficult with conventional methods as chondrocytes dedifferentiate during 2D expansion with the loss of their chondrogenic phenotype [1]. Moreover established protocols are dependent on the use of animal serum (especially FBS) which is not without its drawbacks. These would include inconsistency in outcomes due to the variability in serum lots and the transmission of pathogens. This study sought to address the issue by evaluating a newly developed serum free media which is capable of encouraging cellular growth while conserving the chondrogenic phenotype. The investigation was conducted by culturing chondrocytes plated on either human collagen I (hCol1) or fibronectin (hFN) coated surfaces and maintained using a serum free formulation. Comparisons during proliferation and re-differentiation were made against FBS supplemented cultures.

II. Materials and Methods

Biopsies of articular cartilage were taken from the knee joints of young patients who underwent reparative surgery following knee trauma. Chondrocytes were subsequently isolated via enzymatic treatment and expanded. At P2, the cells were cultured under 3 different conditions : Serum free with hCol 1, serum free with hFN and FBS supplemented media which served as a control. The serum free media consisted of 10% Knockout SR (Invitrogen), 2 ng/ml FGF-2, 2 ng/ml PDGF-AB, 2 ng/ml EGF and 10^{-8} M dexamethasone. Cell proliferation was examined at P2, while major chondrogenic markers such as collagen I, II, X and aggrecan were evaluated via real time PCR or histological staining for the P3 redifferentiated pellet cultures.

III. Results and Discussion

The serum free culturing enhanced cell proliferation over long term as compared to the FBS cultures as shown in figure 2A. The usage of FBS has resulted in a severe loss of chondrogenic phenotype as reported by other investigators

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1255–1257, 2009
www.springerlink.com

[2]. This effect can be countered under serum free conditions. When redifferentiated, the serum free groups exhibited better chondrogenic phenotype with higher deposition of aggrecan and collagen II (figure 1). Moreover there was a reduced tendency of undergoing hypertropy as indicated by the lower collagen X gene expression in the serum free cultures. When the substrate coatings were compared, hCol 1 appeared to be preferable with superior aggrecan secretion and collagen II gene expression. Despite of the promising results with the serum alternatives, the prevalence of collagen I across all groups proved that there was a general loss of hyaline phenotype which could not be completely arrested with the serum free formulation.

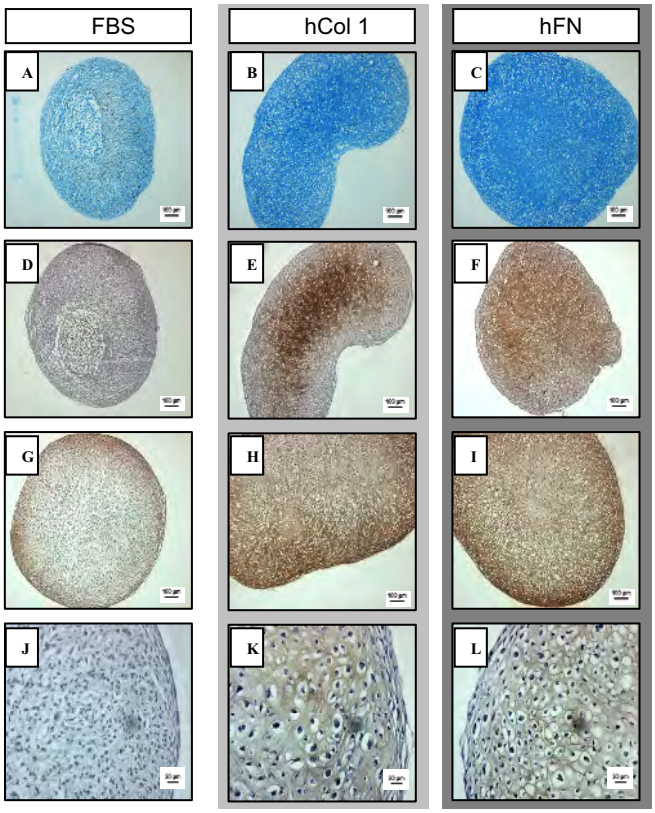

Figure 1. Alcian blue staining (A – C), aggrecan (D – F), collagen I (G – I) and collagen II (J – L) immunostaining of redifferenitated chondrocyte pellets cultured for 14 days. Prior to redifferentiation, the cells were expanded under the 3 different conditions : FBS supplemented media (A, D, G and J), serum free with hCol 1 (B, E, H and K) or hFN (C, F, I and L). All isotype controls were stained negative, while collagen X was absent in all groups (results not shown).

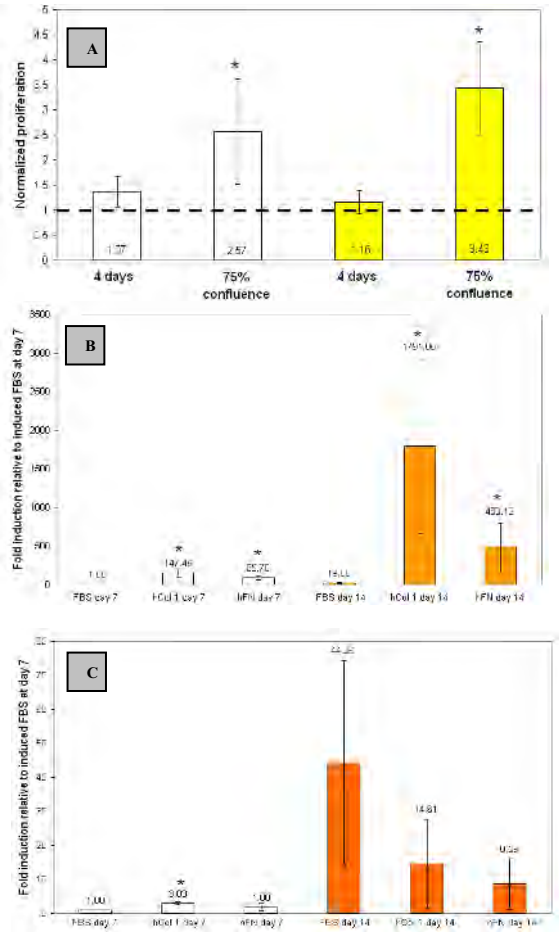

Figure 2. Cell proliferation over 4 days and at 75% confluence is as shown in A. Proliferation in serum free media with hCol 1 or hFN was normalized to that of FBS cultures as indicated by the dotted line. N = 4 for 4 days and N = 3 for 75% confluence. * indicates significant difference when compared to the FBS group at the same time point ($P<0.05$). Collagen II (B) and collagen X (C) gene expression of the redifferentiated chondrocyte pellets derived from the expansion in FBS supplemented media, serum free with hCol 1 or hFN. The results were normalized to that of the 7 days pellet derived from the expansion with FBS. * indicates significant difference ($p< 0.05$) with the FBS group at the same time point. There is no statistical difference ($p> 0.05$) between the serum free groups within the same time point.

IV. Conclusion

The presented work proves the feasibility of maintaining human chondrocytes in a serum free environment. Moreover the findings have shown that the serum free media promoted superior cell growth with a better conserved chondrogenic phenotype as compared to serum supplemented cultures.

Abstract — **High aspect ratio strontium hydroxyapatite nanorod significant enhances the mechanical strength of bioactive bone cement, due to its fiber like nature. However, incompatibility between resin matrix and strontium hydroxyapatite (Sr-HA) reduce the maximum filler loading and excessive strontium release leads to cytotoxicity problem. The aim of this study is to design a high aspect ratio hydroxyapatite nanorod with good resin compatibility and acceptable strontium release rate.**

In this study four C-18 fatty acids with different degree of unsaturation on nanorod morphology were investigated. These include stearic(n=0), oleic(n=1), linoleic(n=2), and linolenic acid(n=3). Functionalized strontium hydroxyapatite nanorod was synthesized by Liquid Solid Solution Method at 160°C for 15 hours.

From TEM analysis, the aspect ratio of linoleic (22.00±11.86) and oleic acid (22.47±6.20) were larger than linolenic(4.76±1.73) and stearic acid (6.14±2.57). Hydrophobic FTIR pattern was shown in linolenic, linoleic and stearic acid functionalized nanorod. The reinforced bone cement has lower setting temperature than PMMA counterpart.

Based on MTT and BrdU assay on mouse fibroblast (L929), proliferation rate of linoleic acid> linolenic acid> oleic acid> stearic acid. Exclude oleic acid all functionalized nanorod has higher relative growth rate than untreated strontium hydroxyapatite nanorod. From Hank immersion study and rat implantation study, the reinforced bone cement showed good bioactivity.

In this study, high aspect ratio strontium hydroxyapatite nanorods can be fabricated by using linoleic and oleic acid. Linoleic acid functionalized strontium hydroxyapatite showed optimal aspect ratio, proliferation rate, cytotoxicity profile and good resin compatibility. New bone cement has lower setting temperature, better match stiffness and high bioactivity; these properties enhance the safety of vertebroplasty application.

Keywords — **Strontium hydroxyapatite, nanorod, high aspect ratio, biocompatibility**

I. Introduction

PMMA bone cement has excellent workability and stability that allow it as the only market player in cement prosthesis fixation for more than four decades. However this product suffers the difficulties such as lack of bioactivity, highly exothermic reaction and monomer toxicity. During recent ten years, such problems could be partially resolved by the addition of bioactive filler [1], bioactivity of the bone cement was improved setting temperature was reduced.

Our group has also developed strontium containing bioactive bone cement since release of strontium can suppress osteoclast proliferation and promote osteoblast differentiation. Due to stimulatory effect of strontium enhance bony ingrowth on the cement surface can stabilize the bone - cement mantle interface. This hypothesis had been proven by goat femur model. [2] High aspect ratio Sr-HA nanorod enhances the mechanical strength of bioactive bone cement via fiber reinforcement mechanism. [3] Based on previous study, we found that adding high aspect ratio Sr-HA nanoparticle dramatically improved the bending strength of bone cement by 78%. However, the incompatibility between resin matrix and Sr-HA reduced the maximum filler loading. In addition, release of high aspect ratio Sr-HA nanoparticle leaded to cytotoxicity. Therefore, surface treatment with silane agent e.g. A174 is a common solution to reduce the particle release. However, silanized filler can release cytotoxic silane agent due to presence of not crosslinked silane. Therefore replacement of silane with biocompatible surface treating agent may improve the bioactivity of bone cement.

C-18 fatty acid is cell membrane component and exists in droplet in human body to store energy. Fatty acid surface treatment is well adopted in polymer industry to reduce the aggregation problem in polymer processing.

Liquid-solid solution method [4] was reported in synthesizing hydrophobic calcium hydroxyapatite nanorod. Fatty acids with different chains geometry have been reported to influence particle morphology and phase purity.[5]

Therefore, the aim of this study is to design a high aspect ratio Sr-HA nanorod with good resin compatibility and good biocompatibility.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1258–1262, 2009
www.springerlink.com

II. Material and Method

C-18 fatty acids with different degree of un-saturation on Sr-HA nanorod morphology were investigated. Stearic(n=0), oleic(n=1), linoleic(n=2), and linolenic acid(n=3) were also included in this study. 5 g of octadecylamine, 40 g of fatty acid and 160ml of ethanol were mixed by agitation. Strontium nitrate solution was prepared by dissolving 6.44g into 75ml distilled water. Strontium nitrate solution was added to the octadecylamine fatty acid-ethanol mixture. 5 g sodium phosphate was dissolved in 75 ml distilled water and added to above mixture. The mixture was agitated for about 10 minutes and then transferred to a 500ml Teflon lined autoclave, which was sealed and treated at 160°C for 15 hours. The precipitates were washed by distilled water, 70% ethanol and dehydrated with absolute ethanol.

Transmission electron microscopy

Particle size and morphology were characterized by measuring 100 particles by Technai G2 transmission electron microscopy.

X-ray diffraction pattern

The composition and phase purity of the fatty acid functionalized strontium hydroxyapatite and strontium hydrogen phosphate impurity was characterized by X-ray diffraction. The peaks were indexed and matched with Joint Committee on Powder Diffraction Card.

Fourier Transform Infrared Spectroscopy

Fatty acid adsorption mode has significant influence on load transfer from bone cement resin matrix to functionalized nanorod. Functionalized nanorod was mixed with KBr and analyzed with BIO-RADFTS-7 at $4cm^{-1}$ resolution.

Thermal gravimetric analysis

The amount of fatty acid adsorbed on Sr-HA nanorod surface was determined by Thermogravimetric analysis (TGA) (TA, Q5000 TA Instruments, New Castle, DE) under air-stream at a heating rate of 20°C/min. Sample gas flow rate was 25ml/minutes.

MTT and BrdU assay

Functionalized nanorod suspension was prepared by dispersing 200μg of nanorod in DMEM culture medium with the assistance of ultrasound. Mouse fibroblast (L929) was used to determine the cytotoxicity of suspended nanorod. Relative growth rate was determined by MTT assay according to Dojino guideline. Proliferation assay was performed to determine whether functionalized nanorod retain stimulatory effect on osteosacroma cell (Sa-OS2). Functionalized strontium hydroxyapatite was compared with untreated strontium hydroxyapatite and calcium hydroxyapatite nanorod.

Bone cement compressive strength

Compressive strength and modulus of bone cement was evaluated by MTS 858 according to ISO 5833 standard.

Hank solution immersion test

After immersion in Hank solution at 37°C for 7 d, the bone cement was observed under SEM Leo 1530 at 5kV and 20kV respectively.

Rat tibia implantation study

In vivo response of linoleic acid functionalized strontium hydroxyapatite reinforced bone cement was evaluated by rat tibia model.

III. Result

Particle morphology and aspect ratio

Fig. 1 a-d, aspect ratio of linoleic (22.00±11.86) and oleic acid (22.47±6.20) were larger than linolenic (4.76±1.73) and stearic acid (6.14±2.57).

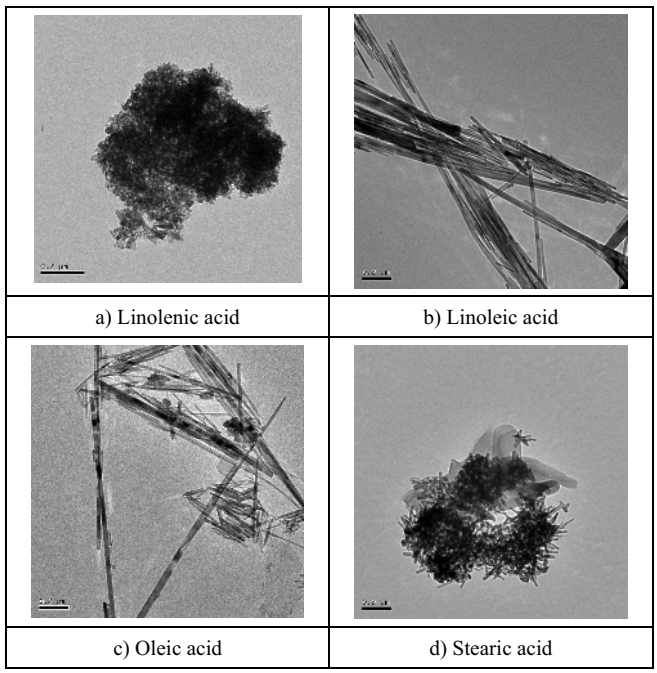

Fig 1. Nanorod functionalized by different fatty acid a) linolenic acid, b) linoleic acid, c) oleic acid d) stearic acid.

Phase purity and chemical composition

From **Fig. 2** linoleic, oleic and stearic acid functionalized nanorod, matched the pattern of strontium hydroxyapatite. Stearic acid functionalized nanorod suffered minor contamination of sodium strontium phosphate hydrate. In addition the particle size was also calculated according to Scherer Equation. The particle size of linolenic acid functionalized Sr-HA (256.68nm) < linoleic acid (453.96nm) < oleic acid (690.8nm) < stearic acid (845.13nm)

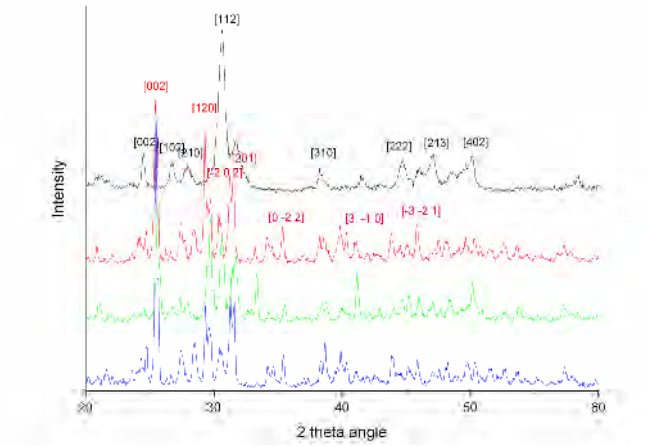

Fig. 2 X-ray diffraction pattern of nanorod functionalized by linolenic (black), linoleic (red) oleic (green) and stearic acid (blue).

Fatty acid adsorption mode

From **Fig. 3** presence of C=O stretching group (1710cm^{-1}) suggests the fatty acid was chemical boned on nanorod surface. In the FTIR spectrum of pure liquid fatty acid was absent. High CH_3 and CH_2 intensity in stearic acid

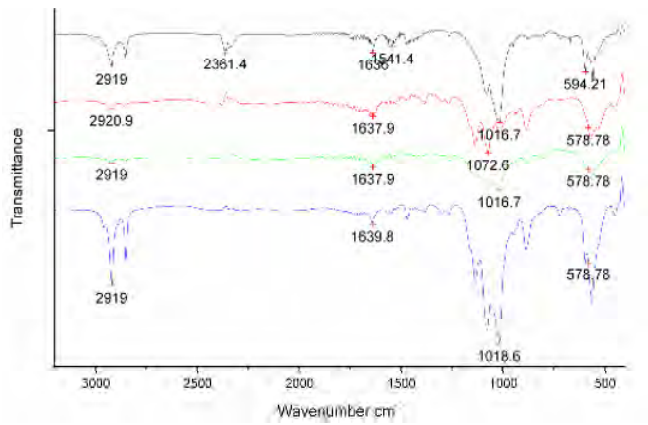

Fig. 3 FTIR spectrum of linolenic (black), linoleic (red), oleic (green) and stearic acid (blue) functionalized nanorod.

functionalized strontium hydroxyapatite suggest significant amount of stearic acid was adsorpted as intercalated layer. Intercalated fatty acid layer tends to weaken the mechanical strength of the reinforced bone cement due to lubricant like effect. TGA pattern found that the presence of intercalated layer in stearic acid functionalized Sr-HA.

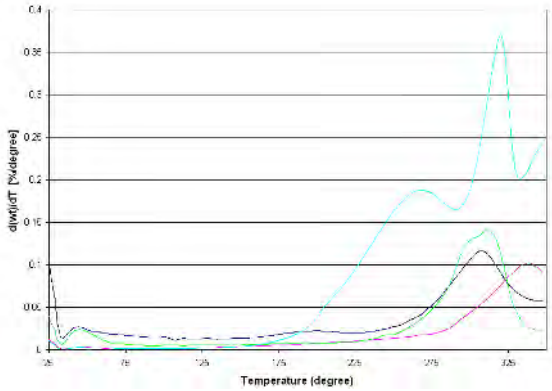

Fig. 4 TGA graph of linolenic (deep blue), linoleic (red), oleic (green) and stearic acid (blue) functionalized nanorod.

Aggregate size determination

Aggregation of filler is the key factor affecting bone cement mechanical strength. Thus, the aggregate size distributions of fatty acid functionalized Sr-HA were determined by Mastersizer 2000E based on laser scatter method by Mie method. Functionalized nanorod was dispersed by ultrasound and stirred by Hydro 2000MU (Malvern Instruments, UK). 5 consecutive tests were performed again to determine the size distribution. The d(0.9) value represent largest 10% particle. Particle size of linolenic acid functionalized Sr-HA d(0.9) =1149.524μm is significant higher than linoleic acid d(0.9) = 35.394μm oleic acid d(0.9) = 31.905μm and stearic acid functionalized hydroxyapatite d(0.9) = 21.544μm.

Cytoxicity of fatty acid functionalized nanorod

Relative growth rate of linolenic acid functionalized nanorod was (81.65±4.71)> linoleic acid functionalized nanorod (79.19±5.98)> stearic acid functionalized nanorod (70.54±15.68) > Sr-HA (68.12± 2.65) > oleic acid functionalized nanorod (51.03±1.38). Except oleic acid group, all functionalized Sr-HA is less cytotoxic than untreated counterpart. Proliferation rate of linoleic acid was (1.5188 ± 0.1400)> linolenic acid (1.5008 ± 0.1085) > oleic acid (1.3727 ± 0.1211)> Sr-HA (1.3398 ± 0.1769) stearic acid (1.1506 ± 0.1769). From BrdU result functionalized nanorod was slightly better than untreated counterpart.

Compressive strength

Compressive strength and modulus of reinforced bone cement was 81.81±1.56MPa and 3385.71±559.89MPa respectively. The bone cement setting temperature is less than 60°C.

Hank solution immersion test

After immersion in Hank solution at 37°C for 7 d, the Osteo-G bone void filler surface was covered with a hydroxyapatite(Hap) like coating. From EDX, the coating Ca/P ratio was around 1.68, close to the stoichiometric ratio of HAp at 1.68, indicating HAp-like material was formed. (**Fig 5**).

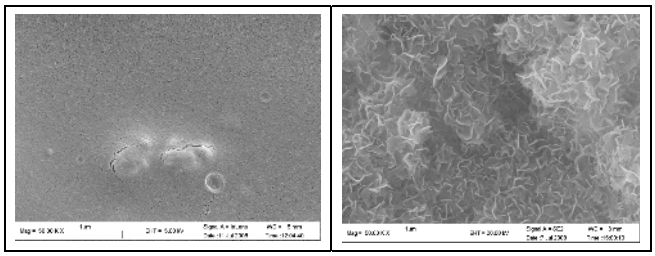

Fig. 5 SEM image of linoleic acid functionalized Sr-HA nanorod before immersion (left) after immersion in Hank solution (right).

Rat tibia μ*CT*

From Fig. 6 significant bone growth was observed near the bone cement implanted area.

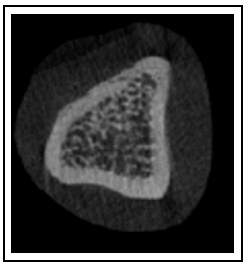

Fig. 6 microCT image of bone cement boundary area after 4 weeks implantation.

IV. Discussion

The kink on linoleic and oleic acid decrease the packing efficiency on the strontium hydroxyapatite nanorod surface that favors higher directional growth along c-axis. During hydrothermal treatment process oleic acid polymerization reduce oleic acid concentration leading to formation of both low aspect ratio and high aspect ratio nanorod. From dynamic light scattering analysis, linolenic acid functionalized nanorod has aggregate size larger than 1μm. Highly branched linolenic acid cannot stabilize the strontium hydroxyapatite nanorod by steric hindrance due to poor packing.

Oleic acid on the strontium hydroxyapatite surface was thermal polymerized to form a single layer polymer layer under hydrothermal condition. This layer is not biocompatible that lead to increase cytotoxicity of oleic acid functionalized Sr-HA.

Due to presence of two double bonds, the kinky linoleic acid is less susceptible to thermal polymerization. The thermal polymerized oleic acid lead to higher cytotocity of oleic acid functionalized Sr-HA nanorod.

V. Conclusion

High aspect ratio Sr-HA can be synthesized with linoleic and oleic acid. After soaking in Hank solution, HAp-like material was formed, thus indicating the cement is bioactive. Linoleic acid functionalized strontium hydroxyapatite nanorod showed optimal aspect ratio, proliferation rate, and cytotoxicity profile. Hydrophobic coating on functionalized nanorod improved resin compatibility. Addition of linoleic acid functionalized nanorod filler reduces the setting temperature and monomer release from the reinforced bone cement.

After 2 months of implantation, no inflammatory response was observed. From μCT images significant bone growth was observed near the cement implanted area. This suggests Sr-HA nanorod reinforced bone cement can stimulate bone growth via local release of strontium ions.

Lower setting temperature and stiffness also improve the safety in using this new cement in compressive dominant application such as vertebroplasty.

The HIV Dynamics is a Single Input System

M.J. Mhawej[1], C.H. Moog[1] and F. Biafore[2]

[1] IRCCyN, UMR-CNRS 6597, Ecole Centrale de Nantes, France
[2]National University of San Martin, School of Science and Technology, Argentina

Abstract — **Modeling, identification and control issues for the HIV infection are challenging issues since the infection spreads worldwide at an alarming rate. Based on real clinical data, the analysis of the impact of antiretroviral therapy on the HIV dynamics shows that the system is essentially a single input system in the sense that one single parameter is mostly affected by the drugs. This result has a strong implication on the design of control strategies.**

Keywords — **HIV, non linear systems, control inputs, therapy effect, parameter identification**

I. Introduction

Treatment of human immunodeficiency virus (HIV) remains a major challenge and it is reported that in 2007, 33.2 million of people were living with HIV/AIDS, 2.5 million people were newly infected and 2.1 million people died due to development of AIDS [1].

Most of the currently available anti-HIV drugs fall into one of two categories: Reverse Transcriptase Inhibitors (RTIs) and Protease Inhibitors (PIs). From a system theoretic approach, these families of drugs represent independent "control inputs" whose role is detailed hereafter. On one hand, RT inhibitors prevent HIV RNA from being converted into DNA, thus blocking integration of the viral code into the target cell. On the other hand, protease inhibitors affect the viral assembly process in the final stage of the viral life cycle, preventing the proper structuring of the viral proteins before their release from the host cell. Highly Active Antiretroviral Therapy (HAART) is the most prevalent treatment strategy for HIV infected patient. It uses two or more drugs, typically one or more RTI and one PI. However, these drugs have a number of side effects on vital human functions. Mathematical models may become an important tool in the quest for optimal dosage strategies because of their ability to predict the response of the average patient to medication.

Analysis and control of HIV dynamics gets an increasing interest from control engineers during these recent years [2], [3]... Optimization of the therapy and the minimization of the costs are open problems. In [4], Kirschner et al. derive an optimal control law which maximizes the population of healthy CD4 cells and minimizes the treatment side effects and costs. On another hand, Shim et al. propose in [5] a control scheme which stimulates the precursors CTLs to drive the patient to the state of a long-term non progressor (LTNP) which doesn't develop AIDS. Many other contributions to therapeutical strategies design may be found, such as model predictive control [5], [6], structured treatment interruptions [7], exact linearization and feedback linearization [8].

The majority of previous studies consider the HIV dynamics as a system with two independent control inputs, each input being related to one of the two drug types *i.e* RTIs and PIs. To the best of our knowledge, it is not confronted to real clinical data. The aim of this work is to check the accuracy of this scheme which is taken for granted in a wide range of contributions [5], [7], [9], [10], [11]. This kind of studies has a great impact on control laws design. In fact, as, said earlier, many control schemes are being developed for the HIV dynamics but their application remains questionable due to the validation of the model. In this paper, we show that the two families of drugs essentially act on one same single model parameter. Thus, the HIV dynamics reduces to a single input system. This conclusion follows from real clinical data analysis.

In Section II, we recall the basic third order model which is used. Section III describes the identification technique used in the paper. Section IV presents the major result of this paper. It states that the HIV dynamics is a single input system based on real clinical data analysis. In Section V we show that the single input system is accessible and fully linearizable by state feedback. Full and partial linearization are also detailed in this section. Section VI concludes.

II. Modelling the infection dynamics

The basic modelling of the HIV/AIDS dynamics is described by a 3-dimensional (3D) continuous-time model ([12], [9]). This model, given by equation (1), includes the dynamics of the uninfected CD4+ T-cells, the infected CD4+T-cells, and the virions.

$$\begin{cases} \dot{T} = s - \delta T - \beta TV, \\ \dot{T}^* = \beta TV - \mu T^*, \\ \dot{V} = kT^* - cV. \end{cases} \tag{1}$$

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1263–1266, 2009
www.springerlink.com

T (CD4/mm^3) represents the amount of uninfected CD4+ T cells, T*(CD4/mm^3) represents the amount of the infected CD4+ T cells and V (RNA copies/ml), the free virions. Healthy CD4+ T-cells are produced at a constant source rate s. Free virus particles infect uninfected cells at a rate proportional to T and V (βTV) and are produced at a rate proportional to T* (kT*). δ, μ and c are the death rates of the uninfected CD4+ cells, infected CD4+ cells and the virus.

III. Parameter identification

According to identifiability theory presented in [13], it is shown that the presented 3D model (1) is algebraically identifiable from output measurements, namely the viral load (V) ant the total CD4 count (T + T*) ([14], [15], [16]).

The identification of all the parameters of the 3D model from standard clinical data was first introduced in [17]. This approach was based on the nonlinear simplex optimization method. A new estimation method was introduced in [18]. It is based on a Monte-Carlo approach which is heuristic and relies also on the simplex optimization algorithm. This method enables having stable and robust results even for ill conditioned problems as it is the case for HIV dynamics. It is implemented in a software available at [19]. The estimations results presented in section IV were directly obtained with this software. The reader can refer to [18], [14], [15], [16] for further details.

IV. Control inputs

A. Parameters sensitivity to therapy: State of the art

Commonly, an HIV/AIDS therapy includes some RTIs and some PIs. The action of RTIs is to block the production of new viral particles since they inhibit the reverse transcription of viral RNA into viral DNA. According to [9], [7], [10], [5], and [11], their action is on parameter β. On another hand, the PIs affect the natural life cycle of the virus by prohibiting the maturation of new virions. As a result, the newly produced virions are defectuous. The PIs effect is admitted to be on parameter k ([9], [7], [10], and [11]). Parameters s, δ, μ and c are usually assumed not to be affected by drugs which is coherent with their biological meaning. When therapy effects are taken into consideration, model (1) reads as follows:

$$\begin{cases} \dot{\mathrm{T}} = \mathrm{s} - \delta \mathrm{T} - \overline{\beta}\mathrm{TV}, \\ \dot{\mathrm{T}}^* = \overline{\beta}\mathrm{TV} - \mu \mathrm{T}^*, \\ \dot{\mathrm{V}} = \overline{\mathrm{k}}\mathrm{T}^* - \mathrm{cV}. \end{cases} \quad (2)$$

where $\overline{\beta} = (1-\eta_{\mathrm{RTI}})\beta$ and $\overline{\mathrm{k}} = (1-\eta_{\mathrm{PI}})\mathrm{k}$ with η_{RTI} and η_{PI} denoting the effectiveness of RTIs and PIs respectively. Thus, the HIV dynamics is a two control inputs system. To the best of our knowledge, little work has been done to validate the above theoretic modelling. The aim of the next section is to show how drugs affect model parameters, based on clinical data from the CHU de Nantes.

B. Parameters sensitivity to therapy: Clinical data results

1. For each of the six patients involved in this study, identification of model parameters was performed twice. The first set of parameters was evaluated using the pre-treatment clinical data and the second using the post-treatment clinical data. Results are depicted in Table (1).Calculation shows that parameters β and k are most sensitive to treatment and that parameter k is much more sensitive to treatment than parameter β.

Table 1 Pre and Post treatment values of parameters k and β

ID	Pre-treatment values		Post-treatment values		Ratio	
	β	k	$\overline{\beta}$	$\overline{\mathrm{k}}$	$\beta/\overline{\beta}$	$\mathrm{k}/\overline{\mathrm{k}}$
P1	1.22E-6	167	5.46E-7	35.1	2.23	4.76
P2	9.05E-7	663	6.66E-7	405	1.36	1.64
P3	8.98E-7	360	2.37E-7	0.037	3.79	9729.7
P4	8.7E-7	79.6	5.94E-7	0.197	1.46	404.6
P5	9.63E-7	633	8.29E-7	64.70	1.16	9.78
P6	1.79E-6	390	1.04E-6	129	1.73	3.02

2. Case of a 7th patient
   This patient started regular therapy for two weeks and then entered in a non-observance phase. Parameters evaluated for this patient are illustrated in Table (2). which confirms that parameter k, *i.e* the production rate of virus, is more sensitive to treatment than parameter β. We argue from the real clinical data analysis that the HIV dynamics system is a single input system.

Table 2 The specific case of patient 7

Regular treatment		Non-observance Phase	
$\overline{\beta}$=1.88E−7	$\overline{\mathrm{k}}$=56	β=1.75E−7	k=1300

C. Discussion

From the results above, one can conclude that

- RTIs and PIs effects can not be considered to be decoupled, at least on the 3D model (1).
- Therapy (*i.e* the combination of the RTIs and the PIs) affects parameter k much more than parameter β.

This conclusion yields to the following single input system:

$$\begin{cases} \dot{T} = s - \delta T - \beta TV, \\ \dot{T}^* = \beta TV - \mu T^*, \\ \dot{V} = (1-u(t))kT^* - cV. \end{cases} \quad (3)$$

where u(t) ($0 \le u(t) \le 1$)denotes the single input affecting parameter k. It represents the efficacy of the whole therapy.

V. Analysis and Control of the Single Input Model

A. Accessibility of the single input HIV 3D model

Definition 1: Accessibility of a nonlinear system

Let $\dot{x} = f(x) + g(x).u$, be a nonlinear system, where f and g are analytic functions. The system is accessible [20] if there exists a positive integer k such as $\forall i \ge k, H_i = \{0\}$, where $\begin{cases} H_1 = \text{span}\{dx_i, 0 \le i \le n\} \\ H_k = \text{span}\{\omega \in H_{k-1}, \dot{\omega} \in H_{k-1}\}, \text{for } k \ge 2 \end{cases}$

For system (3), $H_4 = \{0\}$ if $\delta \ne \mu$ .Thus system (3) is accessible and fully linearizable since all integrability conditions are fulfilled.

B. Feedback linearization

Input-output linearization is a common approach used in controlling nonlinear systems. Let

$$\begin{cases} \dot{x} = f(x) + g(x)u \\ y = h(x) \end{cases} \quad (4)$$

be a nonlinear system. Using the nonlinear geometric control theory, the procedure consists on finding a change of variables (diffeomorphism) $z = P(x)$ and a state feedback, $u(t) = a(x) + b(x)v$ that transforms the nonlinear input-output system to an equivalent linear form. Then, a controller v is designed for the obtained linear system.

Definition 2: Relative Degree

The SISO system given by (4) is said to have a relative degree r if $\begin{cases} L_g L_f^k h(x) = 0 \text{ for all } k \le r-1 \\ L_g L_f^{r-1} h(x) \ne 0 \end{cases}$

Considering this definition of relative degree, the relative degree of system (4) can be considered as the number of times we have to differentiate the output y to have an explicit dependence on the input u.

For the controlled model (3) we have:

$$f(x) = \begin{bmatrix} s - \delta T - \beta TV \\ \beta TV - \mu T^* \\ kT^* - cV \end{bmatrix}, g(x) = \begin{bmatrix} 0 \\ 0 \\ -kT^* \end{bmatrix} u(t) \quad (5)$$

The goal of the control input u(t) is to keep the system around the equilibrium point $\left(T_0 = s/\delta, T_0^* = 0, V_0 = 0\right)$. Although the full linearization of system (3) is theoretically possible, simulation of its implementation was extremely sensitive to initial conditions and parameter values. Moreover, the complexity of the computations generated several numerical problems. To reduce this complexity and prevent initial conditions and parameters sensitivity, a partial linearization of the system is proposed hereafter, which also leads to the desired equilibrium point.

- Partial linearization

Let $y = h(x) = T - T_0$ be the linearizing output. In this case, the system has a relative degree equal to 2 and is partially linearizable. Consider the following change of coordinates $z = \begin{bmatrix} z_1 \\ z_2 \end{bmatrix} = \begin{bmatrix} h(x) \\ L_f h(x) \end{bmatrix}$ and the input $u(t) = \dfrac{v - L_f^2 h(x)}{L_g L_f h(x)}$. To complete the coordinate change we choose $\varphi = T^*$. Thus, system (3) is equivalent to the linear system (6) associated to the zero dynamics $\dot{\varphi}$.

$$\begin{bmatrix} \dot{z}_1 \\ \dot{z}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ c_1 & c_2 \end{bmatrix} \begin{bmatrix} z_1 \\ z_2 \end{bmatrix}, \ (\dot{z}_2 = v = c_1 z_1 + c_2 z_2)$$
$$\dot{\varphi} = \beta TV - \mu\varphi = \beta(z_1 + T_0)\left[\frac{z_2 - s + \delta(z_1 + T_0)}{-\beta(z_1 + T_0)}\right] - \mu\varphi \quad (6)$$

Constants c_1 and c_2 are chosen to ensure the stability of (6) at $z_1 = z_2 = 0$. In this case, $\dot{\varphi}\big|_{z_1 = z_2 = 0} = -\mu\varphi$, and the zero dynamics is asymptotically stable. The input u(t) is depicted on Figure 1. Treatment starts at day 50 and ends by day 375. Figure 1 is a simulation of the partial linearization feedback control after suitable pole placement.

One major advantage of this control scheme is its ability to minimize the viral load by the means of a time-varying effectiveness of the drugs. This means that if the effectiveness of the drug is related to its dosage, no full dosage is needed all the time.

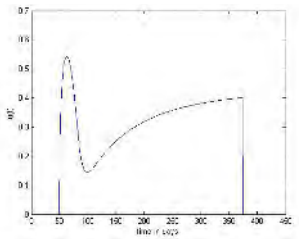

Fig. 1 The control input

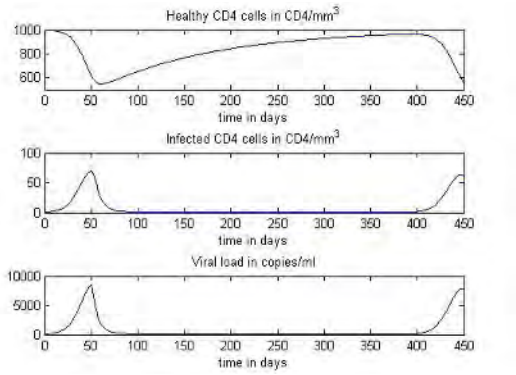

Fig. 2 Infection evolution

VI. Conclusion and perspectives

The main point in this paper was to show that the HIV dynamics is a single input system, based on clinical data analysis. The main contributions of this work are:

- the confrontation of the literature assumptions to real clinical data to get some hints about therapy effects on model parameters
- the proposition of a simplified model, with one single input describing the therapy effect
- the design and simulation of a linearizing control law as an illustration of the feasability of common control strategies on the proposed model.

One perspective of this work is to include pharmacokinetics and pharmacodynamics of antiretroviral drugs.

Evaluation of Collagen-hydroxyapatite Scaffold for Bone Tissue Engineering

Sangeeta Dey, S. Pal*

School of Bioscience and Engineering, Jadavpur University, Kolkata-700032, India

Abstract — **The regeneration of diseased or fractured bones is the challenge faced by current technologies in tissue engineering. Tissue engineering is a new and exciting technique which has the potential to create tissues and organs *de novo*. It involves the *in vitro* seeding and attachment of human cells onto a scaffold. These cells then proliferate, migrate and differentiate into the specific tissue while secreting the extracellular matrix components required to create the desired tissue.Hydroxyapatite and collagen composites (Col-HA) have the potential in mimicking and replacing skeletal bones. In this study, Type I collagen isolated from animal tendons and synthesized Hydroxyapatite were used in different proportions. SDS-PAGE characterization results of protein extracted and purified has showed that bovine type I collagen was successfully obtained. Scaffolds were prepared by controlled freezing and lyophylization of corresponding composite solutions and cross linked using glutaraldehyde (0.3%). The properties of collagen and its composite scaffolds, such as microstructure, chemical, physical, swelling mechanical and degradable properties were studied. Compared to a single component scaffold, the addition of hydroxyapatite to collagen decreased the mean aperture but increased the swelling ability,mechanical stability,biodegradability In enzymatic degradation test, crosslinked scaffolds showed significant enhancement of the resistance to collagenase activity in comparison with non-crosslinked scaffolds. Hydroxyapatite could significantly prolong the biodegradation of collagen-HA scaffolds. FT-IR indicated the presence of bonds between Ca^{2+} ions of HA and R-NH_2 ions of collagen in the composite scaffolds The FTIR spectra result shows that addition of HA in the scaffolds does not alter the structure of collagen. Hence, the novel developed biocomposites have high potential to be used for rebuilding small lesions in bone tissue engineering.**

Keywords — **collagen, Hydroxyapatite, scaffolds, tissue engineering, bone substitute**

I. Introduction

Tissue engineering aims to produce biological substitutes which may overcome the limitations of conventional clinical treatments for damaged tissues or organs. One of the principle methods behind tissue engineering involves growing the relevant cell(s) in vitro to form the required tissue, or organ, before inserting into the body. To achieve this goal the cells must attach to a three dimensional (3D) substrate, known as a scaffold. The scaffold provides the initial extra-cellular matrix required to support the cells and may also define the micro- and macro-structure of the desired-engineered structure [1].The scaffold therefore is a key component of tissue engineering. Several requirements have been identified as crucial for the production of tissue engineering scaffolds. These are that the scaffold should: (1) have appropriate surface chemistry to favour cellular attachment, differentiation and proliferation; (2) be made from a biodegradable or bioresorbable material, that degrades at an appropriate rate with no undesirable byproducts, so that tissue will eventually replace the scaffold; (3) possess adequate mechanical properties to match the intended site for implantation and handling, (4) be easily fabricated into a variety of shapes and sizes and (5) possess interconnecting porosity so as to favour tissue integration and vascularisation [2].

Bone tissue engineering is aimed at repairing diseased or fractured bone, which cannot be replaced naturally. Skeletal tissue is a highly organised structure comprising mainly type I collagen, nanometre sized carbonate-substituted hydroxyapatite crystals, water and various other non-collagenous proteins. Alike many extracellular matrix proteins, collagen type I presents natural binding sites such as the Arg-Gly-Asp (RGD) and the Asp-Gly-Glu-Ala (DGEA) peptide sequence that modulates the adhesion of osteoblasts and fibroblasts [3, 4]. On the other hand, hydroxyapatite is osteoconductive and a good source of calcium and phosphate ions necessary for the survival and proliferation of cells. Although collagen and apatite-based products have been widely used individually in biomedical applications, their combination should prove beneficial for bone tissue engineering due to their natural biological resemblance and properties [5].

II. Material and methods

Collagen Isolation: In this study, Type I collagen was extracted from Sprague dawley rat tail tendon according to the method of Liu *et al*. Sprague Dawley rat tails obtained from the animal house of IICB. This was based on the protocol followed by Liu *et al*[6] with slight modifications. Hydroxyapatite was prepared by synthesis of microwave.

Determination of collagen purity: The purity of isolated collagen was analysed using sodium dodecyl sulphate poly-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1267–1270, 2009
www.springerlink.com

acrylamide gel electrophoresis (SDS-PAGE) according to the method of lammelli.[7].

Fabrication of scaffolds: The differently proportioned Hydroxyapatite -collagen scaffolds were prepared by controlled freezing and lyophylization of corresponding composite solutions

Cross-linking: For cross-linking, the fabricated porous scaffolds were immersed in cross-linking bath with glutaraldehyde of concentration of 0.3%, pH 8 for 2 h at room temperature, then washed by distilled water and lyophilized.

Table-1.Collagen-HA composites compositions

Specimen	Collagen: Hydroxyapatite (w/w)	Concentration of collagen solution (w/v) in acetic acid
Collagen	-	0.5%
CH1	1:2	0.5%
CH2	1:4	0.5%
CH3	1:6	0.5%

Characterization of scaffolds

SEM Study: The surface microstructures of the scaffolds in the cross-section positions before and after cross-linked with glutaraldehyde were observed under scanning electron microscope (SEM, Jeol Jsm 5200) operated at an accelerating voltage of 2-15 kV. The mean pore size of the scaffolds was determined by analysis of the SEM images by importing data to image-J software. Ten apparent pores were measured. The pores were measured in a perpendicular direction through the long axis and the minor axis. Then the average values were calculated and taken as the mean pore size.

Mechanical testing: The tensile strength of the scaffolds were evaluated on an Instron Material tensile testing machine 4204, UK using pneumatic grips with load cell 500N at room temperature. The cross-head speed was set at 1 mm min^{-1}. Four samples were tested for each composition. The specimens were of rectangular shape and the dimensions were measured with a dial calipers as per general practice. Three readings were taken at different positions and mean values were used to calculate the cross-section.

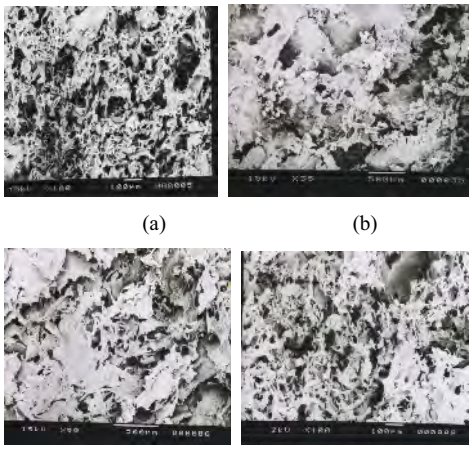
Swelling Study: The water absorption capacities of collagen-HA scaffolds were determined by equilibrium swelling studies [8]. Swelling studies of the scaffolds were carried out in PBS over 3 h periods until equilibrium was reached. Four scaffolds were taken from each specimen. The dry weights of the scaffolds were taken and dipped in 30 ml PBS solution in Petri dishes. The wet weights were taken at every 10 min interval upto 2 h. At each immersion interval, the samples were removed and the absorbed water gently removed with filter paper as much as possible. The samples were weighed accurately on a microbalance to 0.01 mg. The initial sample weight before immersion was recorded as W_o and the sample weight after each immersion interval was recorded as W_e. The percent swelling at equilibrium E_{sw} was calculated from the Flory-Huggins swelling formula:

$$E_{sw}= [(W_e - W_o)/ W_o)]\times 100$$

Infrared spectroscopic measurement and analysis: Infrared spectra were obtained in absorption mode using a FTIR spectrometer (Nicolet™ Thermo 380) from collagen-HA scaffolds.

Biodegradability Testing: In vitro degradation test of cross-linked collagen-HA scaffolds were performed using bacterial collagenase obtained from *Clostridium histolyticum* (EC 3.4.24.3, Sigma Chemical Co., St. Louis, MO. USA) with a collagenase activity of 300 units/mg. The *in vitro* degradation of collagen and its composite scaffolds were carried out at 37°C in 10 ml phosphate buffered solution (pH 7.4) containing collagenase in CO_2 incubator (Lishen –HF151UV). The dynamic degradation of the scaffolds of four different compositions with known dry weights were incubated at different concentrations of collagenases (0.1mg, 0.5 mg, 1 mg, 2 mg) for 24 h incubation and different variation of day.

Hemocompatibility Testing: The percentage Hemolysis of blood was measured using UV-VIS spectrophotometer by comparing the optical densities of the test and control group. The control was a standard biocompatible material. The optical densities were measured at 545 nm. The test was conducted according to ASTM protocol.



III. Results and Discussion

Characterization of composite scaffolds

The different tests were performed on collagen-hydroxyapatite scaffolds to evaluate its characteristics the results were discussed under following tests.

Microstructure evaluation: Figure 1(a), (b) and (c), (d) are Scanning Electron Microscope (SEM) photographs of the surface morphology and pore structure of single collagen and its composite scaffolds. Each scaffold demonstrated an open pore microstructure with a high degree of interconnectivity. Single collagen scaffolds appeared to be macro porous and the collagen-HA scaffolds appeared to have the same morphology but not so regular. The collagen scaffold showed an aperture of 50–100 μm while the composite scaffold showed a smaller aperture of 10–40 μm. of open

pore microstructure with a high degree of interconnectivity. These three-dimensional scaffolds provided a cellular matrix analog that could function as a necessary substrate for host cells to infiltrate and a physical support to guide the differentiation and proliferation of cells toward the targeted functional tissue or organ [9].

(a) (b)

(c) (d)

Fig 1. SEM of 4 different crosslinked & composite scaffolds
(a) collagen scaffold; (b) collagen HA (1:2),
(c) collage: HA (1:4); (d) collagen: HA (1:6)

Mechanical study: The scaffolds for bone tissue engineering should be mechanically stable to keep their structural integrity during the tissue regeneration. Compared with pure collagen (0.246 MPa), the ultimate strength of porous collagen-HA composites increases significantly (0.265 MPa for CHI, 0.323 MPa for CH2, 0.416 MPa for CH3 shown in figure. With the amount of HA incorporated into the collagen matrix increasing, the ultimate strength increases.

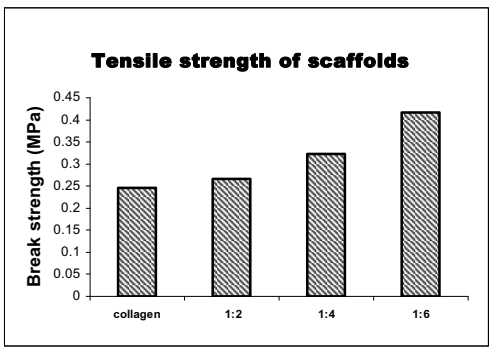


Fig 2. Ultimate strength of scaffolds with various collagen: HA (wt ratio)

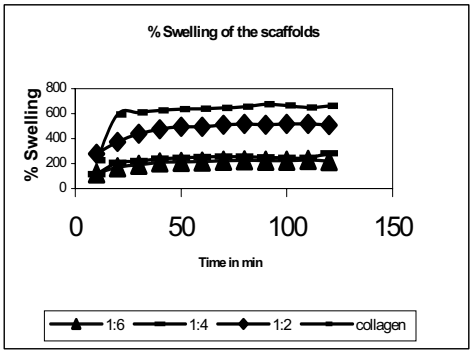

Fig 3. Percent swelling of scaffolds at different immersion intervals

Swelling Study: The swelling results of collagen scaffold was found to be 614 %, and that of the collagen-hydroxyapatite scaffolds of different compositions was decreasing (476.7 % for CH1, 237.3 % for CH2, 208.5 % for CH3) which was much less than that of collagen scaffolds. So by incorporation HA in collagen scaffolds drastically reduced the swelling. This reduction is expected as hydroxyapatite absorb negligible amount of water. Comparison of swelling of collagen and collagen–hydroxyapatite composite scaffolds is shown in figure3.

Infrared Analysis: Infrared spectrum of a composite scaffold after freeze drying is presented in Fig. 4. The FTIR spectra of composite scaffolds showed peaks at 3485.6 cm^{-1} and 1529.57 cm^{-1} due to -NH stretching and N-H bending of secondary amide of collagen I. The antisymmetric phosphate band (1200–1000 cm^{-1}) is characteristic of hydroxyapatite [10]. The data shows the phosphate stretching peaks at (1203.5 cm^{-1}) for hydroxyapatite. So the results indicate the presence of both collagen Type I and hydroxyapatite respectively in the composite scaffolds. It is also important that the HA does not affect the chemistry of collagen, as cells are shown to attach to a higher degree to surfaces containing natural binding sites [11]

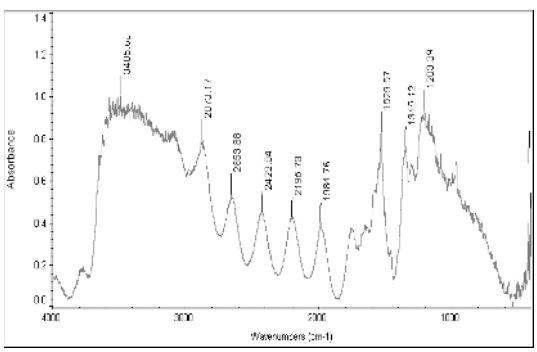

Fig 4. FTIR spectra of collagen-hydroxyapatite scaffold

Biodegradability Testing: In all of the collagenase solutions, crosslinked collagen-HA scaffolds have greater resistances to biodegradation than crosslinked collagen scaffolds The resistance of chemically modified collagen-HA scaffolds was greater than non-cross-linked samples, which was so easily dissolved in the collagenase solution that the degradation test of the scaffolds could not be performed. The dynamic degradation was found to be much faster between 2-6 days. After that the degradation was almost linear, because the activity of enzyme reduced significantly after that. It can depict that HA incorporation can provide collagen-HA scaffolds with improved mechanical property, as well as a reduced biodegradation rate.

Hemocompatibility Testing: The hemocompatibility of collagen and its composite scaffolds were evaluated by this hemolysis study. Blood compatibility is most important requirement for the blood interfacing biomaterials. The implants should not damage the proteins, enzymes or elements of blood (red blood cell, white blood cell and platelets). The results showed that by addition of HA into porous structure of collagen the % of hemolysis increased. The results indicated that collagen-HA composite scaffolds show less hemocompatible than the single collagen scaffolds.

IV. Conclusion

The results obtained in this work clearly showed that collagen and Hydroxyapatite are worthwhile perspectives for the development of composite scaffolds for bone tissue engineering. The biopolymer composite seems to be appropriate for the purpose of generating multifunctional solid surfaces triggering intensive bone cell growth.

Abstract — **Hydroxyapatite (HA) is currently one of the most attractive materials for human hard tissue implants because its close crystallographic resemblance to bones and teeth, conferring HA with excellent biocompatibility. Because of that fact as well as economic and time-saving reasons, we have stressed the need for safe production of HA-powders and ceramics from natural resources, such as animals' bones and teeth, or hydrothermal transformation of shell's aragonite.**

Nevertheless, the applications of pure HA-ceramics are limited to non load-bearing implants, because of HA's poor mechanical properties. Our research group has dedicated a lot of effort to achieve enhancement of mechanical strength and the fracture toughness of sintered HA-ceramics, mainly with HA-powder of natural origin, by fabricating composite materials of HA doped with various types of biocompatible oxides.

This work aims to present that bulk ceramics of pure HA (i.e. with no incorporation of any reinforcing phase), derived from sintered HA–powder obtained from calcinated (at 850°C) bones of sheep (SHA), exhibit the best mechanical properties ever measured for sintered HA ceramics (pure and composites) using naturally (i.e. animal bone) derived HA. The characterization of the new HA-ceramics comprised measurements of density and mechanical properties, namely compressive strength and Vickers microhardness, along with microstructure observation with scanning electron microscopy (SEM). The best mechanical properties were achieved in the samples sintered between 1200°C-1300°C; the highest value of compression strength was achieved after sintering at 1300°C, 180.75 MPa. SEM observations in conjunction with density measurements confirmed the good sintering ability of the SHA-powders to highly condense bulk HA-ceramics.

Keywords — **Hydroxyapatite, sheep derived hydroxyapatite, mechanical properties**

I. Introduction

Skeletal deficiencies, due to trauma, tumors, or abnormal growth, are quite common. Surgical intervention and grafting are usually applied to restore mechanical function and reconstruct the damaged areas. Approximately 500,000 bone grafting procedures are annually performed in the USA. Autogenous grafts feature the problems of the limitation of the available graft area and the fact of extra surgery. Synthetic or naturally derived hydroxyapatite (HA) is the most popular biomaterial for skeletal reconstructions. HA attracts considerable interest over the past two decades due to its excellent biocompatibility [1]. HA, which is the main mineral of bones and teeth, is among the leading grafting biomaterials [2]. Biological HA features several substitutions at the Ca^{2+}, PO_4^{3-}, and OH^- sites of its lattice, which also accommodates several trace elements of high importance in the biological performance of HA after implantation [3] during the osseointegration process [4]. Nevertheless, the brittleness of pure HA materials narrows their application only to low-load bearing applications, such as tooth root substitutes, filling of periodontal pockets, cystic cavities, regions adjacent to implants, spinal fusions, contour and malformation defects and nonunions of long bones [5]. Hence, the incorporation of other phases in HA matrix is indicated as a solution for expanding HA application in hard tissue biomaterials [2]. On the other hand it is well known that the incorporation of a ceramic reinforcement (i.e. fibres, whiskers, platelets or particles) in a ceramic matrix improves the mechanical properties. Nevertheless, with respect to monolitic matrix behavior, the presence of a reinforcement phase opposes somehow sintering process since a second phase is inserted in the matrix. In general, sintering is the term used to describe the consolidation of the product during firing. Consolidation implies that in the product, particles have joined together into strong aggregate. The term sintering is often interpreted to imply that shrinkage and densification have occurred [6]. It is now well recognized that the microstructure and properties of ceramics critically depend on processing routes and densification parameters [7].

HA can be produced chemically or from natural resources, such as hydrothermal converted aragonite from corals or with various methods from bones from humans or animals [8, 9]. There is no harm effect reported from HA which was prepared through chemical means [8]. Synthetic

www.springerlink.com

HA is the most frequently used, but it does not completely match the chemical composition of bone [10]. HA materials which are prepared from bovine and human resources can be very safe when all safety procedures are sufficiently followed. The latter materials are prepared by treating them with diluted HCl acid, which de-mineralizes and freeze-dries the tissues. However, some diseases can survive all controlled processes. Prions, for example, which can alter themselves into very dangerous incurable forms, can survive such processes. Calcination at high temperature can solve this possible disease transmission problem. The deadly prions can not survive calcination temperatures as high as 850ºC [8]. Moreover, sintered BHA is absolutely safe from potentially transmitted diseases like bovine spongiform encephalopathy (BSE) and others [11]. BHA features advantages namely low production costs and high safety regarding elimination of any risk of transmitting of the fatal prion diseases [3]. Furthermore, since years the mad cow disease and others were never seen in many developed countries (including Turkey that this work was performed [12-15]).

There are very few papers in the open literature reporting on the composition of sheep bone. Jan *et al.* have completed some studies about distribution of some organic pollutants in sheep dental tissue and bone [16, 17].

Bellof *et al.* have conducted a study about the major components of bone tissue as Ca 12.92%, P 4.68%, Mg 2.22%, Na 1.20%, and K 9.56% [18].

The histological appearance of the long bone cortical bone of mature sheep is similar to that of goats. In mature goats, the long bone cortical bone consists of both plexiform and Haversian bone tissue. Ribs of mature sheep also display a mixture of secondary and primary tissue, with Haversian tissue serving as a replacement for plexiform tissue. The Haversian canals within the secondary tissue are classified as medium in size and irregular in shape. Hilliar and Bell have demonstrated that differentiation of human from certain nonhuman species is possible, including small mammals exhibiting Haversian bone tissue and large mammals exhibiting plexiform bone tissue. Pig, cow, goat, sheep, horse, and water buffalo exhibit both plexiform and Haversian bone tissue and where only Haversian bone tissue exists in bone fragments, while differentiation of these species from humans is not possible. Haversian system diameter and Haversian canal diameter are the optimal diagnostic measure to use [19].

This study aims, for the first time in the literature (to the knowledge of the authors) to determine the influence of sintering temperature on densification, the development of microstructure and the mechanical properties of sheep derived HA (SHA).

II. Materials and methods

The HA powder used in this study was derived from fresh sheep bones (SHA) which, after cutting into pieces and chemical de-mineralization, was calcined at 850ºC and finally milled into fine powder, according to the method described earlier by Oktar *et al.* [20]. 120 cylindrical compacts of BHA-powder (10 samples for each set of testing conditions) were prepared by dry uni-axial pressing in a steel die, according to British Standards (height = 11 mm, diameter = 11 mm). The compacts were sintered at 1000ºC, 1100ºC, 1200ºC, and 1300ºC for 4 h in air in an electric furnace (Nabertherm HT 16/17, Lilienthal, Germany), at a heating rate of 4 K/min. After sintering, the samples were let to slowly cool down inside the furnace. Measurements of density (using the Archimedes method), Vickers microhardness (200 g load) and compression strength were carried out on the sintered samples (The presenting average values and their standard deviation have been obtained from 10 different independent measurements made with 10 different samples). Compression tests were done with a universal test apparatus (Instron 1195, USA), with a crosshead speed of 2 mm/min. Microstructural observations at fracture surfaces (after chemical etching with acetic acid) were carried out by Scanning Electron Microscope (SEM, S-4100, HITACHI, Japan).

III. Results and discussions

The high temperature of calcination during SHA production (850ºC, [20]) implies that any possible disease existing in the original bone has been completely eliminated. Furthermore, earlier reports have suggested that interesting bioceramics could be produced from high-temperature calcined BHA. This has also been confirmed by cell culture and animal studies [21].

The SEM images of Figures 1 and 2 indicate typical densification of HA ceramics, suggesting that SHA behaves as a typical HA material. In particular, the samples largely maintain the features of the initial powder compact after firing at 1000ºC, suggesting poor sintering (Fig. 1). A completely different microstructure of high density, no porosity and big grains is developed after sintering at 1300ºC (Fig. 2). There is no evidence of glassy phase formation at large extent, which may cause brittleness of the material. Table 1 summarizes the experimental results of density, compression strength and Vickers microhardness of the SHA samples sintered at the four investigated temperatures. The results agree fairly well to the SEM images of Figures 1 and 2 since the denser samples were obtained after sintering at

the highest tested temperatures. Moreover, the denser samples exhibited the higher values of mechanical temperatures.

For comparison purposes, results reported in earlier studies [21-23] for bovine derived HA (BHA) materials sintered at the same temperatures are presented in the Tables 2 and 3. Similar results, where BHA was reinforced with 5% and 10% addition of commercial inert glasses (CIG), are also presented in the Tables 4 and 5, respectively [24].

1300	2.72	60	145

Table 4 Density, compressions strength and Vickers microhardness of composites made of bone derived hydroxyapatite (BHA) matrix and reinforced with 5% additives of commercial inert glasses (CIG) reported in Ref. 24.

T (°C)	d (gr/cm^3)	σ (MPa)	$HV_{0.2}$
1000	2.52	48.3	98
1100	2.42	43.9	149
1200	2.48	67.6	202
1300	2.63	104.8	227

Table 5 Density, compressions strength and Vickers microhardness of composites made of bone derived hydroxyapatite (BHA) matrix and reinforced with 10% additives of commercial inert glasses (CIG) reported in Ref. 24.

T (°C)	d (gr/cm^3)	σ (MPa)	$HV_{0.2}$
1000	2.40	64.0	54
1100	2.41	77.0	135
1200	2.55	133.0	506
1300	1.77	6.9	307

The comparison of the results of the present study (Table 1) with the values of the Tables 2 and 3 suggests that SHA exhibited superior compression strength than the BHA materials. Similar conclusions are suggested for the microhardness as well.

From our reported earlier experience at reinforcing HA matrices, the addition of commercial inert glasses (GIC, 5% and 10%) in BHA resulted in composites with the best values of mechanical properties that we had ever measured (Tables 4 and 5 [23, 24]). Accordingly, the results of the

present study with SHA are even better than values obtained via the concept of producing composite materials. Moreover, SHA completely eliminates the addition of other phases, which may complex sintering processing and also may both jeopardize the biocompatibility of the resultant material and produce fragile phases due to the reaction between HA and the reinforcing phase.

IV. Conclusions

The results of this study indicate SHA as a very promising HA type of biological origin for producing biomaterials that may be successfully bear high loads. The highly dense and homogenous microstructure obtained after sintering at 1200°C and 1300°C resulted in superior values of compression strength and hardness, better even from values obtained by reinforced HA-composites.

Acknowledgments

This study was carried out with the financial support of the Turkish Republic Government Planning Organization in the framework of the Project "Manufacturing and Characterization of Electro-Conductive Bioceramics" (No 2003 K120810). Flow Induced Turbulent Stress Accumulation in Differently Designed Contemporary Bi-leaflet Mitral valves: Dynamic PIV Study

T. Akutsu[1], and X.D. Cao[2]

[1] Dept. of Mech. Eng., Kanto Gakuin Univ., Yokohama, Japan
[2] Graduate School of Engineering, Kanto Gakuin Univ., Yokohama, Japan

Abstract — **Fluid stresses and duration of it on the blood component are considered influential to the cause of hemolysis, thromboembolic complications, and platelet activation. This experimental study was conducted to analyze the accumulated turbulent stresses generated by the differently designed prosthetic heart valves using Dynamic PIV system. Four bi-leaflet valves, the St. Jude Medical (SJM) and the On-X (OX) valves with straight leaflets and the Jyros (JR) and the MIRA (MIRA) valves with curved leaflets were used in the mitral position under pulsatile-flow condition. Dynamic PIV system was employed to trace the particular particle simulating blood element and to analyze the accumulated turbulent stresses on the particular particle by analyzing the time-resolved flow fields affected by the leaflet shapes, valve designs.**

Keywords — **Dynamic PIV, Bi-leaflet valves, Stress accumulation**

I. Introduction

Fluid stresses and duration of it on the blood component are considered influential to the cause of hemolysis, thromboembolic complications, and platelet activation. Experimental study was conducted to analyze the accumulated turbulent stresses generated by the differently designed prosthetic heart valves using Dynamic PIV system.

II. Models and Method

The study was carried out using a cardiac simulator [1] in conjunction with a high-speed (1000 frames/s) and high resolution (1024x1024) Dynamic PIV system for the mapping of the time resolved velocity and the turbulent stress distribution inside the simulated ventricle (Fig.1). Operating condition was simulating normal adult at resting condition: 120/80 mmHg at 72BPM. Saline solution was used as working fluid. Operating waveforms were the sinusoidal waveform.

Four bi-leaflet valves (Fig.2), the St. Jude Medical (SJM) and the On-X (OX) valves with straight leaflets and the Jyros (JR) and the MIRA (MIRA) valves with curved leaflets were tested in the mitral position under pulsatile-flow condition. Dynamic PIV system was used to trace the movement of the fluid particle and investigate the influence of the valve design differences of each valve on the accumulated turbulent stresses for traced particles using Dynamic PIV system.

www.springerlink.com

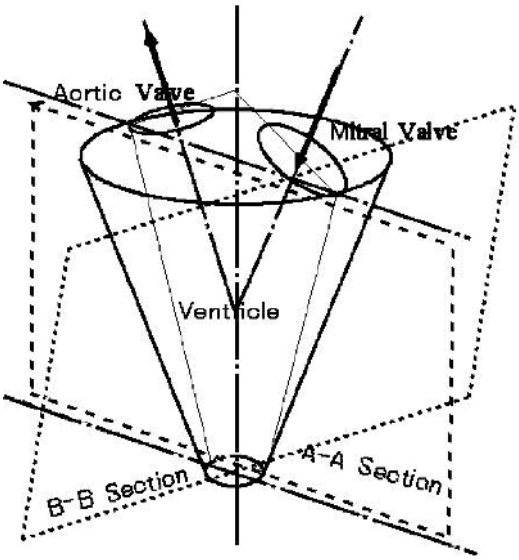

Figure 3 Two slit light sheet locations used for measuring velocity field

Since the flow inside the ventricle is three-dimensional in nature, two vertical planes were selected for PIV measurement (Fig.3). One measuring plane which passes through the centers of the aortic and the mitral valves (A-A section). The other measuring plane is normal to the previous plane and directly downstream of the mitral valve (B-B section).

III. Results and discussion

All valves showed distinct sideway flows immediately after the valve was opened, however, timing of the opening and degree of flow deflection differed widely among different designs. Noticeable differences on the three-dimensional flow were observed during the opening and accelerating flow phase of the valve (Fig.4). Straight leaflet of the OX valve did not deflect the flow when it fully opened, while curved leaflet of the JR and the MIRA valves deflected the flow sideway even the valve was fully opened. The OX and the MIRA valves open quickly and utilize central orifice more effectively than older designs. On the A-A section, flow near the ventricle wall (right flow on Fig. 5) tends to show higher accumulated stress level (Table 1). Because of these characteristic differences, the JR and the MIRA valves with curved leaflet on the B-B section tend to show higher accumulated stress at peripheral area (right flow on the Fig. 6), while the SJM and the OX valves with straight leaflet tend to show higher accumulated stress at more central area (Table 2). Newer valves also showed higher accumulated stress level.

Table 1 Averaged stress values for the SJM, the JR, the OX, and the MIRA valves: during period between accelerating to peak flow phase anti-anatomical orientation, A-A section

	Left flow stress (Pa)	Center flow stress (Pa)	Right flow stress (Pa)
SJM valve	1.63	3.722	5.887
JR valve	0.798	1.870	5.973
OX valve	6.492	5.839	9.887
MIRA valve	3.117	4.058	2.196

Table 2 Averaged stress values for the SJM, the JR, the OX, and the MIRA valves: during period between accelerating to peak flow phase anti-anatomical orientation, B-B section

	Right center flow stress (Pa)	Right mind flow Stress (Pa)	Right flow stress (Pa)
SJM valve	7.742	9.641	2.040
JR valve	7.004	3.448	16.407
OX valve	7.903	19.244	10.871
MIRA valve	7.249	15.306	21.394

IV. Conclusions

Newer designs open quickly and utilize central orifice more effectively than older designs but also showed higher accumulated stress level.

Abstract — **We report a collagen based fibrous scaffold for the encapsulation and seeding of human mesenchymal stem cells. The scaffold was fabricated through interfacial polyelectrolyte complexation (IPC) of an anionic synthetic terpolymer and a cationic methylated collagen in aqueous conditions. The collagen in the fibers was labeled with quantum dots and was found to be evenly distributed in each fiber strand. Encapsulating human mesenchymal stem cells (hMSCs) into these collagen based fibers and maintaining the viability are steps towards the creation of a biofunctionalised scaffold and the existing problems of the lack of cell infiltration in scaffolds and effective nutrient/waste exchange can be overcome. This cell encapsulation in scaffolds technique is simple and least toxic compared to existing fabrication techniques. hMSCs were seeded onto the fibrous scaffold and compared with hMSCs encapsulated within the scaffold. The cytoskeletal organization of seeded hMSCs and encapsulated hMSCs were different and the results were correlated to the gene expressions of both samples.**

Keywords — **Stem Cell, Cell Encapsulation, Polyelectrolyte Complex Fibers, Collagen, Biomimetic Scaffold**

I. Introduction

Tissue development requires the effective infiltration of cells into the scaffolds and typically, seeded cells migrate into the scaffold by either displacing individual scaffolding fibers or digesting them, both of which require extended culture period and appropriate chemotactic factors present within the scaffold [1,2]. Cell infiltration into scaffolds becomes hindered significantly when scaffold thickness increases and pore size decreases. To address this problem, various strategies [3-9] have been proposed and they are based on a common hypothesis: that scaffolds embedded with cells in a controlled spatial distribution can address the current problem of limited cell infiltration and achieve a highly cellularized tissue construct. Despite making significant progress, the said processes are often complex and detrimental to cell viability and therefore, a simpler and milder cell encapsulation technique is desirable.

We introduce a new fiber forming technique, interfacial polyelectrolyte complexation (IPC) [10-12] where stable fibers can be produced at the interface of oppositely charged polyelectrolytes. The polyelectrolyte complex (PEC) fibers are produced in room temperature and aqueous medium and thus, cells can be encapsulated into the newly formed PEC fibers easily without compromising its viability. Here, we study the complexation of a cationic methylated collagen with an anionic terpolymer to produce a hybrid fibrous scaffold that might possess the favourable biological properties of collagen and the tunable physical properties of a synthetic polymer. hMSCs were encapsulated into the PEC fibers and cultured in proliferation medium and the cytoskeletal organization and gene expressions of the encapsulated hMSCs were studied.

II. Materials and methods

Materials: Methyl methacrylate (MMA), hydroxyethyl methacrylate (HEMA) and methacrylic acid (MAA) monomers and 2,2'-Azobisisobutyronitrile (AIBN) were purchased from Sigma-Aldrich Chemicals Ltd. (Singapore). The monomers were purified by vacuum distillation and AIBN was recrystallized in ethanol before use. Collagen Type I (Nutragen, 100mL) was purchased from Nutacon Netherlands. hMSCs were purchased from Cambrex (Poietics; Lonza, Switerzland), cultured and expanded in mesenchymal stem cell growth medium (MSCGM^{TM}). The cells used in the experiments were between passages 4 and 7.

Terpolymer synthesis: The terpolymer was synthesized as described [12]. Briefly, MMA, HEMA and MAA monomers were charged into a 250mL round bottom flask at a molar ratio of 25:25:50 with 0.25 wt% of AIBN as an initiator. The reaction mixture was immersed in a hot silicone oil bath for a 24 hour polymerization process. The terpolymer was precipitated and vacuum dried before it was dissolved in 1M NaOH and dialyzed against deionized water.

Collagen Methylation: 15 mL of collagen was precipitated in 400 mL of acetone and redissolved in 200 mL of methanol containing 0.1 M HCl. The mixture was stirred for

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1279–1281, 2009
www.springerlink.com

2 days at room temperature before it was dialyzed against deionised water (Spectrapor MWCO = 3,500) until the external reservoir reached a pH of 5.5. The methylated collagen was lyophilized and stored at -80°C before use.

Encapsulating hMSCs into PEC Fibers: hMSCs were encapsulated in PEC fibers as described in [12]. Briefly, 3 X 10^5 cells/mL of cell suspension in collagen were used to produce a hMSC-encapsulated fiber (see Fig. 1) and the fibers were collected and cultured in a 6 well Transwell plate and incubated at 37°C with 5% CO_2.

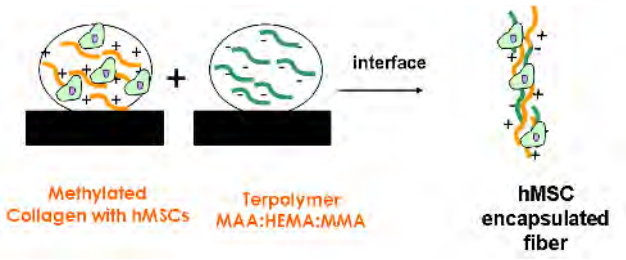

Figure 1: Schematic diagram of cell encapsulation in PEC fiber

Immunofluorescence Staining: PEC fibers encapsulated with hMSCs were fixed and stained with TRITC phalloidin and DAPI before viewing with a confocal microscope.

Gene expression studies: The samples were stabilized with RNAlater RNA stabilization reagent (Qiagen, Singapore) and homogenized with QIAshredder. The RNA was isolated with RNeasy Minikit. Synthesis and amplification of cDNA were carried out with Qiagen One-Step RT-PCR with primers (designed in-house) at an annealing temperature of 60°C for 33 cycles. The PCR products were resolved in 1.2% agarose gel.

III. Results

The (MMA-HEMA-MAA) terpolymer was converted to an anionic polyelectrolyte with the addition of NaOH at the end of the polymerization reaction. The conversion of the sodium carboxylic acid functional groups in MAA to a sodium salt gave the terpolymer a net negative charge at neutral pH. Native collagen proteins were methylated to produce a cationic polyelectrolyte at neutral pH. PEC fiber was formed upon charge neutralization at the interface of the oppositely charged polyelectrolytes and a pair of tweezers was used to draw the PEC fiber up from the interface.

Collagen distribution in PEC fibers: The collagen present in the PEC fibers were labeled with quantum dot 605 nm (Invitrogen) as shown in Fig. 2. The results showed uniform distribution of collagen in the main fiber.

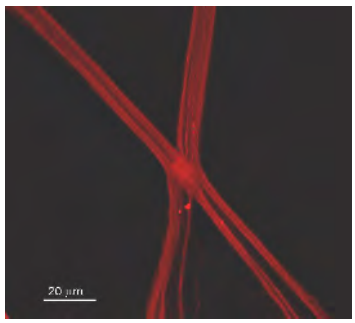

Figure 2: Quantum dot labeling of collagen in PEC fibers

Cytoskeletal Organization and Gene Expressions of Encapsulated hMSCs: To observe the cytoskeletal changes and the resulting gene expressions in encapsulated hMSCs, hMSCs were seeded onto PEC fibers and hMSCs cultured on TCPS (hMSC control) were used for comparison. hMSCs encapsulated in PEC fibers were mostly elliptical and they were observed in different z planes of the scaffold. hMSCs seeded onto the PEC fibers were elongated and found to extend along the fiber axis. The gene expressions showed upregulation of Noggin in both hMSC-encap and hMSC-seeded samples and MAP2 gene in hMSC seeded samples by 14 days.

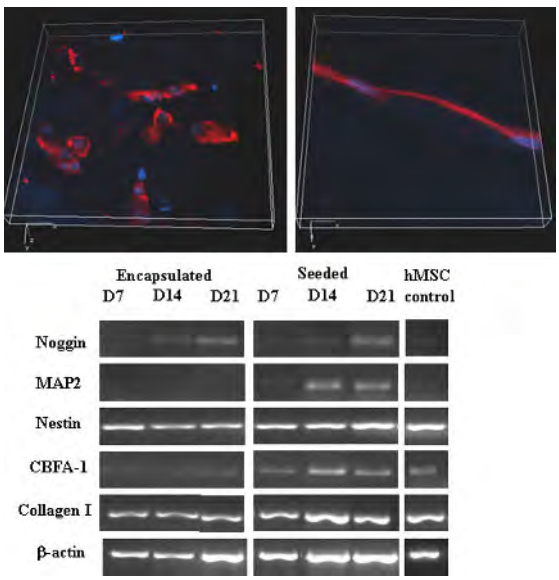

Figure 3: F-Actin/DAPI labeling of encapsulated and seeded cells and the respective gene expressions between day 7 to day 21 of culture

IV. Discussion

The PEC fibers used in this study are a hybrid of synthetic and natural polymers and its inception was based on the desire to produce a fibrous material that has the complementary properties of both polymer types. The process in which such fibers were produced was carried out in aqueous conditions, thus giving PEC fibers additional advantage where biological incorporation into scaffolds is of interest. The uniform collagen distribution in PEC fibers has been verified by immunofluorescence labeling and the mechanical properties of these fibers have been shown to be superior to native collagen fibers and alginate-chitosan PEC fibers [12].

Encapsulated and seeded hMSCs maintained the early markers of chondrogenesis, osteogenesis, adipogenesis and neurogenesis, suggesting that hMSCs when conformed to different morphologies in our PEC fibers did not undergo spontaneous differentiation and maintained its pluripotency for at least 7 days.

MAP2 was downregulated in encapsulated hMSCs and upregulated in seeded hMSCs and this observation could be explained by the elongation of seeded cells along the PEC fibers which could have determined, stabilized the dendritic shape of cells [13] and signaled the expression of this gene. MAP 2 is a dendrite-specific microtubule-associated protein found specifically in dendritic branching neurons [14] and was thought to be involved in microtubule assembly which is an essential step in neurogenesis.

V. Conclusions

The PEC fibers have been shown to support the encapsulation of cells and where mesenchymal stem cells are concerned, the multipotency is maintained at least for the first 7 days of culture despite being conformed to different morphologies. Changes in neuronal gene expressions were observed from 14 days of culture. Fabrication of cell-encapsulated fibers allows the 3D patterning of cells within a matrix and this is a first step towards the creation of a complex biological construct.

Abstract — **Fibers produced from plant proteins such as zein, soyprotein and wheat gluten, glutenin and gliadin have good mechanical properties, excellent water stability and biocompatibility that make them suitable for tissue engineering and other medical applications. Although animal proteins such as collagen are used for medical applications, materials developed from collagen do not have the properties desired for tissue engineering applications. Materials developed from collagen have poor wet strength and also have the risk of carrying diseases. The plant protein fibers developed in our laboratory have better water stability than PLA and collagen fibers in water and films developed from wheat gluten, gliadin and glutenin without using any crosslinking agents have strength, water stability and biocompatibility required for medical applications. The plant protein fibers developed were characterized for their morphological and physical structures, mechanical properties and stability under various physiological conditions. Different types of animal cells were cultured on the fibers and the cytocompatibility and attachment, growth and proliferation of cells on the fibers was studied. It was found that plant proteins fibers supported the attachment, growth and proliferation of animal cells and the fibers were stable in pH 7.2 water for at least 30 days. Some of the plant proteins show better cell attachment and proliferation than PLA. In this paper, we will present the properties and potential of using various plant protein fibers for tissue engineering and other medical applications.**

Keywords — **Plant proteins, Fibers, Tensile Properties, Tissue engineering**

I. Introduction

Proteins are preferred for medical applications due to their biocompatibility, ability to support the attachment, growth and proliferation of cells and presence of various functional groups that facilitate the absorption of different types of drugs for controlled drug release [1]. Collagen and silk fibroin are the two most commonly used proteins for medical applications. However, both collagen and silk have several limitations that limit their use in tissue engineering and other medical applications [1]. Collagen is mostly derived from animal sources and carries the risk of contamination by prions and viruses [1]. In addition, it is difficult to obtain collagen with consistent properties, cannot be autoclaved and products made from collagen have poor mechanical properties when wet [2,3]. Silk fibroin needs to be separated from sericin, has long degradation rates that make it unsuitable for some applications and it has been recently discovered that fibroin can cause amyloidosis, a chronic inflammatory reaction [4].

Compared to collagen and silk, plant proteins such as zein, soyproteins and wheat gluten are abundant and inexpensive proteins that can be made into fibers and films with properties suitable for tissue engineering and other medical applications. However, limited studies have been conducted on understanding the potential of using plant proteins for medical applications. So far, zein and soyproteins have been made into films and used as substrates for tissue engineering [5,6]. It has been reported that zein and soyproteins are biocompatible proteins and have good potential for tissue engineering [5, 6]. Recently, we have reported that fibers made from wheat gliadin are suitable for tissue engineering applications [7].

Fibers are more preferable for tissue engineering applications because fibers are stronger than films, more closely imitate the structure of the extracellular matrix and can guide tissue regeneration. Except for gliadin fibers, the potential of using the other plant proteins for tissue engineering applications has not been studied.

This paper presents an overview of the potential of using plant proteins for tissue engineering applications. Zein, soyproteins, wheat gluten and gliadin have been made into fibers and the properties of the fibers developed and the ability of the fibers to support cell attachment, growth and proliferation has been studied.

II. Materials and Methods

Materials

Zein (F4000) was purchased from Freeman Industries, Tuckahoe, NY. Soyproteins (Profam) were supplied by Cargill Inc and Wheat gluten (WHETPRO 80) was supplied by Archer Daniels Midlands Company.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1282–1284, 2009
www.springerlink.com

Methods

Fiber production: Zein fibers were produced by dry spinning according to the method previously described [8]. Briefly, the required concentration of zein was dissolved in 70% aqueous ethanol and the solution was aged for a particular time. The zein solution was then extruded onto a rotating drum. Fibers formed were collected on the drum after evaporating the ethanol. Soyproteins, wheat gluten and gliadin were dissolved in aqueous urea solution in the presence of sodium sulfite as the reducing agent. The protein solution was aged and later extruded into a coagulation bath consisting of acids and salt solutions. The precipitated fibers were washed several times and water and later dried [7,9].

Drawing and Annealing: The fibers produced were drawn by hand to about 200 to 300% of their original length by dipping the fibers in water. The drawn fibers were later annealed at 125 °C for about 90 minutes. Drawing and annealing were done to improve the mechanical properties of the fibers.

Tensile Properties: The breaking tenacity, breaking elongation and Young's modulus of the fibers was determined using an Instron tensile testing machine according to ASTM standard 3822. A gauge length of 1 inch and crosshead speed of 18 mm/min was used for testing.

Water stability: The stability of the wheat gluten, gliadin and soyprotein fibers was studied in water at various temperatures and physiological conditions. Fibers were dipped in pH 7.2 PBS solution at 50 °C for several days. The strength loss of the fibers in water was compared to the untreated fibers and to PLA fibers. The stability of the fibers was also tested in pH 3 to 11 solutions at 50 °C and the strength loss was determined.

Cell culture: Mouse fibroblasts cells were used to study the potential of using the wheat protein fibers for tissue engineering. The fibrous substrates were placed on the bottom of a 12, 24 or 48 well culture plates ensuring that the bottom of the plates are completely covered. Cells with passage numbers less than 20 were be seeded on the substrates at concentrations of about 1.2 x10^5 cells/ml in Dulbecco's Modified Eagles Media (DMEM) containing 10% (w/w) fetal bovine or calf serum, 3-5% L-glutamine and 1% (w/w) penicillin-streptomycin. The initial concentration of the cells will be determined by counting using a hemacytometer and also by measuring the optical density (OD). The culture plates were then incubated at 37 °C and 5 % CO_2 for the required time.

SEM analysis: The attachment and proliferation of the cells on the protein fibers was observed using a SEM. The cells after the desired duration of growth on the fibers were fixed using glutaraldehyde (2.5% in PBS) and later with osmium tetroxide. After fixation, the substrates were rinsed several times in PBS and then with deionized water and later dehydrated by successively washing with 50, 75, 95 and 100% ethanol. The samples were later dried using critical point drying, coated with gold palladium and then observed under the SEM.

III. Results and discussions

Tensile properties: The tensile properties of the plant protein fibers are compared with collagen and wool in Table 1. As seen from the table, the plant protein fibers have similar strength and elongation to wool fibers. The dry strength of the plant protein and wool fibers is lower than that of collagen. However, the wet strength of collagen is very low. Both gliadin and gluten fibers have good wet strength, similar to the wet strength of the crosslinked collagen fibers. The wet strength of the plant protein fibers can also be increased by crosslinking. Except for zein fibers, the other plant protein fibers have breaking elongation and Young's modulus similar to that of wool.

Table 1 comparison of the tensile properties of the plant protein fibers with wool and collagen

Fiber	Breaking Tenacity, MPa		Breaking Elongation, %	Modulus, GPa
	Dry	Wet		
Gliadin	120 ± 10	23 ± 3	25 ± 3.2	4.2 ± 0.4
Wheat gluten	115 ± 7	17 ± 2	23 ± 2.7	5 ± 0.2
Zein	36-60	-	1.8-5.0	-
Wool	174-260	-	30-40	4.3-6.5
Collagen	224 ± 19	2.4	24	-
Collagen (Crosslinked)	175-197	17-24	15-18	1.7-2.0

Water stability: Wheat gluten and gliadin fibers have better stability in water than PLA fibers in pH 7 water at 50 °C as seen from Figure 1. The gliadin fibers show a increase in strength after treating in water whereas the wheat gluten fibers show a steady decline in strength up to 7 days and the strength loss later stabilizes. The gliadin fibers show no loss in strength even after being in water for 40 days. The PLA fibers show continuous decrease in strength and were very brittle and could not be tested after 20 days in water. The plant protein fibers were also found to have good stability when treated in pH 3 to 9 water at 90 °C for 1 hour.

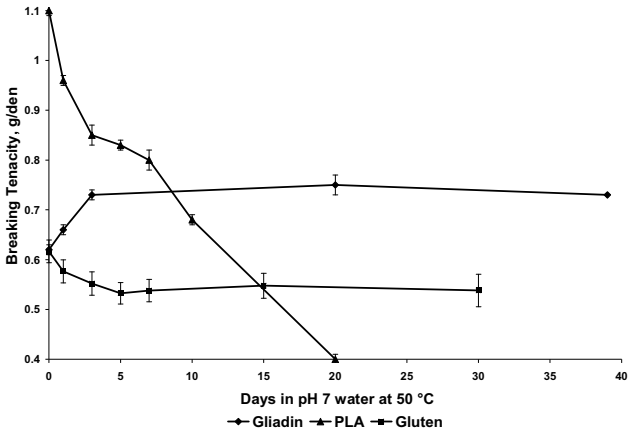

Figure 1 Changes in the breaking tenacity of wheat gluten, gliadin and PLA fibers after treating in pH 7 water at 50 °C for various periods of time.

Figure 2 Mouse fibroblasts showing attachment, growth and spreading on soyprotein fibers, five days after incubation

Cell growth and proliferation: Fibroblasts grown on soyprotein fibers showed good attachment, growth and proliferation. Figure 2 shows an SEM image of mouse fibroblasts grown on soyprotein fibers, five days after seeding. As seen from the figure, the cells have polygonal shapes, are firmly attached and the spreading of the filaments can also be seen. This demonstrates that the soyprotein surface is conducive for cell attachment, growth and proliferation.

IV. Conclusions

Our research demonstrates that plant proteins can be made into fibers with better wet mechanical properties than collagen fibers and better water stability than PLA fibers. The fibers made are conducive for cell attachment, growth and proliferation. Plant proteins could be novel biomaterials suitable for tissue engineering, drug delivery and other medical applications.

Comparison the Effects of BMP-4 and BMP-7 on Articular Cartilage Repair with Bone Marrow Mesenchymal Stem Cells

Yang Zi Jiang[1], Yi Ying Qi[1], Xiao Hui Zou[1], Lin-Lin Wang[1], Hong-Wei Ouyang[1,2 *]

[1] Center for stem cells and issue Engineering, School of Medicine, Zhejiang University; China
[2] Department of Orthopaedic Surgery, Sir Run Run Shaw Hospital, School of Medicine, Zhejiang University; China

Abstract — **To compare the potential effects of bone morphogenetic proteins 4 and 7 (BMP-4 and BMP-7) on the chondrogenic differentiation of mesenchymal stem cells(MSCs) for articular cartilage regeneration in vitro and in vivo.**

In the in-vitro experiment, MSCs were derived from bone marrow. The chondrogenic effects of BMP-4 and BMP-7 were compared at the gene expression level. In the in-vivo experiment, full-thickness cartilage defects (diameter = 4 mm, thickness =3 mm) in the patellar grooves of male New Zealand white rabbits were chosen as model of in-situ cartilage repair. MSCs were treated with BMP4(group II) / BMP7 (group III) in a bilayer collagen scaffold (n=11/group). Full-thickness cartilage defects without treatment was regarded as a control (group I) (n=11). The rabbits were sacrificed at 6 and 12 weeks after operation. The repaired tissues were processed for histology and for mechanical test.

In-vitro study showed increased expression levels of cartilage-related genes after MSCs were treated with BMP4 or BMP7 in culture medium. In-vivo study showed both BMP4 and BMP7 group increased new cartilage formation at 6 and 12 weeks than that of control group. BMP4 group had the largest amounts of cartilage tissue, which restored larger surface area of the cartilage defects. Moreover, BMP4 group had higher ICRS histological scores and more type II collagen in the neo-cartilage matrix than those in other two groups ($p<0.05$). The Young's modulus of the repaired tissue in group III can reach 30% of normal hyaline cartilage tissue, which were significantly higher than group II and group I ($p<0.05$).

Our data indicate that both BMP4 and BMP7 may induce MSCs chondrogenesis and increase the expression of cartilage-related genes. BMP-4 is more potent than BM7 in inducing chondrogenesis, and more inclined to form the hyaline cartilage in vivo.

I. Introduction

Articular cartilage is lack of self-repair capability due to lack of blood supply and limited innervationits vasul less. When damaged and if the defect size was larger than two to four millimeters in diameter, it rarely healed if leave untreated [1]. Unhealed articular cartilage lesions can induce mechanical instability of the joint and often lead to osteoarthritis further [2].Current therapies include microfracture[3], abrasion, drilling[4], osteochondral grafting[5] and autologous chondrocyte implantation (ACI) [6]. Because of the capacity for self-renewal , the potential for multidifferentiation, and their accessibility, mesenchymal stem cells (MSCs) become an attractive option in tissue-engineering approaches to cartilage repair.

Growth factors are very important for bMSCs and chondrocytes proliferation and differentiation, which can be used to improve the quality of cartilage repair. Previours study show that several growth factors, including transforming growth factor b (TGFb), bone morphogenetic proteins (BMPs) and basic fibroblast growth factor (bFGF) can promote chondrocyte proliferation and extracellular matrix (ECM) synthesis in vitro and in vivo [7–10].Studies performed in vitro and in the developing skeleton have led to the identification of bone morphogenetic proteins 4 (BMP-4) as a promising candidate for the promotion of chondrogenesis [11–13]. Previous researches reported that local delivery of BMP4 gene at joint cartilage defect not only enhance the regeneration of subchondral bone but also induce the regen-eration of hyaline-like cartilage in as short a period as 6 weeks [14].BMP7 as a growth factors were used as a osteogeneration in clinical and adipolineage differentia-tion[15] ,has also shows a great effect of the potential for chondrolineage differentiation[14] . However, no evidence is available to correlate those findings and chose optimal BMPs for cartilage repair and regeneration.

This study aimed to compare the efficacy of BMP4 and BMP7 for cartilage regeneration on an established animal cartilage repair model. The findings might be useful for the choice of BMPs for enhancing the therapeutic efficacy of microfracture on articular cartilage repair.

II. Materials and methods

Cell culture: Isolation of rabbit marrow MSCs and differentiation assay in vitro. MSCs were derived from bone marrowaspirates of 4-week rabbit taken from the distal femur. Each aspirate was combined with 25 ml of MSCs

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1285–1288, 2009
www.springerlink.com

growth medium consisting of 89% DMEM–low glucose (Gibco BRL/Life Technologies Inc., Gathersburg,MD), 10% fetal bovine serum (HyClone Laboratories, Inc., Logan, UT) and 1%antibiotic and 1% antimycotic (Gibco). Growth medium was changed every two days. To characterize the pluripotential of MSCs, we induced MSCs towards adipocytes, chondrocytes and osteoblasts formation(data not shown).

BMP4(Stemcell.) and BMP7(Stem cell.) were add into the culture medium at the concentration of 10ng/ml to test the effect of chondrogenesis of MSC.

RNA Isolation and RT-PCR: Total cellular RNA was isolated by lysis in TRIZOL (Invitrogen) followed by one-step phenol chloroform- isoamyl alcohol extraction as described in protocol. 200 nanogram of total RNA was reverse-transcribed into complementary DNA (cDNA) by incubation with 200 U of reverse transcriptase in 20 μL of reaction buffer at 37 centi-degree for 1h. One microliters of the cDNA was used as a template for the PCR. Semi-quantities RT-PCR of the Collagen I, III, decorin and GAPDH was proceeded as previous described [17]. The semiquantitative measurement of the band density was calculated by using Glyko Bandscan (Glyko, Inc., USA). The band intensity was normalized to the band intensity of GAPDH in the same sample. The results were repeated for 3 times. The following 5′ and 3′ primers (listed respectively) were used to evaluate gene expression: collagenII, ATGGACATTGGAGGGCCTGA, and TGTTTGACACGGAGTAGCACCA; Sox9, GGTGCTCAAGGGCTACGACT, and GGGTGGTCTTTCTTGTGCTG; collagen X,GAAAACCAGGCTATGGAACC,and GCTCCTGTAAGTCCCTGTTGTC and; GAPDH, TCACCATCTTCCAGGAGCGA and CACAATGCCGAAGTGGTCGT.

Animal model: Thirty-eight knee joints of male New Zealand White Rabbits (2-2.5 kg) were used in this study. Rabbits were maintained separately in stainless-steel cages. The rabbits were anesthetized by an intramuscular injection. The knee joints were opened with a medial parapatellar approach. The patella was dislocated laterally and the surface of the femoropatellar groove was exposed. A full-thickness cylindrical cartilage defect of 4 mm in diameter and 3 mm in depth was created in the patellar groove using a stainless-steel punch. The defects were either untreated (group I, n=11) or treated with MSC in a bilayer collagen matrix with BMP4(250ng/ml) (group II, n=11), and MSC in a bilayer collagen matrix with BMP7(250ng/ml) (group III, n=11). Sample and time point was arraged as Table.1 shown.

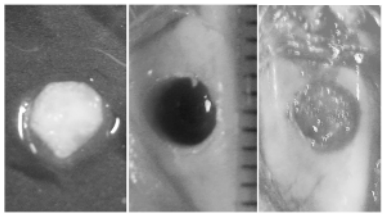

Fig. 1. Animal model of cartilage defect.The MSC were seeding on the collagen scaffold,and implanted into a Afull-thickness cylindrical cartilage defect which was 4 mm in diameter and 3 mm in depth.

All the animals were operated according to the standard guidelines approved by Zhejiang University Ethics Committee.

Table 1 Animal experiment, Samples(N=)

Time points	Normal control	Control group	BMP4 group	BMP7 group
6w		3	3	3
12w	5	8	8	8

Gross morphology and histology: At 6 and 12 weeks post-surgery, the rabbits were sacrificed by intravenous overdose of pentobarbital. The harvested samples were examined and photographed for evaluation. After gross examination, samples were fixed in 4% formalin, decalcified in 10% formic acid, then embedded in paraffin and cut to 7μm thick sections. Sections were stained with Safranine-O for GAG distribution. According to the area of positive Safranine-O staining, the percentage of cartilage tissue in the area of defect was calculated. For the overall evaluation of the regenerated tissue in the defects, the repaired tissues were graded using the International Cartilage Repair Society (ICRS) Visual Hisological Assessment Scale by one blinded observer according to the strategy of previous study [16].

*Mechanical evaluation:*Mechanical evaluation protocol was adopted from previous study [10]. Before testing, samples were placed in Phosphate Buffered Saline (PBS) at room temperature for 3-4 hours to equilibrate. Compressive mechanical properties of the cartilage layer after a long-term (12 weeks, n=5 samples) period in vivo were determined using a 2 mm diameter cylindrical-shaped indenter to compressively load the cartilage tissue in Instron Testing machine (model 5543, Instron, Canton, MA).

Statistical analysis: Histological scoring data and biomechanical test data were assessed for statistical differences using a paired t-test to compare experimental characteristics to control.

III. Results

A. Chondrogenic effects of BMP-4 and BMP-7 on MSC at the gene expression level

Add BMP4 and BMP7 in to the MSC culture medium for three days ,test the gene exprssion level of chondrogenesis. The chondrogenesis marker gene type II collagen,Aggrecan and Sox9 show a positive expression after three days treated with BMP4 and BMP7.

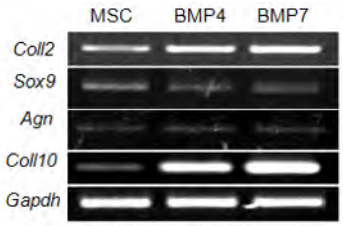

Fig. 2. RT-PCR analysis of collagen II, SOX9,Aggrecan,collagenX gene expressions of MSCs treated with BMP4 and BMP7 for 3days.Col II: collagen II,Sox9:Sox9; AGN:aggrecan;Coll X: collagen X.

B. Gross morphology

The gross examinations of knee joints showed that there were no abrasions on the opposing articulating surfaces and no inflammation at both 6 and 12 weeks time point. (Fig.3)The defects remained empty in small parts at 6 weeks after transplantation

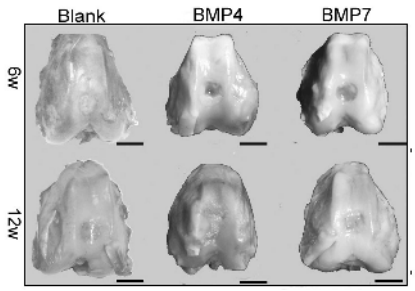

Fig. 3. Animal model of cartilage defect.The MSC were seeding on the collagen scaffold,and implanted into a Afull-thickness cylindrical cartilage defect which was 4 mm in diameter and 3 mm in depth.

C. Results of Histological examination and ICRS

At 6 weeks after transplantation, the defects in group I (n=3) were filled with fibrous tissue (Figure 4.). In group II (n=3) and group III (n=3), the defects were repaired with mixture of fibrous tissue and cartilage-like tissue as shown by Safarnine-O staining. The amounts of chondrocyte-like cells and cartilage-like extracellular matrix in group II were more than those of group III as observed (Figure 4,6w,BMP4,BMP7). At 12 weeks after transplantation, the defects in group I (n=3) were almost filled with fibrous tissue and a little cartilage-like tissue at the margins of the defects (Figure 4,12w,Control). Group III had lager amounts of hyaline cartilage (Figure4,12w,BMP7). Group II has the largest amounts of hyaline cartilage tissue(Figure4,12w,BMP4). The total ICRS histological scores of the specimens at 6 and 12 weeks revealed differences between the three groups. The scores for the repaired tissue of group II were significantly higher than those for other two groups ($p < 0.05$). The histological scores of the specimens at 12 weeks were higher than those of specimens at 6 weeks.

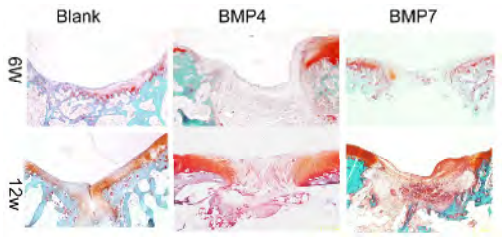

Fig. 4. Histological examination of the three groups at 6 weeks and 12weeks post-surgery.Left is the microfracture group .Middle are the microfracture with MSC and BMP4 in collagen matrix group. Right is the microfracture with MSC and BMP7 in collagen matrix group. Safranine-O staining. Original magnification 40x. Scale is as indicated (bar=500 micrometer).

D. Results of Biomechanical evaluation

The From the indentation test, the Young's modulus of repaired tissues from the three groups (12 weeks) were determined and compared with each other while the tissues from normal rabbit knee joint were used as normal control. At 12 weeks, the compressive modulus of the repaired tissue in group II and group III samples showed greater improvement compared with specimens from group I ($p<0.05$). However, the modulus of repaired tissue in both group II and group III was inferior to that of normal cartilage (0.52 +/- 0.01Mpa) ($p< 0.05$).The Young's modulus of the repaired tissue in group III can reach 30% of normal hyaline cartilage tissue, which were significantly higher than group II and group I ($p<0.05$).

IV. Discussion and Conclusions

Our data indicate that both BMP4 and BMP7 are able to induce MSCs chondrogenesis and increase the expression of cartilage-related genes. This finding is consistent with previous studies [18]. More importantly, it was found that

BMP-4 is more potent than BM7 in inducing chondrogenesis, and more inclined to form the hyaline cartilage in vivo.

Previous study reported that BMP7 significantly inhibited Runx2 expression,and activated UCP gene expression-whereas BMP4 had no effect[15].

Cellular responses to BMPs have been shown to be mediated by the formation of a hetero-oligomeric complex of the type 1 and type 2 BMPs.BMP-4 and BMP-7 bind to the same type II receptors (BMP type II receptor/activin type IIA receptor) and to several common type I receptors ALK-3 and ALK-6. BMP7 binds to different type I receptors ALK-2 [19]. We speculate that the similarity of the chondrogenic responses induced byBMP-4 and BMP-7 reflects the commonality of their receptors ALK3,6, and that the different responses elicited by BMP-7 bespeak the occupation and activation of another set of receptors ALK-2 and the triggering of an alternative signaling pathway.

In summary, we have demonstrated that BMP-4 and BMP-7manifest different potentials for the chondrogenic differentiation of MSCs and induce the formation of cartilaginous tissue with different characteristics. The findings are useful for future application of BMP for cartilage repair. It is of worthy to note that neither BMP-4 nor BMP-7 alone is capable of inducing the complete cartilage repair with MSCs.

A further refinement of the stimulation conditions is needed.

Abstract — **Objective: Microfracture is a routine therapy to release bone marrow from subchondral bone for in-situ cartilage repair. However, it can only treat small cartilage defects (< 2 cm^2). The study aims to investigate whether autologous platelet rich plasma (PRP) transplantation in collagen matrix can synergistically improve the in-situ bone marrow-initiated cartilage repair.**

Experimental design: Full-thickness cartilage defects (diameter = 4 mm, thickness =3 mm) in the patellar grooves of male New Zealand White rabbits were chosen as model of in-situ cartilage repair. They were treated with bilayer collagen scaffold (group II), PRP and bilayer collagen scaffold (group III) and untreated (group I) respectively (n=11). The rabbits were sacrificed at 6 and 12 weeks after operation. The repaired tissues were processed for histology and for mechanical test.

Results: The results showed that at both 6 and 12 weeks, group III had the largest amounts of cartilage tissue, which restored larger surface area of the cartilage defects. Moreover, group III had higher histological scores and more glycosaminoglycans (GAGs) content than those in other two groups ($p<0.05$).The Young's modulus of the repaired tissue in group II and group III were significantly higher than that of group I ($p<0.05$).

Conclusion: Autologous PRP and bilayer collagen matrix synergistically stimulated the formation of cartilage tissues. The findings implicated that the combination of microfracture with PRP in collagen matrix may repair certain type of cartilage defects larger than 2 cm2 which currently require the complex autologous chondrocyte implantation (ACI) or osteochondral grafting. number of researches on ligament and tendon tissue engineering scaffold have been carried out. However, a scaffold which simultaneously possesses optimal strength, porous structure and biocompatible microenvironment is yet to be developed. This study aims to design a new practical ligament scaffold by synergic incorporation of silk material, knitting structure and collagen matrix.

Keywords — **Articular cartilage defect, PRP, collagen matrix, microfracture**

I. Introduction

Articular cartilage has a very limited self-repair capability. When the defect size is larger than 2-4mm in diameter, the damaged cartilage is rarely healed if left untreated [1]. Unhealed articular cartilage lesions can induce mechanical instability of the joint and often lead to osteoarthritis[2]. Current therapies include microfracture[3], abrasion, drilling[4], osteochondral grafting[5] and autologous chondrocyte implantation (ACI) [6]. It is generally agreed that ACI and osteochondral grafting are used for treating lager defect (>2 cm^2) while microfracture is for treating small cartilage defect (< 2 cm^2). However, ACI and osteochondral grafting are complex and costly.

