24-well Cellstar plates (Greiner BioOne) at 50,000/well in 10% FBS, 5% CO_2 at 37°C. After 16 hours, the medium, was changed to DMEM containing 0.5 % FBS, 100 μM of L-ascorbic acid phosphate magnesium salt η-hydrate with or without 500kDa dextran sulfate (DxS) at 100 μg/mL or a combination of 37.5 mg/mL Ficoll 70 with 25 mg/mL Ficoll 400 (Fc). 5 ng/mL transforming growth factor β1 (TGFβ1), in combination with or without antifibrotic substances was added at the same time. Only 2,4-PDCA and BAPN were added daily to Fc crowded cell cultures (accelerated mode).

B. Optical analysis

A bioimaging station comprising of a Nikon TE600 fluorescence microscope plus Xenon illuminator, with an automated Ludl stage and shutter, and equipped with a Photometrics CoolSNAP high sensitivity cooled monochrome CCD camera (model HQ, Roper Scientific) camera was used. Screening of 24-well multiwell plates was made possible by an automated stage and autofocus capabilities. 9 image sites per well were acquired at 2X magnification, stored and analyzed using the Metamorph ® Imaging System software (Molecular Devices). The Count Nuclei module was used for cell enumeration with specific parameters in order for a region to be considered as a positive count (countable nucleus): 1) Areas with pixel intensity value 15 above that of the background. 2) Fluorescent areas with a minimum length of 10 μm and a maximum length of 15 μm. The Integrated Morphometry Analysis module was used to quantify the area of fluorescent collagen I staining which had been deposited on the cell layer. Controls were used to determine suitable fluorescent intensity thresholds (300 for the DxS model and a range between 500-550 for the Fc model) fluorescent signals below a defined pixel intensity value were thresholded out, which eliminated measurement of the background area. Triangle masks were added to eliminate quantitation of corner auto-fluorescence. This analysis resulted in a data set expressed as area of collagen I per nuclei in μm^2 per image field.

III. Results and Discussion

A. 2 collagen deposition modes

The rapid deposition mode is based on our previous observation that negatively charged macromolecules induce dramatic collagen deposition in 48-72 hours in contrast to neutrally charged ones[1, 6]. However, we discovered that neutral Ficoll 70 and 400 in combination double collagen deposition after 6 days in comparison to standard culture,

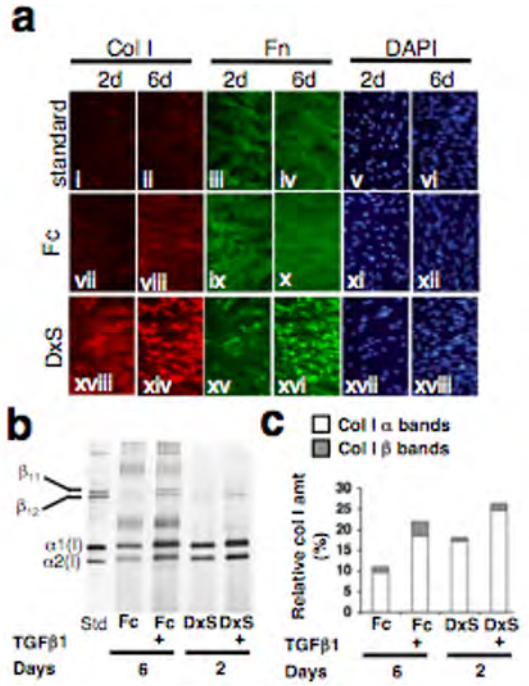

Figure 1. Rapid and accelerated collagen deposition modes. (a) Immunocytochemistry: standard culture with reticular fibronectin matrix and minimal collagen I deposition (i-iv), Fc (accelerated): enhanced reticular collagen I/fibronectin matrix (vii-x). DxS (rapid): granular aggregates of collagen I/fibronectin (xiii-xvi) with highest ECM content. 40x magnification. (b) SDS-PAGE analyses of collagen matrix content in both deposition modes in the absence/presence of TGFβ1. With TGFβ1 both deposition modes give more and faster matrix formation including stronger lysyl oxidase-mediated cross-linking (c) Densitometry of (b).

and remarkably, with a reticular deposition pattern. Thus, amount, velocity and morphology of collagen deposition can be controlled by crowding mode (Fig. 1). The accelerated mode with its longer culture time also produces collagen with a larger extent of cross-linking (Fig. 1b).