Microfracture is a routine simple arthroscopic technique. It is showed to have good results on small cartilage treatment by penetrating the subchondral bone to induce fibrin clot formation and the migration of progenitor cells from the bone marrow into the defective cartilage region [7]. As a result, chondral resurfacing is enhanced by taking advantage of human body's self-healing capacity[8].

However, the number of bone marrow stem cells (bMSCs) is limited. Moreover, bMSCs might leak from the hole since there is no stable scaffold to hold the cells. In addition, the fibrin clot is not always mechanically stable and can not cover larger defect. Hence addition of a scaffold may provide an optimal microenvironment for endogenous MSCs infiltration, proliferation and differentiation[9]. A variety scaffolds have been studied and used [10-14].Among them, collagen-based scaffold is the most promising biomaterial due to its excellent biocompatibility, biodegradability and mechanical properties.

The quality of cartilage repair can be improved by growth factors, which are important for bMSCs and chondrocytes proliferation and differentiation. Endogenous growth factors are often utilized since exogenous grow factors have not been approved for clinical cartilage repair. Platelet-rich plasma (PRP), which can be easily obtained from autologous blood is a natural source of autologous growth factors. PRP has been used successfully in clinical

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1289–1292, 2009
www.springerlink.com

practice. PRP contains many growth factors, such as platelet-derived growth factor (PDGF), transforming growth factor (TGF-beta1, TGF-beta2), insulin-like growth factor (IGF-1, IGF-2) and vascular endothelial growth factor (VEGF)[15]. It has been proven effective for bone defects repair both in experimental and clinic studies [16-18]. It was also demonstrated that PRP could stimulate chondrocytes proliferation and matrix biosynthesis in vitro[19].

To explore a strategy of utilizing body's self-healing capacity for larger cartilage defect repair, the present study hypothesized that the delivery of autologous PRP in collagen matrix can improve the in-situ Bone marrow-initiated cartilage repair. Full-thickness cartilage defects were treated by collagen matrix with and without PRP. The quality and resurfacing area of cartilage defect repair were investigated. The results might be useful to enhance the therapeutic efficacy of microfracture on articular cartilage repair.

II. Materials and Methods

Fabrication of bilayer collagen scaffolds: The biodegradable collagen scaffolds which are used in this study comprised of two layers: a dense layer and a loose layer. The diameter of the scaffolds was 4 mm and the thickness was 3 mm. Insoluble type I collagen was isolated and purified from pig Achilles tendon using neutral salt and dilute acid extractions (21).Then collagen was dissolved in 0.5 M acetic acid (1.0 wt%). The collagen solution was added to a dish (thickness = 4mm) and frozen at -70 °C. Then it was lyophilized in a freeze dryer (Heto Power Dry LL1500) and compressed mechanically. Collagen solution was added onto the compressed collagen matrix and was frozen-dried again. After that, the bilayer scaffold was ready for use. Scanning electron microscope (SEM) photographs revealed that the dense layer had microspores and the loose layer had macrospores. The average pore size in the loose and dense layer of the scaffold was measured as 100-200 μm and 10-50 μm respectively. The relatively small pore size in the dense layer can efficiently prevent cells from leaking. All the pores around the unit area were measured by observation using internal standard (bar), and the average was calculated manually. The scaffold was cross-linked by severe dehydration (dehydrothermal cross-linking) (17). Then the scaffold can be used for the following implantation.

Preparation of platelet-rich plasma (PRP): Prior to surgery, approximately 5 ml of venous blood of a rabbit was drawn into a sterile pipe containing sodium citrate as an anticoagulant for processing PRP. The platelets were enriched by a two-step centrifugation process. During the first centrifugation at 200 ×g for 10 minutes in a Refrigerated Centrifuge 5415R (Eppendorf Corporation, German), the components of blood were separated into two phases: one phase comprises of PRP and the other comprises of erythorocytes and leukocytes. The samples of PRP underwent a second centrifugation at 560 × g for 15 minutes that allowed the precipitation of the platelets, which thereafter were re-suspended in 0.05ml of plasma. Samples of PRP and whole blood were analyzed in an automatic counter (Sysmex F-820). 0.05 ml PRP was loaded onto the scaffold immediately before the insertion into the cartilage defect.

Animal model: Thirty-three knee joints of male New Zealand White Rabbits (2-2.5 kg) were used in this study. Rabbits were maintained separately in stainless-steel cages. The rabbits were anesthetized by an intramuscular injection. The knee joints were opened with a medial parapatellar approach. The patella was dislocated laterally and the surface of the femoropatellar groove was exposed. A full-thickness cylindrical cartilage defect of 4 mm in diameter and 3 mm in depth was created in the patellar groove using a stainless-steel punch. The defects were either untreated (group I, n=11) or treated with bilayer collagen matrix (group II, n=11), and with PRP and bilayer collagen matrix (group III, n=11). 5 knee joints were used as normal control for biomechanical evaluation. The animals were returned to their cages and allowed to move freely without joint immobilization. At 6 and 12 weeks after transplantation, cartilage defect was evaluated histologically (n=3 at each time point of each group). In addition, mechanical properties were evaluated at 12 weeks (n=5).

All the animals were operated according to the standard guidelines approved by Zhejiang University Ethics Committee.

III. Results

A. Platelet concentration in the PRP characterization

The average amount of PRP for transplantation was 0.05ml after processing. The average platelet concentration in whole blood was 2.44 +/- 0.46×105/μl before processing, while it reached to 18.25 +/- 1.21×105/μl in the final PRP for transplantation. In other words, the platelet concentration increased more than seven-fold after processing.

B. Gross morphology

The gross examinations of knee joints showed that there were no abrasions on the opposing articulating surfaces and no inflammation at both 6 and 12 weeks time point. The defects remained empty in small parts at 6 weeks after transplantation (Figure 1. a, e, f).

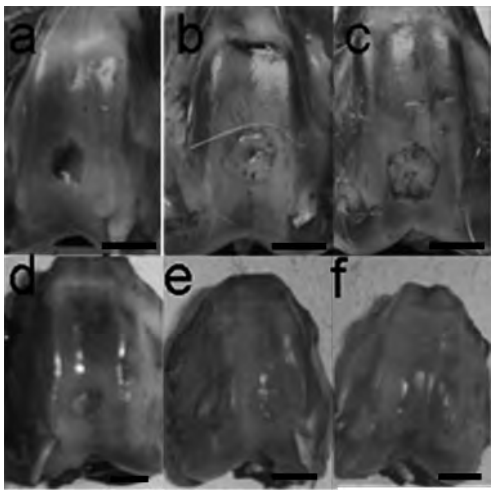

Fig. 1. Macrophotograph shows that the defects in the three groups at 6 weeks (a,b,c) and 12 weeks (d,e,f) post-surgery. a,d the microfracture group (group I); b, e the microfracture with collagen group (group II); c, f the microfracture with PRP in collagen matrix group (group III).

C. Results of Histological examination

At 6 weeks after transplantation, the defects in group I (n=3) were filled with fibrous tissue (Figure 2.). In group II (n=3) and group III (n=3), the defects were repaired with mixture of fibrous tissue and cartilage-like tissue as shown by staining and Safarnine-O staining. The amounts of chondrocyte-like cells and cartilage-like extracellular matrix in group III were more than those of group II as observed from Safranine-O staining (Figure 2,6w).

At 12 weeks after transplantation, the defects in group I (n=3) were almost filled with fibrous tissue and a little cartilage-like tissue at the margins of the defects (Figure 2,12w). Group II had lager amounts of hyaline cartilage (Figure2,12w). Group III has the largest amounts of hyaline cartilage tissue. It was found that hyaline cartilage tissues were formed at the surrounding area of the defects while the fibrous tissues were located at the central part of defects.

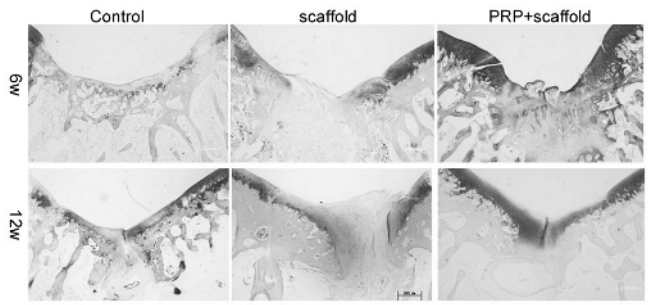

Fig. 2. Histological examination of the three groups at 6 weeks and 12weeks post-surgery.Left is the microfracture group .Middle are the microfracture with collagen matrix group. Right is the microfracture with PRP in collagen matrix group. Safranine-O staining. Original magnification 40x. Scale is as indicated (bar=500 micrometer).

The total ICRS histological scores of the specimens at 6 and 12 weeks revealed differences between the three groups. The scores for the repaired tissue of group III were significantly higher than those for other two groups ($p < 0.05$). The histological scores of the specimens at 12 weeks were higher than those of specimens at 6 weeks.

D. Results of Biomechanical evaluation

From the indentation test, the Young's modulus of repaired tissues from the three groups (12 weeks) were determined and compared with each other while the tissues from normal rabbit knee joint were used as normal control. At 12 weeks, the compressive modulus of the repaired tissue in group II and group III samples showed greater improvement compared with specimens from group I ($p<0.05$). However, the modulus of repaired tissue in both group II and group III was inferior to that of normal cartilage (0.52 +/- 0.01Mpa) ($p< 0.05$). It was found that the difference between the group II and group III has no statistical significance, which may be caused by the limitation of mechanical test. As the diameter of defect was 4 mm and the diameter of the indenter was 2 mm, the compressive test was carried out at the central area of those defects which were mainly fibrous tissue.

IV. Discussion

The present study demonstrated that autologous PRP and collagen matrix synergistically stimulated the formation of cartilage tissues, [20,21]which significantly improved body's self-healing capacity for larger cartilage defect repair by providing scaffolds and growth factors for in-situ bone marrow progenitor cells. The results were useful to enhance the therapeutic efficacy of microfracture on articular cartilage repair. It implicated that the combination of microfracture with PRP in collagen matrix could repair certain type of cartilage defects (larger than 2 cm2) which currently require the complex autologous chondrocyte implantation or osteochondral grafting. Moreover, this study was the first to present that cartilage tissue formation was initiated at the surrounding area of the defects and crept to cover the central part of defects with time. It was different from the format of simultaneous or random cartilage tissue formation at the cartilage defect after ACI, which implicated that the cells or signals from the edge of native cartilage tissue played a crucial role in inducing the bone marrow stem cells for cartilage formation.

V. Conclusions

In summary, autologous PRP and bilayer collagen matrix acted synergistically in stimulating the formation of cartilage tissues in articular cartilage defects. PRP can be easily obtained from autologous blood, and the operation procedure is simple and safe. It appeared that the combination PRP with scaffold might have great potential in clinical application to improve the therapeutic efficiency of microfracture on articular cartilage repair.

Abstract — **Conventional metal prostheses carry the major joint load and cause stress shielding and bone become osteoporotic due to lack of physiological stress flow in a common hip replacement. To develop suitable hip prosthesis having properties similar in terms of density and modulus of elasticity of bone, ceramic reinforced polymer composite material would be an ideal material as bone is also a composite material consisting of collagen fiber matrix and embedded hydroxyapatite mineral. With this idea in mind we developed a composite material using UHMWPE and alumina ceramic in various proportion whose properties are similar to that of bone and tried to integrate it with bone using hydroxyapatite and bio-glass separately leading to new osseous tissue generation for fixation when in intimate contact with bone in animal model.**

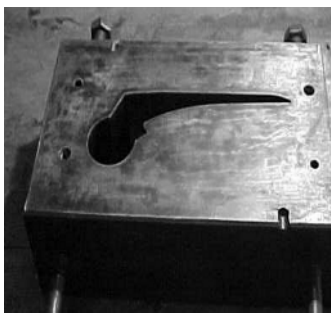
Keywords — **Bioactive coating, Composite prosthesis, hip prosthesis, UHMWPE, alumina**

I. Introduction

Hip joint is one of the most vulnerable joint in human body requiring replacement surgery. It has become the most widely accepted procedure for the treatment of disabling hip arthritis in modern orthopedic surgery [1]. Currently hip prostheses made of stainless steel (316L) are widely used for their good load bearing properties [2]. The density of this metal is heavier by 6-7 times compared to bone, the density of which ranges between 0.8-2.1gm/cc. similarly the modulus of elasticity of surrounding bone (3-30 GPa) is nearly 10-20% that of stainless steel (stainless steel exhibits a modulus of elasticity of 200GPa) [3,4]. So the applied load is mostly transferred through the metal not to the bone [5]. This results in the bone being inadequately loaded and consequently it resorbs and also changes the biomechanical environment [6].

To make suitable hip prosthesis in terms of density and modulus of elasticity ceramic reinforced polymer composite material would be the ideal material as bone itself is a composite material [7,8]. Hip replacement is a common phenomenon in advanced orthopedic surgery. Since hip joint is a load bearing joint, so it is replaced only by the material having load bearing capacity. Generally hip prosthesis is made of stainless steel 316L because it has good load bearing property.

The hip prosthesis must be anchored securely within the narrow cavity of femur for good function. The loose sitting hip prosthesis is painful and such loose hip is also stiff [9](Hirsch C, 1974).



II. Materials and Methods

A. Design and development of Hip prosthesis mould

Hip prosthesis mould was designed in consultation with a local Industrial consultant and developed by us as per the standard size and shape of Austein Moore metallic hip prosthesis. These were highly specialized job. EDM and program controlled wire cut technology were used. The system contains heating arrangement inside the mould. The design & fabrication and machining of the mould were shown in Fig1a& Fig1b respectively.

Fig-3: Mould of Hip prosthesis along with heating arrangement placed in compression machine.

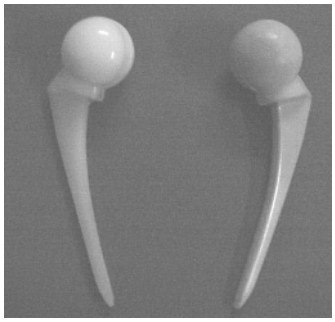

Fig-4: UHMWPE and UHMWPE-alumina ceramic composite Hip prosthesis.

B. Preparation of Polymeric and composite Hip Prosthesis

The UHMWPE (GUR 4020) and UHMWPE-alumina ceramic composite hip prosthesis was prepared in the 3 piece hip mould using compression moulding technique. The accurately weighed UHMWPE powder (50 gms) and mixture of UHMWPE and alumina ceramic powders (65 gms) were taken and placed inside the mould. Initially by pressing the top part of the mould over the powder, the structure of hip prosthesis was made and the top part kept intact. The total assembly was placed between the two plates of a compression machine (ALMIL-make hydraulic press of capacity 2000kN). The powder was cold compressed repeatedly for 5-10 minutes under a pressure of (10 MPa) in order to expel the air entrapped between the mixtures. The temperature of the thermocouple-programmed controller was set to 160^0C and held constant for sufficient time to melt the powder material properly. Heating time of very short duration results in inadequate plasticization. This may be detected by finding a white core in a vertical section through the produced sheet.

After plasticization air-cooling was applied to the compression mould. As the shrinkage of the material progresses, pressure is gradually increased and brought up to 8-10 MPa (load-300KN). This pressure is maintained constant until the total mass came back to ambient temperature. Then the mould was taken out from the press and the desired prosthesis was removed from the mould.

C. Bioactive material coating on hip prosthesis

Since the stem of the composite hip prosthesis were very smooth so surface modification was required to improve the coating adherence to the smooth composite stem. The surface treatment processes of the stem included sand blasting and acid etching. After that the hip prosthesis was cleaned with ethyl alcohol and distilled water to remove the sand particle and acid from the prepared surface. The coating was applied by air spray technique.

The coating solution was prepared by pouring the powder (hydroxyapatite or bio-glass) in ethyl alcohol water mixture at volume ratio (1:1) and continuously stirred to get a homogeneous suspension. The suspension was sprayed in a thin layer over the composite stem surfaces with the help of a spray gun (spray gun was attached to the compressed air) and then dried at room temperature. Several fine layers were applied as per the required thickness. After that the spray coated composite material was placed again in the hip pros-

thesis mould box and compressed at 8 MPa pressure after heating at 95-100°C for 30 min. The load is maintained constant until the total mass came back to ambient temperature. After cooling the mould was taken out form the press and finally we get a bioactive material coated stem of a composite hip prosthesis. The mechanism behind this coating is polymer matrix of the composite was softened during heat treatment and enhanced the coating adhesion to the substrate by mechanical anchoring through loading.

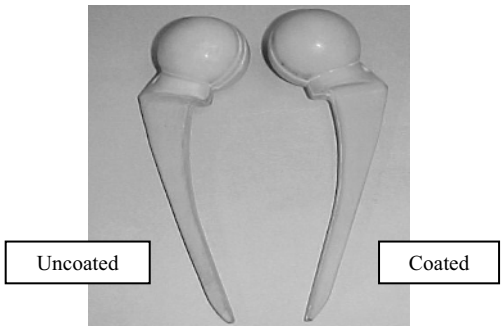

Fig-5: Uncoated and coated hip prosthesis.

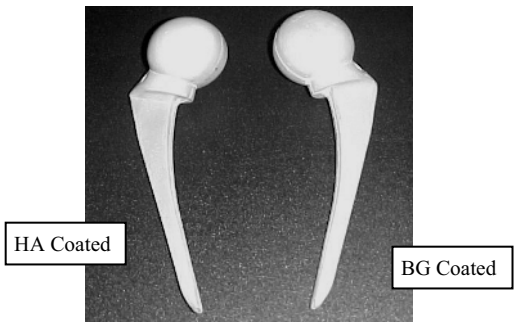

Fig-6: Hydroxyapatite(HA) and Bio-glass(BG) coated hip prosthesis.

III. Coating characterization

After successful deposition of bioactive (HA and Bio-glass) coating over composite hip stem, the coating layer were analyzed using the following methods

A. Surface roughness measurement

The roughness values of both the coated and uncoated stem was measured using Handysurf surface roughness measuring instrument (Handysurf E-30A, made by TSK, Japan). Roughness of the coated stem was measured in longitudinal and transverse directions.

Cells are shown to attach to a higher degree to surfaces containing natural binding sites [11].

Fig-7: Surface roughness measurement by Handysurf E-30A

B. Coating Thickness measurement

Ultra-sonic coating thickness gauge (Quintsonic PRO, Electro-Physik GmbH & Co., Germany) was used to measure the coating thickness of hydroxyapatite and bio-glass coated composite plate.

Fig-8: Coating Thickness measurement by Quintsonic Coating Thickness Gauge

C. Coating strength measurement

The coating strength of the coated hip stem was measured by scratch adhesion testing method using a special tooling for the purpose. . A qualitative adhesion test was carried out to measure the adhesive strength of bioactive coating to the stem.

IV. Results

The average roughness value of the coating over composite hip stem was directly noted from the display screen of Handysurf E-30A, made by TSK, Japan. The surface roughness (Ra) value of the uncoated stem is 0.4050 ±

0.0686μm. After coating, the roughness value of the stem increases. The roughness value of the HA coated stem was 4.2955 ± 0.2508 μm and BG coated stem was 2.1055 ± 0.1882 μm.

The thickness of the bioactive coating layer was measured using ultrasonic coating thickness gauge. The mean coating thickness of the HA coating is 36.1 ± 2.4244 μm and for Bio-glass coating the thickness value is 26.2 ± 2.4855 μm.

In scratch test, it was found that a sufficient scrapping force was to remove the thin bioactive coating from the composite stem. The mean coating strength of HA coating was measured as 618±5.9798 MPa whereas in case of BG coating it was 612 ± 3.3626 MPa.

V. Discussion

Bioactive hydroxyapatite and bio-glass coating over the stem of the composite hip prosthesis has been successfully achieved using combination of spray deposition and compression moulding technique. The quantity of the bioactive particles embedded on the composite surface was controlled by the concentration of the bioactive suspension and the applied coating layers. The mean coating strength was measured as 618 ± 5.9798 MPa and 612 ± 3.3626 MPa respectively for HA and BG coating and will not easily remove from the composite surface. The surface roughness of the coating layer was found 4.2955 ± 0.2508 μm for HA coated stem and for BG coated stem is 2.1055 ± 0.1882 μm and it will influence the bone cell to deposit over it. The coating thickness is sufficient for bone bonding and long term stability. The above mentioned bioactive coating adhere to the surface of the implant, binds with both implant and bone, promotes the formation of new bone and extends the implant life [10,11].We also did some animal study which indicated the integration of the of the implant with the bone[12].

Abstract — **A sensitive, rapid, reverse phase and isocratic high-performance liquid chromatography (HPLC) method has been developed for the estimation of telmisartan in human plasma. Sample detection was carried out at 297 nm using an Ultraviolet (UV)-PDA detector. Plasma sample pretreatment consist of protein precipitation extraction with methanol. The compounds were separated using a mobile phase of sodium dihydrogen phosphate buffer (pH 3.0): acetonitrile (ACN) (42:58, v/v) on a Phenomenex LUNA C_{18}, column (250×4.6 mm i.d., 5µm) at a flow rate of 1.2 ml/min. The total run time for the assay was 4.2 min. The method was validated over the range of 40-1600 ng/ml. The lowest limit of quantification and limit of detection was found 40 and 2.8 ng/ml respectively. The recovery for low, medium and high quality control samples were found 81.13, 79.96 & 82.40 % respectively. The method was found to be accurate and precise. Stability data of analytes revealed that they are stable in plasma under different stability conditions. The results observed conclude that the developed method is very appropriate and applicable for antihypertensive research programs of telmisartan.**

Keywords — **High performance liquid chromatography, telmisartan, plasma, reverse phase, stability**

I. Introduction

Bioanalytical method is the qualitative and quantitative analysis of drug substances in biological fluids or tissues. It plays a significant role in the evaluation & interpretation of bioavailability, bioequivalence and pharmacokinetic data. The sensitivity and selectivity of the bioanalytical methods are essential to the success of preclinical and clinical studies during all phases of the drug development process, i.e. from the initial preclinical phase to the final clinical phases.

Telmisartan, [1,1-biphenyl]-2-carboxylic acid, 4-[(1, 4 -dimethyl-2-propyl[2,6-bi-1H-benzimidazol]-1-yl)methyl] (Fig. 1) is an angiotensin II receptor antagonist that lowers blood pressure through blockade of the rennin-angiotensin-aldosterone system and shows non-competitive inhibition, used in the treatment of hypertension [1]. A few analytical methods for the determination of telmisartan have reported [2-11]. However no methods have been reported for the determination of telmisartan in plasma by HPLC with ultraviolet detection. All these reported methods have some drawbacks such as use of extensive sample preparation methods, excess quantity of sample requirement, long run time and higher cost of sample analysis due to the use of sensitive detectors which is a tedious and costly job for lab scale analysis of telmisartan. In this paper, we describe a sensitive, isocratic & simple HPLC–UV method for the determination of telmisartan in human plasma which includes short run time & small plasma sample volume. The method was validated for different parameters. On the basis of the results obtained it can be said that the method described here would be suitable for determination of pharmacokinetic profiles, drug monitoring and in bioequivalence studies of telmisartan.

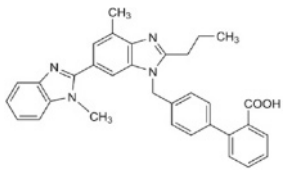

Fig. 1 The chemical structure of telmisartan (TLMS)

II. Experimental

A. Reagents and Chemicals

Telmisartan was kind gift sample from Dr. Reddy's laboratories ltd., Hyderabad, India. Methanol and Acetonitrile (ACN) were of HPLC grade and purchased from Merck ltd., New Delhi, India. Human plasma was kindly obtained from blood bank department, Bhopal Memorial Hospital & Research Centre (BMHRC), Bhopal, India. All other chemicals were of analytical grade and used without further purification.

B. Instrumentation

The HPLC system (Shimadzu Corporation, Japan) consisted of a LC-10AT VP pump, SPD-10AT VP photo diode array (PDA) detector. A manual injector attached with a 20 µl sample loop was used for sample loading. Class LC10/M10A work station was used for data collection

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1297–1300, 2009
www.springerlink.com

and acquisition. The analytical column was Phenomenex Luna C_{18} (250mm X 4.6mm, 5µm), protected by Phenomenex HPLC guard cartridge system.

C. Chromatographic conditions

The chromatographic separations were performed at ambient temperature with an isocratic elution. The mobile phase composed of sodium dihydrogen phosphate buffer (pH 3.0, adjusted with orthophosphoric acid): ACN (42:58 v/v) and was set at a flow rate of 1.2 ml/min. The chromatogram was monitored with UV detection at a wavelength of 297 nm. The mobile phase was prepared daily, filtered & sonicated before use.

D. Sample extraction procedure

Protein precipitation technique was used for extraction of telmisartan from plasma samples by using methanol as a precipitating agent. The satisfactory values for recovery for each plasma sample with single extraction were observed when 1:4 ratios of plasma & methanol were mixed thoroughly and vortexes at room temperature. It was then centrifuged at 10,000 rpm for 10 min at 4 ^{0}C. The decanted clear supernatant liquid was filtered through 0.45µ syringe filter and injected into HPLC system by using a small sample volume (20µl).

E. Preparation of standard stock solution and quality control samples (QC)

Standard stock solution of telmisartan (100µg/ml) was prepared in methanol and stored at 4°C. Serial dilution of the standard stock solution with methanol, lead to solution of concentration of 40-1600 ng/ml. For the preparation of calibration samples, 0.8 ml was taken from the standard stock solution and diluted up to 10 ml with blank plasma to give standard spiked plasma stock solution of 8 µg/ml. From the standard spiked plasma stock solution different concentrations were prepared by taking 0.05, 0.1, 0.2, 0.4, 0.8, 1.2, 1.6 & 2.0 ml and the volume of each was made up to 2 ml with blank plasma. 8 ml of precipitating agent (methanol) was added in all to obtain the final concentration of 40, 80, 160, 320, 640, 960, 1280 and 1600 ng/ml of telmisartan in plasma respectively. After that these different concentrations were followed to sample extraction procedure as described above, and the supernatant was filtered, directly injected into HPLC column for each concentrations. QC samples at different levels of high quality control (HQC, 1600 ng/ml), middle (MQC, 640 ng/ml), low quality control (LQC, 80 ng/ml) and lowest limit quality control (LLOQ, 40 ng/ml) samples were selected to perform various validation parameters.

F. Limit of detection (LOD) and lowest limit of quantification (LLOQ)

LOD was defined as the concentration that yields a signal-to- noise ratio of 3. LLOQ was the smallest analytical concentration which could be measured with defined accuracy and precision under the given experimental conditions. LLOQ was calculated to be the lowest analyte concentration that could be measured with a signal-to-noise ratio of 10. The LLOQ & LOD was found to be 40 ng/ml & 2.8 ng/ml respectively.

G. Linearity

Calibration plots for the analytes in plasma were prepared by spiking drug-free plasma with standard stock solutions to yield concentrations of 40–1600 ng/ml (40, 80, 160, 320, 640, 960, 1280 and 1600 ng/ml) for telmisartan. Five replicate injections (n =5) of each concentration were performed. The linear regression data analysis was used for the calculation of intercept, slope and correlation coefficient (r^2) which were then used to calculate the analytes concentration in each sample.

H. Selectivity

The ability of an analytical method to differentiate and quantify the analyte in the presence of other components in the sample is termed as selectivity. For selectivity, blank sample of the plasma was prepared from six different sources.

I. Accuracy

The accuracy of an analytical method describes the closeness of mean test results obtained by the method to the true value of the analyte. The mean value should be within ± 15% of the actual value except for LLOQ, where it should not deviated by more than ± 20%. It is determined by calculating the percent difference (% bias) between the mean concentrations and the corresponding nominal concentrations. The accuracy samples were analyzed for five replicates (n =5) of LLOQ, LQC, MQC and HQC.

J. Precision

The precision of an analytical method describes the closeness of individual measure of an analyte. Precision of the assay in plasma was determined by assaying all quality

control samples including LLOQ in five replicate (n =5). To determine different precision parameters sample was analyzed within the same day (repeatability of precision), on other day (inter day precision) & by other analyst (analyst to analyst precision). Precision was reported in terms of percent relative standard deviation (% RSD).

K. Recovery

Recovery analysis should be performed by comparing the analytical results of extracted samples with unextracted samples for HQC, MQC & LQC samples which representing 100% recovery. The percentage of the drug recovered from the plasma samples was determined by comparing the peak height ratio after extraction with those of unextracted methanolic solution containing same concentration of telmisartan as in plasma.

L. Stability

Stability analysis should evaluate the stability of the analytes during sample collection and handling after long-term and short-term (bench top) storage at room temperature and after going through freeze and thaw cycles. The different stability conditions are described are Stock solution stability (SSS), Short term (bench top) storage stability (BTS), Post-Preparative Stability (PPS), Freeze–thaw stability (FTS), Long term storage stability (LTS).

III. Results and discussion

A. Selection of HPLC chromatographic conditions

Various combinations of different solvents were tried & investigated to optimize the mobile phase composition to performance and peak shape. The separation of telmisartan and plasma were affected by the composition and pH of the obtain good results for the separation, sensitivity, column mobile phase. Peak shape and run time were improved by adjusting the pH of water to 3.0 with orthophosphoric acid (OPA). Under the chromatographic conditions described above, blank plasma sample did not give any peak at the retention time of telmisartan (Fig. 2) i.e. the peaks were well separated. The retention times of plasma and of telmisartan were 1.78 ± 0.3 min and 3.5 ± 0.3 min, respectively (Fig. 3).

B. Validation of the optimized method

1. Selectivity

No interfering endogenous compound peak was observed at the retention time of blank plasma and telmisartan. Thus the method was selective for analysis of telmisartan in plasma.

2. Linearity

Linearity was determined over the concentration range of 40–1600 ng/ml, which display good linear response to the method. The calibration curves were fitted by linear least-square regression and the correlation coefficient was found to be 0.9998.

3. Recovery of the method

Recovery for telmisartan was evaluated. The overall mean value of recovery was found to be 81.16%. The recovery of the extraction procedure at HQC, MQC and LQC samples of telmisartan were found to be 82.4 %, 79.96 % and 81.13 % respectively (Table 1).

4. Assessment of stability

Telmisartan was found stable under different storage and processing conditions. The stability data of telmisartan under various storage conditions was shown in Table 2.

5. Accuracy and precision measurement

The accuracy (% N conc.) for telmisartan was found to be 100.93 101.30, 103.99 & 108.05 for HQC, MQC, LQC & LLOQ samples respectively (Table 1). The precision data for HQC, MQC, LQC & LLOQ samples were analyzed in replicates of five (n = 5) and were shown in Table 1. For intra-day it was found 1.31 %, 1.53 %, 4.68 % & 7.40 %, for inter-day 1.50 %, 4.82 %, 3.20 % & 5.71 % and for analyst to analyst precision it was found 2.15 %, 1.89 %, 4.67 % & 5.53 % for HQC, MQC, LQC & LLOQ samples respectively. The results were within the acceptance criteria for precision and accuracy, i.e., deviation values were within ± 15% of the authentic values, except for LLOQ, which could show a ± 20% deviation.

Table 1 Accuracy, precision & recovery of the developed method

QC samples **r**	Accuracy		Precision (% RSD)			Mean Recovery (%)
	% N.Conc.[a]	% Bias	Intra day	Inter day	Analyst-to-analyst	
LLOQ[b]	108.05	8.05	7.40	5.71	5.53	-

IV. Conclusion

A rapid, sensitive, selective and validated assay for the quantitative determination of telmisartan in human plasma was described. The result observed from this study concludes that the developed method is very appropriate for quantitative analysis and applicable for toxicokinetic, pharmacokinetic, bioavailability, bioequivalence, therapeutic drug monitoring (TDM) and routine plasma monitoring studies of telmisartan in hypertensive patients.

Acknowledgement

The authors are grateful to Prof. P. B. Sharma (Ex-Vice Chancellor, RGTU, Bhopal, India) for providing generous access to laboratory facility to perform this study, and to the blood bank department, Bhopal Memorial Hospital & Research Centre, Bhopal, India for providing plasma samples. This work was also supported by a grant from the Ministry for Human Resource Development (MHRD), New Delhi, India.

Response of Bone Marrow-derived Stem Cells (MSCs) on Gelatin/Chitosan and Gelatin/Chitooligosaccharide films

J. Ratanavaraporn[1], S. Kanokpanont[1], Y. Tabata[2] and S. Damrongsakkul[1]

[1] Department of Chemical Engineering, Chulalongkorn University, Phaya Thai Road, Phatumwan, Bangkok 10330, Thailand
[2] Institute for Frontier Medical Sciences, Kyoto University, 53 Kawara-cho Shogoin, Sakyo-ku, Kyoto 606-8507, Japan

Abstract — **In this study, we investigated the effects of gelatin, chitosan and chitooligosaccharide on the biological response of bone marrow-derived stem cells (MSCs). Chitosan (CH, MW 1,000 kDa) and chitooligosaccharide (COS, MW 1.4 kDa) were produced from alkaline deacetylation and free radical degradation with hydrogen peroxide (H_2O_2) processes, respectively. Films of gelatin/CH and gelatin/COS with various blending ratios were prepared by solution casting and dehydrothermal crosslinking techniques. MSCs isolated from 3-week-old Wistar rat were cultured on the films to assess cell attachment, proliferation and osteogenic differentiation including alkaline phosphatase (ALP) activity and calcium content. On the 1st day after seeding, it was noticed that spreading areas of MSCs attached on blended gelatin/CH and gelatin/COS films were larger than those on pure gelatin, CH and COS films. It was observed that the morphology of MSCs attached on pure CH films was round compared to those on pure gelatin and COS. The number of MSCs attached and proliferated on gelatin/CH and gelatin/COS films, particularly for the films containing 70% CH and COS, were significantly higher than those on pure gelatin, CH and COS films. Along period of culture, the lowest number of MSCs was found on pure CH film, implying the toxicity of CH. After 7 days of culture under osteogenic differentiation condition, higher amount of ALP and calcium released from MSCs cultured on pure gelatin film were noticed. It was interesting that less ALP and calcium were observed on pure COS film compared to CH film. It could be concluded from the results that chitooligosaccharide was more favorable to the proliferation of MSCs compared to high molecular weight chitosan. On the other hand, high molecular weight chitosan had higher potential to promote osteogenic differentiation of MSCs than chitooligosaccharide.**

Keywords — **mesenchymal stem cells, gelatin, chitosan, proliferation, osteogenic differentiation**

I. Introduction

Three strategies required for the approach of bone tissue engineering consist of osteogenic cells, osteoconductive scaffolds and osteoinductive signaling molecules. Stem cells have potentials of proliferation and differentiation into various cell lineages [1, 2]. Mesenchymal stem cells (MSCs) isolated from bone marrow are most used stem cells in research field and clinical applications due to their high potential of differentiation [3, 4].

Scaffolds used in bone tissue engineering are designed to mimic natural bone matrix which consist of organic and inorganic materials. Usually, materials used to form organic part of bone scaffolds should be biocompatible and biodegradable. Among various types of candidates, gelatin and chitosan are ones of most widely used materials due to their appropriate biological characteristics. Gelatin, a denatured collagen, possesses biocompatible, biodegradable, non-immunogenic and non-antigenic properties and contains Arg–Gly–Asp (RGD)-like sequence that promotes cell adhesion and migration [5-7].

Chitosan, a deacetylated derivative of chitin, is an amino polysaccharide consisting of β-(1,4)-2-acetamido-2-deoxy-D-glucose and β-(1,4)-2-amino-2-deoxy-D-glucose units. It shows antimicrobial, antitumor, and haemostatic properties [8, 9]. In addition, chitosan is reported to accelerate wound healing and enhance bone formation [10]. The molecular weight of chitosan can be varied in a wide range, resulting in different effect on the scaffolds properties and cell response. Our previous study has shown that the molecular weight of chitosan had significant influences on the mechanical and biological properties of collagen/chitosan scaffolds [11]. It was reported that low molecular weight chitosan was more effective to promote the proliferation of mouse fibroblasts.

In this study, we thus prepared high MW chitosan (CH) and water-soluble chitosan called chitooligosaccharide (COS) in order to investigate MW effects on the response of MSCs in the system of blended gelatin/CH and gelatin/COS. To study cell response on such materials without the effect of scaffold morphology, 2-dimensional films of gelatin/CH and gelatin/COS were prepared instead of the scaffolds. Attachment, proliferation and osteogenic differentiation of MSCs on the films were evaluated.

II. Material and Methods

A. Materials

Type A gelatin (pI 9) was purchased from Nitta Gelatin Co., Osaka, Japan. Chitosans (CH) was produced from deacetylation process while chitooligosaccharide (COS)

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1301–1304, 2009
www.springerlink.com

was produced from free radical degradation using hydrogen peroxide (H_2O_2) oxidizing agent. Molecular weight (MW) and deacetylation degree (%DD) of CH and COS were presented in Table 1.

Table 1 Chemical characteristics of CH and COS

Sample	MW (kDa)	DD (%)
CH	1,000	82
COS	1.4	80

B. Methods

Preparation of G/CH and G/COS films: G/CH and G/COS films with various blending ratios were prepared by solution casting and dehydrothermal crosslinking techniques. Sample solutions were cast on glass slips and dried overnight. Dried films were crosslinked by dehydrothermal treatment at 140°C for 24 h in a vacuum oven.

Isolation of MSCs: Marrow-derived stem cells (MSCs) were isolated from the bone shaft of femurs of 3-week-old female Wistar rats according to the technique reported by Tabata *et al*. [6]. The medium was changed on the 4th day after isolation and every 3 days thereafter. The cells of the second- and third-passages at subconfluence were used for all experiments.

Attachment and proliferation tests by MTT assay: MSCs ($2x10^4$ cells/film) were seeded onto the films and cultured in proliferating medium (α-MEM supplemented with 15% FBS) at 37°C, 5% CO_2. The numbers of cells attached on the 1st day and cells proliferated on the 3rd and 5th days after seeding were quantified by MTT assay.

Measurement of cell spreading area: Photographs of at least 100 cells attached on the films at the 1st day after seeding were taken at 10X magnification. Cell spreading area was determined using Metamorph program (Universal Imaging Systems) [12].

Osteogenic differentiation of MSCs on G/CH and G/COS films: Osteogenic differentiation of MSCs cultured on the films under osteogenic differentiation induction was assessed. MSCs ($3.6x10^5$ cells/film) were seeded on the films and cultured in proliferating medium. After one day of seeding, the medium was changed into osteogenic medium (α-MEM supplemented with 10% FBS, 10 mM β-glycerol phosphate, 50 μg/ml L-ascorbic acid and 10 nM dexamethasone) and changed every 2 days thereafter. After 7 days culture in osteogenic medium, ostognic differentiation markers including alkaline phosphatase (ALP) activity and calcium release were determined by *p*-nitrophenyl phosphate and O-cresolphythalein methods, respectively [6].

Statistical analysis: All statistical calculations were performed using MINITAB (Statistical software, version 13.2, PA, USA). The differences of data analyzed using 2 sample t-test were considered at $p < 0.05$ and $p < 0.01$.

III. Results

Fig. 1 demonstrated the number of MSCs attached and proliferated on G/CH and G/COS films. It was observed that MSCs tended to attach and proliferate well on the blended films, particularly for the films containing 70% CH and COS. It was also noticed that the number of MSCs proliferated on pure CH film were significantly lower than the others, indicating the toxicity of CH. In contrast, the number of MSCs attached and proliferated on pure COS film were comparable to those on pure gelatin film, implying less toxicity of COS.

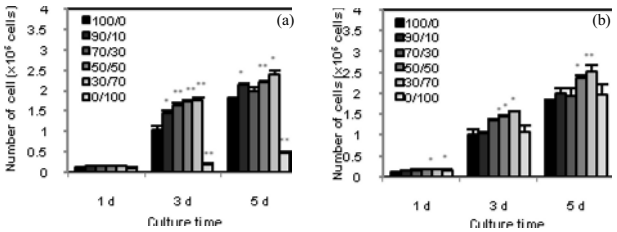

Fig. 1 Number of MSCs attached (1 day after seeding) and proliferated (3 and 5 days after seeding) on G/CH and G/COS films at different blending ratios (a) G/CH films and (b) G/COS films (* and ** presented significant difference at $p<0.05$ and $p<0.01$ relative to gelatin within each group).

Spreading areas of MSCs attached on different films on the 1st day after seeding were presented in Table 2. It was found that area of MSCs attached on the blended films were larger than those on pure gelatin film. Also, it was noticed that areas of MSCs attached on pure CH film were significantly smaller than those on the others. The cell morphologies attached on pure CH film were rounded which was markedly different from those on the other.

ALP activities of both stem cells cultured on different films for 7 days under osteogenic medium were demonstrated in Fig. 2. ALP activities of MSCs cultured on gelatin film were highest. In addition, it could also be noticed that ALP activity on CH surface was significantly higher than this on COS.

Fig. 3 showed calcium released from both stem cells cultured on different films for 7 days under osteogenic differentiation induction. Similar to the results of ALP activity, calcium released from MSCs cultured on pure gelatin and CH films were significantly higher than those on COS film.

Table 2 Spreading area of MSCs attached on G/CH and C/COS films at different blending ratios.

	Cell area (μm^2)

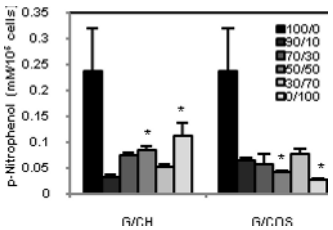

Fig. 2 ALP activity of MSCs cultured on G/CH and G/COS films at different blending ratios for 7 days in osteogenic medium (* presented significant difference at $p<0.05$ between G/CH and G/COS at same blending ratio).

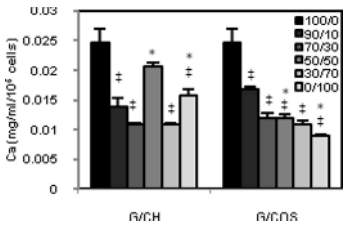

Fig. 3 Calcium release of MSCs cultured on G/CH and G/COS films at different blending ratios for 7 days in osteogenic medium (* presented significant difference at $p<0.05$ between G/CH and G/COS at same blending ratio and ‡ presented significant difference at $p<0.05$ relative to pure gelatin films within each group).

IV. Discussion

MSCs tended to attach and proliferate well on the blended films, particularly for the films containing 70% CH and COS. This was because the interactions of carboxyl (COOH) and amino (NH_2) groups with the cell surface could induce the activation of cells [13]. Therefore, blended G/CH and G/COS would introduce more of free COOH and NH_2 groups than the crosslinked pure gelatin, resulting in better cell affinity. The toxicity of high MW chitosan found in this study corresponded to several works reported. Simon *et al.* also reported that a variety of chitosans were cytotoxic and haemolytic and the extent was being dependent upon their molecular weight, degree of deacetylation and salt form [14]. Toxicity increased with increasing molecular weight and chitosan hydrochloride was the most toxic form. Subsequent studies using lower molecular weight chitosan showed that toxicity could be substantially decreased [15]. Morphologies of MSCs attached on pure CH film were rounded which was markedly different from those on the other, corresponded to the results observed by Tillman *et al.* [16]. They found that spreading area of mouse embryonic fibroblasts showed significant reduction on 2-D chitosan surfaces, compared to tissue culture plastic surfaces. In contrast, areas of MSCs on pure COS film were comparable to other films. This confirmed more toxicity of CH than the COS.

In term of osteogenic differentiation, gelatin was found to be the most preferable material for *in vitro* osteogenic differentiation in this study. This could be due to the hydrophobicity of crosslinked gelatin described previously. Saldana *et al.* have reported that osteoblast-specific activities including ALP activity and mineralization of human MSCs were clearly exhibited when cultured on the hydrophobic Zr-based surfaces [17]. Some studies reported that $–NH_2$- and SH-modified surfaces which showed more hydrophobic property could promote and maintain osteogenic capability when compared to less hydrophobic CH_3-, OH- and COOH-surfaces [18].

Comparing between CH and COS, CH films showed higher potential to induce osteogenic differentiation of MSCs than COS. Kim *et al.* reported the inhibitory effect of COS on activation and expression of matrix metalloproteinase-2 (MMP-2) in primary human dermal fibroblasts [19]. The MMP-2 belongs to a larger family of proteases known as the metzincin superfamily and plays a major role on cell behaviors such as cell proliferation, migration, differentiation and angiogenesis. Another possible reason could be attributed to the higher protein adsorption on highly positive charged of high MW chitosan. This could promote cell differentiation, as found by Amaral *et al.* and Hu *et al.* [20].

V. Concludions

This study presented that system of gelatin/chitosan and gelatin/chitooligosaccharides, except the pure of high MW chitosan, could effectively promote attachment and prolife ration of MSCs. Furthermore, chitooligosaccharide could enhance the proliferation of MSCs as good as gelatin. However, gelatin was the most preferable material for *in vitro* osteogenic differentiation in this study.

Abstract — **The porous calcium phosphate scaffolds with defined pore-channel interconnectivity were successfully prepared via negative replica method. The internal channel architecture was achieved using a water-insoluble polyurethane sponge. The PU sponge was first filled with aqueous slurry of biphasic calcium phosphate material containing pore forming agent. After drying at room temperature, a heat treatment was employed to remove all organic material. The bodies were finally sintered at the temperature of 1200°C. The phase composition and chemical structure of bodies were determined by X-ray diffraction (XRD) and FT-IR methods. Scanning electron microscopy (SEM) was used to study the pore size and distribution and pore-pore and pore-channel interconnectivity. The scaffold bodies were principally composed of HA and β-TCP with some traces of α-TCP. No residue of polymer replica or pore agent was remained. The scaffolds contained an interconnected pore-pore and pore-channel structure with a pore size less than 500 µm. The company of desired phase composition and pore-channel structure here increases the hope for the production of more effective biodegradable scaffolds for hard tissue engineering.**

I. Introduction

The importance of pore characteristics such as their size and interconnectivity along with the biodegradability of scaffold materials have been widely studied in tissue engineering domain [1,2]. The pore size and distribution, pore-channel interconnectivity and fenestration size are thought to play an important role in deep colonization and fast osseointegration of functional porous materials [3,4].

Calcium phosphate (CaP) bioceramics are known as the attractive biomaterials used in hard tissue surgeries [5, 6]. Among the different CaP compounds, mixtures of two or more calcium phosphates such as biphasic calcium phosphates (BCP) containing more stable hydroxyapatite (HA) and more bioactive tricalcium phosphate (TCP) have attracted a growing interest for use as scaffold materials [7]

The BCP compounds exhibit good *in vitro* and *in vivo* biocompatibility but the degree of bioactivity is found to be depended on the proportions of TCP to HA constituents in the mixture. The bodies composed of higher TCP/HA ratios are generally used to achieve high-level resorption and to promote osteoconduction. [8]. BCP powder can be synthesized in different methods such as simple mixing of HA and TCP, solid-state reactions, and co-precipitation [9]

The aim of this study was to prepare the scaffolds using polymeric foam and a pore forming agent. The objective of use of these agents was to produce microcapillaries allowing circulation of biological fluid and pores for seeding and stable cell proliferation during in vitro or in vivo experiments.

II. Materials procedures

The HA and tricalcium phosphate (TCP) powders used in this study were prepared from Merck (Darmstadt, Germany). Porlat (Zschimmer and Schwarz GmbH, Germany) was employed as pore forming agent, with a particle size range of 150-400 µm.

Based on own experiences and reported researches [10], the as received HA and TCP powders were firstly subjected to a calcination process conducted at temperatures of 1000 and 1200 °C respectively. Then, they were mixed with a weight ratio of 50:50. The dough was prepared with the following chemical composition: 16.7 wt% demineralized water and 80 wt% BCP powder, 1.5 wt% ammonia solution (33%, Merck Eurolab BV), 1.5 wt% defloculant (Dolapix, zschimmer and Schwarz GmbH, Germany) and 0.15 wt% binder.

After milling, the dough was injected into the cavities of PU foam through a syringe. This porous polymer structure is substantially insoluble in water, and is thermally decomposable into gaseous residues. After drying overnight, a heat treatment at a controlled heating performed to removal of pore agents and PU foam. After elimination of all organic components, up to 500°C, samples were finally sintered at 1200°C for 5 h in air.

To optimize the heating profile, simultaneous thermal analysis (STA) was performed on Porlat-contained dried dough. The phase composition and chemical structure of the scaffold products were determined by X-ray diffraction (XRD) and FT-IR analyses respectively. Scanning electron microscopy (SEM) was used to investigate the pore size and

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1305–1308, 2009
www.springerlink.com

distribution and the effect of PU foam on the pore-channel architecture.

III. Results and Discusion

The viscosity of dough was taken into account to optimize the solid to liquid proportion in the dough preparation step. The different solid to liquid proportions ranging from 40% to 80% were studied and the optimum condition was found at a proportion equal to 80% (Fig. 1). The viscosity of dough prepared from 0.5, 1 and 1.5% defloculant showed an almost the same value for the 0.5 and 1.5% whereas the sample prepared from 1% defloculant was so thick that it was not possible to inject properly through a syringe.

To fix an appropriate thermal treatment process, the thermal behavior of dried dough with a solid to liquid proportion, defloculant and pore agent amounts of 80%, 1.5% and 10% respectively, was investigated. The weight loss of 20% at about 120°C is related to remained water and pore agent removal.

The exothermic peak seen at 330-360 °C accompanied by a slight weight loss in the TGA curve can be attributed to the burnout of remained polymeric constituents (Fig. 2). Based on the reports of Mothe [11] and Song [12], Polyurethane foams present a thermal decomposition at 300-500°C. It seems that the heat treatment at 500 °C with a holding time of 90 min has been long enough to remove all polymeric residues (Fig. 3).

The XRD analysis revealed the scaffold sintered at 1200°C composed principally of HA and β-TCP phases (36% and 57% respectively) and some trace of α-TCP phase (7%) (Fig. 4).

The increase in the amount of β-TCP phase and the appearance of α-TCP phase are due to HA→α-TCP and β-TCP→α-TCP phase transformations during sintering [13].

Based on the results obtained from FT-IR analyses of dried dough containing defloculant and pore former and powdered sintered body, no residue of polymeric constitu-

ents (PU foam, defloculant and pore former) was identified in the resulting sintered scaffolds. Moreover the O-H characteristic peak of hydroxyapatite at 3520 cm^{-1} decreased through HA to TCP phase transformation (Fig. 5) [13].

The theoretical density and porosity percentage of scaffolds were 0.9 and 74% respectively. The SEM images of figure 6 (a and b) taken from fracture surface revealed the scaffolds contained a pore amount of about 70% with a size ranging from 100 to 450 μm which is consistent with the size range of macroporosity-inducing agent Porlat used in this study. The pore wall thickness was about 30-60 μm. About 40% of pores are interconnected to the channels with a mean diameter size of 50 μm. A pore-capillary connection is clearly shown in the figure 6-b. To determine the effect of PU foam on the pore-channel architecture, the SEM images of the scaffolds were compared with those of samples without the PU foam (Fig 6-c). The pores in the scaffolds were connected through the channels and seemed deeper whereas in the absence of PU foam, the pores were found to be isolated.

The SEM image of scaffold body shown in the figure 7 was taken from the pore wall illustrating a sintered granular microstructure with a grain size of 0.8-4 μm. No grain growth was happened through the sintering.

IV. Conclusions

The porous BCP scaffolds were successfully prepared via negative polyurethane replica method. The pore-channel architecture was obtained using polyurethane foam. The X-ray diffraction revealed the scaffold bodies were principally composed of HA and β-TCP with some traces of α-TCP. Any trace of polymer replica, pore agent and PU foam was detected in FT-IR analysis. The XRD results about HA to TCP phase transformation during the sintering was confirmed by the results of FT-IR analysis when O-H hydroxyapatite characteristic peak was taken into account.

The scaffolds contained an interconnected pore-pore and pore-channel structure. The theoretical porosity and that evaluated from SEM images of scaffolds were about 70-74%. Pore sized from 100 to 450 μm and the pore wall thickness was about 30-60 μm. The results obtained in this research showed the use of PU foams was effective to promote the connection of pores through the channels. SEM studies revealed a typical granular microstructure of sintered bodies without any grain growth during the sintering.

Abstract — **Development of prosthesis materials is a great challenge in biomedical fields. However, no material has been developed successfully for long-term orthopedic implantations. In this context the present investigation is being tried to develop a prosthesis material using apatite-thermoplastic nanocomposites. Hydroxyapatite (HAp) synthesized by sol-gel technique and commercial graded poly(ether ether ketone), PEEK, were used as apatite and thermoplastic, respectively. The HAp-PEEK nanocomposite was made by phase separated precipitation technique. The morphology and component distribution were performed by scanning electron microscopy (SEM) and atomic force microscopy (AFM). The functional groups present in composite materials were evaluated by Fourier transformation infrared spectroscopy. The biocompatibility performance was evaluated through acellular simulated body fluid (SBF) tests of HAp and PEEK-HAp nanocomposite using freshly prepared SBF at physiological condition of 37^{o}C temperature and pH of 7.0. The compositional studies were carried out by x-ray diffraction (XRD) technique. The coating of SBF crystal after SBF study was characterized by SEM, FTIR and XRD techniques. The sintered HAp-PEEK nanocomposite shows higher compressive strength (143 MPa) and modulus (2 GPa) values than that of human cancellus bone and also crosses the lower limit of corticle bone.**

Keywords — **Hydroxyapatite, Poly(ether ether ketone), Nanocomposite, Sol-gel, Simulated body fluid**

I. Introduction

Hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$, HAp] is a best mineral constituent for hard tissue among all the synthetic apatites. It is used in hard tissue implantations since its capability of undergoing bonding osteogenesis and chemical stability for long- term *in-vivo* applications [1]. However, pure HAp material can not be directly used for hard tissue replacement due to its brittleness as reported in our previous work [2]. Hence, several composites of HAp have been tried to improve the mechanical properties for particular biomedical applications. In 1980s, Bonfield et al. has first introduced the concept of bioactive particulate reinforced polyethylene (PE) polymer composite as bone analogue [3]. Then several polymers have been used in bioactive HAp-polymer composites. However, in recent years, the poly(ether ether ketone) [PEEK], -[-O-C_6H_4-O-C_6H_4-CO-C_6H_4-]-, polymer is being started to use in the biomedical field, especially in the area of load-bearing orthopedic fields [4,5,6] due to its good bioinert property, high glass transition temperature (T_g =145^{o}C), and high melting temperature (335-400^{o}C), depending upon grade of polymer [7]. But none of them has been succeeded for long-term applications to date.

Therefore, the aim of this study is to develop high strength materials using apatite-thermoplastic nanocomposites for long-term prosthetic applications. The major objectives of this present work are focused on the synthesis of composites by novel method and to investigate the biocompatibility of the synthetic materials using acellular simulated body fluid (SBF). HAp synthesized by sol-gel technique is used as apatite and commercial grade PEEK is used as thermoplastic. The phase separated precipitation technique is used to fabricate the HAp-PEEK nanocomposite.

II. Materials and methods

A. Materials

All commercial grade chemicals (supplied by M/S Glaxo Smith Kline Pharmaceuticals Ltd., India) like orthophosphoric acid (H_3PO_4), ethanol (C_2H_5OH), and calcium nitrate [$Ca(NO_3)_2$] were used to synthesize the hydroxyapatite in sol-gel technique. The employed thermoplastic polymer was commercial grade PEEK powders (supplied by Gharda Chemicals Ltd., India). Methanol (CH_3OH) was used as a media to prepare composite by phase separation technique.

B. Methods

i. Preparation of hydroxyapatite

The hydroxyapatite was prepared by sol-gel technique as reported in other study [8]. The employed steps for synthesis of HAp are given below.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1309–1312, 2009
www.springerlink.com

A solution-1 was prepared by using 1:5 (v/v) of H_3PO_4 and C_2H_5OH in addition to 60 ml distilled H_2O. A solution-2 was made separately using 1:4 (w/v) of $Ca(NO_3)_2$ and C_2H_5OH in 60 ml distilled H_2O. Then the each solution was vigorously stirred for 24 h at 27°C. The P^{5+} solution (solution-1) was added over Ca^{2+} solution (solution-2) drop wise and stirred vigorously for 4 h at 25°C to prepare a sol. Then the sol was kept for 48 h at 25°C with out any stirring. Further, this sol was stirred at 40°C for 16 h to produce gel. Finally, the remaining gel was soaked at 220°C for 6 h to get a solid form of HAp. The solid HAp was further sintered at 1000°C for 1.5 h followed by powdering with the help of hand mortar to make composite.

ii. Preparation of HAp-PEEK nanocomposite

The HAp-PEEK nanocomposite was prepared by phase separated precipitation technique, which is quite similar with other reports [9,10]. In this technique, 40:60 (w/w) of sintered HAp (SHAp) powder and as received PEEK powder were mixed homogeneously. The composition of 40 wt% SHAp was chosen to get the good mechanical properties for hard tissue implantations, which have been reported for HAp-PEEK composite [6]. Then 15 gm of the dry solid mixture was added in 200 ml of CH_3OH with stirring at 25°C for 16 h in a closed vessel. Here the HAp was partially dissolved in CH_3OH and made a coating slowly on the PEEK particles to form composite. In this time solid phases were separated from the liquid solution and precipitated as a composite paste. Finally, the composite paste was dried at 110°C for 5 h. Then the composite was pelletized by powder metallurgical technique using uniaxial pressure followed by liquid phase sintering at 350°C for 1.5 h. The sintered HAp-PEEK composite (SHAp-PEEK) samples were used for various characterizations. Preparation of specimen for mechanical characterization was made in a suitable mold using uniaxial pressure of about 200 MPa followed by liquid phase sintering.

iii. Preparation of simulated body fluid

The SBF solution was prepared by a technique reported in earlier works [2, 11]. The major chemical component in SBF was highly pure sodium chloride (NaCl) [2,11]. The freshly prepared aqueous SBF solution without using any living cell at physiological conditions of pH 7.0 and 37°C temperature was used to evaluate the acellular SBF conditioned study for the SHAp and SHAp-PEEK nanocomposite specimens.

C. Experimental

The morphology and component distribution were performed by scanning electron microscope (FBI make, model: QUANTA-2000) and atomic force microscope (Molecular Imaging Ltd., USA, model: Pico Scan). The functional group present in composite materials was evaluated by spectroscopic absorption study using Fourier transformation infrared (FTIR) analyzer (Bruker make, model: Vector 22).

The biocompatibility or SBF conditioned study of HAp and SHAp-PEEK nanocomposite pellets was carried out by freshly prepared SBF at a temperature of 37°C and pH of 7.

The SBF crystal was characterized by scanning electron microscope, FTIR and x-ray diffractometer (Seifert Diffractometer make, England, model: ISO Debyeflex-2002).

Mechanical properties are essential criteria for hard tissue engineering, was evaluated by compression test on cylindrical specimens of 7mm diameter and 14 mm height at a crosshead speed of 1 mm/min using Zwick/Roell-Z010 Universal Testing Machine.

III. Results and Discussions

The morphology and component distribution of unsintered HAp and SHAp-PEEK particles are measured by scanning electron microscopy (SEM) and shown in Figs. 1(a) and (b), respectively. Less than 100 nm size HAp particles are found in SEM study.

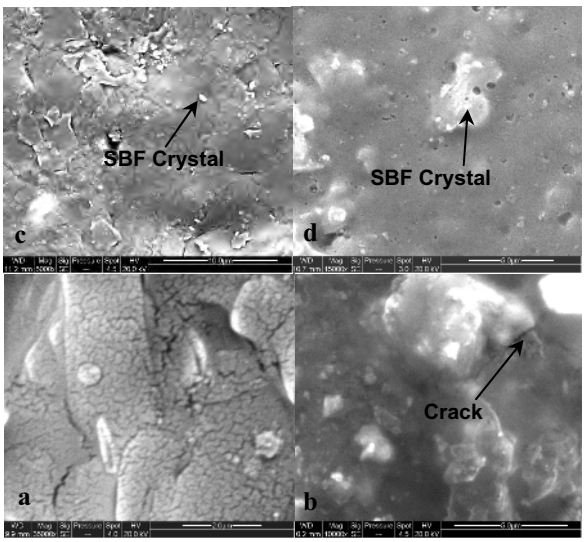

Fig. 1 SEM images of (a) unsintered HAp, (b) SHAp-PEEK, (c) SBF conditioned-SHAp and (f) SBF conditioned-SHAp-PEEK

The good interfacial bond between HAp and PEEK is observed in SHAp-PEEK nanocomposite as shown in the SEM image (Fig. 1(b)). A very few particles of ceramics (HAp) has come out from the polymer matrix (PEEK) during sintering, is also revealed in Fig. 1(b). A very few mi-

cro-cracks are also formed during sintering as indicated in Fig. 1(b). It is also observed in AFM image as shown in Fig. 2(a). This is probably due to the evaporations of gases, which are coming out from the absorbed moisture of HAp. The 50-100 nm size HAp particles have agglomerated with micron size PEEK particles during liquid phase sintering. The SEM images of SBF conditioned -SHAp (after acellular SBF conditioned study of SHAp nanocomposite for 30 days) and SBF conditioned-SHAp-PEEK (after acellular SBF conditioned study of SHAp-PEEK nanocomposite for 30 days) samples after dipping for 30 days in SBF solution are shown in Figs. 1(c) & 1(d), respectively. A layer of SBF crystals on the SHAp-PEEK nanocomposite is observed. The macro porous HAp has shown a good compatibility with PEEK matrix. The detail of the SBF conditioned study is to be discussed in later section.

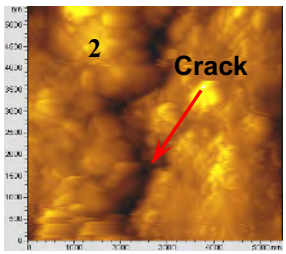

Fig. 2 AFM image (2-D Topography) of SHAp-PEEK nanocomposite

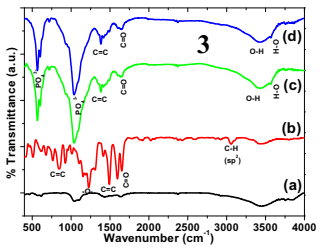

Fig. 3 FTIR spectra of (a) SBF crystal, (b) PEEK, (c) SHAp-PEEK and (d) SBF conditioned-SHAp-PEEK

The characteristic peaks of existing functional groups in PEEK, SHAp-PEEK and SBF conditioned-SHAp-PEEK are characterized by FTIR analysis and shown in Figs. 3(b), (c) & (d), respectively. However, there is no sharp characteristic peak for SBF crystal has been observed in Fig. 3(a). In SHAp-PEEK and SBF conditioned-SHAp-PEEK, the IR absorption peaks at around 1050 and 565 cm^{-1} are attributed for PO_4^{3-} vibration mode of SHAp [2,11,12]. The small sharp peak at around 3600 - 3530 cm^{-1} is attributed to the stretching vibration of molecular OH^- and the broad band at around 3500-3100 cm^{-1} is attributed to the absorbed water (H_2O) or hydrated OH^-. All IR peaks of various functional groups present in PEEK are shown in Fig. 3(b). The peaks at 846 and 1490 cm^{-1} are attributed for aromatic (C=C) group. Other peaks at 1226, 16452 and 3062 cm^{-1} are due to the aromatic ether (-O-), carbonyl (C=O) and aromatic hydrogen (C-H, sp^2) respectively [13].

The characteristic XRD peaks of the virgin PEEK (see Fig. 4(a)) at around 2θ = 18-23° and the sintered HAp (JCPDS Card No. 09-0432) (see Fig. 4(b)) at around 30-35° have found in SHAp-PEEK nanocomposite (see Fig. 4(c)). The XRD pattern of pure PEEK is similar to the other report [14]. The major XRD peaks of SBF crystals are obtained due to its main component NaCl crystals (PDF No. 05-0628) (see Fig. 4(f)). The peaks of SBF crystals are also revealed in SBF conditioned-SHAp and SBF conditioned-SHAp-PEEK as shown in Figs. 4(d) and (e), respectively.

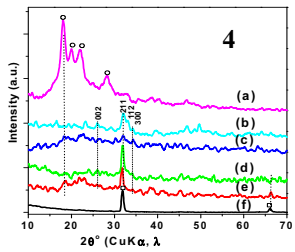

Fig. 4 X-ray diffraction pattern of (a) PEEK, (b) SHAp (JCPDS Card No. 09-0432), (c) SHAp-PEEK, (d) SBF conditioned-SHAp, (e) SBF conditioned-SHAp-PEEK and (f) SBF crystal (PDF No. 05-0628)

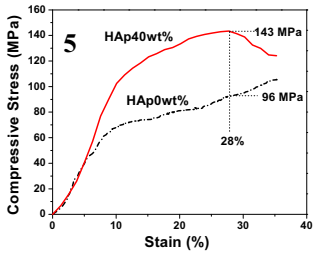

Fig. 5 Compressive properties of PEEK and SHAp-PEEK nanocomposite

The mechanical characterization of SHAp-PEEK nanocomposite and pure sintered PEEK is performed to compare the compressive strength and modulus. In compression test the ultimate strength of SHAp-PEEK nanocomposite is found to be 143 MPa, which is noticeably higher than the pure sintered PEEK (96 MPa) at the same elongation of 28% as shown in Fig. 5. However, modulus (2 GPa) of this nanocomposite has not improved significantly compare to pure PEEK matrix. This is might be due to the porous nature of HAp particles. But both the compressive strength and modulus values of this SHAp-PEEK nanocomposite are still much higher than cancellus bone and also it has crossed the lower limit (120 MPa) of corticle bone [3].

The SBF conditioned study is evaluated by freshly prepared acellular SBF solution. The SHAp and SHAp-PEEK nanocomposite pellets were dipped into the SBF solution for 15 and 30 days. Thereafter, the gradual weight change of the each sample is observed using the equation (1) and shown in Table 1.

$$W_c = 100 \times (W_d - W_i)/W_i \ \% \qquad (1)$$

Where, W_i is initial weight of sample, W_d is dry weight after dipping, and W_c is dry weight change after dipping.

Water absorption property of SHAp-PEEK has improved compare to pure sintered HAp. The amount of absorbed water is lower in SHAp-PEEK as compared to pure SHAp. Also the amount of SBF particles deposited on the top surface of SHAp-PEEK specimen is significantly less compare to pure nano HAp ceramic. As a result the low value of W_c for SHAp-PEEK is observed as illustrated in Table 1. Hence, the bioinert property is improved in SHAp-PEEK nanocomposite produced by phase separation technique as compared

Table 1 Weight change of sintered HAp and sintered HAp-PEEK nanocomposite after dipping in SBF for 15 and 30 days

Sample	Initial weight of sample Wi (gm)	Wet weight after dipping W_w (gm)	Dry weight after dipping W_d (gm)	Dry weight change after dipping W_c (%)	Dipping time T (day)
SHAp	0.536	0.902	0.695	29.66	15
		0.925	0.772	44.03	30
SHAp-PEEK	0.502	0.784	0.642	27.89	15
		0.806	0.678	35.06	30

to pure nano SHAp synthesized by sol-gel method. Therefore, the long term effect of biomaterials may be improved by increasing the bioinert property of a material.

The growth of SBF crystals is observed as a thin film coating on the SHAp and SHAp-PEEK materials as shown in Fig. 1(c) & (d), respectively. The major peaks of the SBF crystals are remain unaltered in SBF conditioned-SHAp-PEEK nanocomposite and SBF conditioned-SHAp as shown in Figs. 4(e) & (d), respectively. The growth of SBF crystal on the SHAp-PEEK nanocomposite is similar to the growth of host tissue on the porous implants as *in-vivo* applications. Hence, this nanocomposite can also enhance the osteoconductive effect due to the presence of HAp.

IV. Conclusions

The HAp was synthesized by a sol-gel technique. The HAp-PEEK nano composite was made by phase separation technique. The good interfacial bond between PEEK and HAp particle in SHAp-PEEK nanocomposite is observed in SEM and AFM micrographs. The observed compressive strength (143 MPa) and modulus (~2 GPa) values of this nanocomposite are higher than the human cancellus bone and also crossed the lower limit of corticle bone. The growth of SBF crystal on the SHAp-PEEK nanocomposite may enhances the osteoconductivity due to the presence of HAp. The less deposition of SBF crystals on the SHAp-PEEK nanocomposite through acellular SBF conditioned study shows that the bioinert property of this composite is better than that of pure HAp. This combined effect of bioinert property and osteoconductive effect of SHAp-PEEK nanocomposite may serve the long-term implantations, which is a main objective of this research.

Abstract — **Due to their unique properties, polymers are potential vehicles for drug delivery and a popular choice among researchers. In this study, a double emulsion technique was used to fabricate PLGA microspheres that encapsulate ABL. It was also found that PLGA microspheres as a delivery vehicle can increase the residence time and improve the therapeutic efficiency of ABL toward cancerous cells Hep3B, KB and MCF-7. Thus, this delivery system using a PLGA microsphere is an efficient vehicle for overcoming the limitations of ABL in drug applications.**

Keywords — **Drug delivery, *Agaricus bisporus* lectin, PLGA, microsphere, cancerous cells**

I. Introduction

ABL is a lectin from an edible mushroom *Agaricus Bisporus*, and it recognizes TF antigen or T antigen which are hidden in healthy cells but are exposed in a high percentage of human carcinomas and other neoplastic tissue [1]. ABL can potentially inhibit cell proliferation in diverse cell lines via a non-cytotoxic mechanism: interfering with nuclear pores and blocking nuclear protein import [2]. Due to the unique properties of ABL, it could be a more suitable agent for inhibiting the proliferation of cancer cells as compared to toxic chemicals. The antiproliferative effects of ABL are reversible. The reversibility of the anti-proliferative effects of ABL is associated with its release from cells after internalization [3]. This limitation requires ABL to be frequently injected or administrated in order to fulfill its functions as a drug. In order to circumvent this, ABL needs a system that can release it at a sustained rate for extended periods.

The purpose of the current work is to investigate the effect of ABL-loaded PLGA microspheres on the inhibition of tumor cells proliferation. This combination will have advantage over other chemical drugs in terms of toxic side effects as ABL is a natural drug from mushroom without any apparent cytotoxicity. Based on the different release speed with different lactic to glycolic acid monomer ratio, we chose PLGA 5050DL as a vehicle for encapsulating the drug. The novelty of this work lies in the use of ABL as a drug that is conjugated with PLGA polymer. In this way, it can make ABL expressing its function in control of proliferation in optimal medicinal effects.

II. Materials and methods

Poly (lactide -*co*-glycolide acid) (PLGA, 5050DL) was purchased from Lakeshore Biomaterials (Birmingham, AL, USA) Chloroform and Poly (vinyl alcohol) (PVA) (Mw 6000) were acquired from Fluka (Steinheim, Germany) and Polysciences (Warrington, PA, USA) respectively. All other chemicals were purchased from Sigma-Aldrich unless otherwise stated.

A. Preparation of protein-loaded PLGA microspheres

A water-in-oil-in-water (w/o/w) emulsion solvent evaporation technique was used to fabricate microspheres as well as to encapsulate the proteins [4]. Briefly, PLGA was first dissolved in chloroform. Then, a mixture of BSA, ABL and phosphate-buffered saline (PBS, 0.01M, pH=7.4) solution was added. Emulsification was carried out using an ultrasonic processor for 40s. The homogenized mixture was immediately dropped into PBS with 0.1 w/v% PVA. After which, the solution was placed under continuous mechanical stirring for 4h to evaporate the organic solvent. The microspheres produced were then washed with deionized water five times to remove the solvent before being placed in a freeze dryer for 36 hours to remove any remaining solvent and water droplets and to get a constant weight of porous microspheres.

B. Preparation of release medium

Base on the data of the release studies in Figure 1, the release medium for culturing cells was prepared. 100mg of the encapsulated microspheres was suspended in 5ml of serum free medium and incubated at 37°C, in a circulating water bath. At pre-determined times, the microspheres were centrifuged, and the resultant supernatant was sterilized with a filter and then stored in a -80°C fridge till bioactivity analysis [5].

www.springerlink.com

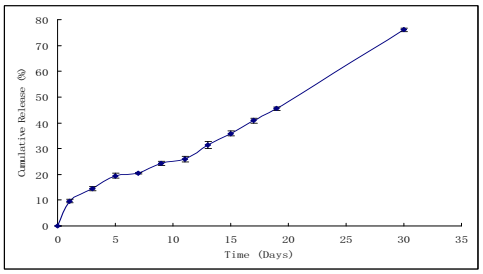

Fig. 1 *In vitro* accumulated protein release of the protein-loaded PLGA microspheres. Values represent means ± SD, n=3

C. Bioactivity assays for the released ABL

The bioactivity of the released ABL from PLGA microspheres was evaluated using cell proliferation inhibition assays. Hep3B liver cells [6, 7], KB human mouth epidermal carcinoma cells [8] and MCF-7 breast cancer cells [9] were cultured in their own medium with 10% serum. The serum-free (SF) medium was defined similarly as the above mentioned serum-medium except that FBS was not added. Cells were seeded in 96-well plate at a density of 8×10^3 cells/well in culture medium and incubated for 6 hours. The medium was aspired out and replaced by the release medium containing ABL. SF medium and SF medium with 20μg/ml and 100μg/ml ABL were used as positive and negative controls respectively. After incubation for 24 hours, MTT quantification assays were used to measure the proliferation. Hep3B cells have well-known cell functionalities, such as P-450 activity, which may be affected by ABL's inhibitory effects. To investigate this, the changes in these cell functionalities were measured. The P-450 activity (CYP1A1/2) represents the detoxification ability of liver cells, which was measured using an ethoxyresorufin-o-deethylase (EROD) assay.

III. Result and Discussion

The bioactivity of ABL/BSA released from PLGA microspheres was assessed by culturing Hep3B, KB and MCF-7 cells in the medium from the release study and studying the inhibitory effects of ABL on them. Cell viability, were used as an indicator of bioactivity by comparing to a positive control (SF medium) and two negative controls (SF medium supplemented with 20 μg/ml and 100 μg/ml ABL respectively). The medium from microspheres encapsulated with BSA alone served as a control for both the effects of released BSA on cell proliferation and any potential cytotoxicity effects of the polymer degradation products [10].

The MTT and EROD results are shown in Figure 2. Generally, the cell proliferation was significantly inhibited by released ABL in these three types of cell as compared to positive controls. Some results at time points with low inhibitory effect may be attributed to the lower amount of ABL released. However, more ABL was released as the PLGA microspheres degraded, and the degraded product of PLGA may also improve the therapeutic efficiency of ABL. Considering the results of the released BSA without cytotoxic, it can be concluded that the inhibitory effect was due mainly to the released ABL. The acidic degraded product of PLGA may stimulate the variation of the molecular conformation of ABL in order to improve its penetration ability such that it may get into the cell more easily so as to achieve the same inhibitory level with a lower concentration of ABL, and thus magnify the inhibitory effect in the process. The results indicated that the bioactivity of ABL released from PLGA microspheres was preserved for at least 30 days, and this proved to be an efficient way to increase the residence time of ABL. It also can overcome the limitation of reversible inhibition and increase ABL's potential application value. Furthermore, the results also implied that PLGA microspheres can serve as vehicles for drug delivery of ABL.

The bioactivity of ABL was also assessed by measuring the cytochrome P-450 activity of Hep3B cells, which is an important hepatic function. It was interesting to draw from the EROD result that the cytochrome P-450 activity of the cells cultured in ABL containing medium was higher than that cultured in the positive control. Although the viability of Hep3B decreased significantly, the cytochrome P-450 activity remained at a relatively stable level. From Figure 2(D), it was observed that cytochrome P-450 activities in the medium containing ABL at every 5 days interval were slightly higher than those in the medium containing only BSA. It was due to ABL stimulation that promoted cell differentiation during the inhibition process of cell proliferation. Therefore, the cytochrome P-450 activity can be maintained at a high level without any sharp decrease, which is consistent with other findings that showed that cells with lower proliferation rates may have higher differentiated functions [11]. At the same time, it verified that ABL inhibited the proliferation of cancerous cells without any cytotoxic effects.

IV. Conclusion

PLGA microspheres, prepared for the potential application for ABL drug delivery, can increase the residence time and improve the therapeutic efficiency of ABL. Through the co-encapsulation investigation, we found BSA was effective as a protector as it can prevent ABL from denaturation or degradation during the fabrication process. The system has

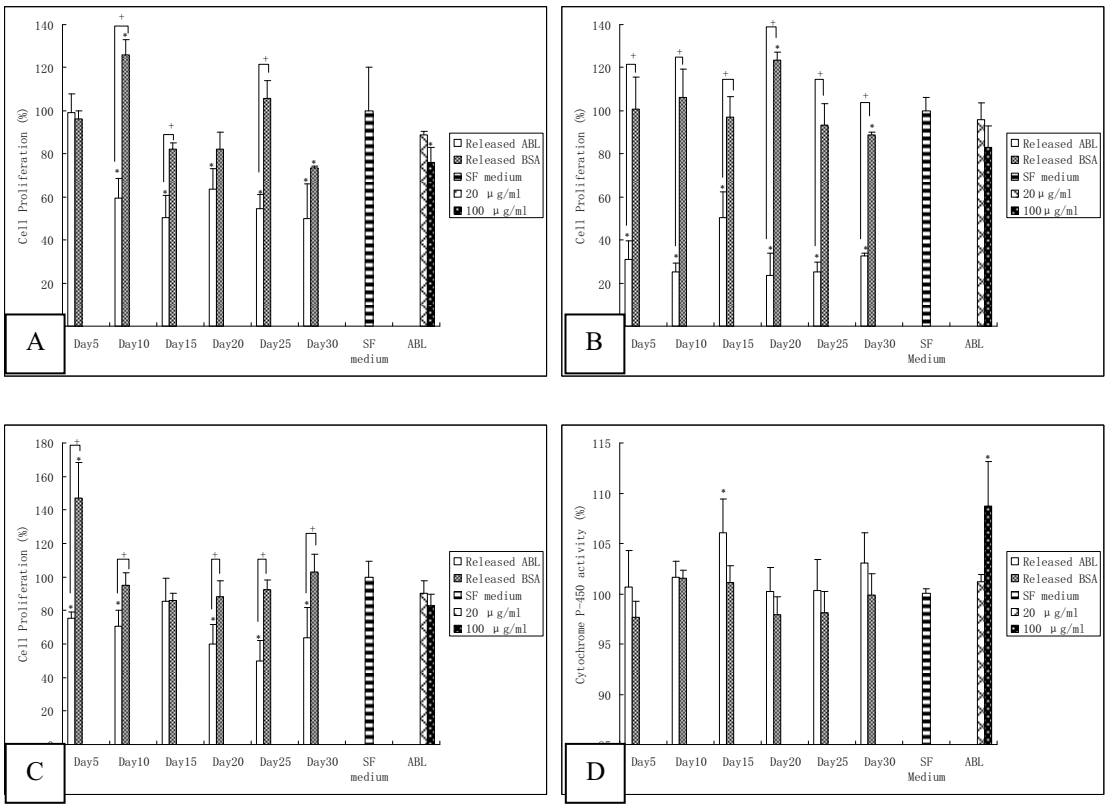

Fig. 2 Assays of incubation with released medium for 24 hours. The results of MTT assays are (A) Hep3B, (B) KB, (C) MCF-7. (D) Hep3B is the result of EROD assay. Value represent means ±SD, n=3. Statistical significance (*$p< 0.05$) were determined by one-way ANOVA with Tukeys's HSD post hoc analysis as compared to the positive control, while ($^{+}P< 0.05$) was determined between the two samples

proven to be a useful vehicle for improving on the limitations of ABL as a drug in application.

Abstract — **A scaffold is necessary for bone regeneration, because the structure of hard tissue is three-dimensional. For application in dentistry, it is desirable for the scaffold to be modified the geometry easily according to the defect. Therefore it is thought that a sponge is suitable as a scaffold. A sponge (Polyvinyl formal®: PVF) was purchased for this study. The sponge was made from polyvinyl alcohol (PVA) with formalin preparation. In this study, the PVF sponges were coated with dextran, because dextran may affect cell adhesion. The effect of dextran for hard tissue formation by bone marrow stem cells in the PVF scaffold was examined *in vivo*. PVF scaffolds (5×5×5 mm) were immersed in each dextran solution of 10 kDa (2 g/dl) and 500 kDa (4 g/dl) and air dried. The coating for the PVF scaffolds by dextran was confirmed by SEM. Rat femur bone marrow cells of 1×10^7 were seeded in PVF scaffolds. They were implanted for four weeks in rat dorsal subcutaneous tissue. In removed scaffolds, hard tissue formation was examined histologically. Bone formation was conspicuously found in the scaffold coated with 10 kDa of dextran. Value of ALP activity measured biochemically in the scaffold was 58.5 mM/scaffold. By immunochemical examination, it was measured that quantity of osteocalcin in the scaffold was 25.9 ng/scaffold and that of Ca was 129.2 μg/scaffold. These values showed a significantly higher in comparison with those of the scaffold with 500 kDa dextran coating and without coating. It was suggested in this study that coating of the scaffold with dextran induce increase of quantity of hard tissue formation in PVF scaffold *in vivo*. It is concluded that 10 kDa dextran coating of PVF scaffolds effectively contribute to adhesion of bone marrow cells in the scaffold.**

Keywords — **bone marrow cells, polyvinyl alcohol, scaffold, sponge, dextran**

I. Introduction

Multifunctional undifferentiated mesenchymal cells are present in bone marrow [1]. It is reported that this mesenchymal stem cells differentiates to osteoblasts, chondrocytes, adipocytes or nerve cells [2]. In dentistry, regeneration of a part of defect or total teeth is attempted [3, 4]. Tooth and the bone should be regenerated three dimensionally. Therefore scaffold is necessary for these regeneration. In the scaffold, stem cells proliferate and differentiate to blast cells. Generally, porous hydroxyapatite (HA) is used as a scaffold for bone regeneration [5, 6]. The defects in tooth are varying in the configurations and in size from small to large. It is desirable that the scaffold can adjust to the geometry of the defect. Therefore, use of the sponge as a scaffold was considered. Polyvinyl alcohol (PVA) treated with formalin is purchased as a sponge (Polyvinyl formal: PVF). The sponge was used in this *in vivo* study.

Bone marrow cells were seeded for osteogenesis in PVF sponges. For effective osteogenesis in a PVF sponge by seeding of undifferentiated mesenchymal stem cells from bone marrow, a number of undifferentiated mesenchymal stem cells should adhere to an inner structure of the scaffold. Dextran, a kind of polysaccharide, was selected for adherent of bone marrow cells in the scaffold. To obtain a larger quantity of osteogenesis in the scaffolds, they were coated by the compound.

The purpose of this study was to examine effectiveness of the PVF sponge as the scaffold and influence of dextran coating to the scaffold for osteogenesis in the scaffold by attachment of bone marrow cells.

II. Materials and Methods

A. Rat bone marrow cell isolation and preparation of the cell suspension

Bone marrow cell isolation: To prepare a rat bone marrow cell suspension, seven-week-old male Fischer 344 rats were used. Rat bone marrow cells were obtained from the bone shaft of femora of seven-week-old male Fischer 344 rats after euthanasia by intraperitoneal overdose of sodium pentobarbital. Minimum essential medium supplemented with 15% fetal bovine serum and antibiotics (100 units/ml penicillin, 100 μg/ml streptomycin, and 0.25 μg/ml amphotericin B) was used as a culture medium. Primary culture for the cell proliferation was performed for 1 week. The culture medium was subsequently renewed two times afterward.

Preparation of the cell suspension: After the primary culture, confluent rat bone marrow cells in the T75 culture flasks were released from their culture substratum using trypsin-EDTA solution (0.5 mg/ml trypsin, 0.53 M/ml EDTA). The rat bone marrow cells were resuspended in the

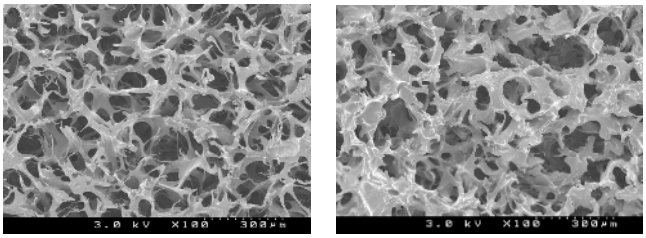

Fig. 1. SEM images of PVF sponge with and without immersion in dextran solution
Left: Inner construction of PVF without immersion in dextran solution. Right: Inner construction of PVF with immersion in dextran solution.

culture medium at a density of 1×10^8 cells/ml for *in vivo* experiment.

B. PVF scaffold

Preparation of dextran solution: Dextran with 10kDa and 500 kDa of molecular weight was purchased. Dextran of 10 kDa molecular weight was prepared at 2 g/dl concentration of solution, and that of 500 kDa was at 4 g/dl concentration. SEM images of PVF scaffold with and without immersion in dextran solution was shown in Fig. 1. Accumulation of substance on the internal structure surface of the sponge with immersion in dextran was clearly observed.

PVF scaffolds: PVA is water-soluble [7]. PVA processed with formalin was commercially available. PVF cross-linked with formalin is insoluble. Commercially available PVF sponges used in this study were purchased. Scaffold of 5×5×5 mm was made from a sheet of PVF. Those pore size was 100 to 130 μm in an average.

Dextran coating of PVF scaffold: The scaffolds were divided into three groups of four each. They were immersed in dextran solution of each concentration for twenty-four hours and then were air dried in clean condition for three days. Four PVF sponges immersed in 10 kDa molecular weight of dextran solution were abbreviated to PVF-A. Other four PVF sponges immersed in 500 kDa of dextran solution was abbreviated to PVF-B. The others without immersion in every dextran solution were abbreviated to PVF-C.

Seeding of bone marrow cells in PVF scaffolds: In each PVF scaffold, 1×10^7 of bone marrow cells (0.1ml of sell suspension/scaffold) were seeded. They were kept in an incubator for three hours before use *in vivo* examination.

C. Osteogenesis in PVF scaffold in vivo

Dorsal subcutaneous implantation of scaffolds: The scaffolds with rat bone marrow cells were implanted in the dorsal subcutis of seven-week-old male Fischer 344 rats. They were removed from the subcutis four weeks post-operatively. Some of the removed PVF scaffolds were decalcified in 10% formic acid and made of 6μm serial section for histological examination. Others were used for immunochemical and biochemical examination.

Histological examination of implanted scaffolds: The scaffolds removed from dorsal subcutaneous tissue of rats were respectively embedded in paraffin, and 6 μm serial sections were made according to the routine histological methods. All sections were stained with hematoxylin-eosin and examined bone formation in the pores of scaffold under an optical microscope.

Immunochemical and biochemical examinations for osteogenesis in implanted scaffolds: The removed scaffolds were homogenized in 1 ml of 10-fold concentration of TNE solution (pH7.4, 10mM Tris-HCl, 1mM EDTA, 100mM NaCl). They were centrifuged for one minute at 16,000×g. Absorbance of the supernatant reacted with *p*-nitrophenylphosphate-substrate at 37°C for thirty minutes was measured at 405 nm for measuring ALP activity. The value was represented as ALP activity per one scaffold. The supernatants were also used for immunochemical quantitative analysis of osteocalcin using Rat Osteocalcin ELISA kit DS (DS Pharma Biomedical Co., Ltd., Osaka, Japan). The precipitation was immersed into 1ml of formic acid and quantity of calcium was measured. Each data was presented as mean ± standard deviations. The results were statistically analyzed respectively using two-way unrepeated ANOVA followed by post hoc analysis using Tukey-Kramer's test. Differences of $p<0.05$ were considered significant.

III. Results

Histological findings of implanted PVF scaffolds: Optical microscopic images of osteogenesis in scaffolds are shown in Fig. 2. Bone was found in many pores in PVF-A. The number of pores including bone in PVF-A was remarkably large in comparison with ones of PVF-B. In PVF-B, a little of pores contained bone were observed. Bone formation in the pores was scarcely seen in PVF-C.

Value of ALP activity, quantity of calcium and osteocalcin in implanted scaffolds: Value of ALP activity, calcium level and quantity of osteocalcin were shown in Fig. 3. Value of ALP activity measured in PVF-A was significantly higher than that of PVF-B and PVF-C. Between ALP activity measured in PVF-B and PVF-C, there was no significant difference. The value of ALP activity in PVF-A was 58.5 mM/scaffold. The calcium level detected in PVF-A scaffolds was 129.2 μg/scaffold. It showed significant differences with that in PVF-B and PVF-C. There were statistically significant differences between molecular weight of

dextran. A quantity of osteocalcin detected in PVF-A was 25.9ng/scaffold. The level of osteocalcin in PVF-A was significantly different from that in PVF-B and PVF-C.

IV. Discussion

Regeneration of a partial or complete tooth has been halfway developed [2, 3]. Scaffold should be used for tooth regeneration. The configuration of tooth and the defect is various. A sponge would be suitable for regeneration of hard tissue with various configurations. PVA is one of the materials of the scaffold for osteogenesis [8]. PVA treated with formalin was used in this study. It was confirmed from the results of this *in vivo* study that PVF sponge shows excellent biocompatibility. However, no bone-like tissue was formed in the pores of PVF-C, which was not immersed in dextran solution. The result showed that few bone marrow stem cells adhered to the PVF scaffold. So the PVF is hydrophilic [9], it is generally hard for the cells to adhere to such a material.

Hydrogels have some unique properties that make them highly biocompatible. They have a low interfacial tension with surrounding biological fluids and tissues. This minimizes the property for protein adsorption and cell adhesion [10]. Therefore it was thought that scaffolds should be coated with a chemical agent for cell adhesion. For the use as the sponge, PVA might be processed with formalin because the PVA was water-soluble. The PVF cross-linked with formalin should be insoluble. It was not proved that the sponge is hydrophobic. In this study, no bone was observed in PVF-C. The result suggested that the sponge was hydrophilic. On the other hand, it was also sure that a dextran, which coated on PVF scaffolds, played a role to attach bone marrow cells and maintained the cells in PVF-A and PVF-B for osteogenesis. It was reported that dextran agglutinated cells [11]. Bone formation in PVF-A and PVF-B would be induced after dextran and bone marrow cell conjugate.

In vitro preliminary experiment, the concentration of dextran solution for use of immersion of scaffold in this study was decided from the result of bone formation level.

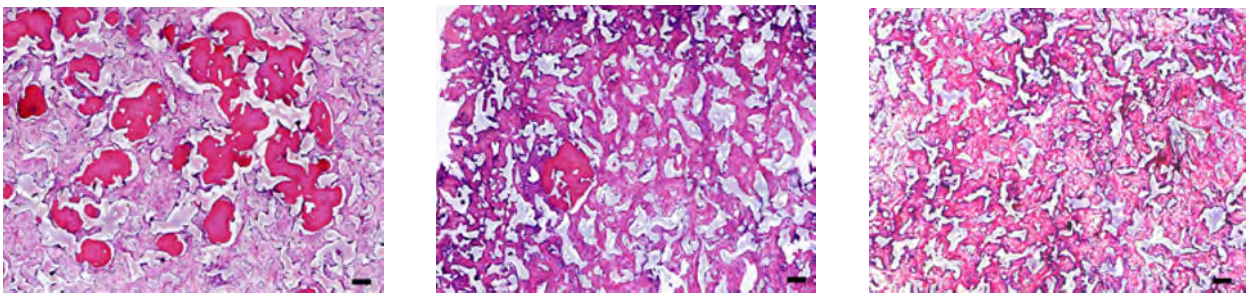

Fig. 2. Optical microscopic images of PVF scaffold implanted *in vivo*
Left: Bone are seen in many pores of PVF-A. (Bar=100μm) Center: A few pores containing bone are seen in PVF-B. (Bar=100μm) Right: There is little bone formed in pores of PVF-C. (Bar=100μm)

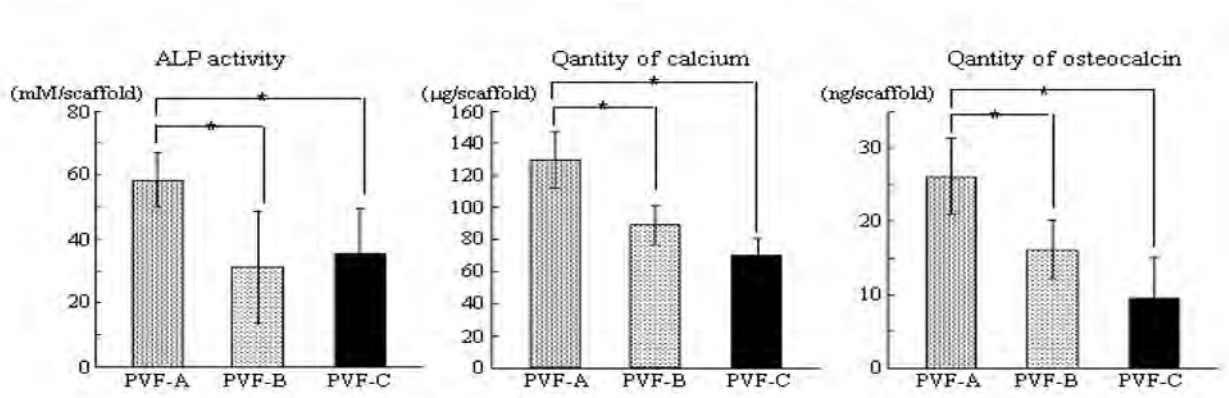

Fig. 3. Biochemical and immuno-chemical measurement of ALP activity, quantity of calcium and osteocalcin in implanted scaffolds (* $p<0.05$)

It could not be confirmed in this experiment that induction of bone marrow stem cell aggregation with a small amount of dextran coated on the scaffold. However, it was thought from this result, that bone marrow stem cells adhered to dextran on the inner structure of PVF and aggregate mutually there. It was also suggested that bone marrow stem cells proliferated and differentiated to osteoblasts in the scaffold immersed in 10 kDa of dextran solution.

On the other hand, molecular weight of dextran should be related closely to osteogenesis in the scaffold. PVF-B showed less formation of bone in the scaffold than PVF-A in this experiment. It was suggested that low molecular weight dextran was effectively form bone in the pores. By dextran of 10kDa molecular weight, many pores with bone were observed in this *in vivo* experiment.

The pore size of the PVF sponge is 100-130μm. The pore size is a suitable dimension for hard tissue formation in the scaffold [12]. Bone marrow cells seeded in the scaffolds with the pores of an appropriate diameter might be almost located in all pores, and supplied nutrition from the subcutaneous surrounding tissue should arrive to the cells in the pores.

Scaffolds made of sponge have some advantages. For application to a defect, the sponge scaffolds can be cut easily. It is easy for the scaffold to adjust the shape to a defect that should be restored. The manufacturing cost for the sponge scaffold may be low than that of HA scaffolds. However, there are several problems for the sponge scaffolds to be improved for clinical use. Biodegradable sponge scaffold has been developed. The biodegradable scaffold may be unsuitable for teeth or bone regeneration from the viewpoint of hardness. Regenerated bone or tooth have to bear a large load. The structural hardness for the scaffolds to bear the load is required.

V. Conclusions

PVF sponge was immersed in dextran solution to promote osteogenesis by bone marrow cells. The sponge was implanted in subcutis and estimate osteogenesis *in vivo*.

Conclusions obtained from the results of this study were as follows:

1) No bone would be formed in the PVF sponge.
2) Osteogenesis occurred in the PVF sponge with immersion in dextran solution.
3) Quantity of osteogenesis in the PVF sponges was under the influence of the molecular weight of dextran.
4) Bone was formed in many pores of PVF sponges immersed in a dextran solution with low molecular weight.

Inactivation of Problematic Micro-organisms in Collagen Based Media by Pulsed Electric Field Treatment (PEF)

S. Griffiths[1,2], S.J. MacGregor[2], J.G. Anderson[2], M. Maclean[2], J.D.S. Gaylor[1] and M.H. Grant[1]

Abstract — **The potential of pulsed electric field (PEF) treatment as a novel/safe method of decontaminating collagen based biomatrices was investigated. Collagen gels (0.3% w/v) were seeded at a concentration of 10^6 CFU/ml with either *Escherichia coli* or *Staphylococcus epidermidis* and then treated with 100 pulses at ~45 kV/cm, using a static PEF chamber. To investigate if the collagen gel had a "protective" effect on the bacteria, PEF inactivation was also investigated in phosphate buffered saline (PBS) and melted collagen gel (heat-treated, 10 min at 80°C, and as a result not set as a gel). When subjected to PEF, different levels of inactivation were observed with *E. coli* and *S. epidermidis* seeded in the different media. In all three media *E. coli* was more susceptible to PEF treatment than *S. epidermidis*. *E. coli* cell counts were reduced by ~3.3 logs in PBS, 2.6 logs in collagen gel and least inactivation (~1.5 log reduction) was observed in melted gel. *S. epidermidis* also showed higher inactivation levels in PBS compared to native collagen gel and melted collagen gel. Current results have established that PEF treatment can inactivate different types of bacteria seeded in collagen gels. However, complete inactivation was not achieved in any of the different types of suspending media, possibly due to the high seeding densities utilized. Previous results have established that PEF does not adversely affect the collagen structure. Future work is required to optimize microbial inactivation levels and to fully establish whether PEF treatment may offer a novel biomatrix decontamination method, which achieves sterility without damaging labile biological components.**

Keywords — **Collagen gel, microbial inactivation, pulsed electric field, sterilization, biomatrices**

I. Introduction

Collagen is a fibrous structural protein and the most abundant protein in mammals. Hence collagen based biomatrices have numerous potential applications within the fields of tissue engineering and regenerative medicine. The use of these biomatrices for clinical applications requires a compatible sterilization method and this is problematic as conventional methods of sterilization (ethylene oxide, gamma irradiation) have been shown to cause detrimental effects on the collagen structure or can produce mutagenic and carcinogenic products [1, 2]. Pulsed electric field (PEF), initially investigated for use in the food industry, is a non-thermal treatment that causes bacterial inactivation through irreversible rupture of microbial cell membranes [3]. Previous work has established that PEF treatment can achieve complete bacterial inactivation of *E. coli* in collagen gel at low levels of contamination [4]. It has also been demonstrated that PEF does not affect the structure of the collagen molecule or its ability to support cell culture[5]. However, when high bacterial densities were seeded in collagen gel complete inactivation was not achieved, one explanation proposed was the protective effect that collagen gel may provide to bacteria suspended within its gel matrix. The present study aims to investigate how the viscosity of the suspending medium affects microbial inactivation. The media examined included collagen gel, melted collagen gel and phosphate buffered saline (PBS), and the PEF inactivation of two different bacteria suspended within these media was investigated.

II. Materials and Methods

A. Microbial inactivation

Two different types of bacteria were chosen for the present study, one a Gram negative rod, *Escherichia coli* National Collection of Type Cultures (NCTC) 9001 and the other a Gram positive coccus *Staphylococcus epidermidis* NCTC 11964. *E. coli* and *S. epidermidis* populations were grown by incubating at 37 °C under rotary conditions for 18 h, in nutrient broth and brain heart infusion broth (Oxoid) respectively. Inocula used to seed the different media were produced at densities of ~10^8 colony forming units (CFU) per milliliter by diluting with PBS.

PEF treatments were performed in three types of suspending media - PBS, melted collagen gel and collagen gel. Collagen gels (0.3% w/v) were prepared by mixing collagen solution (4.29 mg/mL), a mixture of 10X Dulbecco's minimal essential medium (DMEM) and 0.4 mol/l NaOH (2:1), and acetic acid (1:1000 v/v) at a ratio of 7:2:1[6]. The above

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1320–1324, 2009
www.springerlink.com

collagen mixture was seeded with inoculum and vortexed, prior to being set to a gel with 0.5 mol/l NaOH. Melted collagen gel was produced by taking collagen gels (as above but with no inoculum) set in a universal and liquefying them by placing in a water bath at 80 °C for 10 min. The melted gels were seeded once they had attained ambient temperature. PBS samples were seeded in the same manner. Once seeded, all media had a final concentration of ~ 10^6 CFU/ml.

Sterile electroporation cuvettes with 4mm electrode spacing and 800µl volume (Bio-Rad Laboratories) were loaded with 700µl of test sample and topped with 200µl of Tween 80 (covering the top surface of the electrodes and hence preventing any electrical breakdown). The different media when overlaid with Tween had similar conductivities that ranged between 6.0-8.8 ms/cm at 15°C. The cuvette was placed in the chamber which was then pressurized with air to 4 bar. Samples were subjected to high-intensity pulsed electric fields (pulse duration 1 µs, at ~ 45 kV/cm) using the test arrangement illustrated in Fig. 1. A low pulse frequency and water cooling were employed to maintain the treatment medium below 30°C. The pulse frequency was set to 0.1 Hz and 1 min breaks were taken after every 10 pulses to ensure that there were no thermal inactivation effects associated with the energy dissipated in the test chamber. Water cooling (15°C) was controlled by a thermostatic regulator and supplied to the earth connection which was situated along the side of the cuvette. The voltage waveforms generated across the samples were monitored throughout all experiments using a 1,000:1 Tektronix high-voltage probe connected to a Tektronix digital oscilloscope. This also enabled calculations of any temperature increases and provided confirmation that these were insufficient to cause thermal inactivation effects.

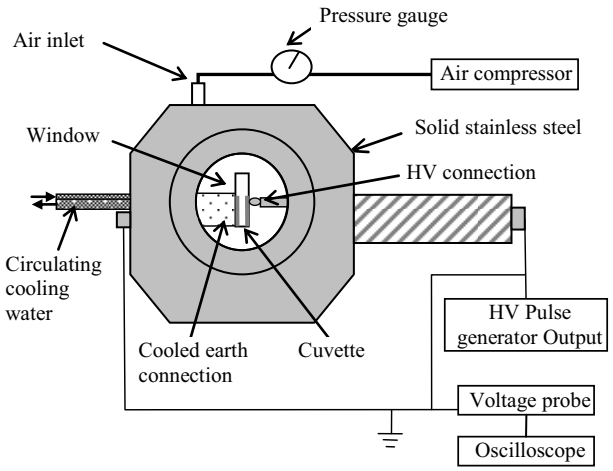

Fig. 1 Schematic of pressurized static PEF chamber.

The level of microbial inactivation was assessed post treatment by removing samples from the cuvette and diluting with PBS prior to plating in triplicate. To recover bacteria from collagen gel, samples were stomached with PBS (using a Colworth Stomacher) prior to further dilutions. The surviving populations, expressed as $\log_{10}$ CFU/ml, were enumerated from duplicate experiments, following incubation for 24 h at 37°C on nutrient agar and brain heart infusion agar, respectively. Where applicable, statistical analysis was carried out using Minitab 14. A one-way ANOVA, combined with Dunnett's comparison was utilized, with a significance level of 95 %.

B. Viscosity Measurements

All measurements were taken at 25°C using a Wells-Brookfield cone and plate viscometer (Brookfield Engineering Laboratories). The system was calibrated with a Newtonian calibration oil (4.4 mPa s at 25°C). Viscosity measurements were carried out on melted collagen gel, PBS and for comparison on collagen solution (3.58 mg/ml), a 50% mixture of glycerol/water and olive oil. Torque values (Nm) were taken over a range of shear rates (s^{-1}) and corresponding shear stresses (Pa) were calculated.

C. SDS-PAGE of melted collagen gel

Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) analysis was used to determine the integrity of the collagen molecules after the collagen gel was melted. Samples analyzed included melted collagen gel (heat treatment at 80°C for 10 min), collagen solution (heat treated as above), a positive control (collagen solution heat treated at 90°C for 1h) and a negative control (non-treated collagen solution). Collagen samples were adjusted to a concentration of 1 mg/ml, prepared in Laemmli buffer, and subjected to SDS–PAGE. Coomassie Brilliant Blue was used to stain the bands obtained.

III. Results and Discussion

The results shown in Fig. 2 compare the effect of different suspending media on PEF inactivation of *E. coli*. The data show *E. coli* populations before and after PEF treatment. After 100 pulses *E. coli* populations were significantly decreased, at the $P < 0.05$ level, in all three types of media. *E. coli* was most susceptible to PEF treatment when suspended in PBS, where a ~3.3 log reduction was observed

compared to 2.6 logs in collagen gel and least inactivation (~1.5 log reduction) was observed in melted gel.

The results of Fig. 3 show the inactivation of *S. epidermidis* when suspended in different media. Significant population decreases ($P < 0.05$) were seen in PBS and collagen gel. The results showed that the greatest inactivation (~0.9 log reduction) occurred in PBS, and then collagen gel (~0.3 log reduction) but no significant decrease was observed for *S. epidermidis* when suspended in melted collagen gel.

Greater inactivation was observed with *E. coli* in all three types of media compared to *S. epidermidis*. The same trend was seen with both organisms, i.e. greater inactivation in PBS compared to native collagen gel and lower inactivation in melted collagen gel compared to native collagen gel.

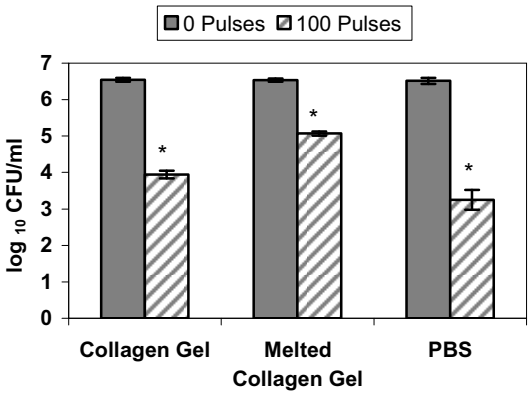

Fig. 2 The effect of suspending media on PEF inactivation of *E. coli*. n=6, data points show mean ± standard deviation. * Significant difference at the P<0.05 level.

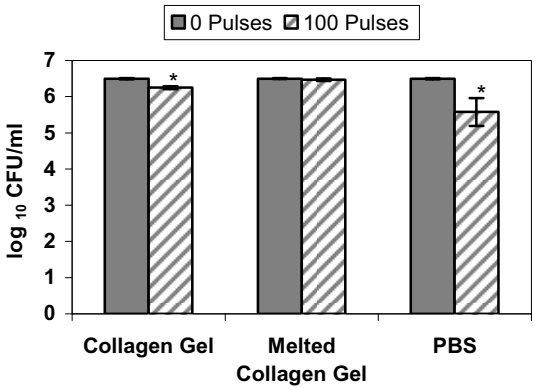

Fig. 3 The effect of suspending media on PEF inactivation of *S. epidermidis*. n=6, data points show mean ± standard deviation. * Significant difference at the P<0.05 level.

Previously it had been thought that suspending bacteria in a gel could possibly provide protective interactions with collagen fibres [4]. By melting the collagen gel and breaking the cross-linked fibres formed during the gelling process and creating a liquid it was considered that greater inactivation might be achieved. In fact, the results showed the opposite effect since less inactivation was observed in melted collagen gel compared to native collagen gel.

The results of SDS-PAGE analysis, Fig. 4, show that there was no obvious sign of damage to the collagen monomer in melted gel samples. The banding pattern seen for the melted gel was similar to that of the negative control with no detectable occurrence of low molecular weight components. These intact fibres when in a liquid suspension may potentially form better interaction with the suspended bacteria and hence provide greater protection from pulsed electric fields. It has also been reported that *S. epidermidis* has the ability, possibly through extracellular lipases to bind to collagen [7]. This may explain why *S. epidermidis* is particularly difficult to inactivate when suspended in collagen gel as shown in these studies.

In order to further understand the differences in cell inactivation (particularly in PBS and melted collagen gel) rheology experiments were conducted in order to establish any substantial difference in fluid viscous properties. Fig. 5 shows the shear stress versus shear rate (of which the gradient is the apparent viscosity) of PBS, melted collagen gel and other sample liquids showing a range of viscosities.

All the fluids tested exhibited Newtonian behaviour as demonstrated by the linear plots. The results for PBS and melted collagen gel have similar gradients and hence viscosities, particularly compared to other (more viscous)

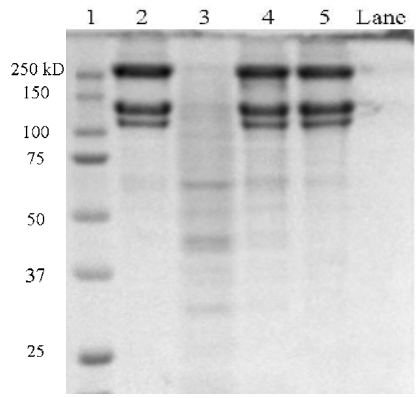

Fig. 4 SDS-PAGE of collagen samples. Lane 1 molecular weight marker, lane 2 negative control (non-treated collagen solution), lane 3 positive control (collagen solution heat treated at 90°C for 1h), lane 4-collagen solution (treated at 80°C for 10 min), lane 5-melted collagen gel (treated at 80°C for 10 min).

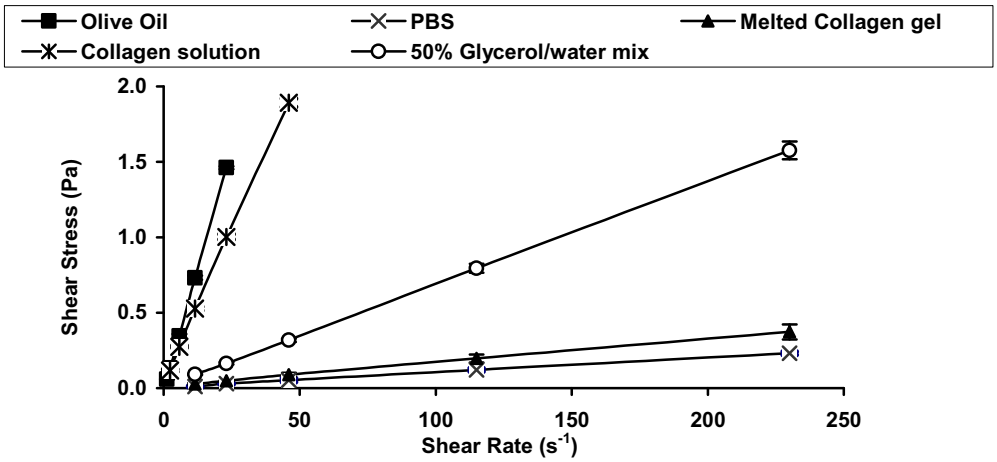

Fig. 5 Viscosity measurements of melted collagen gel and a range of other media at 25 °C, n=7 data points show mean ± standard deviation.

liquids such as collagen solution and olive oil. Due to the similar results for PBS and melted collagen gel, viscosity was not considered to be a major factor influencing bacterial inactivation by PEF treatment.

Limited information is available in the PEF literature on studies comparing liquid and gel suspending media and their effect on microbial inactivation levels. One study has reported that PEF reductions of *E. coli* were lower in skimmed milk than in a buffer solution, potentially due to the presence of proteins [8]. The results of the present study are in agreement, showing bacterial inactivation in PBS was superior when compared to that in collagen gel. However complete inactivation at high contamination levels was not achieved with any of the three suspending media used. Results of the present and previous studies indicate that PEF may be more successful treating low levels of contamination, particularly in collagen gel.

IV. Conclusions

The study has shown that suspending media can affect microbial inactivation by PEF. The "protective" effect associated with collagen is not thought to be the due to the physical properties of the gel itself but to the collagen monomer, as least inactivation was seen in liquid melted collagen gel. Significant decreases in bacterial populations were achieved when seeded in collagen gel. However, to fully establish whether PEF treatment can offer a novel biomatrix decontamination method, further research is necessary. Future investigations will concentrate on optimization of microbial inactivation levels and extending the investigation to include other problematic bacterial species as well as yeast and mould contaminants.

Abstract — **Purpose: Polymeric nanoparticles are frequently employed for drug delivery systems to perform a sustained release behavior of incorporated drug. These polymeric nanoparticles can be used for site specific targeting of encapsulated drug. The objective of present study was to develop a poly (lactide-co-glycolide) (PLGA) nanoparticles drug delivery system of anticancer drug cisplatin with higher therapeutic efficacy, lesser side effects, and with further development to advances in targeted chemotherapy. PLGA nanoparticles were prepared by double emulsion solvent evaporation method and characterized by their morphology, size, polydispersity index, zeta potential, drug encapsulation efficiency and *in-vitro* drug release in phosphate buffer saline (pH 7.4). The influences of several process parameters on the nanoparticles were observed. The results obtained from studies showed that nanoparticles developed in this study could be the nanoparticles for application in the controlled delivery of cisplatin for cancer therapeutics and may be considered promising in targeted therapy of cancer.**

Keywords — **Poly (lactide-co-glycolide), nanoparticles, cisplatin, controlled release, targeted chemotherapy**

I. Introduction

Controlled drug delivery technology represents one of the frontier areas of science. These delivery systems offer numerous advantages compared to conventional dosage forms like improved efficacy, reduced toxicity and improved patient compliance & convenience. Such systems often use biodegradable polymers as drug carriers. [1-3].

Biodegradable polymer, poly (lactide-co-glycolide) (PLGA) is one of the most useful polymers for drug delivery applications. The preparation methods for nanoparticles depend on the nature (hydrophobic or hydrophilic) of the drug to encapsulate. A surfactant is required to stabilize the system [4,5]. Sodium cholate (SC) is one of the most commonly used polymeric stabilizer.

There are different methods for the preparation of polymeric nanoparticles. Among them emulsification solvent evaporation technique is most useful because of simple, fast and economic and also has the advantage of employing non toxic solvents. It may be single emulsion method if the drug is hydrophobic and double emulsion if hydrophilic. In the single emulsion method, PLGA and the drug were dissolved in an organic solvent, which was then emulsified in an aqueous (aq) phase (w) containing stabilizer to make an o/w emulsion. In the double emulsion method the drug was dissolved in an aq phase (w_1) which was emulsified in the PLGA solution (o_1) to make w_1/o_1 single emulsion. This emulsion was again emulsified in an outer aq phase containing stabilizer (w_2) to form a $w_1/o/w_2$ double emulsion. Organic solvent in both of the methods was removed by solvent evaporation technique [6,7].

Cisplatin, an anticancer drug is one of the most potent & effective anticancer drug available today but have limited applications because of the serious side effects produced by the drug [8,9]. Targeted delivery of cisplatin to the specific cancer cells is thus required because it could provide a means of modifying the distribution of cisplatin *in -vivo* and of increasing its concentration in the target sites, thereby improving efficacy and reducing toxicity. Several strategies have been described in the literatures for selective cisplatin drug delivery. Some of these attempts include the administration of cisplatin by its water soluble conjugates, such as with poly (amidoamines) [10] and poly (amidoamines) dendrimers [11]. Anticancer activity of cisplatin entrapped PLGA-methoxy poly (ethylene glycol) nanoparticles on LNCaP prostate cancer cells and the *in vitro* nanoparticle degradation, *in vitro* drug release & *in vivo* drug residence in blood properties of PLGA-methoxy poly (ethylene glycol) nanoparticles of cisplatin have also been investigated [12,13]. Although there was no details available for the effect of change in processing parameters on the characteristics of nanoparticles of cisplatin.

The aim of this study was to define the parameters determining an optimized yield of monodisperse, nanosized particles of cisplatin by using PLGA as a polymer, dichloromethane as an organic solvent and sodium cholate as a surfactant (stabilizer). Experimental parameters such as the polymer concentration (conc), sonication time, internal & external aq phase volume and stabilizer concentration were investigated for surface morphology, particle size, zeta potential, drug encapsulating efficiency, *in-vitro* drug release profile and polydispersity index of nanoparticles. The preparation parameters leading to particles with well-defined characteristics were identified.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1325–1328, 2009
www.springerlink.com

II. Materials and methods

A. Materials

Poly (lactide-co-glycolide) 50/50 (mol. wt. 17,000) was kind gift sample from Sun Pharmaceuticals Ltd., Vadodara, India. Cisplatin was received as a gift sample from Cipla Pharmaceutical Ltd., Mumbai, India. Sodium Cholate (SC) was purchased from S d fine chemicals Ltd., Mumbai, India. Other chemicals used were of reagent grade.

B. Optimization of processing parameters

Different batches of nanoparticle formulations were prepared and the parameters controlling the formation of nanoparticles were systematically varied and optimized to produce small & stable nanoparticles. The influence of the different parameters on the nanoparticle characteristics were observed & summarized in Table 1-5.

C. Preparation of PLGA nanoparticles of cisplatin

Nanoparticles were prepared by a double emulsion solvent evaporation technique. The primary emulsion (w/o) was formed between an organic solution (o) of the polymer (50 mg of PLGA in 2 ml of dichloromethane) and an aq solution (w) of drug (5 mg of cisplatin in 2 ml of distilled water) by using sonication (probe sonicator, Frontline®) for 5 min. Then this primary emulsion was again sonicated in 50 ml of an aq solution (w_1) of sodium cholate (0.5% w/v solution in distilled water) to obtain the double emulsion ($w/o/w_1$). After wards, the solvent evaporation was carried out by gentle magnetic stirring at room temperature. Nanoparticles were recovered by centrifugation (at 20,000 rpm for 1 hr at -4^{o}C), washed with distilled water, lyophilized & stored at cool temp (2-8 ^{o}C).

D. Surface morphology

Scanning electron microscopy (SEM) and atomic force microscopy (AFM) were performed to evaluate the surface morphology of nanoparticles. A JEOL Model-6400 Field Emission Scanning Electron Microscope and a Contact Mode Nanoscope E version Digital Instrument were used to evaluate SEM and AFM respectively.

E. Measurement of nanoparticle size and zeta potential (ζ)

The particle size (nm), zeta Potential (mV) and polydispersity index (PDI) were determined by using a Zetasizer apparatus (Malvern Instruments Ltd, UK) equipped with the Malvern photon correlation spectroscopy (PCS) software (version 4.1). Mean values of these parameters for three batches are illustrated in Table 1-5.

F. Drug encapsulation efficiency

5 mg of the nanoparticle preparation was dissolved in 10 ml of dimethylformamide (DMF). The drug content of this solution was determined by measuring the absorbance at 308 nm with a Shimadzu®-1700 pharmaspec UV/visible spectrophotometer and quantitatively determined by comparison with a standard curve. Percent loading ((% loading) of cisplatin was evaluated by using the following equation 1.

$$\% \text{ loading} = \frac{W_{ds} \times 100}{W_s} \quad (1)$$

Where,

W_{ds} = Amount of drug (mg) found in the sample of lyophilized nanoparticles

W_s = Theoretical amount (mg) of the drug used

G. In-vitro drug release study

The *in-vitro* cisplatin release of the nanoparticle was determined by dialysis method. 2 ml of nanoparticle sample was sealed in cellulose dialysis membrane. The dialysis bag was submerged in 100 ml of phosphate buffer saline (PBS, pH 7.4) and incubated at 37 ^{0}C. At definite time intervals 1 ml sample from the incubation medium was drawn and analyzed for cisplatin. After sampling, the incubation medium was always replaced by the same quantity of fresh PBS solution. Samples were drawn at each day after the start of release study and thereafter for 7 days. The release of drug was observed by using Shimadzu®-1700 pharmaspec UV/visible spectrophotometer after proper dilution and quantitatively analyzed by comparing with a standard curve of cisplatin in DMF.

III. Results and discussion

A. Optimization of processing parameters

The preparation study was carried out at room temperature (excess temperature may cause degradation to encapsulated drug). From the results observed by changing the processing parameters, it was found that an increase in polymer concentration results in to increase in the size of the nanoparticles. The optimum concentration of the polymer selected was 25 mg/ml (Table 1).

An increase in the concentration of stabilizer in the external aq phase can results in an increase in the residual amount of sodium cholate in nanoparticles, which cannot be removed easily during the washing of nanoparticles. For instance, with a concentration of sodium cholate equal to 0.5 %, nanoparticles with size of 199 nm were obtained (Table 2). Other characterization parameters were also found as required.

An increase in drug encapsulation efficiency was found with increase in internal aq phase volume, but excess of internal aq phase volume produced particles with larger size. The volume of 1 ml used in the nanoparticle preparation was good enough to produce particles with smaller size and having satisfactory results for other characterization parameters (Table 3).

On the other hand, an increase in the external aq phase volume could lead to a decrease in the particle size of nanoparticles. The volume (50 ml) of external aq phase selected for the preparation of nanoparticles was sufficient to produce appropriate results (Table 4). There was no prominent effect of external aq phase volume observed on the drug encapsulation efficiency of nanoparticles.

Sonication is an important parameter for the emulsification and size reduction of nanoparticles. Sonication for much more time can cause in rupture of the nanoparticles. The optimum time for sonication was found 5 min at which satisfactory results were obtained (Table 5).

B. Surface morphology of nanoparticles

AFM (Fig. 1) and SEM (Fig. 2) analysis were used to investigate the surface morphology of nanoparticles. The nanoparticles appear spherical and almost no aggregation was observed as illustrated in the respected Figures.

C. Entrapment efficiency & In-vitro drug release study

The entrapment efficiency of cisplatin in the nanoparticles was found up to 24.95 %. As shown in Fig. 3, nanoparticles produced a biphasic cisplatin release profile with an initial burst effect within the first 48 hr. This fast release is related to drug adsorbed on the nanoparticle surface. After this phase a constant slow release of cisplatin was observed for 7 days of study period.

IV. Conclusions

We have developed and optimized a simple and rapid process to produce polymeric nanoparticles by varying the different processing parameters. The influences of several parameters on the preparation of PLGA nanoparticles were shown. The results obtained for different studies showed that PLGA nanoparticles developed in this study could be the nanoparticles for application in the controlled delivery of cisplatin for cancer therapeutics.

Physics underling Topobiology: Space-time Structure underlying the Morphogenetic Process

K. Naitoh

Waseda University, Faculty of Science and Engineering, Tokyo, Japan

Abstract — **Development processes of multi-cellular systems have attracted attention for a long time. One particular aspect of interest is the fusion of the symmetric and asymmetric cell divisions in space. We clarify the physical principle for determining whether asymmetric cell divisions occur in living beings or not. Then, we also reveal the physical reason why the organs such as arms, legs, lungs, vertebrae, and kidneys are left-right symmetric, while the heart and the liver are asymmetric. Next, we examine the temporal aspects underlying the morphogenetic processes. The macroscopic model having six categories of molecules shows that the antagonism between the negative controllers and the positive replication factors induces bifurcations in stem and pluripotent cells at rhythmic intervals comprising about six divisions. This cycle of six divisions, i.e., branching time between periodic bifurcation events, corresponds to the emergence timings of blast cysts, embryos, germ layers, tissues, and organs, which can be observed for about every six cell divisions. Finally, we show that the evolution of negative controllers brings longer non-coding regions in DNA and higher-organisms.**

Keywords — **Morphogenesis, Organs, Topobiology, Cyto-fluid dynamic theory, Asymmetry**

I. Introduction

Development processes of multi-cellular systems can be examined separately from two viewpoints of space and time.

The symbiotic concept of symmetry and asymmetry is a key for understanding the spatial structures in living organisms. Stem cells show asymmetric and symmetric divisions. [1, 2, 3, 4] A left-right symmetric distribution of the eyes, nose, ears, arms, and legs is observed in outward appearance, although the inner body, including the heart and the liver, is asymmetric. We reveal the physics underlying the fusion of asymmetry and symmetry.

Next, let us see the temporal characteristics. It is well-known that each cycle of six cell divisions is the basic morphogenetic cycle determining the bifurcation points of organs in human beings. [5] For example, about six cell divisions of a fertile egg produce blast cysts and the next six divisions lead to the new stage with the complex structures of ectodermal and endoderm cells. In the later part of the morphogenesis of human beings, hands and legs also emerge at six divisions after the first heart beat. Thus, in this report, we will reveal the temporal mechanism promoting the cycle of six cell divisions, "six-stroke engine", by proposing the nonlinear equation derived based on the molecular biology.

II. Spatial structure

The cyto-fluid dynamic theory for describing the deformation and motions of connected cells [6, 7] is used to examine the relation between the type of motion and cell size. The dimensionless deformation rate x of each cell dependent on dimensionless time t can be described as

$$d^2x/dt^2=(e-1)(dx/dt)^2+(e^3-3)x+q(t), \quad (1)$$

where the parameter e and the term $q(t)$ denote the size ratio of the two cells connected under equilibrium conditions and the time-dependent force generated by the other connected particles, respectively. When the particles are spheres under equilibrium conditions, x is zero. A symmetric ratio of 1.0 (e=1) makes the first term on the right-hand side of the equation zero, while an asymmetric ratio of $\sqrt[3]{3}$ around 1.5 (e^3=3) makes the second term zero. Life is relatively quasi-stable because d^2x/dt^2 becomes relatively smaller, when the size ratio of cells connected takes these values of e=1 and e^3=3. The first and second terms also show that *symmetric (e=1) and asymmetric (e^3=3) cell divisions are more stable for the small disturbance of motion (dx/dt) and cell deformation x, respectively.* (Fig. 1.) (Losick et al. writes the review paper that small fluctuations of cells are important for determining the morphogenetic processes. [8] Living microorganisms such as bacteria move round with fine motion, although dead ones are stationary. This fine motion will bring small deformations of cells inside agglomerate of cells. Thus, analysis based on Eq. (1) is important to examine the processes.)

This relation between small deformation and asymmetric division leads to an understanding of the aggregation of cells such as those in a colony. Let us separate cell aggregation into two parts, the internal side around the center of the aggregation and the external side close to the surface. External cells close to the surface move relatively easily under the influence of inhomogeneous force, because one part of the cell is free without any connection to other cells. However, internal cells often receive homogeneous forces from

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1329–1332, 2009
www.springerlink.com

many directions due to the presence of other cells, making it relatively difficult for them to move relative to the origin on the earth. Thus, inner cells deform relatively easily without any translational motion of the gravity center. (Fig. 2.) As a result, the inner and outer cells determine whether cell divisions are asymmetric or symmetric, respectively. [9]

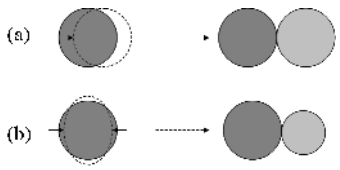

Fig. 1. **Symmetric and asymmetric divisions.**

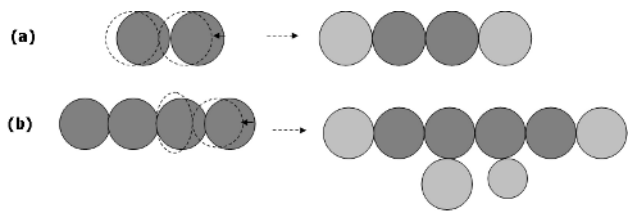

Fig. 2. **Division pattern related to neighboring states of cells.**

Let us examine the cell division process of yeast (Saccharomyces cerevisiae), because symmetric and asymmetric size ratios are also observed at the cell level of microorganisms. Saccharomyces cerevisiae was cultivated at a constant temperature of 37 degrees Celsius on a warm plate and was observed continuously under a microscope until eight cells were formed. Figure 3 shows that internal mother cells (black) generate child cells in asymmetric division, while external mother cells (gray) produce symmetric ones.

The present analysis also clarifies the reason why the left-right symmetric distribution of arms and legs is observed in outward appearance, although the inner body, including the heart and the liver, is asymmetric. It is posited that the lungs are symmetric because of contact with the outer air during breathing. [9] It is clear that the spatial distribution pattern of organs such as the lungs is sensitive to connections with the outer environment, as is also seen in the emergence of the respiratory passage and pulmonary circuit just after birth. (The lungs will be open even before the birth, while filling with water.) The kidneys are symmetric because of continuous contact with outer water in the form of urine owing to the fact that the amniotic fluid of fetus is fetal urine.

The reason why vertebrae in the center of mammals are symmetric is related to the fact that water containing Ca ions enters the inner region when gastrulation occurs, because the primordial gut is also in the outer part of water.

Blood vessels are closed and must not be open to the outer world in order to prevent virus infections. Thus, the heart and liver filled with blood are asymmetric due to the process similar to buckling behavior.

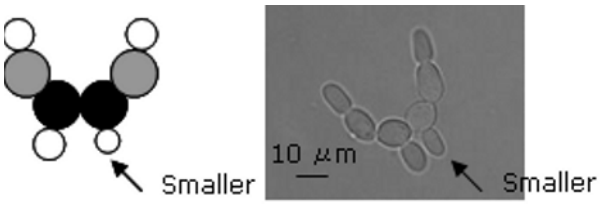

Fig. 3. **Cell division process of Saccharomyces cerevisiae.**

Classification based on the concept of Ectoderm, mesoderm, and endoderm is not deficient for the question whether the organs are left-right symmetric or not. Both asymmetric heart and symmetric kidney come from the mesoderm as an example.

A lot of leaves in plants also have the left-right symmetry in the outer shapes and also in the main vein in the leaf center, although the branch veins in the middle are asymmetric.

It is stressed that the center and outer parts of DNA such as centromere and telomere have symmetric arrays of bases, while the middle part of DNA has asymmetric arrays.

The human body has over 10 trillion cells. *Nature generates the physical rule of self-organization whereby open organs become symmetric, while closed organs show asymmetry. As a result, trillions of cells in human beings can be generated by only forty cell divisions.*

III. Temporal structure

A. 4-cylinder engine

All of the molecules are classified into some categories, based on their representative physical characteristics.

At least two types of molecular categories (enzyme systems), which are for replicating gene groups and enzyme systems, are necessary for achieving a closed reaction cycle. Examples of the former and latter are DNA-replicase and ribosome protein, respectively. This leads to the conclusion that two types of gene groups are also inevitable and serve to code the two enzyme systems. The core cycle for self-replication can be modeled by these four molecular categories, two gene groups and two enzyme systems (Categories D1, D2, R1, and R2). (Fig. 4)

Here, Di and Ri for i = 1 and 2 also denote the density of each molecular category. We assume that the production

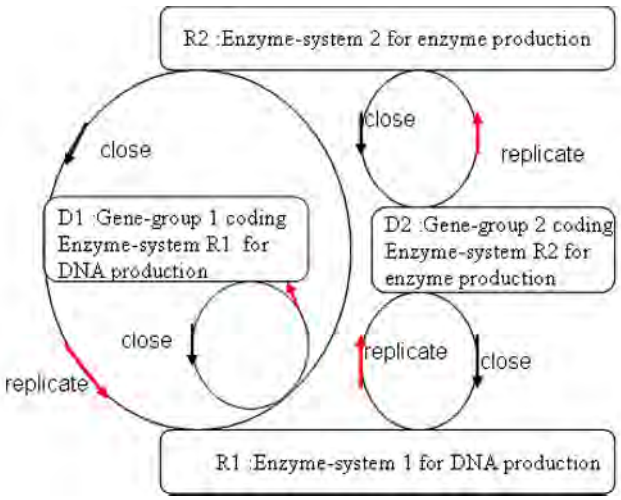

Fig. 4. **Four categories of molecules for minimum replicator.** (D1: Gene group 1 that codes enzyme system R1 for DNA production, D2: Gene group 2 that codes enzyme system R2 for enzyme production, R1: Enzyme system 1 for DNA production, which includes DNA polymerases, topoisomerase, helicases, ligases, and primases, R2: Enzyme system 2 for enzyme production, which includes ribosomes with rRNAs and ribosome proteins, RNA polymerase, mRNAs, and tRNAs)

rate of a category due to the reaction of categories Dj and Rj is restricted by the smaller one of Dj and Rj.

Then, we can describe the densities of four categories averaged over all the cells at generation *N* by Eq. (2).

$$D_i^{N+1} - D_i^N = \alpha_{ij} D_i^N \otimes R_j^N, \quad i = 1, 2,\ j = 1, 2 \tag{2}$$

where $D_i \otimes R_j$ and α_{ij} denote $\min(D_i, R_j)$ and a constant, respectively.

This system of D1, D2, R1, and R2, the 4-cylinder engine for life, can replicate each other. (Fig. 4.) [9]

B. 6-cylinder engine

The negative enzyme system and its gene group (D3 and R3) are then incorporated into the foregoing core cycle of 4-cylinder, because the morphogenetic process of multi-cellar systems in mammals must include negative controllers such as Oct-4 and SOX2 for producing tissues and organs. [10, 11, 12] D3 and R3 can be defined as follows.

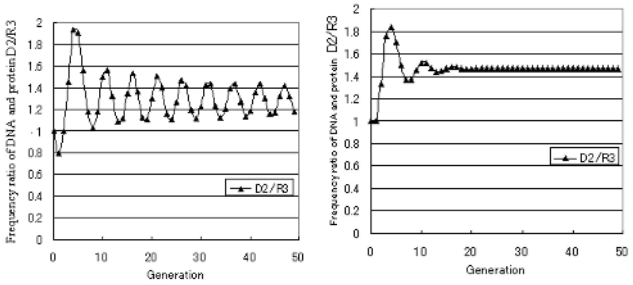
D3: Gene group 3 that codes protein system R3 for suppressing D2 gene expressions

R3: Protein system 3 for suppressing D2 gene expressions, which includes the proteins of the transcription factors such as those of Oct-4 and SOX2. (Only the protein system generated in Category R3, a negative controller, attaches to the positive gene group D2**.** Thus, the production rate of R2 can be re-written in the form of min (D2-R3, R2).)

We can describe the densities of six categories averaged over all the cells at generation *N* by the following equations.

$$D_i^{N+1} - D_i^N = \alpha_{i1} D_i^N \otimes R_1^N, \quad i = 1,2,3 \tag{3}$$

$$\begin{aligned} R_1^{N+1} - R_1^N &= \alpha_{12} D_1^N \otimes R_2^N \\ R_2^{N+1} - R_2^N &= \alpha_{22} \delta(D_2^N - R_3^N) \otimes R_2^N \\ R_3^{N+1} - R_3^N &= \alpha_{32} D_3^N \otimes R_2^N \end{aligned} \tag{4}$$



where $D_i \otimes R_j$ denotes $\min(D_i, R_j)$ for i=1-3 and j=1-3, and also where $\delta(x)$ denotes the larger one of *x* or 0, i.e., max (x, 0). (Here, the constant α_{ij} includes the influences of many types of molecules in the category and the molecule movements on reaction probability. There is an important constraint, i.e., the densities of D1, D2, and D3 are identical, because the three gene groups 1, 2, and 3 are in one set of DNA in each generation. Thus, α_{i1} for D1, D2, D3 is a set having the identical value of 1.0. Initial densities of D1, D2, D3, R1, R2, and R3 are set to be 1.0, respectively.)

Let us denote the number of cell divisions after the mother cell generation as N. Generation N is less than 50, because an adult human body can be generated by about fifty cell divisions from a fertilized egg. Accordingly, the number of cells at generation N is defined as P(N). There are many types of cells among P(N) such as somatic and stem cells. A cell must have one set of DNA. Thus, the number of cells, P(N), is equal to D_i^N.

Broadly speaking, computational results obtained by Eqs. (3) and (4) show nearly exponential or hyperbolic increases of Di and Ri. *Then, the antagonism between the negative controller R3 and the positive replication factors R1 and R2 induces bifurcation events in the stem and iPS cells at rhythmic intervals constituting about six divisions, although the intervals are slightly chaotic and the vibrational amplitude is attenuated. It is stressed that this cycle of six divisions, i.e., branching time between periodic bifurcation events, corresponds to the emergence timings of blast cysts, embryos, germ layers, tissues, and organs, which can be observed for about every six cell divisions.* (Fig. 5a.)

The flexible shapes of transcription factors may give the parameters of α_{i2} various values. However, emphasis is placed on the fact that three system parameters, α_{i2}, have less influence on the time cycle of bifurcations. The cycle of about six divisions is stable. (Fig. 5b.)

The condition of D2/R3 > 1.0 means that a part of D2 is not covered by R3. This implies that several types of proteins in D2 emerge and also several types of somatic cells

(a) (b)

Fig. 5. **Time histories of D2/R3 during 50 generations of the morphogenetic process.** (a) $\alpha_{i2} = 1.5$ and (b) $\alpha_{i2} = 1.0$

are produced to make organs and tissues. The condition of D2/R3 < 1.0 means that D2 is completely blocked by redundant R3, which implies stem or induced pluripotent stem (iPS) cells. This oscillation of D2/R3, which implies the amount of D2 uncovered by protein group R3, will lead to the changes in the gene combination for expressions. This corresponds to the fact that iPS cells can be reprogrammed by the presence of much Oct-4.

Averaged value of D2/R3 is around 1.30. This means that the amount of genes in D2 expressing is about 30 percents and also the 70 percents in D2 are suppressed. The large amount of suppression in D2 may imply non-coding regions such as introns and junk. This also corresponds to the fact that microorganisms without R3 have less introns and junk.

As R3 becomes more effective according to increasing α_{32}, introns and junk become longer according to depression of D2. It is stressed that effective R3 (increasing $\alpha 32$) reduces the dissipation of the D2/R3-oscillation, leading to larger sizes of multi-cellular organism. (Fig. 5) Effective R3 leads to the longer oscillation of six cycles, which produce larger life having more types of organs.

Analysis based on Eqs. (3) and (4) also shows that D2/R2 is large during the early stage before N = 6, indicating a small density of protein R2. This small density of R2 produces fewer proteins and enzymes at the early stage, while gene groups of Di can be generated more. This leads to decreasing cell sizes with each succeeding generation, as is seen in actual blastocysts.

IV. Conclusion

Small deformation of cell shape brings the molecular deformation in DNA and proteins inside cell. This leads to the replacement of the genes expressed. Asymmetric cell division promoted by the fluid-dynamical stability is fixed by the asymmetric usage of genes at molecular level.

The early cell divisions of fertile egg and the cerebral development can also be explained by using fluid-dynamics. [14, 15]

The Properties of Hexagonal ZnO Sensing Thin Film Grown by DC Sputtering on (100) Silicon Substrate

Chih Chin Yang, Hung Yu Yang, Je Wei Lee and Shu Wei Chang

Department of Microelectronics Engineering, National Kaohsiung Marine University, Kaohsiung, 81143 Taiwan, Republic of China

Abstract — **This research was proposed to utilize sputtering system to fabricate sensing material of electronics nose of humidity sensor, and expected to use it in nano and multiple biosensor system with intelligent functions in new generation. The first test was material measurement for zinc oxides (ZnO) deposited on (100) Si substrate in variable thin film thickness and epitaxial growth time. The second test was that the variable growth time will be selected to study characteristics of the sensing material in humidity sensors by measurement of resistance and capacitance. The ZnO nanostructure-like were synthesized on silicon wafer with native buffer layer by the DC sputtering method, and the optimum growth conditions based on growth temperature, oxygen flow rate, and growth time, have been found. We discussed some issue of growth rate, resistivity of thin film, and crystalline of nanostructure, and also explained the sensing mechanism of ZnO hexagonal nanostructure in impedance measurement. It is experimentally demonstrated that the ZnO hexagonal nanostructures have potential growth by DC sputtering growth method on silicon wafer with native oxidation at room temperature. This grown ZnO epitaxial layers would be used in application of sensors.**

Keywords — **ZnO, Sputtering system, Sensing material, Humidity sensor**

I. Introduction

Humidity, gas and temperature measurements are very important concerns in environment fields, such as medical applications for human comfort and industrial uses [1]. Therefore, the requirement for cheap, reliable, and sensitive humidity, gas and temperature sensors are urgent. For the humidity sensor and gas sensing devices, an ideal coating material should adsorb the moisture efficiently and easily. Until now, many nano-materials have exhibited excellent molecular adsorption properties. ZnO nanostructures, in particular, are being considered as prime material for the moisture adsorption due to their large specific surface area.

The ZnO material is also a versatile II-VI semiconductor, with numerous applications ranging from blue and ultraviolet optical devices such as light emitting diodes and laser diodes in the ultra violet range to chemical sensors because of its distinctive optical [2-4], electronic, and chemical properties [5-8]. It has a hexagonal wurtzite structure, with lattice parameters of a=3.2498Å and c=5.2066Å. Among them, ZnO has been receiving considerable attention because of its wide and direct band-gap energy (3.34 eV~3.37 eV at room temperature) and high exaction binding energy (~60 meV). In fact, the high exaction binding energy of ZnO, compared with that for GaN (28 meV) and ZnSe (19meV), would allow for excitonic transitions even at room temperature, which could lead to a higher radiation recombination efficiency for spontaneous emission as well as a lower threshold voltage for laser emission [9]. In order to realize these devices, it is indispensable to grow high-quality ZnO films with p-type conductivity. Undoped ZnO expitaxial films normally exhibit strong n-type conductivity due to intrinsic defects such as interstitial Zn and oxygen vacancies. These intrinsic defects make it very difficult to grow low resistively p-type material. Although ZnO based oxide semiconductors in the area has been grown, a number of problems remain, including difficulties associated with p-ZnO growth and the lack of high quality ohmic or schottky contacts for n type or p type ZnO.

ZnO thin films have been grown using several different deposition techniques, including pulsed laser deposition (PLD) [10-12], spray pyrolysis (SP) [13], molecule beam epitaxy (MBE) [14], atomic layer epitaxy (ALE), metal organic vapor phase epitaxy (MOCVD) [15-16], and electron cyclotron Resonance (ECR) [17]. ZnO has been deposited on various substrates, such as silicon [18], gallium arsenic (GaAs) [19], indium phosphor (InP) [20], diamond on silicon [21], and sapphire (Al_2O_3) [22]. In this study, ZnO thin film materials were fabricated on silicon (100) substrates using native silicon dioxide buffer layers with a hexagonal wurtzite structure similar to that of zinc oxide, with lattice parameters of a=3.11Å and c=4.98Å, by using the DC sputtering growth method. For sensor applications, a greater resistively is necessary. The aim of our works was to find out the sputtering conditions which allow the deposition of ZnO films at high deposition rates with a high electrical resistively without any doping and heating processes. Zinc oxide thin films can be grown on buffer layer by means of lattice-matching epitaxy, since the lattice misfit between these two materials is smaller. On the other hand, epitaxial growth of zinc oxide on a silicon substrate with native oxidation buffer layer is necessary to integrate these films with sensing function.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1333–1336, 2009
www.springerlink.com

II. Experiments

The high quality ZnO nanostructures were fabricated by a dc reactive ion sputtering technique. The system has been constructed with a turbo-molecular pump, a throttle valve pressure controller feedback from the gauge. The load-lock allowed the growth system and zinc target to remain constantly under vacuum. The films were deposited on silicon substrates of (100) orientation. The epitaxial structure consisted of an about 40-400 nm thick un-doped ZnO sensing layer and silicon dioxide layer with native oxidation of silicon. In this experiment, the growth temperature was arranged at room temperature. The sputtering conditions were with zinc target of 2" diameter, sputtering mode of bottom-up, distance of 60 mm between target and substrate, gas of both 50% oxygen source and 50% argon source, and the total gas process pressure on the order of 10^{-5}Torr. The argon flow rate is fixed at 10 sccm with a dc power of 50 W. Many products with different resistively and impedance were obtained using different growth time on silicon substrate. The growth period was 1 to 10 minutes and all the films reported here were grown on silicon substrates degreased and cleaned prior to loading in the growth system.

Film thickness was determined by scanning electron microscopy (SEM, JEOL-JSM- T330A)**.** The film thickness was carefully controlled so that the film had a thickness of 1 μm less. The average size of hexagonal crystallites of the film was estimated to be smaller. The structure and orientation of the zinc oxide films were also investigated by XRD. The XRD patterns were measured using CuKα X-rays from a rotating cathode operated at 40 kV and 180 mA. The carrier concentration and mobility of the ZnO layers were measured at room temperature by Hall effect measurements of van der Pauw method. The sensing impedance values of humidity were measured using LCR meter of Agilent – E4980A.

III. Results and discussion

The XRD measurements of ZnO thin film grown on silicon substrate all show the same characteristics with a preferred (002) orientation indication. The c-axis of the hexagonal ZnO structure is perpendicular to the substrate. Fig.1 shows typical XRD of ZnO sample, well oriented with all crystallites having (002) planes parallel to the growth surface. As we improve the quality of our ZnO films by modification of the growth chamber and investigation of the optimum growth conditions, the (002) peaks become sharper indicating a good quality a material with a single orientation. In this study, single crystalline ZnO films oriented along [002] were successfully grown even on (100) Si

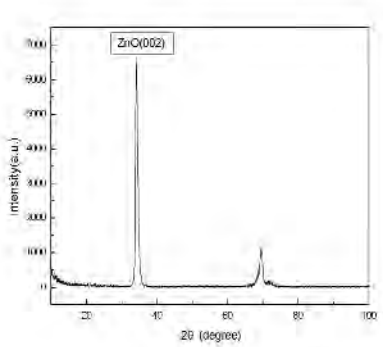

Fig. 1 XRD pattern of ZnO thin film deposited at room temperature.

substrate. Under growth of room temperature, the full width at half maximum (FWHM) of their x-ray diffraction became narrower with low growth temperature. An increase of growth time may improve crystalline of the ZnO films by providing activation energy for ad-atoms to occupy the positions of potential minima and enhancing re-crystallization due to the coalescence of islands by increasing the surface and volume diffusion, resulting in the improvement of the electrical properties with increasing growth time.

The film thickness was carefully controlled so that the film had a thickness of 1 μm less. The average thickness of hexagonal crystallites of the film was estimated to be about 100 nm. ZnO films were deposited on (100) silicon substrates at growth of room temperature. Fig.2 shows a typical scanning electron microscopy image of cross section of the ZnO grown on the silicon substrate at growth of room temperature. Almost the interface of between silicon and ZnO had well-defined shape. The growth rate about 9.6nm/min was obtained by calculation of SEM measurement.

Linear increase in film thickness of ZnO with grown flow rate of 10 sccm at oxygen was observed with increasing growth time as shown in Fig.3. The variation of thickness was performed in the absence of temperature, and the result is also shown in Fig.3.

Interestingly, the resistively variation of ZnO thin films with different growth time was displayed in Fig.4. The resistively is decreased with increased growth time. When a small growth time was utilized in growth of ZnO thin film, the resistively of ZnO thin film exhibited more 260 Ω-cm and the variation of ZnO film thickness had no significant over larger growth time above 5 minute due to the saturation of oxygen in ZnO crystal. All the ZnO films showed n-type conduction. The carrier concentration is of the order 10^{16}cm^{-3}, and almost independent of the substrate temperature. The Hall mobility increases smoothly from 69.9 cm^2/V-s for films deposited at a substrate of room temperature to 2.4×10^2 cm^2/V-s at growth temperature of 400^{o}C.

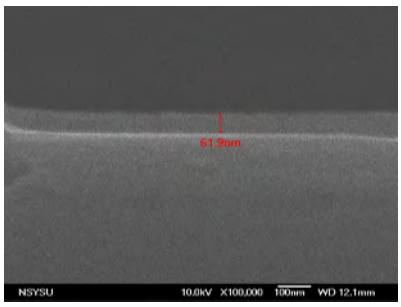

Fig. 2 SEM image of cross section for ZnO thin film.

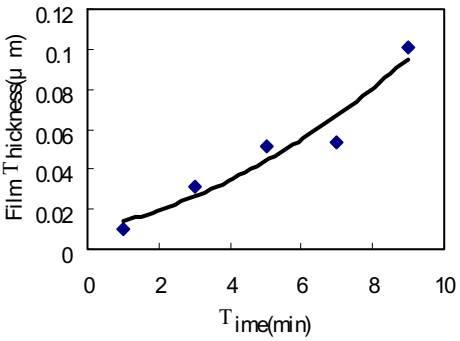

Fig. 3 The deposited time versus film thickness for ZnO thin film in the oxygen flow 10 sccm and the substrate didn't heat.

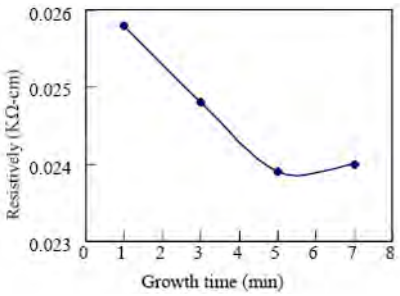

Fig. 4 The deposited time versus resistively for ZnO thin film in the oxygen flow 10 sccm.

The humidity sensing device with finger electrode is fabricated by lithographic method as shown in Fig.5. Concerning the impedance-type sensor, I-V characteristics measured in the relative humidity of 12% and 97% indicate an almost impedance behavior, and evidence a resistance and capacitance strongly dependent on relative humidity, as shown in Fig.6. The ZnO thin film is added moisture on the thin film surface, Fig.6 shows some different for the measurement of the resistances and capacitances by the measurement of LCR Meter. The ZnO epitaxial layers would be successfully in applications of humidity sensor.

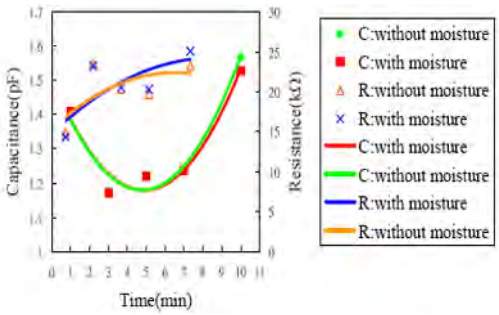

Fig. 5 The resistance and capacitance of ZnO humidity sensor versus growth time in different moisture environment.

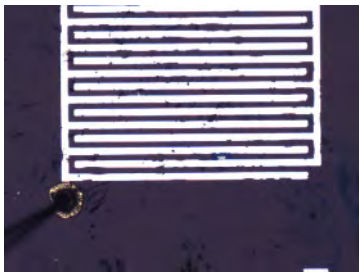

Fig. 6 The ZnO humidity sensor with finger electrodes.

IV. Conclusions

To better understand the influence of the growth process on the sensing characteristic of ZnO humidity sensor on silicon substrate, ZnO films were grown on silicon (100) substrates without initial processing of buffer layer growth. Without initial processing, the ZnO film tended to be grown with crystallographic orientations of (002), though the orientation could be controlled by increasing the growth time but keeping the temperature below the ZnO dissociation temperature. The measurements showed that the carrier concentration and Hall mobility are 10^{16} cm^{-3} and the order of $10^{2}cm^{2}/V$-s, respectively. The film thickness increased with increased growth time linearly. A maximum growth rate of 9.6nm/min was obtained at O_2 flow rate of 10 sccm. At this O_2 flow rate it also displayed a higher preferential and the narrowest FWHM of x-ray. However, with increase in the growth time, the resistively is first started to decrease significantly. While a large growth time, it exhibited less change in resistively and no significant variation is observed above growth time of 7 min. The result shows some different for the measurement of the resistances and capacitances by the measurement of LCR meter in the variation of moisture. The ZnO humidity thin film sensor is successfully fabricated by lithographic method with the use of finger electrodes.

Multi-objective Optimization of Cancer Immuno-Chemotherapy

K. Lakshmi Kiran, D. Jayachandran and S. Lakshminarayanan

Department of Chemical and Biomolecular Engineering, National University of Singapore, Singapore 117576

Abstract — **Relentless research efforts in the recent past have led to the discovery of various cancer treatment modalities. However, there is no specific or absolute therapy for cancer treatment. As a result, doctors/researchers are proposing and employing unprecedented and promising strategies that synergistically combine different therapies to cure cancer. The timing and dosage levels at which the different therapies need to be administered for optimally treating cancer remains not only an interesting research problem but also one that is clinically relevant. In this work, we use a mathematical model comprising of ordinary differential equations to study how immunotherapy and chemotherapy can be optimally employed in cancer treatment. The model elucidates the dynamics of tumor cells, immune cells and therapeutic agents. Our aim is to minimize the tumor size via the optimum application of therapeutic agents. To this end, we use a multi-objective optimization strategy to design an immuno-chemotherapy plan that treats the cancer using minimum therapeutic intervention. We will also compare the best possible single therapy results with the best possible combination therapy protocol.**

Keywords — **Cancer, Mathematical model, Immunotherapy, Chemotherapy, Optimization**

I. Introduction

Presently, cancer is the second lethal disease next to heart disease. The numbers of cancer patients are increasing drastically year by year. According to World Health Organization (WHO) in 2005, about 13% (7.6 million) of the total deaths (58 million) in world were caused by cancer. WHO also speculates that around 9 million and 11.4 million people will die due to cancer by 2015 and 2030 respectively. These figures are alarming and motivate researchers to come up with effective treatment strategies to combat cancer.

Cancer is caused by the external factors such as UV radiations, carcinogenic chemicals as well as transfer of the cancer prone genes from parents. When a normal cell interacts with these external factors, its information system (DNA) gets damaged and the normal cell transforms to a cancer cell. The main characteristics of the cancer cell are its uncontrolled and unregulated growth [1, 2]. Initially, the clump of the cancer cells is confined to particular location and it is regarded as being benign. If the cancer is not diagnosed and treated in the benign stage, it will change into a malignant form, and the cancer cells could migrate to different parts of the body and ultimately may lead to the death of the patient. So, it is better for the cancer patients to be provided suitable treatment at the early stages itself so as to prolong and enhance the quality of their life.

In the past 50 years, many cancer treatment modalities have been discovered. The most common of these are surgery, chemotherapy, radiation therapy, and immunotherapy. However, there is no specific therapy for all types of cancer and each therapy has its own shortcomings. Usually, surgery is favored to remove the tumors. However, the complete clearance of the tumor cells is not assured with surgery. As a result, surgery is followed by chemotherapy or radiation therapy to suppress further tumor growth. In the case of chemotherapy and radiation therapy, precise care should be taken to avert the damage of normal tissue. Among these two therapies, chemotherapy is preferred because it is systemic therapy. In systemic therapy, the drug flows throughout the body and destroys the migrated cancer cells along with residual cancer cells near the surgery location.

Chemotherapy is always given as a course in cycles based on the patient health status rather than as a one-time treatment. This is done so as to maintain the drug concentration within the dosage limits in the body and kill the remaining cancer cells in the subsequent treatments [3] . However, the side effects of the chemotherapy are significant and sometimes they become serious than the disease itself. In this regard, combination of chemotherapy with immunotherapy can be a better alternative. Additionally, immunotherapy has fewer side effects, because, typically, patient's own cells are modified and used as therapeutic agents in contrast to chemotherapy and radiation therapy. Thus, in this paper we focused on immuno-chemotherapy.

The prime objectives of any therapy are to keep the number of cancer cells below a lethal level and avoid the side effects of the therapeutic agents. This can be achieved by optimal scheduling and the optimal administration of the therapeutic agents. Here, we applied multiobjective optimization strategy on the immuno-chemotherapy mathematical

www.springerlink.com

model to achieve the optimal dosage and scheduling of the immune cells and chemotherapeutic drug.

II. Mathematical model and problem formulation for the multi-objective optimization

The model is adapted from [4] and it describes the growth of the tumor cells and its interaction with the immune cells. The model assumes that tumor cells are immunogenic and do not metastasize. In the other words, tumor cells are recognized and attacked by the cytotoxic effector cells. The interactions between the effector cells and the tumor cells are described by a kinetic scheme and are presented as simple equations. The parameters of the model were obtained by using the experimental data presented in [5]. The activity of chemotherapeutic drug is also included in this model [6] . Equation (3) explains the pharmacokinetics and the term *L (T, M)* in equation (2) corresponds to the pharmacodynamics of the drug. *J(M)* is the term related to the death of effector cells due to the excess chemotherapeutic drug.

$$\frac{dE}{dt} = s + \frac{pET}{g+T} - mET - d_1E + s_1 - J(M) \quad (1)$$

$$\frac{dT}{dt} = aT(1-bT) - nET - L(T,M) \quad (2)$$

$$\frac{dM}{dt} = u - \gamma M \quad (3)$$

$$L(T,M) = k(M - M_{th})H(M - M_{th})T$$
$$J(M) = K_l(1 - e^{M})H_1(M - M_{\max}) \quad (4)$$

Where, H and H_1 are the Heaviside functions:

$$if\ (M - M_{th}) < 0, then\ \ H = 0,$$
$$if\ (M - M_{th}) \geq 0, then\ \ H = 1$$
$$if((M - M_{\max}) \geq 0), then\ H_1 = 1$$
$$if((M - M_{\max}) < 0), then\ H_1 = 0$$

$$E(0) = 1\times10^6,\ T(0) = 1\times10^6,\ M(0) = 0$$

In the above model, the states E(t), T(t) and M(t) refer to the effector cells, tumor cells and concentration of chemotherapeutic drug respectively. In equation (1) 's' represents the rate of flow of the inherent effector cells to the tumor location, which is dependent on the number of lymphocytes in the body. The effector cells accumulate at the tumor sites because of events such as release of cytokines and it is proportional to the number of tumor cells. The total degradation of the effector cells is due to its natural degradation and its interaction with the tumor cells. 's_1' is the externally given modified immune cells. The model assumes that tumor growth follows the logistic equation with the constants 'a' and 'b' in the absence of immune interactions. The total decay of tumor cells is the result of interactions with the effector cells and the chemotherapeutic drug. In equation (4), 'u' is the drug delivery rate and 'γ' is the decay parameter of the drug. Equation (4) shows that drug can kill the tumor cells and immune cells only when its concentration is above the threshold limit 'M_{th}' and 'M_{max}' respectively. The three assumptions related to the drug delivery are: (i) infusion of the drug; (ii) spontaneous mixing of the drug with the plasma; and (iii) immediate reach of the drug to cancer site. In this paper, the two contradictory objectives to be minimized are the total number of cancer cells and the total amounts of the therapeutic agents. The time horizon considered to implement the multi-objective optimization is 500 days. Objective 1 is given by equation (5) which is the summation of the running load and final load of tumor cells. Objective 2 is given by the equation (6) and is the combination of the running load of the chemotherapeutic drug and summation of all inputs of the immune cells. We used MATLAB's [7] implementation of genetic algorithm to solve this multi-objective optimization problem. The algorithm starts with an initial population of possible solutions and in each generation, the solutions are updated based on genetic principles. In this work, we considered population number as 100 and the maximum number of generations as 100. The decision variables in the problem are injection times, administration of number of immune cells and amount of drug.

PROBLEM FORMULATION:

Objective 1: $$\min_{u(t_i),s_1(t_i)} \int_0^{t_f} T(u(t_i),s_1(t_i))\,dt + T(t_f) \quad (5)$$

Objective 2: $$\min_{u(t),s_1(t)} \int_0^{t_f} M(u(t_i),s_1(t_i))\,dt + \sum_{i=1}^{10} s_1(t_i) \quad (6)$$

t_f is the final time i.e. the planning horizon
t_i is the ith time injection of the therapeutic agents

Constraints:
Equations (1) through (4) i.e. the mathematical model

$$0 \leq M(t) \leq M_{\max}$$
$$50(i-1) \leq t_i \leq 50i\ \ , i = 1,2....,10$$

Table 1
Parameter values in the model

U_{max}	51	$[D]day^{-1}$
S_{1max}	1e8	cells
K_1	0.6	day^{-1}

[D] is concentration of the drug

III. Results and Discussions

Figure 1 show that the evolution of tumor cells is oscillatory with decreasing amplitude and finally reaches a steady value. It also confirms that only chemotherapy to the patient does not bring down the steady state value of the tumor cells. However, it is clear that the drug lowers the amplitude of the oscillation. While the steady state value of the tumor cells can be brought down (compared to the no treatment case) through increased infusion of the drug, the concentration of the drug may cross the allowable limits and it is undesirable for the patient.

Figure 2 shows that, the combination therapy is better than chemotherapy alone in controlling the growth of the tumor cells. The solutions of injection times for all generations of the genetic algorithm are projected in figure 3. This gives us an idea about the tendency of solutions towards the optimal schedule with the generations. Information on the injection time and the administration of immune cells and chemo drug can be acquired from Figures 3, 4 and 5.

Figures 3, 4 and 5 describe the decisive impact of administration of maximum number of immune cells and maximum amount of drug to the patient at the initial time. Recall that our objective is to minimize the tumor cells with an optimal amount of therapeutic agents. Hence, once the

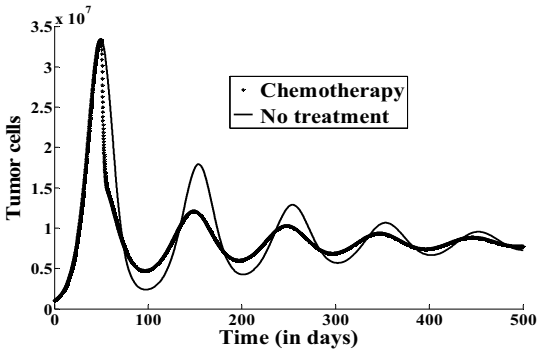

Figure 1: Evolution of tumor cells for chemotherapy only

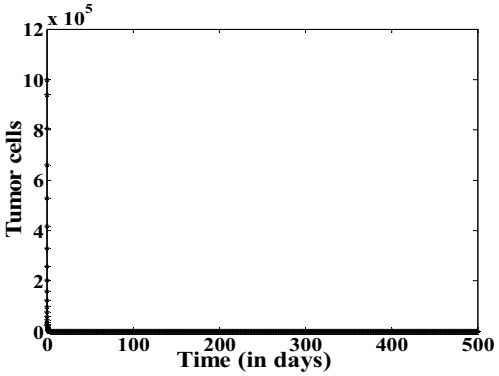

Figure 2: Evolution of tumor cells for combination therapy

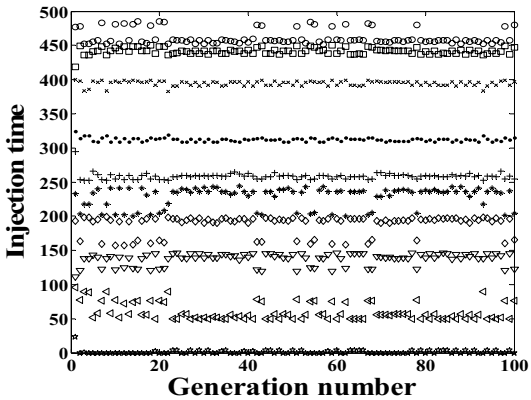

Figure 3: Variation of schedule with generations of the algorithm

tumor cells are reduced with the initial input, lesser number of immune cells and lesser amount of drug is enough in the subsequent time instants to control the tumor cells. Another important feature observed in figures 4 and 5 is that, in many cases, when one therapeutic agent is decreased from its previous input value, the other therapeutic agent is increased. This shows that the optimization procedure prop-

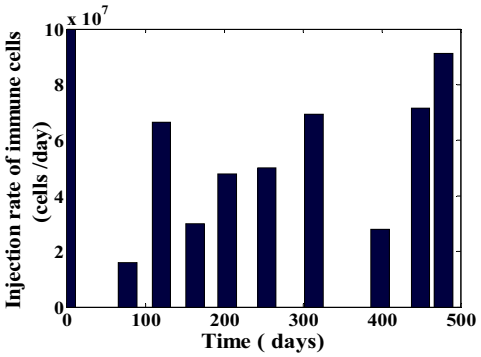

Figure 4: Optimal input of immune cells in combination therapy

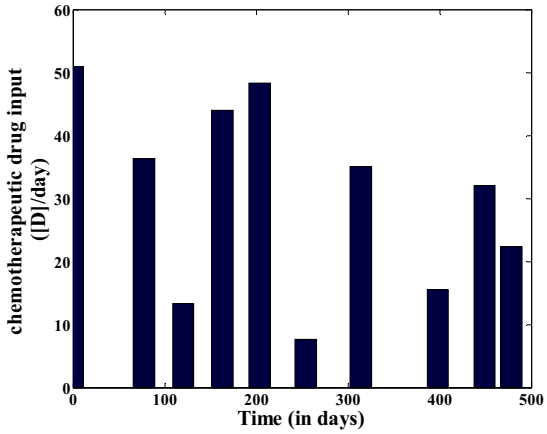

Figure 5: Optimal input of chemotherapeutic drug in combination therapy

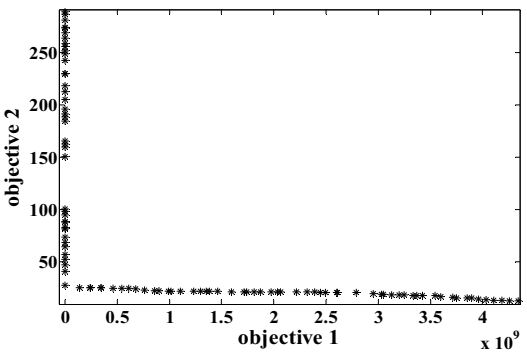

Figure 6: Optimal Pareto solutions for the multi-objective optimization problem

erly balances the administration of therapeutic agents. Figure 6 summarizes the Pareto optimal solutions between the extreme values of the two objectives. Here, we considered the solution when the values of the objective 1 and objective 2 are 3.814e+005 and 2.88e+002 respectively.

IV. Conclusions

We applied multi-objective optimization to find the optimal schedule as well as optimal dosage of the therapeutic agents. A major advantage of the multi-objective optimization method is that we get a set of best solutions and we have the freedom to choose any one solution as per the requirements. The result obtained proves that immunochemotherapy is very much significant than chemotherapy alone in controlling the tumor cells. The obtained protocol design can guide caregivers in treating cancer patients.

Dip Coating Assisted Polylactic Acid Deposition on Steel Surface: Film Thickness Affected by Drag Force and Gravity

P.L. Lin[1], T.L. Su[1], H.W. Fang[1*], J.S. Chang[1], W.C. Chang[2]

[1] Department of Chemical Engineering & Institute of Biotechnology, National Taipei University of Technology, Taipei, Taiwan
[2] Bio-Invigor Corporation, Taipei, Taiwan

Abstract — **Dip coating process has the potential of providing an easier and economical way to form a polylactic acid (PLA) layer on metal surface for various applications. The effects of dip coating operating parameters such as the withdrawal velocity, concentration, and viscosity of the solution on the film thickness were investigated in this study. Our experimental results show that the increase of withdrawal velocity leads to the increase of PLA film thickness at the relatively low withdrawal velocity regime. However, at the relatively high withdrawal velocity regime of the dip coating process, it was observed that the PLA layer thickness starts to decrease with increasing withdrawal velocity. It is suggested that the competition of drag force and gravity during the dip-coating process dominates PLA film formation. A mechanism was proposed to explain this special behavior which was never observed in the dip coating process.**

Keywords — **Coatings, Polymers, Deposition, Dip coating, Polylactic acid, Film thickness**

I. Introduction

Polylactic acid (PLA) based materials have been applied in biomedical applications due to their bioresorbable properties [1–3]. Deposition of biodegradable PLA layer on medical implant surface may assist on drug release and tissue regeneration applications. The dip coating process involves by dipping substrate into reservoir of solution for some time until the substrate is completely wetted, and then withdrawing the substrate from the solution bath [4]. The dip coating process has been applied in various applications such as thin films in sol–gel technology [5], photoresists films [6] and lubricant layers for magnetic hard disks [7]. Not only that the process itself, space required, and equipment used can be simple enough, but it also can be applied to coat thin films onto plates, slabs, or almost any irregular shaped objects.

The purpose of this study is to observe how the dip-coating operating parameters affect the deposited film thickness. Various concentrations of PLA solutions and different withdrawal velocities were applied in the dip coating experiments to see their effects on PLA film thickness. In addition, by comparing the results with the dip coating models in the literature, it is expected to obtain the critical information for further optimization of the dip coating process from practical viewpoint.

II. Materials and methods

A. Materials

Medical grade poly (DL-lactic) acid with an inherent viscosity of 0.55 dl/g was obtained from Bio-Invigor Corporation (Taipei, Taiwan). Three different solution concentrations (15%, 20%, 30%) of PLA solutions were prepared by dissolving PLA into acetone. The rheological properties of the PLA solutions were measured with cone/plate viscometer (Brookfield LVDVIII ultra rheometer) at 25 °C. The medical grade 316 stainless steel disks (3 mm thick, 15 mm in diameter) were prepared as substrate materials for dip coating process. The surfaces of the 316 stainless steel disks were polished to mirror surface with the roughness of Ra=0.11 μm.

B. Dip coating process

The schematic of the dip coating process is shown in Fig.1. A self developed controller was used in the experiment for the dip coating process. The instrument can move clamp vertically at constant speeds between 4 to 100 mm/s. cover lid with designed small slot was designed to prevent solvent evaporation from the surface of the solution. The 316 stainless steel disks were then immersed into the solution and kept an uncoated area on the top of the disk. The disk was then withdrawn from the bath at prescribed withdrawal velocity. The drying process of the coated disk is done by leaving the disk in its natural vertical position in the hood at room temperature.

C. Dip coating process

A surface profilometer (Mahr, Germany) was used to measure the surface profile of the coated 316 stainless steel disks after the dip coating process. The tracing probe was traveling across the boundary of the uncoated and PLA coated areas on the steel plate. The movement of the probe

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1341–1343, 2009
www.springerlink.com

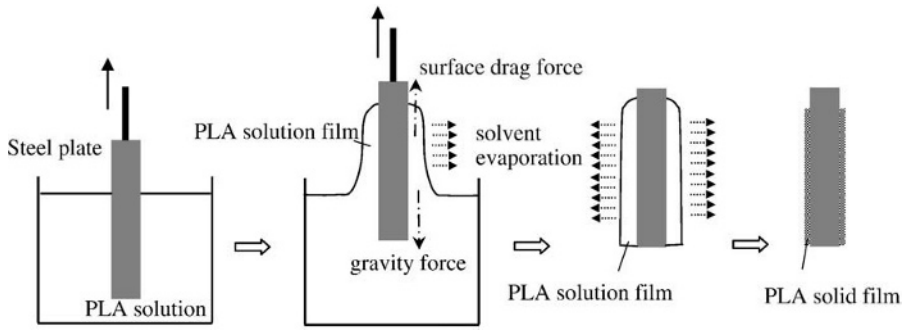

Fig. 1. Schematic of dip coating assisted PLA deposition on steel plate and the factors affecting the solid PLA film formation in a dip coating process.

is recorded for film thickness determination. The PLA film thickness defined in this study presents the gap between the uncoated area and the coated area far from the coating boundary. The measurement was at least repeated 3 times at different locations on the disk to obtain the average film thickness.

III. Results and Discussion

A. Materials

Results of shear stress of the PLA solutions with different concentrations were measured under various shear rates between 1~60 (s^{-1}). It is observed that the viscosity is independent of shear rate. The viscosity of the PLA solution increases with the increase of solution concentration. The average viscosities of the PLA solutions with 15%, 20% and 30% concentrations are 11.2 cp, 20.2 cp, and 107.7 cp respectively.

B. Film thickness

The experimental results of the film thickness versus the withdrawal velocity of dip coating process for PLA solutions with concentrations of 15%, 20% and 30% are shown in Fig. 2. In section I of the plot, the film thickness, h, increases with increase of withdrawal velocity. This trend is expected since the viscous pull drag of steel plate surface on PLA solution is proportional to the withdrawal velocity. With a higher velocity, a greater amount of the liquid is pulled which results in a thicker film. It is also observed from Fig. 2 that a higher concentration of PLA solution leads to the increase of film thickness, h. It is due to the viscosity (pull drag) is larger for high concentrations as indicated in Section I. In other words, at the same withdrawal velocity, the amount of PLA solution moving upwards with the steel plate is larger for a more viscous liquid according to the fact that the drag force is proportional to the solution viscosity.

Section II of Fig. 2 indicates the decrease of film thickness with increase of the withdrawal velocity. We call the point in which the withdrawal velocity creates the maximum PLA film thickness as. The value of differs with each solution and is smaller for PLA solutions with smaller concentrations. We recall that in section I the thickness of the coating film increases as the viscous pull drag is proportional to withdrawal velocity. However as υ further increases in section II, an abundant amount of solution is pulled up with a comparative shorter time. With the lack of sufficient evaporation time, the gravity force of the PLA solution film leads to solution film moving back the solution pool before the solid PLA film formation on steel surface. The outcome of the competition between drag force (solution film moving upward) and gravity (solution film moving downward) as shown in Fig. 1 determines the variation of final solid PLA film thickness while increase of withdrawal velocity during the dip coating process.

C. Model fitting and gravity affect

Landau et al. provided the earliest analysis of the dip coating process [4]. Their model was a one-dimension infinite long plate drawn out of a wetting bath. The analysis was based on the hydrodynamics equations of Newtonian fluid. The relationship between the film thickness and withdrawal velocity is given as,

$$h \propto \upsilon^{0.667} \tag{1}$$

where h is the thickness of the coated layer and υ is the withdrawal velocity. Eq. (1) however is based on the above theoretical situation and for practical purposes and process conditions the above relation is modified as,

$$h \propto \upsilon^{x} \tag{2}$$

in which the power term of 0.667 is replaced with x.

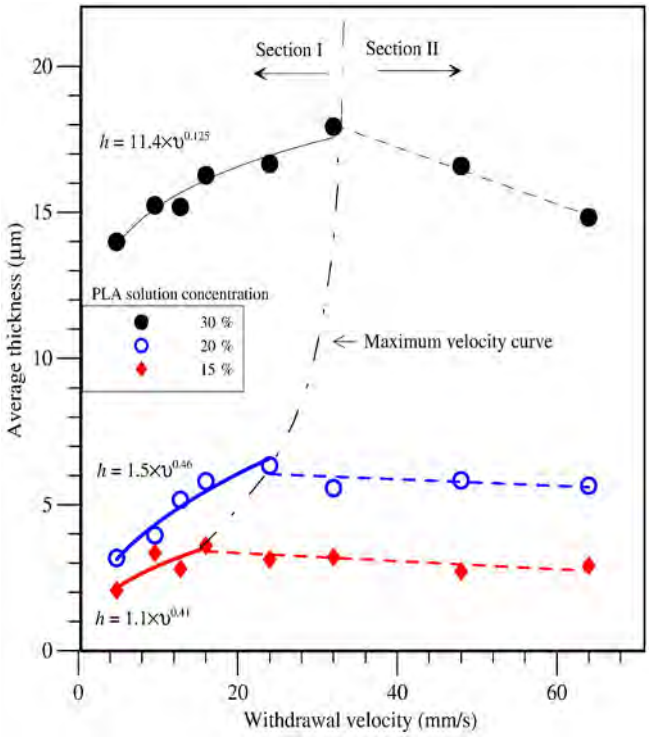

Fig. 2. Solid PLA film thickness as a function of withdrawal velocity with different concentration solutions.

Table 1
υ_{max} and percentage of thickness loss caused by gravitational effect under 3 different concentrations of PLA solutions

Concentration (wt.%)	υ_{max}	Maximum thickness	Percentage of h loss at
		h_{max} (μm)	$2\times\upsilon_{max}$
15.0	16.0	3.6	5.1%
20.0	24.0	6.3	8.0%
30.0	32.0	18.0	17.3%

According to the mathematical expressions of Eqs. (1) and (2), it indicates that there exists a limitation of film thickness increase while $0< x <0.667$. However, the above equations do not show the decreasing effect as the withdrawal velocity is increased. Table 1 lists and the percentage loss compared to the maximum thickness of each concentration.

As shown in Table 1, we have measured a loss of up to 17% of film thickness during the dip coating production. This kind of waste needs to be prevented in practical applications by controlling the operation withdrawal velocity of the dip coating process not exceed to υ_{max}. Control of the solid PLA film thickness can be reached by combined selections of appropriate PLA solution concentration and withdrawal velocity during the dip coating process.

IV. Conclusion

The results indicated that the gravity effect must be considered when dealing with the dip coating process for PLA. The outcome of the competition between drag force (solution film moving upward) and gravity (solution film moving downward) determines the variation of final solid PLA film thickness while increase of withdrawal velocity during the dip coating process. The findings of this study can contribute to the optimization of the dip coating assisted PLA deposition process on medical implant surface in order to improve the functionality.

Abstract — **The aim of this study was to prepare a polymeric surfactant from alginate, to evaluate the properties of this surfactant for pharmaceutical application and to study the effect of the surfactant on immune response. The polymeric surfactant was prepared by the method previously reported. Surface tension of its solution was determined by maximum pull force technique. Proliferation of splenocytes was performed by the measurement of 5-bromo-2-deoxyuridine (BrdU) incorporation during DNA synthesis. The proliferative response of splenocyte to the surfactant was compared to quillaja saponin. The surface tension of the surfactant in water was decreased to 30.37 mN/m. Critical concentrations for micelle formation in water, 5% dextrose, phosphate buffered saline and 0.9% NaCl were 2.95 mg/ml, 3.07 mg/ml, 1.55 mg/ml and 1.52 mg/ml, respectively. The surfactant at the concentration higher than 1.5 mg/ml showed significantly reduction of splenocyte proliferation. The highest stimulation was found at a concentration of 0.75 mg/ml. The alginate-derived polymeric surfactant seems to form micelles in aqueous solutions and to stimulate immune responses. These results indicated that the polymeric surfactant could be a potential vaccine adjuvant.**

Keywords — **alginate, polymeric surfactants, surface tension, splenocyte proliferation**

I. Introduction

Alginate is a linear polysaccharide present in the cell walls of the fronds of various seaweeds, including the giant brown kelp (*Macrocystis pyrifera*), horsetail kelp (*Laminaria digitalis*), and sugar kelp (*L. saccharina*). It consists of 1,4-β-D-mannuronic and 1,4-α-L-guluronic acid residues [1]. Alginate plays important role in product development such as to improve drug stability and to prolong drug release. It is regarded as biocompatible, non-toxic, non-immunogenic and biodegradable which make it widely used for biomedical applications as drug delivery systems for living cells, protein and DNA [2-5]. Recently, alginate has been chemically modified to increase its hydrophobicity for delivery protein [6-12].

Therefore, the goal of this study was to investigate the properties and potential uses of a modified alginate as an adjuvant. The article reports on the surface activity of the modified alginate in aqueous solution. In addition, it was tested in stimulation of splenocyte proliferation in comparison with quillaja saponin.

II. Materials and methods

A. Materials

Sodium alginate was from Carlo Erba Reagenti, Italy. Saponins from quillaja bark (QS) as partial purified extract with 25% of sapogenin content and octylamine were purchased from Sigma Chemical Co., USA. Cell proliferation ELISA, BrdU (colorimetric) kit was purchased from Roche Diagnostics, Germany. All other chemicals were of grade AR.

B. Animals

BALB/c mice, 6–8 weeks old, were purchased from the National Laboratory Animal Center, Thailand. The animals were housed under standard conditions at 25±2°C and were provided with chow pellets and tap water ad libitum. The procedures applied to the mice were approved by the Animal Ethics Committee of Khon Kaen University, in accordance with the requirements of the Ethics of Animal Experimentation of the National Research Council of Thailand.

C. Preparation of alginate-derived polymeric surfactant

Alginate-derived polymeric surfactants were prepared by oxidation and reductive amination [13]. Briefly, one gram of sodium alginate was dissolved in a solution containing 40 ml of water and 10 ml of 1-propanol. Sodium peroxidate was added and the reaction mixture was stirred at 1250 rpm in dark condition at ambient temperature for 24 h [14]. Alginate was partially oxidized to yield 30% oxidized 2,3-dialdehydic alginate. Then, 1 ml of ethylene glycol was added and the mixture was stirred at 400 rpm for 2 h. Sodium chloride (0.5 g) was added and dissolved in the reaction mixture. After addition of 96% ethanol (50 ml), the reaction mixture was centrifuged at 4000 rpm for 5 min. Pellets were re-dissolved in 50 ml of water before adding NaCl (0.05 g) and 96% ethanol (200 ml). The mixture was

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1344–1347, 2009
www.springerlink.com

stirred at 300 rpm for 30 min and then centrifuged as the above condition and pellets were collected. Oxidized 2,3-dialdehydic alginate was dried under vacuum at 40ºC.

Oxidized 2,3-dialdehydic alginate (0.404 g) was dissolved in 20 ml of phosphate-buffered saline, pH 7. Then, 0.092 g of sodium cyanoborohydride ($NaCNBH_3$) was weighed under fume hood and added. The solution was mixed with 10 ml of methanol containing octylamine. The reductive amination was performed for 12 h at room temperature [13]. The mixture was centrifuged at the same condition as described above. Supernatant was used and 96% ethanol (20 ml) was then added. Precipitate was washed three times with 20 ml of 96% ethanol and dried under vacuum at 40ºC.

D. Surface tension measurement

Solutions of the modified alginate were prepared at the concentration of 10 mg/ml in deionized water, 5% dextrose, phosphate buffered saline (PBS), pH 7 or 0.9% NaCl. Serial 2-fold dilutions of the solution were performed to obtain 11 concentrations. Fifty microliters of each sample were added into a conical bottom 96-well microplate. Surface tension of the solutions was measured by using a multi-channel microtensiometer (Delta-8, Kibron Inc. Oy, Germany) at 20°C.

E. Splenocyte proliferation assay ex vivo

Mouse splenocytes were prepared as a method previously reported [15]. The proliferation of splenocytes was performed by the measurement of 5-bromo-2-deoxyuridine (BrdU) incorporation during DNA synthesis in proliferation cells [16]. Briefly, 50 µl of splenocytes (1×10^6 cells) were seeded in 96-well plates. Then 50 µl of various concentrations of the modified alginate or controls were added. After incubation at 37ºC in CO_2 incubator for 3 d, 10 µl of BrdU labeling reagent were added to each well and the plates were incubated for a further 24 h before centrifugation at 2000 rpm for 15 min at 4ºC. After that the culture medium was removed and 200 µl of FixDenat solution were then added to each well. After 30 min, 100 µl of mouse anti-BrdU were added and incubated for 90 min at 37ºC. The plates were washed three times. Then, 100 µl of substrate solution were added and incubated for 30 min at room temperature. Then, the reactions were stopped by incubation with 25 µl of 1M H_2SO_4 for 5 min. The absorbance (Abs) was measured at 450 nm using an ELISA reader. The stimulation index (SI) was calculated as the following equation.

$$SI = \frac{(Abs_{Treated\ cultures} - Abs_{Background})}{(Abs_{Untreated\ cultures} - Abs_{Blank})} \quad (1)$$

F. Statistical analysis

Statistical significance of the differences among stimulation index of various concentrations on the proliferative response of mouse splenocytes were analyzed by one-way analysis of variance (ANOVA) followed by the Tukey multiple comparison test. P-values of less than 0.05 were considered to be statistically significant.

III. Results

Surface activity of the modified alginate: The effect of modified alginate concentration on surface tension of aqueous solutions at 20°C is shown in Fig. 1. The critical micellar concentrations (CMC) of the modified alginate in water, 5% dextrose, phosphate buffered saline (PBS) and 0.9% NaCl were 2.95 mg/ml, 3.07 mg/ml, 1.55 mg/ml and 1.52 mg/ml, respectively. The surface tension of the modified alginate in PBS (29.55 mN/m) and 0.9% NaCl (29.94 mN/m) was lower than those in water (30.37 mN/m). However, its surface tension in 5% dextrose (30.76 mN/m) was closed to those in water.

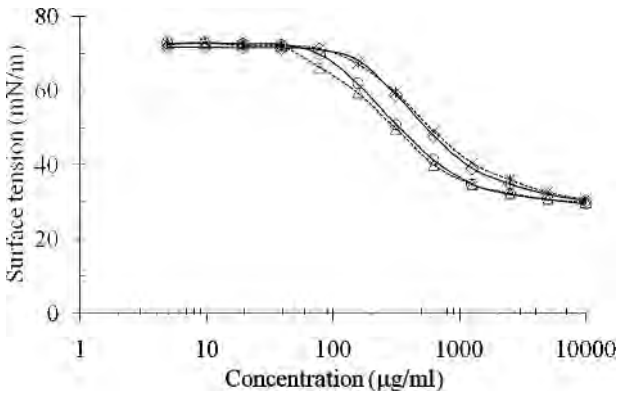

Fig. 1 Critical micellar concentration of modified alginate in (◇) water, (✳) 5% dextrose, (○) PBS, pH 7 and (△) 0.9% NaCl

Effect of the modified alginate on splenocyte proliferation: A spleen was removed from specific pathogen-free BALB/c mouse to prepare a single cell suspension. The proliferative responses were determined by BrdU ELISA. The effect of the modified alginate on splenocyte proliferation is shown in Fig. 2. The highest splenocyte proliferation was found at a concentration of 0.75 mg/ml with the stimulation index (SI) of 1.99±0.21 (mean ± standard error of mean, n=6). The modified alginate at the concentrations higher than 1.5 mg/ml induced splenocyte proliferation significantly less than the modified alginate at the concentration of 0.75 mg/ml did ($p<0.001$).

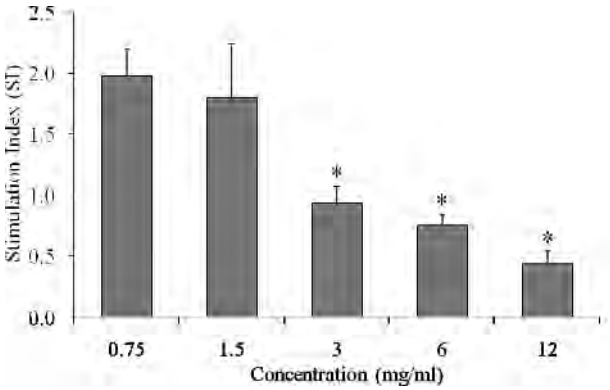

Fig. 2 Effect of the modified alginate on lymphoproliferation.

IV. Discussion

The lowering of water surface tension and the formation of self-aggregates clearly represented amphiphilic character of the modified alginate. The critical micellar concentration is a principal thermodynamic parameter for polymer aggregation and is usually used to evaluate the thermodynamic stability of the aggregates in aqueous solutions [17-19]. The CMC value of modified alginate in 0.9% NaCl and PBS was lowered to about 1.5 mg/ml. These finding suggested that in the presence of strong electrolytes, modified alginate could form micelles like surfactants at the lower concentration [20]. In contrast, the CMC of modified alginate in a solution containing nonelectrolytes such as 5% dextrose was similar to those of in water. This phenomenon could be explained by electrostatic repulsion. Since the carboxylic groups of sodium alginate on the β-D-mannuronate and α-L-guluronate residues were partially modified, the modified alginate had electrostatic repulsion of the charged headgroups in the periphery of ionic micelles. The addition of salts reduces these repulsive forces, lowering the CMC of the anionic surfactant [21]. Nonelectrolytes dissolve in water as intact molecule therefore they might not effect on micellar formation of the modified alginate.

In this study, quillaja saponins were used as positive control for stimulation of lymphoproliferation. Their structure consisted of a hydrophobic aglycone and hydrophilic sugar chains [22]. The usefulness of saponins as adjuvant could be able to induce sufficient both protective humoral- and cell-mediated immune responses [23]. The SI value of quillaja saponin (100 μg/ml) was 1.78±0.29 whereas the SI value of the modified alginate (0.75 mg/ml) was 1.99±0.21. These revealed that the modified alginate at the concentration of 0.75 mg/ml could be an adjuvant. In addition, it could stimulate proliferation of splenocyte at the concentration closed to the critical micellar concentration as found in case of saponins [15].

V. Conclusions

Alginate-derived polymeric surfactant with a linear alkyl group of octylamine were synthesized by oxidation followed by reductive amination of 2,3-dialdehydic alginate. It could aggregate by itself in aqueous solutions. For biomedical application, it might be useful for protecting drugs from hydrolysis and for encapsulating hydrophobic drugs as self-assembly in aqueous solution. In addition, it could be used as vaccine adjuvant. However, further studies on vaccine delivery systems of the modified alginate need to be investigated

Acknowledgment

The authors would like to acknowledge the significant role of Professor Dr.Jörg Kreuter for his advice. We also thank the staff at Institute for Pharmaceutical Technology, University of Frankfurt, Germany for their generous support and providing multi-channel microtensiometer facilities.

Nano-Patterned Poly-ε-caprolactone with Controlled Release of Retinoic Acid and Nerve Growth Factor for Neuronal Regeneration

K.K. Teo[1], Evelyn K.F. Yim[1,2]

[1] Division of Bioengineering, Faculty of Engineering, National University of Singapore, Singapore
[2] Department of Surgery, Yong Loo Lin School of Medicine, National University of Singapore, Singapore

Abstract — **A combination of nanotopography and controlled release could be a potential treatment for damages to the central and peripheral nervous system. Synergistic effects of both physical and chemical guidance were more effective than individual cues in the directional promotion of neurite outgrowth[1]. Hypothesizing that synergistic effect will enhance neuronal differentiation of human mesenchymal stem cells (hMSCs), a fabrication method for neurotrophic factors encapsulation in a nanopatterned (350nm-gratings) poly-ε-caprolactone (PCL) film was developed. Nanotopography directs hMSCs into neuronal lineage while controlled release of neurotrophic factors presents biochemical signals with temporal and spatial control. Preliminary results demonstrated synergistic effect on hMSC cultured on substrates with both nanotopographical and biochemical cues.**

The protein/drug encapsulated PCL films were fabricated by modified solvent casting methods in which the biologics were 'sandwiched' between two layers of PCL on a nanopatterned polydimethylsiloxane mold. Bovine serum albumin (BSA), RA and NGF were encapsulated into the films using this sandwich approach. BSA was first encapsulated to optimize the sustained release. Among different fabrication methods in BSA optimization, encapsulating solid BSA between 2 PCL layers resulted in most sustainable release. Surface topography remained intact after 10 days incubated in PBS with controlled release, verified through SEM.

Continuous release of bioactive RA and NGF was observed over the 1 week release period. Human MSCs aligned and elongated along the nano-patterned films. Enhanced upregulation of neuronal gene such as microtubule associated protein (MAP2) and neurofilament (NFL) was observed in hMSCs cultured on combination cues, as compared to individual cues. Using quantitative PCR analysis, upregulation of MAP2 in hMSCs on the nanogratings with controlled release NGF was verified, highlighting the synergistic effect of both biochemical and nanotopographical cues in directing hMSC differentiation. This fabrication methodology will allow the delivery of multiple therapeutic cues for potential applications in neural regeneration.

Keywords — **Controlled release, synergistic, differentiation, NGF, nanotopography, human mesenchymal stem cells**

I. Introduction

Nanotopography regulates cellular activities and directs human mesenchymal stem cells (hMSCs) into neuronal lineage [2, 3] while controlled release of neurotrophic factors presents biochemical signals with temporal and spatial control. The synergistic effects of both physical and chemical guidance were also more effective than individual cues in the directional promotion of neurite outgrowth [1]. A combination of nanotopography and controlled release could be a potential treatment for damages to the central and peripheral nervous system.

Hypothesizing that the synergistic effect will enhance neuronal differentiation of hMSCs, a fabrication method for neurotrophic factors encapsulation in a nanopatterned (350nm gratings) poly-ε-caprolactone (PCL) film was developed. Preliminary results demonstrated a synergistic effect on hMSC cultured on substrates with both nanotopographical and biochemical cues.

II. Materials and methods

A. Fabrication of nanopatterned film with controlled release of Retinoic acid (RA) or Nerve Growth Factor (NGF)

Poly-ε-caprolactone (PCL, Sigma) films were fabricated on nanopatterned polydimethylsiloxane (PDMS) mold by solvent casting. Bovine serum albumin (BSA, Sigma), RA (Sigma) and NGF (R&D Systems) were encapsulated into the films using a sandwich layer approach.

BSA was first encapsulated to optimize the sustained release. To characterize the controlled release profile of the encapsulated biochemical cues, supernatant obtained from PCL films incubated in phosphate buffered saline (PBS) was quantified for BSA, RA and NGF using BCA assay (Pierce), UV spectrophotometry and β-NGF ELISA (R&D Systems), respectively. Bioactivity of the released RA and NGF was tested for using the PC12 assay.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1348–1351, 2009
www.springerlink.com

The surface topography of the film before and after controlled release was examined by scanning electron microscopy (SEM).

B. Synergistic effects in hMSC differentiation

RNA was isolated from hMSCs (Lonza) cultured on the polymer substrates at day 7. RNA isolated from hMSCs cultured on unpatterned PCL film and tissue culture polystyrene served as controls. Human β-actin was used as the endogenous control. Gene expression was measured by RT-PCR and real time PCR. Synthesis and amplification of DNA were performed with Qiagen One-step RT-PCR kit for RT-PCR. For real-time PCR, PCR was performed using TaqMan Universal PCR Mix with human MAP2 Taqman Gene Expression Assay primer and probes and human β-actin as endogenous control (Applied Biosystems).

III. Results and Discussion

Modified solvent casting methods were used for fabrication of the protein / drug encapsulated films, in which the biologics were 'sandwiched' between two layers of PCL. Among the different fabrication methods in BSA optimization, the most sustainable release profile methodology (arrow in Fig. 1) was achieved by encapsulating BSA in solid form between the two PCL layers.

SEM images showed that surface topography of the PCL substrates, with or without encapsulated protein or RA, remained intact after 10 days incubation in phosphate buffered saline (PBS) (Fig. 2).

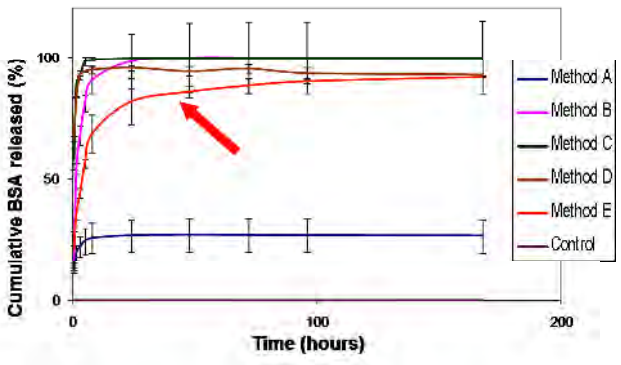

Fig. 1. Cumulative control release profile of bovine serum album (BSA) over a 7 day period.

RA was mixed with the PCL solution for solvent casting, while NGF was encapsulated into the PCL using the sandwich method optimized by the BSA encapsulation. Burst release was observed in both of the RA and NGF-encapsulated film, but continuous release was observed over the 1 week release period. Fig 3 shows the cumulative release profile of the NGF over 7 days incubation. Released

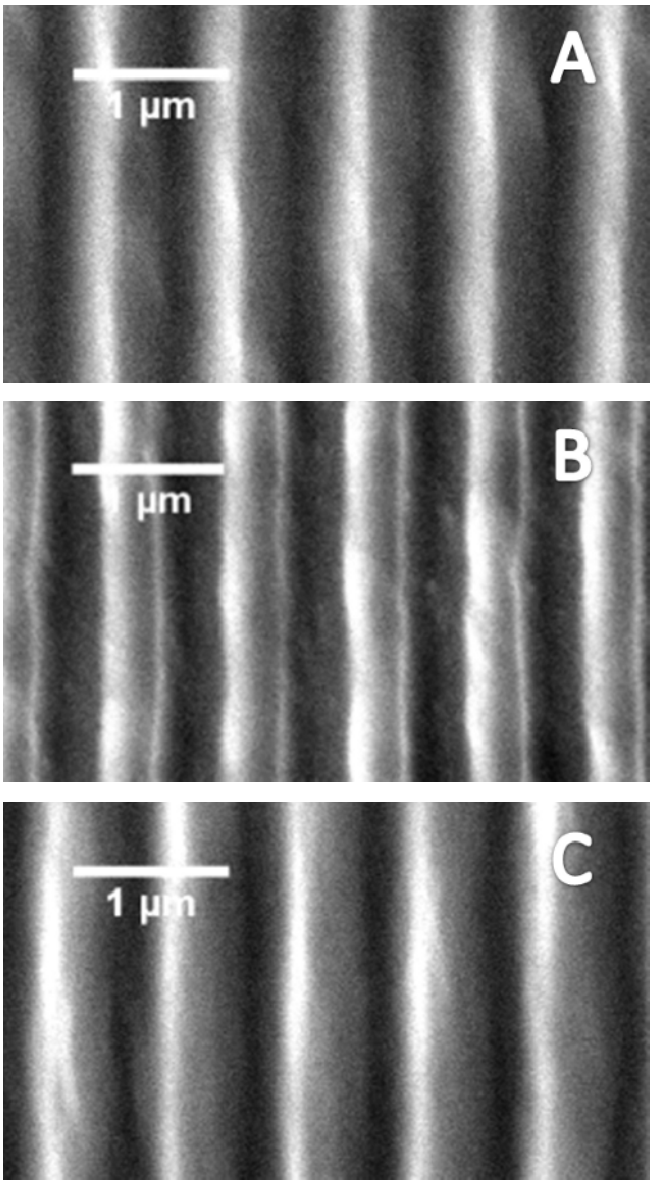

Fig. 2 Scanning electron micrographs of poly(ε-caprolactone) nano-gratings (A) without NGF encapsulation incubated with PBS, (B) with encapsulated retinoic acid incubated with PBS, and (C) with encapsulated NGF incubated with PBS.

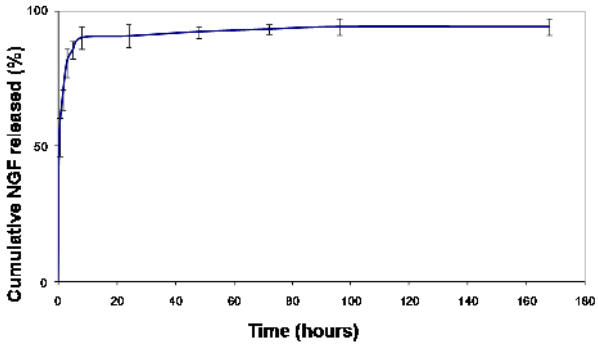

Fig. 3 Cumulative nerve growth factor (NGF) release over a period of 7 days.

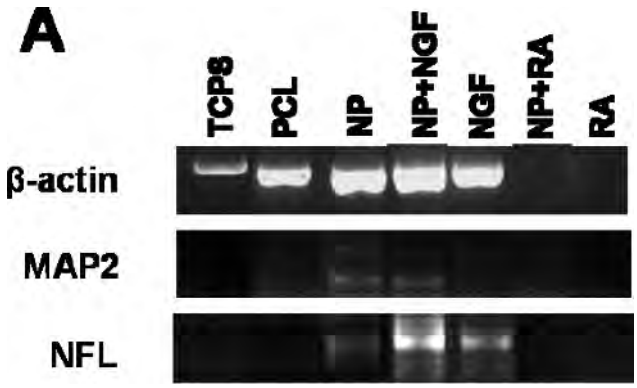

Fig. 4A Gene expression of neuronal markers MAP2 and neruofilament (NFL) in hMSCs cultured on nano-patterned (NP) substrates with or without NGF or RA, and also unpatterned PCL and TCPS controls.

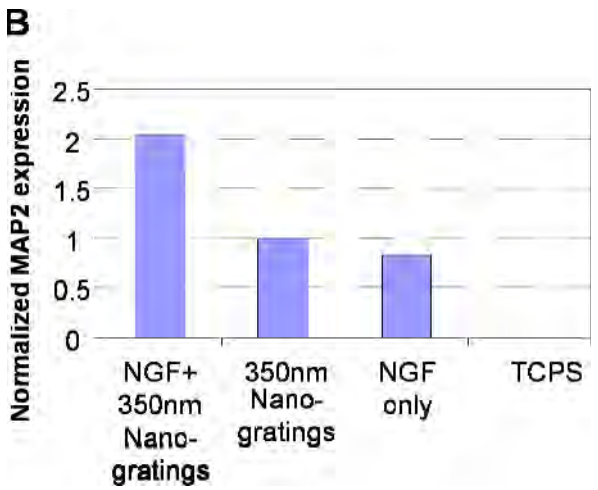

Fig. 4B Quantitative analysis of microtubule associated protein 2 (MAP2) expression in hMSCs on nanogratings with encapsulated NGF (NGF+350nm nanogratings), nanogratings without encapsulation (350nm nanogratings), tissue culture polystyrene with NGF (NGF only) and without NGF (TCPS).

RA and NGF remained bioactive demonstrated through the induction of PC12 neurite outgrowth.

Human MSCs were aligned and elongated along the nano-patterned films. In addition to changes in morphology, enhanced upregulation of neuronal gene such as microtubule associated protein 2 (MAP2) and neurofilament (NFL) was observed in hMSCs on nanopatterned substrates with controlled release of NGF, as compared to individual cues (Fig. 4A). The RNA isolated from the hMSCs cultured on RA-encapsulated substrates, with or without nanogratings, was low. The low yield could be due to the high RA concentration released from the RA-encapsulated substrate, interfering with the RNA isolation and quantification. A slow growth rate was also observed in the hMSCs cultured on the RA-encapsulated substrates; the lower cell density could also decrease the RNA isolation yield.

The quantitative PCR analysis verified the upregulation of MAP2 in hMSCs on the gratings with controlled release NGF (Fig 4B), compared to controls of nano-gratings alone and soluble NGF, highlighting the synergistic effect of biochemical and nanotopographical cues in directing stem cell differentiation.

IV. Conclusions

The fabrication methodology allows bioactive neurotrophic factors, such as the hydrophilic nerve growth factor and the lipophilic retinoic acid, to be released from a nanopatterned substrate, effectively delivering multiple therapeutic cues. The preliminary results showed enhanced neuronal marker upregulation, which suggested that they exerted a synergistic effect on the neural differentiation of hMSCs. The applications of such a multi-functional drug delivery platform have potential for the augmentation of neural regeneration.

Abstract — **The field of tissue engineering is continually expanding and advancing with the development of hybrid biomaterials incorporating active biomolecules, such as mammalian cells and DNA, into scaffolds. Sterilization of these biomaterials for clinical use has become an issue as the most common methods of sterilizing biomaterials, gamma radiation and ethylene oxide treatment, not only have a detrimental effect on the base scaffold, but are also incompatible with biological molecules. There has been long standing interest in the effect of light on biological cells and tissues. Recently, exposure to blue light has become of interest for applications including skin treatment (acne vulgaris) and for the inactivation of problematic microorganisms. High-intensity blue light in the 405 nm region has previously been shown to be an effective bacterial decontamination method and may have a potential application for biomaterials. This study investigated the effect of blue light treatment on both the structure of collagen, the most widely used scaffold for tissue engineering applications, and on the viability of a mammalian cell line (3T3 mouse fibroblasts). Type I collagen solution was treated with the blue light (405 nm) at 10 mW/cm^2 for 1 hour and SDS-PAGE analysis used to determine the effect on the gross structure of the collagen monomer. To determine the effect of the blue light exposure (1.0 mW/cm^2 for 1 hour) on mammalian cell viability the following methods were used: MTT and Neutral Red microplate assays, measurement of reduced glutathione and protein content, and leakage of cytoplasmic lactate dehydrogenase (LDH) activity. Results show that blue light treatment, for the power densities detailed above, had no noticeable effect on the gross structure of the collagen monomer, nor did it affect the viability, redox state, growth rate or LDH leakage of 3T3 cells.**

Keywords — **Blue-light, collagen, 3T3 fibroblasts, cell viability, redox status**

I. Introduction

Tissue engineering is becoming a major area of medical research with the potential to facilitate culture of cells and tissue for transplant surgery [1]. Advances within the field have resulted in the development of complex hybrid biomaterials that incorporate active biomolecules, such as mammalian cells and DNA. For clinical applications such biomaterials must be sterilized. Currently, gamma irradiation and ethylene oxide (EtO) treatment are the most common decontamination methods used for biomaterials, but both are known to cause detrimental effects to the physiochemical and biochemical properties of the biomaterial [2,3], and neither is compatible with many active biomolecules.

Exposure of biological cells and tissue to blue light has recently become of interest for areas such as skin treatment (acne vulgaris) and for the inactivation of problematic organisms. *Propionibacterium acnes* irradiated with blue-light results in photosensitization of intracellular porphyrins, generating reactive oxygen species and therefore causing cell death [4]. Blue-light in the 405 nm region has also been shown to be an effective decontamination method for *Staphylococcus aureus* [5]. Blue-light therefore shows good potential as a decontamination method for hybrid biomaterials, and its biocompatibility was assessed in this study.

To determine the effect of the blue light exposure on collagen structure, SDS-PAGE analysis was carried out. Its effect on mammalian cell viability was measured by MTT and Neutral Red (NR) microplate assays, reduced glutathione (GSH) and total protein content, and leakage of cytoplasmic lactate dehydrogenase (LDH) activity.

II. Materials and Methods

High intensity blue light source: A grid of 9 narrow-band light-emitting diodes (LED) with peak emissions at 405 nm was used. Although LEDs have minimal heat dissipation, a heatsink was integrated to ensure a stable operating temperature was maintained. The LEDs and heatsink combination were mounted on a PVC housing.

Collagen solution: Type I collagen, derived from rat-tail tendon [6], was used at a concentration of 5.25 mg/ml. It was treated with 10 mW/cm^2 blue-light for 1 hour before the effect on its structure was assessed.

Cell culture: 3T3 cells (mouse fibroblast cell line), in Dulbecco's modified Eagles medium (DMEM) supplemented with 10 % foetal calf serum, were seeded on tissue culture polystyrene at 2x10^4 cells/cm^2 and then incubated for 18-24 hr prior to treatment, unless otherwise stated. For treatment, the medium was removed from the cells and replaced with phosphate buffered saline (PBS). Cells were treated at 1.0 mW/cm^2 for 1 hour. On completion of the treatment, the PBS was replaced with medium. For positive control, cells were incubated in 250 μM H_2O_2 in PBS for 1

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1352–1355, 2009
www.springerlink.com

hour, and both positive and negative controls were incubated in the dark.

Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE) analysis: Gels were prepared and analyzed as previously described [7]

MTT microplate assay: The culture medium was removed from each well, and MTT solution (10 mM in PBS, pH 6.75) added. After 4 hours incubation (37 °C) the MTT solution was removed and the product dissolved in DMSO. Absorbance was read at 540 nm.

Neutral Red (NR) Assay: The culture medium was removed and the NR solution (5mg Neutral Red powder in 100ml PBS) added. After an incubation period of 3 hours (37 °C) the excess NR stain was removed, and intracellular NR dissolved with NR destain until a homogenous color was obtained. Absorbance was read at 540 nm.

Cell growth rate, lactate dehydrogenase (LDH) leakage and GSH content: Growth rate was determined by measuring total protein according to the method of Lowry et al [8]. LDH activity in the medium was measured by the method of Bergemeyer et al [9], and GSH content by the fluormetric method as described by Hissin and Hilf [10].

Statistics: ANOVA followed by Dunnett's test, at the 95% level, was carried out to determine significant difference, where applicable.

III. Results

SDS-PAGE analysis of the collagen gel shows that the light treatment with 10 mW/cm^2 did not appear to have any noticeable effect on the gross structure of the collagen monomer (Fig. 1). The pattern of protein bands and the optical density profiles obtained from treated and untreated collagen is similar (Fig. 2).

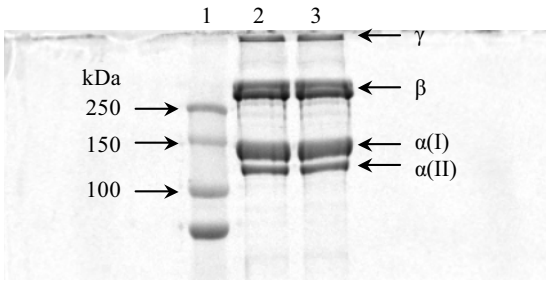

Fig. 1 SDS-PAGE gel; Lanes 1-3 are molecular weight marker, untreated control, and blue-light treated sample, respectively.

The results from MTT and NR show that the blue-light treatment had no significant effect on the viability of the 3T3 cells, compared to the untreated control cells (Fig. 3). The cells treated with H_2O_2 (positive control) showed a 72 % and 78 % decrease in viability from the MTT and NR assays respectively, compared to the untreated cells.

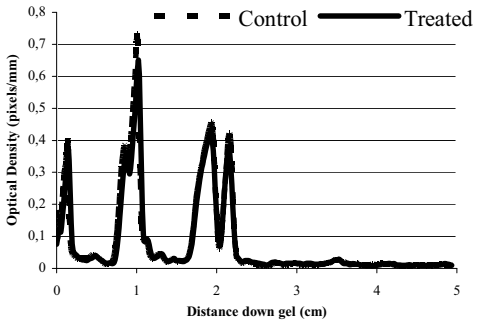

Fig. 2 Optical density profile of the SDS-PAGE gel in Fig. 1

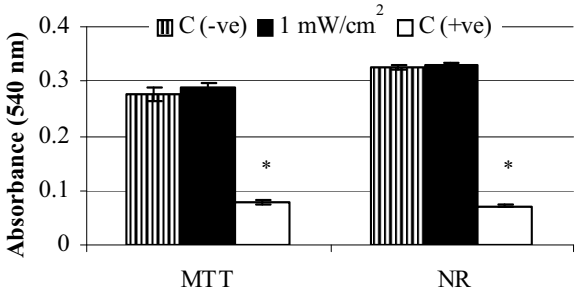

Fig. 3 MTT and NR absorbance for treated and control cells, 24 hours after treatment (n=48, +/- SEM, $p < 0.05$).

The growth rate of the 3T3 cells was assessed by measuring the total protein content of the 3T3 cells, at 24, 48, 72 and 96 hours after treatment. The results showed that the growth rate of the cells appears to be unaffected by the treatment (Fig. 4). Both the control and the treated cells showed a drop in protein content on the fourth day. This drop was due to the cells having reached confluence on the surface of the tissue culture well. Where the cells had been treated with H_2O_2, the total protein measured was significantly less than the untreated cells at all time-points. The protein content at day 1 was similar to that at day 4 for the H_2O_2 treated cells, which shows that the growth rate of the cells had been significantly affected by the treatment.