TGFβ1 increased collagen I deposition by another 1.5-2 fold in the rapid mode. Neutral mixed crowding in the accelerated mode for six days resulted in the doubling of collagen deposition in comparison to non-crowded cultures, and an additional 2-fold increase in the presence of TGFβ1 (Fig. 1c). Moreover, this mode resulted in a fibrillar collagen meshwork with a more even spread of immunosignal (Fig. 1a). TGFβ1 has pleiotropic effects, it slows down matrix turnover by reducing MMP1-expression, upregulating lysyl oxidase activity and increasing the presence of tissue derived inhibitors of MMP's. These effects only come into play with a deposited matrix, underlining the importance of the holistic approach represented by this screening system.

B. Image processing and capturing

To match circular well geometry with rectangular image capturing fields, a macro was written to automatically add triangular masks to conceal auto-fluorescence from the curvature of the wells during quantitation (Fig. 2a-iii and iv). The final quantitation area represents 54% of the total well area, but 83% of assessable area that includes a safety distance from well edges to avoid cell distribution irregularities (Fig. 2a-iv). This capturing mode in combination with a long-range 2x objective renders the bioimaging station independent of the use of expensive optical plates. For cell enumeration, images of DAPI stained nuclei were scored by the software for counting (see Methods (Fig. 2b-i and ii)), and images of immunostained collagen I were thresholded such that pixels with a fluorescent intensity above a selected value derived from controls, were demarcated by the software for quantitation (Fig. 2b-iii and iv). As both area and fluorescent intensity per cell correlated closely with densitometric data, area was selected as a parameter of collagen I deposition (Fig. 2c).

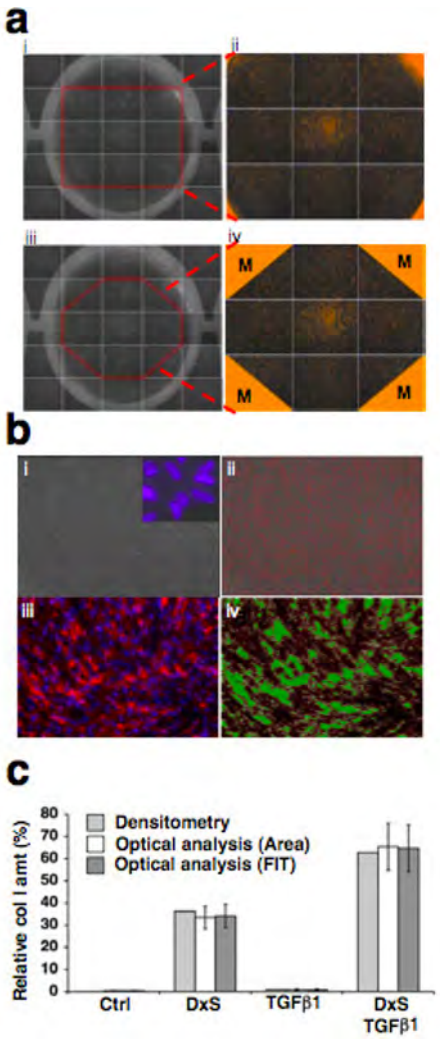

Figure 2. Image acquisition and quantitation of rapid collagen deposition mode. (a) (i) 2x magnification of cells in a 1.9 cm^2 well with superimposed original rectangular image acquisition area (red box). (ii) enlarged red box: corner auto-fluorescence (arrows). (iii and iv) acquisition area after application of triangular masks to eliminate corner auto-fluorescence. (b) Cytometry and quantitation of the area of deposited collagen I. (i) DAPI-stained nuclei at 2x magnification in monochrome pseudocolor, 60x mag (inset). (ii) red scored nuclei by Count Nuclei module for cytometry. (iii) immunostained deposited collagen I. (iv) Regions with fluorescent pixel intensity above a selected threshold are demarcated by the software in green for quantitation of deposited collagen I area. (c) Densitometry versus image analysis for collagen I quantitation.

C. Testing known and novel antifibrotics

Known and novel agents with anti-fibrotic potential were employed to interfere with various key steps along the collagen biosynthesis pathway. Reduction of collagen I deposition relative to untreated controls in both deposition modes was used as a read-out for antifibrotic efficacy. Biochemical analyses were always run in parallel to ascertain the reliability of the optical analyses.

In the absence of TGFβ1, **Trichostatin A (TSA),** a histone deacetylase inhibitor, reduced collagen I deposition to 60% (rapid) and 43% (accelerated). In the presence of TGFβ1, collagen I was reduced to 65% (rapid) and 29% (accelerated), close to baseline amounts of normal conditions without TGFβ1 (Fig. 3a).

We had recently predicted micro RNA **miR29c** to target procollagen $\alpha1_{(I)}$ mRNA by the *rna*22 algorithm[7] and we employed it in the rapid deposition mode. Both negative controls (scrambled oligos) did not affect collagen I deposition. In contrast, pre-miR29c (P29c) reduced collagen I deposition in the absence of TGFβ1. Particularly in the presence of this growth factor, 10 nM and 1 nM P29c reduced collagen I to 13% and 28% of mock transfected controls (Fig. 3b).

Collagen prolyl-4-hydroxylase inhibitors like **2,4-PDCA** and **ciclopirox olamine** render collagen triple helices less thermostable and thus prevent their secretion. Reduction of collagen I was observed in both deposition modes (Fig. 3c). Particularly in the presence of TGFβ1, 2,4-PDCA reduced collagen I deposits to 24% (rapid) and 23% (accelerated). CPX to 2% (rapid) and 20% (accelerated), and in the presence of TGFβ1, to 1% (rapid) and 12% (accelerated) (Fig. 3c). Effects of the hydrophilic 2,4-PDCA were evident in the accelerated mode only if added daily after the first 48 hrs. In contrast, the highly lipophilic CPX had to be added only once.

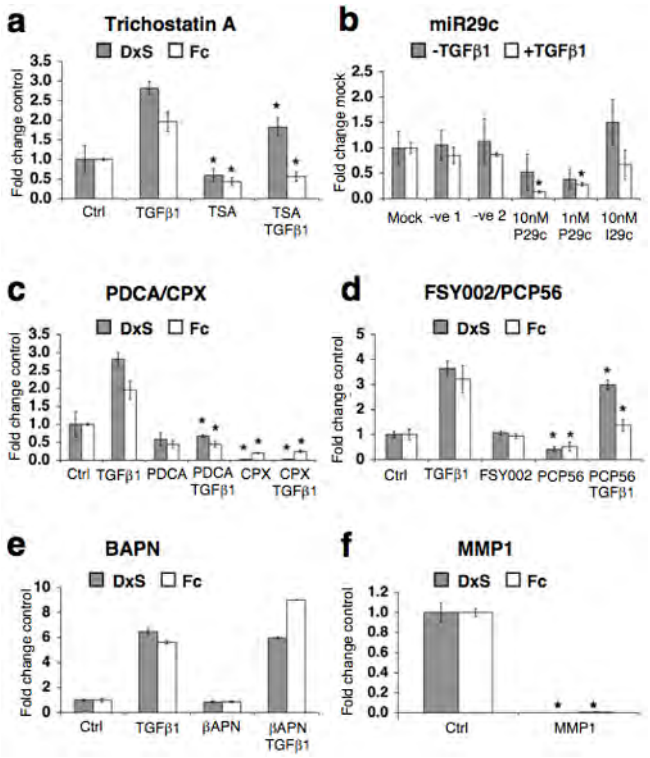

Figure 3 Intra- and extracellular perturbation of collagen biosynthesis by various known and novel inhibitors. Data are expressed as mean ± s.d., calculated from triplicates and as collagen area/cell -fold changes over respective controls

Procollagen C-proteinase/BMP1 controls the supra-molecular assembly of collagen into fibrils via removal of the C-terminal propeptide from the procollagen I molecule. Of two novel inhibitors, the phosphinate **FSY002** did not show any effects, whereas the sulfonamide **PCP56** reduced the deposited area of collagen I to 40% (rapid) and 52% (accelerated), and in the presence of TGFβ1 to 82% (rapid) and 43% (accelerated) (Fig. 3d).