The LDH leakage into the medium was used to determine the membrane integrity of the 3T3 cells during the post treatment incubation period. Figure 5 shows that LDH leakage from the light treated cells follows the same pattern as the untreated control cells, suggesting that the treatment had no significant effect on the integrity of the cell membrane. The results also show that the media recovered from

the H_2O_2 treated cells had significantly higher levels of LDH leakage, compared to the untreated cultures for the first 3 days, demonstrating that the H_2O_2 treatment had significantly compromised the integrity of the cell membranes.

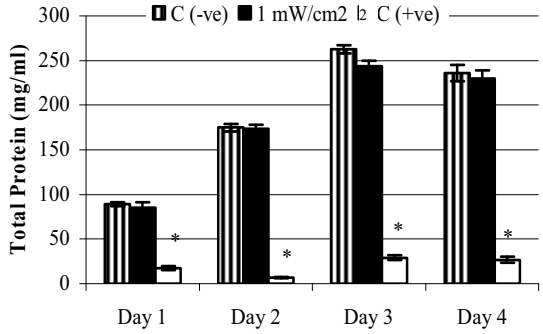

Fig. 4 Total protein content of 3T3 cells (n=4, +/- SEM, $p < 0.05$)

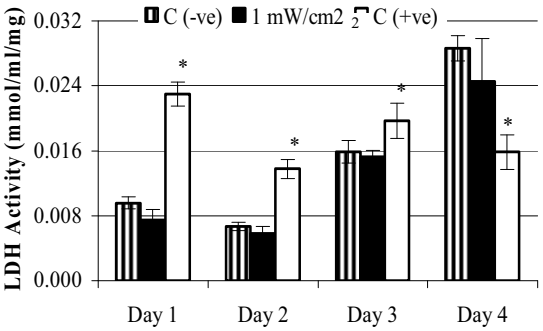

Fig. 5 LDH activity of 3T3 cells (n=4, +/- SEM, $p < 0.05$)

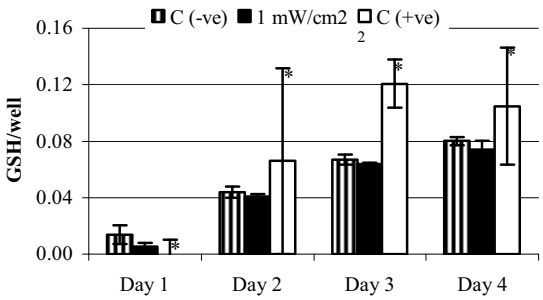

Fig. 6 GSH activity of 3T3 cells (n=4, +/- SEM, $p < 0.05$)

The amount of GSH, a cytoprotective antioxidant that reacts with free radicals and organic peroxides and provides essential redox balance, was measured at each time-point. The results show that with the exception of day 1, where the treated cells show a decreased GSH level, the blue-light treated cells show GSH levels that were not significantly different from those of the untreated (negative) control (Fig. 6). The results for the positive control were very different, showing an almost complete depletion of GSH on day 1, and then increased levels of GSH for the remaining 3 days, when compared with the untreated negative control.

IV. Discussion

Collagen is one of the most widely used biomaterials in tissue engineering and medicine, and can be processed in many forms including sheets, sponges, and injectable solutions [11]. Medical applications include grafts for corneal replacement and shields as corneal bandages in ophthalmology, sponges to promote healing of burns/wounds, subcutaneous injection of soluble collagen for the repair of dermatological defects, and drug loaded inserts (cut from films or as molded rods) for prolonged drug delivery [11,12,13].

It is difficult to sterilize collagen biomaterials without causing detrimental effects. Currently, the most common sterilization methods are gamma irradiation and ethylene oxide treatment. Gamma irradiation, which kills microorganisms by disrupting DNA thus preventing cell division, causes alpha chain fragmentation and/or cross-linking of collagen biomaterials, altering their mechanical properties and degradation rate. Ethylene oxide (EtO) has less of an impact on the physical properties of collagen biomaterials, but is known to cause decreased stability of the collagen molecule triple-helix. It also requires up to 2 weeks post treatment aeration, as the EtO itself is mutagenic and carcinogenic.

It is therefore important to ascertain the impact that blue light treatment has on the collagen monomers. The intensities used in the present study are of the same order as the narrow-band blue light used previously [5] to inactivate *S. aureus*. The results of the SDS-PAGE demonstrate that the blue-light treatment does not cause any noticeable damage to the structure of the individual alpha-chains. This method has previously been used to demonstrate collagen monomer fragmentation as a result of heat degradation [7].

Having established that blue-light treatment offers a potential decontamination method that is compatible with collagen, its impact on the viability of mammalian cells was determined. The incorporation of mammalian cells into novel hybrid biomaterials is an expanding area of regenerative medicine. Compatible sterilisation technologies are being sought to facilitate clinical use of such biomaterials. Broad-band violet-blue light (400-490 nm) has previously been shown to be toxic to mammalian cells, and disrupts cellular processes, such as mitosis, mitochondrial function, and DNA integrity [14].

The purpose of this work was to look at the effects of a narrow-band blue-light (405 nm) on mammalian cell viability and redox state. After treatment at 1.0 $mWcm^2$, the viability of the 3T3 cells was not significantly different to that of the untreated control cells, as ascertained by a combination of the MTT and NR assays. This suggests that blue-light treatment does not have a major effect on the cell viability. This is supported by the results of the LDH assay, which demonstrated that treatment with H_2O_2 significantly compromises the integrity of the 3T3 cell membrane, but blue-light does not appear to have any significant effect.

Treatment with blue light had no significant effect on the GSH levels in the cells, demonstrating that blue-light treatment also does not cause any disturbance to the redox status within the cell. This was an important result as it has previously been reported that violet-blue light toxicity is due to light-induced reactive oxygen species (ROS) generated from excitation of endogenous photosensitizers; the most likely ones being porphyrin ring structures and flavins [14, 15]. Although the results show that blue-light does not disturb the redox state of the cell, it is important to note that it has been suggested that the oxidative stress response may be cell-type-specific [14], and may depend on the energy consumption of the specific cell [16]. GSH is a crucial thiol within cells and is involved in regulation of cell division and function. When cells suffer oxidative stress, they work hard to replenish cellular GSH levels; therefore cell GSH levels may be linked to the cell-specific ability to cope with oxidative stress.

It has previously been suggested that blue light exposure, from dental curing sources, can inhibit cell proliferation [17]. In this present study, cells treated with blue-light had a similar growth rate to that of the untreated control cells for up to 4 days post-treatment, suggesting that the treatment has no effect on cell proliferation. This indicates that blue light could be used to sterilize cell-seeded matrices for tissue regeneration. There is much work yet to be carried out to demonstrate that the technology does not affect cell function or differentiation.

V. Conclusions

Blue-light treatment shows good potential for use as a decontamination method for complex hybrid biomaterials as the results demonstrate its compatibility with both collagen and mammalian cells. This work is being expanded to investigate the limits of the tolerance intensities and durations, and the effect of the blue-light treatment on the decontamination of problematic bacteria, such as *Staphylococcus aureus* and *Staphylococcus epidermidis*, is also being investigated.

Abstract — **Silk sericin (SS) is a natural protein derived from silkworm *Bombyx mori*. It is applicable as an antioxidant in the field of medicines, cosmetics, foods, and food additive SS protein can be blended with polymers, to produce materials with improved properties. SS films were prepared using different polymers which are polyvinyl alcohol (PVA), polyoxyethylene-polyoxypropylene block copolymer (Plu) and glycerine (G) and fixed concentration of SS (3.0% w/v). The physical properties and some structure characteristics of siricin films were analyzed. The result showed that SS films prepared by cast method containing 3.0 % w/v SS with 2%PVA+1%G, 2%PVA+2%G, 0.2%Plu-F68+1%G, 0.2%Plu+2%G, 2%PVA and 1%G showed good film property from observation. The solubility studies showed that SS was rapidest released from film containing 3%SS+2%PVA which released all SS content within 10 minute whereas other films released all SS content within 1 hour. Humidity-absorption studies of SS film showed that 3%SS+2%PVA+2%G film had the highest moisture absorption rate after incubated in 70-80% humidity environment.**

Keywords — **sericin, silk, polymers**

I. Introduction

In the cocoon shell of silkworm *Bombyx mori* composes of two proteins named fibroin, held together by a gum-like protein called "sericin" (SS). SS is a water-soluble globular protein and its molecular weight ranges from 10 to 310 kDa[1]. SS protein is made of 18 amino acids, especially rich in aspartic acid (~19%) and serine (~32%) [2], which has a high content of the hydroxyl group. SS is applicable as an antioxidant in the field of medicines, cosmetics, foods, and food additive [3]. The protein is also used as a coating material for natural and artificial fibers, which can prevent abrasive skin injuries, the development of rashes and antibacterial for the products such as diapers, diaper liners, and wound dressing [4]. SS is particularly useful for improving polymer materials such as polyesters, polyamide, polyolefin, and polyacrylonitrile. Moreover, it can also be applied to degradable biomaterials, biomedical materials, functional bio-membrane materials and functional fibers [4, 5]. We have blend SS with different polymers and investigated their physical properties.

II. Materials and methods

A. Sericin extrction

The cocoon shells of *Bombyx Mori* were cut into pieces (about $1cm^2$) and then immersed in water in ratio 1:30 by weight. Aqueous SS solutions were extracted with hot water under pressure at 121º C for 1 hour using an autoclave. The solution was then filtrated to remove fibroin and impurities. Finally, the solution was freeze dried by Heto PowerDry LL3000 Freeze Dryer (Thermo electron corporation). SS sample powder was white in color.

B. Preparation of SS film with different polymers.

SS films were prepared using different polymers which are polyvinyl alcohol (PVA), polyoxyethylene-polyoxypropylene block copolymer (Plu) and glycerine (G) and fixed concentration of SS (3.0% w/v). Polymers were heated at 80ºC until they were melted and then 3.0% w/v SS was added. The solutions were poured and casted at room temperature for 1 hour. The SS/polymers were dried at 60ºC for 24 hours in oven.

C. The solubility studies

SS films were immersed in phosphate buffer pH 7.4 and stirred. The samples were then sampling collected at different time points to analyze protein concentration by Pierce® BCA Protein Assay Kit.

D. Humidity-absorption studies

SS films were exposed to water vapor from different salts sush as potassium acetate, potassium carbonate, sodium bromide, sodium chloride and potassium chloride in desiccators. Then, the weight of films were measured at different time point until the weight of films were constant.

III. Results and discussion

A. The solubility studies

Table 1 shows the solubility results of SS films prepared by casting method containing 3.0 % w/v SS with

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1356–1358, 2009
www.springerlink.com

2%PVA+1%G, 2%PVA+2%G, 0.2%Plu-F68+1%G, 0.2%Plu+2%G, 2%PVA and 1%G. The solubility studies showed that SS with 2% PVA has the fastest released from film, which released all SS content within 10 minute, as shown in Fig. 1. Other SS films released all SS content within 1 hour.

Table 1 Solubility of SS films

Films	Protein concentration at steady state (μg/ml)
3%SS+2%PVA	3596.96
3%SS+1%G	1807.70
3%SS+0.2%Plu+1%G	1638.04
3%SS+0.2%Plu+2%G	1590.63
3%SS+2%PVA+1%G	1097.30
3%SS+2%PVA+2%G	1074.33

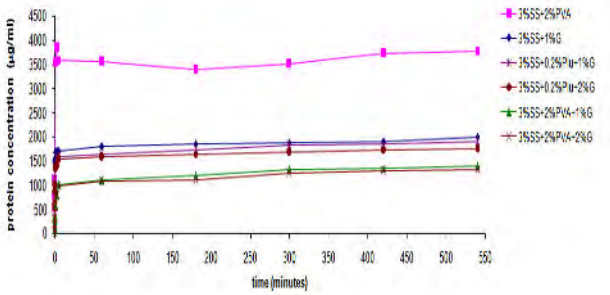

Fig. 1. Solubility of SS films.

The component of 3%SS+2%PVA film had PVA that is a water-soluble synthetic polymer[6]. The water solubility of polyvinyl alcohol films can be regulated and weakly soluble in cold water[7]. It may be dissolved rapidly and released SS much faster compared to other films.

B. Humidity-absorption studies

The reference values of relative humidity of each salt is shown in Table 2 [8]. SS films composed of 3%SS+2%PVA+2%G film had the highest moisture absorption rate after incubated in 70-80% humidity environment, as shown in Fig 2 whereas the weight of SS films in other humidity environment did not change from initiate weight.

Table 2 Relative humidity of salts [8]

Salts	Relative Humidity
Potassium acetate	22.51±0.32
Potassium carbonate	43.16±0.39
Sodium bromide	57.57±0.40
Sodium chloride	75.29±0.12
Potassium chloride	84.34±0.26

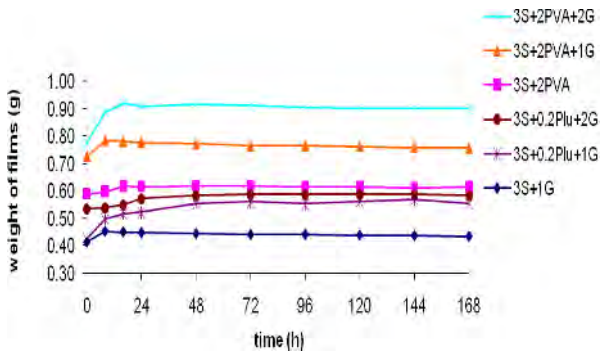

Fig. 2. The weight of SS/polymers films in chamber of potassium chloride.

SS can absorb water [4]. PVA and glycerine are the main components to reinforce the moisture absorbtion of 3%SS+2%PVA+2%G film. The result is similar to previous reports by other researchers that PVA left at high humidity environment could absorb more moisture [6, 7]. Moreover, glycerine can even make the films moisturized.

IV. Conclusions

We study the solubility and humidity-absorbtion properties of SS/polymers film. SS with PVA films show good physical property. SS can be released from film at different rate, depending on type and concentration of polymers.

Abstract — **In the bio-medical materials category, the bone tissue material is receives people to take. The bone tissue material not only substitutes for the human body skeleton supports (scaffolds), but also stimulates the cell to grow, to paste attaches and to split up. It drives the bone tissue researches from the originally organization replacement to the nowadays organization regeneration.**

Surfactant tri-block copolymer (F127) was used as the structure-directing agent for synthesis of mesoporous SiO_2-CaO-P_2O_5 sol-gel glasses. The specific surface area and crystallite size of mesoporous SiO_2-CaO-P_2O_5 calcined at different temperature were evaluated. The phase structure, N_2 adsorption/desorption isotherm and powder morphology were analyzed by XRD, BET and HRSEM.

The powders with high specific surface area (224.6m^2/g) and pore size of ~5.5 nm mesoporous structure were used as tissue generation materials directly. Basic effects of the nature of the bio-active evolution of these materials were discussed.

Keywords — **bioactive glasses, mesoporous, sol-gel, scaffolds, in vitro test**

I. Introduction

In recent years, mesoporous materials have attracted the attention of many scientists, mainly due to their unique structural properties which have high surface area, pore volume and pore size, with narrow pore diameter distribution. For the reasons, applications in the field of catalysis, inductors, sensors, lasers, carriers, etc. have been proposed and developed.[1-2]

Zhao et al. successfully synthesized highly hexagonally ordered mesoporous bioactive glasses by template with a non-ionic tri-block copolymer, $EO_{20}PO_{70}EO_{20}$ (P123). That made hydroxylcarbonate apatite changed into mesoporous materials which accumulated the enhancement of specific surface areas, promoted the speed of growth and reduced bone tissue has formed the time in the clinical treatment.[3]

In the present study, the mesoporous SiO_2-CaO-P_2O_5 sol-gel glasses powders with high specific surface area (224.6m^2/g) and pore size of ~5.5 nm mesoporous structure were used as tissue generation materials directly. Basic effects of the nature of the bio-active evolution of these materials were discussed.

II. Materials and methods

A. Materials

Calcium nitrate $Ca(NO_3)_2{\cdot}4H_2O$ was purchased from SHOWA, Japan. Triethyl phosphate(TEP) was purchased from Fluka, China. Tetraethyl orthosilicate (TEOS) was purchased from ACROS, U.S.A.

B. Preparation of mesoporous bioactive glasses

In sol-gel synthesis, 4.0g of F127 was dissolved in 60g of ethanol (EtOH). Stock solutions, which were prepared by mixing 1.4g of calcium nitrate $Ca(NO_3)_2{\cdot}4H_2O$, 6.7g of tetraethyl orthosilicate (TEOS), 0.73g of triethyl phosphate(TEP) and 1.0g of HCl (0.5 mol/L), stirred at room temperature for one day, and then were aged at room temperature for 72 h to form sol state. After that, sols dried at 50°C for 24 h. The calcination of the powder sample was conducted in an Al_2O_3 boat in a temperature range of 500–600°C. The temperature was increased at a heating rate of 5°C /min to the preset temperature and held for 5 h. The calcined sample was cooled to room temperature at a rate of 5°C/min. Finally, the calcined powders were obtained.[2][4]

C. Assessment of in vitro bioactivity

The calcined powders were immersed in simulated body fluid (SBF). The chemical composition of SBF was similar to that of human plasma. Afterward, the solution put in shaker under 160 rpm/min for one day and was kept at 37°C. Then, the powders were taken out with filtering, washed three times with acetone, and dried in air for further characterization.[5-6]

III. Results and discussion

The relation between textural and calcined temperature of the synthesized SiO_2-CaO-P_2O_5 powders has been examined earlier by Brunauer-Emmett-Teller (BET) method. The nitrogen adsorption/desorption isotherm of the 500°C, 550°C, 600°C shown in Figure 1. The samples were all identified as typical type IV isotherms with the same hys-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1359–1361, 2009
www.springerlink.com

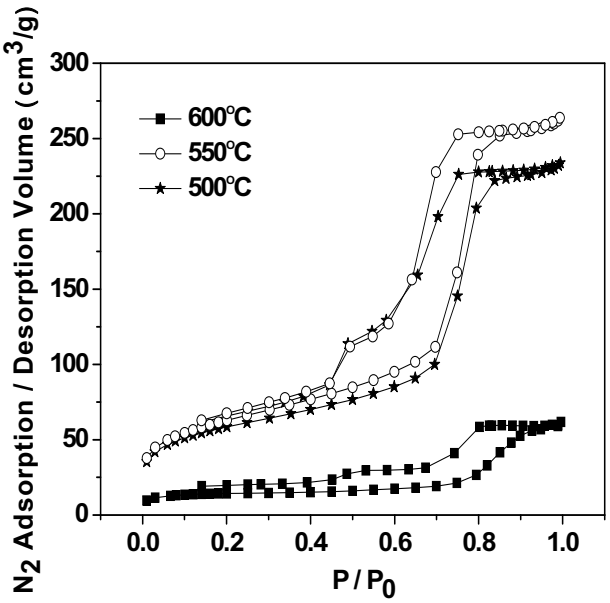

Fig. 1 Nitrogen adsorption/desorption isotherms of the SiO_2-CaO-P_2O_5 precursor powders precipitated at various temperatures for 5h.

teresis loops of H1 type. It reveals that mesoporous structure formed in this temperature range.

To elucidate what is responsible for it, the Textural Properties of Mesoporous SiO_2-CaO-P_2O_5 Sol-gel Glasses are shown in Table 1. It indicate that after calcined at 500°C and 550°C for 5 h, the calcined powders all with high specific area in the range of 208.3~224.6 m^2/g. Further heating of the precursor powders decreased sharp to 49.5 m^2/g. Pore volumes were calculated and illustrated a same trend. After calcined at 500°C and 550°C for 5 h, the calcined powders all with high pore volumes ~0.4g/cm^3. Further heating of the precursor powders decreased sharp to ~0.1g/cm^3. [4][7-8]

Therefore, powder of 500 ^oC and powder of 550^oC both have high BET specific surface area and pore volumes.

The XRD patterns of SiO_2-CaO-P_2O_5 glasses soaking in simulated body fluid (SBF) at various times (a) 0h (b) 24h (c) 48h. It indicates a sharp reflection peak of around 32^O appeared, While the sample after soaking in SBF for 24h, which can be ascribed to (211) and (112) reflections of hydroxylapatite [3][5][7-9].

The in vitro bioactivity of the powder has been investigated by soaking them in simulated body fluid (SBF). HRSEM images of the powder before and after soaking in SBF for 24h are shown in Figure 3a, 3b.

The smooth surface was shown in Figure 3a, after being soaked in SBF for 24h, small stick-liked deposits of about 200nm on the surface of the powders were visible. The small stick-liked deposits were becoming more according to

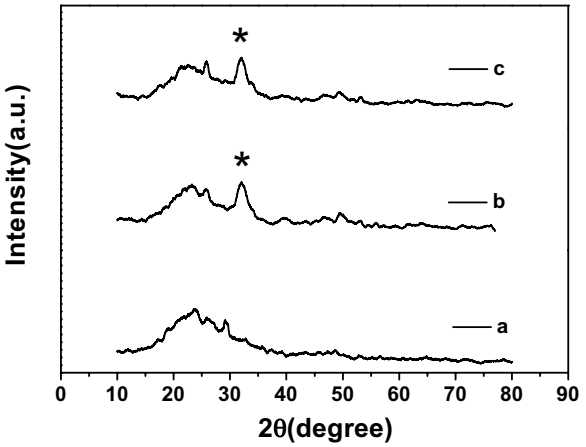

Fig. 2 XRD patterns of SiO_2-CaO-P_2O_5 glasses soaking in simulated body fluid (SBF) at various times (a) 0h (b) 24h (c) 48h.

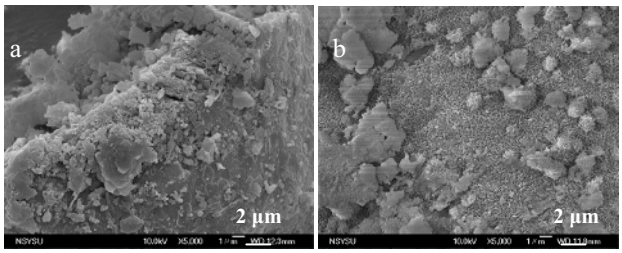

Fig. 3 HRSEM micrographs of SiO_2-CaO-P_2O_5 glasses soaking in simulated body fluid (SBF) at various times (a) 0h (b) 24h.

Table 1 The data list of nitrogen adsorption/desorption isotherms of the SiO_2-CaO-P_2O_5 precursor powders precipitated at various temperatures.

Calcinated Temperature	Specific Surface Area	Pore Volume
500 ^oC	208.3 m^2/g	0.4 cm^3/g
550 ^oC	224.6 m^2/g	0.4 cm^3/g
600 ^oC	49.5 m^2/g	0.1 cm^3/g

the length of soaked time, as also indicated by the wide-angle XRD.[3][6][8]

The nitrogen adsorption/desorption isotherm of SiO_2-CaO-P_2O_5 glasses soaking in simulated body fluid (SBF) at various times, 0h, 4h, 6h, 24h as Fig.4 shown. They were identified as type IV isotherms with the same hysteresis loops of H1 type and means identical in the type of mesopores even after immersing in SBF.

The Textural Properties before and after soaking in SBF for 4 h, 6 h and 24 h shown in table 2. It revealed that BET specific surface area is in the range of 270.2m^2/g ~ 283.4m^2/g and pore volume is in the range of 0.5cm^3/g ~0.6 cm^3/g. There is the same condition of distributed pore size.

They show the length of soaking time do not influence BET specific surface area a lots. For further observation of

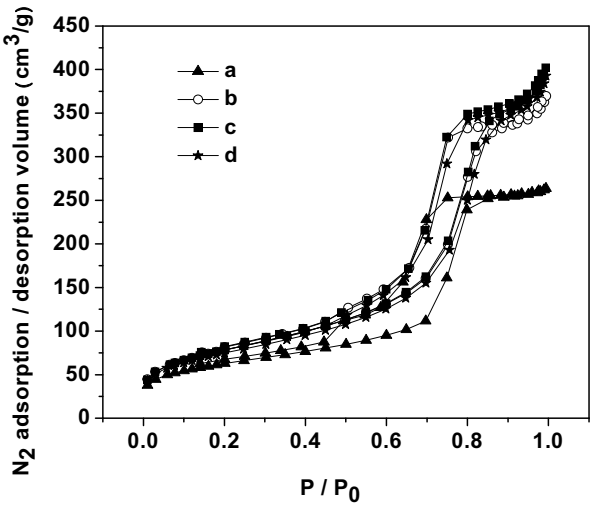

Fig. 4 Nitrogen adsorption/desorption isotherms of SiO_2-CaO-P_2O_5 glasses soaking in simulated body fluid (SBF) at various times (a) 0h (b) 4h (c) 6h (d) 24h.

Table 2 The data list of nitrogen adsorption/desorption isotherms of the SiO_2-CaO-P_2O_5 precursor powders soaking in simulated body fluid (SBF) at various times.

Soaking Time	Specific Surface Area	Pore Volume
0 h	224.6 cm^3/g	0.4 cm^3/g
4 h	282.9 cm^3/g	0.5 cm^3/g
6 h	283.4 cm^3/g	0.6 cm^3/g
24 h	270.2 cm^3/g	0.6 cm^3/g

the microstructure of hydroxylapatite, the HR-SEM micrographs before and after soaking were shown in Fig. 3. The surface of the sintered pellets prior to soaking (a) was smooth, and after soaking for 24h, the surface was covered by nanometric needles.

IV. Conclusions

In the system regulation, calcined temperature is the main factor to affect bioactive glasses (BG) specific surface area , pore volume, pore size. The BG calcined at 550 ^oC own high specific surface area 224.66 cm^3/g, 5.5nm of the pore size, and the pore volume is 0.354 cm^3/g. XRD and FESEM both indicated that the BG powder soaked in simulation body fluid(SBF)for 24h could succeed in the growth of hydroxycarbonate apatite (HA)crystallization.

Abstract — **Mesoporous bioactive glasses (MBGs) have been successfully synthesized by templating with a block co-polymer.**

The specific surface area and crystallite size of mesoporous bioactive gel glasses scaffold calcined at different temperature are evaluated. The phase structure, N_2 adsorption/desorption isotherm and powder morphology were analyzed by XRD, BET and FE-SEM.

The influences of the heat-treated temperature on pore morphology and specific surface area of the cubic ordered MBGs Scaffold were very important.

High Specific Surface area Mesoporous Bioactive Glasses (MBGs) scaffold successful fabricated by calcined the co-precipitated dry gel at 500°C and dwell 2h. After soaking these MBGs scaffolds in simulated body fluid (SBF) for 24 h, it can be observed that the formation of needle shape hydroxylapatite (HAP) crystal on the surface of the MBG scaffolds.

Keywords — **Calcined Temperature, Scaffold, Mesoporous Bioactive Glasses**

I. Introduction

Current clinical procedures for the repair of bone defects are transplantation or implantation [1]. However, there are some disadvantages of the abilities to self-repair, maintain a blood supply, and modify their structure and properties in response to environmental factors.

Bioactive glasses(BGs) have attracted much attention in recent years because such materials not only chemically bond to and integrate with living bone in the body, but also used in regenerative medicine to restore diseased or damaged bone to its natural state and function[2].

A hierarchical bioactive glass scaffold exhibits enhanced bioactivity and resorbability, due to its macropore (larger than 100μm) and mesoporous texture (pore diameters in the range of 2-50nm) [3]. It raise the adsorption rates of bone tissues due to the advantages of mesopore [4], including high specific surface area, uniform and pore controllability [5]. That would be very helpful to form the bonding with hydroxylapatite, promote to repair and regenerate, and then shorten the recover time [6].

In sol-gel process, the different thermal temperatures lead to changes in the structural and textural properties.

In the present study, mesoporous bioactive gel glasses scaffold have been successfully synthesized in temperature range of 400–700°C. The preparation technique, crystal structure, as well as thermal temperatures behavior of Mesoporous Bioactive Gel Glasses Scaffold have been discussed in detail.

II. Experimental section

A. Prepared of MBGs

The hierarchical bioactive glass scaffolds were synthesized by using nonionic block copolymer $EO_{100}PO_{65}EO_{100}$ (F127) and polyurethane (PUF) as the template. In typical synthesis, a ternary MBGs (CaO - SiO_2 - P_2O_5) were prepared by mixing 4.0g of F127, 6.7g of tetraethyl orthosilicate (TEOS), 1.4g of $Ca(NO_3)_2$. $4H_2O$, 0.73g of triethyl phosphate (TEP), the molar ratio of Si:Ca:P is 80:15:5, and 1.0g of 0.5m HCl were dissolved in 60g of ethanol , then stirred at room temperature for one day. PUF were then immersed into the sol and dried for one day. The same procedure was repeated several times, and then dried at 100°C for 24h. The calcination of precursor scaffold was conducted in an Al_2O_3 boat in a temperature range of 400–800°C and dwell for different times (2 h, 3 h, 5 h, 7 h). The scaffold was obtained as Fig. 1 shown.

Fig. 1 Image of precursor scaffold calcined at 500°C for 3h.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1362–1365, 2009
www.springerlink.com

B. Bioactivity tests

The bioactivity of the scaffold in vitro was tested by immersing the samples in SBF at a solid: liquid ratio of 1 mg/mL at 37°C and 160 rpm for 24h. Afterward, the scaffold washed with acetone, and dried in air for further characterization.

III. Results and Discussion

The samples were identified in Fig.2 as type IV isotherms with the same hysteresis loops of H1 type. The surface area values decrease with temperature in the range of 400°C to 800°C.

To quantify it, we therefore consider the specific surface area of 400°C as 100%. These other specific surface areas were then normalized. Fig. 3 shows normalized surface area of the precursor scaffold calcined at various temperatures for 2h. The specific surface area decreased with calcined temperature, and trends a two-step drop-off. At the calcined temperature below 600°C, the Normallized surface area decreased from 100% to 87%, further heating of the precursor scaffold decreased sharp to 1.3%.

To identify what is responsible, pore volumes were calculated and illustrates a same slow descending trend in the first step. As Table 1 shown, the pore volume decreased only from 0.6 cm^3/g to 0.46cm^3/g. It reveals that that the crystallinity is improved with increasing calcination temperature at this stage.

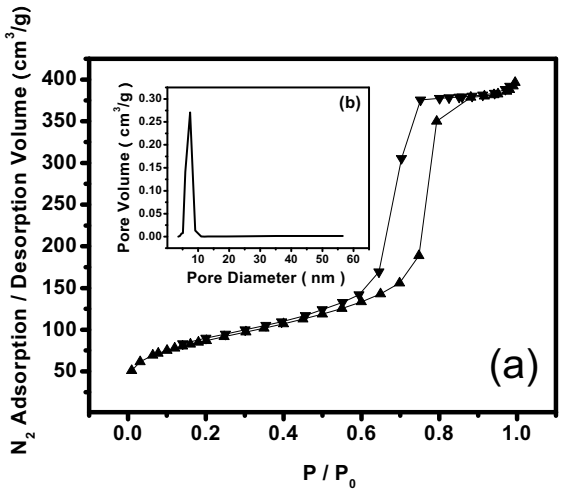

Fig. 2 The typical nitrogen adsorption/desorption isotherms of MBGs.

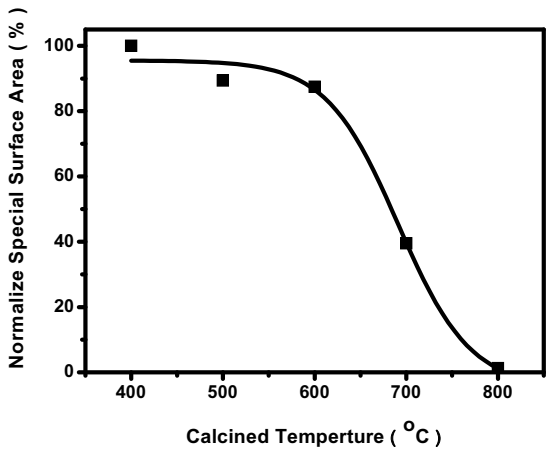

Fig. 3 Normalized surface area of the precursor scaffold calcined at various temperatures for 2h.

Table 1 Textural Properties of mesoporous Bioactive Glasses

Temperature (°C)	Specific Surface Area (cm^2/g)	Pore Volume (cm^3/g)
400	311.4	0.60
500	278.1	0.34
600	272.3	0.46
700	123.1	0.19
800	3.6	0.003

In the second step, the thickness of the pore wall were large enough to fill the pore[7,8]. These results can be proved from the pore volume decreased from 0.46 cm^3/g to 0.003 cm^3/g when calcined temperature increased from 600°C to 800°C.

Considering the high specific surface area and all residual species were removed, used 500°C as heat-treated condition to analyze the textural properties at different dwell time (2 h, 3 h, 5 h,). Regarding the specific surface area of 500°C -2h as 100%, these value were normalized.

Temperature dependence of the time was shown as Fig. 4, illustrating the specific surface area of the MEGs decrease with time.

Moreover, there was the high specific surface area in the dwell for 2h. That would be not only effective to promote cell adhesions and tissue ingrowths, but also shorten the process of preparing bioactive glass materials. For these reasons, dwell for 2h is the best condition.

The specific surface area, pore size and the residual species remove would be considered, the sample under the condition of 500°C -2h, which was measured as the best, was chosen for bioactivity test. The values of textual prosperity (specific surface area, pore size and residual species remove) were 236 cm^3/g, 6.5 nm, 0.46 cm^3/g.

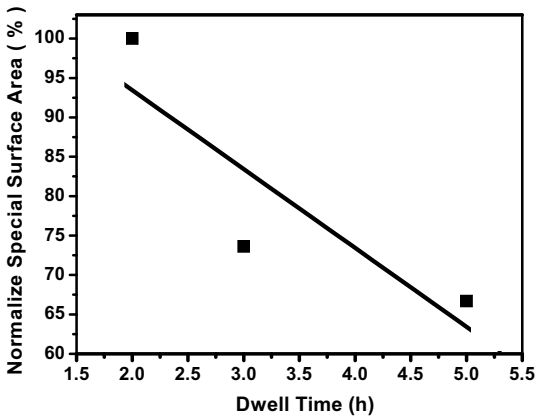

Fig. 4 Normalized surface area of the precursor scaffold calcined at 500°C for different times.

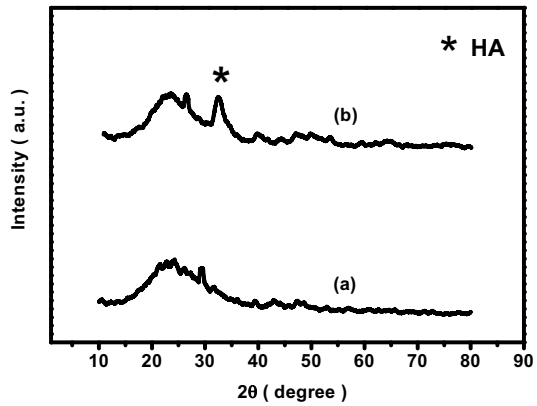

Fig. 5 XRD patterns of MBG_S before (a) and after (b) soaking in SBF for 24h.

Table 2 EDS analysis of scaffold before and after soaking in SBF for 24 h.

Element	Wt%	
	Before soaking	After soaking
Si	21.70	13.06
P	12.93	22.06
Ca	15.87	25.01
O	49.50	39.06
Total	100.00	100.00

The XRD patterns of the bioactive glass scaffold and after soaking in SBF for 24h of sample (b) are shown in Fig. 5.

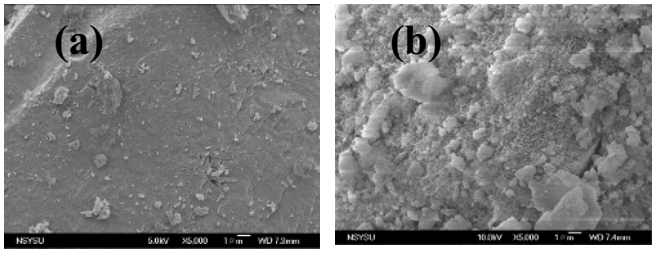

Fig. 6 FE-SEM micrographs of scaffolds before (a) and after (b) soaking in SBF for 24 h.

It indicates a sharp reflection peak of around 32° appeared, While the sample after soaking in SBF for 24h, which can be ascribed to (211) and (112) reflections of hydroxylapatite [9].

The semi-quantitative element had been examined by Scanning Electron Microscope and Energy Dispersive X-Ray Spectrometer (SEM/EDS) shown in Table 1. The variation of nominal composition (Si: Ca: P = 80: 15: 5) of the samples before and after soaking in SBF were measured by weight percentage. After soaking in SBF, Si diminished from 22% to 13%, while Ca and P became predominant, separately raise from 16% to 25% and 13% to 22%. That is, the content after soaking in SBF of MBGs changed, which Ca and P increased but Si decreased, indirectly proved the growths of hydroxylapatite [9].

For further observation of the Microstructure of hydroxylapatite, the FE-SEM micrographs before and after soaking were shown in Fig. 6. The surface of the sintered pellets prior to soaking (a) was smooth, and after soaking for 24h, the surface was covered by nanometric needles. Needle size was in the range of 300 nm.

IV. Conclusions

Mesoporous bioactive gel glasses scaffold have been successfully synthesized in temperature range of 400–700°C. The best bioactive glass scaffolds in ternary CaO - SiO_2 - P_2O_5 system which have both macropores and mesopores is being heat-treated at 500°C for 2h. The specific surface area, pore size, pore volume were 236cm^3/g, 6.5nm, 0.46cm^3/g.

The specific surface area decreased with calcined temperature, and trends a two-step drop-off. At the calcined temperature below 600°C, the Normallized surface area decreased from 100% to 87%, further heating of the precursor scaffold decreased sharp to 1.3%.

The MBGs scaffold after soaking in SBF for 24h can be observed the length ~300nm hydroxylapatite needles.

Abstract — **Hierarchically 3D porous mesoporous bioactive glasses (MBGs) scaffolds with advantages of both macroporosity and mesoporosity have been successfully synthesized through evaporation-induced self-assembly (EISA) in the presence of a nonionic block copolymer $EO_{100}PO_{65}EO_{100}$ (F127) and polyurethane (PUF) as co-templates.**

Higher pore volume and uniform mesopore sizes are formed when F127 concentration over the critical micelle concentration (CMC).

After soaking these MBGs scaffld in simulated body fluid (SBF) for 4 h, it can be observed that the formation of hydroxyl apatite (HAP) on the surface of the MBG scaffolds.

Keywords — **Critical Micelle Concentration, Mesoporous Bioactive Glass Scaffolds, Bioactivity**

I. Introduction

Recently, mesoporous bioactive glasses have shown to be excellent candidates for biomedical applications. It is well known that mesoporous materials have the attractive feature of large surface area, ordered mesoporous structure, tunable pore size and volume. Due to these properties, mesoporous materials have been expanded into the field of biomaterials science. Increasing the specific surface area and pore volume of BGs is especially important to accelerate the kinetic deposition process of hydroxycarbonate apatite and therefore enhance the bone-forming bioactivity[1]. MBGs with three-dimensional (3D) porous structures provide more advantages than the normal powder or granules, because ideal 3D scaffolds consist of an interconnected macroporous network to allow cell migration, nutrient delivery, bone ingrowth, and eventually vascularization, thereby allowing them to have better in vivo bioactivity[2,3].

The formation of a long-range cubic mesostructure are known largely depends on the concentrations of F127[4]. In this study, we investigated the influence of the concentration of the surfactant on mesoporous bioactive glass scaffolds, and the assessment of in vitro bioactivity of the MBGs scaffolds was carried out in a SBF solution to monitor the formation of hydroxyl apatite (HA) on the surface of the MBG over time.

II. Materials and Methods

A. Preparation of the MBGs scaffolds

In a typical synthesis, different amounts of F127 ($EO_{100}PO_{65}EO_{100}$, BASF) were dissolved in ethanol (EtOH) with HCl solution. Afterward tetraethyl orthosilicate (TEOS, ACROS), $Ca(NO_3)_2{\cdot}4H_2O$ (SHOWA), and triethyl phosphate (TEP, FLUKA; 80:15:5 Si:Ca:P molar ratio) were added and stirred at room temperature for 1 day. Then the polyurethane foam was completely immersed into the sol and compressed in order to force the sol to migrate into all pores; the excess sol was then squeezed out. After 1day of drying, the same procedure was repeated, and then dried the samples at 100°C for 24 h. When the samples were completely dry, they were calcined at 500°C (ramp of 10°C/min) for 5 h. This stage was aimed to decompose and burn out the polyurethane foam support without collapsing the scaffold[7].

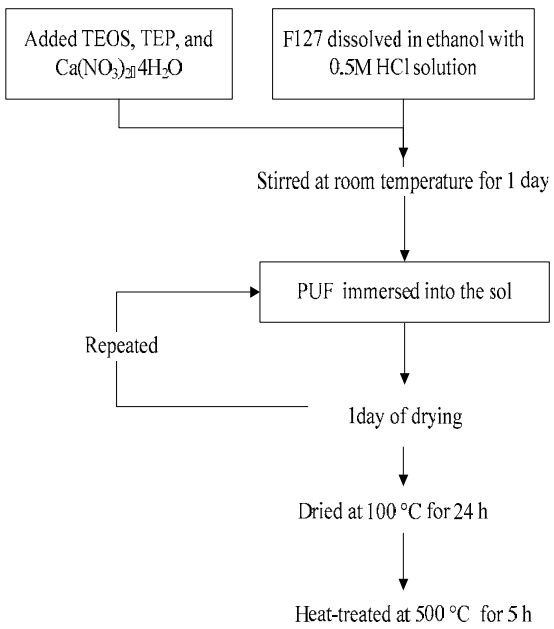

Fig. 1. Process flow chart of MBG materials.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1366–1368, 2009
www.springerlink.com

B. Assessment of in Vitro Bioactivity

The bioactivity of the scaffold in vitro was tested by immersing the scaffold samples with a dimension of 5 × 5 × 5 mm^3 in simulated body fluid (SBF) at a solid:liquid ratio of 1 mg/mL at 37 °C in 160 rpm/min to monitor the formation of hydroxyapatite on the surface of the sample every 0, 4, 6 and 24 h. Afterward, the scaffold was taken out, washed three times with acetone, and dried in air for further characterization.

III. Results and Discussion

A. The influence of the concentration of F127 on mesoporous structure

In this study, it was found that the weight ratio of the triblock copolymer, F127, significantly affects the formation of the mesostructure. Using a low weight ratio of F127 (F127/total solution = 2.1 wt%; the concentration < Critical Micelle Concentration) induces heterogeneous reactions between F127 and the inorganic species, which lead to the inferior pore textural properties (Fig. 2) . As the result, 2.1 wt% F127 has a low specific surface area of 41.46 m^2 g^{-1} and large pore size, which comes from its having large slit-like pores between the particles rather than a mesostructure. Increasing the weight ratio of F127 allows homogeneous reactions to take place between the templates and inorganic species, and subsequently leads to mesostructure formation. The sample with an amount of F127 greater than 5.42 wt% (CMC) finally formed a 3D ordered mesostructure, shows an H2-type hysteresis loop[8]. The specific surface area increases to 262.3 m^2 g^{-1}, but the pore volume is relatively low. A mesostructure with a better and longer range arrangement was formed by increasing the weight ratio of the F127 from 5.42 wt% up to 9.11 wt%. It exhibits a type IV isotherm with a sharp capillary condensation step at high relative pressures and an H1 hysteresis loop in the mesopore range, that is indicative of uniform and homogeneously distributed mesopores. In particular, the mesopore volume of the scaffold with 9.11 wt% F127 was considerably increased about 31.8%.

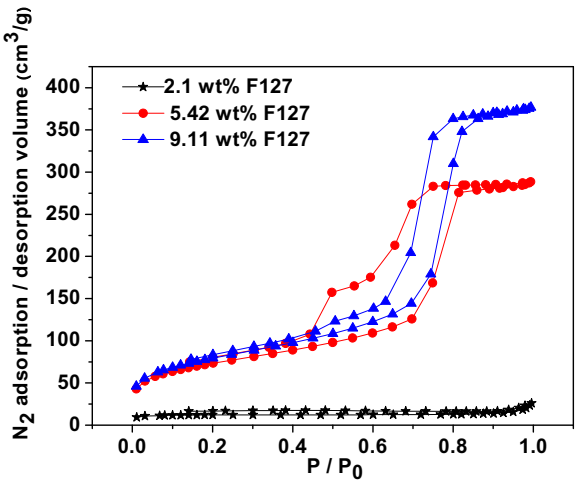

Fig. 2. N_2 adsorption–desorption isotherms of the MBGs scaffolds with different weight ratio of F127

B. In Vitro Bioactivity Tests

It has been accepted that the bioactive characteristic of the scaffold biomaterials is their ability to bond with living bone through the formation of an apatite layer on their surface both in vitro and in vivo. The XRD patterns can be used to evaluate the changes on the scaffold surfaces. Fig.3~5 shows the XRD patterns of the MBGs scaffolds with different weight ratio of F127 after soaking in SBF for

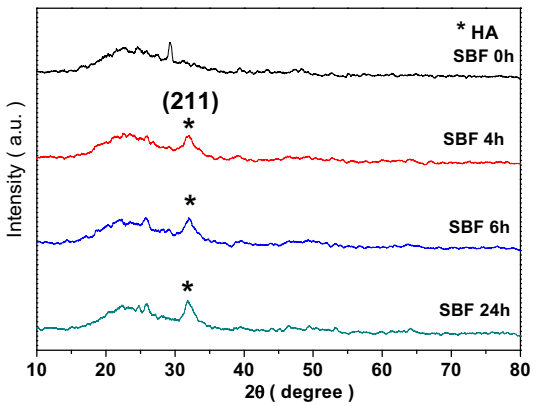

Fig. 3. XRD patterns of the 2.1 wt% F127 MBGs scaffold after soaking in SBF for 0, 4, 6 and 24 h.

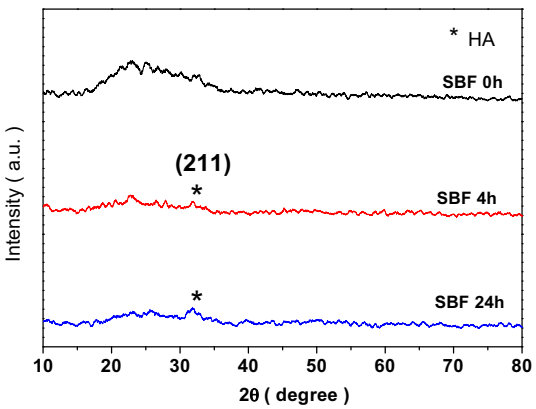

Fig. 4. XRD patterns of the 5.42 wt% F127 MBGs scaffold after soaking in SBF for 0, 4 and 24 h.

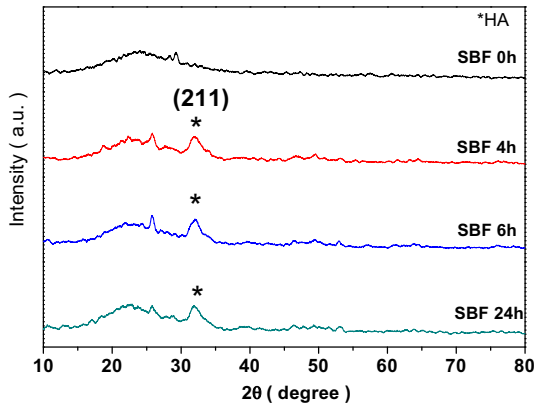

Fig. 5. XRD patterns of the 9.11 wt% F127 MBGs scaffold after soaking in SBF for 0, 4, 6 and 24 h.

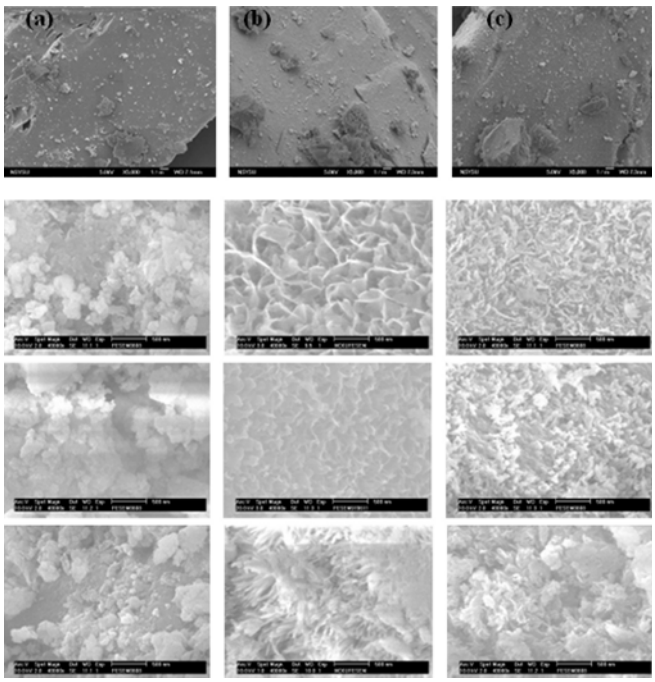

Fig. 6 FE-SEM images of the MBGs scaffolds with different weight ratio of F127 (a) 2.1 wt% (b) 5.42 wt% (c) 9.11 wt% after soaking in SBF for 0, 4, 6, and 24h.

0, 4, 6, 24 h. It can be observed that there are only one broad reflection in the 2θ range of 15-40° before soaking. After soaking these MBGs scaffolds in simulated body fluid (SBF) for 4 h, the XRD patterns show several new diffraction peaks, which are the characteristic peaks of apatite phase[9] (Standard card number: JCPD 24-0033).

Fig. 6 shows the FE-SEM image of the MBGs scaffolds with different weight ratio of F127 after soaking in SBF for 0, 4, 6, 24 h. The scaffolds before soaking show a smooth and homogeneous surface. The FE-SEM image reveals that the surface of the MBG undergoes important changes during the reaction with SBF. The scaffold with 2.1 wt% F127 after soaking for 4 h, although it has no mesostructure but the surface was covered by roundish nanoparticles. And the scaffold with 5.42 wt% F127 after soaking for 4 h, the surface was covered by flower-like deposited layer. The amount of the deposited layer increased with increasing soaking time. When the scaffold with 9.11 wt% F127, it can be observed that a layer composed of needle-shaped crystallites fully covered the surface. Furthermore, the thickness of the needlelike crystallites increase is subsequently observed after 24 h.

IV. Conclusions

(1) When the concentration of F127 is 9.11 wt%, shows an H1 hysteresis loop in the mesopore range with uniform and homogeneously distributed mesopores.

(2) The concentration of F127 and the time of scaffolds soaking in SBF are important factors to influence the morphology of HA in human bones.

(a) When the concentration of F127 is 2.1 wt%, although the scaffold has no mesostructure but the surface was covered by roundish nanoparticles.

(b) The scaffold with 5.42 wt% F127 after soaking for 4 h, the surface was covered by flower-like deposited layer.

(c) The scaffold with 9.11 wt% F127, it can be observed that a layer composed of needle-shaped crystallites fully covered the surface after soaking for 4 h.

Abstract — **ESCs are pluripotential, but their application for cartilage regenration has not been explored. Our study was designed to explore a strategy of using human embryonic stem cell-derived mesenchymal stem cells(hESC-MSCs) with BMP7 in collagen scaffold to improve the therapeutic efficacy of cartilage defect repair. Full-thickness cartilage defects (diameter=2mm, thickness=2 mm) were made in the patellar grooves of male SD rat and randomly divided into four groups: No treatment group, collagen scaffold group, hESC-MSCs in collagen scaffold group or hESC-MSCs with BMP7 in collagen scaffold group, respectively (n=11 in each group). The rats were sacrificed at 4 and 8 weeks after operation. The repaired tissues were processed for histology and for mechanical test. The histological results showed that the group treated with hESC-MSCs had more amounts of hyaline cartilage, higher ICRS histological scores and Young's modulus of the repaired cartilage tissue. Moreover, hESC-MSCs with BMP7 group had the highest histological scores and Young's modulus of the repaired cartilage tissue. The amounts of hyaline cartilage were significantly higher than those in hESC-MSCs group. Our results demonstrated that hESC-MSCs can improve the regeneration of cartilage tissue. It acts synergistically with BMP7 in stimulating the formation of hyaline cartilage tissues. These findings suggested that the combination of hESC-MSCs with BMP7 in collagen matrix may be used to improve the quality of cartilage repair.**

Keywords — **hESC-MSC, BMP7, collagen scaffold, Cartilage defect**

I. Introduction

Human adult bone marrow mesenchymal stem cells(BMSCs) are known to possess the capability to differentiate into chondrocytes[1], but the availability of tissues for MSCs isolation remains limiting and requires invasive procedures, and expansion of MSCs is finite. Morever, chondrogenic potential of MSCs declines with age and MSCs caused ectopic bone formation[2]. Recently, it is realiazed that ESCs could potentially be an source of consistently uniform MSCs for therapeutic applications. These human ESC-derived MSCs (hESC-MSCs) have similar cell surface markers, differentiation potentials, and immunological properties to adult BMSCs[3]. However, the application of hESC-MSCs for cartilage regenration has not been explored.

In recent years, BMP-7 has become the subject of major research aimed at therapeutic strategies for the treatment of cartilage defects[5] despite that BMP7 have osteoblastic and adipogenic differentiation potential[5]. Interestingly, BMP-7was proved to be a key regulator in the regenerative response to ischemia,which is similar to hypoxia and low serum condition in knee joint. Thus, we speculate that hESC-MSCs combines with BMP7 may promote chondrocyte regeneration.

The present study tested the hypothesis that hESC-MSCs promote the therapeutic efficacy of cartilage defect repair and they act synergistically with BMP7 in stimulating the formation of hyaline cartilage tissues. Therefore, hESC-MSCs with or without BMP7 in collagen scaffold were implanted into defects in a rat model. The quality and resurfacing area of the cartilage repair were investigated.

II. Materials and methods

A. Cell Culture and cell labeling

Human embryonic stem cell (Hues9) derived mesenchymal stem cells were used. hESC-MSCs were cultured in DMEM medium containing 10% fetal calf serum, 100 U/mL penicillin, and 100 mg/mL streptomycin at 37°C in 5% CO_2. 90% confluent cells were digested and incubated with DiI (1μg /mL) at 37°C for 5 minutes. hESC-MSCs labeled with DiI were washed 3 times with Phosphate Buffered Saline (PBS) before loading in collagen scaffolds.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1369–1372, 2009
www.springerlink.com

B. Collagen scaffold fabrication and cell loading

Insoluble type I collagen was isolated and purified from pig Achilles tendon using neutral salt and dilute acid extractions. The diameter was 2 mm and the thickness was 2 mm. DiI- hESC-MSCs (5×10^5) were resuspened in 3 % alginate acid solution with or without human recombninat BMP7 (500ng/ml, R&D system, Inc.USA). And then each scaffold immerged into the suspension and incubated at 37°C in 5% CO_2 for 30 minute. Finally, they were added into 102 mM $CaCl_2$ solution to get the gels for experiment.

C. Animal model

Male SD rats (230-250g) were immunodepressed with cyclophosphamide (150mg/Kg) three days before experiment. A full-thickness cylindrical cartilage defect of 2 mm diameter and 2 mm depth was made in the patellar groove of the bilateral knees using a stainless-steel punch (Figure 1.a). The experiment consisted of the following three treatment groups as in Table 1. hESC-MSCs or hESC-MSCs with BMP7 in scaffold was implanted to the defects (Figure 1.b). The rats were sacrificed at 4 and 8 weeks after transplantation.

Table 1: Design of experimental groups

groups	4 weeks	8 weeks
Group I: Defect with collagen scaffold	n=3	n=8
Group II: Defect with hESC-MSCs in collagen scaffold	n=3	n=8
Group III: Defect with hESC-MSC and hBMP7 in collagen scaffold	n=3	n=8

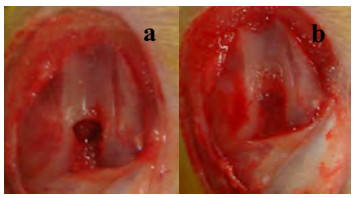

Fig. 1. Macroscopic photograph showing a full-thickness cartilage defect of 2 mm diameter in a patellar groove(a). The defect was covered with the scaffold (b)

D. Gross morphology and histology

At 4 and 8 weeks post-surgery, the rats were sacrificed by intravenous overdose of pentobarbital. Three harvested samples of each group were examined and photographed for evaluation. After gross examination, the survival of the transplanted hESC-MSCs was demonstrated by the presence of fluorescence from DiI-labeled cells (KODAK Image Station In-Vivo FX.USA). Samples were fixed in 4% formalin, decalcified in 10% formic acid, then embedded in paraffin and cut to 5μm thick sections. Sections were stained with Hematoxylin and Eosin (H&E) for the study of morphological evaluation. For the overall evaluation of the regenerated tissue in the defects, the repaired tissues were graded using the International Cartilage Repair Society (ICRS) Visual Histological Assessment Scale[6] by one blinded observer.

E. Mechanical evaluation

Compressive mechanical properties of the cartilage layer following long-term (8 weeks, n=5 samples) period in vivo were determined using a 1 mm diameter cylindrical-shaped indenter to compressively load the cartilage tissue in Instron Testing machine (model 5543, Instron, Canton, MA) fitted with a 10 N maximum load cell. The ratio of equilibrium force to cross-sectional area was divided by the applied strain to calculate the equilibrium modulus (in MPa).

F. Statistical analysis

Histological scoring data and biomechanical test data were assessed for statistical differences using a paired t-test to compare experimental characteristics to control.

III. Results

A. Gross morphology

The gross examinations of knee joints showed that there were no abrasions on the opposing articulating surfaces and no inflammation at both 4 and 8 weeks time point. The defects remained empty in small parts at 4 weeks after transplantation (Fig.2). Red fluorescence in the defect areas are clearly photographed in all of the 4-week samples and in most of the 8-week samples (Fig.2g). The posibility in 8-week samples is about 3/4.

B. Histological examination

At 4 weeks after transplantation, the defects in group I (n=3) were filled with fibrous tissue (Fig. 3a). In the group II (n=3) and group III (n=3), the defects were repaired with the mixture of fibrous tissue and cartilage-like tissue as shown by H&E staining. The amounts of chondrocyte-like cells and cartilage-like extracellular matrix in the group III were more than those of group II by means of H&E staining (Fig. 3b,3c). At 8 weeks after transplantation, the defects in group I (n=3) were almost filled with fibrous tissue and a little cartilage-like tissue at the margins of the defects

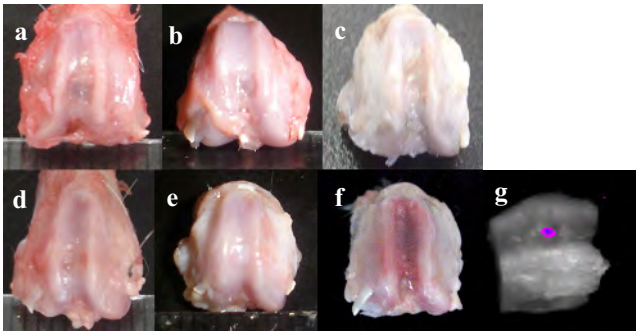

Fig. 2. Macrophotograph shows that the defects in the three groups at 4 weeks (a, b, c) and 8 weeks (d, e, f) post-surgery. a, d group I; b, e group II; c, f. group III. G. Red area indicates the fluorescence in the defect areas in 8-week sample.

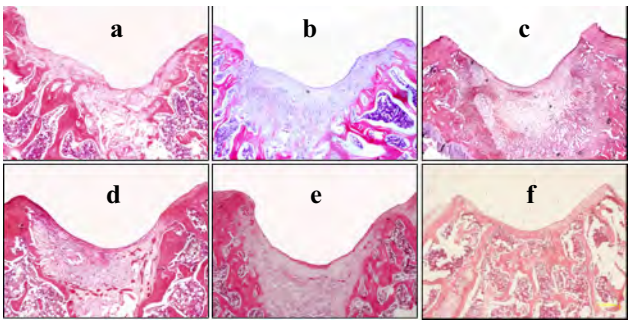

Fig. 3. Histological examination of the three groups at 4 weeks (a,b,c) and 8 weeks (d,e,f) post-surgery. a, b. Group I; b, e. Group II; c, f. Group III.

(Fig. 3d). Group II had lager amounts of hyaline cartilage (Fig. 3e). The group III has the most amounts of hyaline cartilage tissue (Fig. 3f). It was found that hyaline cartilage tissues were formed at the surrounding area of the defects while the fibrous tissues were located at the central part of defects.

The total ICRS histological scores of the specimens at 8 weeks revealed differences between the three groups (Table 2).The scores for the repaired tissue of group III were significantly higher than those for other two groups (#p < 0.05).

Table 2: Comparison of the total ICRS histological scores (Total scores are 18 points)

groups	ICRS histological scores
Group I	5.52±1.15
Group II	9.17±1.34
Group III	11.12±0.32

C. Biomechanical evaluation

Biomechanical analysis of the repaired tissues at 8 weeks post-surgery (n = 5 in all groups). At 8 weeks post-surgery, as shown in Table 3, the compressive modulus of the repaired tissue in group II and group III samples showed greater improvement compared with specimens from group I (**p<0.01). The compressive modulus in group III showed significant higher than that in specimens from group II (*p<0.05).

Table 3: Summary of biomechanical evaluation

groups	Young’s modulus (MPa)
Group I	0.0397±0.0087
Group II	0.0528±0.0072
Group III	0.0634±0.0072

IV. Discussion

The present study demonstrated that hESC-MSCs can existed in the defect area at least 8 weeks as evidenced by tracing the red Dil labed hESC-MSCs (Fig.2g). hESC-MSCs improved the regeneration of cartilage tissue in vivo model. The histological results showed that the group treated with hESC-MSCs had more amounts of hyaline cartilage, higher ICRS histological scores. More importantly, the Young's modulus in group II increased to 0.0528±0.0072 Mpa at 8 weeks, which was significantly higher than 0.0397±0.0087 Mpa in group I. These findings suggested that hESC-MSCs can be one of the seed cells for cartilage tissue engineering.

Although it is not clear about the detail mechanism, the improvement effects could be explained by possibility of the chondrogenesis of hESC-MSCs. The local environment in the defect area may facilitate chondrogenic differentiation in hESC-MSCs, such as hypoxia[7] and the change of the cartilage matrix[8].

Nevertheless, recent reports have suggested that the reparative effects associated with MSC transplantation are not mediated by direct differentiation of MSCs but by paracrine factors secreted by MSCs. hESC-MSCs may secrete a variety of cytokines, which inhibit apoptosis in hypoxia and low serum condition of knee joints, enhance differentiation of stem cells or cartilage-intrinsic reparative.

In present study, BMP7 and hESC-MSCs acted synergistically. BMP7 significantly improved the efficacy of hESC-MSCs in promoting the formation of hyaline cartilage tissues as shown in Fig. 2 and Fig.3. Combination of BMP7

with hESC-MSCs in collagen matrix also increased the function of cartilage as evidenced by the elevation of Young's modulus (0.0634±0.0072Mpa), which was the highest level among these three groups. Thus, we demonstrated that BMP7 with hESC-MSCs promote new hyaline-like cartilage formation in vivo. This finding is consisted with the report in MSCs [9].

BMP7 has positive influence on the cartilage matrix environment, which is reported to regulate the chondrogenic differentiation[10]. BMP7 increases the synthesis of aggrecan , type II collagen, proteoglycan, hyaluronan synthase-2 and hyaluronan production[11]. However, the detail relationship between BMP7 and hESC-MSCs are not clear. For example, whether BMP7 has direct effect on hESC-MSCs or not? Further studies are needed to focus on the mechanism of hESC-MSCs and BMP7, including the relationship between them.

In this experiment, the degradable alginate gel was designed to contain hESC-MSCs and BMP7 in the defect areas to prevent the loss of implanted cells and cytokine. Moreover, the use of degradable alginate gel loaded with BMP-7 in collagen scoffold might offer the advantage of a better distribution and a prolonged delivery of BMP7 within the tissueengineered site and consequently an enhanced effect both on the differentiation of hESC-MSCs and on the metabolism of the host's chondrocytes, by which promote the repair of cartilage defect.

V. Conclusions

This study demonstrated that hESC-MSCs can improve the regeneration of cartilage tissue. The combination of hESC-MSCs with BMP7 in collagen scaffold may have greater potential to repair larger cartilage defects. But the underlying mechanism are remained to be elucidated.

Abstract — **Current treatment options for restoring large bony defects due to trauma or tumor ablation are limited by the host bone tissue availability and donor site morbidity of bone implantation. Creation of implantable functional bone tissue that could restore bony defects may be a possible solution. Previously, many *in vitro* studies have indicated the potential of using electrospun nanofibrous scaffolds for tissue repair. However, few studies demonstrated their utility in tissue repair models. We hypothesized that the electrospun nanofibrous membrane improves the efficacy of currently-used collagenous guided bone regeneration (GBR) membrane in repairing large cortical bony defect. A practical biodegradable nanofibrous poly-L-lactic-acid (PLLA) membrane honeycombed with one layer of collagen matrix was developed. Bone defect with 10 × 15 mm^2 area was covered by nanofiber-reinforced bi-layer membrane or collagenous membrane. 3 and 6 weeks after operation, bone defect healing was assessed radiologically and histologically. The radiolographic data showed that the group treated with nanofiber-reinforced bi-layer membrane had more bony tissue formation at 3 weeks. The histology results were consistent with that of radiographic findings at 3 weeks. Moreover, the defects treated with bi-layer membrane were repaired perfectly by dense cortical bone at 6 weeks, while whose treated with collagenous membrane were filled with spongy bone and fibrous tissues. The results demonstrated that electrospun nanofibrous membrane can be combined with collagenous GBR membrane to improve guided bone regeneration technology. And this type of membrane may provide implantable functional bone tissues for patients with large bone defects.**

Keywords — **Tissue engineering, Electrospun nanofiber, Guided bone regeneration, Bone defect**

I. Introduction

Guided bone regeneration (GBR) is a standard procedure to protect a tissue defect from the ingrowth of surrounding fibrous tissue. Biodegradable GBR membranes, such as collagen and synthetic biodegradable polymers, have been developed [1]. Among these, collagen-based membranes have been well-accepted by clinicians [2-4]. However, although the excellent biodegradability and biocompatibility of collagenous membrane has been demonstrated *in vitro* [5], the same positive results have not been evident *in vivo* [6]. Collagenous membrane is mechanically weak, making it difficult to shield a bone defect efficiently. In addition, the rapid degradation time does not match with that of the bone-healing process. So, further investigations are needed to overcome these disadvantages.

In recent years, electrospinning technology has been used to produce nanofibrous scaffolds, which are superior in surface area, mechanical strength, and biomimetic properties. Numerous studies have shown that nanofibrous architecture is beneficial to the proliferation and differentiation of cells [7-8]. These special properties may be utilized to overcome the disadvantages of the collagenous GBR membrane.

The present study tested the hypothesis that electrospun nanofibrous membrane improves the efficacy of currently-used collagenous GBR membrane for large bony defect repair. Therefore, a novel degradable bi-layer guided bone regeneration (GBR) membrane consisting of an electrospun nanofibrous membrane and a collagenous membrane was designed for bone defect repair, with the aim of developing a more efficient GBR membrane.

II. Materials and methods

A. Fabrication of the membranes

Nanofibrous poly-L-lactic acid (PLLA) fibers were fabricated by electrospinning [9]. All electrospun fibrous membranes were stored in desiccators for several days before use. Collagen was extracted and purified from tendons [10]. The solution was then dialysed, frozen and freeze-dried to obtain the collagen. The collagen was dissolved again in 10 mg/ml 0.5 M HAc and placed onto the nano-PLLA membrane. The composite was freeze-dried and treated at 110°C under vacuum for 48 h to cross-link the collagen matrix. Consequently, a bi-layer membrane was produced (Fig. 1a). Collagenous membrane, as a control, was also produced using the same procedure without the nanofibrous membrane. The properties of 12 specimens (6 PLLA and 6 collagenous membranes) were characterized using a mechanical testing machine (Instron 5530, USA) and scanning electron microscopy (SEM).

www.springerlink.com

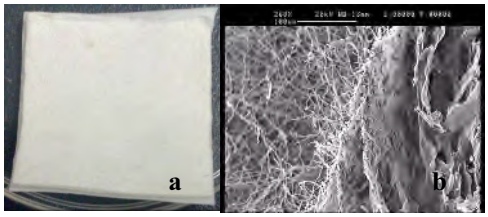

Fig. 1. (a) Optical image of bi-layer membrane. (b)The SEM image of the bi-layer membrane (side view).

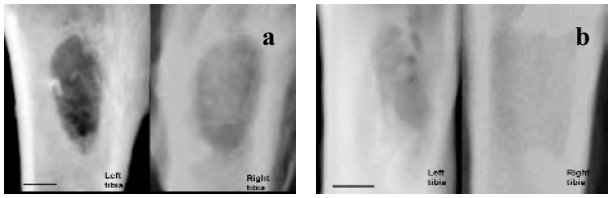

Fig.2. Radiographs Obtained at 3 weeks(a) and 6 weeks (b). (bar = 0.5cm).

B. In vivo studies

Eight adult male NZW rabbits weighing 2.59 ± 0.35 kg were randomly divided into two groups of 4, and anesthetized before surgery. A defect 10 mm wide and 15 mm long in the anteromedial cortex of the proximal tibia, starting 5 mm below the joint line, was created using a micro-burr and saline irrigation to minimize thermal damage. With this method, bilateral defects were created, and collagenous membrane (control group), or the bi-layer membrane (experimental group) of 10 × 15 mm^2 was placed into left or right defect respectively. The incision was then closed. Four animals were sacrificed at 3 and 6 weeks respectively. The region surrounding the implant was harvested and processed for X-ray evaluation and histological analysis.

C. Bone score

The degree of new bone formation during the healing period was estimated from the sections, using a semiquantitative score from 0 to 4. The score values were defined as follows: 1 = few and isolated centers of ossification; 2 = more, but still discontinuous new bone formation; 3 = beginning, but incomplete bridging of the defect. The scores were added to estimate the overall bone formation in the defect at a given time.

III. Results

A. Physical properties of bi-layer membrane and collagenous membrane

SEM examination of the bi-layer membrane (Fig. 1b) revealed excellent integration of the two layers, without any PLLA nano-fibers melting on the collagen scaffold. The elastic modulus of PLLA was 83.55 ± 18.82 MPa, while that of collagen was 1.68 ± 0.30 MPa.

B. X-ray evaluation

At 3 weeks, new bone formation was detected in the experimental and control groups. But in the control group, the medial region of the defect contained little mineralized bone, which was only seen at the margin of the defect (Fig. 2a). No radiographic differences were detected in the defects filled with collagenous membrane alone or bi-layer membrane at 6 weeks (Fig. 2b).

C. Histological assessment

No infiltration of multinucleated cells was found at 3 or 6 weeks. The location of the defect was easily recognizable by the degraded membrane (Fig. 3).

At 3 weeks in the experimental group, nano-fibers were seen to guide a layer of newly formed bone as a bridge over the defect. New bone formation was observed around the periphery of the defect, and intense remodeling was seen in the adjoining cortical bone. But in the control group at 3 weeks, the defect was filled with a few islands of newly-formed bone dispersed among a mass of fibrous connective tissue, and no bone bridges over the defect were found.

At 6 weeks, only the bi-layer membrane-treated bone defects displayed nearly complete regeneration of cortical bone tissue with a physical contour. The newly-formed bone tightly contacted the residual nanofibrous membrane. In the control group, the quantity of newly-formed bone increased greatly with time. However, this new bone was disorganized and appeared to be spongy rather than cortical bone. Moreover, the contour of the tibial defect was not restored, due to the evident invasion of fibrous tissue.

D. Bone score

Table 1 summarizes the results of bone score evaluation. New bone formation in the bi-layer membrane group was significantly greater than that in the collagenous membrane control at 3 weeks ($p<0.01$). At 6 weeks, defect closure was

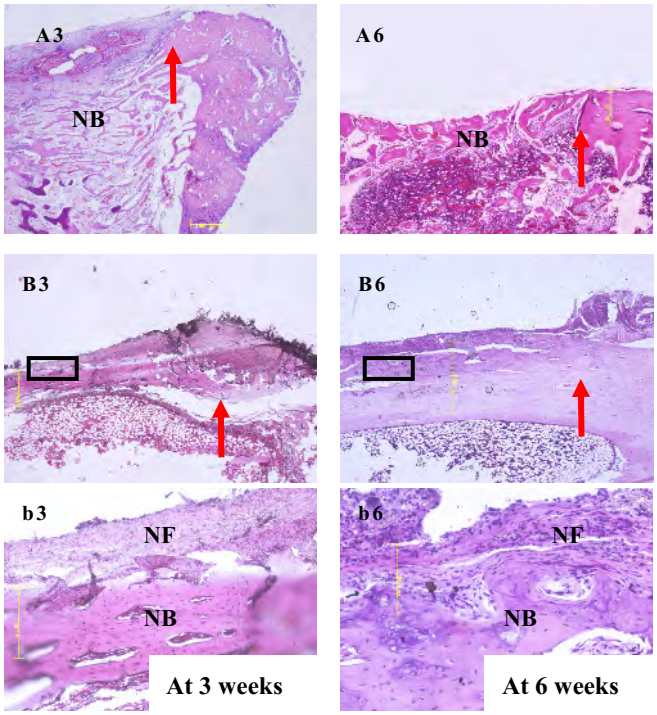

Fig.3. Representative photomicrographs of defect sites. (A = Control group; B = Experimental group; red arrowhead = defect margin; NB = newly formed bone; NF = nanofibers; H–E stain; original magnification: 40x (A3, 6 and B3, 6), 400x (b3 and b6).

significantly greater in the bilayer membrane group than in the collagenous membrane control ($p<0.01$).

Table 1: Summary of bone score evaluation

groups	3 weeks	6 weeks
Bi-layer membrane	3.60±0.58	3.65±0.50
Collagen membrane	1.78±0.50	2.55±0.58

IV. Discussion

The present study describes a novel bi-layer nano/micro-porous GBR membrane in which a pliable and substantially cell-impermeable nanofibrous membrane was honeycombed with cell-permeable collagenous membrane. The bi-layer GTR membrane allowed physical cortical bone formation with normal contour in a rabbit model. This is the first demonstration that nanofibrous membrane improves the efficacy of collagenous GBR membrane in creating a satisfactory biological environment for accelerating new bone growth at a large bone defect. Moreover, it is worth emphasizing that the bi-layer GBR membrane led to cortical bone formation rather than the spongy bone found in collagenous GBR membrane-treated defects. These results are of considerable interest for improving current GBR technology.

Some studies have demonstrated nanofiber-induced bone tissue growth *in vitro* when seeded with bone cells or stem cells [11-13]. However, little is known about the effects of nano/micro-porous bi-layer membrane on bone wound healing in animal models. By *X-ray evaluation* and histological analysis, the ratio of new bone formation increased in the control group and became comparable to that of the bi-layer membrane group at 6 weeks. This can be explained by the fact that there was a great deal of new bone formation in the first 3 weeks, but subsequently bone remodeling rather than bone formation became the major repair process in the bi-layer membrane group. This indicates that bi-layer membrane improved the quantity of new bone tissue at early stages, and the quality of bone repair at later stages.

Collagen has relatively poor mechanical strength and is rapidly degraded. The early absorption of membrane results in reduced bone formation and incomplete bone filling [14]. The bi-layer GBR membrane had good biomechanics and a relatively slow degradation rate, providing enough space to selectively guide cells in growth, and acting as a periosteum-like scaffold.

In the present study, resorption and distortion of the nanofiber membranes were seen 3 weeks after they were grafted onto the tibia defects. Previous data has indicated that biodegradation through hydrolysis can have adverse effects [15-16]. But this bi-layer membrane did not elicit a severe local or systemic inflammatory response *in vivo*. One of the reasons may be due to its specific characteristics, including the rate of degradation, the large surface area, and the surface chemistry. Another may be due to the composite of collagen and PLLA in the bi-layer GBR membrane, which only contained a few micrograms of PLLA polymer.

In order to study the efficiency of this bi-layer GBR membrane for relatively large bone defect healing, we created the full-thickness defect (10x15 mm^2) in the proximal tibia. It is bigger than those critical defects of 5mm wide and 15 mm long reported by previous studies [17-18]. In our pilot study, it was found that the defect can not be even bigger without fractures.

Further studies are needed to investigate more intelligent, functionally degradable multi-layer GBR membranes. Moreover, nano-PLLA/micro-collagenous membranes incorporating osteoinductive factors are yet to be investigated.

V. Conclusions

This study demonstrated that the nanofiber-reinforced bi-layer membrane repaired a large tibial bone defect with physical cortical bone tissue and normal contour. Therefore, this type of membrane might be able to act as a novel GBR membrane, and provide implantable functional bone tissues for patients with large bone defects.

Abstract — **Silk fibroin from *Bombyx mori* silkworm is one of attractive biomaterials for tissue engineering because of its excellent mechanical properties, biocompatibility and slow biodegradation. Silk fibroin from Thai yellow cocoon "Nangnoi-Srisaket 1" was employed to prepare aqueous-derived fibroin scaffolds via salt leaching method. The porous structure of scaffolds could be regulated by the size of granular NaCl used. Surface of Thai silk fibroin scaffolds were modified by gelatin conjugation. Furthermore, scaffolds were immersed in $CaCl_2$ and Na_2HPO_4 solutions alternately in order to deposit hydroxyapatite into the scaffolds. After alternate soaking, hydroxyapatite was observed on the porous surface of scaffolds. The comparison between Thai silk fibroin and conjugated gelatin/Thai silk fibroin scaffolds exhibited that the deposition of hydroxyapatite in Thai silk fibroin scaffolds was more than in conjugated gelatin/Thai silk fibroin scaffolds. Gelatin conjugation and hydroxyapatite deposition could enhance the compressive modulus of Thai silk fibroin scaffolds. *In vitro* biocompatibility of Thai silk fibroin-based scaffolds using rat bone-marrow derived mesenchymal stem cell (MSCs) showed that the number of proliferated MSCs, determined by DNA assay, in conjugated gelatin/Thai silk fibroin scaffolds and hydroxyapatite-conjugated gelatin/Thai silk fibroin scaffolds were higher than pure Thai silk fibroin scaffolds, possibly due to RGD sequence contained in gelatin. As gelatin conjugation and hydroxyapatite deposition could alter the morphology of Thai silk fibroin scaffolds and promote the proliferation of MSCs on the scaffolds, these scaffolds have a potential to be applied in tissue engineering applications.**

Keywords — **silk fibroin, gelatin, hydroxyapatite, scaffold, tissue engineering**

I. Introduction

Three-dimensional scaffolds having appropriated porous structure, mechanical integrity, and good biocompatibility are required to promote cell and tissue growth [1]. Various types of biomaterials have been extensively used to fabricate scaffolds for *in vitro* study of cell–scaffold interactions. The scaffold material, as well as the three-dimensional structure of the scaffold, have significant effects on cell activity. They act as a physical support structure and a regulator of biological activity that affects cell response such as migration, adhesion, and proliferation.

Silk fibroin is a major constituent of raw silk fiber from *Bombyx mori* silkworm which has been used in many biomedical applications because of its impressive mechanical properties and biocompatibility [2]. Recent studies showed the benefits of RGD coupling growth and gelatin conjugation to silk fibroin surface on the osteoblasts, fibroblasts and bone marrow mesenchymal stem cell [3-4]. Furthermore, the surface modification with hydroxyapatite is known to have high affinity for various types of cells. Especially when hydroxyapatite is implanted in bone defectes, bone formation between the implanted hydroxyapatite and host cell is reportd [5].

In this study, silk fibroin scaffolds were prepared from Thai silk fibroin via salt leaching method. Gelatin conjugation and hydroxyapatite deposition was introduced to modify the porous surface of Thai silk fibroin scaffolds. The influences of both gelatin conjugation and hydroxyapatite deposition on the morphology and *in vitro* biocompatibility of the scaffolds were evaluated.

II. Materials and methods

Cocoon of Thai silkworm "Nangnoi-Srisaket 1" from Nakhonratchasima province, Thailand, and type A gelatin from Nitta Gelatin, Japan, were used as raw materials. All chemicals used were analytical grade.

A. Preparation of Thai silk fibroin scaffolds.

Thai silk fibroin fibers were prepared as described by Kim *et.al* [1]. Briefly, cocoons were boiled for 20 min in an aqueous solution of 0.02M Na_2CO_3 and then rinsed thoroughly with deionized water to extract the sericin. The degummed Thai silk fibroin was dissolved in 9.3M LiBr solutions at 60°C for 4 h to form 25wt% solution. The solution was dialyzed in deionized water at room temperature for 2 days. The final concentration of Thai silk fibroin aqueous solution was 6.5wt%. Thai silk fibroin scaffolds were prepared by adding 9 g of NaCl (particle size: 600 – 710 μm) into 3 ml of Thai silk fibroin solution in a container. The containers were left at room temperature for

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1377–1380, 2009
www.springerlink.com

24 h. Then, salt was leached out by water and left to be dried overnight. The Thai silk fibroin scaffolds were punched into 11mm in diameter, 2mm in height.

B. Preparation of conjugated gelatin/Thai silk fibroin scaffolds (CGSF)

Conjugated gelatin/Thai silk fibroin scaffolds (CGSF) were prepared by coating Thai silk fibroin scaffolds with 0.5wt% gelatin solution, followed by conjugation via dehydrothermal treatment at 140°C for 48 h in a vacuum oven. After that, the scaffolds were treated with carbodiimide solution (14mM 1-ethyl-3-(3-dimethyl aminopropyl) carbodiimide hydrochloride (EDC) and 5.5mM N-hydroxysuccinimide (NHS)) under vacuum for 2 h [6].

C. Preparation of hydroxyapatite/Thai silk fibroin (SF4) and hydroxyapatite-conjugated gelatin/Thai silk fibroin scaffolds (CGSF4)

The alternate soaking process was used to deposit hydroxyapatite into the scaffolds [7]. First, Thai silk fibroin scaffolds and conjugated gelatin/Thai silk fibroin scaffolds were immersed in 0.2M $CaCl_2$ solutions for 30 min, followed by immersing in 0.12M Na_2HPO_4 solution for another 30 min. This was considered as one cycle of alternate soaking. The alternate soaking was performed for 4 cycles to allow the deposition of hydroxyapatite into the scaffolds. The weight percentage of hydroxyapatite deposited was determined from the weight increased after alternate soaking as followed

$$\%HA = \frac{W_{HA} - W_0}{W_0} \times 100$$

Where W_{HA} and Wo is the weights of dried scaffold after and before alternate soaking, respectively. The reported values were the mean±standard deviation (n=5).

D. Morphological observation

The morphology of scaffolds was investigated by scanning electron microscopy (SEM).

E. Mechanical test

The compression tests were performed using a universal testing machine (Instron 5567) at the constant compression rate of 0.5 mm/min. The compressive modulus reported was the mean±standard deviation (n=5).

F. In vitro cell culture

The scaffolds were placed into 24-well tissue culture plates and were sterilized using ethylene oxide. After sterilization, the scaffolds were immersed in phosphate buffered saline (PBS) for 24 h. Rat bone-marrow derived mesenchymal stem cells (MSCs) were seeded at a density of 2×10^4 cells per scaffold onto each scaffold placed in medium (α-MEM containing 10% FBS and 50 U/ml penicillin streptomycin) and incubated at 37°C in air containing 5% CO_2. After cultured for 6 h, 1, 3, 7 and 14 days, the number of cells were determined by DNA assay. The samples were washed with PBS and lysed in SDS lysis buffer at 37°C in air containing 5% CO_2 for 24 h. Hoechst 33258 dye was added into the cell lysate and the fluorescent intensity of the solution was measured in a fluorescence spectrometer at the excitation and emission wavelengths of 355 and 460 nm, respectively [8]. All data were expressed as mean±standard deviation (n = 3).

III. Results and Discussion

A. Morphological observation

Fig. 1 showed the cross sectional morphology of Thai silk fibroin-based scaffolds. Porous structure with smooth surface of SF scaffolds was noticed as illustrated in Fig. 1(a). The pore size of scaffold structure corresponded to the size of salt crystals used. Gelatin conjugation could form fibers inside the porous structure of fibroin scaffolds (Fig.

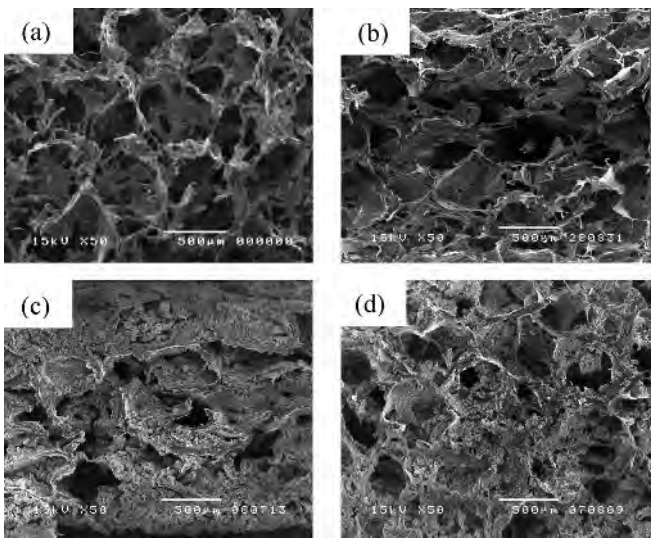

Fig. 1 SEM micrographs of (a) silk fibroin scaffolds, (b) conjugated gelatin/silk fibroin scaffolds, (c) hydroxyapatite/Thai silk fibroin scaffolds and (d) hydroxyapatite-conjugated gelatin/Thai silk fibroin scaffolds.

Table 1 The percentage of hydroxyapatite deposited in silk fibroin scaffolds (SF) and conjugated gelatin/silk fibroin scaffolds (CGSF).

Scaffolds	%HA
SF	130.3±12.8
CGSF	102.5±9.3

1(b)). After alternate soaking, hydroxyapatite/Thai silk fibroin scaffolds (SF4) and hydroxyapatite-conjugated gelatin/Thai silk fibroin scaffolds (CGSF4) exhibited the deposition of hydroxyapatite inside the pore of the scaffolds as shown in Fig. 1(c) and (d), respectively. The deposition of hydroxyapatite in SF was greater than in CGSF as shown in Table 1. This could be a result from a difference in the morphology. Gelatin conjugation caused less pore volume of scaffolds which could limited the deposition of hydroxyapatite into the scaffolds.

B. Mechanical Property

The compressive modulus of SF, CGSF, SF4 and CGSF4 shown in Figure 2 indicated that the compressive modulus of CGSF was higher than that of SF. This could be a result from the conjugation reaction by dehydrothermal and EDC treatments. Dehydrothermal brings about chemical bonding between the amino and carboxyl groups within molecules of polypeptide. Further treatment with EDC, the primary amines on the peptides formed a stable amide bond between the peptide of gelatin and silk fibroin [9]. After hydroxyapatite deposition, compressive modulus of SF increased by 52.3% while that of CGSF increased by 19.4%. The results indicated that gelatin conjugation and hydroxyapatite deposition enhanced the compressive modulus of Thai silk fibroin scaffolds.

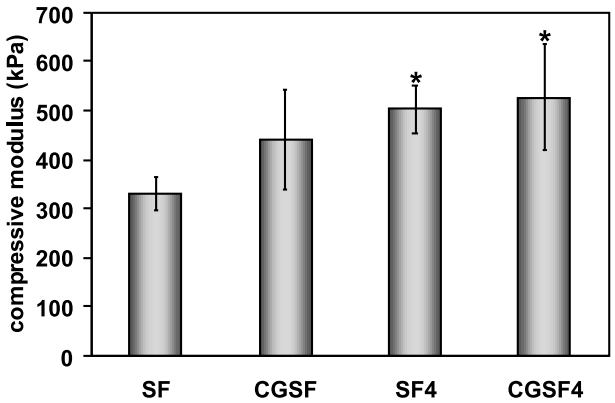

Fig. 2 Compressive modulus of silk fibroin scaffolds (SF), conjugated gelatin/silk fibroin scaffolds (CGSF), hydroxyapatite/Thai silk fibroin scaffolds (SF4) and hydroxyapatite-conjugated gelatin/Thai silk fibroin scaffolds (CGSF4).
* represent the significant difference ($p<0.05$) relative to silk fibroin scaffolds.

C. In vitro cell proliferation tests

Fig. 3 presented the number of MSCs determined by DNA assay after 6 h, 1, 3, 7, and 14 days of the culture. It could be noticed that there were no significant differences between the cell adhered on SF, CGSF, SF4 and CGSF4 after 6 h of seeding. After 1 day of seeding, CGSF showed the highest number of MSCs. At longer culture time, the number of proliferated cells on CGSF continuously increased, compare to other scaffolds. The number of cells on SF, CGSF, SF4 and CGSF4 after 14 days of cell seeding was about 3.4, 4.2, 3.2 and 3.5 folds of those after 6 h of seeding. This could be the result of arginine-glycine-aspartic (RGD) sequence contained that in gelatin that was reported to promote cell adhesion and migration [10]. SF4 and CGSF4 tended to have a slightly fewer proliferated MSCs compared to SF and CGSF, respectively. This might be attributed to the different morphology of scaffolds. Hydroxyapatite deposited on the surface of scaffolds might obstruct the cell migration into the scaffolds.

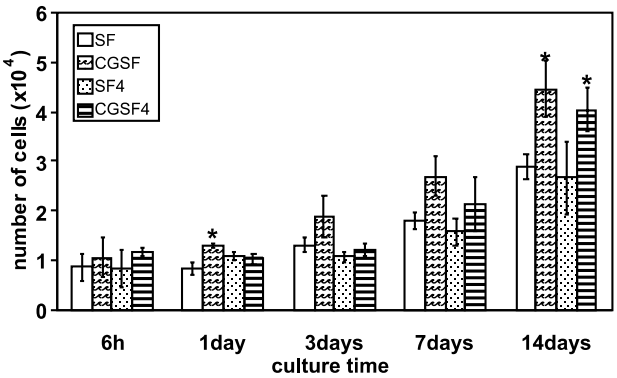

Fig. 3 Number of MSCs on silk fibroin scaffolds (SF), conjugated gelatin/silk fibroin scaffolds (CGSF), hydroxyapatite/Thai silk fibroin scaffolds (SF4) and hydroxyapatite-conjugated gelatin/Thai silk fibroin scaffolds (CGSF4) after 6 hours, 1, 3, 7 and 14 days of the culture.
* represent the significant difference ($p<0.05$) relative to silk fibroin scaffolds at each culture time.

IV. Conclusions

Gelatin conjugation and hydroxyapatite deposition influenced on the morphology and compressive modulus of salt-leached Thai silk fibroin scaffolds. The morphology of the scaffolds was more fibrous after gelatin conjugation. Hydroxyapatite deposition on both silk fibroin scaffolds, with and without gelatin conjugation, resulted in less pore volume. *In vitro* study revealed that the conjugated gelatin/Thai

silk fibroin and hydroxyapatite-conjugated gelatin/Thai silk fibroin scaffolds supported the proliferation of bone-marrow derived mesenchymal stem cell. The results on the physical, mechanical and biological properties of hydroxyapatite-conjugated gelatin/Thai silk fibroin scaffolds implied that the scaffolds had a potential to be applied in tissue engineering.

Abstract — **There is a pressing need for bone graft substitutes to augment bone regeneration in patients with damaged or diseased bone tissues. Currently, autologous bone graft is the gold standard but its use is limited by supply and donor site morbidity. Consequently, tissue engineering is seen as a solution to the shortage of functional bone graft substitutes. In the scaffold-guided approach to bone tissue engineering, it requires the development of a three-dimensional scaffold to mimic the native 3D environment of the bone cells. In addition, the scaffold material would need to be biocompatible, biodegradable, and possess the appropriate mechanical properties similar to that of the native tissue.**

In this study, silk and chitosan were combined to produce a blended scaffold using the lyophilization technique. The resulting scaffolds were seeded with bone marrow derived mesenchymal stem cells and subjected to osteogenic stimulation. Results were shown to support cell growth and proliferation, eventually resulting in a mineralized extracellular matrix. It is hoped that the resulting scaffold would become a highly functional bone graft substitute and further optimization work will be done to achieve this goal.

Keywords — **Silk, Chitosan, Bone marrow derived mesenchymal stem cells, Freeze drying, Bone Tissue Engineering**

I. Introduction

There is a great need for bone graft substitutes in the repair and replacement of damaged or diseased bone tissues. Currently, autologous bone grafts remain as the current gold standard as it possess osteogenic, osteoconductive and osteoinductive properties, without the undesirable immune rejection experienced when allogenic bone grafts are used. However, autografts are associated with donor site morbidity and a limited supply. Tissue engineered bone could provide an answer to the shortage of bone grafts.

Tissue engineering is the use of a combination of cells, engineering and materials methods and suitable biochemical and physico-chemical factors to improve or replace biological function [1]. More specifically, suitable materials favorable for survival and normal function of relevant cells are used to fabricate scaffolds. These scaffolds then serve as templates for tissue construction, mechanical support for the cells and a source of multi-factorial cues necessary for cellular functions. Eventually, the scaffold materials will degrade and be replaced by extracellular matrix. With the critical choice of cells and materials, tissue engineering provides the prospects of an autogenic, osteogenic, osteoconductive and osteoinductive bone graft.

In this study, silk and chitosan are the materials chosen to fabricate scaffolds for bone tissue engineering. Desirable characteristics of scaffolds include biocompatibility, adequate pore size, high porosity, interconnected architecture, appropriate mechanical strength and biodegradability [2, 3]. Silk has long been used in biomedical applications as suture materials. It is a viable material because of its permeability to oxygen and water, cell adhesion and growth characteristics, relatively low thrombogenicity, low inflammatory response, protease susceptibility, and high tensile strength [4, 5]. Furthermore, silk can be subjected to aqueous or organic solvent processing and can be chemically modified to cater for a wide range of applications. Recent bone tissue engineering studies performed using silk scaffolds resulted in extensive mineralization, alkaline phosphatase activity (an early marker for osteoblast differentiation) and cortical mineralized network [6, 7]. This indicates that silk is indeed a favorable material for use in bone tissue engineering.

On the other hand, chitosan is a partially deacetylated product of chitin, a crystalline polysaccharide found in crustaceans and insects, which is structurally similar to glycosaminoglycans (GAG) [8]. Chitosan can be fabricated to form porous, interconnected structures and the cationic nature of chitosan allows for pH dependent electrostatic interactions with anionic GAG and proteoglycans [9]. Other desirable characteristics of chitosan include wound healing properties, non-toxicity, and minimal foreign body response with accelerated angiogenesis [9]. Like silk, chitosan also has biomedical applications as wound dressings and drug delivery systems.

There are already several studies investigating the characteristics of silk-chitosan blend hybrid material [10, 11]. A recent study by She *et al* investigated the HepG2 cell culture behavior of the silk-chitosan scaffolds [11]. The aim of this study is to develop a silk-chitosan scaffold cultured with bone marrow derived mesenchymal stem cells (BMSCs). The investigators seek to determine the morphology and structure of the blended scaffold, and to study the response of the BMSCs-loaded scaffolds under osteogenic stimulation.

II. Materials and methods

A. Silk fibroin and Chitosan Dissolution

Bombyx mori silk fibers (local name: "Nang Lai" silk fibers) were used in this study. Raw silk fibers were immersed in a degumming solution of 0.25% (w/v) Na_2CO_3 and 0.25% (w/v) sodium dodecyl sulfate (SDS) between 98°C and 100°C for 30 minutes. After 30 minutes, the solution was refreshed. This process was repeated until most of the sericin has been removed. The degummed silk was then rinsed with distilled water for 1 hour to remove the residual degumming solution before leaving them to air dry. The degummed silk was then dissolved in $CaCl_2$–C H_3CH_2OH–H_2O (molar ratio = 1:2:8) at 65°C with continuous stirring. The resulting silk solution was dialyzed against distilled water using a SnakeSkin Pleated Dialysis Tubing (PIERCE, MWCO 3500). The concentration (w/v) of the dialyzed solution was determined and adjusted to 3% w/v by using distilled water to dilute or by concentrating the solution at 60°C.

Chitosan solution was prepared by dissolving chitosan from crab shells (minimum 85% deacetylation: Sigma-Aldrich) at 3% (w/v) in 2% acetic acid. Chitosan powder was added slowly with continuous stirring to obtain a viscous solution.

B. Silk-Chitosan Blend Scaffold Fabrication

An equal volume of the same concentration of silk was added to prepare a 50:50 blend and allowed to mix for 15 minutes. The blended solution was then poured into polypropylene molds (diameter, 17 mm; height, 15 mm), frozen in a -80°C freezer for 1 hour, followed by lyophilization for 18 hours. The dried sponges were removed from the molds and treated in a 50:50 (v/v) methanol: sodium hydroxide (1N) solution for 30 minutes, to induce an amorphous to silk II conformational change in the silk-chitosan sponges to prevent resolubilization in the cell culture medium. The NaOH was removed by soaking the sponges in phosphate buffered solution (1x PBS) with solution changes every hour until the pH had equilibrated to 7.4. The sponges were freeze-dried for another 18 hours to remove the water before finally cutting them into individual scaffolds (diameter, 17 mm; height, 3 mm). Prior to seeding, the scaffolds had to be sterilized in 70% ethanol, followed by washing in PBS.

C. Determination of the Optimal Concentration of Silk-Chitosan Scaffold

For vascularization purposes, the pore size range of the scaffolds should be about 300μm or slightly larger for angiogenesis. Yet, the mechanical properties of the scaffold should be adequate for bone tissue engineering. Various concentrations (2%, 2.5%, 3% and 3.5%) of the silk-chitosan blends were fabricated to determine the optimal pore size and mechanical properties.

D. Scaffold Characterization

For characterization, the dried scaffolds were coated with gold using a Sputter Coater (JEOL, JFC 1600). The morphology was observed by a scanning electron microscope (Quanta FEG 200) operated at a voltage of 10 kV. Sagittal and transverse views of the scaffolds were obtained by cryosectioning and observed using light microscopy.

E. Isolation of Rabbit BMSCs

Rabbit BMSCs were obtained from whole bone marrow aspirates from New Zealand white rabbits and culture expanded according to procedures previously described [12]. Rabbit MSCs were isolated from fresh whole bone marrow aspirates from New Zealand White Rabbits (8 weeks old), culture expanded in low glucose culture medium containing Dulbecco's modified Eagle's medium (LG-DMEM; Gibco, Invitrogen, CA), 15% v/v fetal bovine serum (HyClone, Logan, UT), penicillin and streptomycin. Nonadherent cells were removed upon first passage of the cells. When primary MSCs became near confluent, they were detached using trypsin (0.25%) /1mM ethylenediamine-tetraacetic acid (EDTA) and replated at a 1:3 ratio. The second passage cells were then used for further study. All cell cultures were maintained at 37oC in an incubator with 5% humidified CO_2. The cultures were replenished with fresh medium at 37°C every 3 days.

F. Cell seeding and Culture

BMSCs were pre-cultured in a T175 flask with osteogenic medium (DMEM supplemented with 50μg/ml ascorbic acid-2-phosphate, 10nM dexamethasone and 10mM β-glycerolphosphate). The cells were harvested upon reaching 80% confluence and seeded onto the scaffolds with a density of $2x10^6$ cells / scaffold. Two methods were used, static and perfusion seeding. Static seeding is via pipetting 100μL of the cell suspension dropwise onto the scaffold. Perfusion seeding is achieved using a setup which pumps the cell suspension from the medium reservoir into the scaffolds, which are loaded in a bioreactor. The seeded scaffolds are then cultured in-vitro on non-treated 6-well plates in a 5% CO_2 incubator at 37°C. Culture period was 2 weeks and medium was changed every 3 days.

G. Proliferation and Differentiation Assays

The viability of the cells present within the scaffold was determined using the Alamar Blue (Invitrogen, CA) colorimetric assay. Briefly, the cells were incubated in medium supplemented with 10% (v/v) Alamar Blue dye for 3 hours. Two hundred microliters of medium from each sample was read at 570/600nm in a microplate reader (Tecan). Medium supplemented with 10% Alamar Blue dye was used as a negative control and the percentage of Alamar Blue reduction was calculated according to the formula provided by the vendor.

H. Histological Analysis

Samples were fixed in 4% formaldehyde, dehydrated and embedded in paraffin, and 10µm sections were cut. To identify mineralization, Von Kossa staining was done.

III. Results and Discussion

A. Morphology of the scaffold

To restate, the pore size range of the scaffolds was chosen to be about 300µm for vascularization purposes. It was observed that the scaffolds fabricated using 2% and 2.5% were not mechanically strong and the scaffold architecture was disrupted when the sponge was cut into the desired dimensions. The mean pore size of the fabricated scaffolds using 3% and 3.5% blends were 311µm and 282µm respectively. Hence, a 3% silk-chitosan blend was chosen because a pore size range of 300-400µm has been suggested to be the optimal pore size for attachment, differentiation and growth of osteoblasts and vascularization [13, 14].

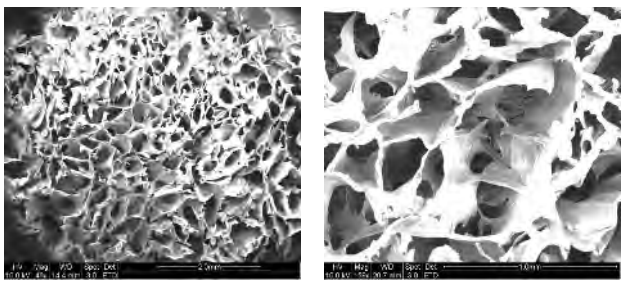

Figure 1: SEM images of silk-chitosan scaffolds (45X and 158X)

Figure 1 shows that the overall pore architecture was rather homogenous. Heterogeneous scaffold architectures could lead to variable cell adhesion and influence the ability of the cell to produce a uniform distribution of extracellular matrix proteins [15]. Therefore, it is important that the freeze-drying process is fine-tuned to produce scaffolds with homogenous pore architecture.

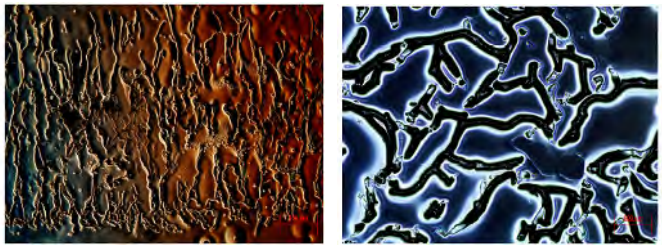

Figure 2: (A) Sagittal and (B) Transverse sections of the scaffold

The scaffolds were section vertically to reveal the sagittal cross sections of the scaffolds. This was done using the cryostat. From Figure 2(A), the width of the channels of similar dimensions suggests similar pore sizes with depth. The presence of pore interconnectivity was investigated by taking horizontal cross sections to reveal the transverse cross sections of the scaffolds. The light microscopic image of Figure 2(B) shows that each pore opens up to another, suggesting highly interconnected pores in the 3% silk-chitosan scaffolds.

B. BMSC-Scaffold Construct in Static Culture

From Figure 3, it can be seen that the cells were still capable of proliferating after seeding onto the scaffolds. Although samples that underwent static seeding cannot be compared to those that underwent perfusion seeding (due to different basal metabolic activities as a result of different culture treatments), it was interesting to note that the percentage reduction actually dipped in the later phase of the culture. This trend was observed in several repeats of the experiment. This suggested that static seeding might have caused cells to be localized at or near the surface of the scaffolds. Over time, the competition for nutrients and the accumulation for metabolites might have limited the proliferation capacity of the cell population. Nevertheless, the findings showed that BMSCs were still able to proliferate after seeding onto the silk-chitosan scaffolds.

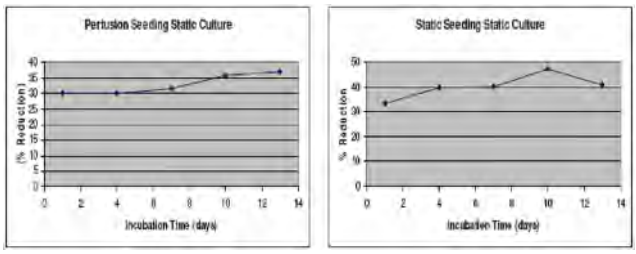

Figure 3: Proliferation studies after perfusion and static seeding

C. Deposition of bone minerals

Von Kossa technique stains calcium minerals black. Hence differentiation potential can be qualitatively determined from light microscopic images of the stained sections because the ability to deposit minerals is the marker for mature osteoblasts.