β-aminoproprionitrile (BAPN) irreversibly inhibits lysyl oxidase, an amine oxidase that is crucial in stabilizing ECM by cross-linking collagen chains. In both deposition modes, BAPN caused no reduction of area collagen I/cell (Fig. 3e).

MMP1 controls collagen turnover in the ECM by cleaving collagen at a single site. Cell layers with ECM created under both deposition modes were exposed to exogenous recombinant MMP1. We observed detachment of cells during MMP1 treatment especially in matrix derived from the rapid mode. Therefore, the total area of collagen I/well was quantified without normalisation for cell numbers. MMP1 reduced the area of deposited collagen I to 0.03% and 0.6% in the rapid and accelerated modes respectively (Fig. 3f).

IV. Conclusion

In conclusion, the Scar-in-a-Jar offers a novel pathophysiologically relevant screening tool for antifibrotic lead compounds that shall prove highly useful in indication discovery and evaluation of novel compounds to cure fibrosis, which is a serious global clinical problem yet to be solved.

Abstract — **We are interested in the design and assembly of nanoparticles designated for delivery to cancer cells. Through the controlled manipulation of surface ligands, we have developed a lipid-based gene vector that improves cancer-specific delivery. Our ligand of interest is a short peptide with high affinity for the Urokinase Plasminogen Activator receptor (uPAR), a receptor overexpressed on the surface of many tumours. We modified the surface of optimized liposomal vectors with uPAR-specific peptides by physical and chemical incorporation methods. Using luciferase-based i*n vitro* and *in vivo* models, we demonstrate the improved efficiency of such targeted nanoparticles by DNA transfection and RNAi protein knockdown. We conclude that both the nature of the liposomal platform (stability, zetapotential), along with the presentation of surface ligands, contribute to the maximisation of a nanoparticle's targeting effect.**

Keywords — **liposome, peptide, cancer, receptor targeting, nanoparticle assembly**

I. Introduction

To aid site-specificity and uptake of nano-sized cancer therapies, nanoparticles must be formulated to exhibit optimised characteristics and surface chemistries. Size, for example is an important feature, where diameters of under 150nm are required to fit through the fenestration in the tumour epithelial cells. [1] Generation of appropriate surface chemistries is essential in preventing inter-nanoparticle aggregation in circulation, an environment where nanoparticles are also subject to being coated with and masked by serum proteins. Varying surface zeta potentials, as well as incorporating stealth polymers such as polyethylene glycol chains are methods of minimising aggregation. To improve site-specific delivery, ligands with specific affinity can be used to decorate the nanoparticles' surface, through either covalent or non-covalent attachment. These ligands act as a homing device, guiding nanoparticles towards cells which express the receptor to which the ligands have affinity for, and aiding cellular uptake by inducing receptor-mediated endocytosis.

The receptor we want to target is the urokinase plasminogen activator receptor (uPAR), a receptor found to be over-expressed on a variety of cancer cells such as those of the prostate and the breast. [2, 3] Its natural ligand, the urokinase plasminogen activator (uPA) binds to uPAR, forming an uPAR-uPA conjugate that enters cells by clathrin-coated, receptor-mediated endocytosis. [4] Studies by Appella *et. al.* have described the binding sequence within uPA that is involved in the binding to uPAR. [5] Derived from this sequence is a 11mer peptide, u11, with which previous studies in our group have shown to have high binding affinity for the uPAR. Using different methods of surface modification, we intend to study the effect of extension of ligands from the nanoparticle surface on ligand-targeting efficiency.

Firstly using luciferase-based reporter gene plasmid DNA assays, we investigated and optimised parameters such as charge and ligand organisation for improved receptor bio-recognition and targeting. Then by using RNA interference technology (knocking down protein expression by delivery mRNA-inhibiting siRNA), we showed that the optimised liposomal platform for in vivo delivery can successfully down-regulate luciferase expression in a bone metastatic mouse model.