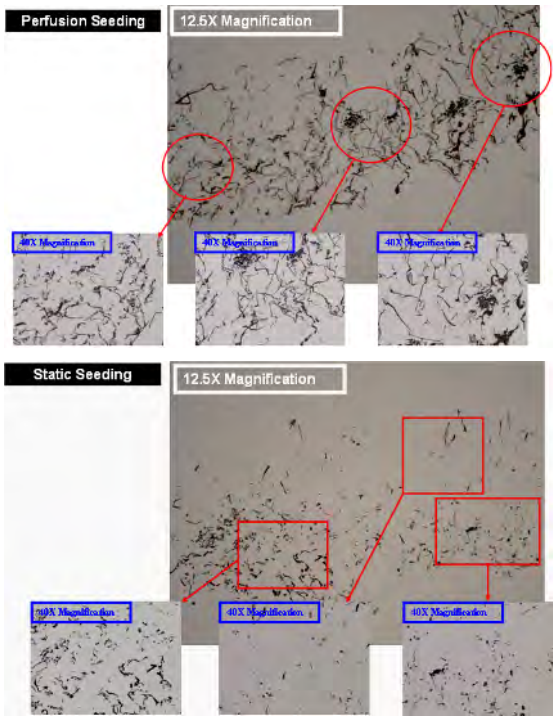

Figure 4: Von Kossa sections, showing signs of mineralization

From Figure 4, it can be seen that the BMSCs that were seeded into the silk-chitosan scaffolds remain differentiated and went into the mineralization phase to deposit mineralized extracellular matrix, which was detected in this procedure.

IV. Conclusion

This study demonstrated the potential of silk-chitosan scaffolds for bone tissue engineering application. Coupled with BMSCs, which is a good source of autologous osteogenic cells, this scaffold may be able to provide highly functional substitutes of native tissues. Future studies on gene expression of bone markers will be carried out to determine the expression level of bone markers such as alkaline phosphatase, osteocalcin and osteopontin. More work also needs to be done to better quantify the DNA and calcium content within the cell-scaffold constructs.

Effects Of Plasma Treatment On Wounds

R.S. Tipa, E. Stoffels

Department of Biomedical Engineering, Eindhoven University of Technology, PO Box 513, 5600 MB, Eindhoven, The Netherlands

Abstract — **Cold plasma treatment of wounds is gaining much interest, because it will offer a non-contact, painless and harmless therapy to manage large-area lesions (burn wounds, chronic ulcerations). One of the important issues in plasma wound healing is the safety of the method. In this work we study in vitro the effects of plasma treatment on cell death, proliferation and wound healing. Many methods have been developed to study the cell viability and proliferation, but one of the most appreciated ones is the MTT Assay. There are many advantages of using this method such as: the method is safe, fast and convenient, and allows simultaneous analysis of many samples (e.g. cell samples prepared in 96 well plates). Viable cells transform the added MTT tetrazolium salt into purple formazan, which is detected by colorimetric methods. The amonut of viable cells is proportional to the amount of formazan. We performed a parametric study of plasma-treated 3T3 fibroblast cells. For the treatment, a cold atmospheric plasma needle (13.56 MHz micro-jet in helium) was used. The influence of plasma on cell viability was measured using the MTT assay. We observed the long-term effects of plasma on cell viability, dependent on the dosage of plasma treatment. Under high doses cell suffered damage that led to decreased viability. Cell death by apoptosis and necrosis was considered.**

Keywords — **MTT assay, spectrophotometry, cell proliferation**

I. Introduction

Cold plasma treatment of wounds is gaining much interest, because it will offer a non-invasive method (the plasma needle operates without incision in the skin), painless and harmless therapy to manage large-area lesions (burn wounds, chronic ulcerations), shorter time for wound healing and also disinfection of the wound.. One of the important issues in plasma wound healing is the safety of the method. In this work we study *in vitro* the effects of plasma treatment on cell death and proliferation and also the model of the wound.

When the skin is damaged, in the body there are chemical and biological processes that are helping the skin to repair the area that has been exposed to a traumatism. The process of wound repair is starting with the inflammatory phase (remove of bacteria) and continues with the releasing factors for helping the proliferative phase (angiogenesis, collagen deposition, epithelialization, wound contraction), maturation and remodeling phase [1]. The current research tries to get more deep in the effects of plasma to the cells, focusing on the healing time for the wound after plasma treatment.

II. Experimental set – up

A. The plasma needle

For our experiments we used a small-size cold atmospheric plasma source, having the frequency of 13.56 MHz. The gas used is Helium, as a matrix, because is inert (non-toxic), has a low breakdown voltage and high heat conductivity. The voltage of the system is 200-400 V p.p, and the power consumption is bellow 100 mW [2]. Compared with other types of plasmas, the plasma needle has also the advantage of working at the room temperature (non-destructive), and also allow the treatment without overheating the cells which will lead them to die. After some other fundamental studies will be done, our main goal is to have the plasma needle working on same parameters for in vivo experiments, where are expected promising results. In Figure 1 is presented the plasma needle with the glow that appears at the tip of the needle when plasma is working.

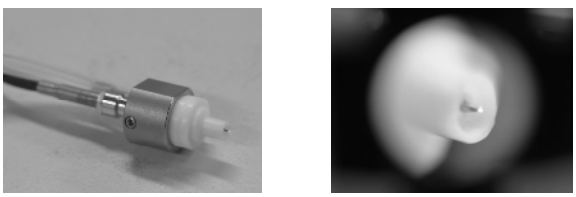

Figure 1 Appearance of the plasma glow – the way plasma appears at the tip of the needle before treatment of the samples

For being able to create cold atmospheric plasma the 13.56 MHz voltage is applied to a sharp metal needle so the plasma is being created at the tip of the needle. The diameter of the needle is about 0.3 mm and is inserted in a Teflon tube with the inner diameter of 0.4 cm. The helium bottle is connected to Brooks series 5850E so the flow can be setted to 1 l/min. The diagram of the experimental set-up is shown in Figure 2.

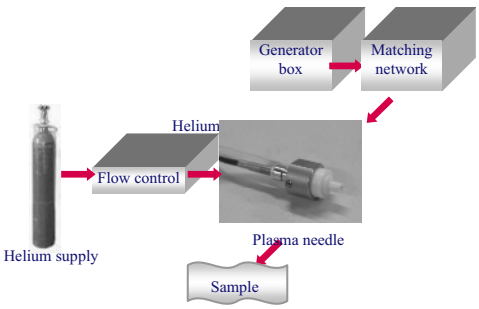
www.springerlink.com



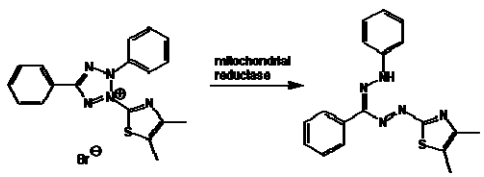


Figure 2 The diagram of the experimental set-up for the plasma needle; we can see the plasma needle confined in a Teflon tube, the connection with the matching box, the Helium supply

B. MTT Assay

Many methods have been developed to study the cell viability and proliferation, but one of the most appreciated ones is the MTT Assay. There are many advantages of using this method such as: the method is safe, fast and convenient, and allows simultaneous analysis of many samples (e.g. cell samples prepared in 96 well plates). Viable cells transform the added MTT tetrazolium salt into purple formazan, which is detected by colorimetric methods. The amount of viable cells is proportional to the amount of formazan.

We performed a parametric study of plasma-treated 3T3 fibroblast cells. For the treatment, a cold atmospheric plasma needle (13.56 MHz micro-jet in helium) was used. The influence of plasma on cell viability was measured using the MTT assay. We observed the long-term effects of plasma on cell viability, dependent on the dosage of plasma treatment. Under high doses cell suffered damage that led to decreased viability. The component for the assay is (3- [4,5-dimethylthiazol-2-yl]-2,5-diphenyl tetrazolium bromide) or MTT. For being able to use the MTT assay, the cultured cells were washed two times with PBS, then added the MTT solution and incubated between 2-4 hours, period in which the purple formazan crystals are formed. After incubation is added isopropanol (to solubilize the crystals) and in the end the absorbance was readed, using the plate reader.

III. Plasma Treatment of the Wounds. Results and Discussions.

A. Cell treatment

The aim of the experiment is to see in time the effects of plasma to the cells in the model of the wound. One of the most important to think of are that we are interested in getting a faster healing of the damaged area, avoiding the side effects like overheating the cell membrane which will lead the cytoplasm out of the cell and causing in the end necrosis. For the experiment, we used 3T3 cells. Those cells lines are the most common fibroblast cultures in the laboratory and were established from disaggregated tissue of an albino Swiss mouse (Mus musculus) embryo. The shape of the cells can be seen in the Figure 3.

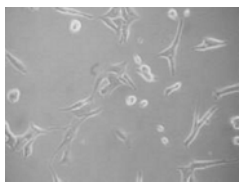

Figure 3 3T3 cells after a few hours of incubation

The 3T3 line was established by George Todaro and Howard Green in 1960. For our experiment, the 3T3 cells were cultured in T75 flasks for 2-3 days and then transferred into 6 well plates. The medium for growing the 3T3 cells contain Dulbecco's modified Eagle's medium with 4.5 g/L glucose (100%), L-glutamine (1%), FBS (10%), Penicillin / Streptomycin (1%). Before culturing the cells in the well plate, they were counted and then the medium was added. In within 3 days, the tissue tends to fill the whole surface, but the best results are when we have 80% confluent cells. In the case of 100% confluence, the growing of the cells is reduced and also can appear the die of the cells. After the tripsinization process, when the cells are round, in time they change the shape and try to adhere of the surface they are cultured on. The fibroblast locomotion is due both lamellipodia and filopodia (lamellipodia is a cytoskeletal actin projection on the mobile edge of the cell. It contains a two-dimensional actin mesh; the whole structure pulls the cell across a substrate (Alberts, et al, 2002). Within the lamellipodia are ribs of actin called microspikes, which, when they spread beyond the lamellipodium frontier, are called filopodia (Small, et all, 2002). The lamellipodium is born of actin nucleation in the plasma membrane of the cell (Alberts, et al, 2002) and is the primary area of actin incur poration or microfilament formation of the cell.)[3]. The cells are ready for treatment when most of them had an

elongated shape and are adherent of the area they are cultured on.

For plasma treatment we used the setup from Figure 4. The plasma power is in the range of 50-250 mW, the voltage 200-400 V p.p and the range of time used for plasma treatment to the cells between 10 - 30 s (the optimal time of treatment, when we got the best results were between 10 – 15 s). in the case of applying a higher voltage or long time treatment, one can see necrosis of the cells. The necrotic cells detached of the surface and are floating like some clouds at the surface of the liquid. This result is due to the fact that the membrane brake and the internal structure is leaking.

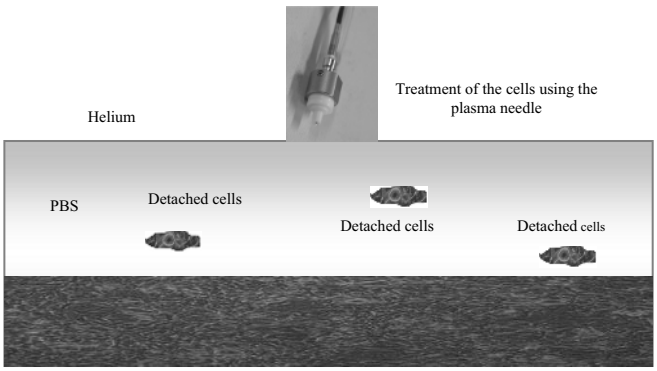

Figure 4. Treatment of the cells using the plasma needle

The graph from Figure 5 is showing cell growing after 24 hours of incubation for plasma treated samples and untreated samples. We can see that the plasma treated samples has a higher rate of growing compared with the untreated samples The method used for analysis is the MTT Assay.

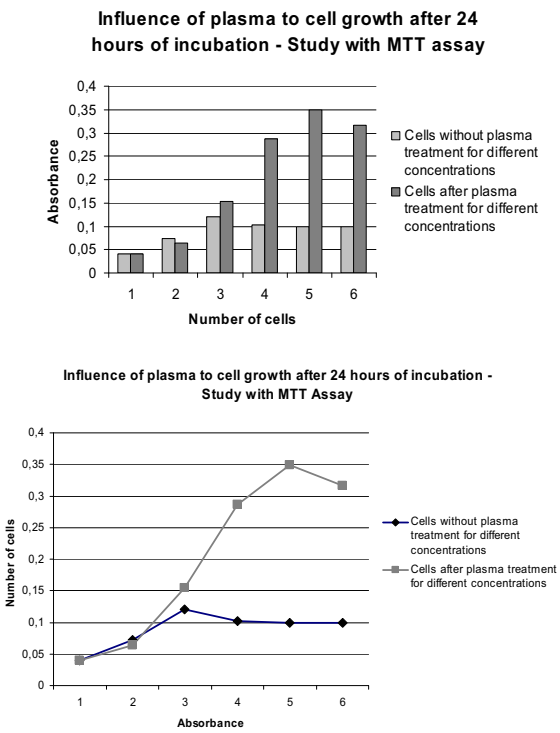

Figure 5. Influence of plasma to the cell growth after 24 hours of incubation

B. Model of wound

In order to create the model of the wound, we used the 3T3 fibroblast cell line. To prepare the samples for the experiment, cells were trypsinized for 5 minutes, then added 10 ml culture medium containing contain Dulbecco's modified Eagle's medium with 4.5 g/L glucose (100%), L-glutamine (1%), FBS (10%), Penicillin / Streptomycin (1%). Then the cells were centrifuged for 5 minutes, the medium was extracted and then to the palette of cells added 1 ml medium. After that cells were counted and recultured in 6 well plates for 2 days in an incubator containing 5% CO_2, at 37ºC. When the cells become 80% confluent they were rinsed 2 times with PBS and inside every plate made scratch using a cell scrapper. In the end, the scratched area was treated using the plasma needle. The treatment time varied between 5 – 30 sec. We could see that the best treatment time operates in the range of 5 – 15 sec. After plasma treatment, the cells were again incubated using the same conditions as described above and the results of the treatment were checked every day. The results of analysis are shown in Figure 6.

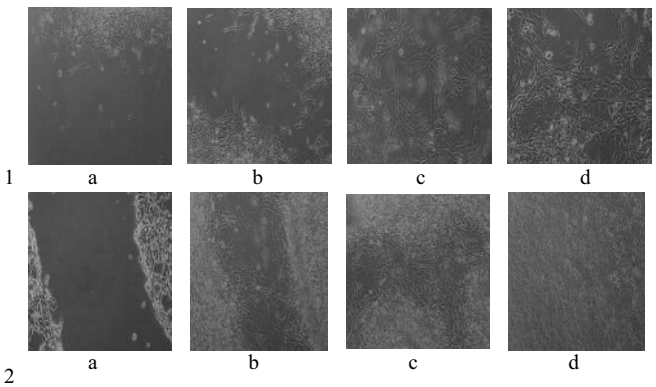

Figure 6. The model of the wound for untreated samples (1) and treated samples (2) – measurements after 0 hours of incubation (a), 24 hours of incubation (b), 48 hours of incubation (c) and 72 hours of incubation (d).

The period for data analysis was between 0 hours (immediately after treatment) and 3 days of incubation. The period of 3 days was chosen because the cells become 100% confluent and the cells are starting to detach and die. From data analysis we can see that for the plasma treatment in case of a wound is more efficient, the complete healing process is faster due to the plasma. In the case of untreated samples, the complete healing process takes longer, about 5 days.

IV. Conclusions

The experiment shows that plasma treatment has a non-destructive effect when we apply plasma treatment for a short time, cells are not dying but growing faster. This is an important feature for our future research regarding the plasma treatment of wounds. How is plasma influencing the healing process? How fast is the healing if we use the plasma treatment? At this question we can answer after doing some additional experiments and we will be able to explain more detailed how this mechanism are working and what is the influence of plasma to the biochemical reactions inside the cells.

During plasma treatment we could see that some of the cells are detaching, but not dying. If we transfer the detached cells to a new plate and adding new medium, after a while cells are starting to attach again.

Abstract — **This article surveys the application of using the electrical field for cell growing. The design of the experimental setup for generating the electrical field will be described and the procedure used for the biological tests that have been made. In the end are shown the results of the tests that confirm the fact that the electrical field has a positive influence on 3T3 cells, helping them to grow faster in time.**

Keywords — **electrical field, fibroblasts, cell growth**

I. Introduction

Many papers have been published relating that cells are affected by an electric field. This method is generally called electroporation which means that the permeability of the membrane increases. Electroporation occurs when a external electric field is applied to a biological cell. Depending on the charging time of the membrane either electroporation occurs at the cell membrane or at the intracellular membrane. The first kind of electroporation is well known and probably the best understood. When electroporation occurs at the cell membrane, protein channels in the cell membrane will open, figure 1, causing a change in ion concentration.

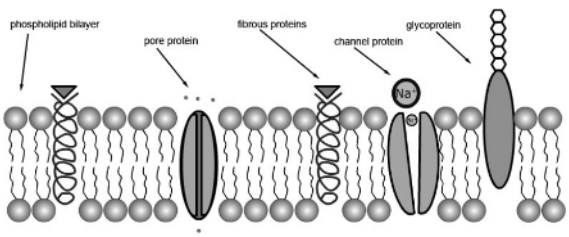

Fig. 1 Cell membrane

This change in ion concentration will cause cell stress. When the electric field is not too high (so that the voltage over the membrane is around the critical threshold of 1 Volt) and of relative short duration the cell will recover itself. Electroporation can be applied for example in gene transport and drug delivery[1][2]. Higher electrical fields, higher voltage across the cell membrane, and of longer duration causes irreversible damage to the cell and eventually cell death. This method is under investigation for applications as cold pasteurization and sterilization[3]. The critical voltage to affect the cell membrane is at least 1V. Since the size of a eukaryote is around 10^{1}m, a externally applied field in the order of 1KV/cm over the cell membrane is needed. A often used electrical model to simulate the voltage across the cell membrane in a conducting fluid is made by Dr. Schoenbach, figure 2. Dr. Schoenbach has done a lot of research in the area of cell treatment with pulsed electric fields [4]. The effects on a cell with an externally applied field can be described by a conductive body (cytoplasm) surrounded by a dielectric layer(membrane). The fluid outside the cell is represented by capacitors(Cs) and resistor(Rs). The membrane and its permeability is represented by capacitors(Cm). Resistor(Rc) represents the cytoplasm (interior) of the cell. The electric parameters for biologic cells are known from literature and it is therefore possible to calculate these electrical equivalent values [5]. The protein channels are modeled as voltage dependable conductance in series with voltage sources.

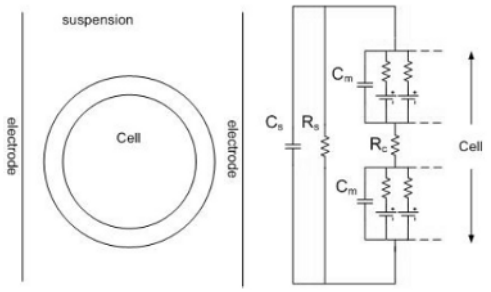

Fig. 2 Equivalent model of the cell

The charging time of the cell membrane is determined by the following formula [1].

$$\tau_m = ((\frac{1+2V}{1-V})\frac{\rho_s}{2} + \rho_c)C_m a$$

$$C_m = \frac{\epsilon_0 \epsilon_r}{d}$$

The required membrane voltage to affect the cells intracellular membrane is found to be of the same order as for the cell membrane and is therefore 1 Volt. The dimensions of the intracellular structures are roughly a factor 10 smaller compared to the cell size so the electric field must be

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1389–1392, 2009
www.springerlink.com

around 10kV/cm. To affect the intracellular membrane the cell membrane must be transparent. This is done by applying a pulse much shorter then the charge time of the cell membrane. Various effects have been observed after applying ultra short pulses to cells such as apoptosis (programmed cell death) and intracellular calcium release (indication for intracellular perturbation) [6][7]. However it is still unclear what exactly happens when these microsecond electric fields are applied.

II. Materials and methods

A. Description

The 3T3 cells were cultured in T75 flask and then transferred to well plates before the experiments. The incubator used for the cells had a constant temperature of 37º C and a 5% concentration of CO2. The medium used for the cell culture was DMEM (Dulbecco's modified Eagle's medium) on which we added 10 % fetal bovine serum (FBS), 1% glutamine and 1% penicillin / streptomycin. After 2-3 days in culture (when the cells reached a 80% confluence) the cells were counted and transferred to Ependorf tubes to be tested.

B. Exposure of the 3T3 cells in the electric field

In order to study the effects of the electrical field on the cells, the tubes containing the cell culture were exposed in the electrical field using the following set up. The electrical field is induced in the single winding coil. For the practical implementation of the RLC circuit, the setup used in the paper 'Multiple-gap spark gap switch' was first considered without the trigger circuit[8]. This would give a good impression about the capabilities of a low self inductance RLC series circuit.

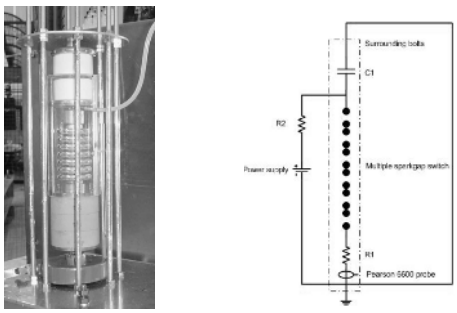

Fig. 3 Multiple spark gap

The article shows that an increasing number of spark gaps (keeping the total gap distance the same) and a coaxial structure give a very short rise time. Instead of the trigger circuit a dc voltage source was connected directly to the capacitor. Picture 12 shows the setup. The single winding coil wasn't placed in the circuit yet since this wouldn't increase the self inductance significantly. From top till bottom two capacitors, with high voltage cable to charge them, followed by the multiple spark gap and resistor can be seen. The Pearson 6600 current probe on the bottom was used to measure the current. Rise times of several tens of nanoseconds and a current of 600 Amps were measured. Although the article claims that an increasing number of spark gaps will decrease the rise time, own measurements showed that no significant difference in rise time were measured between two and six spark gaps (keeping the total distance the same). This is probably because an increasing number of spark gaps increases the height of the setup and will therefore increase the self inductance of the circuit. An increasing self inductance will then cause a longer rise time. Given this information decided was to use a spark gap consisting of two gaps so that the height of the circuit should be as short as possible and that the eight bolts surrounding the circuit would be replaced by a brass tube. In order to keep the height of the setup as short as possible the setup could be pressurized so that the distance between the spark gaps could be kept to a minimum. An air pressure of 8 bar and an voltage source of 50KV were available which means that the total distance between the gaps could be 2mm.

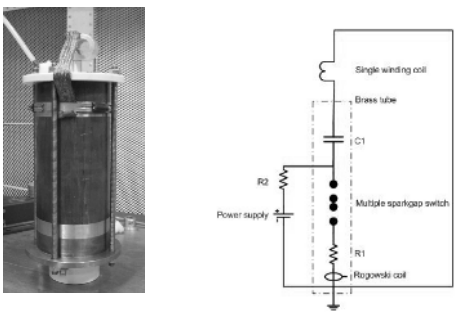

Fig. 4 The new set up

The new setup is practically the same as the former one, except that the tube is sealed with two flanges that keep the pressurized air inside the tube. The top flange had to be made out of an isolator since not only the single winding coil connection but also the high voltage and compressed air outlet had to go through the top flange. The material Ertalyte was chosen as isolator since is has a high breakdown voltage, 22KV/mm.

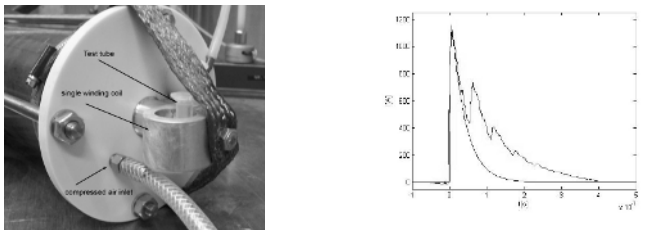

Fig. 5 Test tube in single winding coil and current measured during treatment

III. Results

The pictures taken of the cells treated between 1 and 5 minutes show an increase in cell growth as compared to the control sample.

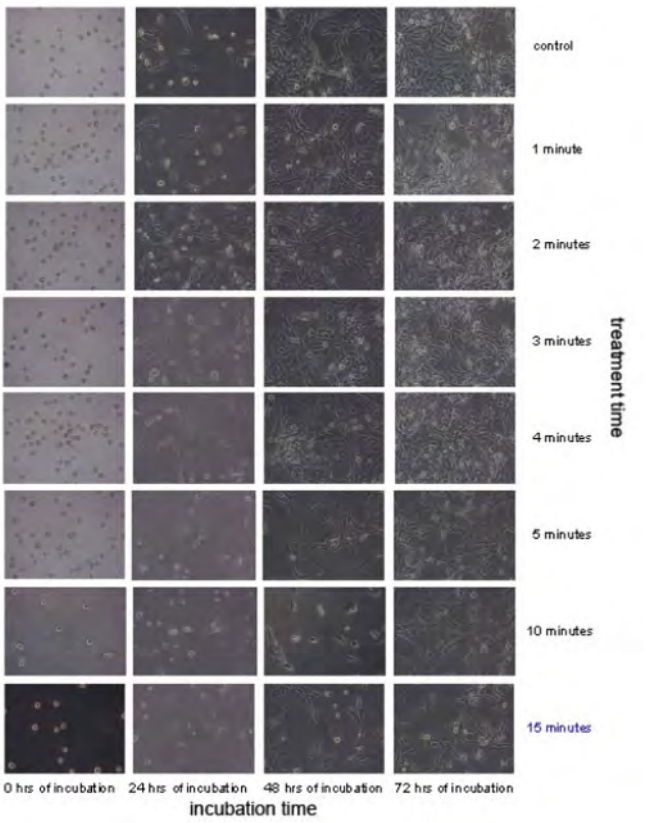

Fig. 6 Pictures of the samples after treatment (incubation time between 0-72 hours of incubation)

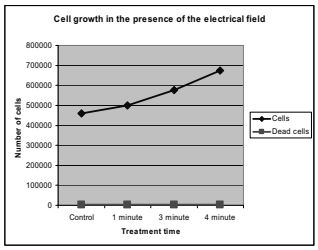
If we take a look to the graph from Figure 7, we can see that even if the treatment is longer, the number of dead cells is the same as for the case of untreated samples.



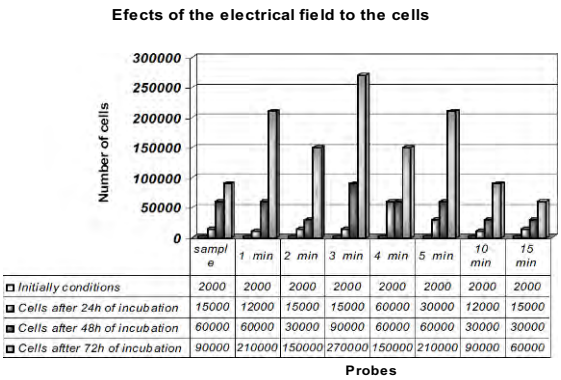


Fig. 7 Effects of the electrical field to the cells

Experiments of cells treated between 10 and 15 minutes show a decrease in cell growth compared to the control sample. Figure 7 shows the number of cells from 4 different pictures taken of the same sample, after a treatment time up to 15 minutes. This figure again shows an increase of the number of cells at a treatment time of 3 and and a decrease of the number of cells at a treatment time of 10 and 15 minutes.

	sample	1 min	2 min	3 min	4 min	5 min	10 min	15 min
Initially conditions	2000	2000	2000	2000	2000	2000	2000	2000
Cells after 24h of incubation	15000	12000	15000	15000	60000	30000	12000	15000
Cells after 48h of incubation	60000	60000	30000	90000	60000	60000	30000	30000
Cells after 72h of incubation	90000	210000	150000	270000	150000	210000	90000	60000

Fig. 8 Cells growth in time (The first 4 columns represent the cell growth for the untreated samples and the next ones the cell growth in time for cells exposed in the electrical field)

IV. Conclusions

The 3T3 cells are clearly affected by the pulsed electric field. Depending on the treatment time a noticeable effect on the cell growth was observed. For treatment times of about 2-5 minutes the cell growth increases as compared to the control samples. For longer treatment times(10-15 minutes) the cell growth significantly reduces, as compared to the control samples. More tests must be done to determine how significant these effects are. The underlying mechanism of these findings is not known, further research is necessary to obtain more insight.

^{99m}Tc(I)-tricarbonyl Labeled Histidine-tagged Annexin V for Apoptosis Imaging

Y.L. Chen[1], C.C. Wu[1], Y.C. Lin[1], Y.H. Pan[1], T.W. Lee[2] and J.M. Lo[1,3]

[1]Department of Biomedical Engineering and Environmental Sciences, National Tsing Hua University, Hsinchu 30013, Taiwan
[2]Institute of Nuclear Energy Research, Longtan 32546, Taiwan
[3]Institute of Nuclear Engineering and Science, National Tsing Hua University, Hsinchu 30013, Taiwan

Abstract — **Annexin V labeled with a γ emitter can be used for the imaging of apoptosis. ^{99m}Tc is very suitable for clinical imaging with its 140-keV γ ray, 6-h half life and economical availability from a ^{99}Mo-^{99m}Tc generator. In this study, we have constructed a form of annexin V with a N-terminal extension containing six histidine residues. The histidine-tagged annexin V (his-annexin V) can be directly labeled with ^{99m}Tc(I) tricarbonyl ion, $[^{99m}Tc(OH_2)_3(CO)_3]^+$.**

In labeling, $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was freshly synthesized and incubated with his-annexin V at 37°C for 1 h. The resultant ^{99m}Tc(I)-his-annexin V was assayed by high performance liquid chromatograph (HPLC) with size exclusion column. The labeled yield was ≥ 87%. ^{99m}Tc(I)-his-annexin V was evidenced to be stable in PBS and serum. From the work, ^{99m}Tc(I)-his-annexin V has been characterized as a potent apoptosis imaging agent.

Keywords — **annexin V, his-annexin V, ^{99m}Tc(I) tricarbonyl ion, ^{99m}Tc(I)-his-annexin V, imaging agent for apoptosis**

I. Introduction

Apoptosis is initiated by externalization of phosphatidylserine (PS) from the inner leaflet of the cell membrane. Annexin-V, a human endogenous protein (35.8 kDa), binds selectively with nanomolar affinity (Kd=0.5-7 nM) to the membrane-bound, externalized PS. A γ-emitting nuclide labeled annexin V is applicable as an agent for imaging apoptosis.

Clinical experience has been taken with the ^{99m}Tc-labeled annexin V complex modified with a hydrazinenicotinamide ligand (^{99m}Tc-HYNIC-annexin V) [1]. However, there is still a need to improve ^{99m}Tc labeling annexin V with high specific activity, radiostability and bioactivity. ^{99m}Tc(I) tricarbonyl ion, $[^{99m}Tc(OH_2)_3(CO)_3]^+$ has recently been explored as a potent precursor for ^{99m}Tc labeling of biomolecules [2]. Histidine is capable of forming complex of very high stability with $[^{99m}Tc(OH_2)_3(CO)_3]^+$ [3]. In this study, annexin V with a N-terminal extension with peptide sequences containing six histidines was constructed for ^{99m}Tc labeling. By the method, the ^{99m}Tc(I) labeled histidine-tagged annexin V (^{99m}Tc(I)-his-annexin V) may most likely retain its membrane binding affinity and protein folding [4]. pETBlue-1-his-annexin V plasmid was constructed and transformed in *E. coli* and the his-annexin V protein expressed was extracted and purified by an affinity chromatography. Efficient labeling of his-annexin V with $[^{99m}Tc(OH_2)_3(CO)_3]^+$ and stability of the radiolabeled product, ^{99m}Tc(I)-his-annexin V in PBS and serum were demonstrated in the work.

II. Methods and meterials

A. Construction and verification of plasmid

1. Polymerase chain reaction (PCR)

A plasmid was constructed to express mutant form of human annexin V in *E. coli* under control of the phage T7 promoter. The forward primer Anx V-*Eco*R V-his-F: 5'-GATATCATGGCCCATCATCATCATCATCACGCTC-3'was designed with a *Eco*R V cutting site and six histidine DNA sequences. The forward primer was designed as previously described [4]. The primer Anx V-*Eco*R I-R : 5'GAATTCTTAGTCTTAGTCATCTTCTCCACAGAGC AGCAG - 3' was designed with a *Eco*R I cutting site. PCR of the template pOTB7 (Invitrogen) which encodes wild-type annexin V, was performed with proofreading *Pfu* DNA polymerase (Invitrogen) and with three steps of amplification as follows : 94°C for 30 sec, 53°C for 45 sec, 68°C for 45 sec each with 30 cycles. The PCR product was subjected to electrophoresis in 2% agarose gel and purified by gel extraction kit (Qiagen).

2. Digestion with restriction enzyme

The PCR product was ligated into pETBlue-1 vector (Novagen). 4 μL of appropriate 10X restriction enzyme buffer (25mM Tris-Acetate, 100mM potassium acetate, 10mM magnesium acetate, 1mM DTT), 1μL *Eco*R V, 1μL *Eco*R I , 3μg insert DNA or pETBlue-1 plasmid DNA, and sterile water were added to a final volume of 40 μL. The solution mixture was incubated at 37°C for 1 h. The product was cleared up by PCR purification kit (Qiagen).

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1393–1396, 2009
www.springerlink.com

3. Ligation reaction

1 μL 10X T4 DNA ligase buffer (300 mM Tris-HCl , 100 mM $MgCl_2$, 100 mM DTT and 10 mM ATP), 1μL of T4 DNA ligase (Promega), 50 ng of vector DNA and 500 ng of insert DNA were added and adjusted to a total volume of 10 μL by sterile water. The mixture was incubated overnight at room temperature and then kept on ice for transformation.

4. Transformation

One tube of ECOS™ competent cells (Yeastern Biotech Co.,Ltd) frozen at -70°C was taken out and put on ice for liquefaction until 1/3 volume was thawed. 100μL of the competent cells was mixed with 5 μL of the ligation product. The mixture was incubated on ice for 30 min and heat-shocked the cells in a 42°C water bath for 45 sec and incubated on ice for 2 min again. The cells were spread over the surface of the pre-warmed LB agar containing 50 μg/mL carbenicillin, 70 μg/mL X-gel, and 80 mM IPTG. The plate medium was incubated overnight at 37°C. Plasmid DNA was prepared from white carbenicillin-resistant colonies and screened by PCR and restriction mapping for the presence of the desired insert. Finally the positive clones were subjected to Protech Technology Enterprise Co., Ltd. to verify the presence of the desired insert.

B. Expression and purification of the protein

1. Protein expression

pETBlue-1/his-annexin V plasmid was transformed into the *E. coli* strain, Tuner(DE3)pLac I (Novagen). Each clone was grown overnight at 37 °C with shaking in Terrific Broth (Invitrogen) containing carbenicillin (50 μg/mL). The cells were separated from culture medium by centrifugation for 20 min at 6000*g* and washed in ice-cold buffer **1** (50 mM Tris-HCl, 150 mM NaCl, pH8.0). Bacteria were ruptured by sonication in ice-cold buffer **2** (50 mM Tris-HCl, pH 7.2, 10 mM $CaCl_2$), being every 10-sec sonication following every 10-sec pause time in ice bath, with a total sonication time of 20 min. Then the mixture was centrifuged for 40 min at 16000 *g*. The supernatant was discarded, and the annexin V bound to bacterial membranes was released by resuspending the pellet in EDTA buffer (50 mM Tris-HCl, pH7.2, 20mM EDTA). Bacterial membranes were removed by centrifugation for 40 min at 16000*g*; the supernatant containing annexin V was filtered with a 0.45 μm filter and then dialyzed against binding buffer (20 mM Tris-HCl,0.3 M NaCl, and 5 mM imidazole, pH 7.9) at 4 °C.

2. Purification of the protein

A 10 mm diameter plastic column tube was packed with 6 mL of Ni^{2+} sepharose 6 fast flow (GE Healthcare). The Ni^{2+} sepharose column was equilibrated with 50 mL binding buffer (20 mM Tris-HCl, 0.3 M NaCl, and 5 mM imidazole, pH 7.9) and then loaded with the dialysand of his-annexin V. The bound protein was eluted steppedly with 20 mL pH 7.9 buffer (20 mM Tris-HCl, and 0.3 M NaCl) containing increasing concentrations of imidazole (20 mM, 40 mM, 80 mM, 100 mM, 150 mM, 300 mM, and 500 mM, respectively). The eluate containing his-annexin V was collected and dialyzed against 20 mM HEPES, pH 7.4, 100mM NaCl. The dialyzed product was concentrated by Amicon® Ultra-15 Centrifugal Filter Devices using a 10 kDa cutoff membrane and stored at -70°C.

3. SDS-Page and immunoblotting

Samples were taken from the different elutions during purification and subjected to 10% SDS-PAGE gel. The separated protein was stained with Commassie brilliant blue R-250 or electroblotted on nitrocellulose for Western blotting analysis. After being blocked with 5% non-fat milk in PBS, the membrane was washed four times with PBS for 15min and incubated further with a 1:2000 dilution of his-tag monoclonal antibody (Novagen) to his-annexin V for 1 h. The membrane was washed with 0.05% Tween/PBS for 10 min and incubated with a 1:5000 dilution of horseradish peroxidase (HRP)-labeled goat anti-mouce IgG (Novagen). The membrane was washed four times with 0.05% Tween/PBS for 15 min and was visualized by the addition of the G: BOX (SYNGENE) and exposure to for 5–10 min.

C. Radiolabeling of his-annexin V with $[^{99m}Tc(OH_2)_3(CO)_3]^+$

1. ^{99m}Tc(I) Tricarbonyl Ion Labeling His-annexin V

$[^{99m}Tc(OH_2)_3(CO)_3]^+$ was prepared as previously described [5]. Labeling of $[^{99m}Tc(OH_2)_3(CO)_3]^+$ to his-annexin V was carried out by adding 50 μg (50 μL) of his-annexin V to 100 μL (20 mCi) of $[^{99m}Tc(OH_2)_3(CO)_3]^+$ solution, and the solution mixture was heated at 37°C for 1 h. The resultant ^{99m}Tc(I)-his-annexin V product was purified with a Sephadex G-25 packing column, using normal saline as the eluent at a flow rate of 1 mL/min. Non-reacted $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was simultaneously removed from the separation method. The purity of ^{99m}Tc(I)-his-annexin V was checked by high performance liquid chromatography (HPLC) on a size exclusion column(Ultrahydrogel™ 250 7.8×300 mm column) using PBS as the eluent at a flow rate of 0.8 mL/min.

2. Stability Test for ^{99m}Tc(I)-his-annexin V in PBS and Serum

The purified ^{99m}Tc(I)-his-annexin V eluate as described above was diluted 10 times and 0.1 mL of the solution was

incubated with 0.9 mL of PBS or serum at 37°C. The stability of the radiolabeled annexinV in PBS or serum was assayed by radio-HPLC after incubation for 0.5, 1, 2, 4 and 6 h.

III. Results and Discussion

A. Construction of recombinant expression plasmid

The Anx V-*Eco*R V-his-F primer and Anx V-*Eco*R I-R primer were used to amplify a 984 bp fragment (Fig. 1), which contained the entire wild type coding region, six histidine coding region, and endonuclease sites . The fragment was ligated into pETBlue-1 plasmid at *Eco*R V/ *Eco*R I sites to create a recombinant molecule pETBlue-1/his-annexin V (Fig. 2). The result of the sequence analysis of the insert DNA of the positive clone indicates that it contains 984 nucleotides and its amino acid sequences (data not shown).

pETBlue-1/ his-annexin V was transformed into *E. coli* strain Tuner(DE3)pLac I, which supplied sufficient *lac* repressor from the compatible pLacI plasmid and screened in Terrific broth containing carbenicillin (50 μg/mL). The plasmid extracted from positive clone was further investigated by the restriction endonuclease cutting and DNA sequencing.

It was observed that there existed a very intensely staining protein band with an apparent molecular mass of 36 kDa (Fig. 3, lane 1), as indicated by scanning the protein density of the SDS–PAGE gel. The harvested cells were sonicated in ice-cold buffer **2** on ice and centrifuged. SDS–PAGE analysis showed that almost all expressed his-annexin V was precipitated by addition of calcium ion, with little his-annexin V remaining in the supernatant (Fig. 3, lane 2). Soluble rh-his-annexin V was released effectively by resuspending the precipitate in the EDTA buffer (Fig. 3, lane 5). The major proportion of target protein was found in the supernatant, accounting for over 50% of the total soluble cellular protein as estimated by densitometric analyses, while little target protein appeared as inclusion body in the pellet (Fig. 3, lane 4).

A single-step affinity chromatography with Ni^{2+} sepharose column was performed for further purification. His-annexin V was eluted at eluent buffer contaning 40 mM and 80 mM imidazole (Fig. 4, lane 2 and 3). Single protein band exhibiting a molecular mass of 36 kDa was present in SDS–PAGE gel (Fig. 5A, lane 1). The antigenicity of his-annexin V was confirmed by Western blot analysis with a his-tag monoclonal antibody (Fig. 5B, lane 1). The final yield of protein was approximately 39 mg of protein/L of culture with a purity of ~98% as judged by SDS-PAGE.

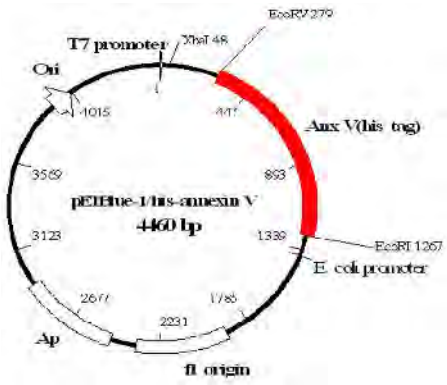

Fig. 2 Schematic representation of pETBlue-1/his-annexin V expression.

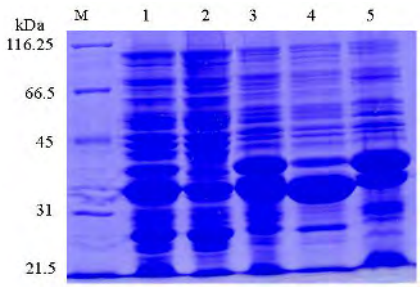

Fig. 3 Expression of cloned his-annexin V. Tuner(DE3)pLac I containing expression vector pETBlue-1/his-annexin V was disrupted by sonication. The soluble and precipitated fractions were separated by centrifugation and applied to 10% SDS-PAGE gel stained with Coomassie blue R-250. Lane M, molecular weight markers; lane 1, total protein of E. coli incubated overnight at 37 °C; lane 2, supernatant of Escherichia coli sonicated in calcium buffer; lane 3., precipitated fraction after being sonicating; lane 4, his-annexin V released from the pellet by EDTA buffer; lane 5, remaining protein in the pellet after being treated with EDTA buffer

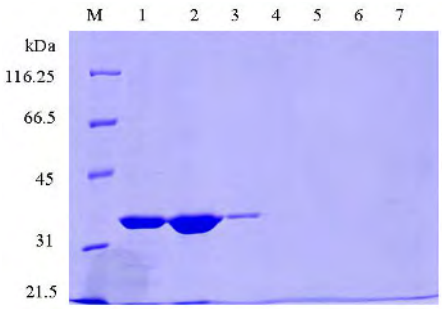

Fig. 4 SDS–PAGE analysis of the purity of rh-his-annexin V during the purification process. Elute the bound protein with various concentration imidazole eluent buffer. Lane M, molecular weight markers; lane 1, 20 mM imidazole; lane 2, 40 mM imidazole; lane 3, 80 mM imidazole; lane 4, 100 mM imidazole; lane 5, 150 mM imidazole; lane 6, 300 mM imidazole; lane 7, 500 mM imidazole.

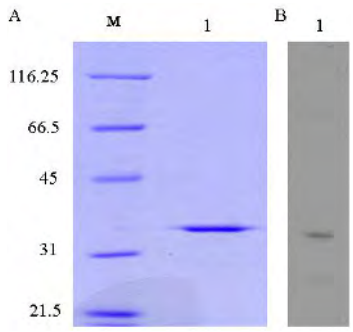

Fig. 5 SDS-PAGE analysis and Western blot analysis of mutant proteins. Recombinant mutant annexin V molecule was analyzed on a 10% gradient gel and stained with Commassie Brilliant Blue. Molecular mass standards (with Mw in parentheses) were *β*-galactosidase (116.25 kDa), albumin (66.2 kDa), ovalbumin (45 kDa), carbonic anhydrase (31 kDa), soybean trypsin inhibitor (21.5 kDa).

B. Labeling his-annexin V with ^{99m}Tc(I)-tricarbonyl ion

The preparation of his-annexin V labeled with $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was assayed by HPLC on a size exclusion column using phosphate buffer saline(PBS) as the eluent. The retention time of ^{99m}Tc(I)-his-annexin V was approximately at 9.1 min as detected by a radio-detector (Fig. 6). The radiolabeled yield of ^{99m}Tc(I)-his-annexin V was estimated to be greater than 87%.

The radiochemical purity of ^{99m}Tc(I)-his-annexin V maintained at greater than 95% when incubated either in PBS or serum at room temperature even for as long as 6 h. The ^{99m}Tc(I)-his-annexin V was evidenced to be stable in PBS and serum.

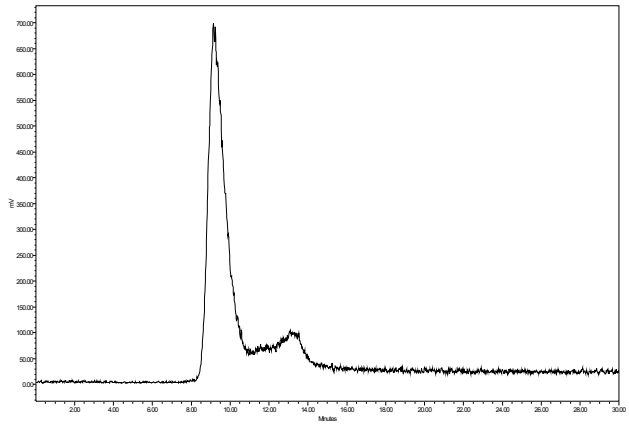

Fig. 6 Size exclusion HPLC of 99mTc(I)-his-annexin V with radio-detection

Abstract — **Tendon is a specific connective tissue composed of parallel collagen fibers. The effect of matrix orientation on tendon differentiation has not been investigated. The recent discovery of tendon stem cells (TSPCs) [1] provided an ideal cell model for tendon biology study. This study focused on investigating the effect of cell orientation, which induced by aligned electrospun poly (L-lactic acid) (PLLA) nanofibers, on human TSPCs differentiation..**

The multipotency and stem cell surface markers of the fetal human TSPCs were identified. The TSPCs were then seeded onto the aligned and randomly oriented PLLA scaffolds. Cell morphology, tendon specific genes expression were evaluated by SEM, and RT-PCR. The degree of extra cellular matrix (ECM) production was evaluated by comparing the amount of collagen on aligned and randomly oriented scaffolds.

TSPCs on the aligned nanofibers were spindle-shaped and oriented in the direction of the nanofibers. The SEM micrograph also revealed the appearance of filament-like structures, which were suspected to be focal adhesions, connected between cells and nanofibers. The expression of tendon specific or bone specific genes was upregulated in the TSPCs growing on random nanofibers, while tendon specific genes but not bone specific genes were upregulated in aligned nanofibers, suggesting that nanofibers structure can influence TSPC differentiation.

In conclusion, cell orientation has effect on hTSPCs differentiation, moreover, the aligned nanostructures of biomaterials provides an instructive microenvironment to modulate and guide TSPCs differentiation ranging from cell orientation to gene expression and could be serve as proper scaffolds for tendon tissue engineering.

Keywords — **TSPCs, differentiation, aligned nanofibers**

I. Introduction

Tendon injuries are common clinical problems due to the poor regeneration ability of tendons. The tendon stem cells (TSPCs), which are derived from human tendon, exhibit universal stem cells characteristics such as clonogenic, self-renewal and multipotency[1]. This cell population resides within an in vivo niche that comprises primarily of ECM. In the same study, it is also showed that human TSPCs formed tendon-like tissue in vivo 8 weeks after transplantation with HA/TCP and Matrigel carriers. Hence, the identification of such cells promises a great potential for tendon repair. However, induction of TSPCs into mature tenocytes has become a major challenge of tendon tissue engineering.

In this study, we attempt to culture TSPCs on aligned nanofibers scaffolds. Nanofibers have been proven a promising biomaterial for bone tissue engineering [2].Moreover, human ligament fibroblasts (HLFs) cultured on aligned nanofibers is showed to have similar morphology to ligament fibroblasts in vivo. They are spindle-shaped and oriented on the fiber direction. The aligned structure also induced an increase in ECM production rate [3]. Based on those researches, we hypothesize that nanofibers alignment induces the differentiation of TSPCs. This study focused on investigating the potential of aligned electrospun poly(L-lactic acid) (PLLA) nanofibers on teno-lineage differentiation of human TSPCs and their performance with randomly oriented PLLA nanofibers is compared as well.

II. Materials and methods

Cell culture: After isolation from human fetal tendon, the TSPCs are cultured in a control medium contains Dulbecco's Modified Eagle Medium (DMEM, low glucose) with 10% fetal bovine serum (FBS) and 1% penicillin-streptomycin (P/S). Media change is performed every 3 days. After 8-10d, the colonies that formed are visualized using methyl violet staining. Monocloning selection is conducted and 6 clones are obtained.

Monocloning selection: hTSPCs passage 2 were used for cloning. After subculture, the cells were counted using a hemacytometer. Then, 1000 cells were plated on a 10cm dish for mono-cloning selection. In addition, two 6 cm dish were with the density of 300 and 1000 cells per dish were also used to assess the colony forming efficiency of hTSPCs. The cells were cultured in DMEM-LG containing 20% FBS and 1% P/S. The medium was changed every 3 days. The individual clones are allowed to develop until they reach several mm in diameter. The locations of clones to be removed are then marked on the lids of the dishes. After 12 days, 4 clones were selected by using pipette and tip to detach cells in the circles marked previously under a microscope. The cultured room was sterilized under UV 30min prior to selection. After that, the clones were trans-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1397–1400, 2009
www.springerlink.com

ferred to four 3.5cm dishes and continue to be cultured in DMEM-LG medium with 10% FBS and 1%

Methyl violet staining: 10 days after cloning, methyl violet staining was performed to visualize the colonies in the 6cm dish that initially contained 1000 cells. First, the medium was discarded and the cells were washed with PBS. After that, methyl violet was added to the dish which was then incubated at room temperature for 10 min. After methyl violet was removed, the cells were washed with PBS again till the clones were visualized. Approximately, there were 50 clones formed.

Fluorescence-activated cell sorting (FACS) analysis: Cells ($5x10^5$) were incubated with 1 μg of PE- or FITC-conjugated mouse specific to human monoclonal antibodies for 1 h at 4 ºC. PE-or FITC-conjugated isotype-matched IgGs (BD Pharmingen) were used as controls. After two washes with PBS containing 1% FBS, the stained cells were subject to FACS analysis (Coulter Epics XL). The percentage of the cell population in each quadrant was calculated. All antibody conjugates were purchased from Pharmingen/BD Biosciences unless specifically mentioned, which include FITC-conjugated mouse specific antibodies to human CD18 (clone 6.7, IgG1, κ), CD34 (581, IgG1, κ),CD90 (5E10, IgG1, κ), and PE-conjugated mouse specific antibodies to human CD44 (515, IgG1, κ). For non-conjugated mouse specific antibody to human CD105, they were incubated with 1 × 106 cells for 1 h 4ºC. After washing, the cells were incubated with rabbit anti-mouse IgG-FITC conjugated for 45 min on ice. After washing, the samples were analyzed using a Coulter Epics XL flow cytometer**.**

Multipotent differentiation: We studied the *in vitro* multidifferentiation potential of the hTSPCs toward osteogenesis, adipogenesis and chondrogenesis as described previously[4][5][6].

von Kossa staining: The cells are rinsed on 100-mm^2 plates with phosphate-buffered saline and fixed in 4% paraformaldehyde for 1 h at room temperature. They were then incubated in 5% silver nitrate for 30 min in the dark, after which they were rinsed with distilled water and exposed to ultraviolet light for 1 h.

Oil Red O staining: The cells are rinsed on 100mm plate with PBS and fixed in 10% formalin for 1h. They are then stained with propylene glycol (2x5min), Oil Red O (1x7min) then agitate and 85% propylene glycol (1x3min) respectively. After rinsed in distilled water, they are continually stained with Hematoxylin in 1 minute, rinsed again then mouted with aqueous mounting media, Glycerin Jelly.

Safranin O staining: The cells are rinsed on 100 mm plate with PBS and fixed in 10% neutral buffered formalin for 1h at room temperature. The cells are then embedded in paraffin. The pellet sections are then deparaffinized in xylene (3x3min), 100% ethanol (2x3min), 95% ethanol (2x3min) and 70% ethanol (1x3min). Stain the sections in Weigert's iron hematoxylin for 4 mins, then destain in fresh acid alcohol (1ml concentrated HCl in 100ml 70% ethanol) and rinse in tap water. Continue stain in 0.02% aqueous fast green FCF fro three minutes, then wash in 1% acetic acid for 30s. Finally, the sections are stained in 0.1% aqueous Safranin-O for 5 mins then dehydrated in 95% ethanol (2x5min), 100% ethanol (3x5min), then xylene (3x5min).

Scanning electron microscopy: 2 days after seeding cells on nanofibers scaffold, the cell morphology and distribution are visualized using SEM. Specimens are fixed in 0.25% glutaraldehyde solution, then rinsed in phosphate-buffered saline 3 times, 30 minutes each time The specimens were immersed in OsO_4 for 40 min and then rinsed in phosphate-buffered saline (PBS; Gibco) 3 times, 30 minutes each time and dehydrated in increasing concentrations of acetone (from 30%-50%-70%-80%-90%-95%-100%-100%-100%, 10 mins for each concentration). After drying, the specimens were mounted on aluminum stubs and viewed in a Hitachi S-3000N SEM with an accelerating voltage of 15 kV.

RNA Isolation and Semiquantitative Reverse Transcription-Polymerase Chain Reaction (RT-PCR): Total cellular RNA was isolated by lysis in TRIZOL (Invitrogen) followed by one-step phenol chloroform- isoamyl alcohol extraction as described in protocol. 200 nanograms of total RNA was reverse-transcribed into complementary DNA (cDNA) by incubation with 200 U of reverse transcriptase in 20 μL of reaction buffer at 37 centi-degree for 1 h. The semiquantitive measurement of the band density was calculated by using Glyko Bandscan (Glyko, Inc., USA).

*Collagen assay:*1, 4 and 7 days after seeding, the amount of deposited collagen in the scaffold and the collagen in medium were quantified using two collagen assay kits and following the manufacturer's protocol (Jiancheng Ltd., Nanjing, China).

III. Results

Study the characteristics of hTSPCs

In order to demonstrate tendon-derived cells are stem cells, we isolated and cultured single-cell suspensions to do colony-forming assay. Fig. 1, A shows the morphology of hTSPCs. After 10-12d, colonies which had formed from single cells were visualized by methyl violet staining (Fig1 B, C). Two independent experiments showed that the colony-forming efficiency was 5%~10%. The results from methyl violet staining proved the stem characteristics: clonogenic and self-renewal of hTSPCs

We determined the multidifferentiation potentials of hTSPCs toward adipogenesis, osteogenesis and chondro-

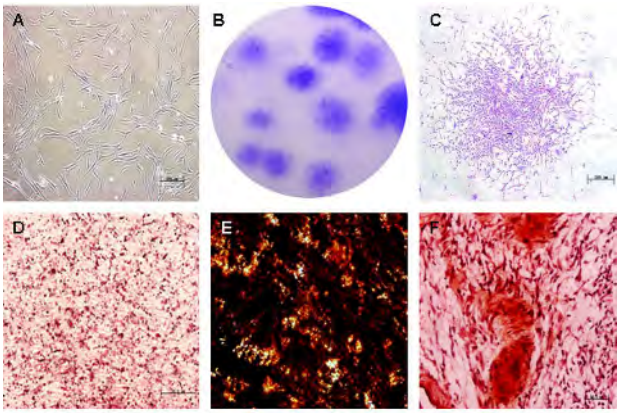

Fig. 1 Characteristics of hTSPCs. (A) morpholosy of hTSPCS. (B, C) colony formation of hTSPCs. (D-F) shows the multipotential of the hTSPCs

genesis. 3 weeks after adipogenic induction, Oil Red O staining was performed to visualize the lipid drops which indicate the differentiation of adipocytes (Fig.1, D). Von kassa staining was performed to give evidence of successfully osteogenic differentiation (Fig.1, E). Chondrogenic differentiation after 4 weeks induction in chondrogenic medium was assessed in pellet culture by Safranin O staining of the proteoglycan-rich ECM (Fig.1, F).

In this study, flow cytometric analysis was used to examine the presence of surface antigens on hTSPCs. Five CD markers were used: CD34 (hematopoietic stem cell marker), CD44, CD90, CD18 (bone marrow stem cell markers) and CD105. The results showed that hTSPCs were positive with CD90, CD105, and CD44 and negative with CD34 and CD18. This results, which were consistent with previous reports [1], further confirmed that hTSPCs was tendon stem/progenitor cells (TSPCs).

Scaffold and cell morphology characterization

Aligned and random poly (l-lactic acid) (PLLA) scaffolds were fabricated by electrospining to assess the effect of cell orientation on hTSPCs differentiation. After fabrication, SEM micrographs (Hitachi S3000N, 15kV) of both aligned and randomly oriented nanofiber scaffolds were taken to assess the degree of alignment (Fig.2, A, B). The results showed that the diameters of the nanofibers of the aligned nanofiber scaffolds and randomly oriented nanofiber scaffolds were comparable. The majority of the fibers in the aligned scaffolds formed angles from 0 to 10°with respect to the vertical axis. Hence, the fibers can be considered to be parallel with each other.

Before the scaffolds were used, the toxicity test was conducted to ensure the PLLA nanofiber scaffolds were nontoxic and could be used to accommodate hTSPCs. The next day after seeding cells on the nanofibers, the cell morphology on the scaffolds was observed under a scanning electron microscope (Fig. 2, C, and D). The SEM micrograph showed that the cells on the aligned nanofiber scaffolds were spindle-shape and oriented in the direction of the nanofibers whereas they look different on the randomly oriented scaffolds. The cells secrete ECM (extra cellular matrix) in both scaffolds.

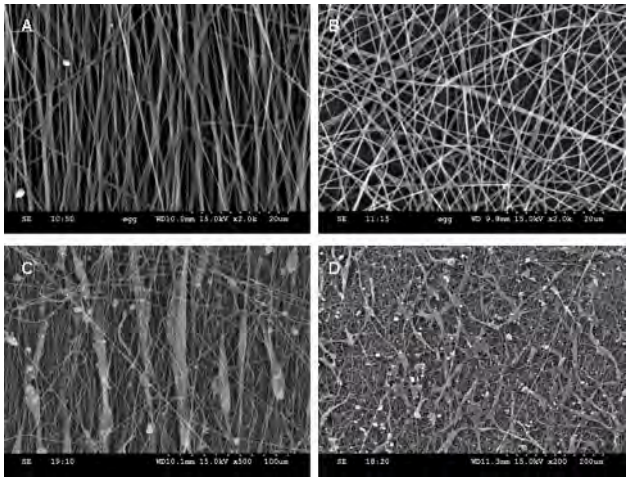

Fig. 2 SEM micrographs of aligned nanofibers (A) and random nanofibers (B). SEM images show the hTSPCs orientation on nanofibers (C) and random nanofibers (D)

Semi-quantities RT-PCR and collagen assay analysis

The gene expression changes of hTSPCs cultured on scaffolds were evaluated by Semiquantitative RT after 3 days, 7 days, and 14days. A and R indicates the gene expression of cells cultured on aligned nanofibers and randomly oriented nanofibers, respectively. A general increase in expressions of tendon specific genes (six 1, eya2) and matrix genes (collagen I and collagen III) was observed when cell grown on nanofibers, when compared to the cells before seeding on the nanofiber scaffold (Fig. 3). Moreover, we noticed the expression level of an osteogenic marker, Runx 2, was significantly upregulated in hTSPCs on ran-

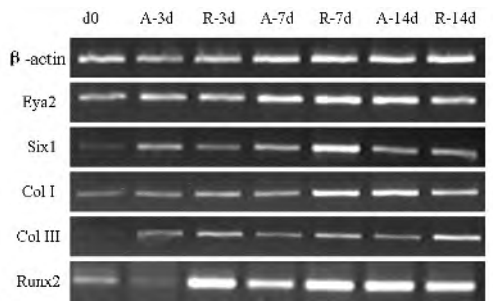

Fig. 3 semiquantitive RT-PCR analysis. A, aligned scaffold; R, random scaffold.

domly oriented nanofibers compared with that on aligned ones (Fig. 3).

We also examined the total collagen secreted by hTSPCs in the medium and on the scaffolds. The hTSPCs cultured on aligned nanofibers produced more collagen than the cells on random oriented ones at 1d, 4d and 7d (data not shown) .

These results shows aligned nanofibers, which can promote hTSPCs tendon-lineage differentiation whereas inhibit osteogenesis, are suitable for tendon tissue engineering.

IV. Discussion

The present study indicate that hTSPCs cultured on the aligned nanofibers were similar with tenocytes in vivo and could be serve as proper combination for tendon tissue engineering.

Adult hTSPCs, which had been reported by Bi, Y et al, had great tendon-formation potential. However, the fetal TSPC may be optimal seed cells as the tendon regeneration potential of fetal cells [1]. As showed in the results, fetal cells had similar morphology with tenocytes and high efficiency of colony formation. The phenotype and multipotency is similar with BMSC and adult TSPC. Therefore, fetal TSPC could provide as optimal seed cells for tendon tissue engineering.

Aligned PLLA nanofibers were fabricated using a simple rotating collector. The diameter and the arrangement of the aligned nanofiber scaffold is a biomimetic structure that is similar with collagen fibers of tendon. Previous work demonstrated that the structure and materials of the scaffold play an important role in cell differentiation and tissue repair and is suitable for ligament cell proliferation and overall ligament and tendon strength [3].

To evaluate the differentiation and ECM production of hTSPCs seeded on aligned nanofibers, we assessed cellular responses, tendon and bone specific gene expression and ECM production. hTSPCs attached to the nanofibers through the small filaments connect to the scaffold. Cells seeded on aligned nanofibers become spindle-shaped that similar with tenocytes in vivo. Gene expression of the hTSPCs shows that the tendon-related genes, such as six1, collagen III were upregulated after seeding on nanofibers.

However, osteocytes also express those genes. hTSPCs seed on random fibers showed higher runx2 expression compare to cells seeded on aligned scaffold. Moreover, those cells seeded on aligned nanofibers showed lower runx2 expression than those of normal cells and the effect was reversed after 7 days culture. It indicated that the nanofibers may induce the osteogenesis and the aligned nanofibers may inhibit this effect and induce tenogenesis by inducing the hTSPCs as spindleshaped tendon-like oriented cells . Those results indicated that the hFTSCs and aligned nanofibers could serve as an optimal material for tendon tissue engineering. However, we did not know the mechanism of this phenomenon. A future study should be explored to find out the mechanism.

V. Conclusions

In conclusion, cell orientation has effect on hTSC differentiation, moreover, the aligned nanostructures of biomaterials provides an instructive microenvironment to modulate and guide TSCs differentiation ranging from cell orientation to gene expression and could be serve as proper scaffolds for tendon tissue engineering.

Abstract — **Hydroxyapatite (HA) coatings are usually used to improve the bonding abilities between implants and surrounding bone tissues. By means of a novel laser cladding technology, a good quality metallurgy bonding interface can be successfully formed between coatings and titanium-based materials. However, dissipation of phosphorous (P) from HA during laser cladding process is a main concern, because the alteration of Ca/P ratio may cause bioactivity degradation of the coatings. The aim of this study is to overcome this problem and enhance the bioactivity of the coatings. Two biocompatible titanium oxides (TiO_2) with different crystal structures (anatase and rutile) were added with HA powders in the initial stage, and these mixtures were then coated on the Ti-6Al-4V plates by the Nd-YAG laser. All the samples were characterized by a range of techniques for investigating and evaluating how these TiO_2 additives affected the microstructure, chemical composition, Ca/P ratio and bioactivity of the coating products.**

Keywords — **laser cladding, hydroxyapatite, TiO_2, Ti-6Al-4V**

I. Introduction

Hydroxyapatite (HA) is the major coating material on biomaterial applications. In recent HA laser cladding research works, most efforts are devoted on promoting the adhesion between the coating layer and substrates [1-2]. However, due to the melting point of phosphorous (P) in HA is relatively low, it is easily vaporized during the melt-coating process and cause the bioactivity degradation of produced coatings [3]. For eliminating this phenomenon, bioactive powder materials were added in HA coatings for improving the bioactivity of final products [4-5]. Titanium dioxide (TiO_2) is one of the attractive candidates, due to its bioactivity and also helps to enhance the adhesion strength between the coating layer and substrate [6-7].

TiO_2 is also called titanium white, which can be categorized into anatase, rutile, and brookite by its crystal structure. Anatase has the best bioactivity but relatively lower strength among three structures. It can effectively attract protein molecules and reduce the formation of connective tissue after implantation [8]. Rutile has a relatively lower bioactivity but better strength than anatase [9], after mixing with HA, which acts as an important role for improving the coating strength. In most bioactivity studies on adding TiO_2 into HA, are focused on the adhesive between the coatings and substrates, and the bonding between the coating layers and surrounding bone tissues. Allen [10] utilized a sol-gel method to coat a TiO_2 layer on Ti-6Al-4V substrate and tested its bioactivity in calcium phosphate liquid and simulated body fluid (SBF), respectively. It was found that the produced TiO_2 coatings were able to attract Ca and P ions, and the following formed HA can help the growth of osteoclast. Kim [11] coated HA+TiO_2 layers on Ti, and found TiO_2 transferred from the bioactive anatase into rutile after heat treatment. It was also observed that the adhesive between the coating and substrate is increased with the increase of TiO_2 addition in HA [11-12].

Laser cladding technology has been applied on HA coatings in previous study. Although the recent developed laser coating method can get a better quality of metallurgical bonding, it still has not solved problems such as non-stoichiometric composition of coatings that degrades in bioactivity. The aim of this study is to overcome this problem and improve the bioactivity of the coating layers. Anatase and rutile were added with HA powders, respectively, in the initial stage, and these mixtures were then coated on the Ti-6Al-4V plates by the Nd-YAG laser. All the samples were characterized by a range of techniques for investigating and evaluating how these TiO_2 additives affected the microstructure, chemical composition, Ca/P ratio and bioactivity of the coating products.

II. Experiment procedures

Ti-6Al-4V substrate was prepared into plates with dimensions of 100mm×60mm×3mm. Its chemical composition can be seen in Table 1. In order to remove the surface oxidation, the plates were grinded by #120 SiC paper, cleaned by acetone, and then dried in an electric oven. 50 wt.% HA+50 wt.% anatase (HA+A) and 50 wt.%

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1401–1404, 2009
www.springerlink.com

HA+50 wt.% rutile (HA+R) powder mixtures were used as coating materials, respectively. The powder mixtures were stirred well with water glass (WG, $Na_2O{\cdot}nSiO_2$) binder and then applied 0.9mm thickness on Ti-6Al-4V substrates via pre-place method. The laser cladding experiment was conducted in continuous wave (CW) mode by Nd-YAG laser of 5° incident angle and 15mm defocus length in an Ar shielded atmosphere with 25 l/min flow rate. The travel speed was 200, 360, 480 and 600 mm/min, respectively, and the laser output power was 850W. The microstructure of the specimens was characterized via optical microscopy (OM) and scanning electron microscopy (SEM). Their chemical composition was analyzed by energy dispersive spectroscopy (EDS) and X-ray diffraction (XRD). Their adhesive strength was determined by the crack formed by the diamond pyramid of Vickers hardness tester.

Table 1 Chemical composition of Ti-6Al-4V used in the study (in wt.%)

Al	V	O	Fe	C	N	H	Ti
6.1	4.24	0.152	0.16	0.017	0.008	0.0006	Bal.

III. Results and Discussion

A. Cross section morphology and bead profile of the weldment

Fig.1 shows the cross section morphology of weldments under different cladding factors. The fusion zone can be classified into coating layer and transition layer. It can be observed that the area of the fusion zone, heat affected zone (HAZ) and the penetration depth were decreased with the increase of laser travel speed. This is due to the average input heat was decreased with the travel speed. On the other hand, porosity and cracks can be found in the fusion zone in both HA+A and HA+R specimens. Since the solidification speed of melts is relatively high, the vaporized WG were trapped in the melts and the pores were formed in the structure afterwards [13]. Furthermore, some white particles were observed on the upper coating layer of HA+A and HA+R specimens, show in Fig.2. From their identified chemical composition, it is assumed that they are compounds from melted WG+TiO_2.

B. Ca/P value and microstructure characterization of coating layer

Ca/P value analysis was obtained from the top, center and bottom area of coating layer. The results reveal show in Fig.3, that the Ca/P value is higher than HA due to the dissipation of P from HA during laser cladding process. It is also observed that the center area has a highest Ca/P value and the top area has a lowest value. Moreover, it is found that the Ca/P value in the HA+A specimens is decreased with the increase of laser travel speed, but the one in the HA+R counterparts shows an opposite trend.

Laser power (W)	Travel speed (mm/min)	Coating layers	
		HA+Anatase	HA+Rutile
850	200		
	360		
	480		
	600		

Fig. 1 The morphology of weldments with different TiO_2 addition in HA

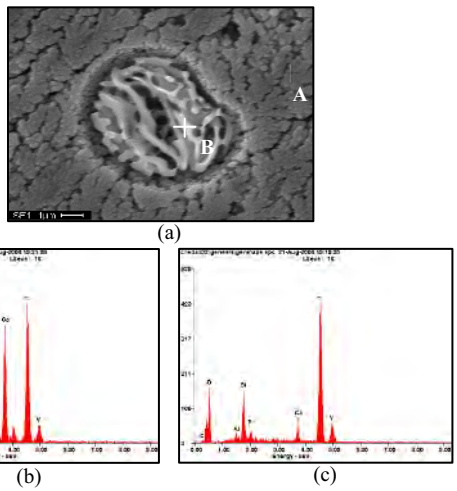

Fig. 2 Characterization of white particles on the top of coatings: (a) SEM image of HA+TiO_2 coating, (b) the EDS analysis of Ca-Ti-O rich phase at point A, and (c) the EDS analysis of Si rich phase at point B

The SEM images in Figs. 4 and 5 show the coral-shaped microstructure (top view) of HA+A and HA+R coatings, respectively. The white areas (points 5A and 6A) were identified as Ti-O rich phases, whereas the dark areas (points 5B and 6B) were identified as Ca-Ti-O rich phases. It is supposed that the Ca-Ti-O phases are composed of the dissipated Ca from HA, and Ti and O from the TiO_2.

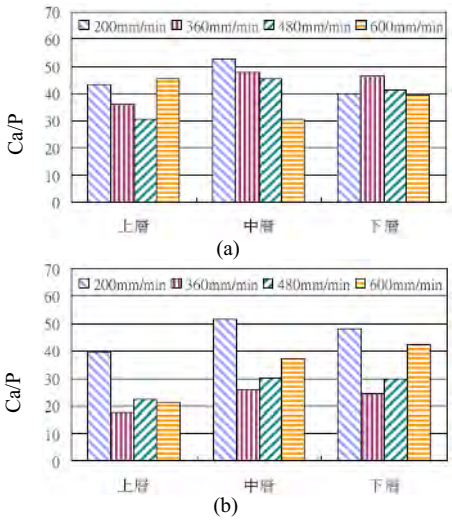

Fig. 3 The Ca/P value comparison of coatings with different TiO_2 addition and laser travel speed: (a) HA+A, and (b) HA+R

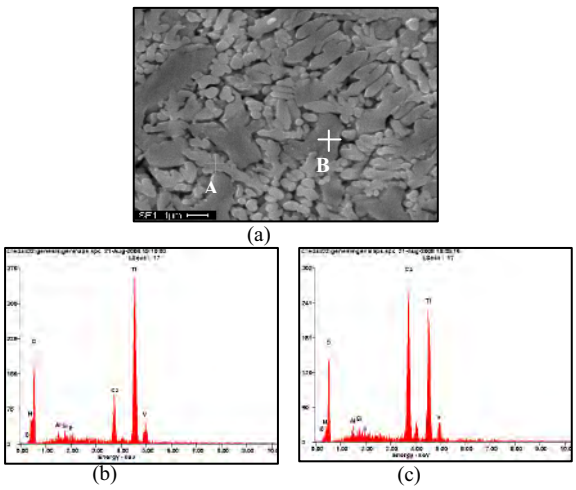

Fig. 4 Characterization of HA+A coating: (a) SEM image of HA+A coating, (b) the EDS analysis of Ti-O rich phase at point A, and (c) the EDS analysis of Ca-Ti-O rich phase at point B

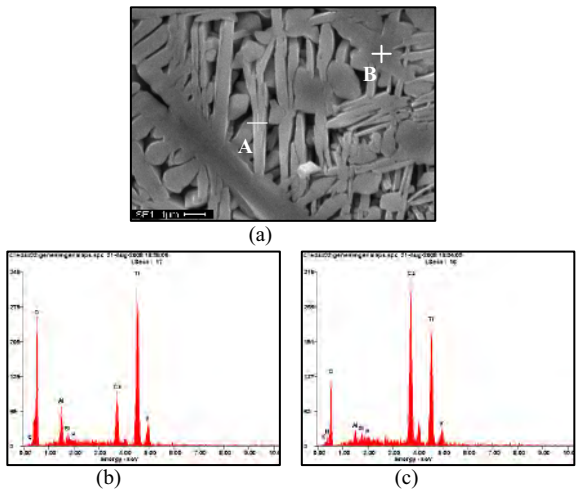

Fig. 5 Characterization of HA+R coating: (a) SEM image of HA+R coating, (b) the EDS analysis of Ti-O rich phase at point A, and (c) the EDS analysis of Ca-Ti-O rich phase at point B

C. XRD analysis of coating layers

The results of XRD analysis can be seen in Fig. 6. Anatase, rutile, HA, β-$Ca_3(PO_4)_2$, $CaTiO_3$ and $CaCO_3$ were found in the HA+A specimen; whereas rutile, HA, Ti_2O_3, $CaTiO_3$ and $CaCO_3$ were found in the HA+R specimen. These phases are supposed to be synthesized from the decomposed HA+TiO_2 precursors during laser cladding, where the rutile (high temperature phase) found in the HA+A specimen was originally from the anatase (low temperature phase).

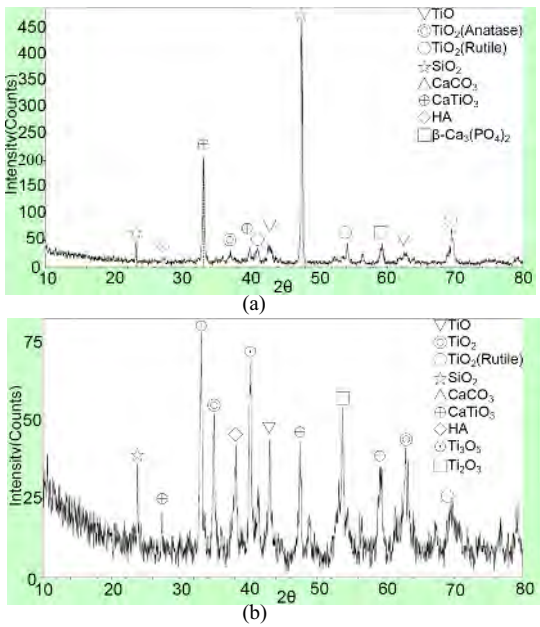

Fig. 6 The XRD analysis of: (a) HA+A coating, and (b) HA+R coating

D. Interface bonding analysis

Currently, tensile test and HV hardness test are the two methods to evaluate the bonding strength between the coating layer and substrate. HV hardness method was adopted in this study and the results can be seen in Fig. 7. It is revealed that no crack was observed from all specimens of different cladding factors and coating precursors, which indicates a sufficient bonding strength of coating is obtained by adding TiO_2 into HA.

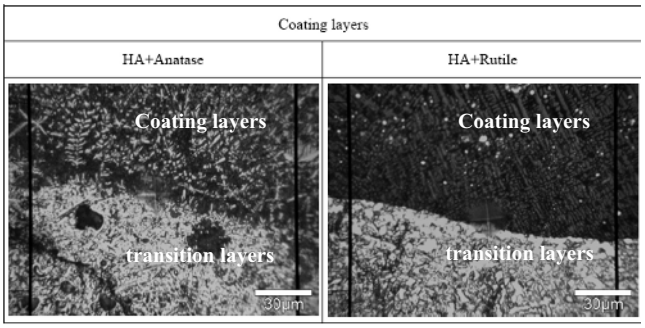

Fig. 7 The OM images of the interface between different coatings and substrate after HV hardness tests

IV. Conclusions

1. The morphology of weldments reveals the area of the fusion zone, HAZ and the penetration depth were decreased with the increase of laser travel speed. More pores and cracks were observed in the HA+A coating than HA+R counterpart.
2. HA+A coating has a higher Ca/P value than HA+R counterpart. All the coatings show that the center area has a highest Ca/P value and the top area has a lowest value. The coatings revealed a coral-shaped microstructure, which is believed that favorable for the attachment and growth of cells.
3. The XRD analysis shows all coatings have HA, $CaTiO_3$ and $CaCO_3$ phases. Additionally, β-$Ca_3(PO_4)_2$, which has good bioactivity was found in the HA+A coating, whereas Ti_2O_3 was observed in the HA+R coating, respectively.
4. The interface bonding strength evaluation revealed that no crack was observed from all specimens of different cladding factors and coating precursors, which indicates a sufficient bonding strength of coating is obtained by adding TiO_2 into HA.

Abstract — **Primary hepatocyte *in vitro* culture is a challenging area in liver tissue engineering. Hepatocyte viability and functions drop significantly after isolation step. The perfusion culture is a promising culture method to maintain cell viability and function *in vitro* for long term. Hepatocytes cultured in perfusion condition have better oxygen and nutrient supply due to improved mass transfer. The metabolite wastes excreted by cells can also be removed effectively in the perfused flow, avoiding local accumulation of these wastes which deteriorates cell functions. However, hepatocytes are sensitive to shear stress associated with the flow rate in perfusion culture and are shielded by sinusoidal endothelial cells in the liver to avoid direct exposure to shear stress. Fluid-induced high shear stress in perfusion culture may cause detrimental effect on hepatocyte viability and functions. In the current study, we simulated the profile of fluid-induced shear stress under different flow rate in our sandwich perfusion bioreactor using computation fluid dynamics (CFD) method, and investigated the effect of shear stress on the cell function. The results indicated that hepatocyte function can be maintained in long term under moderate shear stress in perfusion culture.**

Keywords — **Liver failure, hepatocytes, fluid shear, bioreactor, CFD**

I. Introduction

Patients with fulminant hepatic failure (FHF) have a mortality rate of more than 80% [1]. Transplantation remains the only curative option for patients with liver failure [1,2]. However, liver transplantation is constraint by cost, donor scarcity and compatibility [1]. Recently, bio-artificial liver devices are emerging as one of the promising solution in bridging for transplantation and/or liver regeneration [1,2,4]. These artificial liver devices make use of isolated liver cells, i.e. hepatocytes, either of allogeneic or xenogeneic origin to replace the liver-specific functions of patients with FHF.

Of the myriad of culturing techniques currently employed by today's bio-artificial liver devices, sandwich culture method has demonstrated excellent ability of re-establishing hepatocytes polarity with long-term maintenance of specific-liver functions and viability [3]. Studies have indicated that the hepatocytes culture in sandwich configuration generally provide better control in terms of the uniformity of cell distribution and the regulation of microenvironments mimicry of that found *in vivo* [3].

Perfusion bioreactor provides an ideal solution to the support and culturing of vast liver cell mass (in the range of 100×10^6 - 2×10^9) through efficient transport of essential nutrients and gases to the cell surfaces. However, it remains that one of the major engineering concerns facing bioengineers in the development of bio-artificial liver is the effect of fluid-induced shear stress on the hepatocytes [3,4]. Studies have shown that fluid shear stress exceeding 0.5 dynes/cm^2 is detrimental to the viability of the hepatocytes culture [4]. Computational fluid dynamics (CFD) technique provides an efficient and reliable means to assess the flow characteristics in the perfusion bioreactors, with the technique gaining wide acceptance among present day tissue-engineers in the optimization of bioreactor design [4].

At present, the characteristics of fluid-induced shear stress in sandwich culture have not been adequately addressed. Through computational modeling, the current study set out to investigate the effect of fluid shear on the hepatocytes sandwich culture.

II. Methods

A. Perfusion Bioreactor

The bioreactor used in the current study is shown in Figure 1. It consisted of a circular culture chamber (15 mm dia.) with inlet and outlet ports for medium perfusion.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1405–1408, 2009
www.springerlink.com

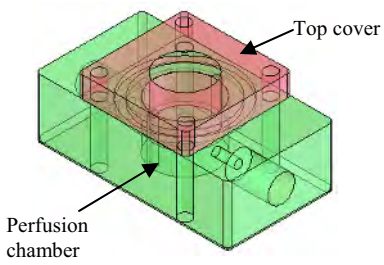

Fig. 1 Schematic of the perfusion bioreactor

B. Computer Model

Figure 2 shows the 3D fluid volume of the bioreactor. Half model of the fluid volume was solved since the flow characteristics through the culture chamber are considered symmetric about the stream-wise plane.

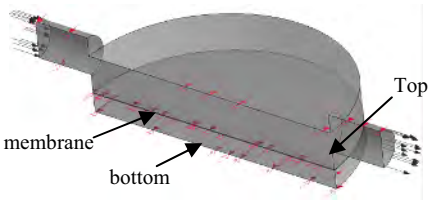

Fig. 2 Half-model of fluid volume of bioreactor

The 3D fluid model comprises of three domains; 1) top, 2) porous membrane, and 3) bottom domains. The top domain consisted of the inlet and outlet conduits. The porous membrane consisted of the membrane with an experimentally derived permeability value. The bottom domain is where the sandwich cell culture is located. The thickness of the porous polycarbonate membrane is 50 μm, while the height of the flow channel in the top and bottom domains are 2 and 1 mm, respectively. The 3D model was first created using Solidworks (Solidworks, Singapore) before being discretized using ANSYS meshing software ICEM CFD (ANSYS, Singapore). Tetrahedral meshing was used for the volume discretization resulting in a total of 408,952 nodes and 2,209,336 elements.

C. Modeling Fluid Flow

A finite element approach was adopted in order to evaluate the distribution of fluid shear stress on the cell surface through the porous membrane at various flow rates. To simulate the flow, the commercial CFD package (ANSYS Inc, Singapore) was used to numerically solve the steady-state Navier-Stokes equations. Fluid properties were set to those of the culture media and the culture medium was modeled as an incompressible, isothermal, Newtonian fluid with a density of 1000 kg/cm^3 and a dynamic viscosity of 0.889 mPa s. Flow rates of 0.1, 0.06, 0.03 (with and without membrane) and 0.018 mL/min were simulated for comparison. The selection of 0.03 mL/min to study the effect of membrane on cell functions is based on our preliminary *in vitro* experiments flow rate optimization, which demonstrated enhanced liver-specific functions at flow rate of 0.03 mL/min compared to other flow rates. Outlet boundary condition was set at zero pressure outflow, while the no-slip walls boundary conditions were used along the walls of the model.

D. Experimentally Derived Permeability Value, α (1/m^2)

The porous membrane may be considered as a momentum sink that contributes to the pressure drop in the porous media, which is composed of two parts, a viscous loss term (Darcy's law) and an inertia loss term (kinetic loss):

Momentum sink, Si = Viscous loss + Inertia loss

$$Si = \nu(\frac{\mu}{\alpha}) + \frac{1}{2}(C\,\rho\,\nu^2)$$

where Si is the momentum sink or pressure drop per unit membrane thickness (Pa/m), ν is the fluid velocity (m/s), μ is the fluid viscosity (Pa s), α is the fluid membrane permeability (m2), ρ is the density of the fluid (kg/m3) and C is the inertial resistance factor. Under laminar flow, pressure drop is directly proportional to velocity and the viscous loss is dominant, thus C can be considered to be zero. The membrane permeability α was thus derived from measuring the pressure drop per unit thickness across the membrane and the output flowrate as shown in Figure 3.

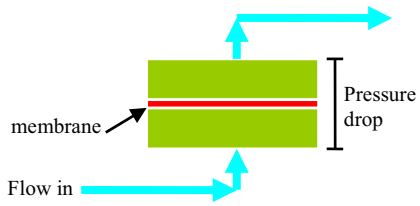

Fig. 3 Schematic of setup to measure the permeability of porous membrane experimentally

From the slope as shown in Figure 4, (μ/α) = 1 x 10^7 m^2 Pa^{-1}s^{-1} and taking μ = 8.81 x 10^{-4} Pa s, thus α = 8.81 x 10^{-11} m^{-2}. The simplified porous membrane momentum sink equation with empirically derived α was used in the CFD model to simulate the shear stress at different flowrates.

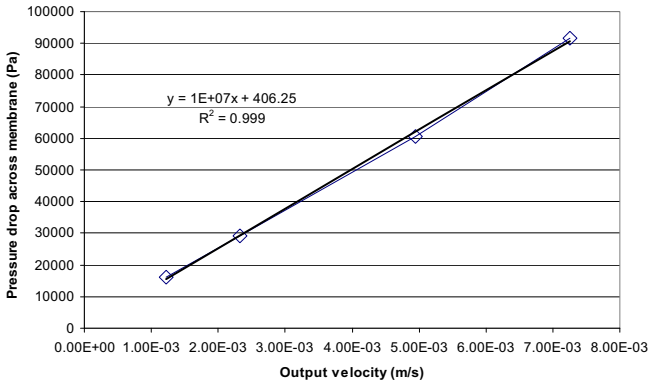

Fig. 4 Permeability of the polycarbonate membrane is measured as the slope of pressure drop vs output velocity

III. Results

Table 1 tabulates the mean shear stress, velocity and Re with corresponding flow rates. The mean shear stress experienced by the cell surface at flow rate of 0.03 mL/min is lower at 0.70 dynes/cm^2 with membrane compared with that without membrane at 0.85 dynes/cm^2.

Figure 5 shows the shear strain distribution across the cell surface below the porous membrane. Elevated fluid shear values were observed in the stream-wise plane while those of lower values were observed along the edge of the culture chamber.

Table 1 Mean shear stress, velocity and Re with corresponding flow rates

Flow rates (ml/min)	Mean shear stress (x 10^{-3} dynes/cm^2)	Re	Velocity (m/s)
0.100	2.10	3.136	5.3276E-04
0.060	1.13	1.882	3.1978E-04
0.030	0.70	0.941	1.5989E-04
0.018	0.37	0.564	9.5935E-05
0.030 (w/o) membrane	0.85	0.934	1.5941E-04

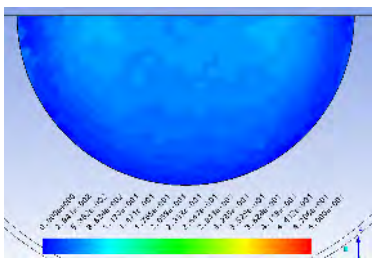

Fig. 5 Shear strain contour plot at flow rate of 0.03 mL/min (with membrane)

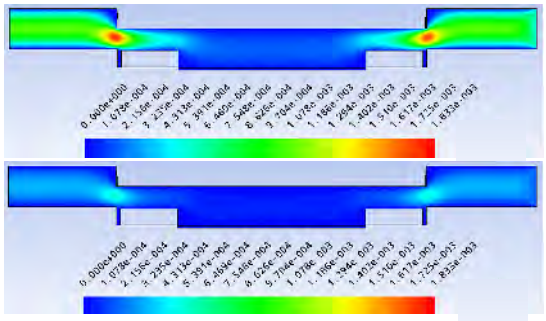

Fig. 6 Velocity contour plot at flow rates of flow of 0.1 and 0.03 L/min

Higher flow velocity was observed at inlet and outlet ports of the chamber as a result of the constriction of flow area in these regions (Fig. 6). Low recirculating regions were typically observed at the sudden expansion and contraction regions within the chamber as a result of the flow separation.

Figure 7 compares the stream-wise shear strain profile across the cell surface below the porous membrane. The profile was characterized by two peaks along the flow

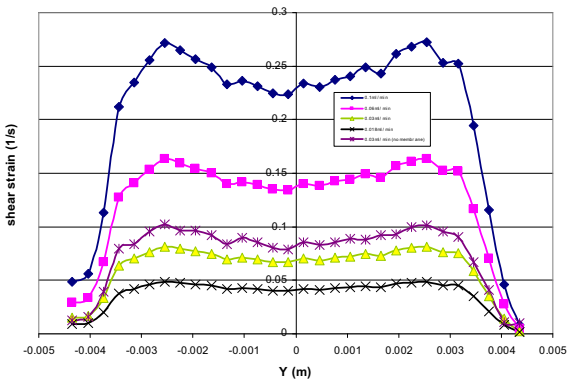

Fig. 7 Shear strain across the cell surface at different flow rates

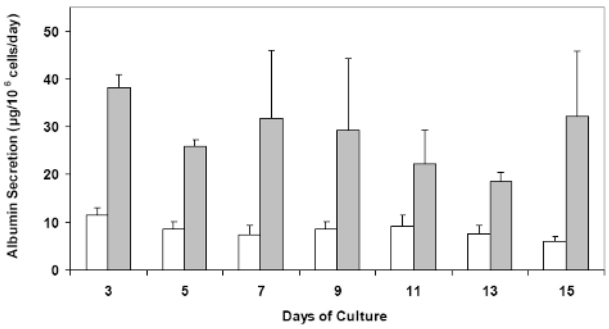

Fig. 8 Albumin secretion function of sandwich perfusion culture at flow of 0.03mL/min compared with sandwich static culture.

stream. These were due to the boundary layer detachment at inlet port and its subsequent attachment within the culture chamber (Fig.8). Both Table 1 and Figure 7 show that the fluid shears generated by the different flow rates were well below the threshold value of 0.33 dynes/cm^2 [4]. Figure 8 albumin secretion function of sandwich perfusion culture at flow rate of 0.03mL/min, which is optimized using CFD simulation of the shear stress to be well below the threshold value. The function of perfusion culture was maintained for 15 days and was consistently higher than that of static culture.

IV. Discussions

Fluid-induced shear stress is an important consideration in bioreactor designs. Hepatocytes in native liver are arranged in plates, separated and shielded from the direct effect of fluid shear by layer of sinusoidal cells. Studies have shown that primary hepatocytes cultures are sensitive to external flow conditions [1,2,4]. Two opposing fluid associated conditions may determine the outcome of the hepatocytes cultures, namely, the shear stress and the transport of nutrients and oxygen. Higher flow rates invariably improve the convective transport of oxygen to the cell surfaces but the corresponding elevated shear stress values could prove detrimental to viability of the cell culture. Conversely, lower flow rates could lead to inadequate supply of oxygen, even though the shear stresses are well below the critical threshold value.

Several innovative bioreactor designs have been suggested to regulate the wall shear stress experienced by the hepatocytes. One such device is developed by J. Park *et al* in which micro-fabricated concentric grooves in glass are used to shield the monolayer hepatocytes culture from the effect of fluid flow without compromising on the supply of nutrients and oxygen to the cell surface [4]. Our preliminary *in vivo* experiments with sandwich configuration showed that hepatocytes culture perfused at the rate of 0.03 mL/min demonstrated enhanced liver-specific functions and viability compared to those at other flow rates. The shear stresses experienced by the hepatocytes with and without the membrane at 0.03 mL/min were 0.7 x 10^{-3} and 0.85 x 10^{-3} dynes/cm^2, respectively. Our computational study has also demonstrated the sensitivity of hepatocytes cultures to the different flow conditions. The difference between mean shear stresses at flow rates of 0.06 and 0.03 mL/min was ~0.4 x10^{-3} dynes/cm^2, while that between the flow rates of 0.03 and 0.018 mL/min was ~0.30 x10^{-3} dynes/cm^2.

The top membrane in a sandwich culture, besides providing an anchorage for the hepatocytes attachment, also acts as a shield to protect the hepatocytes from the direct effect fluid flow. Comparison of the hepatocytes cultures at 0.03 mL/min showed only a difference of 0.7 x10^{-3} dynes/cm^2 and 0.85 x10^{-3} dynes/cm^2 for cultures with and without membrane, respectively. Effectively, the 50 μm thick membrane was able to reduce the shear stress by ~0.1 x10^{-3} dynes/cm^2. However, it should be noted that our current study did not include a layer of coated collagen on the membrane when measuring its permeability. The coating of an additional layer of collagen onto the membrane should further reduce the shear stress experienced by the cell surface. But a corresponding reduction in the transport of nutrients and oxygen should be expected.

V. Conclusions

The study has demonstrated the sensitivity of the hepatocytes to fluid-induced shear stresses. The membrane in sandwich culture is able to act as a shield for the hepatocytes from the direct effect fluid flow. However, a compromise between the transport of oxygen and nutrient and magnitude of shear stresses need to be considered when using sandwich culture. Hepatocyte functions were well improved in the perfusion culture at optimized flow rate by CFD simulation.

Abstract — **The authors have been developing a sophisticated artificial myocardium for the treatment of heart failure, which is capable of supporting contractile function from the outside of the ventricle. The purpose of this study was to construct the control methodology of functional assistance by an artificial myocardium using small active mechanical elements composed of shape memory alloy fibres (Biometal). In order to achieve a sophisticated mechanical support by using shape memory alloy fibres, the diameter of which was 100 microns, the mechanical response of the myocardial assist device unit was examined by using PID (Proportional-Integral-Derivative) control method. Prior to the evaluation of dynamic characteristics, the relationship between strain and electric resistance of the shape memory alloy fibre and also the inditial response of each unit were obtained in the electrical bridge circuit. The component for the PID control was designed for the regulation of the myocardial contractile function. An originally-designed RISC microcomputer was employed and the input or output signals were controlled by pulse width modulation method in respect of displacement controls. Consequently, the optimal PID parameters were confirmed and the fibrous displacement was successfully regulated under the different heat transfer conditions simulating internal body temperature as well as bias tensile loading. Then it was indicated that this control methodology could be useful for more sophisticated ventricular passive or active restraint by using the artificial myocardium on physiological demand interactively.**

Keywords — **Artificial myocardium, shape memory alloy fibre, PID control, dynamic characteristics**

I. Introduction

In general, ventricular assist devices (VADs) such as artificial hearts are used for the surgical treatment of the final stage of severe heart failure. However, it is anticipated that the interface between artificial materials and blood might cause severe complications from thrombosis or hemolysis in the application of blood flow pumps. On the other hand, the direct ventricular mechanical assistance is well known for the effective cardiac support from outside of the heart without thrombogenicity on the surface of the device. We have been developing an original artificial myocardial assist system, which is shown in Figure 1, for the treatment of severe heart failure by using a sophisticate shape memory alloy fibre. In order to achieve the effective cardiac assist on physiological demand for the patients' quality of life, the sophisticated mechanical control should be considered in the device. The special features of the shape memory alloy fibre which we employed in this study are along with its high durability and controllability. The purpose of this study was to evaluate its basic dynamic characteristics and parameters for proportional-integral-derivative (PID) feedback control for more sophisticated and effective mechanical assistance in our artificial myocardial assist system.

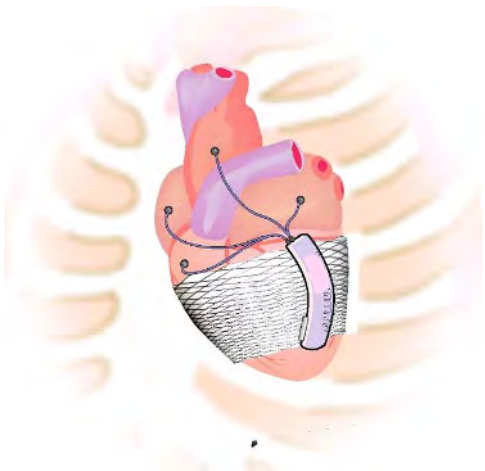

Fig. 1 Schematic illustration of our artificial myocardial assist system using shape memory alloy fibres (Biometal)

www.springerlink.com

II. Material and Methods

A. Mechanical structure of the artificial myocardium using shape memory alloy fibres

Special features of the shape memory alloy fibre (Biometal®) which was to be employed as the actuator of the artificial myocardium were as follows: a) composition of covalent and metallic bonding structure, b) 4-7 % shortening by Joule heating induced by the electric current input, c) linear characteristics of electric resistance against shortening, d) strong maximum contractile force of 10N with 100um-fibre, e) high durability of over one billion cycles, f) contractile frequent response by 1-3 Hz, g) selectable maltensitic temperature by fabrication processing from 45 to 70 Celsius, and h) elective diameter size smaller than 30um.

The myocardial assist system consisted of a shape memory alloy band unit as shown in Figure 2. The diameter of each fibre employed in this study was 100 microns, and it was contracted by the Joule heating. In general, Ti-Ni alloy is well known as a material with the shape-memory effect[13]-[15]. The fibre material is able to be covered with a silicone tubing (diameter: 150um).

B. Examination of dynamic characteristics of the shape memory alloy fibre

The basic dynamic characteristics for the sophisticated PID parameters of the artificial myocardium were examined in the setup as shown in Figure 3. The heating conditions for each shape memory alloy fibre unit could be determined by the driver which consisted of a microcomputer and a power MOS-FET, and the driving signal for the contractile procedure of the unit was programmed and installed into the controller.

In order to obtain the dynamic characteristics, the length and displacement of the fibre were measured by using a laser displacement sensor (Keyence, LB-01), which was connected to the edge of the bias spring as shown in Figure 3 (bottom). The changes in the voltage between terminals of the fibre was also derived by the operational amplifier (Analog Devices, AD623), and the electric resistance was calculated by each voltage. Those data was digitally recorded simultaneously by the sampling rate of 1kHz.

As shown in Figure 4, the parameter of 'e0' could be calculated as the resistance of the shape memory alloy fibre unit (BMF), when the resistance ratio in the Wheatstone bridge was set to be constant as follows:

$$e_0 = (1 + \frac{100 \times 10^3}{R_G}) \times \frac{R_1 R_2 - R_{BMF} R_3}{(R_{BMF} + R_1)(R_2 + R_3)} E \qquad (1)$$

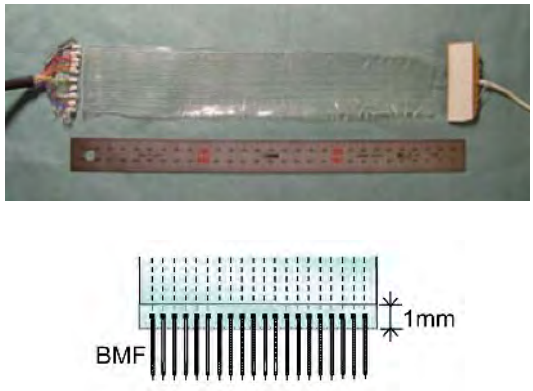

Fig. 2 Whole view of an artificial myocardial assist device (top) and schematic illustration of its cross sectional structure (bottom); each shape memory alloy fibre was covered by a silicone rubber tubing.

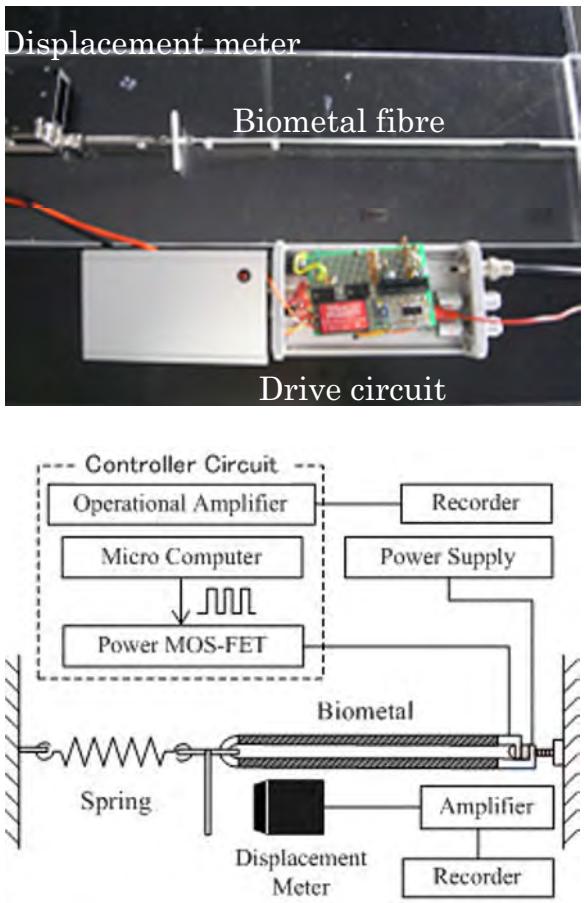

Fig. 3 Whole view of the test apparatus for the examination of dynamic characteristics for artificial myocardium units (top), and the schematic drawing of the circuit for the test of a single shape memory alloy fibre (bottom).

III. Results and Discussion

A. Dynamic characteristic evaluation of the shape memory alloy fibre for the artificial myocardium

As shown in Figure 7 and 8, the changes in displacement as well as the electric resistance of each fibre could be obtained. And the PID control parameters could be defined by the three components, floating time 'T', time constant 'L', and process gain 'K' under the conditions of different electric voltage supplied for each fibre as shown in Table 1. The PID control parameters were also calculated as shown in Table 2.

Table 1 Font sizes and styles

Floating time T	Time constant L	Process gain K
0.061	0.043	1.0

Table 2 PID parameter calculated

Proportion gain K_P	Integral time T_I	Derivative time T_D
1.2T/KL	2L	1.5L

B. Interactive control without displacement sensor

As the precise structural characteristics of the fibre material remains to be seen from the metallic materials science point of view, the dynamic change at the strain range over around 4.5 % could not be expressed by the linear relationship between strain and resistance. On the other hand, it was possible to write those relations as a linear function at the strain range of 4% or less. Figure 9 was an example of the application of PID control for the same unit, and it was indicated that this specific method would be useful to implement interactive control to the artificial myocardium without displacement sensors.

IV. Conclusions

The improvement of an artificial myocardial control using the sophisticated covalent shape memory alloy fibres could be achieved with the implementation of PID control method. And the linearity of the material enables us to establish more sophisticated procedure of contraction by using PID control method. As the load of this myocardial system, which was generated by the natural cardiac function, could be estimated by measuring the electrical resistance of the shape memory alloy fibre, the mechanical myocardial assistance might be effective for heart failure conditions according to the cardiovascular physiological demand.

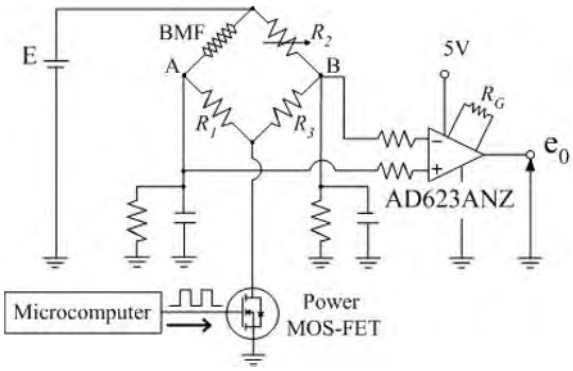

Fig. 4 Schematic drawing of the electric circuit; the shape memory alloy fibre (BMF) was connected to the portion of the Wheatstone bridge, and the changes in voltage between the terminal of the fibre as 'e0'.

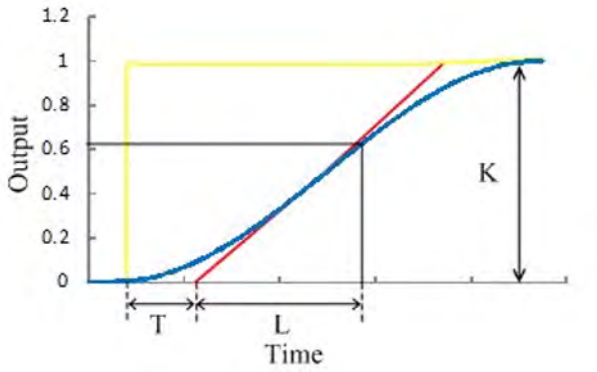

Fig. 5 Schematic illustration for the typical changes in the displacement of the shape memory alloy fibre obtained by step response examination; 'T' as the floating time, 'L' as the time constant, and 'K' as the process gain were calculated for the determination of PID control parameters.

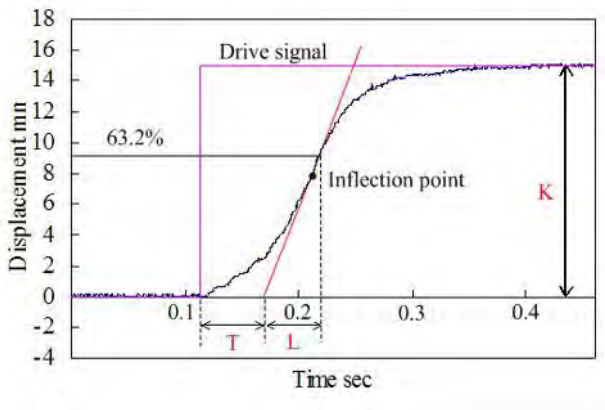

Fig. 6 Changes in the displacement obtained at the shape memory alloy fibre under the terminal voltage condition of 36 Volts.

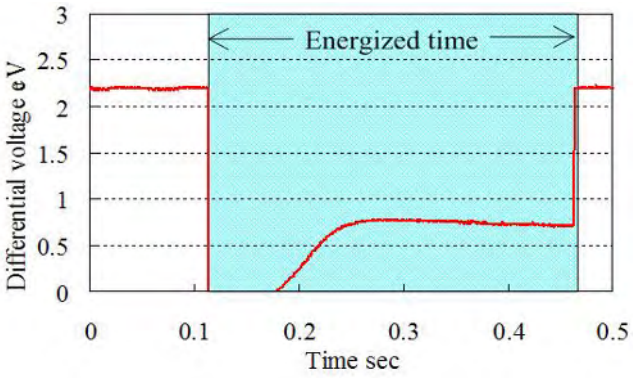

Fig. 7 Relationships between the electric 'step' input and the changes in the displacement obtained at the shape memory alloy fibre; the contraction change was saturated and stabilized against the stress of the bias spring.

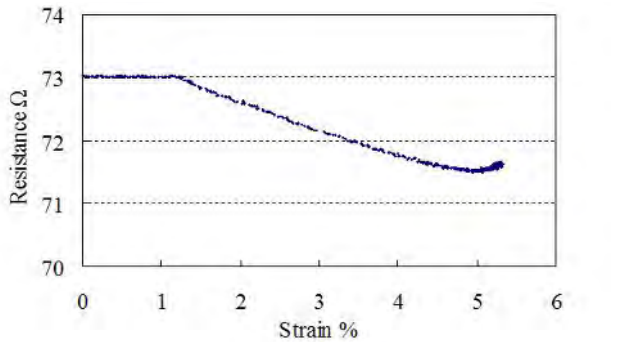

Fig. 8 Dynamic characteristics obtained at the displacement range of 0 to 5% of the single unit measured by the Wheatstone bridge circuit; the particular characteristics of this material could be investigated over 4% shortening, which might be caused by the structural changes in metallic bonding and crystallization in the shape memory alloy material.

Synthesis, Surface Characterization and In Vitro Blood Compatibility Studies of the Self-assembled Monolayers (SAMs) Containing Lipid-like Phosphorylethanolamine Terminal Group

Y.T. Sun, C.Y. Yu and J.C. Lin

Department of Chemical Engineering, National Cheng Kung University, Tainan, TAIWAN

Abstract — **Creating a surface with structure mimicking the phospholipid configuration, the most abundant component of the cell membrane, has been considered as one of the important methods to improve the blood compatibility of artificial surfaces. In this study, self-assembled monolayers (SAMs) formed by alkanethiol with phospholipid terminal group, 11-mercaptoundecanephosphorylethanolamine (PE), were explored as the potential surface modification technique to vary the blood contacting characteristics of metallic biomaterials.**

The surface characteristics and blood contacting properties of the SAMs formed from different solvents and concentrations are evaluated in this study. It was noted that the SAMs with phosphorylethanolamine terminal functionality is more hydrophilic, especially the ones formed using PBS as the solvent, than those with methyl terminate and the non-modified pure gold. ESCA analyses have suggested these phosphorylethanolamine terminated SAMs are less- ordered, likely due to the steric hindrance as well as the charging effects caused by this terminal end. This less-ordered configuration might explain the surface hydrophilicity of phosphorylethanolamine terminated SAMs was not as high as expected from its chemical structure. In addition, the ESCA analyses have shown that unbound thiols were noted within the SAMs, resulted from the steric hindrance caused by these bulky phospholipid-like terminal ends. Blood-contacting property evaluation has shown that parts of the SAMs surfaces exhibited platelet activation and aggregation while others didn't as compared to those prepared from the alkanethiol with methyl terminal end. Further study is undergoing to explore this unique blood contacting phenomena.

Keywords — **self-assembled monolayers, solvent effect, surface property, blood compatibility, ESCA**

I. Introduction

It is believed that creating a structure that is biomembrane-mimicking can improve the biocompatibility of materials. Biomembrane are composed of phospholipids and protein. Phospholipid is a fatty-like compound, but one of the fatty acid is replaced by phosphate, like phosphatidylcholine and phosphatidylethanolamine. Previously, there were numbers of studies submitted ideas to improve blood compatibility. For example, phospholipid could be copolymerized [1,2] or graft onto copolymer chains. But phase separation and function groups embedded for polymers were serious problems to overcome. Therefore, to discuss surface property and blood compatibility, a well-defined surface by self-assembled monolayers method was explored in the present study.

Self-assembled monolayers (SAMs) prepared by organosulfur compounds on metal surfaces have been extensively studied because of the wide varieties of potential applications. In particular, alkanethiol SAMs on gold have been thoroughly studied due to their highly reproducibility, well-defined and highly stable structure, as well as ease of preparation. The surface properties of the SAMs can be tuned by varying the terminal functionalities of the monolayers. In the view of energy, the well-ordered surface structure is formed by the interactions among head group, alkyl chain, and terminal ends. Numbers of topics have been studied, such as tilt angle between SAMs and substrate [3], intermolecular energy [3], chain length effect [4], solvent effect [5], wetting properties [6], kinetic of adsorption [4], and microstructure of surfaces [7,8]. The potential applications of SAMs were in protection of corrosion, biomimetics, and biosensors, to name a few.

Generally, the solvent used in preparation of SAMs was ethanol, because it is cheap, low toxicity, high purity, and doesn't act with SAMs [4]. There were studies with different solvents [9,10], and it was found that solvents did affect the structure of SAMs. In the present study, different solvent was used in order to explore its likely effects on the surface properties and blood-contacting characteristics of the SAMs prepared.

II. Materials and methods

A. Materials

11-Undecylenyl alcohol (98%, Aldrich), phosphorus oxychloride (99%, RDH), triethylamine (TEDIA), 4-Dimethylamino-pyridine (99%, Sigma), triisopropylbenzenesulfonyl chloride (>98%, Fluka), ethanolamine hydrochloride (>99%, Aldrich), thioacetic acid (95%, Fluka), and 2,2′-Azobis (2-methylpropionitrile) (98%, Showa) were all of analytical reagent grade and were used as received.

B. Synthesis of 11-mercaptoundecanephosphoryl ethanolamine

Alkanethiol with phospholipid terminal group, 11-mercaptoundecanephosphorylethanolamine (PE) was synthesized by the scheme shown in Figure 1.

C. Preparation of gold substrates and SAMs

Silicon wafers (1.5 cm × 5 cm) were cleaned by dipping into the Piranha solution (70 % H_2SO_4 and 30% H_2O_2) for an hour at 90°C. These substrates were rinsed with deionized water and ethanol several times and were then dried with nitrogen. The substrates were prepared by thermal evaporation of 300 Å titanium as an adhesion layer onto silicon wafer, followed by 2000 Å of gold. The PE SAMs formation was carried out by immersing gold substrates into methanol (MeOH), ethanol (EtOH0, deionized water (H_2O), and PBS at the concentration of 1mM and 0.1mM thiol solution for 24hrs. The CH_3-terminated thiol dissolved in ethanol solution at concentration of 1mM and 0.1mM (named as $1CH_3$ and 0.1 CH_3, respectively) were used as comparison. After the immersion, the samples were rinsed with deionized water and ethanol to remove physically adsorbed thiol, and dried with nitrogen. The nomenclature for the PE SAMs prepared was as follow: xxYY, where xx is the thiol concentration while YY is the solvent used.

D. Surface characterization and in vitro platelet analysis

The surface hydrophilicity was measured by sessile drop method (Face CA-A, Kyowas Kaimenkagaku Co. Ltd, Japan). Deionied water was used as the wetting liquid. The same-sized liquid drops were extruded to contact the SAMs surface, and the contact angles were determined on averaging the results obtained on three to five spots.

Electron spectroscopy for chemical analysis (ESCA or XPS) spectra were obtained by PHI Quantera SXM spectrometer under monochromatic AlKα source (hν=1486.6 eV) and the take-off angle was set at 45°.

Scanning electron microscope (SEM, S-2500, Hitachi, Japan) was to determine the morphology of the SAMs prepared as well as the adhered platelets. The 1000× image was used to calculate number of platelets adhered while 2000× one was used for platelets activation observation. Human platelet–rich plasma (PRP, 3.5×10^{10} platelets/mL) was used for *in vitro* platelet adhesion assay.

III. Results and Discussion

It was clearly noted that the SAMs prepared from PBS at 0.1mM (0.1PBS) and 1mM (1PBS) concentration were the most hydrophilic ones with contact angle values less than 10° (Figure 2). However, for other PE SAMs prepared, the contact angle values were all greater than the reported value for $–PO_3H_2$ terminated SAM, 37° [12], except those prepared by ethanol. The contact angle of CH_3-terminated SAMs and the bare gold was consistent with the literature values [13,14]. The small contact angle values noted on the SAMs prepared from PBS are very likely resulted from the adsorption of salt ions, as indicated by the existence of salt ions on the ESCA spectra. As for the high contact angle values for other PE SAMs, this can be attributed to the less-ordered structure resulting from the steric hindrance effect caused by the bulky PE terminal ends.

The surface elemental composition was determined from the XPS survey spectra. The atomic concentration of S2p is smaller than the theoretical one (Table 1). This is due to the inelastic collisions of sulfur photoelectrons prior arriving the detector. Such results indicated that the sulfur was resid-

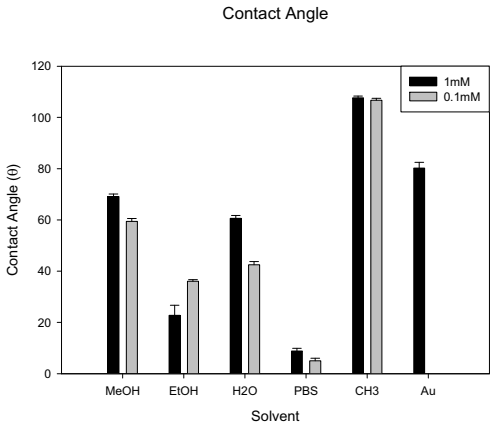

Fig. 2 The contact angle of PE SAMs prepared from different solvent and concentration as compared to the CH_3-terminated SAM and non-treated bare gold

Table 1 Atomic composition of PE SAMs
(the number within parentheses indicates the theoretical value)

Solvent	At%				
	C_{1s}	O_{1s}	N_{1s}	P_{2p}	S_{2p}
1MeOH	61.1 (65.0)	26.2 (20.0)	4.6 (5.0)	5.1 (5.0)	3.0 (5.0)
0.1MeOH	60.3	26.7	4.7	5.3	3.3
1EtOH	61.1	25.8	4.7	5.7	2.6
0.1EtOH	62.0	25.3	4.9	5.5	2.4
$1H_2O$	61.6	26.4	4.4	5.5	2.2
$0.1H_2O$	62.4	24.8	4.4	5.5	3.0
1PBS	63.4	23.1	4.1	5.9	3.5
0.1PBS	64.0	23.3	4.7	5.4	2.7
$1CH_3$	80.3 (90.9)	17.3 (0.0)	--	--	2.3 (9.1)
$0.1CH_3$	85.8	10.2	--	--	4.0

ing within the deeper layer of the SAM, implicating the thiolate (Au-S) was formed. The atomic percentages as well as the N/S and P/S ratios were all similar to each other. In addition, the N/S and P/S ratios were all greater than the theoretical ones (i.e. 1.0). This finding suggested that the PE SAMs formed were not quite ordered. The $–NH_3^+$ terminal ends can either be exposed at the surface or buried within the monolayer randomly.

Figure 3 depicted the N1s spectra, which can be curve-fitted into two peaks, $-NH_2$ (~399.8 eV) and NH_3^+ (~401.5 eV). The $–NH_2$ peak was resulted from the deprotonation of NH_3^+ during SAM formation stage or after washing steps. The amount of $–NH_2$ within the N1S peak is around 10-35%. This value, however, cannot be related to the ionization capability of the solvent used.

The S2p spectra shown in Figure 4 can be resolved into bound and unbound thiol centered at ~162 eV and 164 eV, respectively. In addition, peak representing oxidized sulfur ($-SO_x$, ~167.8 eV) was noted on the PE SAMs prepared from methanol at 0.1 mM and 1mM as well as that from ethanol at 1 mM. The notation of oxidized sulfur likely resulted from the oxidation of the –SH terminal ends that exposed to ambient environment due to the formation of bilayer structure through the ionic interactions between the

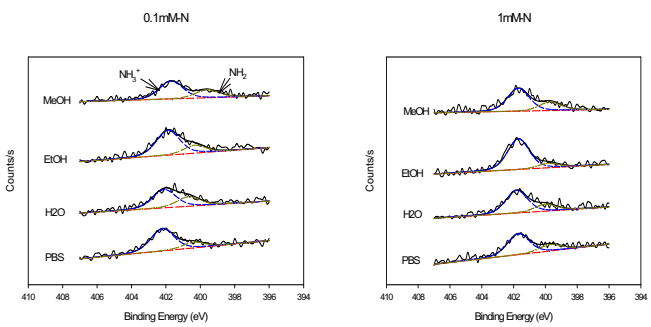

Fig. 3 XPS N1s spectra for PE SAMs prepared.

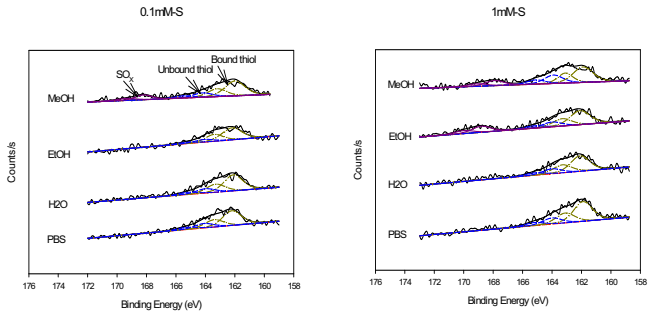

Fig. 4 XPS S2p spectra for PE SAMs prepared.

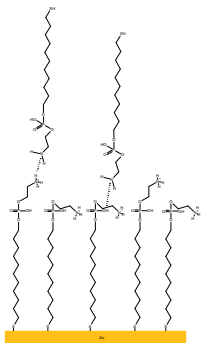

Fig. 5 Schematic representation of bilayer formation during PE SAM formation

ionic PE ends of adsorbed thiol and free one within the solution (Figure 5). In addition, the area ration for the unbound thiol was about 17-28%. These unbound thiols should be resulted from the steric hindrance as well as the hydrogen bonding and ionic interactions associated with the phosphorylethanolamine functionalities. In contrast, no unbound thiol and oxidized sulfur peak were noted on SAMs prepared from thiol with small $–CH_3$ terminal ends.

The morphology of adhered platelets on different PE SAMs, $-CH_3$ terminated SAM and non-treated gold control was shown in Figure 6. Generally, these PE SAMs can be classified into two categories: I. Significant activation and aggregation of platelets. This phenomenon was noted on 0.1MeOH, 1EtOH, $0.1H_2O$, $1H_2O$ and 0.1PBS samples. II. Slight activated platelets, sometimes, with pseudopod extension on surface. These samples include 1MeOH, 0.1EtOH and 1PBS. With same numerating procedure, the number of platelets adhered was shown in Figure 7. In combine of the two abovementioned observations for the platelets adhered, these PE SAMs exhibited better platelet-contacting property as compared to the $–CH_3$ terminated SAM and non-treated gold control, in which significant platelet activation (i.e. fully spreading platelets) was noted.

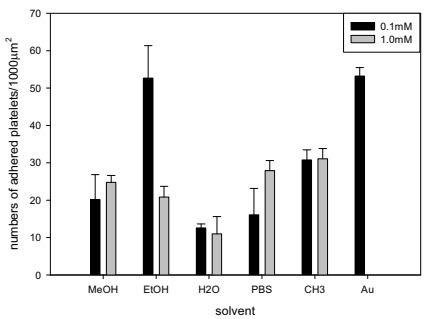

Fig. 7 Platelets adhesion density on various SAMs

IV. Conclusions

The surface properties and blood-contacting characteristics of the phospholipid-mimicking PE SAMs have been shown to be affected by the solvent and concentration used. The PE SAMs prepared were less platelet-activating than the methyl-terminated SAM ad non-treated gold control.

Surface Characterization and *In-vitro* Blood Compatibility Study of the Mixed Self-assembled Monolayers

C.H. Shen and J.C. Lin

Department of Chemical Engineering, National Cheng Kung University, Tainan, TAIWAN

Abstract — **Self assembled monolayer (SAM) of the long-chain alkanethiols ($HS(CH_2)_nX$, n=10) with variant terminal functionalities adsorbed on Au substrate can serve as a well-oriented surface with a broad range of chemical configuration for studying the blood-material interactions. The mixed SAM can be produced by adsorption from mixtures of two alkanethiols with different types of terminal groups and the complicated microstructures of this surface can be explored and tailored to mimic the physiological microenvironment associated with variant biological entities.**

In this study, two different mixed SAMs by mixing lab-synthesized sulfonic acid terminated alkanethiol, which carried heparin-like chemical structure, with the methyl terminated alkanethiol or hydroxyl terminated one were prepared. Surface characterization results showed that the contact angle was gradually decreased with the increase the solution mole fraction of $–SO_3H$ thiol ($\chi_{SO3H,soln}$) on $–SO_3H/-CH_3$ mixed SAMs. On $–SO_3H/-OH$ mixed SAMs the surfaces were hydrophilic. The surface composition of the $–SO_3H$ thiol ($\chi_{SO3H,surf}$) was analyzed by X-tray photoelectron spectroscopy (XPS) and the adsorption behavior of two mixed SAMs was all presented as "$-SO_3H$ poor". The surface charge was evaluated by streaming potential and the charge of these mixed SAMs was all negative in PBS (pH 7.4). *In vitro* platelet adhesion assay indicated that the amount of adhered platelets was similar on both mixed SAMs, except on the pure –OH SAM. The adhered platelets on $–SO_3H/-CH_3$ mixed SAMs were more activated than on $–SO_3H/-OH$ mixed SAMs. This finding suggested that the surface wettability and surface charge could affect the material's platelet compatibility synergistically.

Keywords — **alkanethiol, mixed SAMs, surface charge, platelet adhesion**

I. Introduction

Thrombus formation, induced by a series protein adsorption, and platelet adhesion and activation is still an obstacle for biomaterial scientists to develop a truly blood compatible synthetic materials [1]. Some factors noted in interfacial reactions between synthetic materials and biological environment can affect these materials' blood compatibility. Henceforth, to optimize the surface properties of the artificial biomaterials has become the major research theme.

Self-assembled monolayers technique can provide a densely packed, well-defined, and highly ordered surface [2]. Alkanethiol assembled on gold is widely used due to easy preparation and forms such a strong covalent bonding between the head group of sulfur atom and gold layers that it can be stable even in harsh environment. Among these applications, the long chain alkanethiol with variant functional groups adsorbed on Au substrates has been widely used to study the blood-material interactions [3-5]. But SAMs prepared by pure alkanethiol have some limitations because of the high surface density of specific functional ends as well as the likely steric hindrance effect caused by bulky terminal ends. Mixed SAMs composed two or more alkanethiols on gold may solve the problems. By modulating the solution mole fraction of the alkanethiol, chain length of the thiol and solvent, different physicochemical property of surfaces can be produced [6]. In this study, we prepared two different series of mixed SAMs, which composed the mixture of the sulfonic acid terminated alkanethiol with the methyl and the hydroxyl terminated one, respectively. Surface characterization and *in vitro* platelet adhesion test were evaluated to investigate the roles of surface microstructure related to platelet adhesion characteristics. In addition, the concentration of the mixture alkanethiol solution has been chosen as either 2mM or 0.1mM in order to analyze the likely "concentration" effect on the SAM packing quality.

II. Materials and Methods

A. Synthesis of 10-mercaptodecanesulfonic acid

The alkanethiol with $–SO_3H$ functional group was synthesized by the strategy illustrated in Figure1 [1]. The spectral data for identifying this structure was as follows: ^{1}H NMR(300 MHz,D_2O): δ1.25-1.33 (overlap, 13H), 1.5-1.57 (m, 2H), 1.64-1.69 (m, 2H), 2.44-2.49 (t, 2H), 2.78-2.83 (t, 2H).

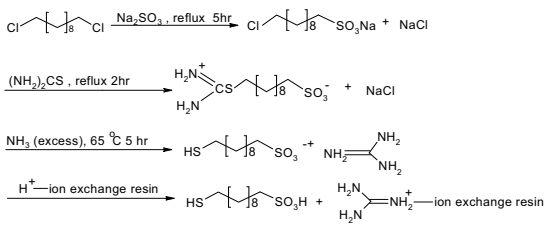

Fig. 1 Synthesis procedure of $–SO_3H$ terminated alkanethiol

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1418–1421, 2009
www.springerlink.com

B. Preparation of gold substrates and SAMs

The Si wafers was used as substrate for preparing SAM for contact angle experiments, X-ray photoelectron spectroscopy (XPS) and *in vitro* platelet adhesion analysis. The Si strips were cut in moderate size and were cleaned by immersion in piranha solution at 90°C for 2 hours. The surface was rinsed with a large amount of deionized water and absolute ethanol thoroughly and then blown dry with nitrogen. The gold substrates were prepared with thermal evaporator by pre-depositing Ti (100 Å, 1 Å/s) to improve the adhesion and then Au (1000 Å, 5 Å/s) was deposited onto Si strips. The fresh gold substrates were immediately immersed into two different series of mixed alkanethiol solutions, containing the mixture of the 10-mercaptodecanesulfonic acid with 1-dodecanthiol or with 11-mercapto-1-undecanol in absolute ethanol at room temperature for 24 hours. The total concentration of thiol solution was 2mM and 0.1mM. Upon removal, these strips were rinsed with absolute ethanol and deionized water and blown dry with nitrogen.

The mixed SAM formed on the cover glasses as substrates were used for zeta potential determination. The preparation of gold coated cover glasses and mixed SAMs was similar to that onto the Si strips mentioned above.

C. Surface characterization and in vitro platelet analysis

The contact angle measurement was carried out by sessile drop technique after the SAMs preparation and the probing liquid was deionized water. The surface composition of these mixed SAMs was characterized by XPS. Zeta potential measured by streaming potential technique was used to determine the surface charge of the mixed SAMs in PBS at pH 7.4. Human platelet–rich plasma (PRP, 3.5×10^{10} platelets/mL) was used for *in vitro* platelet adhesion assay. The experimental procedure is similar to our previous reported study [1].

III. Results and Discussion

A. Contact angle

The contact angle value of $-SO_3H/-CH_3$ mixed SAMs prepared from 2mM and 0.1mM as the function of solution mole fraction of the $-SO_3H$ terminated thiol ($\chi_{SO3H,soln}$) was shown in figure 2-(a). With the increase of $\chi_{SO3H,soln}$, the contact angle was gradually decreased. This was resulted from the increase of the $-SO_3H$ functional ends within the mixed SAMs. Furthermore because of the variations in surface assemblies at nano-scale the contact angle values of the $-SO_3H/-CH_3$ mixed SAMs prepared from 2mM were similar to those prepared from 0.1mM, except at $\chi_{SO3H,soln}$= 0.7 and 1.

For the $-SO_3H$/-OH mixed SAMs, the contact angle indicated that all surfaces were all hydrophilic. (Fig.2-(b)) In addition, the contact angle for the $-SO_3H$/-OH mixed SAMs prepared from 2mM was all lower than that of pure $-SO_3H$ SAMs ($\chi_{SO3H,soln}$ =1) and pure $-CH_3$ SAMs ($\chi_{SO3H,soln}$ =0), but for those prepared from 0.1 mM the contact angle was gradually decreased with the increase of $\chi_{SO3H,soln}$. Such phenomena were likely resulted form the hydrogen bonding or polar interactions among the hydrophilic ends of alkanethiol.

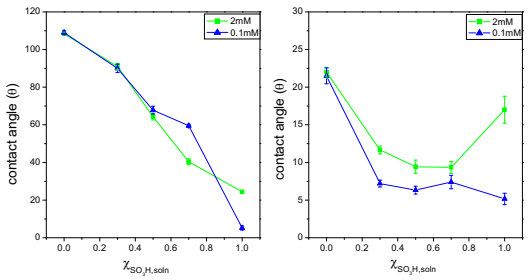

Fig. 2 The contact angle of (a) $-SO_3H/-CH_3$ mixed SAMs and (b) $-SO_3H$/-OH mixed SAMs prepared from 2 mM and 0.1 mM as the function of the mole fraction of $-SO_3H$ thiol in the ethanolic solution.

B. XPS

The surface composition determination of these two series of mixed SAMs was carried out by XPS. The relationship between surface composition of the $-SO_3H$ SAMs and solution mole fraction of the $-SO_3H$ terminated thiol was presented in Figure 3. All of these mixed SAMs showed "negative derivation" (i.e. below the 45° diagonal line) and indicated that they were "$-SO_3H$ alkanethiol poor" on these SAMs. It was likely due to the differences in solvation capability of the alkanethiol within the ethanolic solution. A higher solubility of the $-SO_3H$ terminated thiol than the $-CH_3$ terminated thiol and the –OH terminated one was suggested. Therefore, the variations in adsorption rate and thiolate formation rate might result in this observation.

C. Zeta potential

Because the surface charge of these mixed SAMs couldn't be directly measured, it was represented by the zeta potential, which was the charge on the shear plane. The electrolyte solution was chosen as PBS at pH 7.4 because of the close similarity to the body fluid.

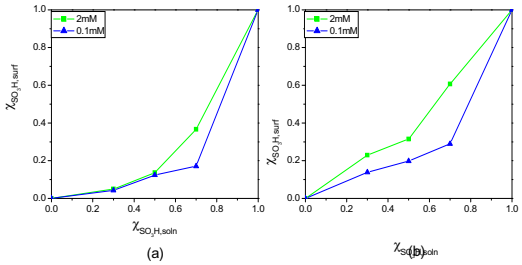

Fig. 3 Surface composition *vs* solution composition of the (a) $–SO_3H/-CH_3$ and (b) $–SO_3H/-OH$ mixed SAMs.

The zeta potential of $–SO_3H/-CH_3$ mixed SAMs in PBS at pH 7.4 as prepared form 2mM and 0.1mM with various $\chi_{SO3H,soln}$ was shown in Figure 4. The zeta potential of all these mixed SAMs was negative. On the apolar surface without dissociated sites, like pure $–CH_3$ SAMs, the negative surface charge might be resulted from the highly oriented water molecules near the surfaces and this structure makes anions preferentially adsorbed. [7-8] The zeta potential of the $–SO_3H$ SAMs was negative in PBS at pH 7.4 because sulfonic acid functionality was a strongly dissociated acid group at this pH.

Statistical analysis using ANOVA (analysis of variance) and Tukey method revealed that the zeta potential of $\chi_{SO3H,soln}$ =0 (pure $–CH_3$ SAMs) was similar to $\chi_{SO3H,soln}$ =1 (pure $–SO_3H$ SAMs), but was significantly more negative than others as prepared from 2mM mixture solution.

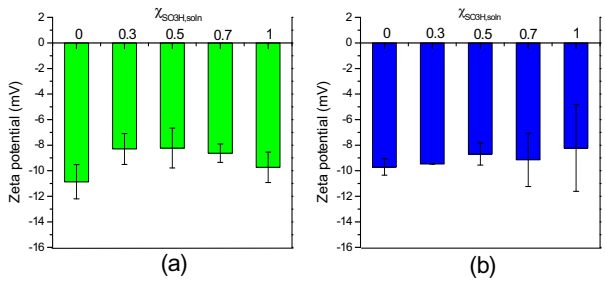

Fig. 4 The zeta potential of $-SO_3H/-CH_3$ mixed SAMs prepared from (a) 2 mM and (b) 0.1mM as the function of the mole fraction of $–SO_3H$ thiol in the ethanolic solution as determined in PBS pH 7.4.

Figure5 showed the zeta potential of the $–SO_3H/-OH$ mixed SAMs prepared from 2mM and 0.1mM in PBS at pH 7.4. The zeta potential of these mixed SAMs was also negative. Since the –OH functionality was polar but not dissociated in PBS at pH 7.4, the negative zeta potential might be caused by the preferentially anions adsorption. As compared to the apolar hydrophobic pure $–CH_3$ SAM, less negative surface charge on pure –OH SAM was noted. It was due to the loosely ordered water molecules near surfaces that resulted in less anions adsorbed.

As determined from the statistical analysis, $\chi_{SO3H,soln}$ =0 (pure –OH SAMs) has less negative zeta potential than others which contained $–SO_3H$ terminated alkanethiol for SAMs prepared from all concentrations. However, the negative charge didn't varied significantly with the amount of $–SO_3H$ terminated thiol added in the solution.

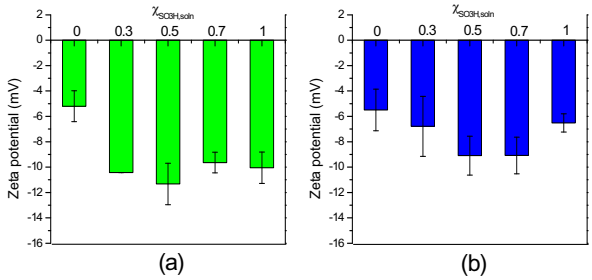

Fig. 5 The zeta potential of $-SO_3H/-OH$ mixed SAMs prepared from (a) 2 mM and (b) 0.1mM as the function of the mole fraction of $–SO_3H$ thiol in the ethanolic solution as determined in PBS pH 7.4.

D. In vitro platelet adhesion analysis

The platelet adhesion density on $–SO_3H/-CH_3$ mixed SAMs prepared from 2mM and 0.1mM is shown in Figure6. By statistical analysis with ANOVA and Tukey methods, pure $–CH_3$ SAMs ($\chi_{SO3H,soln}$ =0) exhibited the highest platelet adhesion density while others showed similar adhesion platelet density among each other. Moreover the adherent platelets on $\chi_{SO3H,soln}$ =0 was highly activated but with the increase of the $\chi_{SO3H,soln}$, the platelets adhered were less activated.

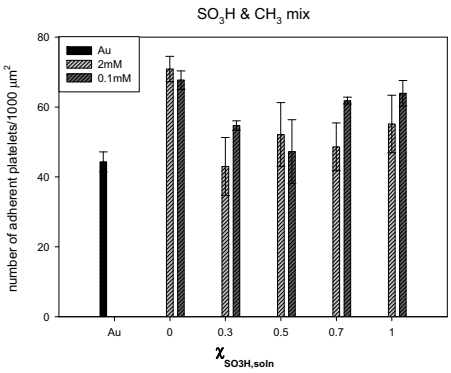

Fig. 6 Number of adherent platelets on $–SO_3H/-CH_3$ mixed SAMs prepared from 2mM and 0.1mM.

Figure 7 showed the platelet adhesion density on –SO_3H/-OH mixed SAMs prepared from 2mM and 0.1mM. In contrast to the –SO_3H/-CH_3 system, statistical analyses revealed that the –OH SAMs ($\chi_{SO3H,soln}$ =0) adhered the least amount of platelets. For other mixed SAMs, the platelet adhesion density was similar to each other. Moreover, SEM analyses have shown that the platelets adhered on –SO_3H/-OH mixed SAMs was less activated.

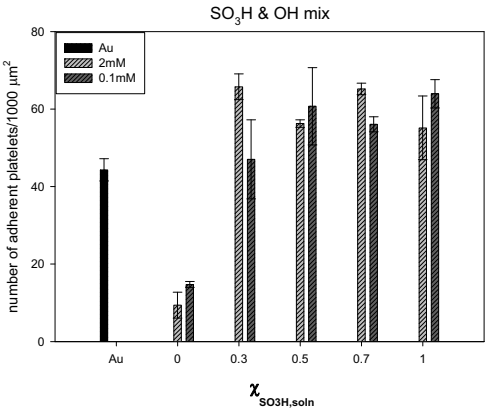

Fig. 7 Number of adherent platelets on –SO_3H/-OH mixed SAMs prepared from 2mM and 0.1mM.

IV. Conclusions

In this study, the surface properties and platelet-contacting properties of two different mixed SAMs series were examined. The surface wettabilities of –SO_3H/-CH_3 mixed SAMs varied from hydrophobic to hydrophilic with the increase of $\chi_{SO3H,soln}$ while all surfaces were hydrophilic on –SO_3H/-OH mixed SAMs. XPS results revealed that –SO_3H/-CH_3 mixed SAMs and –SO_3H/-OH ones were "-SO_3H alkanethiol poor" during SAM formation. All of the surface charge of these two mixed SAMs was negative in PBS pH 7.4 and the pure –OH terminated SAM was the least negative surface charged among the samples tested. *In vitro* platelet adhesion assay indicated that these two mixed SAMs exhibited similar amount of platelets adhered except for pure –CH_3 (the highest platelet adhesion density) and –OH (the lowest platelet adhesion density) terminated SAMs. Therefore the less negative surface charge might lead to the fewer platelets adhered, likely due to the differences in the amount of protein adsorbed as well as the variation in its conformation after adsorption.

Microscale Visualization of Erythrocyte Deformation by Colliding with a Rigid Surface Using a High-Speed Impinging Jet

Abstract — **Erythrocyte deformation by colliding with a rigid surface using a high-speed impinging jet was studied with microfluidic techniques. We aim to investigate the relevance of colliding erythrocytes with hemolysis. A micro-channel chip was made of polydimenthyl-siloxane (PDMS), which comprised a T- and Y-shaped junction with a micro-nozzle and diffuser in order to attain a high-speed microflow with a jet velocity of m/s scale. A high-speed camera with a microscope imaged colliding erythrocytes by shadow imaging. Porcine erythrocyte with a hematocrit of 0.5 % in phosphate buffer saline was utilized. At the Y-junction, erythrocytes showed buckling due to an impulsive, longitudinal, compressive deformation. Such anomalous phenomena were not detected at the T-junction, where erythrocytes underwent sequential compressions as approaching the colliding surface. Erythrocyte after buckling showed a hazy membrane while being released from the colliding surface, suggesting the ejection of hemoglobin out of the pore on a membrane. Flow-induced hemolysis has been considered as a model of viscous shear stress and exposure time. From our data, however, it was suggested that hemolysis due to a high-speed impinging flow characterized by mechanical heart valve flows may arise as an impulsive failure of erythrocyte membrane upon collision.**

Keywords — **Hemolysis, erythrocyte, microfluidics, heart valve, turbulence**

I. Introduction

Prosthetic mechanical heart valves require a mandatory drug therapy including anticoagulation. Blood cell damage, such as hemolysis and platelet activation, is one of the relating phenomena. Such damage can be observed by shearing flows in a rotating viscometer and a turbulent jet [1-5]. Likewise, blood flow in mechanical heart valves is widely accepted to promote damage of flowing cells, but the underlying phenomena remain to be fully understood due to the complexity of actual flows. Indeed, a number of studies revealed abnormal streams characterized by transient high shear, turbulence, squeezing flow and cavitation [6-9]. These flows require verifications in a cellular scale to elucidate their anomaly with the relevance of blood cell damage.

We propose a new challenge termed *macroscale modeling and microscale verification*. From our previous study of macroscale modeling [10], we hypothesize that turbulence promotes an impinging flow, which then causes the collision of erythrocytes. The similar knowledge can be applied to valve closure, where erythrocytes impulsively collide with a rigid leaflet upon closure. Herein we aim to investigate such an erythrocyte deformation upon collision using high-speed microfluidic techniques in order to verify the involvement of impinging flows with hemolysis.

II. Method

The overview of an experimental setup is shown in Fig.1. A micro-channel was set on a linear stage. A flow was driven by a syringe pump (SP-70, NIPRO Corp., Japan). An imaging system comprised a high-speed camera (FASTCAM-1024PCI, Photron, Japan) and a metal halide lump. The camera was equipped with a zooming microscope (DZ-3, Union Optical Co., Ltd., Japan). The light source was aligned as shadow imaging. Experiments were made in a temperature-controlled box at 37 degrees.

A micro-channel geometry was shown in Fig.2. These channels were fabricated by polydimenthyl-siloxane (PDMS). In order to attain microscale high-speed flows, channels had a micro-nozzle and diffuser at the upstream and downstream of a test section, respectively. A flow rate was set at 18 and 36 mL/h to make a desired flow condition, in the T- and Y- shaped channel, so that a bulk jet velocity at the nozzle outlet could reach 1 m/s in both channels.

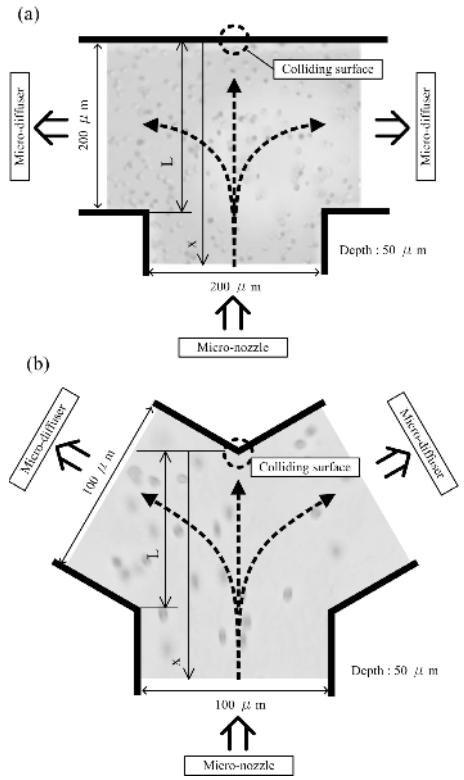

Fig. 2 Schema of micro-channels with a T- and Y-shaped junction

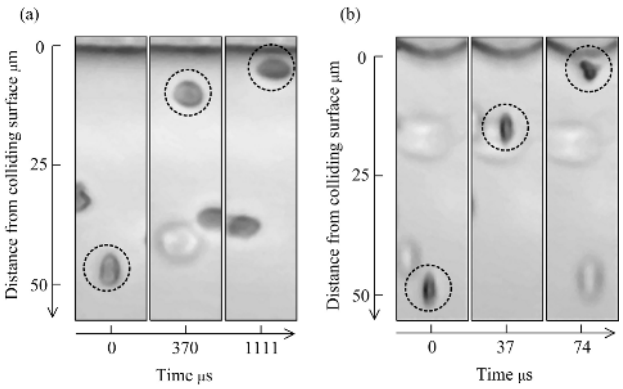

Fig. 3 Erythrocyte deformation upon collision at a T- and Y- shaped junction (a,b)

Fresh porcine blood was collected and was immediately centrifuged at 1000 g for 5 min. The plasma and buffy coat containing white blood cells and platelets were removed, and erythrocytes were washed three times in phosphate buffer saline (PBS). Porcine serum albumin (Sigma Aldrich, U.S.A.) was added at a concentration of 5.5×10^{-2} [g/dL]. A hematocrit was adjusted to be 0.5 % by suspending erythrocytes in the PBS solution.

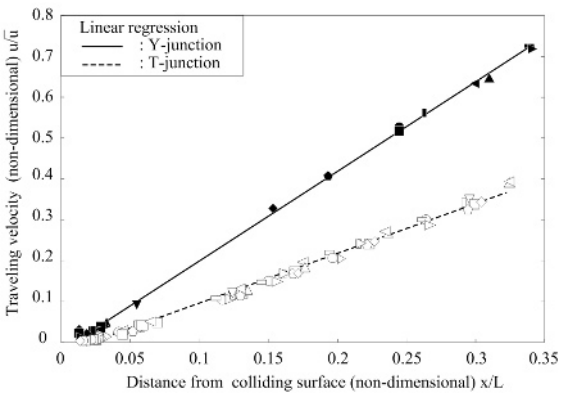

Fig. 4 Traveling velocity of erythrocytes in the vicinity of a colliding surface

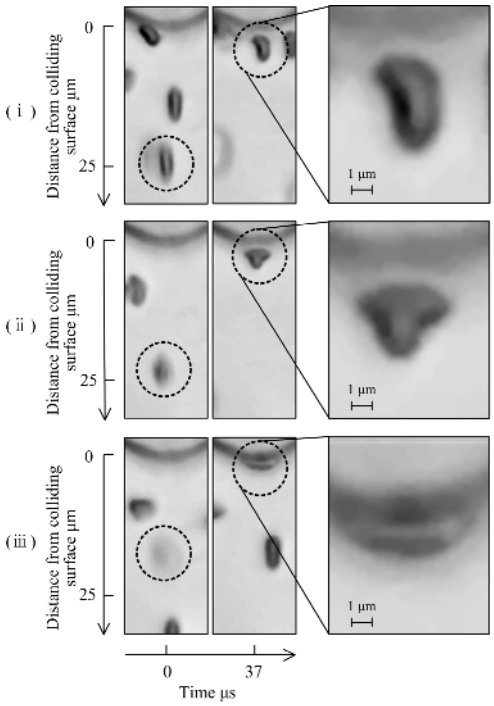

Fig. 5 Characteristic deformation of erythrocyte upon collision at a Y-junction

III. Results and Discussion

A. Comparison of colliding erythrocytes between T- and Y-shaped channels

We first compared the deformation pattern of erythrocytes upon collision between T- and Y-shaped junctions (Fig.3 (a), (b)). We limit herein ourselves to describe the erythrocytes that collided with a surface at a test section (Fig.2). Other erythrocytes appearing in Fig.3 were those

disappeared without collision. In the T-junction, flowing erythrocytes were elongated at a far field from a colliding surface, became spherical as approaching the surface, and were laterally deformed in the vicinity of the surface. The lateral deformation, though affected by rotating effects, indicated a compression of erythrocyte upon collision.

On the other hand, colliding erythrocytes in the Y-junction showed an impulsive deformation (Fig.3(b)). The erythrocytes maintained their elongated shapes further as they approach the colliding surface, and then they abruptly altered the shapes upon collision without showing a sequential deformation seen in the T-junction. These include impulsive bending and buckling as characterized by the longitudinal deformation unlike lateral one in the T-junction, and will be detailed later. Here, the varying collision dynamics between T- and Y-shaped junction is considered. Fig.4 shows the traveling velocity of erythrocytes. The velocity was non-dimensionalized using a bulk flow velocity at the outlet of the micronozzle (1 m/s). The velocity plot in the Y-junction showed the greater deceleration. The corresponding slope was about 1.8 times higher. These velocity differences attributed to varying degrees of stagnation. It was believed that the T-junction had a blunt pressure field, whereas the Y-junction had a sharp field. As a result, erythrocytes at the Y-junciton maintained the higher speed towards the colliding surface, resulting in the impulsive, longitudinal and compressive deformation upon collision.

B. Buckling of erythrocytes upon collision

At a Y-junction, we observed some abnormal erythrocytes at the same flow conditions. Fig.5 summarized their characteristics; (i) and (ii) show a significant bending upon impingement, and (iii) was similar to that observed in a T-junction. The impulsive bending of erythrocytes indicated that erythrocytes underwent buckling due to an impulsive longitudinal compression. Furthermore, such erythrocytes often showed a hazy membrane while being released out of the collision (Fig.6). These anomalous phenomena may indicate the ejection of hemoglobin out of the membrane pore, as illustrated in Fig.7. These locations more likely corresponded to a stretched part of membrane, rather than bending. It was suggested that the erythrocyte membrane received an impulsive stress with a structural instability upon buckling and this phenomenon resulted in the pore formation. Such impulsive phenomena have not been observed at a T-junction, suggesting the geometrical significance of the colliding surface.

IV. Conclusions

The present study utilized high-speed microfluidic techniques to study colliding erythrocytes on a rigid surface. A Y-shaped junction caused the buckling of erythrocytes due

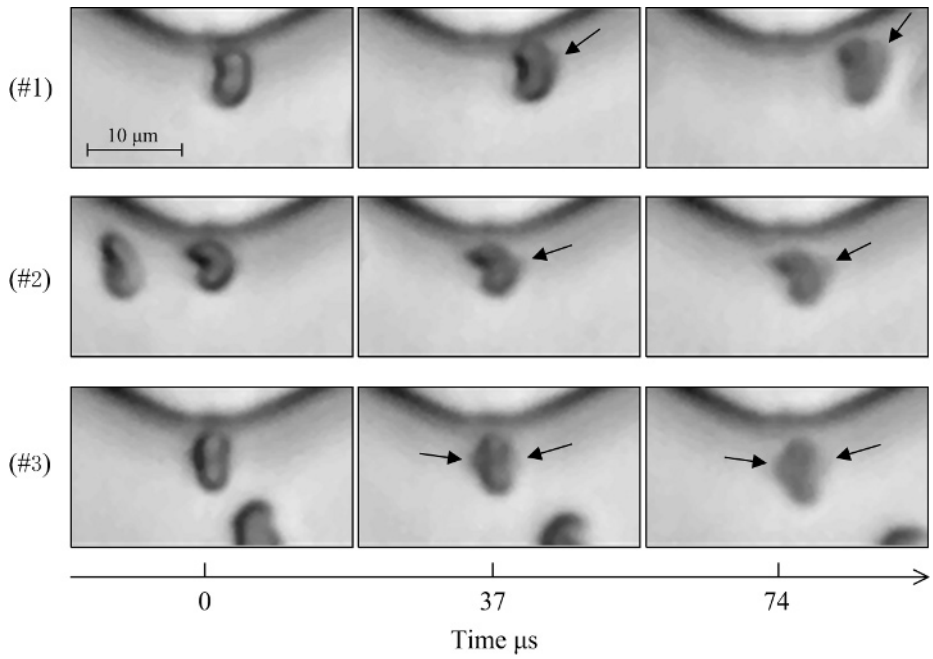

Fig. 6 Anomalous erythrocytes after undergoing buckling.
A hazy membrane indicated by an arrow suggests hemoglobin released out of erythrocyte membrane.

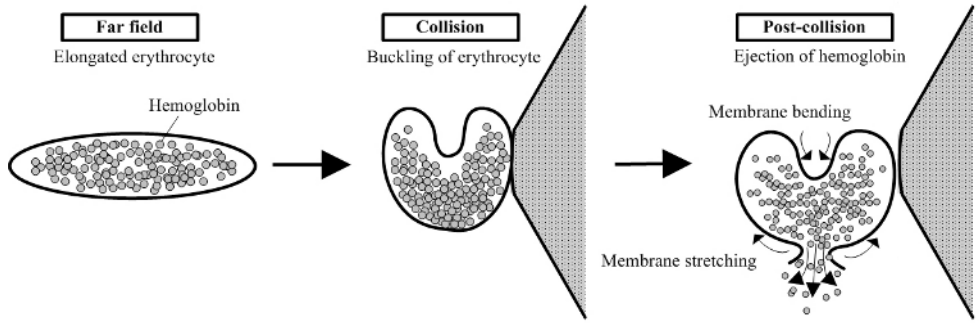

Fig. 7 Model of erythrocyte deformation by colliding with a Y-shaped junction

to an impulsive, longitudinal, and compressive force upon collision. Anomalous erythrocytes included those showed a hazy membrane at a post-collision phase, suggesting the ejection of hemoglobin from a membrane pore. These results deserve further microscale verifications of impinging flows with the relevance of hemolysis. Particularly, the effect of hematocrit is of prime importance. Actual valve flows were all transient with a velocity scale reaching a few m/s, where impinging flows further elevate an impulsive force upon collision according to our previous study of macroscale modeling. Conventionally, flow-induced hemolysis has been considered as a model of viscous shear stress and exposure time. From our data, however, it was suggested that hemolysis in actual valve flows may arise rather instantaneously as an impulsive failure of erythrocyte membrane upon collision.

Abstract — **A miniaturized video camera system integrated with a scaffold for blood vessels and tissue induction that is implantable into an animal body was developed. A small auto-focus camera with USB interface was used as an imaging device. A close-up lens was added to reduce the focusing point. Also 45-degree reflecting prism was added for the compact system design. A spongy polyglycolic acid sheet of 0.3 mm thickness was used as a scaffold. The observation area was about 8 x 6 mm and the tissue was induced from sideways. The camera was implanted into a muscular layer of a goat for more than 60 days to observe the skeletal muscle induction. Tissue induction to the scaffold started from second week and it took about 5 weeks to cover the entire area by the tissue, Vigorous angiogenesis was observed at the front region of tissue induction resulting dense distribution of capillary vessels and red blood cells. The density of capillary vessels reduced considerably behind the front region and arterioles and venules started to appear.**

Keywords — **Implantable microscope, Angiogenesis, Tissue regeneration**

I. Introduction

Recent progress in biotechnology is astonishingly successful. Not only one can predict the various disease risks from gene diagnosis, one may even create genetically identical individuals from stem cells. From the viewpoint of regenerative medicine, however, the success is limited. One can create many square meters of skin by cultivating epidermal cells for several weeks. Or one can create a cardiac muscle cell sheet, which beat spontaneously. But we are not successful in generating an entire heart or any other functioning organs for regenerative medicine. The cultivation is limited to a two-dimensional structure with a single cell species. The most of human organs are of three-dimensional structure with several cell species. Two major obstacles hampered the artificial generation of three-dimensional functioning organs;

1. One has to supply nutrients and oxygen to cells deep inside the structure.
2. Plural cell species have to be cultivated in a harmonized manner to achieve the desired function.

In naturally formed organs, the blood cells and vessels supply nutrients and oxygen. Angiogenesis or vessel formation could be a crucial process for the 3-D structure formation. We are hoping that the observation of structure formation, in vivo, provide crucial information for the artificial realization of functioning organs. So, we were small and were high resolution and developed implantable microscope camera system.

II. Experimental Method

A. System design

Figure 1 shows a cross-section of the camera system. A small CMOS camera (Hitachi Maxell, PM7, Tokyo, Japan) with USB interface is used as an imaging device. The imaging device that has 1.3 mega pixels and has 1/3-inch CMOS sensor was mounted on a printed circuit board together with the auto-focus lens was taken out from original case and used. Extra close-up lenses were added to shorten the focal length. Further 45-degree prism was inserted to reduce the

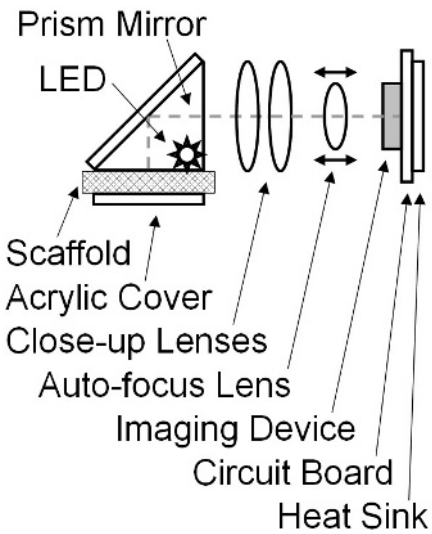

Fig. 1 Cross-section of the camera system

www.springerlink.com

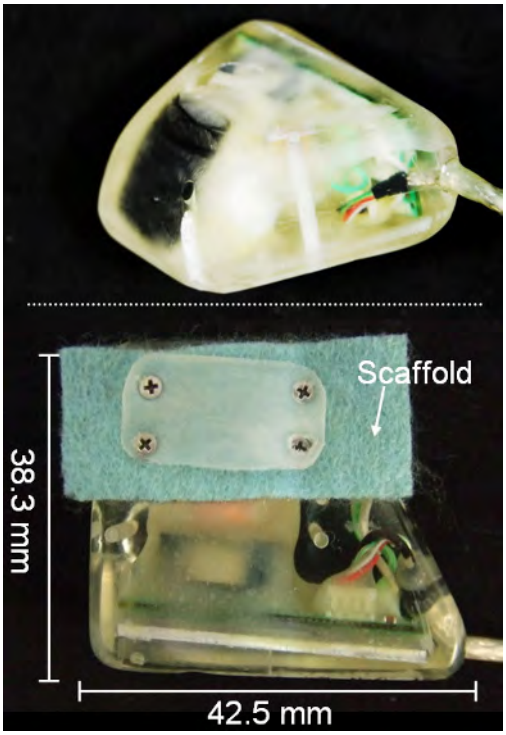

Fig. 2 The camera system with a scaffold sheet

system size. And this design, the device can be implanted with out stress. A scaffold sheet was directly attached to the bottom of the prism. The scaffold is made of poly glycol acid (PGA: Gunze, NV-N-015N, Kyoto, Japan), and the hickness is 0.3mm. The scaffold type and thickness were selected by basic research. A white-color LED device (Nichia-kagaku, NSPW500BS, Tokushima, Japan) was placed at the side of the prism for scaffold illumination. Entire system except the scaffold was embedded in transparent medical epoxy resin and the camera system can be implanted into an animal body. The scaffold at the bottom of the prism is sandwiched with an acrylic plate, so the cells can be induced from the sides. Figure 2 shows the picture taken from the bottom. This system is small (W 42.5mm x D38.3mm x H18mm) enough to implant. This system can record high resolution picture (1280 x 1024 pixels: SXGA) and movie (1280 x 1024 : 15fps, 640 x 480 : 30fps).

B. Animal experiment

We implanted the camera system into an animal and observed vessel generation and tissue induction process. We used the goat (female, ~50kg) as experimental animals. We implanted the system between the skeletal muscle (latissimus dorsi) and skin at the side of the body. Figure 3 shows implantation of camera system on the muscle.

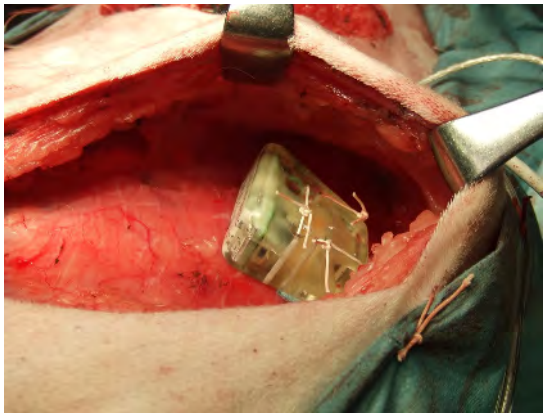

Fig. 3 Operation of camera system on the muscle

We record the picture (1280 x 1024 pixels) every 30 minuets with a personal computer. The camera system was connected to the PC by USB2.0 interface. This experiment was continued for nine weeks.

C. Tissue Extraction

At the end of experiment, camera system and regenerated tissue were extracted from the body. The tissue was stained with hematoxylin eosin for histological analysis.

III. Result and Discussion

A. Regenerating pictures

We implanted the device into the goat and we observed regenerating tissues and vessels.

Figure 4A-D shows regenerating pictures by the camera system for 6weeks. No induction was observed under the camera view for the 2 weeks. We observed at initial stage, the blue section is a scaffold.

The tissue induction in the camera view was started in the third week (Figure 4-A). We observed scaffold almost all camera view and we observed many small capillary at the right and left side in the view.

Figure 4-B shows result at 4th week. Vessels and tissue were regenerating from last week. At front section have many capillary, and at the rear section, capillary disappered, and have some big vessels.

Figure 4-C shows result at 5th week. Most scaffolds were hydrolyzed. Regenerated tissue from both sides were growing and connecting at the centre of the camera view. At front regenerating section have many capillary. At middle regenerated section have some vessels branched from big vessels. At rear section the density of capillary vessels were reduced.

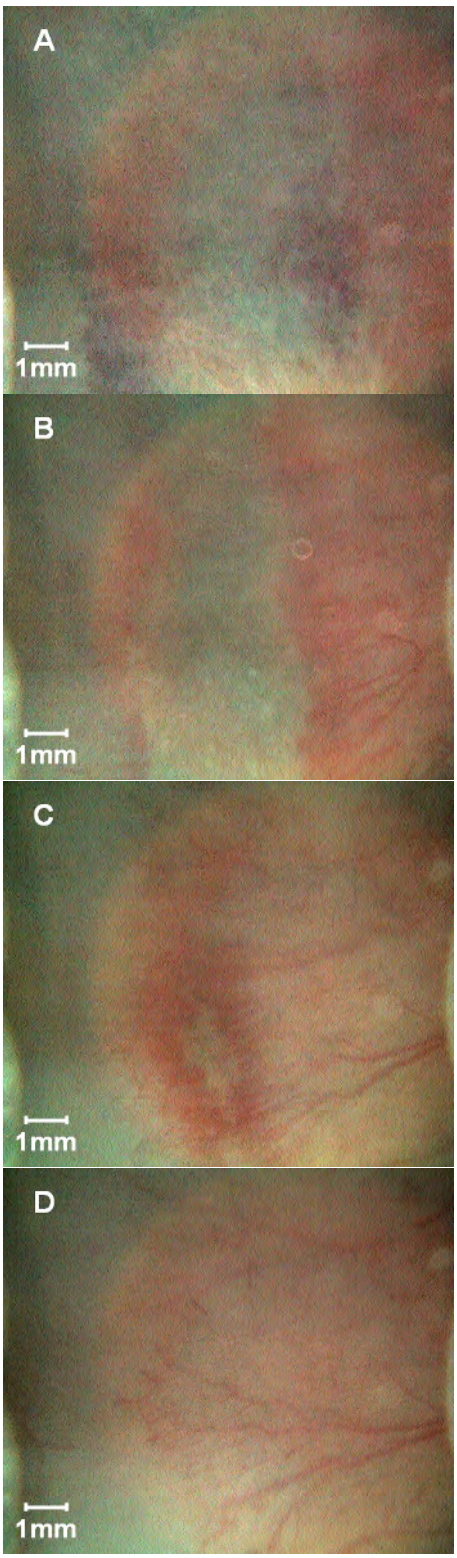

Fig. 4 Regenerating vessels and tissues pictures (A - D)

Figure 4-D shows result at 6th week. The blood vessels and tissue have covered on the whole camera view. Growth rate was within the range of 0.15-0.20mm/day through the whole experiment.

After the 6th week, the camera view did not have big change. We continued this experiment for nine weeks.

B. Tissue extraction

At the end of experiment, camera and regenerated tissues were extracted from the body. And the tissue was stained with hematoxylin and eosin for histological analysis.

Figure 5 shows the generated tissue which it sliced in parallel to the PGA scaffold plane. We observed the small vessels branched from large vessel. With higher magnification, we observed red blood cells in the vessels. We were not able to observe the PGA scaffold any where, because it was hydrolyzed.

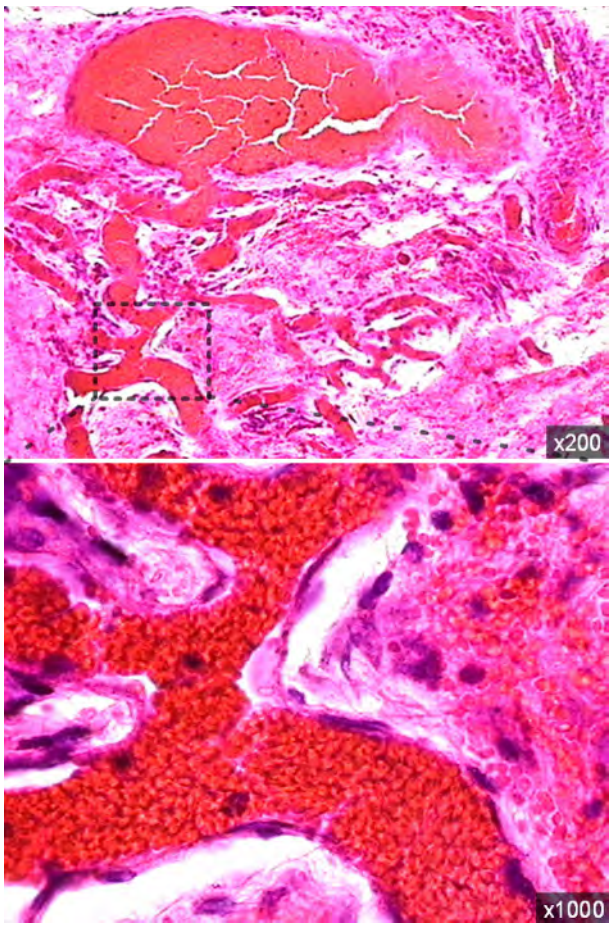

Fig. 5 H.E. stained generated tissue (Parallel slice)

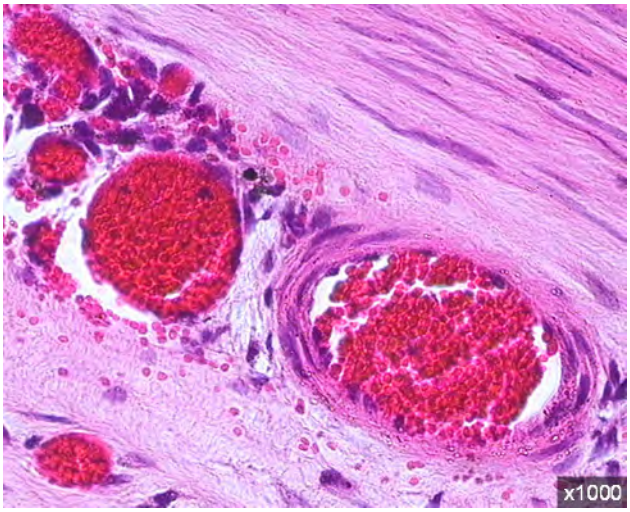

Fig. 6 H.E. stained generated tissue (Vertically slice)

Figure 6 shows the generated tissue which it sliced in vertically to the PGA scaffold plane. We observed cross sections of several vessels. We observed small artery which have thick wall. And we observed veins beside the artery.

IV. Conclusions

We developed the implantable small camera with scaffold for tissue and vessels induction observation. The device is small enough to implant. And the device had high resolution and function so as to observe regenerated tissue.

We observed blood vessels when 2weeks after an experiment start. Many blood vessels were observed at front section of new tissue. Almost all capillaries were disappeared at rear section where growth rate decreased, but arterioles and venules were generated. At the 6th weeks the generated tissues have covered on the whole camera view. Exchange of interconnection points among arterioles were observed. Hierarchical branchings of vessels were frequently observed.

At end of an experiment, we dyed generated tissues with H.E. staining. We observed active generation of capillaries at the front section. And we observed small artery and small vein.

We developed the real-time observation device. In future, we will intend to continue experiment with this device.

New challenge for studying flow-induced blood damage: macroscale modeling and microscale verification

T. Yagi[1,2], S. Wakasa[1], N. Tokunaga[1], Y. Akimoto[1], T. Akutsu[3], K. Iwasaki[4], M. Umezu[1]

Abstract — **Prosthetic heart valves often induce blood cell trauma, but its mechanism is not clearly understood due to the complexity of dynamical flows. We herein propose a new challenge, termed *macroscale modeling and microscale verification.* This report is the former, and here we aim to clarify the physical interpretation of Reynolds stress for flowing cells. One polymer and two mechanical valves are compared, and the Reynolds stress is visualized using a novel analytical technique including time-resolved particle image velocimetry and continuous wavelet transform. The method enables to analyze the dynamics of Reynolds stress in a spatial and temporal domain. As a result, it is found that the Reynolds stress should be considered as an indicator of impinging flows for circulating cells. Such flows may impulsively apply a colliding force on a membrane of flowing cells. As microscale verification based on this new hypothesis, we are currently investigating such collision phenomena of flowing cells using high-speed microfluidic techniques.**

Keywords — **turbulence, hemolysis, heart valve, collision, impinging flow**

I. Introduction

Prosthetic heart valves often require a mandatory drug therapy including anticoagulation. Blood damage, such as hemolysis and platelet activation, is one of the underlying phenomena. Such damage can be observed in controlled flows, such as shearing flows and turbulent jets [1-3]. However, actual flows are dynamically complex including transient high shear, turbulence, squeezing flow, hinge flow and cavitation [4-7]. Currently, understanding a mechanism of causing blood trauma in dynamical flows is still immature. These aspects indicate the necessity of *verifying* the anomaly of flows in a cellular scale in an effort to detect the most critical phenomenon for blood trauma. Here, we propose a new challenge termed *macroscale modeling and microscale verification*. This study is the former, and herein we aim to make a physical model of turbulence for flowing cells. Reynolds stress has been used as an indicator of turbulence, but it is also known as apparent stress in fluid dynamics. Due to the limitation of classical fluid dynamics, the physical interpretation of Reynolds stress for flowing cells remains controversial [8-9], which is of prime interest in modeling turbulence in a cell scale and verifying the relevance with blood cell damage.

II. Method

We made a pulsatile flow circuit to reproduce a physiological aortic flow at a pump outlet (Fig.1). A working fluid consisted of glycerol and water with a volume fraction of 44 and 56 %, respectively. And its kinematic viscosity and density was ν=3.3 cSt and ρ=1100 Kg/m^3 at room temperature. The flow had a 5L/min mean rate and 80-120 mmHg pressure variation at a pulse rate of 70 bpm. Reynolds number and Womersley parameter was approximately 1600 and 14.9, respectively. The Jellyfish polymer valve (JF), the St. Jude Medical bileaflet valve (SJM), and the Medtronic Hall

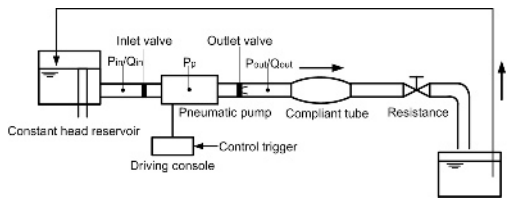

Fig.1 Schema of experimental rig

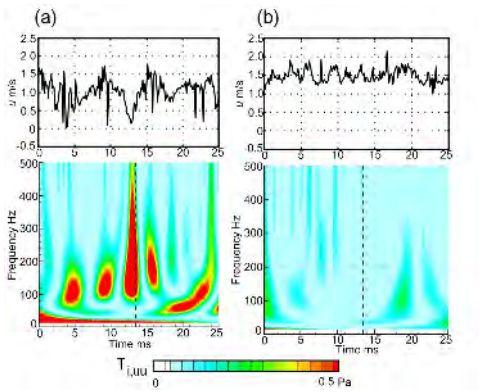

Fig.2 Continuous wavelet transform of turbulent jet in a prosthetic heart valve (a: shear layer, b: downstream)

www.springerlink.com

monoleaflet valve (MD) were compared, and their flows were quantitatively visualized using Time-resolved 2D Particle Image Velocimetry (TR-PIV). A 1.5 mm-thick laser light sheet was symmetrically aligned passing through a valve center. Temporal and spatial resolution of TR-PIV was 7400 Hz and 0.64×0.64 mm^2, respectively.

Then, continuous wavelet transform was made using the following equation,

$$T(a,b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} u(t)\psi^*\left(\frac{t-b}{a}\right)dt \quad (1)$$

where T denotes wavelet coefficient, $u(t)$ is a velocity signal as a function of time, and ψ^* is a complex conjugate of a wavelet function. In this study, the streamwise velocity was selected. Parameters a and b indicate scaling in dilating and translating the wavelet function, respectively. $1/\sqrt{a}$ is a weighting function. The wavelet coefficient was computed using the Mexican hat wavelet,

$$\psi(t) = \frac{2}{\sqrt{3}\sqrt[4]{\pi}}(1-t^2)e^{-t^2/2} \quad (2)$$

and its admissibility constant C_g is equal to $4\sqrt{\pi}/3$ [10]. A wavelet turbulent spectrum was calculated using the following formula,

$$\tau_i(f,t) = \frac{\rho}{\Delta f_c C_g}\left|T(f,t)\right|^2 \quad [\text{Pa}] \quad (3)$$

where Δ is a sampling period and f_c is a characteristic frequency of the wavelet (f_c=0.251Hz) [10]. A wavelet frequency is defined as follows.

$$f = \frac{f_c}{a \cdot \Delta} \quad (4)$$

Note that if the wavelet spectrum is integrated over time and frequency, it becomes equal to the magnitude of conventional Reynolds stress. Fig.2 illustrates examples for better understanding. Times-resolved velocity series were transformed to a time-frequency domain, where the color contour corresponded to the magnitude of turbulent spectrum, namely *instantaneous Reynolds stress*. All above computations were carried out using an in-house MATLAB code.

III. Results and Disucussion

A. Reynolds stress during systole

Fig.3 compares mid-systolic flows. Wavelet transform was carried out for time-resolved 2D velocity data sets, and the stress field was colored by representing the magnitude at

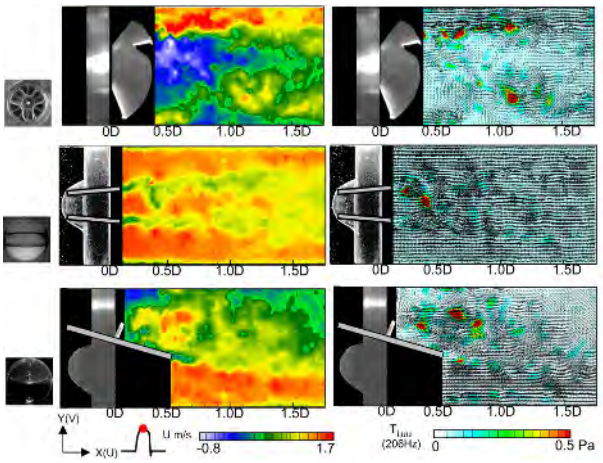

Fig.3 Instantaneous velocity field (left) and Reynolds stress (right) during peak phase (top: JF, mid: SJM, bottom: MD)

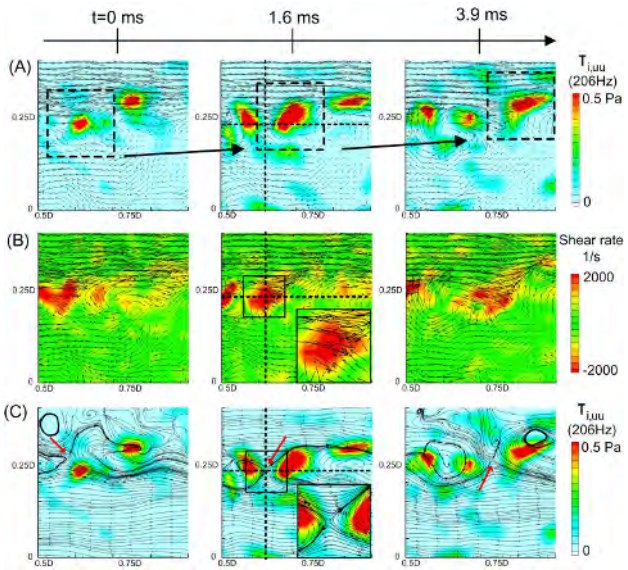

Fig.4 Dynamics of turbulent cell in a shear layer (A: Reynolds stress, B: Shear rate, C: Streamline). Streamlines were obtained in a relative coordinate by subtracting the traveling speed of the turbulent cell. Dotted-line squares showed incipient, growinges by tracking a single cell, and solid-line squares corresponded to zoomed views of colliding surface as indicated by red-colored arrows.

a frequency of 206 Hz. This stress mapping enabled to visualize the dynamic motions of Reynolds stress in a spatial and temporal domain. The Reynolds stress emerged in a mixing process of varying magnitude of momentum, which was observed along with shear layers and at the downstream of expanding flows. Fig.4 illustrates a spatio-temporally evolving Reynolds stress along with the shear layer. The Reynolds stress begun to be spatially organized (t=0), grew by entraining the ambient fluid (t=1.6 ms), and elongated its

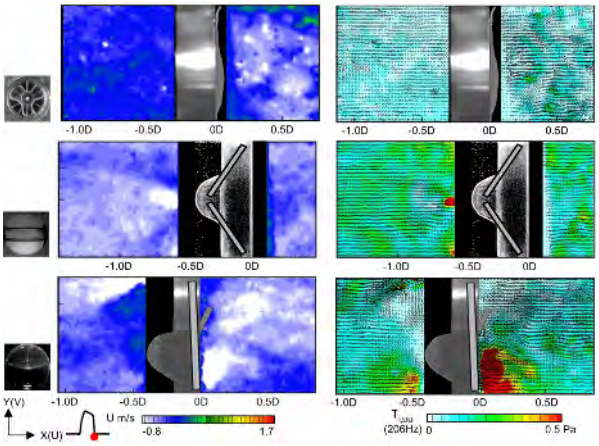

Fig.5 Instantaneous velocity field (left) and Reynolds stress (right) immediately before valve closure (top: JF, mid: SJM, bottom: MD)

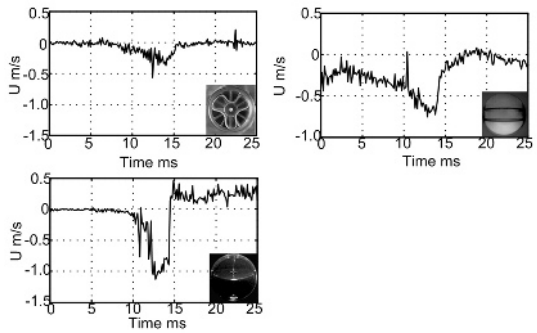

Fig.6 Streamwise velocity profile upon valve closure. The value was represented in the vicinity of a closing leaflet. A spike-like signal indicated an impact of valve closure.

structure (t=3.9 ms). In the further downstream, the Reynolds stress was decayed and finally disappeared by diffusing. This spatially organized pattern of Reynolds stress is termed *Turbulent cell (T-cell)*. Interestingly, while the T-cell traveled downstream with a certain speed, it was followed by a cluster of shear rate (Fig.4). In order to understand their relationship, streamlines were obtained in a relative coordinate, where the velocity in a fixed coordinate was subtracted by the traveling speed of the T-cell (see Section C). Then, we found that streamlines from the upstream and downstream were collided within the shear cluster. In other words, the incoming jet impinged with the T-cell because the traveling speed of T-cell was substantially smaller than the convective jet velocity. Since the T-cell grew by entraining the ambient weak flow, this impinging flow was observed with a large velocity fluctuation, such as seen in Fig.2 (a), which is exactly a core of Reynolds stress analyzed conventionally. By entraining the ambient flow periodically along with the shear layer, a core jet was collapsed and diffused. During this process, the velocity profile became blunt, such as seen in Fig.2 (b). Taken together, it can be said that the physical interpretation of Reynolds stress during systole is an indicator of impinging flows.

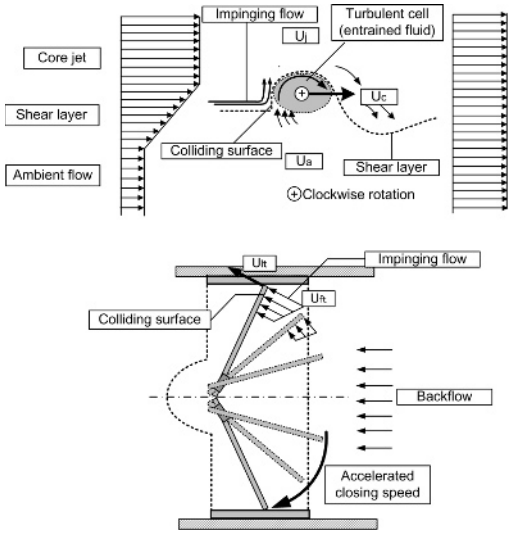

Fig.7 Model of impinging flow
(top: Shear layer, bottom: Valve closure)

B. Reynolds stress during valve closure

Fig.5 compares Reynolds stress immediately before valve closure. The Reynolds stress appeared impulsively with a sudden halt of valve leaflet, and the varying magnitude observed among three valves attributed to the distinct closing mechanics. The polymer valve was closed more smoothly thanks to the flexible leaflet and the central backflow that promoted the closing motion of the leaflet. In contrast, the closing speed of mechanical valves was accelerated by an adverse pressure gradient. In addition, the leaflet was impulsively halted by the hinge mechanics. Since the closing leaflet speed may reach an order of m/s immediately before closure, the instant of valve closure had a spike-like velocity profile (Fig.6), resulting in the impulsive and extensive formation of the Reynolds stress (Fig.5). Herein as well, the Reynolds stress can be considered as an indicator of impinging flows.

C. Physical interpretation of Reynolds stress

Fig.7 summarizes illustrations for above cases. In both cases, Reynolds stress can be considered as an indicator of impinging flows. At the shear layer, the core jet entrains the ambient flow impulsively (*entrainment*). The traveling velocity of entrained fluid U_c is substantially lower than that of the jet convective velocity. This finding was already described by pioneers in 1966 [11]. Thus, the colliding

velocity U_{col} becomes $U_{col}=U_j-U_c$, which declines sharply towards the colliding surface as indicated by a cluster of shear rate (Fig.4). The traveling velocity of a T-cell in Fig.4 was approximately 0.6 m/s at t=0 to 1.6 ms and 1.3 m/s at t=1.6 to 3.9 ms. Since the jet velocity reached as high as 1.7 m/s approximately (Fig.4), the colliding velocity may reach an order of m/s. On the other hand, during valve closure, the closing leaflet speed is equal to the fluid velocity nearby (Fig.7). The closing speed of mechanical valves is exponentially accelerated, and the terminal velocity may reach an order of m/s at the tip of leaflet. At this instant, the leaflet tip speed U_{lt} becomes equal to the fluid convective velocity U_{ft} in the vicinity. This elevated fluid momentum impulsively collided with a leaflet upon closure ($U_{col}=U_{lt}=U_{ft}$)

To the best of our knowledge, there are little studies done to investigate the relevance of impinging flows with blood trauma. So far, the most popular parameter to study hemolysis and platelet activation is a bulk viscous shear stress τ and exposure time t_{exp}. Paul et al. [1] reported that a measurable damage increase was not detectable below τ=425 Pa and t_{exp}=620 ms. This order of shear stress corresponded to a shear rate of 85,000 1/s, indicating a velocity difference of 0.85 m/s per 10 μm. This level of shear rate is overwhelming. Indeed, the shear rate observed during systole was in the order of several thousands. Although the present study did not rigorously investigate the hinge flow, the recent studies done by Simon et al. [6] indicated that the hinge jet velocity was around a few m/s with a hinge gap of several hundred of micrometers. Thus, the shear rate does not appear to reach a critical value. In addition, the phenomenon is transient, thus the time scale being extremely small in contrast to t_{exp}=620 ms. As summary, it was concluded that an impulsive loading system upon collision should be considered in elucidating turbulent-induced hemolysis in artificial heart valves.

IV. Conclusions

The present study served as *macroscale modelin*g of prosthetic heart valve flows, where we utilized time-resolved PIV and continuous wavelet transform to obtain the physical interpretation of Reynolds stress. As a result, the Reynolds stress was found to be an indicator of impinging flows for circulating cells. Impinging flows may apply an impulsive force on a cellular membrane upon collision. The knowledge of impinging flows as a cause of blood cell damage has yet to be accumulated. We are currently investigating such phenomena using high-speed microfluidic techniques as *microscale verification*.

Pollen Shape Particles for Pulmonary Drug Delivery: *In Vitro* Study of Flow and Deposition Properties

Meer Saiful Hassan and Raymond Lau

Nanyang Technological University (NTU), School of Chemical and Biomedical Engineering (SCBE), Singapore

Abstract — **Pollen shape hydroxyapatite (HA) particles have been synthesized in this study. The flow and deposition properties of these pollen shape particles are compared with needle, cube and plate shape particles of similar size range of around 5 µm. The flow properties of the particles are characterized by the angle of slide (θ) method. The deposition properties of the particles are studied *in vitro* by using an eight-staged Anderson cascade impactor with a Rotahaler®. Pollen shape particles exhibits better flow behavior, higher emitted dose and higher fine particle fraction compare to particles of other shapes. The surface structure of the pollen shape particles increases the distance between particles, hence reduce the interparticle forces and aggregation tendency.**

Keywords — **Pulmonary drug delivery, pollen shape particles, cascade impactor, emitted dose, fine particle fraction**

I. Introduction

Pulmonary drug delivery has been gaining considerable interests as an alternative route of drug administration. Most studies are focused on the effect of particle size on the efficiency of drug delivery. Drug particles with an aerodynamic diameter (d_a) with a range 1-5 µm were found to have the highest delivery efficiency [1,2]. Crowder et al [3] found an increase in respirable fraction by lowering the aerodynamic diameter of the particles through surface treatment and turn the particles into elongated shape. Theoretically, shape can affect drag force and terminal settling velocity of the particles, which would also affect the aerodynamic behavior of the particles [2,3]. Particle shape also affects the dispersion property of the particles, which is directly related to the design of inhalation devices. However, the study of particle shape on delivery efficiency or dispersion property is limited. It is believed that a pollen shape structure can increase the effective distance, reduce the contact area and van der Waals force between two particles [4]. It would be ideal to design drugs with a pollen shape structure to increase the dispersion property and delivery efficiency.

In this study, the flow and deposition properties of pollen shape particles are compared with needle, cube and plate shape particles of similar size range. The particle flow property is characterized by the angle of slide method. The deposition properties of the particles are determined in vitro using an Anderson cascade impactor.

II. Experimental

A. Materials and Method

Pollen shape hydroxyapatite (HA, $Ca_5(PO_4)_3(OH)$) particles are synthesized by hydrothermal reaction using KH_2PO_4, $Ca(NO_3)_2{\cdot}4H_2O$, poly(sodium-4-styrene-sulfonate) (PSS), and urea [5]. 30 ml of KH_2PO_4 (0.02 M) solution is mixed with 50 ml of Ca $(NO_3)_2.4H_2O$ (0.02 M) solution. PSS and urea are then added to the mixture to get the respective concentration of 40 g/liter and 7.5 M. The solution mixture is poured into an autoclave and kept in an oven at 200°C for 6-12 hours. Finally, the precipitated product is collected, washed and then dried at 70°C.

Plate shape calcium oxalate (CaC_2O_4) is synthesized by precipitation reaction of $Na_2C_2O_4$ and $CaCl_2$ using Poly-(styrene-alt-maleic acid) (PSMA) as surfactant [6]. 0.8 ml of $Na_2C_2O_4$ (0.1 M) solution is added to 80 ml aqueous solution of PSMA (0.5 g/liter) and adjust the pH to 4 by adding dilute HCl. Then 0.8 ml of $CaCl_2$ (0.1 M) is added and kept the mixture at 25°C under static condition for 24 h. The product is then collected, washed and dried.

Cube shape calcium carbonate ($CaCO_3$) is produced by precipitation reaction of Na_2CO_3 and $CaCl_2$ using CTAB as surfactant [7]. 1.28 ml of Na_2CO_3 (0.5 M) solution is added to 80 ml aqueous solution of CTAB (1 g/liter) and then adjust the pH at 10 by adding NaOH. 1.28 ml of $CaCl_2$ (0.5 M) solution is added. The mixture is kept at 80 °C under static condition for 24 h before the final produced is collected.

Needle shape $CaCO_3$ particles are synthesized by precipitation reaction of $KHCO_3$ and $CaCl_2$ [8]. Equal volume of 0.1M $KHCO_3$ and $CaCl_2$ are brought to boiling temperature. Then, they are added together to get carbonate precipitate. The precipitate is then filtrated, washed, and dried at 110 °C.

B. Mean Particle Diameter and Particle Shape

Images of the four types of particles used are taken using scanning electron microscope (SEM) (JEOL JSM-5600). The SEM images are taken randomly from different area of the sample. The dimensions of the particles are determined based on the SEM images. At least two hundred particles are measured to get the average volume equivalent diameter

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1434–1437, 2009
www.springerlink.com

of the particles. The surface morphologies of the particles are assessed qualitatively based on the SEM images. The bulk (ρ_{bulk}) and tap (ρ_{tap}) densities of all the samples are measured according to Shi et al. [11].

C. Powder flowability

The flowability of the particles of different shapes is characterized by the angle of slide method [9]. A fixed volume of particle sample is placed on a dry glass plate. A lab jack is used to tilt the slide vertically upwards until the major portion of the powder slides. The angle between the tilted plane and horizontal (angle of slide, θ) is then measured.

D. In Vitro Deposition Property

An eight staged Anderson cascade impactor (ACI) (Copley, UK) is used to determine the emission and deposition properties in vitro. The experiment is carried out with a preseparator at an air flow rate of 30 liter/min. In each experiment, 8 ml of the dissolving solvent (2% HNO_3) is poured inside the preseparator and a coating of 1% w/v solution of silicon oil in hexane is used on the impaction plates to prevent particle bounce and re-entrainment. A Rotahaler® (GSK, U.K.) is used to aerosolize the powder inside the impactor. 20mg of each sample is loaded into a hard gelatin capsule (Gelatin Embedding Capsules, size 4, 0.25 cm^3, Polysciences, Inc., Warrington, PA) manually. An actuation time of 20 seconds is allowed for each capsule to completely disperse all the particles. Experimental runs are conducted in triplicate. The emitted dose (ED) and fine particle fraction (FPF) are determined.

III. Results and Discussion

A. Particle characteristics

The SEM images of the four particles used in this study are shown in Fig 1. The physical properties of the particles are listed in the table 1. The pollen shape particles has petal like surface structure and an average geometric diameter of 5.7 μm. The plate shape particles are rectangular shape with a length of 3.1-5 μm and width of 1.8-3.2 μm. The thickness of these particles is approximately 0.5 μm. The cube shape $CaCO_3$ particles have a uniform side length of around 3 μm. Needle shape $CaCO_3$ particles have a length of 12.5-25 μm and a width of 1.25-2 μm. From table 1 it can be seen that all the four particles are in similar equivalent diameter range. The bulk densities of the particles are also comparable in the range of 0.275-0.346 g/cm^3.

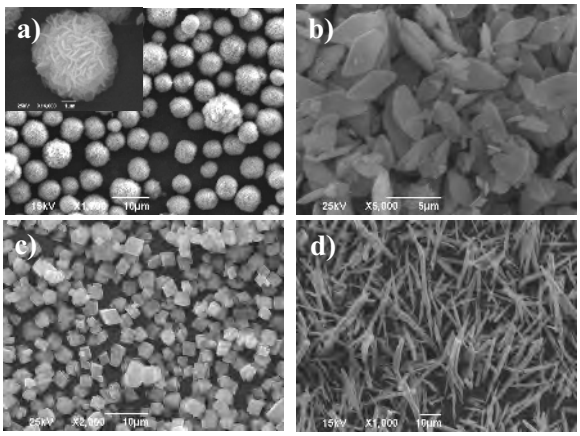

Fig. 1 SEM images of different shape particles, a) Pollen shape, b) Plate shape, c) Cube shape and d) Needle shape.

Table 1 Physical properties of different shape particles

Shape	d_{eq} range (μm)	ρ_{bulk} (g/cm^3) (n=0)	ρ_{tap}(g/cm^3) (n=2500)	θ (°)
Pollen shape	3.9-6.9	0.346	0.719	35.3±2.3
Plate shape	1.8-2.3	0.392	0.661	51.0±6.1
Cube shape	1.6-4.1	0.286	0.617	55.7±5.5
Needle shape	2.0-3.0	0.275	0.458	40.7±1.5

B. Flow property

The flow property of the particles is measured by the angle of slide method. θ values of the four particles are listed in Table 1. θ indicates the ability of particle flow in the presence of shear. The lower the θ, the better the shear flow property. It can be seen that pollen shape particles has the lowest θ compared with the other particles. As the density and size of the particles are comparable, the interparticle forces would be proportional to the area of the contact surface. The surface asperities of pollen shape particles result in small contact area between particles and hence low aggregation tendency. Plate and cube shape particles have the highest contact surface and indeed shows the largest θ. The angle of slide test does show that pollen shape particles have better shear flow property compared with particles of other shapes.

C. In Vitro deposition Property

ED and FPF of the different shape particles are determined in an eight staged Anderson cascade impactor. ED is defined as the mass percentage of particles delivered from the inhaler. FPF is defined as the mass percentage of the particles deposited in stage 2 or lower in the cascade impactor. Though ED and FPF both indicate the flow property of

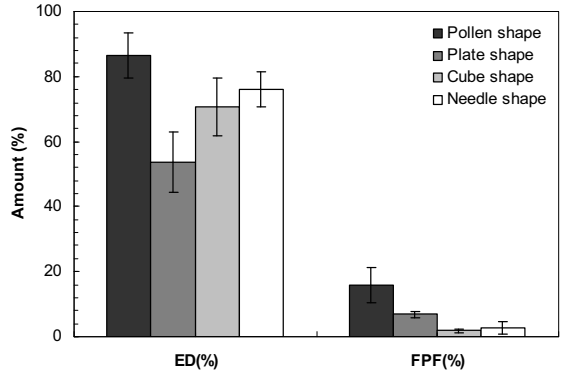

Fig. 2 Comparison of ED and FPF of the different shape particles.

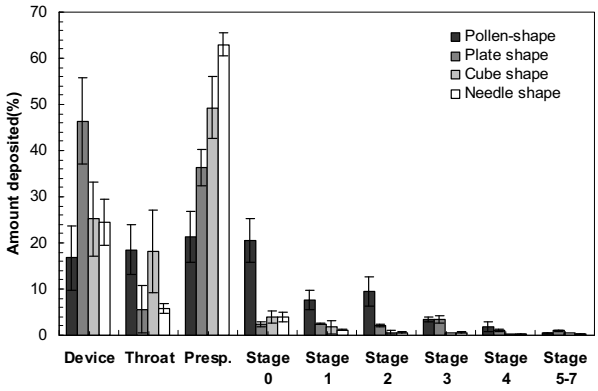

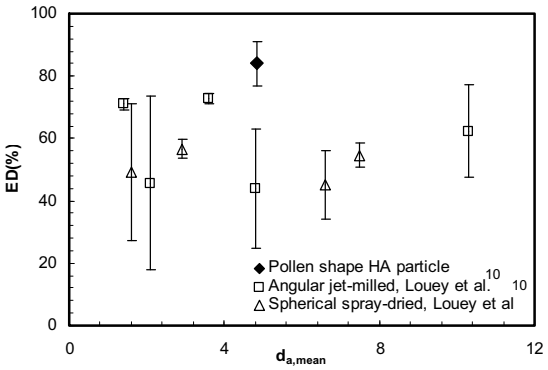

Fig. 3 Percent deposition of the samples in different stages of cascade impactor.

particles, they show different aspects of particle flows. As the particles are discharged from the capsule, fraction of the particles will be dispersed and flow with the gas stream. The rest of the particles will remain in the chamber and the capsule and entrained by gas flow. Therefore ED takes into account both the dispersion ability of particles as well as shear flow property. FPF, on the other hand, considers only the flow property of dispersed particles. A comparison of the ED and FPF of the different shape particles is shown in Fig. 2. The pollen shape particles have both higher ED and FPF than the particles in other shapes. For pollen, needle and cube shape particles, θ, ED and FPF correlates well with each other. Pollen shape particles are superior in all the three parameters while cube shape particles are inferior in θ and FPF. Plate shape particles, however, show poor shear flow ability (θ) and poor dispersion in gas flow (ED). Nonetheless, once the particles are dispersed, the flow of plate shape particles in a gas stream is better than cube and needle shape particles, though not as good as pollen shape particles. This may be owing to the plate shape structure that let the particles to glide along the gas flow and enhances the FPF.

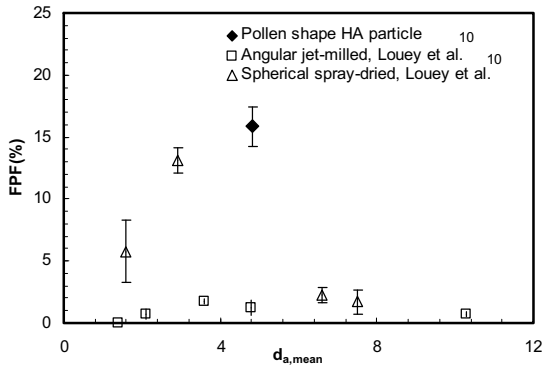

Fig 3 shows the detailed breakdown of the regional deposition of the different particles. A high percent deposition in the inhaler device and preseparator is observed for the plate, needle and cube shape particles. Though these three types of particles has different regional deposition percentage in the inhaler and preseparator, the high deposition percentage in the region would indicate a substantial loss of particles in these regions and would not be ideal for drug delivery. The pollen shape particles have low and uniform deposition percentage in the inhaler and preseparator region. This is a good indication that pollen shape particles have good dispersion property in gas flow and the deposition is independent of flow geometry. In general, particle size, density and material would also play important role in the deposition behavior. In this case, the size and density of the four particles are in a similar range. All the materials ($CaCO_3$, CaC_2O_4 and $Ca_5(PO_4)_3(OH)$) are inorganic derived with calcium metal. All the properties of the different particles can be considered similar except the shape. Therefore, the difference in ED and FPF result among the particles indicates a strong dependence of deposition behavior on the particle shape. In this case, pollen shape is found to exhibit the best flow and deposition property in terms of ED and FPF among other shapes.

Aerodynamic diameter is generally used as the characterizing property of aerosol particles. The aerodynamic diameter is defined as the diameter of a sphere of unit density that has the same terminal settling velocity as the particle under consideration, $d_a = d_g\sqrt{\frac{\rho_e}{\lambda\rho_p}}$ where ρ_s= 1 g/cm^3, d_g is the particle geometric diameter, ρ_e is the effective particle density and λ is the particle shape factor [2,3]. The effective density can be approximated by the tap density, ρ_{tap}. The shape factor of the particles is estimated based on the dimensions obtained from the respective SEM images. The ED and FPF of the pollen shape HA particles are compared with some prior studies as a function of mean aerodynamic diameter.

There is limited ED and FPF result using single particle formulation in cascade impactor. The ED of the HA particles are compared with angular jet milled and spherical spray dried mannitol particles with aerodynamic diameter lower than 10 μm [10]. The mannitol particles were aerosolized at an air flow rate of 60 liter/min whereas the flow rate used in this study is 30 liter/min. Despite the lower air flow rate, the HA particles show higher ED than the angular and spherical particles as shown in Figure 4(a). An increase in flow rate can substantially increase the total particle emission from an inhaler [11]. It is anticipated that the HA particles would exhibit even higher ED at a flow rate of 60 li-

(a)

(b)

Fig. 4. Comparison of (a) ED and (b) FPF of pollen shape HA particles with angular jet-milled and spherical spray-dried particles.

ter/min. The FPF of the HA particles is also compared against the FPF of the mannitol particles. A clear improvement is observed in FPF of pollen shape HA particles over the FPF of the mannitol particles. It is apparent that pollen shape HA particles are highly effective in improving the ED and FPF of drug particles in inhalation delivery.

IV. Conclusions

The flow and deposition properties of pollen shape HA particle is investigated along with particle of other shape. Plate shape particles have poor shear flow and dispersion property but good FPF. Pollen shape particles exhibit better flow and deposition property in angle of slide, ED and FPF. A comparison ED and FPF of pollen shape particles with other particles in literature indicates that pollen shape is effective in improving delivery efficiency.

Effect of *Tephrosia Purpurea* Pers on Gentamicin Model of Acute Renal Failure

Avijeet Jain, A.K. Singhai

Natural Product Research Laboratory, Dept of Pharmaceutical Sciences, Dr H S Gour Vishwavidyalaya, Sagar, MP, India

Abstract — ***Tephrosia purpurea*** **leaves were studied for its protective and curative effect against gentamicin-induced acute renal injury in albino rats of both sexes. The maximum free radical scavenging activity of ethanolic extract was made the basis of selection of this extract for in vivo study. In study, gentamicin intoxication caused significant increase in blood urea (69.48 ± 4.34) and serum creatinine (3.017 ± 0.208) from normal levels 33.72± 1.92 and 0.818 ± 0 .073, respectively, in control group. In the preventive regimen, the extract (200 mg/kg) showed significant reduction in the elevated blood urea (45.44 ± 1.88) and serum creatinine (1.84 ± 0.192), respectively. Histopathological changes were in line with biochemical findings. In the curative regimen (200 mg/kg) blood urea was found to be 41.21 ± 2.28 and serum creatinine level was 1.42 ± 0.122, which revealed significant curative effect. In vivo antioxidant activity was also determined. Reduced glutathione (GSH) level was significantly (P< 0.05) increased in the extract treated groups whereas malondialdehyde (MDA) was reduced significantly (P< 0.05). The findings suggest that the ethanol extract of *Tephrosia purpurea* leaves possesses marked nephroprotective and curative activities without any toxicity. The proposed mechanisms of activities are antioxidant activity and inhibition of overproduction of NO and Cox-2 expression. It is further concluded the activities may be attributed to phenolic and flavonoidal compounds like quercetin. Our study reveled that *Tephrosia purpurea* could offer a promising role in the treatment of acute renal injury caused by nephrotoxin like gentamicin.**

Keywords — ***Tephrosia purpurea,*** **blood urea, serum creatinine, neproprotective, nephrocurative**

I. Introduction

Tephrosia purpurea (Linn.) Pers. (Leguminosae), commonly known in Sanskrit as Sharapunkha is a highly branched, sub-erect, herbaceous perennial herb [1]. According to Ayurveda literature this plant has also given the name of *" wranvishapaka "* which means that it has the property of healing all types of wounds [2]. It is an important component of some preparations such as Tephroli and Yakrifit used for liver disorders [3]. In Ayurvedic system of medicine various parts of this plant are used as remedy for impotency, asthma, diarrhoea, gonorrhoea, rheumatism, ulcer and urinary disorders. The plant has been claimed to cure diseases of kidney, liver spleen, heart and blood [4]. The dried herb is effective as tonic laxative, diuretics and deobstruents. It is also used in the treatment of bronchitis, bilious febrile attack, boils, pimples and bleeding piles. The roots and seeds are reported to have insecticidal and piscicidal properties and also used as vermifuge. The roots are also reported to be effective in leprous wound and their juice, to the eruption on skin. An extract of pods is effective for pain, inflammation and their decoction is used in vomiting [5]. The ethanolic extract of seeds has shown significant in vivo hypoglycaemic activity in diabetic rabbits [6]. The ethanolic extracts of *Tephrosia purpurea* (TP) possessed potential antibacterial activity. The flavanoids were found to have antimicrobial activity [7]. The phytochemical investigations on TP have revealed the presence of glycosides, rotenoids, isoflavones, flavanones, chalcones, flavanols, and sterols [8].

Acute renal failure refers to the sudden and usually reversible loss of renal function, which develops over a period of days or weeks. Among the causes of acute renal failure, acute tubular necrosis, which occurs due to ischemia or nephrotoxins like cisplatin and gentamicin, is most common, accounting for 85% of the incidence. There is a continuous search for agents, which provide nephroprotection against the renal impairment caused by drugs like cisplatin and gentamicin for which allopathy offers no remedial measures. Thus, it is imperative that mankind turns towards alternative systems of medicine for treatment. Hence, the present study is an attempt to screen TP leaves for its nephroprotective and curative activities.

In the ethnobotanical claims, TP plant (mentioned above) is used for the treatment of renal diseases. To the best of our knowledge there is no scientific report is available in support of the nephroprotective activity of TP leaves. Therefore, to justify the traditional claims we have assessed the nephroprotective and curative effect of TP leaves using gentamicin intoxicated rats.

Free radical scavenging and in vivo antioxidant activities were also determined. Ethanolic extract with maximum free radical scavenging activity was selected for in vivo studies.

II. Material and methods

A. Collection

The plant of *Tephrosia purpurea* was collected from the forest around Dr. H.S. Gour Vishwavidyalaya, Sagar in the month of September 2006 and identified at Department of Botany, Dr. H.S. Gour Vishwavidyalaya, Sagar (M. P.).

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1438–1442, 2009
www.springerlink.com

B. Preparation of extracts

The TP dried leaves were coarsely powdered and defatted with petroleum ether in soxhlet (72 h). The defatted drug was soxhlet extracted with various solvents chloroform, ethyl acetate and ethanol for 48 h. Water extract was prepared by decoction method. Percentage yield was calculated for each extract after drying under vacuum. The percentage yield of chloroform, ethanol, ethyl acetate and water extract were 4.1, 5.7, 10.14, and 8.9%, respectively.

C. Phytochemical Screening

All the extracts were subjected for phytochemical screening.

D. Animals

Healthy adult albino rats (100–150 g) of both sex aged 60–90 days were used for the study. The rats were housed in polypropylene cages and maintained under standard conditions (12-h light: 12-h dark cycle; 25 ±3 .C; 35–60% humidity). The animals had free access to standard lab chow (Hindustan Lever Ltd., Mumbai, India) and water *ad libitum*. Study was conducted after obtaining institutional animal ethical committee clearance (412/01/ab/CPCSEA, India).

E. Acute toxicity studies

The ethanolic extract was suspended in gum acacia (2% w/v) and administered to animals in increasing dose levels. The dose of the extract was calculated as 1/10th of the maximum tolerated dose (2000 mg/kg b.w.).

F. Superoxide free radical scavenging activity

This was determined by the NBT (Nitro Blue Tetrazolium) reduction method. The assay was based on the capacity of sample to inhibit blue formazan formation by scavenging the super oxide radical generated in riboflavin-light-NBT system. The reaction mixture contains EDTA, riboflavin, Nitro Blue Tetrazolium, various concentrations of extracts (1-100 μg/ml) and phosphate buffer pH (7.6) in a final volume of 3 ml. The tubes were uniformly illuminated with an incandescent lamp for 15 min and absorbance was measured at 590nm before and after illuminated. The percentage inhibition of super oxide generation was measured by comparing absorbance value of control and those of test [9].

G. DPPH free radical scavenging activity

A stock solution of 0.1 ml of DPPH was prepared in ethanol. This solution was mixed with equal volume of solutions (different concentrations) of compound A in ethanol. The reaction was allowed to complete in the dark for about 20 minutes. The absorbance was taken at 517 nm. Experiment was repeated three times. The difference in absorbances between the test and the control was calculated and expressed as percentage scavenging of DPPH radical [10].

H. Total antioxidant activity

Total antioxidant activity of all the extracts was measured in concentration of 10 -1000 μg/ml [11]. Briefly, peroxidase (4.4 unit/ml, 0.2 ml), H_2O_2 (50 mM, 0.2 ml), ABTS [2,2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid), 100 mM, 0.2 ml] and distilled water (1.4 ml) were mixed and kept in dark for 1 h to form a bluish green complex. After adding the various concentrations of the tested extracts (1 ml), the absorbance at 734 nm was measured.

I. Gentamicin-induced renal damage

Test samples were prepared in the distilled water. Weighed quantity of the ethanolic extract was suspended in distilled water by trituration. Extract was taken in pastel motor and triturated continuously to get homogenous suspension. Suspension was stored in airtight bottle in cool and dry place.

The animals were divided into 4 groups of 6 rats each and all testing drugs were administered orally at the calculated dose.

Group I: control to which neither drug or gentamicin was administered

Group II: Treated with only gentamicin (40mg/kg b.w.) s.c.

Group III (Preventive): Treated with ethanolic extract suspension (200 mg/kg/day b.w.) 30 minute before the gentamicin administration.

Group IV (Curative): Treated with ethanolic extract suspension (200 mg/kg/day b.w.) 7 days onwards the gentamicin administration.

In preventive groups, dose of gentamicin and extracts were given once a day, whereas in curative regimen gentamicin was administered twice a day. After16 days animals were scarified by cervical dislocation and blood samples were collected from the inferior vena cave. To get serum from the blood sample, freshly drawn blood was centrifuged at 2500 rpm for 30 minute and placed in refrigerator.

J. Biochemical determinations

Blood urea concentration in the blood was estimated by enzymatic method using urease enzyme kit by modified Berth Elot method [12]. Absorbance was read using UV-240 Vis spectrophotometer (Shimadzu Corporation, Japan).