II. Materials and methods

All cell lines were obtained from ATCC. Lipids were purchased from Avanti Polar Lipids. All amino acids and peptide synthesis reagents were from Novabiochem. Cell culture reagents were purchased from Invitrogen.

A. Nanoparticle preparation

The liposomal platform was formulated with lipids at different molar ratios. These include cationic lipids CDAN and DODAG (Imuthes), fusogenic (DOPE), PEGylated plus the targeting lipids. Lipids were dissolved in chloroform, mixed in a glass round-bottomed flask and dried *in vacuo* to form a lipid film. The film was then hydrated with H_2O and sonicated at 40°C for 30mins. pDNA or siRNA solution in H_2O (encoding luciferase gene) was then added to the vector solution under heavy vortex at a ratio of 1:12 (lipid:pDNA, w/w).

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1503–1507, 2009
www.springerlink.com

B. Nanoparticles with short ligand extension

This method was used to prepare targeted nanoparticles with ligands of short extension from the surface. On assembly of DNA-encapsulated nanoparticles, a solution of previously synthesised u11 peptide-lipid amphiphiles in H_2O was added and incubated at 37°C for 1 hr. Unincorporated amphiphiles were then removed by ultracentrifugation (MWCO=30k).

C. Nanoparticles with ligands extended from surface

The second method of ligand incorporation was used to extend the U11 ligand further away from the nanoparticle surface, by chemical conjugation of the ligand onto the distal end of surface PEG chains. In this case, the PEGylated lipid in the formulation was changed to one that was functionalised by a maleimide group at the extended end of its PEG chain. After vector assembly and before nucleic acid encapsulation, the vector solution was stirred with a solution of a Cysteine-functionalised 11mer peptide (u11). Nucleic acids were then encapsulated and removal of unconjugated Cys-u11 peptide was performed by centrifugal purification.

D. In Vitro Nanoparticle cell uptake and transfection

All cell lines were maintained in DMEM (plus 1% penicillin and streptomycin and 10% Fetal Calf Serum). Luciferase transfections were carried out on cells in OptiMEM ™ for 4hrs before removal of transfection media and replacement with growth media. Cells were then grown for 48 hrs before lysis (using lysis buffer) and analysed for relative light units and total protein content. For fluorescence uptake studies, nanoparticles were labelled with 1 molar % of DOPE-Rhodamine, and applied to cells for cell uptake. After 60mins incubation, the cells were fixed with paraformaldehyde and analysed for cell-associated fluorescence by fluorescence microscopy.

E. Photon correlation spectroscopy (PCS) and zetapotentials

Nanoparticle diameters and zetapotentials were measured on a Malvern ZS zetasizer at room temperature. All nanoparticles were prepared at $0.5 mgml^{-1}$ (of total lipid mass) in H_2O.

F. In Vivo study using RNAi technology

Nanoparticles were formulated as before with the inclusion of a higher % of PEGylated lipids for extra stability *in vivo*. Male balb/c mice were inoculated with 1 x 10^6 cells (PC3-M-luc) into under the knee cartilage in both knees and tumours were grown for 2 weeks until used for experiment. Mice were injected with a dose of 50µg anti-luciferase siRNA (encapsulated in nanoparticle) in PBS and luciferase expression in tumours was monitored by the In Vivo Imaging System (IVIS, Xenogen) on all days leading to and after nanoparticle administration.

III. Results and Discussion

A. High Charge Vectors

High charge nanoparticle platforms were prepared based on the formulation of commercially available transfection reagents. We combined high molar percentages of cationic lipids (50%) with fusogenic lipids (48.5%), plus 0.5% of $DSPE\text{-}PEG^{2000}$ lipids. An amount of PEGylated lipid is required to increase colloidal stability in serum and buffered solutions, but high molar percentages could lead to steric shielding of the short surface peptides. The non-extended targeting peptide was incorporated through self-insertion of a peptide-lipid amphiphile into the hydrophobic layers of the particle. The molar percentage of the peptide-lipid must also be adapted as over-loading can lead to inter-colloidal aggregation caused by the hydrophobic interactions between the surface peptides. Our data shows that the 0.5% PEGylated of total lipid molarity was enough to keep the balance of aggregation prevention and maintenance of the effect of the surface ligands. It was also found that a maximum loading of 1 molar % of the peptide-lipid amphiphile could allow the display of the ligand's targeting effect but any more would induce the nanoparticle's aggregation.