Serum creatinine level in serum was estimated by the alkaline picrate method using creatinine kit [13]. Absorbance was read by UV-240 Vis spectrophotometer.

K. In vivo antioxidant activity

Reduced glutathione (GSH) and malondialdehyde (MDA) were estimated to access in vivo antioxidant activity. Methods of Ellamn Georg [14] with some modification and Uchiyama and Mihara [15] were used respectively.

L. Histopathological examination

Animals from each group were sacrificed on the day of blood withdrawal and kidneys were isolated. Tissue samples were immersed in 10% formalin for histopathological studies. Samples were embedded in paraffin, sectioned and stained with haematoxylin and eosin.

M. Statistical analysis

Results are given as mean ±SEM. Data were analyzed using one-way ANOVA. The statistical significance of difference was taken as $P<0.05$.

III. Results

A. Phytochemical study

All the extracts were subjected for phytochemical studies. Ethanolic extract showed positive test for flavonoids, glycosides, phenolic compounds, alkoloids, carbohydrates and amino acids etc.

B. Super oxide scavenging activity

NBT method was applied for screening of super oxide free radical scavenging activity. All the extracts were screened in concentration of 1-100 µg/ml. Ethanolic extract showed maximum percent reduction followed by aqueous, ethyl acetate and chloroform extracts. This activity was dose dependent in all cases.

C. DPPH free radical scavenging activity

Ethanolic extracts at 1000 µg/ml showed maximum inhibition. Other 3 extracts showed results in similar pattern.

D. Total antioxidant activity

All the extracts were screened in concentration of 10-1000 µg/ml. Ethanolic extract showed maximum inhibition amongst all the extracts.

In vitro antioxidant activity screening was made basis for the selection of extract for further studies and as results revealed ethanolic extract was subjected for in vivo studies.

E. Acute toxicity studies

In acute toxicity ethanolic extract was found to be safe up to a dose of 2000 mg/kg.

F. Gentamicin induced renal damage

Gentamicin induced renal injury that was evidenced by the elevated blood urea and serum creatinine levels. Table 1 shows the results of biochemical estimation in various groups, where blood urea and serum creatinine estimations are reported to access nephroprotective and curative activities of ethanolic extract. Study has reveled increased level of blood urea (69.48 ± 4.34) and serum creatinine (3.017 ± 0.208) in gentamicin intoxicated animals compare to control 33.72± 1.92 and 0.818 ± 0 .073, respectively. On other hand, it was observed that 16 days administration of the extract (200 mg/kg) prior to gentamicin administration (40 mg/kg, single dose) in the prophylactic regimen, provided marked protection against gentamicin induced renal injury. Similarly, in the curative regimen of the gentamicin model, the ethanol extract recovered the renal damage induced by gentamicin suggesting that it has nephrocurative activity in gentamicin models of renal injury. Histopathological studies supported the results

G. In vivo antioxidant activity

Activity was accessed by estimation of reduced glutathione (GSH) and malondialdehyde (MDA). Results are cited in Table 2. Results of study clearly revealed increase in the levels of MDA in gentamicin intoxicated rats (462±4.3) compare to control group (197.7±2.1). Treatment with extracts significantly prevented and as well recovered this raise in levels. GSH has significantly increased in extract treated groups whereas gentamicin intoxicated group has shown significant decrease in levels compare to control group. Curative groups have shown better results.

H. Histopathological studies

In histopathological studies, gentamicin intoxicated group showed definite signs of nephrotoxicity, when compared to the control groups. The intoxicated group has shown presence of peritubular and glomerular congestion, tubular casts, epithelial degeneration, interstitial edema, blood vessel congestion and infiltration by inflammatory cells, which are features of acute tubular necrosis observed

Table 1 Determination of blood urea and serum creatinine in Serum of rats

Groups	Treatment regimen	Blood urea mg/dl	Serum creatinine level mg/dl
Group I	Control (Vehicle)	33.72± 1.92	0.818 ± 0 .073
Group II	Control (Gentamicin)	69.48 ± 4.34***	3.017 ± 0.208***
Group III	TP 200 + Gentamicin (Preventive)	45.44 ± 1.88**	1.84 ± 0.192***
Group IV	TP 200 + Gentamicin (Curative)	41.21 ± 2.28***	1.42 ± 0.122***

All the values are expressed as Mean± SEM. *P<0.05, **P<0.01, ***P<0.001 shows level of significance compare to control group

Table 2 Determination of blood urea and serum creatinine in rats.

Groups	Treatment Regimen	Blood urea mg/dl	Serum creatinine level mg/dl
Group I	Control (Vehicle)	33.72± 1.92	0.818 ± 0 .073
Group II	Control (Gentamicin)	69.48 ± 4.34***	3.017 ± 0.208***
Group III	TP 200+ Gentamicin (Preventive)	45.44 ± 1.88**	1.84 ± 0.192***
Group IV	TP 200 + Gentamicin (Curative)	41.21 ± 2.28***	1.42 ± 0.122***

All the values are expressed as Mean± SEM. *P<0.05, **P<0.01, ***P<0.001 shows level of significance compare to control group

in the histopathological sections and indicative of the extent of damage done at the tissue level whereas control group shows normal architecture. All the preventive and curative groups have shown sign of recovery.

IV. Discussion

Gentamicin, an aminoglycoside antibiotic is used as an effective agent against gram negative infections. Its chemical stability, rapid bactericidal action has made it a first-line drug in a variety of clinical situations. However, nephrotoxicity is the major side effect of amino-glycosides accounting for 10 - 15% of all cases of acute renal failure [16]. Studies have also shown that 30% of the patients treated with gentamicin for more than 7 days show signs of nephrotoxicity [17]. It has been shown that the specificity of gentamicin renal toxicity is related to its preferential accumulation in the renal convoluted tubules and lysosomes [18].

In present study, ethanolic extract of TP leaves was selected based on its in vitro antioxidant activity for screening of nephroprotective and nephrocurative activities using Gentamicin induced nephrotoxicity. In preventive and curative regimens, the ethanol extract at dose levels of 200 mg/kg, significantly recovered the raised blood urea, serum creatinine compare to control group and supported by histopathology. Thus results suggest nephroprotective and curative activities of TP.

In various studies it have been reported that gentamicin activates phospholipases and alters the lysosomal membrane in addition to oxidative stress [19]. Although the mechanism of gentamicin-induced nephrotoxicity is not completely known. However, studies have implicated reactive oxygen species particularly superoxide anion radical in the pathophysiology of gentamicin nephropathy [20]. It has been demonstrated that gentamicin administration increases renal cortical lipid peroxidation, renal nitric oxide generation and mitochondria H_20_2 generation [21, 22]. Ethanolic extract has shown good superoxide radical scavenging, DPPH scavenging and total antioxidant activity along with significant in vivo antioxidant activity. In treated groups, GSH has been significantly increased whereas MDA level, results from lipid peroxidation has been significantly reduced. Previously, *Aerva lenata* has been reported for nephroprotective activity due its antioxidant activity i.e. free radical scavenging activity [23].

Natural and synthetic antioxidants and free radical scavengers are claimed to provide nephroprotection in gentamicin renal injury. Vitamin C, Vitamin E, selenium, etc are among the natural free radical scavengers. Previously, Natural antioxidants ascorbic acid and alpa-tocopherol have also been found nephroprotective in animal model [24]. Flavonoids and phenolic compounds are well known potent antioxidant and free radical scavengers. Renoprotective effects have been reported for polyphenols such as quercetin [25]. Previously presence of quercetin in TP is well documented and our chromatographic studies have also reveled its presence in the extract. Phytochemical study revealed that flavonoids and phenolic compounds are present in the extract. Various in vitro models have shown significant free radical scavenging activity of TP. Significant increased in GSH level and reduction in MDA level revealed its vivo antioxidant activity. Hence, the probable mechanism of nephroprotection by TP may be attributed to its antioxidant and free radical scavenging property, while free radical scavenging activity may be attributed to flavonoids and phenolic compounds like quercetin.

In addition, it has been already demonstrated an increased NO production during ischemia and gentamicin-induced renal failure [26, 27]. NO has been reported as oxidant in presence of superoxide anions. Both of these react and produce peroxynitrite, which is a potent and versa-

tile oxidant [28]. GSH is the natural antioxidant present in the renal tissues. In our study it is clearly reveled that pre and post treatment with the ethanolic extract is able to recover the reduced GSH level. It is also evidenced that extract reduces the lipid peroxidation. Quercetin, one of the most abundant flavonoids, is a potent oxygen free radicals scavenger and a metal chelator [29]. In addition, several studies indicate that quercetin inhibited the expression of COX-2 and (Inducible nitric oxide synthesis) iNOS [30]. Thus it is able to reduce overproduction of NO. In vitro experimental systems also showed that flavonoids possess anti-inflammatory properties [31]. Hence, another probable mechanism of nephroprotective and curative activities of TP may be ability to maintain GSH level and inhibit overproduction of NO and inhibition of Cox-2 expression due to presence of quercetin and other flavonoidal and phenolic compounds.

V. Conclusions

To conclude, our studies have shown that leaves of *Tephrosia pururea* possesses marked nephroprotective and nephrocurative activities without any toxicity and thus has a promising role in the treatment of acute renal injury induced by nephrotoxins especially gentamicin. It is further concluded that mechanisms involved probably are antioxidant activity and inhibition of overproduction of NO and Cox-2 expression. We also conclude that the activities are attributed to phenolic and flavonoidal compound specially quercetin. Further isolation of active components and its role in renal diseases is being targeted. Further work is in process with few more models.

Successful Reproduction of In-Vivo Fracture of an Endovascular Stent in Superficial Femoral Artery Utilizing a Novel Multi-loading Durability Test System

K. Iwasaki[1,2], S. Tsubouchi[2], Y. Hama[2], M. Umezu[2]

[1]Waseda Institute for Advanced Study, Waseda University, Tokyo, Japan
[2]Integrative Bioscience and Biomedical Engineering, Graduate School of Waseda University, Tokyo, Japan

Abstract — Aim: High rates of stent fracture have been reported in the treatment of diseased superficial femoral artery (SFA). Understanding of in-vivo mechanical-loading environments, therefore, draws serious attention. We have developed a novel multi-loading durability tester which can apply cyclic twist and stretch on stents. Here, in-vitro stent fracture patterns were compared with stent fracture observed in vivo. Methods: The angle of cyclic twist as well as cyclic stretch exerted to the stents was regulated to physiologic conditions by utilizing referenced data of MR angiography of SFAs obtained in the spine and fetal position. Stiffness of the silicone vessel models were regulated to that of SFAs. As the SFAs are intrinsically stretched in vivo, stents were tested not only in the non-stretched vessel model but also in the 50% pre-stretched vessel model, respectively. The simultaneous cyclic multi-loads were exerted to the stents under the mean luminal pressure of 100mmHg at 60 cycles per minute. Considering the data that average Japanese walk 7378 steps per day, the cyclic numbers of the in-vitro durability tests were converted to the equivalent durability in vivo. Results: Only minor fracture was observed at the stent strut after one-year-equivalent duration when the stents were tested using the non-stretched vessel models. However, employment of the novel pre-stretched vessel model resulted in complete stent fractures in the middle of longitudinal direction in 2-months-equivalent duration. Moreover, the fracture pattern was clearly coincident with the stent fracture in vivo. Conclusions: This is the first demonstration that the pre-stretch of vessel model is a requisite condition in durability tests of stents for SFA. Moreover, these results indicated that reproduction of multi-loading environments including cyclic twist and stretch is of great significance in order to obtain reliable durability data of endovascular stents for SFA.

Keywords — **Stent fracture, Superficial femoral artery, Accelerated durability test, Regulatory science, Endovascular stent**

I. Introduction

Maintaining patency after recanalization of stenotic superficial femoral artery (SFA) is one of the most challenging themes in endovascular therapy. Stenting in SFA yielded frequent stent fractures, for example 64 of 261 implanted stents (24.5%) after mean follow-up of 10.7 months. Moreover it became evident that stent fractures were associated with restenosis or reocclusion [1] as shown in Fig.1. Therefore, establishment of practical in-vitro durability test system and reliable methodologies become high priority for not only medical companies but also governments [2]. SFA receives multiple forces such as bending, twist, compression, stretch / shortening in response to daily life activities (Fig.2) [3]. However, there is no practical durability test system as well as reliable methodology to predict in-vivo performance of endovascular stents. We, here, developed a novel durability

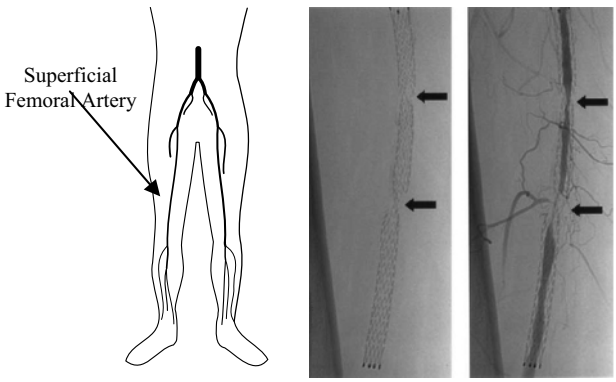

Fig.1 A nitinol stent 9 months after implantation showing severe stent fractures and reocculusion

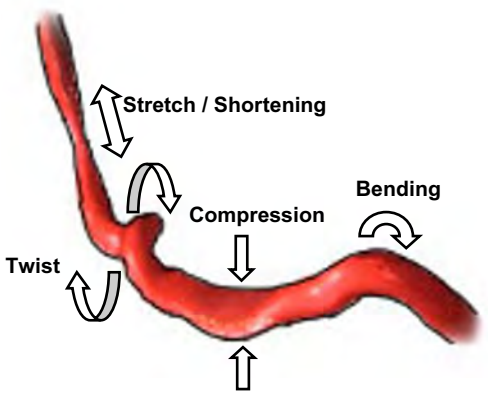

Fig.2 Mechanical loads exerted to the superficial femoral artery in daily life activities

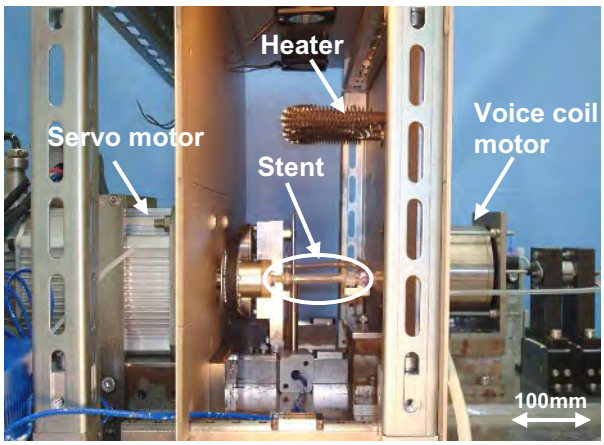
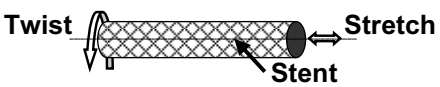
www.springerlink.com



test system which can mimic in-vivo multi-loads environment for testing endovascular stents. Then, influences of loading conditions on stent fractures were investigated. Moreover, we investigated, for the first time, the influence of pre-stretch of the vessel model before stent implantation on durability, because the artery is kept stretched in human body.

II. Method



Understanding of mechanical loads exerted to SFA is essential to determine the specification of durability test system. We referenced the in-vivo deformation data of SFA in the supine and fetal position (Table1) [4]. It was shown that during the transition of supine and fetal positions, cyclic twist and stretch forces are exerted to SFA. Therefore, we developed the novel durability tester which can apply the multi-loads of twist and stretch forces to the stents installed in a blood vessel model (Fig.3). The durability test system consists of a servo-motor for producing twist force, and a voice coil motor for producing stretch force, a heater for regulating environmental temperature to 37°C, and a vessel model for incorporating the stents. Because the SFA is present in stretched condition, investigation of its influence on durability was included in the durability tests. Figure 4 shows a schematic representation of the test condition that the silicone vessel model is pre-stretched before stent placement. The SFA model with stiffness of 19.8, which matches to that of human SFA, was manufactured. In the experiment using the pre-stretched vessel model, the stiffness of the vessel model after pre-stretch was adjusted to 19.8. In order to apply the exact amount of twist force as well as stretch force to the stents, both the ends of the stents were fixed to the force generators. Typical simultaneous waveforms of cyclic twist, stretch, and pressure in the durability test in accordance with the maximal deformation of SFA among 8 volunteers were shown in Fig.5. The twist and stretch forces were exerted to stents 60 times per minute.

(a) Cyclic twist and stretch

(b) Pressure

Fig.5 Simultaneous loads waveforms in the durability test

According to the data of Annual Reports of Health and Welfare in Japan [5], the average Japanese walk 7378 steps per day, therefore, 1.3 x 10^6 cycles (7378steps/2legs x 365days) were considered as one-year-equivalent cycles. The durability tests were conducted for one-year-equivalent duration, except for termination by the incidence of stent separation.

III. Results

The durability tests were conducted in the following three typical conditions. In the first experiment, cyclic twist and stretch forces were regulated to those consistent with the maximal data among 8 volunteers. The conventional non-stretched vessel models were used. In 5.5 x 10^5 cycles (equivalent to 5 months in vivo), a single strut fracture was observed at the middle area of the stent (Fig.6) However, further fracture did not occur until the termination in one-year-equivalent test. The second experiment was conducted using the pre-stretched vessel model. The loads condition was regulated to that of the average data of 8 volunteers. In 2.2 x 10^5 cycles (equivalent to 2 months), 6 strut fractures were observed at the middle area of the stent. Multiple strut fractures were observed after one-year-equivalent test (Fig.7). The third experiment was conducted using the pre-stretched vessel model. The loads condition was regulated to that of the maximal data of 8 volunteers. In 1.1 x 10^5 cycles (equivalent to 1 month), a single strut fracture was observed. In 1.5-months-equivalent duration, the number of strut fractures reached over 10. Complete separation of the stent eventually occurred in 2-months-equivalent duration (Fig.8).

IV. Discussion

Even though the maximal loads of twist and stretch among 8 volunteers were exerted, only one strut fracture occurred when the non-stretched vessel models were used. However, complete separation of the stents was induced when the pre-stretched vessel model was employed under the identical maximal-loads environment. These investigations demonstrated that employment of the pre-stretched vessel model strongly affects on the durability of the stents. We, for the first time, demonstrated that employment the pre-stretched vessel model is requisite parameter in the durability tests of endovascular stents. The stent fractures rapidly propagated in response to increase in loads. Iida et al. reported that patients with a habit of walking > 5000 steps per day had higher fracture rates than the patients who did not exercise [6]. These clinical data do match with our in-vitro accelerated durability test results. In this study, we used Wallstent (Boston Scientific, Natick, MA). Scanning electron microscope examination revealed

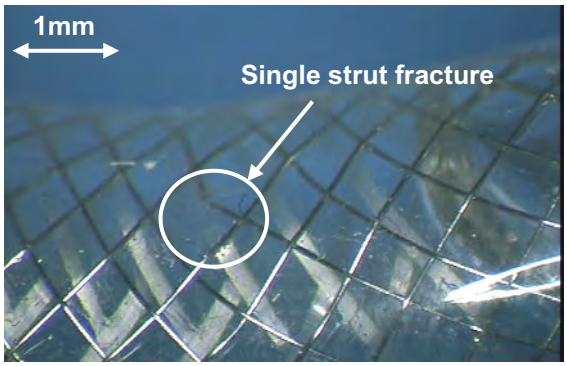

Fig.6 Single strut fracture after one-year-equivalent durability test. The maximal loads among 8 volunteers were exerted to the stent placed in the conventional non-stretched vessel models.

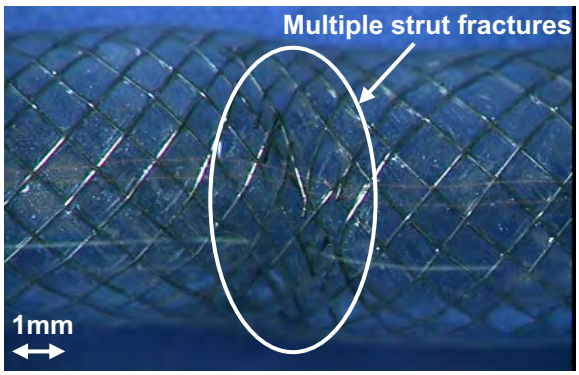

Fig.7 Multiple strut fractures after one-year-equivalent durability test. The average loads among 8 volunteers were exerted to the stent. The novel pre-stretched vessel model was employed.

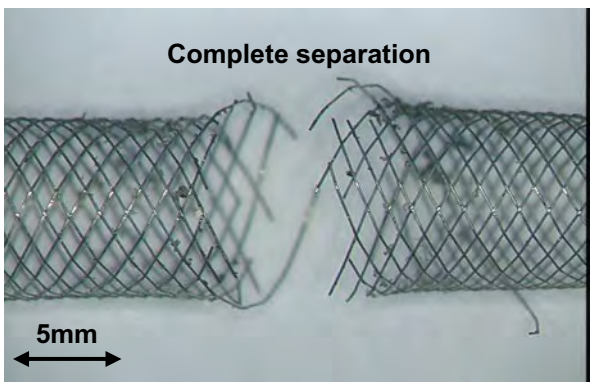

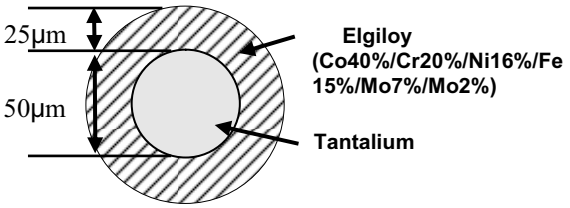

Fig.8 Complete separation of the stent after 2-months-equivalent durability test. The maximal loads among 8 volunteers were exerted to the stent placed in the pre-stretched vessel model.

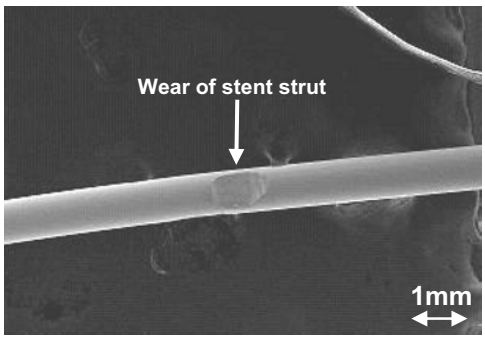
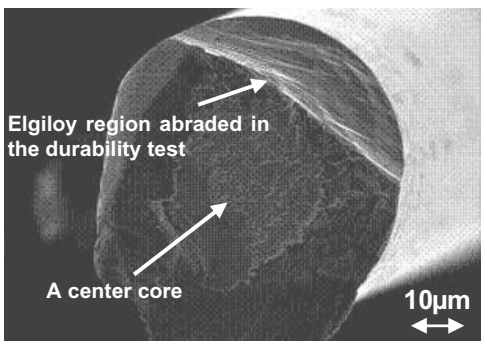


the fracture pattern of Wallstent. As shown in Fig.9, Wallstent consists of a center core made of Tantalium, and Elgiloy covering the core. It was found that stent fracture occurred when wear of Elgiloy region reached to the Tantalium.

V. Conclusions



We developed the novel multi-loading durability test system, which can reproduce in-vivo equivalent mechanical environments. It was demonstrated that cyclic twist and stretch forces are important parameters in the durability test of endovascular stents. Moreover, to our knowledge, this is the first demonstration that pre-stretch of the vessel model before stent placement is requisite in order to produce the similar fracture pattern as observed in clinical reports. These efforts will contribute to establishment of a reliable durability testing methodology for endovascular stents.

Abstract — **One potential way to overcome the side effects of chemotherapy is to develop therapeutic drug delivery systems that can enhance tumor cytotoxicity but reduce the adverse effects to the normal cells. Recently the studies of nanoparticle formulation of anticancer devices via drugs associated with synthetic polymers have been used as delivery systems for this purpose. In this study, we attempt to synthesize a novel star-shaped biodegradable polylactide (PLA) with chemo-photodynamic dual therapeutics for cancer treatments.**

The branched star porphyrin-PLA (BSPPLA) conjugate was synthesized by ring-opening polymerization of lactides from porphyrins with benzyl alcohol. The doxorubicin-loaded BSPPLA nanoparticles with 59.8±21.4 nm were fabricated by a modified solvent evaporation/extraction technique. Intracellular distribution, cell viability and phototoxicity of this novel BSPPLA nanoparticle were evaluated *in vitro*. The results show that BSPPLA nanoparticles, mainly localized in endosome/lysosome compartments, was non-toxic below 10 μM, but significantly induced cell death after suitable irradiation in MCF-7 cells. Furthermore, the photodynamic treatment obviously improved the cytotoxicity of doxorubicin-loaded BSPPLA nanoparticle through synergistic effects by median effect analysis. In conclusion, doxorubicin loaded BSPPLA nanoparticle showed considerable potential as a bimodal biomaterial for chemo-photodynamic drug delivery system for cancer therapy.

Keywords — **Photodynamic therapy, chemotherapy, Doxorubicin, polylactide, nanoparticles**

I. Introduction

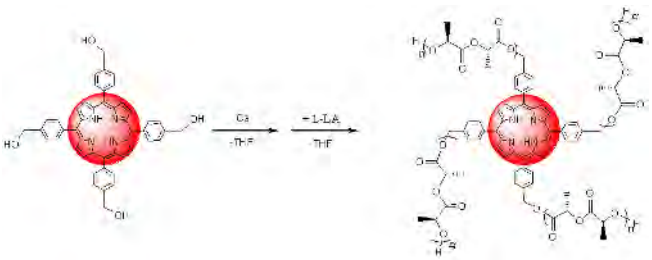
Photodynamic therapy (PDT) is a treatment that utilizes the combined action of photosensitizers (PSs) and specific light sources for the treatment of various cancers. Following the activation of PSs by photochemical reaction, reactive oxygen species (ROS) are generated from molecular oxygen and act to destroy cancer cells [1, 2]. Important advantages of PDT over other therapies are that it is a precisely targeted treatment through selective illumination, it can be repeated in the same site if needed and it is less invasive than surgery. Despite these significant advantages, the biodistribution of PSs is unfavorable, and phototoxicity to the skin, mainly caused by existing agents' hydrophobicity and non-selectivity, is a considerable limitation of their use [3]. An ideal photosensitizer should be non-toxic if it has not been irradiated and should induce a large amount of damage to cells when exposed to a specific light source of long wavelength, which has advantages in the treatment of deeper lesions; fast accumulation in the target tissue, rapid clearance and tumor selectivity must also be considered [1, 4, 5].

In recent years, nanomaterials such as polymer–drug conjugates [6], liposomes [7], nanoparticles [8] and polymeric micelles [4, 5] have been considered as potential carriers for hydrophobic drug delivery that may resolve the aforementioned problems. Polymeric micelles composed of amphiphilic block copolymers demonstrate a series of attractive properties in drug delivery systems, such as good biocompatibility and high stability *in vitro* and *in vivo*, and can be successfully used for various poorly-soluble agent encapsulations. These nanosized micelles consist of a hydrophilic outer shell and a hydrophobic inner core that can be used to incorporate lipophilic drugs in aqueous solution [9-11]. Recently, potential micelle composed of terminal-modified amphiphilic copolymers for PDT has been developed in our lab.

In this study, a porphyrin-centered, 4-armed star poly(L-lactide) (PLA) was synthesized and its potential as a drug delivery carrier evaluated. Hydrophobic chemotherapeutic agents, such as doxorubicin (Dox), can then be encapsulated into the core region of this nanoparticle, presenting a combined chemotherapy/PDT strategy in one delivery system. Our results show that the cytotoxicity of the Dox-loaded micelle can be further enhanced after combination with PDT technology. Besides, Dox-resistance in MCF-7 breast cancer cells can be overcome by this carrier. This star-shaped PLA nanoparticle can be a promising biomaterial for dual therapies.

II. Materials and Methods

A. Synthesis of meso-tetra-(p-hydroxymethylphenyl) porphyrin



To a suspension of 0.28 g of lithium aluminium hydride in 15 ml. of tetrahydrofuran (THF)(dry and distilled over lithium aluminium hydride) was added slowly 200mg of meso-tetra-(p-carbomethoxyphenyl)porphyrin dissolved in 85 ml of dry THF and refluxed for an hour. Another 50ml

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1447–1450, 2009
www.springerlink.com

portion of dry THF was added to the reaction mixture and refluxing was continued for an additional 30 minutes. To unreacted lithium aluminium hydride was decomposed with most ether at 0 °C and filtered through a celite bed. Since the filtrate was almost colorless (indicating that the celite bed absorbed all the porphyrin), the celite was repeatedly extracted with pyridine. The combined pyridine extracts were distilled under reduced pressure, and the residue was triturated with acetone and filtered. The purple solid was dried in vacuo.

B. Synthesis of branched star porphyrin- PLA (BSPPLA)

The schematic representation of BSPPLA was shown in Scheme 1. BSPPLA was synthesized by ring-opening polymerization (ROP) of lactides with *meso*-tetra-(p-hydroxymethylphenyl) porphyrin as an initiator under $(DAIP)_2Ca]_2$·(THF) calcium complex (where DAIP-H = 2-[(2-dimethylamino-ethylimino)methyl]phenol) catalyst [12]. The molecule weight of BSPPLA obtained from ^{1}H NMR analysis is 19800 and the polydispersity index is 1.4 (measured by GPC).

Scheme 1 Synthesis of BSPPLA

C. Preparation of Dox encapsulated BSPPLA nanoparticles

The nanoparticles with 0.1mg Dox were prepared by solvent evaporation/extraction technique (the single emulsion technique). Typically, 1μl TEA and 2mg of BSPPLA were dissolved in 1ml acetone. The solution of organic phase was slowly poured into the stirred 5ml ddH_2O of 0.03% TPGS. The formed oil-in-water (O/W) emulsion was gently stirred at room temperature by a magnetic stirrer for overnight to evaporate the organic solvent.

D. Cell line and culture conditions

Human breast adenocarcinoma (MCF-7) cells and doxorubicin-resistant cells (MCF-7/ADR) were obtained from Dr. Lou of the Department of Otolaryngology, National Taiwan University Hospital. The cells were maintained in DMEM supplemented with 10% heat-activated fetal bovine serum (FBS), 2 mM L-glutamine and 1% antibiotics. The MCF-7/ADR cells were maintained continuously in 0.25 μM Dox.

E. Cytotoxicity of Dox or BSPPLA/Dox- mediated PDT

The cytotoxicity of Dox to MCF-7 and MCF-7/ADR cells was assessed by incubating the cells for 6h in medium containing different concentrations of Dox, followed by washing of the cells 3 times, incubation in fresh culture medium and then subjecting the cells to viability assays using MTT method.

The effect of PDT was assessed by incubating the cells with various concentrations of BSPPLA or BSPPLA/Dox for 6h at 37°C, washing the cells 3 times followed by incubation in phenol red-free medium for a further 48h. Then the cells were exposed to the light source with dose from 0.7J to 2.1J/cm^2 and subsequently subjected to the cell viability assays.

III. Results

A. Characterizations of BSPPLA or BSPPLA/Dox nanoparticles

The BSPPLA nanoparticles without or with Dox loading were prepared by solvent evaporation method. As shown in Table 1, BSPPLA nanoparticles exhibited a uniform size around 51 nm. After Dox loading, the size of BSPPLA nanoparticle decreased to 45.5 nm with PDI ~ 0.243. The encapsulation efficiency is almost 90% at polymer/Dox ratio = 10/1.

Table 1 Characterization of BSPPLA and BSPPLA/Dox nanoparticles (polymer/drug = 10/1 (w/w)

Nanoparticles	Size (nm)[a]	PDI	EE%[b]
BSPPLA	51.1	0.151	--
BSPPLA/Dox	45.5	0.243	89.8

[a] determined by DLS
[b] EE%[encapsulation efficiency] = (actual drug loading /theoretical drug loading)×100%

B. Cytotoxicity and phototoxicity of BSPPLA nanoparticles

Fig. 1 shows the cytotoxicity of BSPPLA nanoparticles without or with irradiation in MCF-7 cells. Obviously, more than 83 % of cells survived after BSPPLA nanoparticles incubation. After irradiation, the increased phototoxicity of BSPPLA nanoparticles was observed in MCF-7 cells as the light dose increased. It indicates that the BSPPLA exhibited successfully the PDT effects after irradiation.

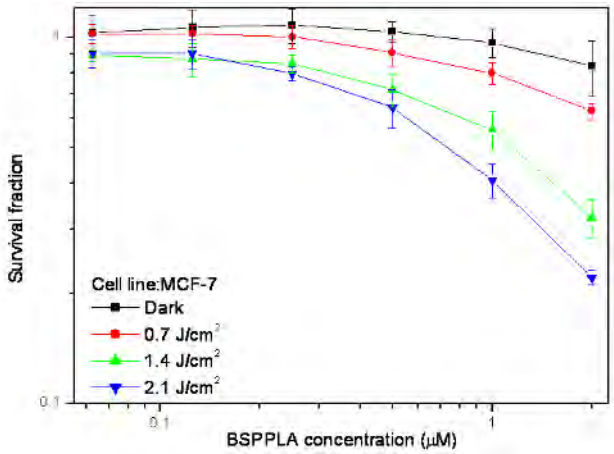


Fig. 1 Cytotoxicity and phototoxicity of BSPPLA in MCF-7 cells.

C. Cytotoxicity and phototoxicity of BSPPLA/Dox nanoparticles

Fig. 2 shows the cytotoxicity of BSPPLA/Dox nanoparticles without or with irradiation in MCF-7/ADR cells. Obviously, the cell viability in the dark was inhibited about 17% by Dox alone and 84% by BSPPLA/Dox at the highest Dox concentration (10μM) for 24 hours. These results reveal that Dox-loaded nanoparticles showed enhanced cytotoxic activity in MCF-7/ADR cells. After 2.1 J/cm^2 light irradiation, more than 95% of cells were killed by BSPPLA/Dox at 10 μM Dox concentration, whereas there was no conspicuous difference with Dox alone. Interestingly, Dox combined with PDT can improve the cytotoxicity of BSPPLA/Dox at a Dox concentration of 0.5375 μM from slight toxic (more than 85% cell survival) to toxic (55% cell survival). This enhancement of cytotoxicity may be due to the effect of photochemical internalization (PCI). PCI, a specific branch of PDT, is a novel technology for the site-specific release of macromolecules within cells. The mechanism of PCI is based on the breakdown of the endosomal/lysosomal membranes by photoactivation of photosensitizers [13]. The micellar photosensitizing agent can be taken by cells via endocytosis and entrapped into the endosome/lysosome. After irradiation, PCI can disrupt the endocytic vehicles and enhance drug release to the cytosol [14-16].

D. Intracellular localization of free Dox and BSPPLA/Dox without or with PCI

Fig. 3 shows the intracellular distribution of Dox or BSPPLA/Dox nanoparticles in MCF-7/ADR cells. After uptake by MCF-7/ADR cells, doxorubicin was localized in discrete granules in the cytosol. Interesting, Dox was observed in nuclei after BSPPLA/Dox nanoparticles treatment for 12 hours without PCI. This may result in the cell toxicity of BSPPLA/Dox nanoparticles. However, the detail mechanism is not clear. After PCI, the Dox was obviously translocated from cytosol to nuclei that can cause the cell death.

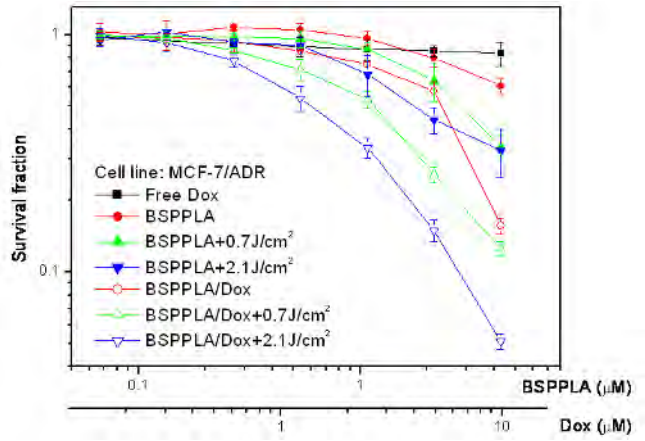

Fig. 2 Cytotoxicity and phototoxicity of BSPPLA/Dox in MCF-7/ADR cells.

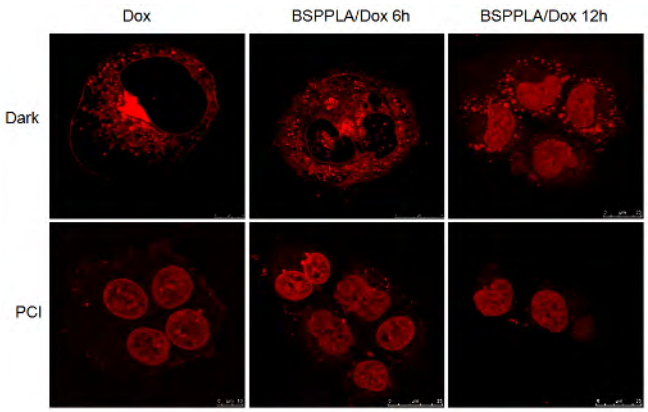

Fig. 3 Intracellular distribution of BSPPLA/Dox without or with irradiation.

IV. Conclusions

In this study, 4-armed star-shaped porphyrin-cored PLA were synthesized and characterized. These porphyrin-cored PLA could self-assemble to form nanoparticle using solvent evaporation method, which act as nanosized photosensitizing agents for PDT and further encapsulate hydrophobic drugs such as doxorubicin. Our results showed that these nanoparticles can improve the cytotoxicity of Dox significantly in MCF-7/ADR cells after irradiation in a synergistic effect. This functionalized nanoparticle delivery system is a potential dual carrier for the synergistic combination of

photodynamic therapy and chemotherapy for the treatment of cancer.

Abstract — **Multiple drug resistance (MDR) is a major clinical problem that seriously reduces the efficacy of many chemotherapy agents. In doxorubicin-resistant breast cancer cells, drugs accumulate only within discrete cytoplasmic organelles and almost none is detectable in the nuclei, the target of anthracycline drugs. Photochemical internalization (PCI), a specific branch of photodynamic therapy, is a novel technology utilized for the site-specific release of macromolecules within cells. In this study, the phototoxicity of dendrimer phthalocyanine (DPc)-encapsulated polymeric micelle (DPc/m) combined with doxorubicin was studied in drug-resistant MCF-7 cells. After photoirradiation with a LED (670 nm), the internalized DPc/m showed unique photochemical processes inside of the cells that can disrupt the endosomal/lysosomal membrane and thereby cause the doxorubicin release from the lysosome to nuclei. In conclusion, DPc/m-mediated PCI destroyed endosomal/lysosomal membrane efficiently that can reverse the MDR phenotype of doxorubicin resistant MCF-7 cells. The technique is a promising new approach to overcome the drug-resistance in breast cancer cells.**

I. Introduction

Photodynamic therapy (PDT) is an effective strategy for treatment of solid tumors via systemic administration of porphyrin- or phthalocyanine-based photosensitizers (PSs), followed by local irradiation with the light of a specific wavelength [1, 2]. Upon photoirradiation, PSs generate reactive oxygen species (ROS) such as singlet oxygen, leading to photochemical destruction of tumor vessels and tumor tissues. PDT is a recognized therapeutic modality for the treatment of a variety of human pre-malignant and malignant diseases. Photochemical internalization (PCI), a specific branch of PDT, is a novel technology utilized for the site-specific release of macromolecules within cells. The mechanism of PCI is based on the breakdown of the endosomal/lysosomal membranes by photoactivation of photosensitizers, aluminum phthalocyanine disulfonate ($AlPcS_{2a}$) or disulfonated meso-tetraphenylporphyrin ($TPPS_{2a}$), that localize on the membranes of these organelles [3]. The PCI strategy has been utilized to release macromolecules such as toxins, DNA delivered as a complex with cationic polymers or dendrimer-doxorubicin conjugates from endocytic vesicles to the cytosol [4-6].

The PSs applied on PDT/PCI are small molecules that may have several drawbacks *in vivo*. The development of tumor-selective PSs and their formulations is expected to restrain unfavorable side effects and improve the PDT efficacy against intractable tumors. In this context, the use of long-circulating nanocarriers such as polymer-drug conjugates [6, 7] and polymeric micelles [8-10] are a promising way to improve the tumor-selectivity of PSs based on the enhanced permeability and retention (EPR) effect [11]. Recently, the highly efficient ionic dendrimer photosensitizers with the core of porphyrin or phthalocyanine for PDT were developed by Prof. Kataoka [9, 12]. These dendrimer PSs can be encapsulated into polyion complex (PIC) micelles with remarkably high photocytotoxicity against cancer cells and successful treatment for experimental disease models of choroidal neovascularization in rats [8]. As previous study, DPc/m was accumulated in endosome/lysosome via endocytosis and disrupted the endosomal/lysosomal membrane successfully after irradiation that cause the enhancement of transgene expression [13]. DPc/m exhibited similar transfecion activity of $AlPcS_{2a}$-mediated PCI but without inevitable phototoxicity.

Multiple drug resistance (MDR) is a major clinical problem that seriously reduces the efficacy of many chemotherapy agents. In doxorubicin-resistant breast cancer cells, drugs accumulate only within discrete cytoplasmic organelles and almost none is detectable in the nuclei, the target of anthracycline drugs [14, 15]. This leads to increased drug sequestration in acidic vesicles, followed by transport to the outer cell wall and extrusion into the external medium as the protonation, sequestration, and secretion (PSS) model [16]. Recently, this plight can be overcome successfully via the disruption of endosomal/lysosomal membrane by $TPPS_{2a}$-mediated PCI *in vitro* [17]. However, $TPPS_{2a}$ exhibited several drawbacks including lower exciting wavelength, inevitable phototoxicity and poor tumor selectivity, DPc/m

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1451–1454, 2009
www.springerlink.com

provides an obvious deeper penetrating of light, passive targeting ability and lower phototoxicity that can specific destabilize the endosomal/lysosomal membranes for further PCI application.

In the present paper, we have studied *in vitro* photocytotoxicity of DPc/m combined with doxorubicin when drug-resistant MCF-7 cells were photoirradiated by a light emitting diodes (LEDs, 670 nm), and found that DPc/m showed unique photochemical processes inside of the cells to induce endosomal/lysosomal membrane and thereby cause the doxorubicin release from the lysosome to nuclei.

II. Materials and methods

A. Cell line and culture conditions

Human breast adenocarcinoma (MCF-7) cells and doxorubicin-resistant cells (MCF-7/ADR) were obtained from Dr. Lou of the Department of Otolaryngology, National Taiwan University Hospital. The cells were maintained in DMEM supplemented with 10% heat-activated fetal bovine serum (FBS), 2 mM L-glutamine and 1% antibiotics. The MCF-7/ADR cells were maintained continuously in 0.25 μM doxorubicin.

B. Cytotoxicity with doxorubicin and DPc/m mediated PDT given separately

The cytotoxicity of doxorubicin to MCF-7 and MCF-7/ADR cells was assessed by incubating the cells for 6h in medium containing different concentrations of doxorubicin, followed by washing of the cells 3 times, incubation in fresh culture medium and then subjecting the cells to viability assays using MTT method.

The effect of PDT was assessed by incubating the cells with various concentrations of DPc/m for 18h at 37^{o}C, washing the cells 3 times followed by incubation in phenol red-free medium for a further 6h. Then the cells were exposed to the light source with dose from 10J to 40J/cm^2 and subsequently subjected to the cell viability assays.

C. Stability assay of lysosomal membrane after DPc/m-PCI treatments

To evaluate the efficiency of different PCI strategies on endosomal/lysosomal membrane, acridine orange (AO) was utilized as an intracellular indicator of acid organelles in MCF-7/ADR cells. When normal cells were excited by blue light, highly concentrated lysosomal AO emitted an intense red fluorescence, while nuclei and cytosol showed weak diffuse green fluorescence [6]. In this study, cells were grown overnight on glass slides in 35-mm petri dishes and then treated with different concentrations of DPc/m for 18 hours. For 'light before' strategy, cells were irradiated by light source with 10 J and then the cultures were then incubated with 6 μM AO for 15 minutes. For 'light after' experiment, cells were incubated with 6 μM AO for 15min and then photoirradiated with 10J. After PCI and staining, the fluorescence of AO was immediately imaged by Leica-SP5 confocal laser scanning microscope.

D. Intracellular localization of doxorubicin after DPc/m-PCI treatments

To evaluate the influence of PCI on the intracellular distribution of doxorubicin, MCF-7/ADR cells were documented before and after the photochemical treatment by confocal laser scanning microscope. In brief, cells were grown on glass-based 35-mm petri dishes. After overnight, cells were incubated with 15 μM of DPc/m for 18 hours. For 'light before' strategy, cells were irradiated by light source with 10 J and then the cultures were then incubated with 5 μM doxorubicin for 1 hour. For 'light after' experiment, cells were incubated with 5 μM doxorubicin for 6 hours and then photoirradiated by LED light source at 10J. After treatment, the intracellular distribution of doxorubicin was assessed immediately by Leica-SP5 confocal laser scanning microscope.

E. Cytotoxic effects of PCI combined with doxorubicin

For the PCI studies (doxorubicin plus PDT), the cells were treated with various concentrations of DPc/m plus light dose from 10J to 40J/cm^2 as described above. Doxorubicin (2.5μM) was applied to the cultures immediately after light delivery for an incubation period of 6h, as the results from the experiments on intracellular drug localization showed that this was more effective than giving the doxorubicin before the light.

III. Results

A. Doxorubicin treatment in MCF-7 or MCF-7/ADR cells

Fig. 1 shows the cytotoxicity and intracellular localization of doxorubicin in MCF-7 or MCF-7/ADR cells. It is obviously that almost 90% MCF-7 cells were killed after 2.5 μM doxorubicin treatment for 24 hours, meanwhile, more than 80% MCF-7/ADR cells survived with 10 μM doxorubicin incubation. As shown in Fig. 1B, doxorubicin was accumulated only within discrete cytoplasmic organelles and almost none is detectable in the nuclei. Therefore,

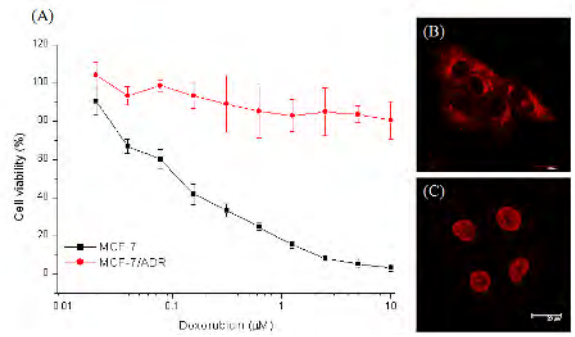

Fig. 1 Cell viability and intracellular localization of doxorubicin in MCF-7 and MCF-7/ADR cells

doxorubicin-resistance was observed. However, doxorubicin was localized in nuclei after 6 hours incubation in MCF-7 cells (Fig. 1C) that will cause the cell death.

B. Photochemical disruption of the endosomal/lysosomal membrane

To assess whether DPc/m could disrupt the endosomal/lysosomal membrane and could help doxorubicin escape from the lysosomes after irradiation, AO was utilized as a marker to trace the integrity of the endosomes/lysosomes. Without treatments, endosome/lysosome can be labeled as red spots (Fig. 2A). For "light after" PCI at 10 J/cm^2 light dose, red spots decreased with 1.5 μM DPc/m (Fig. 2E) and almost disappeared with a 3 μM DPc/m (Fig. 2G). However, red spots were almost non-detectable with 1.5 μM DPc/m "light before" PCI (Fig. 2F) at 10 J/cm^2 light dose. These results demonstrated that the endocytozed DPc/m, which accumulated in the endosomes/lysosomes, could destabilize the endosomal/lysosomal membranes and cause a rapid loss of AO staining of acidic organelles after

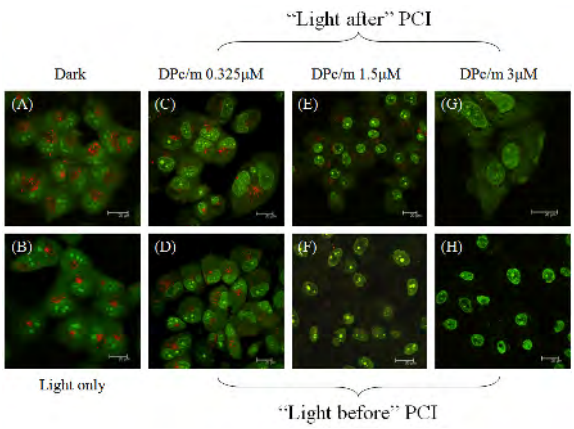

Fig. 2 Estimation of lysosome disruption capability of DPc/m with 10 J/cm^2 irradiation.

irradiation. Moreover, "light before" PCI strategy seems more efficient than "light after" PCI.

C. Intracellular localization of doxorubicin combined with DPc/m-PCI

Fig. 3 shows the distribution of doxorubicin in MCF-7/ADR cells without or with PCI. After uptake by MCF-7/ADR cells, doxorubicin was localized in discrete granules in the cytosol (Fig. 3A). After PCI, the distribution of doxorubicin in MCF-7/ADR cells was apparently changed. For "light after" PCI, red spots in cytosol decreased and slight fluorescence of doxorubicin increased in the nuclei. For "light before" PCI, no red spots can be observed in the cytoplasma and the doxorubicin was translocated from cytosol to nuclei. It is evidently that "light before" PCI is more efficient in endosomal/lysosomal disruption and enhancement of nuclear accumulation of doxorubicin than "light after" PCI.

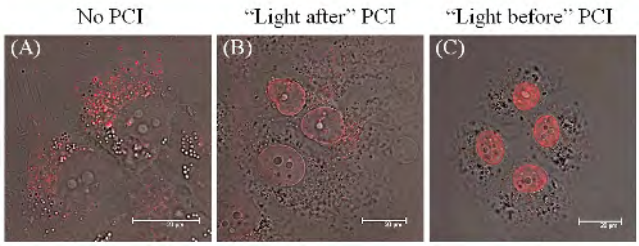

Fig. 3 The intracellular distribution of doxorubicin before and after PCI.

D. Cytotoxicity of doxorubicin combined with DPc/m-PCI

Fig. 4 shows the dose-dependent nature of the cytotoxicity and phototoxicity of DPc/m with or without doxorubicin treatment in MCF-7/ADR cells. It is obvious that the cytotoxicity of doxorubicin can be enhanced after 0.3125 μM DPc/m-mediated PCI at 20 or 40 J/cm^2 light dose. This enhancement of cytotoxicity may be due to the effect of PCI. The micellar photosensitizing agent can be taken by cells via endocytosis and entrapped into the endosome/lysosome. After irradiation, PCI can disrupt the endocytic vehicles and enhance doxorubicin translocation to nuclei.

IV. Conclusions

Drug-resistance is a major problem of clinical chemotherapy. We demonstrated that the DPc/m is a promising biomaterial to overcome the drug resistance based on PCI effect. Moreover, "light before" PCI strategy is more efficient to improve the cytotoxicity of doxorubicin in MCF-7/ADR cells. As PDT is becoming increasingly used for

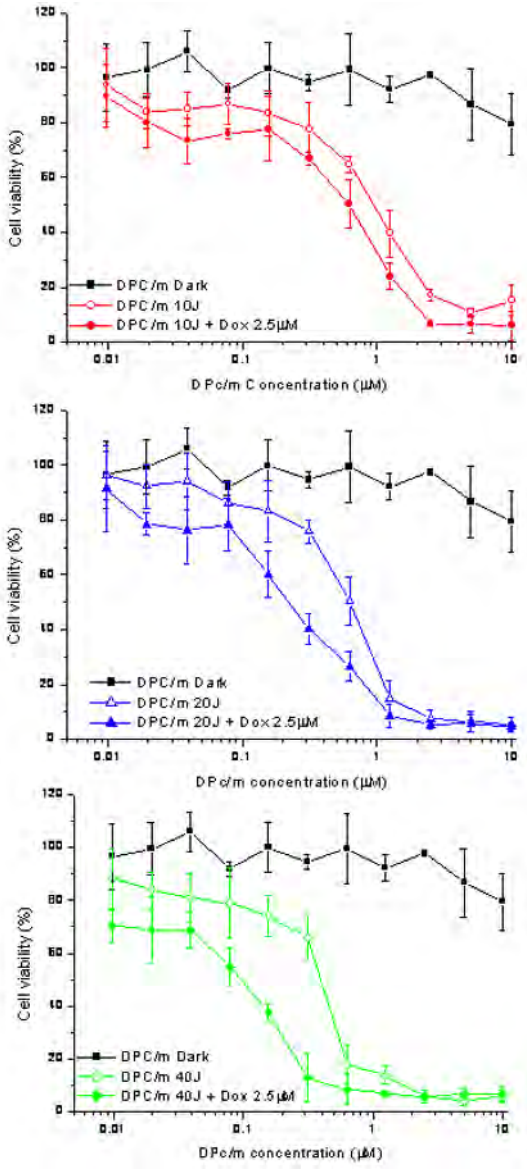

Fig. 4 Cell survival of doxorubicin combined with "light before" PCI in MCF-7/ADR cells.

cancer treatment, these findings may have important implications for the use of chemotherapy agents like doxorubicin in patients with drug resistant cancers.

Amino Acid Coupled Liposomes for the Effective Management of Parkinsonism

P. Khare and S.K. Jain*

Department of Pharmaceutical Sciences, Dr H. S. Gour University, Sagar (M.P.)-470003 INDIA

Abstract — **Purpose: The Blood Brain Barrier restricts the brain uptake of many valuable hydrophilic drugs and limits their efficacy in the treatment of brain diseases because of the presence of tight junctions, high metabolic capacity, low pinocytic vesicular traffic and efficient efflux mechanisms. Parkinson's disease is a brain disorder caused due to deficiency of dopamine-HCl (Neurotransmitter). In the present project, amino acid coupled liposomes bearing dopamine-HCl were prepared to deliver the drug to the brain for the management of Parkinsonism utilizing receptor-mediated transcytosis. Method: Uncoupled liposomes were prepared by cast film method using phosphatidylcholine and cholesterol whereas coupled liposomes were prepared using phosphatidylcholine, cholesterol and lysine stearylamine conjugate (LSC) in the film. These liposomes were characterized for entrapment efficiency, vesicle size, shape, in vitro drug release and in vivo studies. The vesicle size was found to increase upon coupling of liposomes, whereas percent entrapment efficiency was reduced from 38.40±1.94% to 34.15±1.70% after coupling of liposomes. The in vitro percent cumulative drug release studies exhibited 58.7% drug release for uncoupled liposomes and 43.9% drug release for coupled liposomes at the end of 24 hours. These selected formulations were subjected for in vivo performance, which was assessed by periodic measurement of drug (Chlorpromazine) induced catatonia in albino rats (Wistar strain) and fluorescence microscopy studies of the rat brain using fluorescent marker. The results were compared with plain dopamine-HCl solution. Conclusion: Studies revealed that dopamine-HCl can be effectively delivered to the brain via lysine-coupled liposomes and exhibited superiority of coupled liposomal formulation over uncoupled formulation.**

Keywords — **Brain targeting, Parkinsonism, Catatonia, Liposomes**

I. Introduction

The drug delivery to the brain in effective concentration is a challenging task due to the presence of blood brain barrier. It is well established that blood brain barrier (BBB) is a unique membranous barrier that tightly segregates the brain from the circulating blood [1, 2]. The BBB is formed by brain capillary endothelial cells, which are linked to each other by tight junctions and lack in fenestrations. Hence the delivery of many essential substances is dependent on carrier mediated transport systems that are present on the membrane of brain capillary endothelial cells [3]. Metabolic substrates such as glucose and some amino acids have insignificant lipid solubility and penetrate the BBB rapidly by means of specific carrier transport systems. Numerous strategies have been developed for the effective transport of drug molecule across the BBB [4]. Among these strategies receptor mediated endocytosis is one of the specialized methods.

Liposomes have been widely used as drug carriers which are self assembled vesicles composed of a lipid bilayer that forms a closed shell, surrounding an internal aqueous phase and able to entrap hydrophilic and hydrophobic molecules [5,6]. Also they are non-toxic, biodegradable and composed of natural biomolecules. Increasing interest in receptor mediated targeting of liposomes has led to development of a variety of procedures for the coupling of ligands to preformed liposomes [7-9]. The reagents employed during coupling may destabilize or penetrate the vesicle bilayers and inactivate or modify entrapped agents. This problem can be avoided by the coupling of ligands to lipids, which are then incorporated into liposomes. The brain capillary endothelial cells of BBB are rich in amino acid transporters and hence L-lysine coupled liposomes bearing dopamine-HCl were developed to facilitate the transport of drug across BBB via receptor-mediated endocytosis. The dopamine-HCl is a drug of choice for treatment of Parkinsonism. But it does not cross BBB and is degraded in systemic circulation. Thus, its therapeutic use for treatment of the disease is limited. Hence the drug was encapsulated in the L-lysine coupled liposomes to facilitate its delivery across the BBB as well as to protect its degradation in the systemic circulation.

II. Experimental section

Materials

Phosphatidyl choline (PC), Cholesterol (CH), Stearylamine, L-lysine, Triton X-100 and Dicyclohexylcarbodiimide (DCC) were procured from Sigma chemicals, St Louis, MO, USA. Dopamine-HCl was generously supplied by Troikka Labs, Ahemdabad (Gujarat), INDIA, as gift sample. All the solvents used were of analytical grade.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1455–1458, 2009
www.springerlink.com

A. Synthesis of L-Lysine Stearylamine Conjugate

The conjugate was prepared in two steps via carbodiimide reaction, first di-BOC-lysine was synthesized and then amino acid-stearylamine conjugate was synthesized. The formation of conjugate was confirmed by IR-spectroscopic study of the conjugate.

B. Preparation of liposomes

Liposomes were prepared by film cast method. Uncoupled liposomes were prepared by taking phosphatidylcholine and cholesterol in ratio 7:3 (PC: CH, optimized ratio) whereas coupled liposomes were prepared by using phosphatidylcholine, cholesterol and L-lysine stearylamine conjugate in a ratio of 7:3:1.5 (PC: CH: LSC, optimized ratio). The lipid components were dissolved in chloroform and methanol mixture (2:1) and the solvent was evaporated to cast a thin film on the inner surface of round bottom flask using a rotary vacuum evaporator. The dried film was hydrated with phosphate buffer saline (PBS) of pH 7.4 containing dopamine-HCl. All the preparations were briefly sonicated for a period of 30 seconds. Coupled and uncoupled formulations were characterized for vesicle size, percentage entrapment efficiency and in vitro drug release**.** Entrapment efficiency of the coupled and uncoupled liposomes was determined using the method described by Fry, et al. [10]. Drug content was analyzed spectrophotometrically at 280 nm using the method reported in USP [11]. The *in vitro* drug release from the coupled and uncoupled liposomal formulations was analysed using dialysis method.

C. In vivo studies

The *in vivo* efficacy of the coupled and uncoupled formulations was assessed by measuring the reduction in the degree of drug-induced catatonia in albino rats (wistar strain). The study was approved by University Animal Ethical Committee. The performance of plain drug solution, uncoupled formulation and coupled formulation was compared.Twenty-four animals were selected, weighed and divided in four groups, with six rats in each group. First group was kept as control while second, third and fourth group animals were intravenously (i.v) administered plain dopamine-HCl solution of (1mg/ml), uncoupled formulation and coupled formulation, respectively. The Chlorpromazine (5mg/kg) was injected intravenously to all the animals 30 minutes after the drug treatment. The reduction in the degree of catatonia was recorded periodically.The reduction in degree of catatonia was assessed by scoring the animals periodically. Difficulty in moving and changing the posture by the animals was evaluated by alternately placing the paw of the rat on a 3-cm-and 9-cm-high block.

D. Fluorescence Microscopic Study

The fluorescence microscopy was performed in order to confirm the brain delivery of the coupled liposomes and uncoupled liposomes. 6-carboxyfluoroscein was used as fluorescence marker, which was encapsulated into the coupled and uncoupled liposomes. The formulations were administered to albino rats intravenously. Rats were sacrificed after 30 minutes and brain from these animals was excised Then microtomy was done with the help of microtome and ribbons of sections obtained were fixed on slides using egg albumin solutions as fixative.

III. Results and Discussion

The L-lysine coupled liposomes were prepared by incorporation of L-lysine Stearylamine conjugate (LSC) in the lipid film, which was synthesized using carbodiimide chemistry. The conjugate was characterized by IR spectroscopy, which revealed different peaks (Fig.1).

Peaks at 3343cm^{-1} (N-H stretching), 1465cm^{-1} (N-H bending), and 1683cm^{-1} (C=O stretching) revealed the formation of amide bond between L-lysine and stearylamine, which confirmed the formation of Lysine stearylamine conjugate (LSC). Peaks at 2921 cm^{-1}, 2851 cm^{-1}, 1465 cm^{-1}, 722 cm^{-1} show different methyl and methylene group vibrations.

Shape of liposomes was found to be spherical in both uncoupled and coupled formulations (Fig. 2).

The average vesicle size of the uncoupled and L-lysine coupled liposomes was determined and found to be in the range of 1.25±0.06 to 0.36±0.04 μm and 1.56±0.09 to

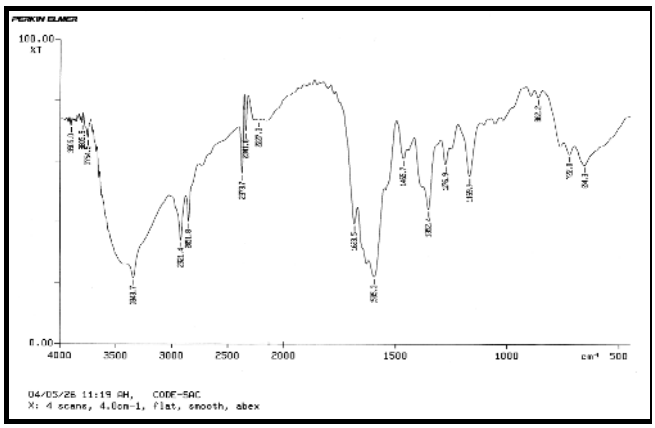

Fig.1. IR of L-Lysine Stearylamine Conjugate (LSC)

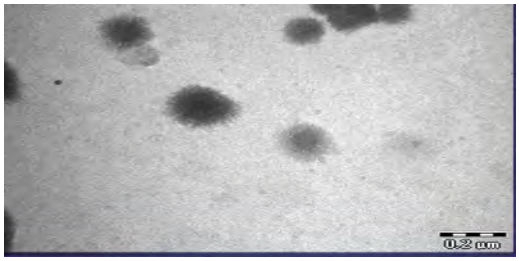

Fig.2. TEM photomicrograph of Coupled liposomes

Table 1: Characterization of liposomal formulation

Formulation code	PC: CH: Molar ratio	Lipids: LSC ratio	Vesicle size (µm)	Percent encapsulation efficiency
			Initial/ After coupling	Initial/ After coupling
LIP-A	9:1		1.25±0.06	43.56±2.17
LIP A-C		9:1:0.5	1.86±0.09	36.23±1.81
LIP-B	8:2		1.05±0.05	41.45±2.07
LIP B-C		8:2:1	1.65±0.08	34.93±1.71
LIP-C*	**7:3**		**0.41±0.04**	**38.40±1.94**
LIP C-C*		**7:3:1.5**	**0.56±0.06**	**34.15±1.70**
LIP-D	6:4		0.36±0.04	35.89±1.79
LIP D-C		6:4:2	0.52±0.05	22.14±1.10

Values are mean±sd, where n= 3. * Optimized parameter

0.52±0.05 µm, respectively. The increase in size for coupled liposomes was due to the inclusion of L-lysine stearylamine conjugate in the liposomal bilayer. The percentage entrapment efficiency was found to be 38.40±1.94% for uncoupled formulation and 34.15±1.70% for coupled formulation (Table 1). This could be due to change in the bilayer statistics and less available space for entrapment.

The *in vitro* drug release was analysed by calculating percentage cumulative drug release. It was found to be 58.7±2.94% for uncoupled formulation whereas it was 43.9±2.18% for coupled formulation, at the end of 24 hours. The lower value for coupled formulation could be due to the retardation of drug release caused due to the incorporation of LSC in the liposomal bilayer, which enhanced the structural integrity of the bilayer (Fig. 3).

The *in vivo* performance of the plain dopamine solution and the liposomal formulations was evaluated by measuring reduction in drug-induced catatonia in albino rats. Observations are tabulated in Table 2. Results revealed that dopamine-HCl solution did not show any reduction in degree of catatonia (score 3.5 after 180 minutes) while the animals in the third group which received uncoupled liposomal formulation showed partial reduction in catatonia (maximum score 3.5 for 4 animals and 1.5 for 2 animals).

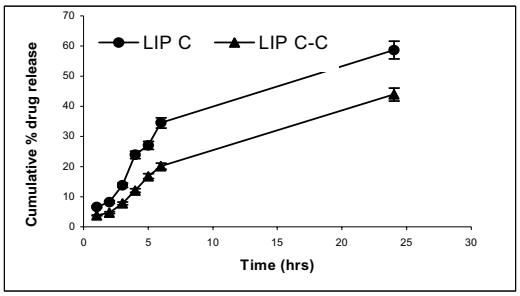

Fig.3. Cumulative Percent Drug Released after i.v. administration of coupled and uncoupled liposomes

Table 2: Effect of different formulations on the drug-induced catatonia in albino rats.

Action	Dopamine-HCl Solution (100mg/kg)	LIP C	LIP C-C (100mg/kg)
No reduction	6	4	None
Partial reduction	None	2	2
Complete reduction	None	None	4

The animals of the fourth group, which received coupled formulations showed almost complete reduction in catatonia (maximum score 1.5 for 2 animals and 0.5 for 4 animals). This could be due to enhanced uptake of L-lysine coupled liposomes through amino acid transporters present at BBB surface with subsequent delivery of dopamine-HCl to the brain effectively (Table 2).

Furthermore Fluorescence microscopy was performed to establish a qualitative over view of the liposomal targeting to brain and to confirm the brain uptake of lysine coupled liposomes by using 6 CF (6-carboxyfluoroscien) as fluorescence marker (Fi. 4). Fluorescence microscopic studies exhibited no fluorescence in the brain tissue when plain dye solution was administered and fluorescence was observed only in the blood vessels whereas on administering uncoupled liposomes, the fluorescence was observed in the adjoining area of the blood vessels of the brain which could be due to the entry of a little amount of the uncoupled liposomes containing 6 CF which might have gained entry through the Jonula occludence of the endothelium, crossing the nervous tissue. On the other hand lysine coupled liposomes containing 6 CF showed uniform intensity of fluorescence in the neuroglia and cerebral spinal fluid while uncoupled liposomes did not access these parts of the brain.

Therefore, it can be concluded that lysine coupled liposomes can localize efficiently in the brain and can subsequently deliver the therapeutics to the brain as compared to the uncoupled liposomes.

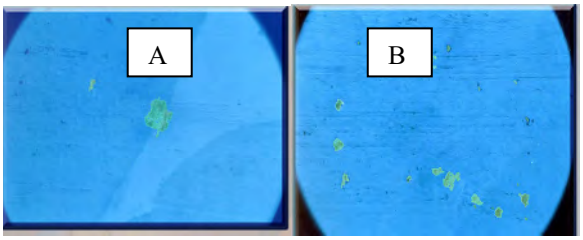

Fig. 4. Fluorescent photomicrographs of brain sections.
A: Photomicrograph after administration of Unoupled liposome.
B: Photomicrograph after administration of Coupled liposome.

IV. Conclusions

Conclusively it can be stated that dopamine-HCl can be delivered effectively through L-lysine coupled liposomes to the brain for effective management of Parkinsonism. Also, they hold great potential for targeting of therapeutics across BBB. However, a deep pharmacokinetic and clinical assessment is needed to establish their efficacy and quality.

Corrosion Resistance of Electrolytic Nano-Scale ZrO_2 Film on NiTi Orthodontic Wires in Artificial Saliva

C.C. Chang[1] and S.K. Yen[2]

[1]Department of Dental Technology, Shu Zen College of Medicine and Management, Kaohsiung , Taiwan
[2]Department of Materials Science and Engineering, National Chung Hsing University, Taichung, Taiwan

Abstract — **Nano-Scale ZrO_2 films were produced on NiTi alloy orthodontic wires using electrolytic deposition to prevent corrosion and nickel ion release. Nickel ion release was observed in cyclic potentiodynamic test in artificial saliva at 310K. The amount of the nickel ion release was measured by inductively coupled plasma-atomic emission spectroscopy (ICP-AES), and for the Electrolytic ZrO_2 films samples, the nickel ion release level was 58 ppb. The ZrO_2 film reduced the nickel ion release level by 78%. The cyclic potentiodynamic test results showed the lower corrosion density of electrolytic ZrO_2 film than uncoated.**

Keywords — **Corrosion Resistance, Ion Release, Electrolytic Deposition, ZrO_2, NiTi Wires**

I. Introduction

Ti and Ti alloys have been widely used for dental applications due to their good mechanical properties, corrosion resistance, and biocompatibility. However, corrosion of Ti and Ti alloys still occur in some clinical circumstances. The release of metal ions from dental alloys may have adverse biological effects, depending on the ion species and its concentration. In conventional orthodontic treatment, NiTi alloy, which contains about equi-atomic Ni and Ti, is one of the most common orthodontic wires applied clinically due to its good working and mechanical properties [1].

Ni is capable of eliciting toxic and allergic responses [2,3]. In vivo study, NiTi alloys show cytotoxic reactions [3]. It is clear that the potential risk associated with corrosion, in the use of NiTi orthodontic wires, comes from the biological side effects of Ni.

Recently, electrolytic Al_2O_3 and ZrO_2 coatings on metal have been verified to improve the corrosion resistance and wear resistance [4-6] of biomedical alloys. This method has several potential advantages, including the cheap deposition technology, low preparation temperature, high purity of deposits, the ability to cover complex shapes of various materials and the application of multi-component oxides [7]. Especially, the film thickness can be controlled under 300 nm [8] which is required for the orthodontic wires. Electrolytic deposition is achieved via hydrolysis of metal ions or complexes by electrogenerated base to form hydroxide or peroxide deposits on cathode substrates. Hydroxide and peroxide deposits can be converted to corresponding oxides by thermal treatment [7,8].

In this study, the electrolytic nano-scale ZrO_2 film has been deposited on NiTi wires in $ZrO(NO_3)_2$ aqueous solutions. The characteristics of the film have been examined corrosion resistance.

II. Experimental

Materials: An equiatomic NiTi (Rematitan® Life, Dentaurm, Prorzheim, Germany) wire with a diameter 0.016 inch was employed in experiments.

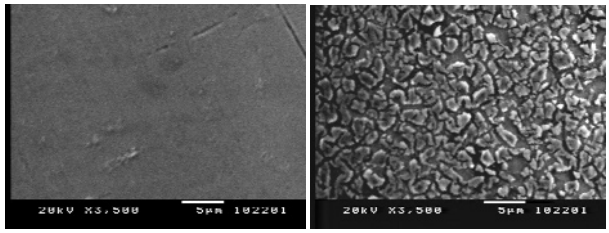
Electrolytic Deposition: The electrolytic ZrO_2 film was deposited on NiTi wire in 0.03125 M $ZrO(NO_3)_2$ aqueous solution at voltage -1.2 V for 500 and 1000s at room temperature, using an VersaSTAT^3 potentiostat (Princeton Applied Research). The sample was the cathode, graphite bars (φ= 5 mm, l= 55 mm) were the anode and saturated Ag/AgCl was the reference electrode. The coated specimens were then naturally dried in air and annealed for 3 h at 723K.

SEM: The surface morphology of coated specimens was observed by scanning electron microscopy (SEM, JEOL, JSM-5400, Japan).

Polarization Test and ICP-AES: The corrosion resistance of the ZrO_2 film was evaluated by an electrochemical cycle dynamic polarization test in artificial saliva (Table 1) at

Table 1 The composition of artificial saliva

composition	mg/L
NaCl	400
KCl	400
$CaCl_2 \cdot 2H_2O$	795
$NaH_2PO_4 \cdot H_2O$	690
KSCN	300
$Na_2S \cdot 9H_2O$	5
Urea	1000



Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1459–1461, 2009
www.springerlink.com

310K, also by using VersaSTAT[3]. After the open-circuit potential became steady, the cyclic polarization test was from -0.2 V (vs. open-circuit potential) to 1 V (Ag/AgCl), then back to open-circuit potential at a scanning rate of 0.167 mV/s. The first oxidation-reduction equilibrium potential E_{01} was derived when current density equaled zero during the applied voltage increased (forward cycle). If oxidation is due to the corrosion of electrode, this potential is also named corrosion potential E_{corr}, and the corrosion current density i_{corr} can be calculated at this potential. The second oxidation-reduction equilibrium potential E_{02} was derived when current density was back to zero again during the applied voltage decreased (backward cycle). If the oxidation is decreased abruptly at some passivation potential E_{pass}, because of the formation of passivation films and corrosion rate falls to very low, and the beginning current density is named the critical passive current density i_{crit}, and the stable current density is named the passive current density i_{pass}. If the oxidation is increased abruptly at some pitting potential E_{pit} because of the breakdown of passive film and the localized corrosion of the electrode, the crossover of the backward cycle and the forward cycle on the anodic polarization region will be found because of repassivation and defined as protection potential E_{pp}.

The amount of the nickel and Ti ions release after cycle dynamic polarization test was measured by inductively coupled plasma-atomic emission spectroscopy (ICP-AES, ICAP 9000, Jarrell-Ash, USA).

III. Results and Discussion

Surface Morphology: The SEM observations of specimens coated at -1.2V for 500 and 1000 s after annealed at 723K are show in Fig. 1(a) and (b), respectively. No cracks are found in Fig. 1(a), but they are found for a longer deposition time or thicker film, as shown in Fig 1(b). These cracks occur because the evaporation rate of H_2O from the coating surface is higher than the diffusion rate of H_2O from the bulk of coating, during drying in air. Thus, a tension effect will be found on the film surface due to shrinkage as it contains less H_2O than the bulk. SEM cross sectional observation of the ZrO_2 film specimen is shown in Fig. 2. The thickness of ZrO_2 film was approximately 150 nm.

(a) (b)

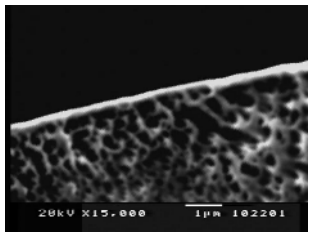

Fig. 2 SEM Cross-sectional observation of ZrO_2 coated for 500s after annealed at 723K for 3 h.

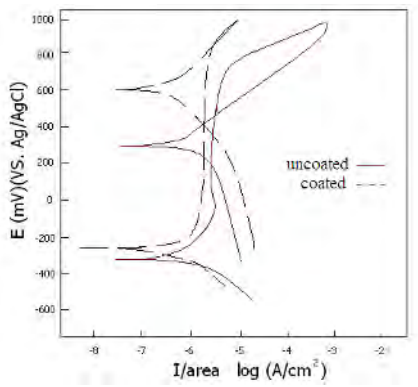

Fig. 3 Polarization curves of the uncoated and ZrO2 coated specimens in artificial saliva at 310 K.

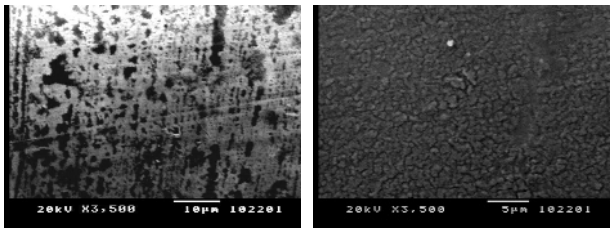

Corrosion Resistance: Electrochemical cycle polarization curves of the uncoated and coated specimens in artificial saliva at 310 K are show in Fig. 3. From the forward curves, E_{01} (or E_{corr}), i_0 (or i_{corr}), E_{pass}, i_{crit}, i_{pass} and E_{pitt} were analyzed, and from the backward curves E_{02} and E_{pp} were measured, as given in Table 2. The ZrO_2 film specimens

Table 2 List of the first redox potential E_{01} (E_{corr}), exchange current density i (i_{corr}), critical passive current density $i$crit, passive current density i_{pass}, pitting potential E_{pit}, the second redox potential E_{02} and protection potential E_{pp} of the uncoated and ZrO_2 coated specimens, derived form the polarization tests in artificial saliva

Specimens	E_{01} (E_{corr}) (mV)	i(i_{corr}) (10^{-6}A/cm^2)	i_{crit} (10^{-6}A/cm^2)	i_{pass} (10^{-6}A/cm^2)	E_{pitt} (mV)	E_{02} (mV)	E_{PP} (mV)
NiTi wire	-322	0.92	51	18	772	322	462
ZrO_2/NiTi wire	-250	0.45	-	37	854	604	840

revealed the higher E_{corr}, E_{pitt}, and lower i_{corr} and i_{pass}. After polarization tests in 3.5% artificial saliva, the large area corrosion on the uncoated was observed, as shown in Fig. 4a, but none on the coated, as shown in Fig. 4b.

Table 3 show the concentration of Ni and Ti ions in artificial saliva after the electrochemical cycle polarization tests that had been released from wires. As a result of the electrochemical cycle polarization tests, the ZrO_2 film coating reduced the amount of the Ni and Ti ions release by 78% and 76%, respectively. That is presumably due to these properties of ZrO_2 film, the Ni ion release from the orthodontic wires was reduced. The primary concern with NiTi orthodontic wires is a possible influence of Ni ion release on biocompatibility. Applications of the ZrO_2 film to prevent the Ni ion release problem are very appropriate.

(a) (b)

Fig 4. SEM observations of (a) the uncoated and (b) ZrO_2 coated specimens after polarization test in artificial saliva at 310 K.

Table 3 Concentration of Ni and Ti ions released from the NiTi wires

Specimens	Ni concentration (ppb)	Ti concentration (ppb)
NiTi wire	264	374
ZrO_2/NiTi wire	58	88

IV. Conclusions

In this study, ZrO_2 film was deposited on NiTi wires and the effects of ZrO_2 film coating on the Ni ion release from orthodontic wires were investigated. Using electrolytic deposition process, ZrO_2 films were deposited on NiTi wires successfully. In the electrochemical cycle polarization test, it was observed the amount of the Ni and Ti ions release were reduced by 78% and 76%, respectively. Applications of the ZrO_2 film to prevent the Ni ion release problem of NiTi wires are very appropriate.

Abstract — **High flux dialysis the first choice of therapy for hemodialysis patients within the last decade due to its clinical outcome. In this study the effect of dialysis environment on the mechanical and structural stability of high flux dialyzers containing polysulfone membranes were investigated. Dialysis sessions were performed on a certain group of patients with dialysis ages less than two years and without any other accompanying disease. Mechanical data and XRD results revealed the differences in material characteristics between virgin and used membranes obtained from polysulfone membranes. With the help of tensile tests it was shown that the mechanical properties used membranes were reduced in terms of ultimate tensile strength. XRD experiments revealed that the degree of crystallinity of the polysulfone dialysis membranes were raised. It was concluded that high flux dialyzer membranes are becoming more brittle and having more crystallinity after dialysis session. By this way the membranes are more prone to mechanical defects during dialysis. The degree of crytallinity increases under cyclic loading which resembles the changing of the pump speed or transmembrane pressure during dialysis in case of clinical situations like hypotension during dialysis. This issue is very important for dialysis centers performing reuse procedures for dialysis centers, because any damage to dialysis membranes would cause very serious clinical complications.**

Keywords — **High flux, hemodialysis, x-ray diffraction, mechanical properties**

I. Introduction

Due to their clinical outcome high flux dialyzers containing new generation of dialyzer membrane materials have been widely used for patients with chronic renal failure within the last decade [1]. Improved survival for hemodialysis patients was reported for synthetic, high-flux compatible membranes [2,3]. Dialyzer membranes are more prone to damage to the harsh environment during high flux dialysis. Reuse of dialyzers has advantages such as better biocompatibility and lower cost. Any damage of the dialyzers membrane during reuse of the dialyzers can also cause very serious clinical complications. Therefore; reuse of the dialyzers is an issue that has to be approached more cautiously [4]. In this study polysulfone dialyzer membranes were investigated in terms of mechanical properties and changes in crystallinity before and after dialysis sessions. Internal and external pressures are applied to the dialysis fibers by the pump of the hemodialysis machine, dialysate and blood. The dialysis membrane has to withstand these pressures during hemodialysis because any damage in any part of the hemodialysis membrane will cause changes in the material exchange properties of the membrane. Dialysis sessions were performed on five patients with dialysis ages less than two years and without any other accompanying disease at the Hemodialysis Department of Istanbul Haydarpasa Numune State Hospital.

II. Materials and method

A. Tensile Test Studies and SEM Studies

Many factors contribute to the differences in fiber tensile behavior, including fiber geometrical shape, morphological structure and fiber fracture mechanism [5].

In order to have more information about the mechanical behavior of the dialysis membranes tensile testing studies were performed. As dialysis membranes are produced as hollow fibers with thousands of pores on each fiber, this structure can not be ignored from fracture mechanics point of view. Under loading condition, circular shape of the pores may be converted into elliptical shape. At the end of major axes of ellipse high amount of stress concentration is expected. The pore sizes of virgin polysulfone membranes and used polysulfone membranes after tensile test can be compared on figures 1 and 2.

These experiments were performed by using Instron tensile testing machine. All tests were run at room temperature and in laboratory atmosphere and the load cell, which was used for the experiments was 50 kilograms. Crosshead speed was kept constant (50 mm/min) and the gauge length was always 40 mm for all tensile testing studies.

In this study virgin and used hollow fibers originating from dialyzers with polysulfone membranes were used. For virgin fibers tensile test with monotonic loading until fracture was performed. For used fibers two different tensile testing methods were performed:

Experiment 1: Tensile test with monotonic loading until fracture of a used fiber
Experiment 2: Cyclic test with 90% of the maximum stress required for fracture for a used fiber followed by tensile test with monotonic loading until fracture.

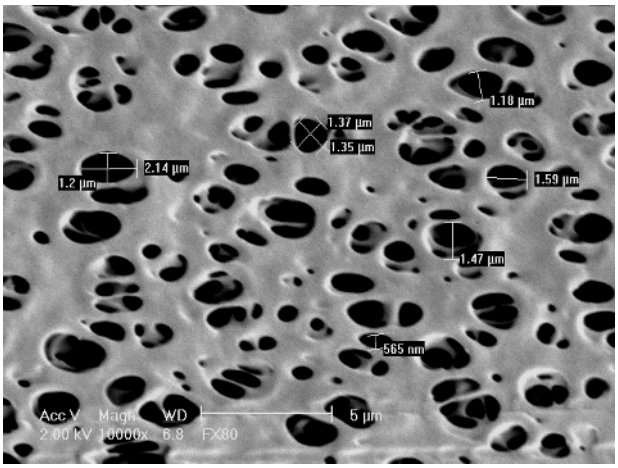

Fig. 1 Pore sizes of a virgin polysulfone membrane.

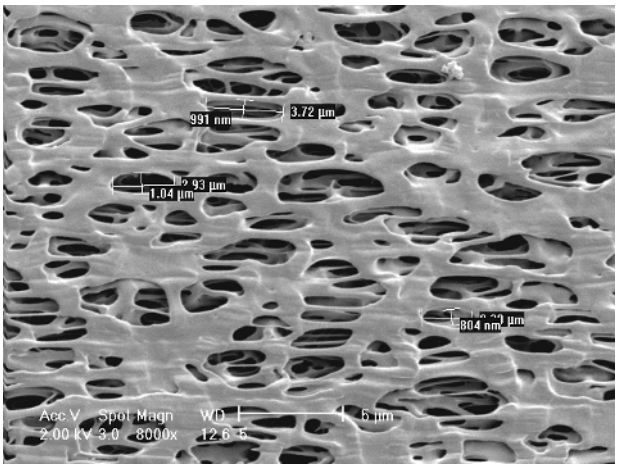

Fig. 2 Pore sizes of a used polysulfone membrane after tensile test.

B. XRD (X-Ray Diffraction) Studies

X-ray diffraction (XRD) is one of the most powerful technique for qualitative and quantitative analysis of crystalline compounds. A polymer can be considered partly crystalline and partly amorphous. Many polymers can be identified by using the XRD method. Polymers are, at least in part, crystalline or pseudo-crystalline with partially ordered structures. The degree of crystallinity can be quantified with this nondestructive, analytical technique. If the degree of crystallinity is increased in a material, it becomes more brittle [6]. The crystallinity parts give sharp narrow diffraction peaks and the amorphous component gives a very broad peak [7].

Following XRD studies have been performed for virgin and used polysulfone membranes, which were used for five different patients. The patients were chosen among the patients with dialysis ages less than two years. Following XRD experiments were performed:

XRD studies on virgin polysulfone membranes
XRD studies on used polysulfone membranes after dialysis
XRD studies on used polysulfone membranes after tensile testing.
XRD studies with used polysulfone on which cyclic tests were applied before continuous monotonic loading until fracture

XRD studies were performed with Rigaku Dmax 2200 XRD instrument. The d-spacing value was 1,54059 Å. X-Ray voltage and current values were 40kV and 40mA. Copper x-ray tube was used for XRD the experiments.

III. Experimental Results

A. Tensile Test Results

Depending on the results of the tensile tests performed it was concluded that virgin polysulfone membranes can resist higher loads compared to used ones. After one dialysis session ultimate tensile strength of a used polysulfone membrane lowers by approximately 30,94 % compared with the values virgin membranes, but it was also observed that the strain required for fracture of a used polysulfone membrane was 38,12% higher than virgin ones. It can be observed that membranes are becoming more ductile after first use and can only resist lower loads (Fig.3).

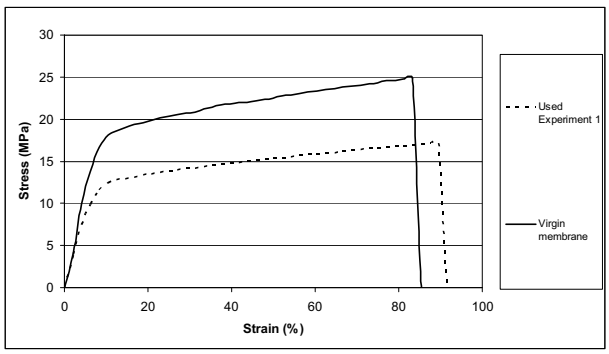

Fig. 3 Tensile testing results of virgin and used polysulfone hollow fibers.

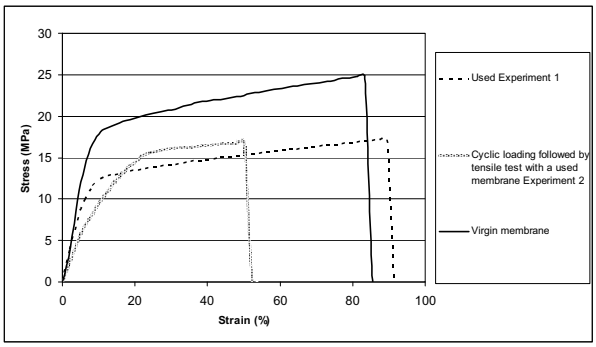

Fig. 4 Tensile testing results of virgin and used polysulfone hollow fibers (Experiment1 and 2)

The second types of tensile testing experiments included cyclic tests with 90% of the maximum stress required for fracture for a used fiber followed by tensile test with monotonic loading until fracture It was observed that the ultimate tensile stress value is near to the one of the used membrane, but this value was 35,89 % lower than to the ultimate tensile stress value of a virgin membrane. Cyclic loading followed by tensile test cause a 7,1 % reduction in stress values of the polysulfone membranes compared to used ones The reduction in strain values after cyclic loading followed by tensile test was 28,75% compared to virgin membranes. When the tensile test data of used membranes are compared a 48,4% reduction in strain values can be observed (Fig.4). These data show us that membranes are becoming more brittle with loading and unloading processes.

B. Results of the XRD Studies

After the XRD experiments it has been observed that there are three main intensity peaks in virgin polysulfone membrane and four main intensity peaks in used polysulfone membranes. The first three peaks at 2θ =14, at 2θ = 17 and at 2θ = 27 are present in the XRD data of both virgin and used polysulfone membranes, but the fourth peak at 2θ = 33 is only observed in used membranes (Fig.5).

The intensity values of all the peaks are getting their highest values when the membrane after cyclic loading followed by continuous monotonic tensile test. In used membranes the mean intensity value at 2 θ = 27 is 44,4 % higher compared to the same intensity value of a virgin membrane. The mean intensity value of used polysulfone membranes at 2θ = 17 is 20 % higher than the XRD value of a virgin membrane. At the intensity of 2 θ = 27 data obtained from XRD studies of used membranes are 40 % higher than the data from virgin membranes.

When cyclic loading followed by continuous monotic tensile test is applied to used membranes, the intensity values elevated between 59% - 70% compared with the values of virgin membranes.

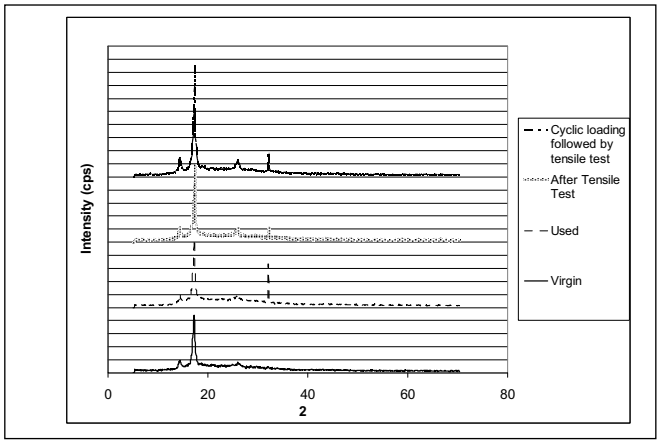

Fig. 5 Overview of the XRD results virgin and used fibers originating from patient M.D.

IV. Discussion

High flux dialysis has already proven itself with its superior clinical outcomes compared to low flux dialysis. Membranes for high flux hemodialysis have to resist a much more harsh environment due to factors such as increased flowrates compared to low flux dialysis. Depending on the results of the tensile test and XRD experiments the membranes are becoming more ductile and more brittle after the first use. The problem worsens when cyclic loading is applied to the polysulfone membranes. During hemodialysis the pump speed or the transmembrane pressure is lowered, when patients have a severe hypotension periods. When the clinical status of the patient stabilizes, the pump speed or transmembrane pressure is slowly elevated by the physicians. From the mechanical point of view this situation resembles the cyclic loading procedure performed during our experiments. Depending on the study by Lameire there is no significant risk between using new or reused membranes for hemodialysis [8]. But depending on the data obtained in our experiments the reuse issue with high flux membranes is still a question that has to be further investigated.

Abstract — **An accurate method of blood glucose measurement for Diabetes patients is presented in this paper. The people affected with Diabetes Mellitus use Glucometers for measuring their blood glucose level. The present days Glucometers use the principle of Reflective Colorimetry for calculating the Glucose concentration in the capillary blood applied over the Test Strips. This measurement has an accuracy of plus or minus 20 variations. This variation could be reduced if we apply the Sixth order polynomial for conversion of glucose concentration in the capillary blood into current value which is shown in the display unit of Glucometer. The analysis of Blood Glucose is very important in self monitoring, since by proper monitoring and control , we can delay the onset and slow down the progressing of Diabetes complications. Recent clinical studies have shown the correlation between the glucose variability and the long-term diabetes related complications. The method proposed in this paper has been validated with simulated datas and tested with success in the retrospective analysis of real patient's data sets. The feasibility of this method to normalize blood glucose concentrations is demonstrated.**

Keywords — **Estimation of blood glucose level, Glucometers, Reflective Colorimetry, Polynomial Equations**

I. Introduction

Diabetes Mellitus is a disorder of carbohydrate metabolism, usually occurring in genetically predisposed individuals, characterized by inadequate production or utilization of insulin and resulting in excessive amounts of glucose in the blood and urine, excessive thirst, weight loss, and in some cases progressive destruction of small blood vessels leading to such complications as infections and gangrene of the limbs or blindness. It is a disorder of the metabolism characterized by the inability of the pancreas to secrete sufficient insulin which plays a key role in regulating glucose level in blood stream. The complications could be reduced by proper monitoring and control of blood glucose level (BGL). People use Glucometers for this monitoring of BGL.

II. Self monitoring blood glucometers

Multilayer thin film dry technology is adopted in most of the handheld Glucometers. A Colorimeter slide as shown in

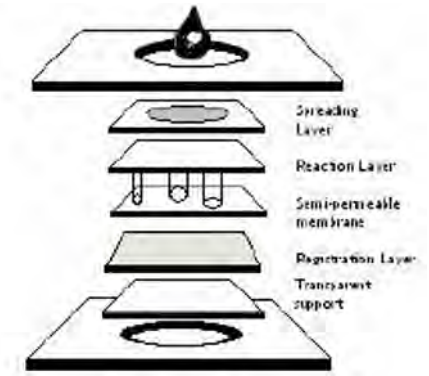

Fig 1: Colorimeter Dry Slide

Figure.1 comprises several layers coated on transparent plastic support. The sample is applied to the top of the spreading layer. This ensures uniform dispersion. It is also a micro filter, removing small particulate material and large molecules, such as proteins. It also contains a white diffuse reactant which acts as a reflecting medium during colorimetry made through the transparent support.

Various underlying layers have different functions. They include a reaction layer which usually contains an enzyme catalyst and a registration layer where colored dye is formed in proportion to the analyte concentration. The color density is measured by a reflection spectrometer. Other layers may include physical barriers such as semi permeable membranes and scavenger layers which chemically alter potentially interfering endogenous substances. Interferences are thus minimized.[4-5]

For each test a mathematical function is stored in the analyzer's central processor. It is used to convert the dye density into analyte concentration. The function is a third degree polynomial. Its three coefficients are determined during calibration.[6]

III. Problem definition

These glucometer readings do have a variation of plus or minus 20 from the actual value. The polynomial equations of higher orders (Sixth order) give better, accurate and quicker results compared to lower order polynomials (Third order).

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1466–1468, 2009

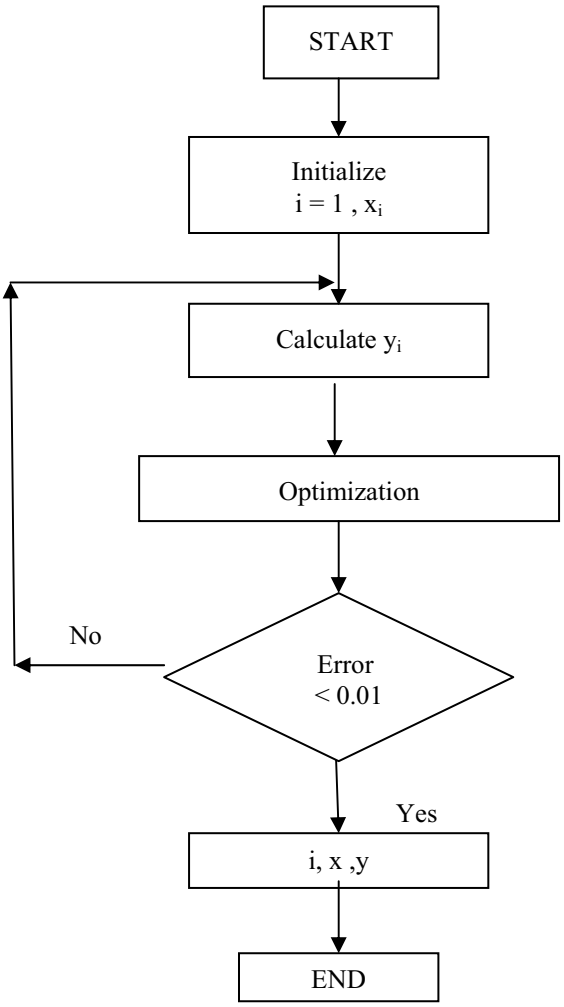

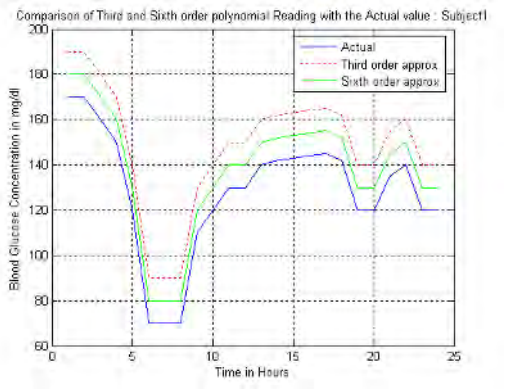

Fig. 2: Flow chart to calculate y

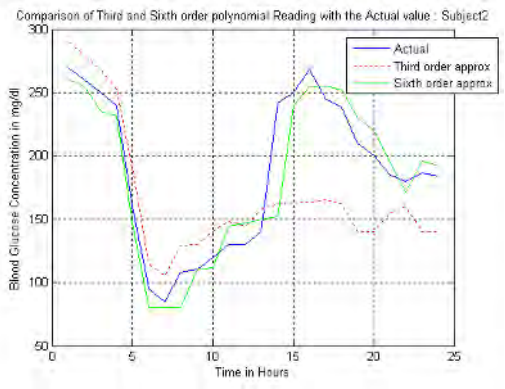
A. Methodology



The formulas of a predictive model have normally been used only for calculating the future values of predicted variables. The polynomial theory proposes to use predictive polynomials as the basic means for the general investigation of dynamic system. The polynomial theory enable us to obtain polynomial description of a component by observing their inputs and outputs during a comparatively short time. The polynomial description does not require any information about initial condition.

For measuring the concentration of Blood Glucose, the Saturation(x) values obtained for various known concentrations of Glucose (y) are fit into an m^{th} order polynomial equation.[6]

$$y = a_m x^m + a_{m-1} x^{m-1} + \ldots\ldots + a_2 x^2 + a_1 x + a_0$$

(a)

(b)

Fig. 3: Comparison of actual values with 3rd and 6'th order polynomial for two (a and b) different subjects

From this equation, (m+1) simultaneous equations will be generated. Solving these (m+1) simultaneous equations using Cramer's rule, the value of the unknowns a_m to a_0 can be calculated.

This polynomial equation is suitable for non linear responses also. Once this polynomial equation is ready then the saturation (x) of the unknown Glucose concentrated assay can be substituted and the unknown Glucose concentration (y) can be estimated. Calculation of y is given in flow chart as shown in figure 2.

B. Results

A third order polynomial equation and a sixth order polynomial equation have been taken and are used to estimate the Blood Glucose level of two subjects for a 24 hour day. The readings have been compared with the actual laboratory measurement value.

The reading obtained from the sixth order polynomial has a lesser variation than that of the third order polynomial

from the actual value. The error is less than plus or minus 10.

These observations have been simulated using the MATLAB.

IV. Conclusion

We perceive that this system will prove useful when integrated into whole body glucose homeostasis simulators. The Sixth order polynomial has proved to converge in lesser no of iterations than the Third order polynomial when both are solved by Newton Raphson method.

Abstract — **Conventional human mesenchymal stem cells (hMSC) cultures are carried out on tissue culture polystyrene (TCPS) surfaces while human embryonic stem (hES) cells are normally propagated on feeder layers or Matrigel™. However, TCPS culture of MSCs lead to senescence [1] and decreased self-renewal [2, 3]; while hES cells cultured on xenogenic feeder layers or Matrigel™ express immunogen which presents a xenogenic risk thus hampering transplantion [4]. Culture of MSCs on TCPS does not emulate the natural stem cell microenvironment, which consists of soluble factors, neighbouring cells and extracellular matrix. The extracellular matrix (ECM) is a complex supramolecular assembly of various proteins, some of which binds growth factors like FGF-2 and TGFβ1 [5]. We have directed ECM deposition by human fibroblasts through application of excluded volume effect (EVE) [6, 7] followed by detergent lysis to achieve a cell-free matrix. The matrix obtained contained proteins such as collagens, fibronectin, glycoproteins, proteoglycans and growth factors, FGF-2 and TGFβ1. Proteins within the matrix were analysed by gel electrophoresis, and the protein profile obtained highlighted its complexity. Matrix propagation was observed to enhance the proliferation rate of hMSCs, resulting in more cells in a shorter time compared to TCPS controls. In addition, hMSCs pre-cultured on matrix prior to adipogenesis showed increased differentiation compared to TCPS control based on flow cytometry and adherent cytometry , indicating better retention of differentiation capabilities despite long term culture. The population doubling rate of hES cells cultured on matrix surpassed those on feeder-free culture on Matrigel™ in defined culture medium in just 3 weeks, while maintaining similar expression of pluripotency marker Oct4 as Matrigel controls. In conclusion, we demonstrate that the application of EVE to obtain a collagen-rich fibroblasts layer followed by detergent lysis results in a cell-rich matrix rich in diverse proteins. Culture of hMSCs on such a matrix increases their proliferation rate while still retaining differentiation potential. hES cells grown on matrix also proliferated faster with retention of stem cell markers.**

Keywords — **Extracellular matrix, macromolecular crowding, mesenchymal stem cell, human embryonic stem cell**

I. Introduction

Complex cell–ECM interactions play an integral role in modulating stem cell development and function *in vivo* by providing signals via growth factors and integrin interactions. However, current culture practices neglect this aspect. hMSCs extensively propagated on TCPS show a more differentiated progeny with reduced capacity for self-renewal [1-3]; while hES cells are cultured on mouse embryonic fibroblasts (MEFs) or murine Matrigel with MEF-conditioned medium which introduce a xenogenic threat [4]. Such culture conditions result in progressive loss in the ability of stem cells to differentiate into multiple lineages. Cells present in the initial culture undergo unsymmetrical division during expansion to produce a vast progeny of committed and differentiated daughter cells which progressively dilutes the original stem cell population, resulting in a heterogeneous population [8].

In view of this, such imperfect systems could be replaced by development of an ECM made by human fibroblasts, the professional ECM producer. We hypothesize that the application of such an *in vitro* human derived bio-assembled matrix could recapitulate these interactions *in vitro* thus providing a more physiologically relevant environment to (i) retain multipotentiality of human mesenchymal stem cells by delaying senescence during extensive *ex vivo* expansion and (ii) sustain growth and maintain pluripotency of human embryonic stem cells (hES). The ability to engineer such a specialized microenvironment would be of great benefit for tissue engineering applications involving stem cells.

To generate our bio-assembled ECMs, we applied macromolecular crowding on human fibroblasts culture with Dextran Sulfate 500kDa (DxS) which has been shown to enhance deposition of collagen I and fibronectin in aggregates [6,7]. To render the ECM cell-free, *in situ* detergent (sodium deoxycholate; DOC) lysis was employed to remove the fibroblasts without complete solubilization of the ECM proteins.

In our study, we focused on characterizing the composition of our decellularised matrix and the effect of propagat-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1469–1472, 2009
www.springerlink.com

ing the two types of human stem cells – human embryonic stem cells (hES) and mesenchymal stem cells (hMSCs) on matrix, in comparison to their regular systems.

II. Materials and methods

A. Generating Bio-assembled Matrices

Embryonic lung fibroblasts, WI-38 (CCL-75) obtained from American Type Culture Collection were routinely cultured up to passage 22 in Dulbecco's Modified Eagle Medium supplemented with 10% fetal bovine serum which was changed every 3-4 days. At confluency, fibroblasts were seeded at a ~25,000 cells/cm^2 in either 24- or 6-well culture plates. After 24 hours, adhered cells were supplemented with 0.5% fetal bovine serum and 30μg/ml of L-ascorbic acid, with or without 500kDa Dextran Sulfate (USB; DxS) at 100μg/ml. After 3 days incubation, cell layers were lysed with 0.5% DOC to remove cellular components.

B. Characterising Bio-assembled Matrices

Immunostaining for ECM and cellular components: Immunofluorescence was used to detect retained key ECM proteins- Collagen I and fibronectin; and also to verify the complete removal of cellular debris – nuclei, endoplasmic reticulum (ER) and the F-actin filaments. Briefly, monolayers were fixed with 4% methanol-free formaldehyde for 15mins at 37°C, permeabilized with 0.2% Triton X-100 then blocked with 10% normal goat serum in PBS. Col I was detected by mouse anti-human collagen I (1:1000); fibronectin was stained by rabbit anti-human fibronectin (1:100); F-actin filaments were stained using AlexaFluor 594 phalloidin (50U/ml); ER was stained by mouse anti-protein disulfide isomerase (1:1000) while cell nuclei were counterstained with DAPI. Images were captured with an IX71 inverted fluorescence microscope (Olympus).

SDS-PAGE quantitation of Col 1 retained in matrices: Soluble procollagen was removed together with culture medium while intact cell layers and DOC-lysed matrices were pepsin-treated (0.25mg/ml; Roche) to isolate collagens. Digested samples were separated by SDS-PAGE and the protein bands were quantified by silver-staining and densitometry.

C. Matrix propagation of stem cells

Human embryonic stem cells (hES): (WiCell Research Institute, WA09) received at passage 49 were adapted to mTeSR1 culture medium (StemCell Tech). For propagation, cells were passaged every 5-7 days using 1mg/ml collagenase in Dulbecco's Modified Eagle Medium – Nutrient Mixture F-12 and reseeded onto 6-well plates coated with either matrix or Matrigel as a control. Medium was changed daily. During subsequent passages, respective hES cells were seeded onto fresh matrices. For cell counting at every passage, 3 replicate wells of a 24-well plate were plated in parallel and resuspended with TrypLE to obtain single – cell suspensions.

Human Mesenchymal Stem Cells (hMSCs) were obtained commercially (Cambrex) at passage 2 and propagated in low glucose Dulbecco's modified Eagle's medium (Gibco) supplemented with Glutamax and 10% fetal bovine serum on either 100mm regular tissue culture polystyrene plates (TCPS) or matrix-coated TCPS plates (Matrix). After 4 passages, hMSCs were trypsinised, reseeded into 24-well TCPS plates (50,000/well) and adipogenically induced with the addition of 3-Isobutyl-1-methylxanthine (0.5 mM), dexamethasone (10^{-7}M) and indomethacine (0.2 mM) in high glucose Dulbecco's modified Eagle's medium (HG DMEM, Gibco-BRL) supplemented with 10% fetal bovine serum [9].

D. Characterizing hMSCs post matrix-propagation

hMSC growth kinetics: hMSCs seeded at 350,000 per 100mm plates (BD) ± matrix were passaged at confluence (~7-10 days) using Collagenase IV (0.5mg/ml) followed by 0.5% trypsin/1mM EDTA; viability was assessed by trypan blue exclusion prior to hemocytometer counting. Cells are then re-seeded at 350,000/plate and allowed to re-grow to confluence. Population doubling was calculated based on the increase in number of cells at confluence as a measure of time to attain confluence.

Nile Red Adherent Cytometry: Mature adipocytes are characterized by cytoplasmic lipid droplets detected by the lipophilic dye, Nile red. Briefly, monolayers in 24-well plates were rinsed with PBS, fixed in 2.5% paraformaldehyde (PFA) then co-stained with Nile red (0.05mg/ml in PBS; 1hr) and DAPI (0.5μg/ml; 30min). Fluorescence was accessed in a montage of 9 sites within each well (Metamorph); absolute amount of lipid droplets in each well was quantified from thresholded fluorescent events and normalized to cell number based in DAPI fluorescence. End data correspond to total amount of lipid droplets present per well relative to cell number.

Nile Red FACS: Monolayers were washed twice in PBS, trypsinized then resuspended in 350ul of Nile red (0.05mg/ml in PBS) for 15min followed by the addition of 150ul of 0.5% PFA. Fluorescent events were detected using a FACScan flow cytometer (BD).

E. Characterizing hES cells post matrix-propagation

OCT-4 Flow Cytometry (FACS): hES cells were trypsinized to obtain single-cell suspensions and fixed with 4% methanol-free formaldehyde at 37°C for 15 mins. Samples were immunostained with goat anti-Oct4 (Santa Cruz), AlexaFluor 488 chicken anti-goat (Molecular Probes) and DAPI. Flow cytometry was done on a CyAn ADP High-Performance Flow Cytometer (Dako cytomation).

III. Results

A. Characterizing Bioassembled matrices

Immunofluorescence co-staining of matrices for Collagen I, Fibronectin, DAPI, phalloidin and actin confirmed that lysis had retained extracellular matrix proteins while completely removing intracellular structure (data not shown). To determine the retention of Collagen I, densitometry on SDS-PAGE of pepsin digests of intact cell layers and lysed matrices was performed. By comparing the densities of collagen α1(I) bands, we observed that DOC treatment of DxS-crowded matrix retained about 20% of the collagenous material compared to the cell layer samples (Fig.1).

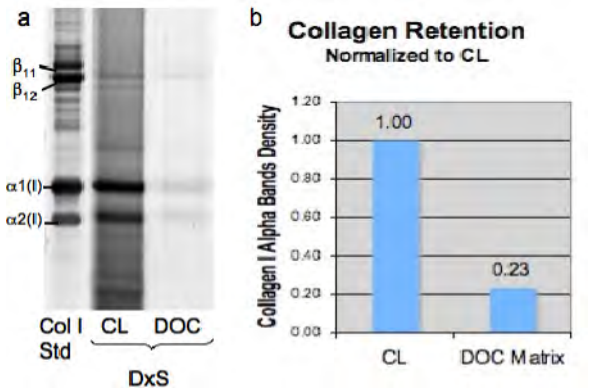

Fig. 1 Treatment with DxS yields more insoluble collagen I deposited on the cell layer by fibroblasts. (a) SDS-PAGE (b) Densitometry analysis of collagen I alpha bands

B. Matrix enhanced proliferation of hMSCs

hMSC growth kinetics during expansion was investigated over 58 days, where cumulative cell doublings of the populations were plotted against time in culture. It was observed that hMSC on plates without matrix (TCPS) had a cumulative population doubling of 11.9 while those on matrix had attained nearly double that, at 20.3 population doublings (Fig.2).

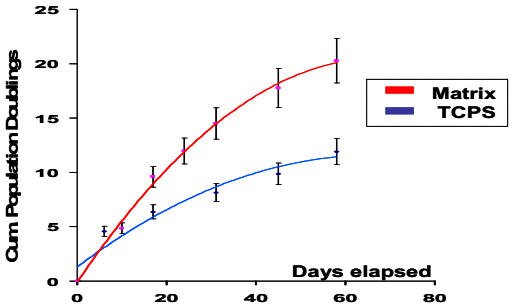

Fig. 2 hMSC growth kinetics with propagation on either TCPS or Matrix for 58 days.

C. Pre-propagation on matrix enhanced adipogenic differentiation of hMSCs

The effect of pre-propagation on either TCPS or matrix for 4 passages prior to hMSC adipogenesis was examined via Nile Red adherent cytometry and FACS. We observed that with pre-propagation on matrix, cytoplasmic lipid accumulation increased from 18.9% to 22% (Fig.3).

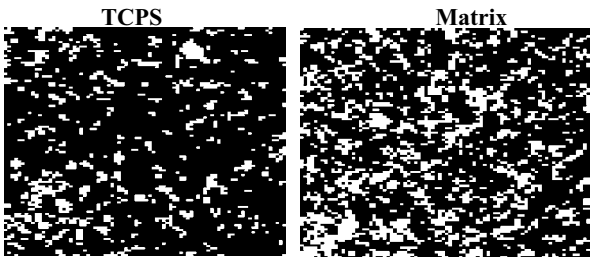

Fig. 3 Nile Red stained adipocytes post-propagation on either TCPS or matrix, white patches indicates lipid droplets. (2x)

Flow cytometry also demonstrated that pre-propagation on matrix increased the percentage of the population that differentiated from 12.47% to 22.9% (Fig.4), in agreement with adherent cytometry.

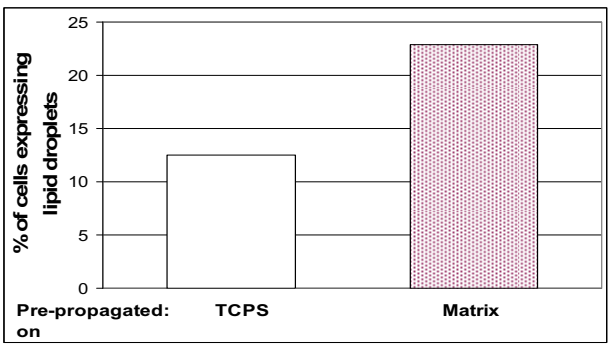

Fig. 4 Flow cytometry of nile red stained adipocytes post-propagation on either TCPS or matrix.

D. Matrix restrains hES spontaneous differentiation

To analyze for spontaneous differentiation, hES cells were stained for the pluripotency marker, Oct-4, then analyzed by FACS and immunostaining. We observed from FACS that there was a dramatic increase in the number of hES cells expressing Oct-4 on matrix compared to matrigel control (17.81million versus 3.88 million; Fig. 4). This is also reflected in OCT-4 immunostaining of hES colonies after 2 weeks of propagation (data not shown).

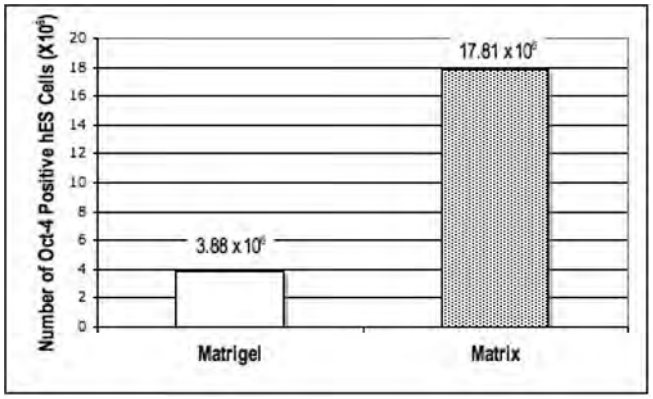

Fig. 5 Flow Cytometry of hES cells propagated on either Matrigel or matrix immunostained for Oct-4.

IV. Discussion

Current culture systems inadequately sustain stem cell self-renewal during expansion, this presents a major bottleneck in the downstream use of these stem cells for translational tissue engineering where large numbers of cells still capable of differentiating into multiple lineages are required. We hypothesize that this is due to the absence of complex cell-ECM signals which are present *in vivo*. To tackle this issue, we have introduced the use of a human derived bio-assembled matrix to recapitulate these physiological signals *in vitro*. We demonstrate that our bio-assembled matrix retains the key ECM proteins, collagen I and fibronectin, in their native forms. The propagation of hMSCs on this matrix was shown to substantially increase their population doubling rate compared to the current expansion system, while pre-propagation on matrix prior to adipogenic induction was observed to retain a greater differentiation capability. Similarly, propagation on matrix substantially increased population doubling for hES cells but this exceptional increase in proliferation did not result in a proportionate increase in spontaneous differentiation based on percentage of cells still expressing the pluripotency marker OCT-4. This indicates that the hES cells on matrix were obtained through self-renewal rather than differentiation into daughter cells. The results obtained will lay the foundation for the further development of improved *ex vivo* stem cell culture systems based on a bio-assembled matrix for translational tissue engineering, enabling the expansion of stem cells in a manner that is based on symmetric self-renewal thus reducing heterogeneity and retaining differentiation capacity.

Quantitative Immunocytochemistry (QICC)-Based Approach for Antifibrotic Drug Testing *in vitro*

Wang Zhibo[1], Tan Khim Nyang[1] and Raghunath Michael[1,2]

[1] Tissue Modulation Laboratory, Division of Bioengineering, Faculty of Engineering, NUS
[2] Department of Biochemistry, Yong Loo Lin School of Medicine, NUS

Abstract — **Aim: Chemicals that can reduce extracellular collagen accumulation and inhibit the transdifferentation of fibroblast into myofibroblasts marked by expression of α-SMA (α-smooth muscle actin) will be promising antifibrotic drugs. We developed a QICC-based approach using microplate-reader to quantify the deposited collagen and α-SMA for antifibrotic drug testing. Methodology: Fibroblasts IMR-90 were cultured under standard and EVE (excluded-volume effect) conditions. "Footprints" were revealed by removing cells with detergent. TSA (trichostatin A) with or w/o TGF-β1 or CPX (ciclopirox olamine) was added under EVE conditions. Collagen I and α-SMA were labeled by immunocytochemistry. The fluorescence signal was quantified by BMG PHERAstar with a focusing lens system. Biochemical evaluation of collagen production served as a benchmark. Results: The QICC-based assay detected 7-fold enhanced collagen deposition under EVE condition and "footprints" was 40% of total collagen matrix, well comparable with that of biochemical assay. Dose-dependent inhibition of TGF-β1-induced collagen production and α-SMA expression by TSA and 90% decrease of collagen production by CPX were successfully detected by QICC-based approach. Conclusion: We have shown, for the first time, the feasibility of QICC-based approach using microplate-reader to quantify collagen deposition and α-SMA *in vitro*, thus enabling screening for candidate drugs that are likely to prevent scarring.**

Keywords — **Quantitative immunocytochemistry, fibroblasts, antifibrosis, collagen, α-SMA**

I. Introduction

Excessive accumulation of collagen in extracellular matrix and contractile myofibroblasts trans-differentiated from fibroblasts are two hallmarks of fibrotic diseases and peri-implantational fibrosis [1, 2]. Peri-implantational fibrosis is the end stage of foreign body reaction generated by host to implants. Fibrosis can severely impair organ function and compromise the performance of implants. Chemicals can reduce collagen accumulation and/or inhibit the transdifferentiation of fibroblast into myofibroblasts will be promising antifibrotic drugs.

Quantification of the deposited collagen and/or expression of α-SMA is the essential technique for potential antifibrotic drug testing. However, current methods for collagen quantification, such as amino acid analysis, hydroxyproline determination or radioactive labeling and Sircol™ dye assay, are labor and time-consuming without type-sorting. Immunoblot for collagen and α-SMA fail to retrieve morphology information.

Moreover, current methods measure procollagen in medium or intracellularly due to the tardy enzymatic processing of procollagen into collagen by N- and C-propeptidases in standard cell culture condition. Our group has accelerated collagen deposition by EVE [3]. Here, we developed a QICC-based approach using PHERAstar microplate-reader with a focusing lens system to quantify collagen matrix and α-SMA *in vitro*. The antifibrotic potential of Histone deactylases inhibitor TSA was investigated in fibroblast cultures under EVE conditions.

II. Methods

A. Cell culture and treatment

Lung Human embryonic lung fibroblasts IMR-90 (10, 000/well) were cultured in 96-well plate (Greiner Bio-one Lumox™) in 0.5% FBS DMEM under standard and EVE conditions (100μg/ml DxS) which was described in [3]. Different concentrations of TSA with or w/o TGF-β1 (5ng/ml) were added to IMR-90 cultured under EVE conditions.

B. QICC

Prior to ICC, "footprints' were revealed by lysing the cells with 0.5% sodium deoxycholate (w/v). ICC was done by adding mouse monoclonal anti-collagen type I antibody (Sigma) or mouse monoclonal anti-α-SMA (Dako) as the primary antibody, followed by Alexa Fluor 594 (AF594) goat anti-mouse antibody (Invitrogen) as the secondary antibody. The fluorescent stain 4', 6-diamidino-2-phenylindole (DAPI) (Invitrogen) was used to visualize nuclei. The fluorescence intensity (FI) of the AF594 dye as well as that of DAPI was quantified by PHERAstar microplate reader with a focusing lens system (BMG LABTECH). The ratio of FI of AF 594 to FI of DAPI was used to represent collagen deposition or α-SMA per cell.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1473–1475, 2009
www.springerlink.com

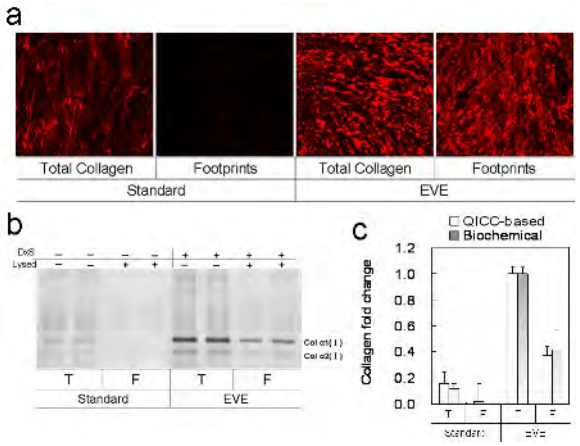

Fig.1 Total collagen deposition and "footprints" were quantified by QICC-based approach and biochemical assay. (a) Representative pictures of deposited Col (I) from QICC-based assay (b) Representative SDS-PAGE from biochemical assay. (c) Comparison of collagen deposition fold changes between two approaches.

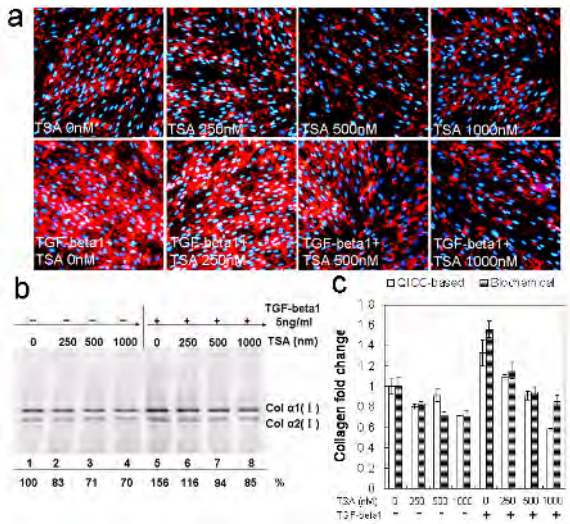

Fig.2 Antifibrogenesis effect of TSA was detected and visualized by QICC and biochemical assay. (a) Representative pictures from QICC-based approach (b) Representative gel from 3 independent experiments. The quantification result from QICC-based approach (c) Comparison of collagen fold changes between two approaches.

Quantitative biochemical evaluation of collagen production was done by pepsin digestion followed by SDS-PAGE. Collagen bands were visualized by silver staining (Silver-Quest, Invitrogen).

III. Results

Around 6-7 folds enhanced total collagen deposition under EVE can be detected by QICC-based approach and the "footprints" were around 40% of total deposited collagen under EVE, which was well-comparable with that of biochemical assay (Fig.1)

Antifibrogenic effect of TSA was quantified by QICC-based approach. TSA can dose-dependently inhibit TGF-β1 induced collagen production. TSA 500nM can bring collagen production to basal level in IMR-90 treated with TGF-β1. TSA alone modified the normal collagen synthesis modestly (Fig.2).

Dose-dependent inhibitory effect of TSA on TGF-β1 induced α-SMA expression was quantified by QICC-based approach. TGF-β1 induced the expression of α-SMA which is a marker of myofibroblasts to 5-6 folds. The expression of α-SMA was inhibited by an increasing concentration of TSA (Fig.3).

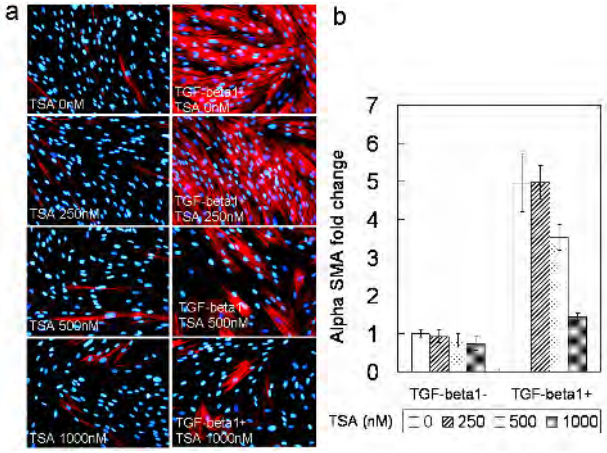

Fig.3 Dose-dependent inhibition of TGF-β1 induced α-SMA by TSA was detected by QICC-based approach. (a) Representative pictures of α-SMA expression (b) α-SMA expression fold changes.

IV. Conclusions

We have shown, for the first time, the feasibility of QICC-based approach using microplate-reader to quantify collagen deposition and α-SMA *in vitro*, thus enabling screening for candidate drugs that are likely to prevent scarring.

Abstract — **The use of metallic fusion cages in lumbar interbody fusion is often associated with serious complications including implant subsidence and corrosion. A bioresorbable scaffold with distinct architectural design has recently been fabricated from medical grade polycaprolactone and beta-tricalcium phosphate (mPCL-TCP) for bone tissue engineering at weight bearing sites. Porous mPCL-TCP scaffolds demonstrate mechanical and biological properties comparable to cancellous bone and have been shown to enhance new bone formation at ectopic and cranio-facial sites. In this study, we evaluated the fusion performance of mPCL-TCP implants in a porcine model of anterior interbody lumbar fusion (ALIF). Twenty two pigs underwent a two-level (L3/4 and L4/5) ALF surgery in four experimental groups namely, standalone scaffolds, scaffolds + stem cells, scaffolds + rhBMP-2 and bone autograft. Results indicate a significant enhancement in stiffness of motion segments implanted with scaffolds + rhBMP-2 compared to other groups including autografts as early as three months ($p<0.01$). A trend of increasing mineralization was also observed over six months with significant bone ingrowth in scaffolds loaded with rhBMP-2 as well as stem cells compared to standalone scaffolds ($p<0.05$). Finally, accurate radiographic assessment was not hampered by this radiolucent scaffold on follow-up. This is the first time that mTCP-PCL has been used as a fusion cage in a large animal, weight bearing condition for bone healing.**

I. Introduction

Low back pain is a common problem in many clinics around the world. In one study, low back pain was reported to represent more than half of the musculoskeletal impairments reported in the USA annually [1]. When conservative treatment fails, a vast majority of these patients require spinal fusion (arthrodesis) with over 200,000 procedures performed annually in the USA alone.

The gold standard procedure for spinal arthrodesis involves the use of metallic fusion cages packed with moserlized autologous bone grafts harvested at time of surgery. There are several problems associated with both the harvesting of autogenous bone [2] and the implantation of metallic devices [3]. Donor site morbidities such as chronic pain and visceral hernia as well as difficulties with radiographic assessment due to metallic interference are some of the common drawbacks in addition to cage subsidence or outright implant migration. To overcome some of the shortcomings of current techniques, allograft bone materials have been used as an alternative to autograft bone. However, the inherent risk of disease transfer and rejection remarkably limit the use of fresh frozen allografts [4].

The evolution of bone tissue engineering has stimulated the development of "tailor made" bioresorbable implant materials capable of significantly enhancing repair and regeneration at bone healing sites. Bioabsorbable fusion cages (biocage) offer many distinct advantages over conventional metallic fusion cages including biological and mechanical compatibility with host bone [3]. Furthermore, polymer cages could act as delivery systems for potent growth factors and osteogenic cells thus abrogating the need for autogenous bone graft incorporation.

Despite these and other stated advantages, the use of biocages in spinal reconstructive surgery has been limited because of the need to tailor cage porosity with adequate mechanical strength required for weight bearing and stabilization of the healing bone ends. Many previous studies have described bioresorbable materials for use in orthopaedic tissue engineering however, many of these materials are fabricated from polymers that leave toxic degradation products and lead to chronic inflammatory reaction that eventually result in failure of joint fusion [3]. In the present study, mPCL-TCP polymer device was implanted into the lumbar intervertebral space of SPF Yorkshire pigs in combination with either bone marrow stem cells (MSCs) or recombinant human bone morphogenetic protein type 2 (rhBMP-2). The main aim of this study was to evaluate the efficacy of the novel mPCL-TCP bioresorbable scaffolds as a fusion cages when used in combination with MSCs and rhBMP-2.

II. Materials and methods

A. Materials

Bioresorbable scaffolds fabricated from medical grade polycaprolactone and tricalcium phosphate mPCL-TCP (80:20) was from Osteopore International (Singapore) (Fig. 1). The morphological and topological parameters of the scaffolds used are as listed in Table 1. Pedicle screws and rods were purchased from DePuy Orthopaedics, Inc. Winterthur, Switzerland. Recombinant human bone morphogenetic protein-2 (rhBMP-2) was from Medtronic INFUSE® Sofamor Danek. Twenty two male SPF Yorkshire pigs aged 6 months old and weighing 50-60 kg were used in this study. All animal related procedures were in accordance with the principles of laboratory animal care [National Institutes of Health (NIH) publication no. 86-23, revised 1985] and were approved by the institutional review committee on the use of laboratory animals. Animals were randomized into four groups for interbody fusion surgery (L3/4, L4/5) according to implants used viz: 1) standalone bioresorbable scaffolds (n = 6) 2) bioresorbable scaffolds wrapped with autogenous mesenchymal stem cells treated with dexamethasone to differentiate into osteogenic lineage over a 14-day in vitro culture period (n = 6); 3); bioresorbable scaffolds filled with 0.6mg rhBMP-2 (n = 6); 4) autologous iliac crest bone graft (n = 4). Pedicle screws fixation was performed for both levels on all pigs

SCAFFOLD PREPARATION

In order to improve cell-scaffold interaction, the surface of all scaffolds was modified by soaking in 1M sodium hydroxide for 3 hours to enhance their hydrophilicity followed by thorough rinsing in distilled water and drying in an oven at 40^{o}C overnight as described previously [5]. The scaffolds were sterilized in 70% ethanol and lyophilized with bovine collagen (Symatese, France) to enhance biocompatibility and create a mesh structure within the scaffold pores for enhanced cell seeding, attachment and proliferation.

IMPLANTATION PROCEDURE AND FOLLOW UP

Surgeries were performed under strict aseptic conditions. The pigs were anesthetized with ketamine (15mg/kg) and maintained with inhalational anesthesia (halothane). After identification of disc levels of interest, the discs were completely removed, adjacent endplates were decorticated and disc space was distracted using a Casper distractor for insertion of appropriate fusion models. Prophylactic parenteral antibiotics (Ampicillin/Cloxacillin 500mg/500mg) and analgesics (intramuscular injection of ketorolac (1mg/kg) for 3 days) were administered routinely. After surgery, pigs were housed individually. Stock diet and tap water were available *ad libitum*. Daily activity and wound conditions were monitored. At designated time points, animals were sacrificed with an overdose of pentobarbital injected intravenously. Subsequently, the spine segments were harvested from L1 to sacrum, cleaned of excess soft tissues, and functional spine unit of interest were dissected out for freezing at -80 C until examination.

COMPUTED TOMOGRAPIC ANALYSES (μ-CT)

The microstructural morphology of harvested specimen were evaluated using a μ-CT system (Shimadzu, SMX-100 CT, Kyoto Japan). Isotropic slice data obtained by the system were used for 2D image reconstruction employing 3D Studio Max software version 1.2 (Volume Graphics GmBH, Germany). From each section, a 10 X 8 X 2 mm^3 volume of interest (VOI) was selected at implant site. The VOIs were represented in 22 x 22 x22 mm^3 voxels and segmented using an individually optimized density threshold value. These images were further compiled and used to reconstruct 3D images for quantitative bone ingrowth parameters.

MECHANICAL TESTING

After thawing at room temperature overnight, specimen were prepared for mechanical testing as described previously [6]. Soft tissues and facet joints of each harvested motion segment were removed so that only the fusion mass was left connecting the two vertebrae. Following embedding in polymethylmethacrylate (PMMA) bone cement, the segments were tested in flexion and extension, left and right lateral bending and axial rotation at a constant loading rate (1.0°/s) using a servo-hydraulic materials-testing system (MTS 858 MiniBionix, MTS Corp., Eden Prairie, MN).

STATISTICAL ANALYSIS

Data obtained were analyzed by SPSS software package (SPSS, Inc., Chicago, IL). All values are reported as means ± standard deviation (SD). Unpaired *t* tests were used to compare mean values among groups. $P < 0.05$ was considered significant.

III. Results

All segments treated with mPCL-TCP scaffolds loaded with rhBMP-2 showed radiographic fusion at three months as opposed to only 25% of animals receiving autograft bone, (Table 2). At six months, 50% of animals receiving autograft bone showed radiographic fusion. However, animals who had received scaffolds alone as well as those with scaffolds + MSCs did not show any radiographic evidence of fusion even at six months (Fig. 1).

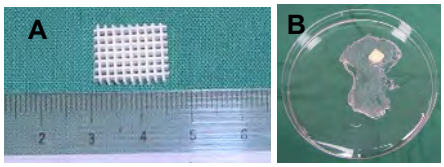

Figure 1: An mPCL-TCP scaffold prior to implantation (A) and (B) *in vitro* differentiated mesenchymal stem cell sheet is wrapped around the scaffold for implantation.

Table 1: Architectural design parameters of mPCL-TCP scaffolds used in bone regeneration at weight bearing sites

Morphology parameter	Value
Pore interconnectivity	100%
Pore size range	350-500μm
Scaffold porosity	65%
Lay-down pattern	0/90°
Cage dimension	15 x 12 x 10˜

Micro-CT analysis revealed significant bone ingrowth in all groups except groups receiving scaffolds alone (Fig. 2 and 3). Over the course of six months, mineralized tissue deposition increased in all groups thus making the scaffold denser.

Table 2: Spine fusion on x-ray assessment. Fusion was observed in all segments receiving rhBMP-2 loaded cages as early as 3 months

Groups	3 m	6 m
Scaffolds	0/6 (0%)	0/6 (0%)
Scaffold + MSCs	0/6 (0%)	0/6 (0%)
Scaffolds + BMP	6/6 (100%)	6/6 (100%)
Autograft	1/4 (25%)	2/4 (50%)

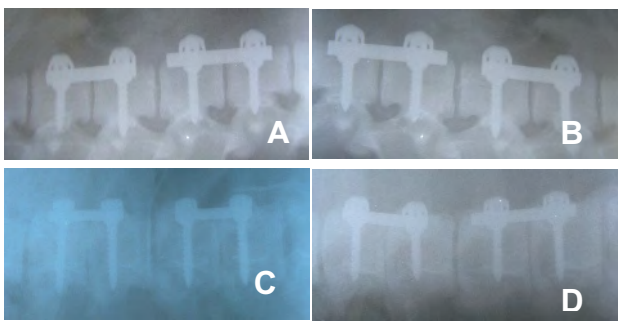

Figure 2: Representative x-ray photographs (lateral view) of segments with scaffold alone (A); scaffolds + MSCs (B); scaffolds + rhBMP-2 (C) and autograft bone (D) at 3 months.

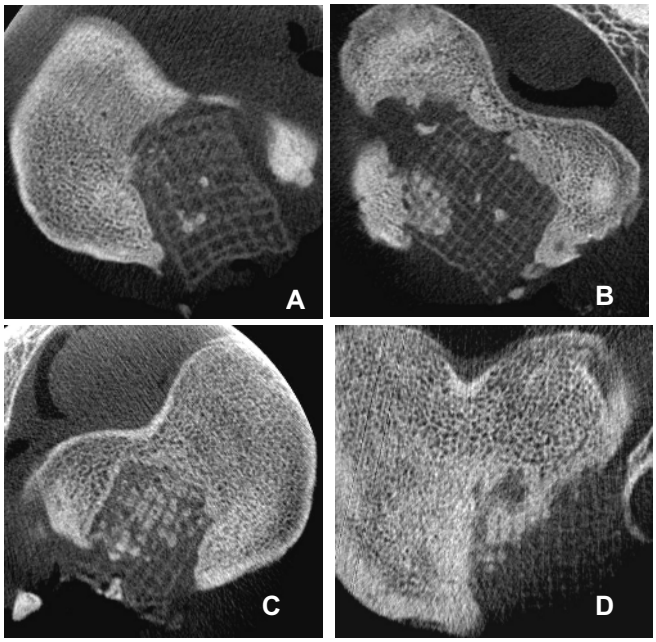

Figure 3: Micro-CT assessment of bone ingrowth after 3 months at implant sites. Notice minimal bone ingrowth among scaffolds alone (A) as compared with improved ingrowth with scaffolds + MSCs (B), scaffolds + rhBMP-2 (C) and autograft bone (D). New bone was laid down in a squared pattern similar to the 0/90° topology of the scaffolds.

Morphometric analysis indicates statistically significant increase in bone ingrowth volume among motion segments treated with bioresorbable mPCL-TCP scaffolds loaded with rhBMP-2 compared to autograft bone ($p<0.05$) as well as standalone scaffolds and scaffold + cells ($p<0.01$) at 3 months (Fig. 4).

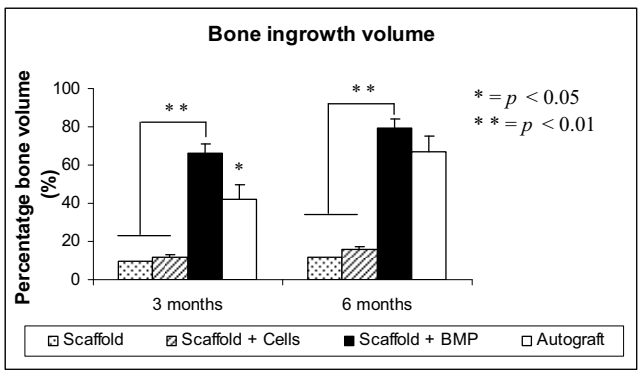

Figure 4: Bone ingrowth at 3 and 6 months into defects created at sites of implantation.

At 6 months this increase in bone volume was not statistically significant between autograft group and scaffold + BMP group.

Similarly, stiffness analysis revealed significantly stiffer motion segments in the group treated with mPCL-TCP scaffolds loaded with rhBMP-2 when compared with cell seeded scaffolds, autograft bone and standalone scaffolds (Fig. 5).

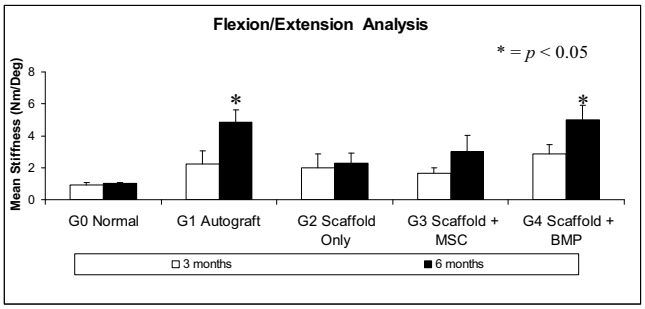

Figure 5: Flexion/extension analysis at 3 and 6 months compared with intact (non-operated) segments to determine fusion.

IV. Discusion

Anterior lumbar interbody fusion (ALIF) represents a challenging micro-environment for bone healing because of the complexity of compressive and torsional forces acting on this site. The need for a stable environment in bone healing has necessitated the use of metallic cages despite the high risk of associated complications [7].

Our results show bone ingrowth as early as three months in mPCL-TCP scaffolds incorporating low dose rhBMP-2 (Fig. 2 and Table 2). Furthermore, radiographic and mechanical fusion was demonstrated in scaffolds receiving rhBMP-2 as compared to intact bone. These findings suggest that the customized mPCL-TCP scaffolds are mechanically and biologically suitable for bone healing at a partial weight bearing site.

Absence of fusion in the standalone scaffold group was to be expected as the influence of an osteoinductive component in tissue engineered constructs has been recognized in several recent studies. The osteoconductivity of mPCL-TCP scaffolds reported in previous study was not sufficient to support fusion at this bone healing site [8]. Failure of early fusion after seeding of in vitro differentiated stem cells could indicate a less than optimal environment in the construct for stem cells after implantation or that the appropriate number of cells had not been implanted. However, the increasing quantity of mineralized tissue formation suggests that prolonged implantation could result in increased new bone formation and that may eventually lead to bone bridging and spine fusion. Moreover, the radiolucent feature of this scaffold offers unobstructed x-ray follow-up assessment.

V. Conclusion

In conclusion, low dose rhBMP-2 loading unto surface modified mPCL-TCP scaffolds promoted early fusion compared to autograft materials in this large animal multi-level anterior lumbar interbody fusion model.

Abstract — **Bone tissue engineering scaffolds have two challenging functional tasks to play; to be bioactive by encouraging cell proliferation and differentiation, and to provide suitable mechanical stability upon implantation. Composites of biopolymers and bioceramics unite the advantages of both materials resulting in better processibility, enhanced mechanical properties through matrix reinforcement and osteoinductivity. Novel composite blends of poly(L-lactide-co-D,L-lactide)/tri-calcium phosphate (PLDLLA/TCP) were fabricated into scaffolds by an extrusion deposition technique customised from standard rapid prototyping technology.**

PLDLLA/TCP composite material blends of various compositions were prepared and analysed for their mechanical properties. PLDLLA/TCP (10%) was optimised and fabricated into scaffolds. Compressive mechanical properties for the composite scaffolds were performed. In vitro studies were conducted using porcine bone-marrow stromal cells (BMSCs). Cell-scaffold constructs were induced using osteogenic induction factors for up to 8 weeks. Cell proliferation, viability and differentiation capabilities were assayed using phase contrast light microscopy, scanning electron microscopy, PicoGreen DNA quantification, AlamarBlue metabolic assay; FDA/PI fluorescent assay and western blot analysis for osteopontin.

Microscopy observations showed BMSCs possessed high proliferative capabilities and demonstrated bridging across the pores of the scaffolds. FDA/PI staining as well as AlamarBlue assay showed high viability of BMSCs cultured on the composite scaffolds Cell numbers, based on DNA quantitation, was observed to increase continuously up to the 8th week of study. Western blot analysis showed increased osteopontin synthesis on the scaffolds compared to tissue culture plastic. Based on our results the PLDLLA/TCP scaffolds exhibit good potential and biocompatibility for bone tissue engineering applications.

Keywords — **Composite, bioresorbable scaffolds, PLDLLA, tissue engineering, bone**

I. Introduction

In the clinical setting, bone graft substitutes are commonly used in the treatment of bone injuries and diseases where the host bone tissue needed to be removed. Autogenous and allogeneous bone grafts are the most common, they also entail many shortcomings. The demand for alternative bone graft has been growing dramatically. Selection of an effective bone graft substitute is paramount for the repair of bone defects and fractures; revision surgeries should be avoided as they would lead to higher risks, costs and even increased non-onion chances.

Some major drawbacks associated with bone regeneration are the lack of a suitable scaffold and materials to meet the mechanical and functional requirements at the defect site. An ideal scaffold should be biocompatible, bioresorbable, able to retain the shape and structure of the defect site while providing mechanical support, be porous and osteoconductive for bone regeneration to occur [1, 2]. It should also be a suitable carrier for cells or growth factors which could be included to enhance the bone regeneration therapy.

Bone tissue engineering scaffolds made of polymers or ceramic have extensively reported [3-7]. However, polymers and ceramics individually have several shortcomings, and by creating polymer-ceramic composite scaffolds, advantageous properties from both materials could be harnessed to improve on mechanical and biological properties to improve cell proliferation and differentiation [8-11]. Novel composite blends of poly(L-lactide-co-D,L-lactide)/ tri-calcium phosphate (PLDLLA/TCP) were fabricated into scaffolds by an extrusion deposition technique customised from standard rapid prototyping technology and characterised in the paper.

II. Materials and methods

Polylactide (PLA) generally has superior mechanical properties as compared to polycaprolactone (PCL), and has vastly different degradation rates and processibility chal-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1480–1483, 2009
www.springerlink.com

lenges. Tri-calcium phosphate bioceramic is a common and typical bone filler material used in bone grafting. Composite scaffolds were intricately designed and fabricated with these novel biopolymer-bioceramic composite materials with superior mechanical properties [2]. Poly(L-lactide-co-D,L-lactide) (PLDLLA) was purchased from Boehringer Ingelheim GmbH and β-Tri-Calcium Phosphate (TCP) from Progentix BV.

A composite material blend was mixed together using an in-house screw-extruder and various compositions were prepared for the pilot material analysis. The particle size distribution of the TCP particulates were determined on a laser diffraction particle size analyzer (Partica LA-950, Horiba; range 0.01-3000μm) and averaged 15μm. This novel composite blend was prepared into dumb-bell shaped specimen for tensile tests by injection molding.

An in-house rapid prototyping (RP) system, namely the screw extrusion system (SES) was developed between Temasek Polytechnic, Singapore (TP) and National University of Singapore (NUS). This customised system allows for exploratory novel polymeric-based materials to be extruded into porous three-dimensional (3D) scaffolds. The working principle of the SES is similar to the FDM [2, 12, 13]. The final composition for scaffold fabrication was PLDLLA (90%wt) and TCP (10%wt).

Scaffolds ($5\times5\times10mm^3$) were cut from larger blocks which were fabricated with a 0-90° lay-down pattern, for mechanical studies. Tensile and compression tests were conducted on an Instron 4302 Material Testing System, operated by Series IX Automated Materials Tester v. 7.43 system software, with a 1 kN load cell. For tensile test, the specimens were pulled in tension at a rate of 1mm/min until break; while for the compression test, the compression rate was 1mm/min up to a strain level of 0.6. The stress–strain (σ –ε) curves were obtained to evaluate the elastic/stiffness (modulus) and compressive yield strength of the scaffolds. The modulus was calculated from the stress–strain curve as the slope of the initial linear portion of the curve, with any toe region from the initial settling of the specimen neglected. A sample size of n = 5, was tested for each group.

Thinner scaffold sheets of $5\times5\times4mm^3$ with a 0-60-120° lay-down pattern were also prepared for the in vitro cell culture study. The scaffolds were treated with 5M sodium hydroxide for 10 minutes and rinsed with 5 changes of de-ionised water; this would yield a more hydrophilic and corrugated material surface for cell culture. The scaffolds were then sterilized in 70% ethanol for 2 hours and under UV light for 20 minutes for each side.

Each scaffold was seeded with 100 000 primary porcine bone marrow stem cells (BMSC) expanded from our frozen stock (passage 3-4) in growth media: Dulbecco's Modified Eagle medium (DMEM) with 10% fetal bovine serum (FBS), 1% penicillin and 1% streptomycin (all from Gibco). The seeded cells were cultured up to 8-weeks in static culture supplemented with osteogenic media comprising of DMEM growth media with 10 nM of dexamethasome, 50 μM of ascorbic acid 2 phosphate and 10 mM of β-glycerolphosphate (all from Sigma).

The cell-scaffold constructs were observed and analysed at various time points with phase contrast light, confocal laser microscopy (CLM) and scanning electron microscopy (SEM). The BMSC proliferation and development was examined on a phase-contrast light microscopy. For CLM analysis, the cells within the scaffold construct was stained using fluorescent dyes, fluorescein diacetate (FDA) and propidium iodide (PI) (both from Molecular Probes Inc) and viewed on a confocal laser microscope (Olympus IX70-HLSH100 Fluoview). Viable cells were stained green (FDA) while apoptotic cells were stained red (PI). The samples were then fixed in 3.7% formaldehyde, dehydrated over a graded ethanol series and samples gold sputtered for SEM observation at 15 kV accelerating voltage (Philips XL30 FEG).

Semi-quantitative measurements were also done with the AlamarBlue assay (Biosource) and PicoGreen dsDNA quantification assay (Molecular Probes Inc), to investigate the metabolic activity (n=5) and cell numbers (relative to DNA content, n=5) over various time points. At each time point, culture medium was aspirated and mixed with 5% AlamarBlue. The mixture was incubated for 2 h at 37°C in and absorbance was measured on a plate reader (Safire^2 – Tecan) at wavelengths of 560nm and 600nm, together with blank controls using medium with reagent and medium only. Cell-construct metabolic activity was directly correlated to the percentage reduction of AlamarBlue reagent. For dsDNA quantification, specimens were subjected to freeze-thaw cycles of 1 hour each (between -80°C and 37°C) for 3 cycles to breakup the cell and nuclear membranes to obtain a homogenous cell suspension. 100μl of PicoGreen working solution was added to 100μl of specimen and incubated at room temperature for 5 minutes. Fluorescence was then measured with a plate reader (Safire^2 –Tecan) at excitation and emission wavelengths of 480nm and 520 nm, respectively. The amount of DNA was calculated by extrapolating a standard curve.

Western blot analysis was performed to observe presence of osteogenic proteins synthesized in the constructs. Pro-

teins from specimen were isolated in a lysis buffer (5mM MgCl2, 150mM NaCl, 1% triton-100, pH7.5) at 4°C for 20 minutes after rinsing in cold PBS three times. Lysates were collected after centrifugation at 12 000g at 4°C, for 5 minutes. The total amount of protein obtained was quantified with the Micro BCA kit (Pierce) with a standard curve derived from bovine serum albumin (Sigma). Polyacrylamide gel electrophoresis (SDS–PAGE) was performed and the separated proteins were then transferred to nitrocellulose membranes and incubated with of rabbit anti human osteopontin antibody (OPN-Abcam) and rabbit anti human β-actin (Delta Biolabs) as control. The protein bands on the membrane were detected by chemiluminesence (SuperSignal West Pico-Pierce) and the intensity measured with a densiometer (BioRad VersaDoc 5000).

III. Results and Discussions

The tensile test of the composite material with increasing percentage of TCP revealed that reinforcing the polymer matrix resulted in an increase of stiffness for the new composite material (Figure 1). However, with higher TCP contents the processibility of the material becomes a challenge as the overall viscosity of the material increases.

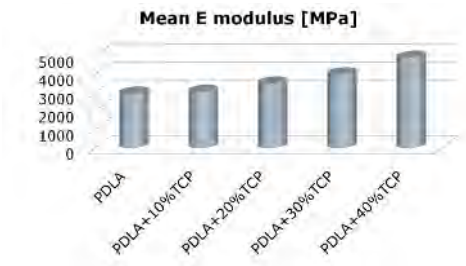

Figure 1. Modulus of dumb-bell shaped test specimen of PLDLLA and composite PLDLLA/TCP.

The SES fabricated PLDLLA/TCP (10%) scaffolds have a highly porous three-dimensional structure manufactured by the deposition of individual layers of struts in two angles (Figure 2). Gross morphological observations show good strut fusion between the layers, homogeneity and consistency of the deposited struts (average diameter ~400μm). The pores created were also regular and coherent to the design. The scaffold gross morphology had a neat spatial arrangement of pores and channels which were fully interconnected throughout the whole scaffold.

The compression tests revealed that the 2-angled scaffold design (0-90°) had a compressive stiffness of about 80MPa and a maximum compressive strength of 3MPa (Figure 3). These values are near and in the range of normal cancellous bone which had a reported stiffness of 90 - 400MPa and strength of 2-5MPa [14]. These mechanical properties indicate the potential application of these scaffolds in the field bone engineering. For load-bearing tissues, especially bone and cartilage, the 3D scaffold platform should be bioresorbable and provide adequate mechanical stability over the required period of time to withstand the *in vivo*.

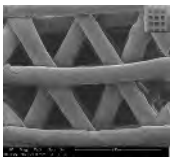

Figure 2. Plan view of an SEM micrograph of a 3-angle scaffold with picture of a 2-angle scaffold inset (*top right*).

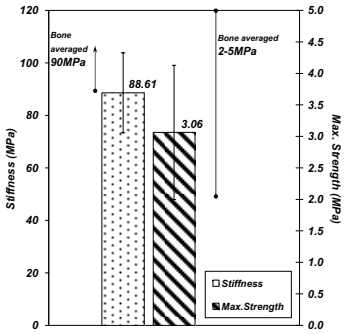

Figure 3. Compression stiffness (modulus) and maximum strength of the PLDLLA/TCP scaffolds. Arrowed and bulbed indicators indicate range of values for cancellous bone [14].

The importance of scaffold interconnectivity and porosity is essential for cell proliferation and exchange of nutrient and waste products [1]. Its effects and relation to mechanical stability has also been clearly defined. As porosity increases, a decrease in scaffold material, its mechanical properties would suffer correspondingly. Zein *et al.* [13] and Lam *et al.* [15] have demonstrated the dependence of mechanical properties on scaffold porosity when designing and fabricating scaffolds via rapid prototyping. The relationship of increasing porosity and declining mechanical properties has been found to follow a power law relationship [16]. The high dependence of mechanical properties on scaffold porosity had also been reported by Thomson *et al.* [17] and de Groot *et al*. [4]. Reinforcement through incorporation of filler material into the polymer matrix is one alternative of increasing the mechanical properties.

Cell-scaffold constructs cultured in static conditions up to 8 weeks showed a promising scaffold with suitable surface characteristics and architecture for cell proliferation and growth. AlamarBlue assay revealed increasing metabolic activity from day 0 to day 28, when the peak was reached (Figure 4). Phase contrast microscope observation and SEM observations concurred with the cell proliferation

in the scaffold and forming layers and sheets covering the scaffold struts and bridging the pores (Figure 4). Confocal laser microscope observations confirmed the cell morphology and distribution of viable cells in the cell-scaffold construct. DNA quantification with the PicoGreen assay also confirmed the increase in cell population. Subsequent western blot analysis for osteopontin revealed presence of the osteo-protein, indicating differentiation capability and plasticity of the BMSCs on the composite scaffolds.

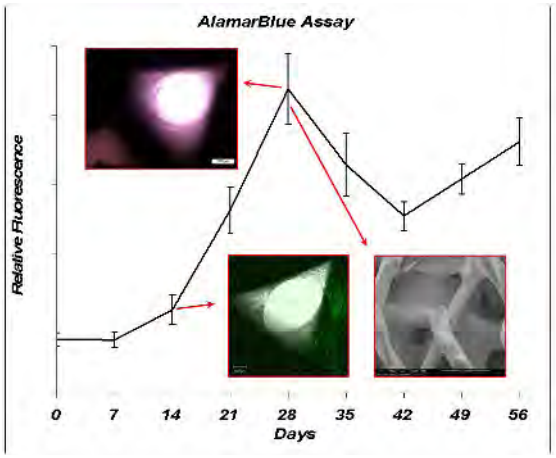

Figure 4. Composite pictures of PLDLLA/TCP scaffold on a graph showing the observed AlamarBlue relative fluorescence readings, metabolic activity on the uptrend; dipping slightly after day 28 and continue to increase shortly after. Inset images: Microscope image at day 28; pBMSC has proliferated and formed dense sheets adhering to the PLDLLA/TCP scaffold struts and structures. They also form bridging over the open pores (*Top*). Confocal microscope image showing majority of viable cells (*green*) already bridging the pores at day 14; dead cells would fluoresce red (none observed) (*bottom left*). SEM image at day 28 showing dense cell sheets spread over the pores and struts of the scaffold architecture (*bottom right*).

IV. Conclusions

These results demonstrate the PLDLLA/TCP scaffolds exhibit good biocompatibility and potential, for both functional mechanical and biological role requirements, as a scaffold for bone tissue engineering applications or bone graft substitute.

Effects of Biaxial Mechanical Strain on Esophageal Smooth Muscle Cells

W.F. Ong[1], A.C. Ritchie[1*] and K.S. Chian[1]

[1] School of Mechanical and Aerospace Engineering, Nanyang Technological University, Singapore

Abstract — **Esophageal cancer has one of the highest mortality rates compared to other types of cancer. Tissue engineering promises a bio-artificial prosthesis for enhanced surgical treatment. To facilitate the tissue engineering of the esophagus, a bioreactor capable of two-dimensional mechanical strain was designed and fabricated. Esophageal smooth muscle cells are seeded onto oxygen plasma treated polyurethane sheets and mechanically stimulated for 3 days at 420 cycles/day. The cells are then assessed for cell alignment by phase contrast microscopy and cell proliferation by MTS assay. After mechanical stimulation, the smooth muscle cells showed alignment under varying biaxial strain conditions in different regions of the bioreactor while the cell proliferation assay suggests the possibility of the change in the metabolic and phenotypic state of the cells over the 3 days of mechanical stimulation.**

Keywords — **bioreactor, mechanical stimulation, smooth muscle cells, esophagus tissue engineering**

I. Introduction

Esophageal cancer has one of the highest mortality rates compared to other types of cancer [1, 2]. Although the survival rate of esophageal cancer has been increasing over the years, the overall survival rate is still considered low [2]. Epidemiological studies have shown that esophageal cancer is 10 to 100 times more prevalent in Asia and Africa when compared to the United States [1-3]. The most common treatment method for managing esophageal cancer is surgical resection [3-6]. This results in a significant decrease in the quality of life for the patient after surgery [7, 8]. In cases where surgical treatment is not possible, artificial devices and the intraesophageal stent have been used to manage the disease with limited success [9]. The biocompatibility of the materials used is still far from ideal [10, 11].

Tissue engineering may provide a viable alternative for the treatment of esophageal cancer [10, 12]. *In vitro* studies on vascular cells have shown that mechanical stimulation is able to improve the structural and functional properties of cell/scaffold constructs for the purpose of tissue engineering organ replacements [13, 14]. However as previous studies have focused on vascular and cardiac cell types [15], their results may not be representative of the cell types found in the esophagus. This study aims to investigate the effects of mechanical stimulation on esophageal smooth muscle cells to develop a tissue engineered esophagus.

II. Materials and Methods

A. 2-Dimensional strain bioreactor

A bioreactor capable of providing biaxial mechanical strain by out-of-plane circular substrate distention [16] was designed and fabricated. A schematic drawing of the bioreactor design is shown in Figure 1. Figure 2 shows the complete system. The 2-dimensional strain bioreactor is actuated using a microprocessor controlled syringe pump to provide fluid displacement to induce mechanical strain on a flexible polyurethane membrane held between the top and bottom chambers.

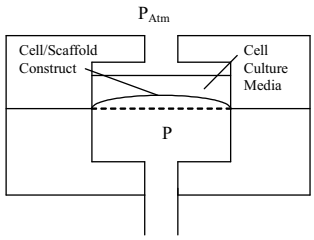

Fig. 1. Schematic drawing of 2-D strain bioreactor

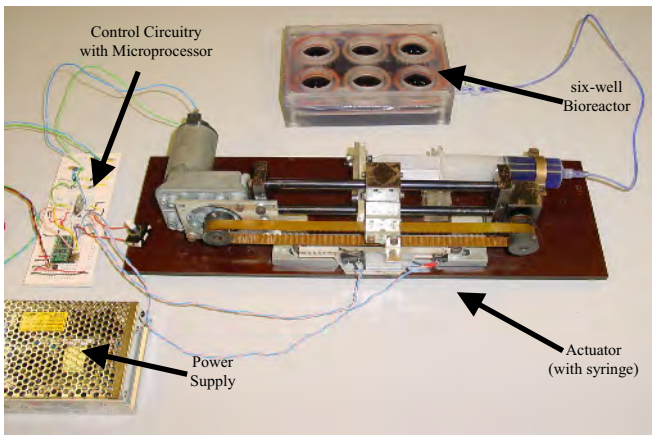

Fig 2. Two-dimensional strain bioreactor system

B. Fabrication of polyurethane membrane

Flexible polyurethane membranes were fabricated using Chronoflex® AL80-A pellets (CardioTech International)

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1484–1487, 2009
www.springerlink.com

dissolved in 1,4-dioxane (Merck). The polyurethane-dioxane solution was then cast onto a glass mould with a wet thickness of 2mm and air dried. The polyurethane sheet is then extracted from the glass mold and vacuum dried for 3 days at 24°C to extract residual solvents. The prepared polyurethane sheet is then treated with oxygen plasma to facilitate cell attachment prior to the experiment.

C. Culture of esophageal smooth muscle cells

Esophageal smooth muscle cells were isolated from the muscle layer of fresh porcine esophagus using enzymatic dissociation with collagenase. The isolated smooth muscle cells were then allowed to grow to confluence in a humidified 5% CO_2 incubator (Sanyo) at 37°C and passaged at a split ratio of 1:5 every 7 days. Smooth muscle cells from passages 4 to 6 were used for the bioreactor experiments. The isolated smooth muscle cells are cultured using Dulbecco's Modified Eagle's Medium (Hyclone) with 10% Fetal Bovine Serum (Hyclone) and 1 % Antibiotic Antimycotic Solution (Sigma).

Cells were seeded onto the polyurethane sheet within the bioreactor at a density of ~2.6×10^4 cells/cm^2 and left to attach for 24 hours before commencement of the mechanical strain regime. Control experiments were carried on oxygen plasma treated polyurethane sheets in static culture.

D. Mechanical strain regime

Mechanical strain (2% magnitude) was applied to the smooth muscle cells for 420 cycles at a rate of 5 cycles per minute every 24 hours for 3 consecutive days, as shown in figure 3. This mechanical stimulation wave form is designed to closely resemble the mechanical forces experienced by the cells *in vivo* based on the pressure waveform generated by the esophagus during ingestion of solid food.

E. Assessment of cell response to 2-dimensionalmechanical strain

Cell alignment

After mechanical stimulation for 3 days, alignment of the smooth muscle cells was observed using phase contrast microscopy. Three regions of the polyurethane sheet were examined due to their different states of strain.

MTS assay

To determine the effects of 2-dimensional mechanical strain, a cell proliferation assay was performed using CellTiter96® AQ_{ueous} One Solution Reagent (Promega) by mixing 1 part of MTS reagent to 4 parts of fresh culture medium. The light absorbance was then measured at a wavelength of 490nm using a GENios micro plate reader (TECAN).

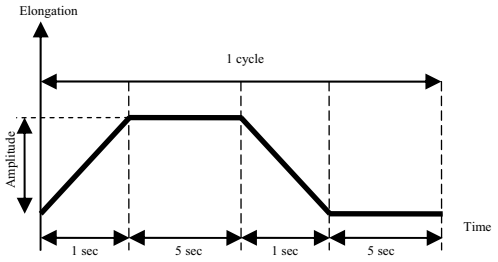

Fig. 3. Mechanical strain cycle for esophageal smooth muscle cells

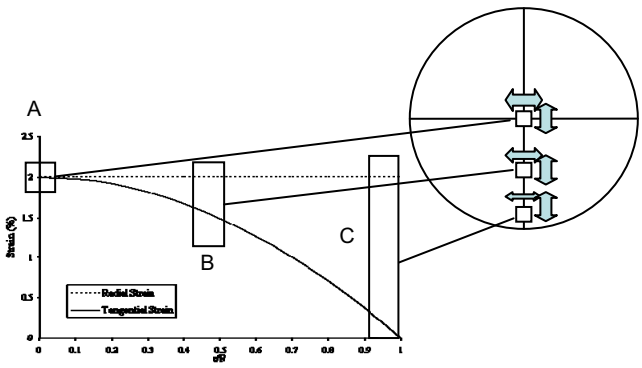
III. Results and Discussion

A. Cell alignment

The 2-dimensional bioreactor imparts a complex state of strain on the polyurethane sheet. Due to the deformation geometry of the polyurethane sheet during mechanical stimulation, the polyurethane sheet changes from a flat sheet to a spherical cap[17]. As a result of this deformation, the radial strain remains constant throughout the polyurethane sheet as determined by its curvature, while the tangential strain is at a maximum at the centre of the bioreactor and would decrease to zero at its edge. Figure 4 shows the state of strain at the 3 locations of interest: well centre (A), mid radius (B) and well edge (C).

After 3 consecutive days of mechanical stimulation, the smooth muscle cells grown on the polyurethane membrane were observed using phase contrast microscopy. Figure 4 shows the phase contrast micrographs of the mechanically stimulated smooth muscle cells at the 3 locations of interest compared to the cells grown on polyurethane sheet control.



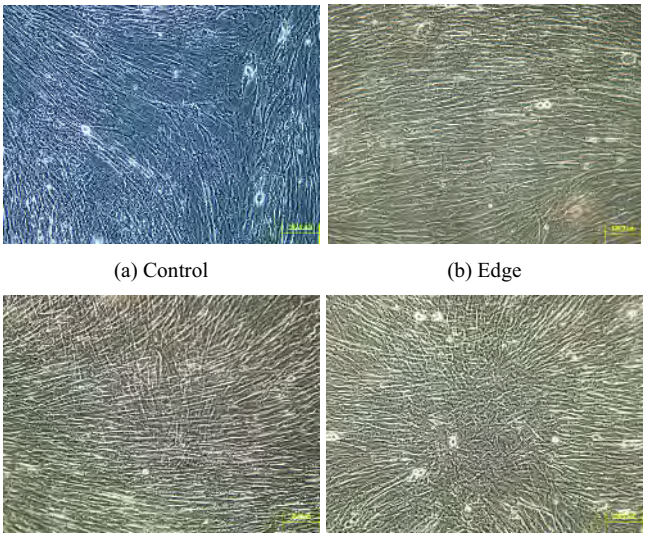


Fig 4. Profile of state of strain within the polyurethane sheet

(a) Control (b) Edge

(c) Mid radius (d) Centre

Fig 5. Phase contrast micrographs of esophageal smooth muscle cells at different locations of the bioreactor (20× objective)

The phase contrast micrographs presented in Figure 5a shows that the esophageal smooth muscle cells in static conditions exhibit random alignment. The characteristic hill and valley growth and pattern is observed as it reaches confluence in all areas. Although small domains of local alignment of the smooth muscle cells can be observed, the cell alignment is still random on a macroscopic scale. This phenomenon is also exhibited by smooth muscle cells cultured on other tissue culture surfaces [18, 19].

Mechanically stimulated esophageal smooth muscle cells exhibited varying alignment in all 3 locations of interest. At the well edge (Figure 5b), the cells are aligned perpendicular to the radial strain in the absence of tangential strain. This result corresponds to previous work on smooth muscle cells subjected to uniaxial strain [13, 20-25]. Buck [25] postulated that smooth muscle cells align perpendicular to the direction of applied strain to minimize mechanical stress by moving the long axis of the cell away from the direction of applied strain, preserving their existing focal adhesion points.

At the mid radius of the bioreactor, the state of strain is predominantly radial with some tangential strain (Figure 5c). Most of the smooth muscle cells align perpendicular to the radial strain while some cells align parallel to it. This may be due to the presence of the tangential strain component, which increases from the edge to the centre. When both radial and tangential strains are present, the cell must align perpendicular to one of the principal strains to minimize the stress it experiences. At the centre of the bioreactor, smooth muscle cells were observed to align perpendicular to one another. At this location, the radial strain and the tangential strain are equal. From the geometrical perspective, the equi-biaxial state of strain is created by a series of radial strains passing through the central axis of the bioreactor well. The cells are observed to align parallel to the radial strain, radiating outwards from the bioreactor centre (Figure 5d) as there is little difference between the radial and tangential strain in the areas just outside the bioreactor centre.

B. MTS Assay

To investigate the effects of cyclic two-dimensional mechanical strain on esophageal smooth muscle cells, a cell proliferation assay was conducted using CellTiter® AQ_{ueous} One Solution Reagent. The MTS assay was performed after each day of stimulation to determine the effects of mechanical stimulation on cell proliferation. Figure 6 shows the light absorbance values of the stimulated esophageal smooth muscle cells compared to the static controls.

The light absorbance of the MTS assay reveals that the mechanically stimulated cells display consistently lower light absorbance for all 3 days when compared to the control cells.

The MTS light absorbance for the static controls can be seen to increase to confluence on days 2 and 3 (Figure 6) while the mechanically strained cells show a sudden decrease after 1 day of stimulation. On days 2 and 3, the MTS values have increased significantly.

As the MTS assay measures cell numbers through the metabolic conversion of the reagent to a soluble formazan colored product [26], the metabolic state and phenotype of the cells used in this assay must be generally similar to make a valid comparison. In these experiments, mechanical

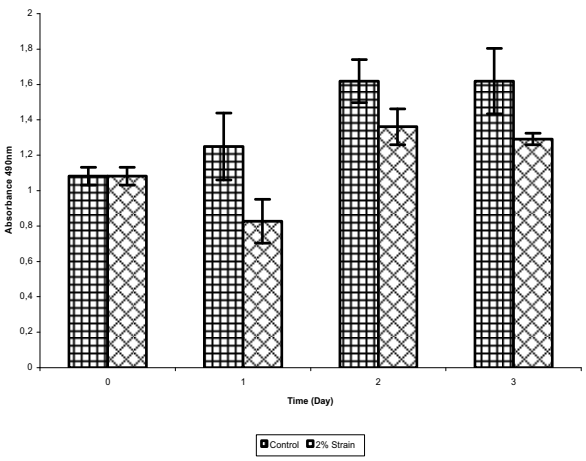

Fig 6. MTS cell proliferation assay between mechanically stimulated and control

stimulation may induce a change in cell metabolism and a change in phenotype. Under high strain magnitudes and cyclic frequency, cells are known to detach from smooth surfaces due to their poor attachment [25]. The sudden drop in MTS values may be due to a shift in the cell metabolism after the sudden shock of the commencement of mechanical stimulation. There may also be loss of poorly attached cells from the surface. After the 2nd day of mechanical stimulation, the MTS values for the strained cells reach a plateau, possibly indicating differentiation.

IV. Conclusion

From the results obtained from this study, biaxial mechanical strain stimulation is shown to be able to induce alignment of the esophageal smooth muscle cells. In addition, the MTS assay results obtained have suggest the possibility of metabolic changes of the mechanically strained cells and also a possible phenotypic change.

The two-dimensional mechanical strain bioreactor has demonstrated that differential biaxial strain would cause the smooth muscle cells to align to one of its principal stress axis to minimize the mechanical stresses on the cell.

The two-dimensional mechanical strain bioreactor has demonstrated that it is able to induce alignment in smooth muscle cells and may induce differentiation of the smooth muscle cells. This knowledge will be used for mechanical stimulation of a tubular 3 dimensional scaffold to facilitate the tissue engineering of a clinically functional esophagus.

Characterization of Electrospun Substrates for Ligament Regeneration using Bone Marrow Stromal Cells

T.K.H. Teh[1], J.C.H. Goh[1,2], S.L. Toh[1,3]

[1] Division of Bioengineering, National University of Singapore, Singapore
[2] Department of Orthopedic Surgery, National University of Singapore, Singapore
[3] Department of Mechanical Engineering, National University of Singapore, Singapore

Abstract — **Challenges persist in the tissue engineering and regeneration of ligaments. Of the various aspects contributing to the success of ligament tissue engineering (such as the scaffold, cell source and stimulatory biochemical and mechanical cues), architecture and material involved in scaffold design remain as a significant area of study. Essentially, the scaffold for ligament regeneration, especially the cell-seed substrate, should be viable for cell attachment, promotes nutrient and waste transfer, be mechanically viable, and stimulates initial cell proliferation and ECM production. In this study, electrospun substrates using the silk fibroin (SF) and PLGA material, with different electrospun fiber arrangements (aligned (AL) and random (RD)) were compared for their ability to promote MSC attachment and subsequent differentiation down the ligament fibroblast cell lineage. The rationale for such characterizations lies in the hypothesis that SF, being a natural protein, provides significantly more favorable surface chemistry for cell attachment and differentiation than synthetic polymers such as PLGA. On the other hand, the aligned electrospun fiber arrangement will mimic the native ligament ECM environment, to guide MSCs down the fibroblast lineage. Electrospun PLGA and SF substrates were fabricated by first dissolving the respective material in HFIP (7-10% w/v). Following which, aligned PLGA and SF substrates were collected from a rotational electrospin setup, while the random types were collected from a grounded plate. These four groups of substrates (SF-AL, SF-RD, PLGA-AL, PLGA-RD) were then characterized in terms of cell adhesion, proliferation, viability and function via post-seed cell counting, AlamarBlue™ assay, Fluorescence Microscopy, Sircol® Collagen Assay and SEM. Results from this characterization show that cells remained viable when cultured on these substrates, with the AL types being mechanically stronger and promoted increased proliferation and collagen production as compared to the RD types. SF substrates promoted cell attachment and differentiation, as inferred from the increased collagen production.**

Keywords — **Scaffold, Electrospin, Alignment, PLGA, Silk**

I. Introduction

In the pursuit of functional tendon/ligament tissue engineering, several factors have been identified by various groups as essential. [1, 2] They include the various aspects of the scaffold, cell source and stimulatory biochemical/mechanical cues. Of the different aspects involved for scaffold design, the architecture and material used remain significant.

In view of the surface topology at which cells are exposed to in their native environment, a scaffold architecture involving aligned ultra-fine fibers is envisioned. The fabrication method of choice is electrospinning, which produces non-woven fibrous structures of different fiber orientations, including the aligned and random fiber arrangements. With diameters in the range of nanometers to microns, integrating to produce structures with interconnected pores and high surface area to volume ratio, electrospun fibers can mimic the native extracellular matrix (ECM) to serve as a suitable seeding substrate for tissue engineering.

Using electrospinning, aligned fibers are produced to act as guidance structures for cells. Lee et. al. carried out assessments of cellular responses, histological observation, proliferation and ECM production of human ACL fibroblasts (HLF). They found that HLFs on the aligned fibers were spindle-shaped and aligned in the direction of the fibers. Such HLFs formed tissue like, oriented bundles, which were confluent over the surface. Significantly more collagen was produced on aligned fiber sheets than on randomly oriented sheets. [3] Xu et. al. compared the cell-cell adhesion and proliferation of human coronary artery smooth muscle cells (SMC) on TCP, plane polymer film and aligned polymer fiber. They observed that SMCs migrated along the axis of the aligned fibers and expressed spindle-like contractile phenotype. [4] Mauck et. al. employed fibrous scaffolds for the tissue engineering of the meniscus. They seeded mesenchymal stem cells (MSC) on aligned and random fibers. Results showed that aligned fibrous scaffolds serve as a micro-pattern for directed tissue growth and that when seeded with MSCs, produce constructs with improved mechanical properties compared to random scaffolds. [5] These studies have shown the potential of aligned fibers as tissue engineering scaffolds/substrates. However further optimization should be carried out and applied for ligament regeneration. Assessements for the differentiative potential down the ligament fibroblast cell lineage by aligned substrates have also not been conclusive.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1488–1491, 2009
www.springerlink.com

From the scaffold material aspect, PLGA has been identified as a suitable candidate for electrospinning of fibrous scaffolds. Mao et. al. had produced PLGA fiber scaffold with an architectural morphology similar to those of natural ECM. Such scaffolds were cytocompatible with hMSCs and their osteoblast and chondrocytes lineage. [6]

Apart from synthetic polymers, recent efforts have been spent on using natural materials such as silk for electrospinning. As a potential material for tissue engineering, silk displays properties of enhanced environmental stability due to extensive hydrogen bonding and significant crystallinity. Min et. al. have produced silk fibers which have been shown to promote cell adhesion and spreading of type I collagen. They also discussed the possibility of surface modification of the nanofibers with ECM proteins. [7]

As such, this study is set to perform a comparative study between electrospun substrates using silk fibroin (SF) and PLGA material. It is hypothesized that SF, being a natural protein, provides significantly more favorable surface chemistry for cell attachment and differentiation than synthetic polymers such as PLGA. On top of that, different electro-spun fiber arrangements will be compared for their ability to promote rabbit MSC attachment and subsequent differentiation down the ligament fibroblast cell lineage.

II. Materials and Methods

A. Substrate Fabrication

Silk Degumming: Sericin, the antigenic part of raw silk, was first removed prior to dissolving for electrospinning purposes. Bombyx mori raw silk (Thailand), was soaked in degumming solution, containing aq. Na_2CO_3 and Sodium dodecyl sulphate (SDS), 0.25%(w/v) each (Sigma Chemicals) at 98~100^{o}C for 30 mins and thereafter rinsed in distilled water for 30 mins.

Electrospin Solution Preparation: PLGA (85:15) polymer pellets were dissolved in hexafluoro-2-propanol (HFIP) (Fluka) at 7% w/v to obtain PLGA solution. To obtain electrospinnable SF solution, degummed silk was first dissolved in saturated aq. lithiumthiocyanate (LiSCN) (Sigma Chemicals) solution, and upon full dissolution, dialyzed in distilled water for 3 days. The dialyzed aq. SF solution was then lyophilized to obtain regenerated SF sponge. The SF sponge was then dissolved in HFIP at 10%w/v to obtain the electrospinnable SF solution.

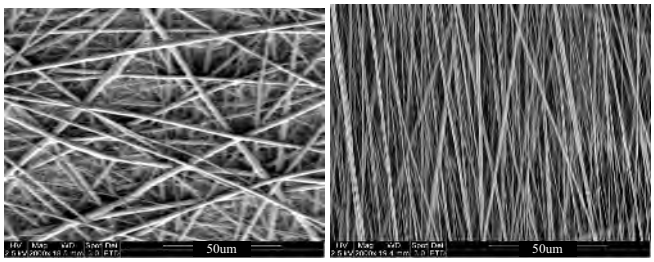
Electrospinning: Aligned electrospun fibers were obtained using a customized rotational electrospin setup involving a combination of positive electric field plates and a rotating collector device. Using such a setup, the path of the polymer jet is restricted such that highly aligned electrospun fibers can be obtained on the grounded rotating frame. Randomly arranged electrospun fibers were collected from a grounded metallic collector. Four groups of substrate: PLGA random (PLGA-RD), PLGA aligned (PLGA-AL), SF random (SF-RD) and SF aligned (SF-AL) were collected on 40 x 22mm glass slides for characterization purposes.

Sterilizations: Prior to cell seeding, the scaffold substrates were sterilized by means of formaldehyde (37%) (JT Baker) gassing for 24 hours. All other equipment was sterilized by autoclaving.

B. Cell Culture

Bone marrow stromal cells (BMSC) extracted from New Zealand white rabbits were cultured in DMEM culture medium (Sigma) with fetal bovine serum (FBS) (Hyclone) of 15% v/v concentration. P3 cells cultured at 70% confluence were used for all the four groups of substrates.

C. Characterization of Electrospun Fiber Substrate



Substrate Gross Morphology: SEM images of the electrospun fibers were taken to observe the morphology of the fibers. To measure the fiber diameters and degree of alignment in the fibers, the software ImageJ (U.S. National Institutes of Health) was used. The angles from the vertical of each individual fiber (n=30) were measured and given a value from -90° to 90°. The distribution of the angles from the vertical was plotted for both aligned and random fibers.

Cell Seeding Efficiency: After incubating the cell-seeded substrates (n=3, $0.7x10^6$ cells/substrate) for 36 h, the culture medium was collected from the wells and cell count of unattached cells performed. The cell seeding efficiency was expressed as a percentage of the number of attached cells to the number of cells seeded.

Cell Proliferation Assay: Alamar Blue™ (Biosource) assay was used to assess cellular proliferation. The assay was carried out at D1, 3, and 7, whereby seeded substrates (n=3 each) were exposed to 10% Alamar Blue™ reagent in DMEM for 3h. The percentage reduction of Alamar Blue™ reagent was computed and taken to be an indication of cell proliferation levels.

Collagen Production Assay: The amount of collagen synthesized and deposited onto the substrate structure was determined by SirCol Assay (Biocolor) at D3, 7 and 14. Substrates from the four groups (n=3 each) were sacrificed and digested in pepsin from porcine mucosa (4000U/mg, Sigma) in 0.5M acetic acid (100ul) to isolate the sample collagen triplehelix from all non-collagenous protein.

Cellular Alignment and Morphology: DAPI and phalloidin (Invitrogen) staining were carried out on the nuclei and actin filaments of the cells respectively at D7 and D14.

a b

Fig. 1 SEM images: (a) randomly oriented and (b) aligned electrospun fibers. (2000x Magnification)

Staining was carried out on BMSCs-seeded substrates to observe the morphology and orientation. Briefly, the seeded substrates at the respective timepoints were fixed and permeabilized in 0.1% Triton X-100 (Sigma). Staining was carried out subsequently.

D. Statistical Analysis

Data were expressed as means ± standard deviation (SD). Single factor analysis of variance (ANOVA) technique was used to assess the statistical significance of results between groups. For pair-wise comparisons, two-tailed, unpaired Student's t tests were used. A $p<0.05$ was considered statistically significant.

III. Results

A. Substrate Gross Morphology

SEM imaging was performed on the aligned and random electrospun fibers (Fig. 1). From the images, the measured diameters of the electrospun fibers were of the range of 400-800nm. As observed from the histograms (results not shown), nanofiber alignment was achieved using the rotating electrospin setup. In contrast, no specific orientation was observed from the randomly deposited fibers.

B. Cell Seeding Efficiency

The cell seeding efficiency was found to be as follows. PLGA-AL: 95.4±1.11%, PLGA-RD: 94.1±1.35%, SF-AL: 97.3±0.90%, and SF-RD: 96.6±0.68%.

C. Cell Proliferation Assay

Fig. 2 shows the percentage Alamar Blue™ reduction by the four groups of cell-seeded substrates. There was significant proliferation when BMSCs were cultured in the substrates from D1 to D7. Within each timepoint, no significant difference ($p>0.05$) was found in Alamar Blue™ reduction between the two materials. However, BMSCs seeded onto the aligned substrates proliferated significantly faster ($p<0.05$) than the random counterparts by D7.

D. Collagen Production Assay

The amount of insoluble collagen synthesized increased over the 14 days experimental period for all the four groups of substrates (Fig. 3). There was significant difference ($p<0.05$) in the amount of collagen deposited between the substrates with aligned fibers and that with randomly oriented fibers from D7 onwards. Significantly more collagen ($p<0.05$) was also deposited for the silk substrates as compared with the PLGA type substrates after D7.

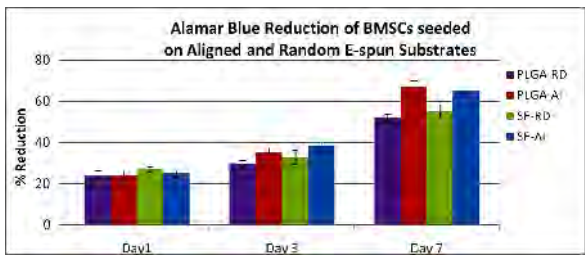


Fig. 2 Proliferation rates as represented by the Alamar Blue reduction by BMSCs seeded electrospun substrates

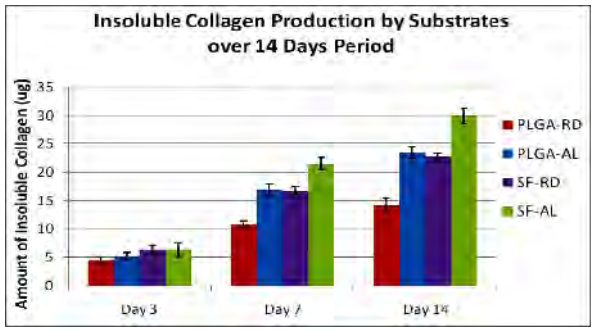

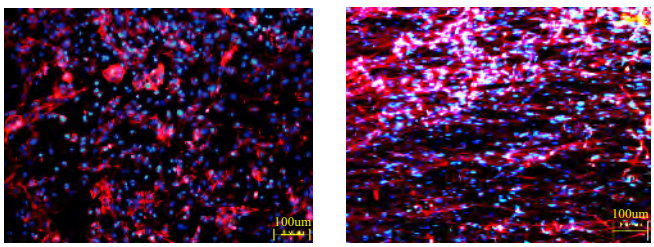

Fig. 3 Insoluble collagen produced by BMSCs seeded electrospun substrates

a b

Fig. 4 Fluorescence micrograph of BMSCs (actin: Red, nucleus: Blue) after 14 Days culture on random (a) and aligned (b) electrospun substrates

E. Cellular Alignment and Morphology

Fig. 4 illustrates the alignment and morphology of BMSCs after 14 days of culture on substrates with different fiber orientation. Cells assumed a more rounded morphology when cultured on randomly arranged electrospun fibers, while cells are elongated and aligned along the fiber direction when cultured on the substrates with aligned fibers. Cellular alignment was determined by the presence of aligned actin filaments in the aligned fiber substrates. Such alignment was not apparent in the random fiber substrates.

IV. Discussion

The aligned surface topology has been shown by several groups to have a positive effect on cell proliferation and collagen production. [3, 4, 8] Specifically, Lee et. al. had suggested that such cellular responses are likely due to a cell-cell interaction or cell-matrix interactions. [3] Yim et. al. had also presented a comprehensive review of the interaction of cells with nanoscale topography. Their findings indicate that cells respond to topography of synthetic substrates in the nanometer range in terms of adhesion, proliferation, migration and gene expression. [8]

This study further exemplifies these phenomena and demonstrates a method of producing aligned electrospun fibers that is suitable for the application of tendon/ligament tissue engineering. The advantage of such a structure lies in the biomimicry of the aligned electrospun fibrous substrate to native tissue environment of the tendon/ligament, where there is a high level of ECM and fibroblasts cellular alignment. This is evident from the proliferation and insoluble collagen assays, which show that the aligned substrates, regardless of materials, stimulated significantly higher proliferation and collagen deposition after D7 of experimentation.

Other than the architectural effect, the substrate material used also affects cellular responses. BMSCs seeded on SF substrates synthesized significantly more collagen than those seeded on PLGA substrates after 7 days culture. Although there was no significant effect on proliferation, the use of SF as seeding substrate material did improve collagen deposition. This is likely due to the increased number of protein binding sites, which facilitated the deposition of synthesized collagen. Further studies will be required to ascertain the types of collagen that are bound and the efficiency involved.

The use of aligned SF electrospun fibers (SF-AL) is thus shown to be advantageous as seeding substrate for tendon/ligament tissue engineering whereby higher proliferation and improved collagen deposition is desired.

V. Conclusion

A method of producing aligned electrospun submicron fibers of PLGA and SF was described. Aligned fibers as such stimulated increased proliferation and collagen depostion. SF type fibers provided a suitable surface for ECM deposition as indicated by the increased insoluble collagen deposited. Aligned SF electrospun fiber mesh was thus shown to be a promising seeding substrate for tendon/ligament regeneration.

Abstract — **Fibrous membranes composed of wool keratin and Poly-L-Lactide (PLLA/keratin) were prepared using wool keratin particles, with the weight ratios of PLLA/keratin at 2:1, 1:1, 1:2, 1:4 and 1:8. In vitro cytotoxicity tests and cell adhesion experiments were performed on these fibrous membranes using osteoblasts for assessment of the cytocompatibility of the membranes. The cytotoxicity of the PLLA and PLLA/keratin fibrous membranes changed as the concentration of wool keratin increased. PLLA/keratin at a ratio of 2:1 or 1:1 was nontoxic to the cells, while 1:4 and 1:8 PLLA/keratin membranes were remarkably cytotoxic. In addition, cell adhesion was influenced by the keratin concentration. Cell adhesion to the membranes decreased when keratin concentration increased. These results suggest that high concentration of wool keratin can be cytotoxic, and the concentration of wool keratin particles influences the cell adhesion on PLLA/keratin fibrous membranes significantly.**

Keywords — **Wool keratin, PLLA, Cytotoxicity, Cell adhesion, Tissue engineering**

I. Introduction

Tissue engineering employs natural and synthetic polymers to fabricate biomedical scaffolds [1-12]. Two basic preconditions are necessary for biomedical materials which support cell proliferation for tissue regeneration. Firstly, they should be non-cytotoxic [13] and secondly, they should allow cell proliferation [1, 6-9].

Arising from different compositions such as silk, collagen, chitin, chitosan, and other proteins, polymers play a pivotal role as biomaterials for tissue engineering [4-6, 8, 12, 14-22]. Poly-L-Lactide (PLLA), which is a kind of biodegradable polymer with high biocompatibility, was thought to be suitable for potential biomedical applications in the human body [5, 12, 23].

From our previous investigation, wool keratin/PLLA composite fibrous membranes were found to improve cell proliferation [24]. Thus, in this study, in vitro cytotoxicity tests and cell adhesion experiments were undertaken to assess the effects of PLLA/keratin composite fibrous membranes on cell proliferation.

II. Materials and Methods

A. Materials

Poly-L-Lactide (PLLA) (IV6-8) was purchased from Purac, Netherlands Ltd. Wool fibres were purchased from the Nanjing Wool Market. Wool keratin particles were obtained by using spray drier (Buchi, B-290) and wool keratin emulsion which was prepared according to a patent-pending technique [25].

B. Fabrication of PLLA/keratin Fibrous Membranes

Nano wool keratin particles and PLLA were added into an organic solvent mixture composed of chloroform and N, N-dimethylformamide (DMF) (10:1, w/w) and subjected to electrospinning to obtain PLLA/keratin fibres at weight ratios of 2:1, 1:1, 1:2, 1:4 and 1:8 (Pk21, Pk11, Pk12, Pk14 and Pk18 respectively) [26].

C. Cytotoxicity Test

According to the standard, EN ISO 10993-12:2007, sterilized membranes were rinsed with PBS three times, then immersed into culture medium at the ratio of 0.1g/mL and kept in the incubator at 37°C for 24 hr to get the extractions. The extractions of the membranes were applied for cell culture. Meanwhile, PLLA extraction was used as a negative control. Cells (25μl) at a density of 4×10^5 cells/ml were seeded in a 96-well plate, to which was added membrane extraction and normal culture medium. Morphological changes of the cells were observed through an inverted microscope [27].

D. Cell Adhesion

Osteoblasts (MC3T3, ATCC) used in this study were maintained in Dulbecco's Modified Eagle's Medium (DMEM) with 10% foetal bovine serum (FBS, Invitrogen, USA) in a 37°C and 5% CO_2 incubator. The medium was replaced twice weekly. All of the membranes were sterilized by ultraviolet irradiation for 20 minutes after being immersed in 70% ethanol for 1 hour. Each membrane was

www.springerlink.com

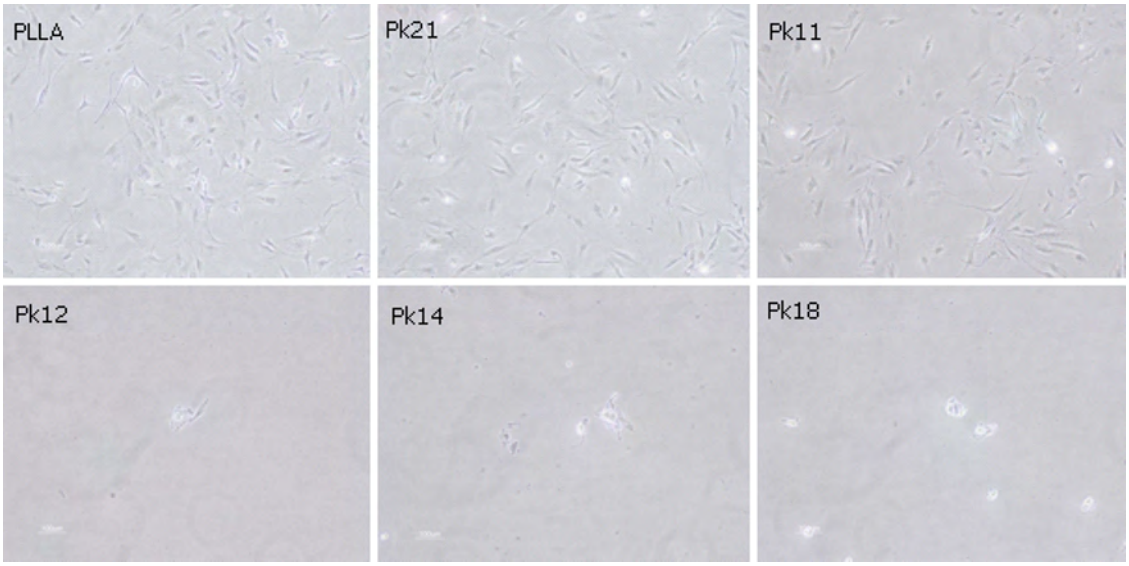

Fig.1. Morphological changes of cells cultured with different extractions of PLLA/keratin fibrous membranes. Morphological changes and detachment of the cells were observed in the extractions of Pk12, Pk14 and Pk18 membranes through the inverted microscope.

seeded with 2×10^4 cells and kept in the incubator for one day. An MTS assay was employed to assess the cell adhesion on membranes.

E. Scanning Electron Microscopy (SEM)

Electrospun fibrous membranes with cells were coated with gold and then their morphologies were observed by scanning electron microscopy (JEOLJSM-6335F, 20kV).

F. Statistical Analysis

Values were expressed as means ± standard deviations. Statistical differences were determined by one-way Analysis of Variance (ANOVA). *P* values of less than 0.05 were considered to be statistically significant.

III. Results

A. Cytotoxicity of PLLA and PLLA/keratin Membranes

To determine the cytotoxic effects of the PLLA/keratin fibrous membranes, cytotoxicity tests were performed using the membrane extractions.

The morphological changes and detachment of the cells were observed through an inverted microscope. As shown in Fig.1, the Pk12, Pk14 and Pk18 membranes inhibited cell proliferation. The Pk21 and Pk11 membranes did not change the cell morphology significantly, which implies that these two membranes are suitable for cell proliferation.

B. Cell Adhesion

Cells were cultured on PLLA and PLLA/keratin membranes for one day before applying an MTS assay for checking cell adhesion (see Fig.2 which compares PLLA and PLLA/keratin fibrous membranes).

As shown in Fig. 2, the cell adhesion of Pk21 is significantly higher than that of the other Pk membranes, and there

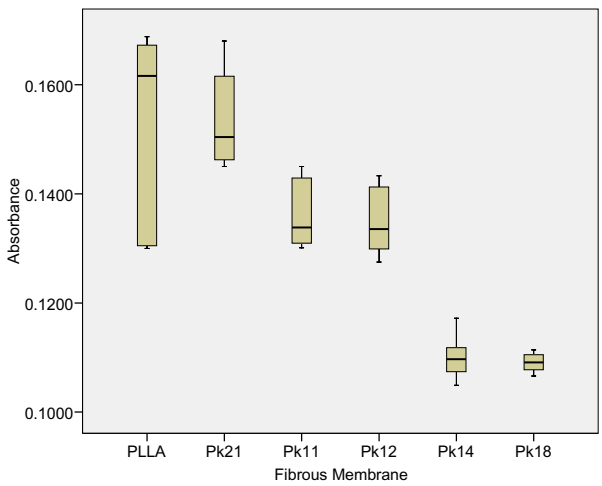

Fig.2. MTS assay results of cell adhesion on PLLA and PLLA/keratin fibrous membranes. Pk21 is significantly higher than that of the other Pk membranes and there is no significant difference between the Pk21 and PLLA membranes.

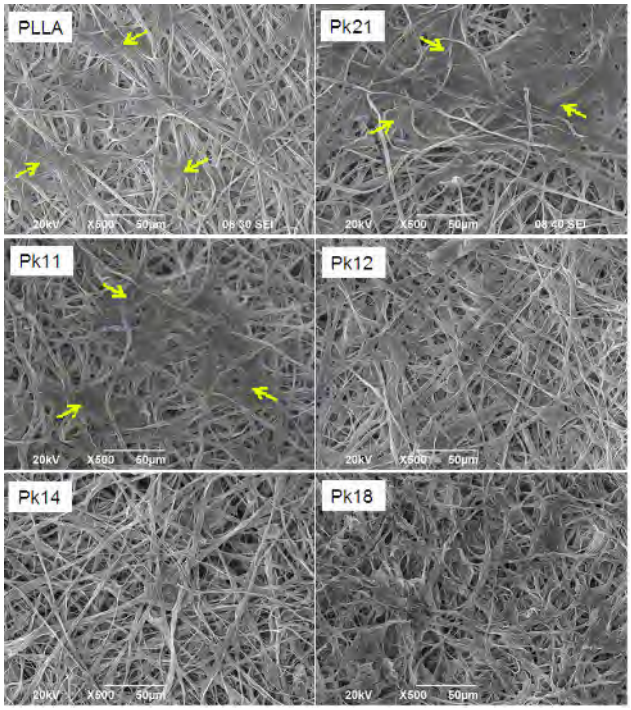

Fig.3. SEM images of PLLA/keratin fibrous membranes with cells cultured for three days. Cells can be seen stretched and spread like translucent films on PLLA, Pk21 and Pk11 membranes (arrows), few cells can be seen on the Pk12, Pk14 and Pk18 membranes.

is no significant difference between the Pk21 and PLLA membranes.

In addition, cells had been cultured on membranes for three days for observing cell adhesion through SEM. In accordance with the MTS assay results, confluent cells were found to stretch and spread spanning the fibers as translucent films on PLLA, Pk21 and Pk11 membranes (Fig.3, arrows), while confluent cells were hard to be seen on the other Pk membranes.

IV. Discussion

Tissue engineering matrices for loading cells have to fulfill two preconditions. Firstly, they must not be cytotoxic [13]. Secondly, they must be suitable for cell adhesion [7, 18]. In this study, PLLA/keratin fibrous membranes were assessed to discover whether they fulfilled these two preconditions.

In vitro cytotoxicity tests were firstly performed using the extractions of the membranes to determine which membranes were cytotoxic. The Pk12, Pk14 and Pk18 membranes were found to inhibit cell proliferation. The cells cultured in the extractions of these three membranes underwent significant morphological changes, and very few cells could be seen through the inverted microscope. These observations suggested that high concentrations of wool keratin can be cytotoxic.

In addition, the cell adhesion result for the Pk21 membrane was significantly higher than those of the other Pk membranes. Although it was not obvious in one day cell adhesion experiment, the Pk11 membrane showed the potential for cell adhesion in SEM images. These results imply that the level of cell adhesion is one of the important factors for successful cell proliferations on Pk membranes.

Tachibana *et al*. reported that wool keratin scaffolds would be useful for long-term and high-density cell culture [19, 20]. Our previous study also found that the Pk membranes improved cell proliferation significantly [24]. As a degradable material, PLLA could provide a good matrix for long-term cell culture scaffolds with a non-cytotoxic wool keratin concentration. So, PLLA/keratin composite membranes are reasonable scaffolds for tissue engineering.

In summary, wool keratin can influence the cell adhesion on PLLA/keratin fibrous membranes significantly, and using the right concentration will avoid the problem of cytotoxicity.

V. Conclusions

High concentrations of wool keratin can be cytotoxic, and the concentration of wool keratin particles influences cell adhesion on PLLA/keratin fibrous membranes significantly. Thus, PLLA/keratin membranes of the correct ratio can provide a non-cytotoxic surface for cell adhesion.

Tissue Transglutaminase as a Biological Tissue Glue

P.P. Panengad[1], D.I. Zeugolis[2] and M. Raghunath[3]

[1]Tissue Modulation Laboratory, Division of Bioengineering, Faculty of Engineering, National University of Singapore, Singapore
[2]National Center for Biomedical Engineering Science, National University of Ireland, Galway, Ireland
[3]Tissue Modulation Laboratory, Division of Bioengineering, Faculty of Engineering, & Department of Biochemistry, Yong Loo Lin School of Medicine, National University of Singapore, Singapore

Abstract — **Surgeons have long sought an efficient biological method of wound repair that requires little time and minimizes discomfort for their patients, yet produces a good cosmetic outcome. Our aim is to develop a biological tissue glue based on the extracellular matrix stabilizing enzyme transglutaminase 2 to covalently bond tissue layers to promote suture-less closure of surgical wounds. We used human skin tissue as a model to test our hypothesis. Human skin samples were studied for endogenous transglutaminase activity and probed for target structures for commercial enzyme using standardized histochemistry. Tissue bonding between two skin sections was monitored under phase contrast microscopy.**

Keywords — **Transglutaminase, biological tissue glue, skin, histochemistry**

I. Introduction

Transglutaminases (TGases) constitute a family of enzymes that stabilize protein assemblies by Gamma-glutamyl Epsilone-lysine crosslinks [1]. Six different gene products are so far known in the human genome, of which at least three play important roles in the skin. TGase 2 (tissue TGase) is likely to be involved in crosslinks anchoring fibrils of the dermoepidermal junction [2] and is active during different phases of wound healing and can function to promote wound repair [4]. We hypothesize that primary closure of wounds by covalent transamidation cross linking of extra cellular matrix proteins will achieve wound repair at molecular level, efficient primary intention healing and thereby prevention of scarring, due to high biocompatibility.

II. Methods

A. Assay of native Transglutaminase activity

Cryostat sections (5μm) of human skin were assayed for native transglutaminase activity as described earlier [3].

B. Assay of exogenous Transglutaminase activity

Cryosections (5μm) of human skin were air-dried for 10 min at room temperature (RT), incubated with 10 mM solution of TGase inhibitor iodoacetamide in 0.1 *M* Tris/HCl, pH 8.4, for 1.5 h and washed in PBS. Assay of residual native TGase activity was performed in one section and the rest of the sections were then incubated for 1.5 h at RT with transglutaminase & substrate peptide in the buffer at different concentrations at pH 8.4. The TGase reaction stopped with EGTA was used as control. The slides washed in PBS were incubated for 30 min at RT with Streptavidin-DTAF, counter stained with DAPI, and mounted after final washing in PBS. Images were captured with inverted epifluorescence microscope (Olympus IX71) [5].

C. Study of Tissue adhesive property of Transglutaminase

Commercial TGase at optimum concentration was dried on a glass slide and contact transferred to the incision surface of excised skin tissue. After transfer incision was closed by approximation and tissues were incubated for 2 h sandwiched between two tissue papers soaked in calcium buffer under optimum compression. Later the tissues were cryosectioned across the fusion and immuno-localization of commercial TGase performed, followed by activity assay of TGase and measurement of strength of adhesion. The strength of fusion was assessed by controlled stretching of the cryosections picked on a designed microscope slide and live phase contrast imaging.

III. Results

Native Ttransglutaminase Activity Assay: Native transglutaminase activity assay on human skin cryosections showed TGase activity in epidermis as well as dermis. Epidermal activity was confined to the stratum granulosum and the basement membrane. Dermal activity was diffuse but more intense in the papillary dermis which is rich in capillary plexi (Fig 1.)

Assay of exogenous Transglutaminase activity: Assay of commercial transglutaminase activity was carried out with Recombinant Human TGase 2 on human skin. Assay was performed with different concentrations of the commercial enzyme and 250 μg/ml was found to be optimum. All the

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1496–1498, 2009
www.springerlink.com

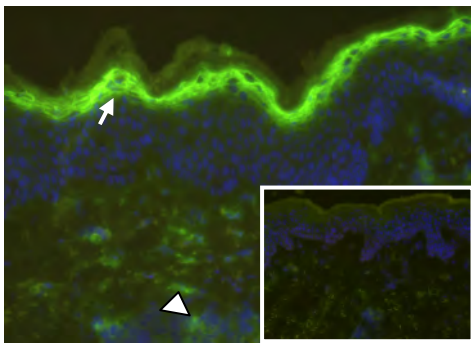

Fig. 1 Native TGase activity in skin incorporates tagged substrate peptides in the presence of calcium. Preferential activity is seen as zone of green fluorescence in both dermis (TGase2) (triangle) and epidermis (TGase1) (arrow). Picture inset - Calcium chelation with EGTA abolished enzymatic activity.

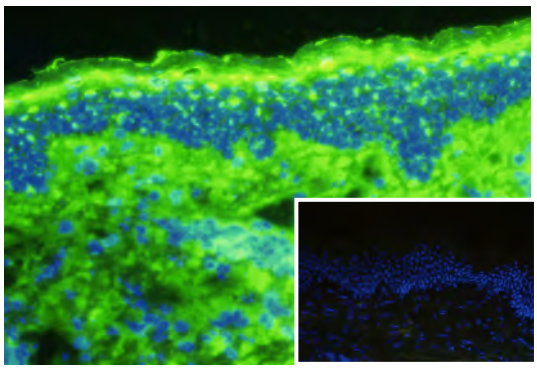

Fig. 2 Exogenous/ commercial TGase2 added to substrate cocktail crosslink the tagged peptide into all the layers of the skin with preference to the dermis indicating the presence of abundant enzyme substrate sites for this enzyme here. Picture inset - Calcium chelation with EGTA abolished enzymatic activity.

layers of human skin showed abundant substrate sites for human TGase 2 (Fig 2).

Localization and activity assay for Transglutaminase after TGase adhesion: Histology of *in vitro* tissue adhesion samples shows a solid line of fusion after TGase 2 application compared to the EGTA control. Immuno-localization of recombinant human TGase 2 indicated that surface concentrated enzyme can be contact transferred to tissue surface to achieve high concentration of the enzyme at the plane of fusion. Assay for TGase activity after tissue fusion indicated a focused and high activity at the line of fusion after contact transfer of dried enzyme (Fig 3).

Test of yielding strain: Test of yielding strain of *in vitro* skin tissue adhesion samples revealed fragmentation/failure of tissue surrounding the fusion line before achieving partial

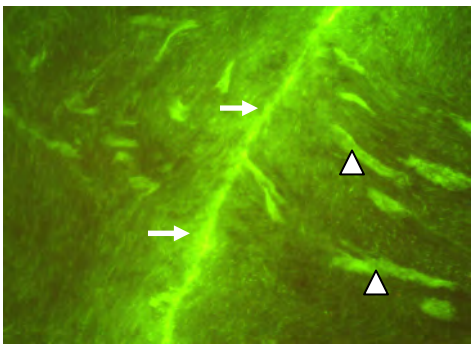

Fig. 3 Exogenous/commercial TGase2 activity along the fusion line (arrows). Native transglutaminase activity along the dermal capillaries is visible at multiple sites (triangles).

Fig. 4 Application of graded tensile force perpendicular to the TGase 2 fusion line. EGTA control: already minimal tensile strain caused gaping of tissue interfaces. TG2 Adhesive: In the presence of Ca^{++} TGase2 caused a stable fusion that withstood much higher tensile strain. At maximum, the fusion would split only partially while the surrounding tissue would fragment, demonstrating the stability of the crosslinking.

gaping of adhesion line in TGase 2 adhesion sample proving enzymatic adhesion strength matching neighboring intact skin tissue while the EGTA control sample failed at the fusion line at a very minimal level of strain (Fig 4).

IV. Conclusion

Human skin tissue has abundant dermal substrate sites for TGase2 and contact transfer of dry enzyme, concentrates active enzyme at tissue fusion plane. More over bonding strength of TGase 2 - mediated tissue adhesion matches with the surrounding skin tissue. Hence we have shown the potential of extracellular matrix crosslinking enzyme – transglutaminase 2 as a biological tissue glue to achieve rapid and efficient tissue repair.

Abstract — **Fibrosis represents an excessive accumulation of collagen in tissues. The resultant consequences range from cosmetic disfiguration, impairment of implants to organ failure. The development of effective anti-fibrotics is therefore an important clinical goal. Unfortunately, screening for anti-fibrotics has been limited by incomplete procollagen processing and poor matrix formation in vitro and the inability to normalise the amount of deposited collagen for the cell number in the same culture well. The "scar-in-a-jar" concept is based on advanced cell culture technology making use of macromolecular crowding. This system ensures that the complete biosynthetic and depositional cascade of collagen matrix formation is in place. We have developed a rapid (2 days) and an accelerated matrix formation protocol (6 days) with the latter allowing for crosslinking of the deposited matrix in vitro. Automated adherent cytometry and in situ quantitation of immunofluorescence intensity of extra- and intracellular antigens is combined with automated image acquisition and semi-automated image processing, This discovery tool allows for a novel *in situ* assessment of the area of deposited collagen(s) normalised to cell number thereby simultaneously monitoring cell proliferation/cytotoxicity. In addition, multiplexing enables quantitation to include non-collagenous ECM proteins. Bioimaging data obtained with known and novel antifibrotic compounds at the epigenetic (histone deacetylase), post-transcriptional (miRNA), post-translational (Prolyl-4-hydroxylase) and post-secretional level (C-proteinase, lysysl oxidase, matrix metalloproteinase-1) correlated excellently with biochemical analyses.**

Keywords — **Fibrosis, collagen, quantitation, bioimaging, macromolecular crowding**

I. Introduction

Scarring, a physiological tissue response to wounding, has been highly conserved in evolution and across species. As the last step of the wound-healing cascade it is usually self-contained. However, if this step is perpetuated by repeated tissue insults and/or ongoing inflammation, fibrosis ensues. Its histopathological correlate is an excessive production and deposition of collagen that converts normal tissue into scar tissue with associated loss of function. Therefore, causes as diverse as chronic infections, radio -and chemotherapy, chronic exposure to alcohol and other toxins can all lead to fibrosis with a considerable global disease burden. Not only organ, but also localized fibrosis can severely impair the quality of life in millions of patients, for example through implant failure .

The development of effective antifibrotics is therefore an important unmet clinical need. It necessitates careful *in vitro* screening of lead compounds before they are tested in animal models. However, this has been severely hampered by biological and technical problems. Firstly, fibrogenic cells in monolayer culture do not lay down significant amounts of collagen in a useful time window for screening. This is due to a tardy enzymatic conversion of procollagen to collagen in vitro even under full procollagen synthesis[1]. Secondly, the amount of deposited extracellular matrix (ECM) in relation to the number of cells in the same culture well currently requires the destruction of cell layers to obtain protein or DNA [2]. Whatever little collagen is deposited in the ECM must be solubilized prior to analysis [3]. Thirdly, collagen quantitation is problematic with non-specific methods like the popular picro-sirius red dye assay[4]. Determination of hydroxyproline content is far more collagen-specific, however it is tedious and time consuming. Other methods which rely on laser scanning confocal microscopy[5] are slow during image acquisition and are not capable of handling multi-well plates.

Lastly, antifibrotics should preferably target collagen, and the monitoring of other ECM proteins should be done to confirm a specific down-regulation of collagen in order to rule out undesired inhibition of general protein synthesis. For the first time, all these features have been combined to allow for multiplex analysis in one well.

II. Materials and Methods

A. Cell culture

Normal primary lung fibroblasts (WI-38) were selected on the basis of their strong collagen I production in our hands. The cells were routinely cultured at low passage (3-8) as outlined earlier [1]. Fibroblasts were seeded on