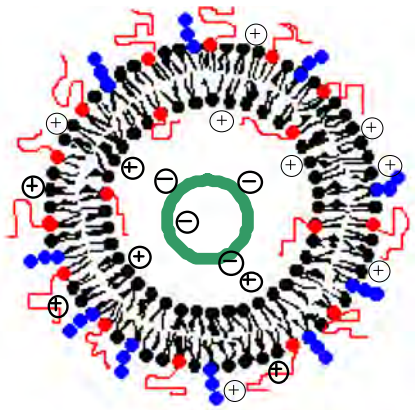

Fig. 1 Representation of the targeted nanoparticle, with short-extended ligands on the surface (blue). The liposomal compartment consists of cationic, fusogenic and PEGylated lipids, which directly encapsulates the nucleic acids within the core (green, pDNA).

Table 1- Summary of luciferase transfection on DU145 cells by targeted vectors (with 1 molar % of ligand) of various preparations. The high charged targeted nanoparticles showed a low increase in transfection, 4-fold in comparison to its non-targeted counterparts, where as the low charged targeted nanoparticles gave up to a 20-fold increase. The transfection level of the targeted low charge vectors were increased further to 30-fold when the targeting ligand is presented at an extended length from the nanoparticle surface.

Molar % of cationic lipid	ζ potential	Ligand extension	% RLU of non-targeted control
50	High (+62.3mV)	Short	400
20	Low (+47.6 mV)	Short	2,000
20	Low (+20.4mV)	Long	3,000

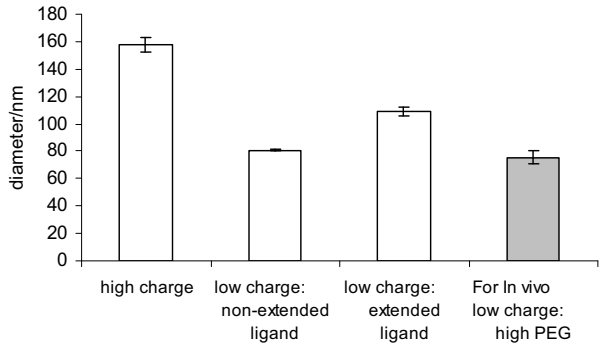

Fig. 2 Diameter sizes of targeted nanoparticles in H_2O, as measured by PCS. All particles have diameters under 150nm, important for *in vivo* kinetics plus receptor-mediated endocytosis.

The secondary conformation of the peptide ligands was examined using circular dichroism. Results show that the original β-sheet secondary aggregation of the peptide-lipids is disrupted as they are inserted into liposomal layers. This finding indicates the ability of peptide-lipid amphiphiles to separate from aggregated and heavily-strained macrostructures to form more separated strands as they come into proximity of a lipid-based surface.

Using DU145, an uPAR-overexpressing prostate cancer cell line, luciferase transfection experiments were performed to compare optimised targeted nanoparticles with their non-targeted counterparts (Table 1). The targeted vectors were able to induce a transgene expression that is up to 4-fold higher than the non-targeted nanoparticles. It is likely that this increase in transfection is a result of the increased uptake of targeted vectors by receptor-mediated endocytosis, as the diameter of the particles are <150nm, hence small enough to enter the cell via such an uptake mechanism (Fig 2). On the other hand, transfections on HEK293 cells (uPAR negative) showed lower levels of transfection by targeted delivery, due to non-specificity of the targeting peptide for surface membrane receptors. Uptake of targeted and non-targeted nanoparticles was examined by fluorescence microscopy, where rhodamine-labelled targeted nanoparticles again showed higher cell-associated fluorescence.

To improve the targeting effect of the surface ligands, the reduction of non-specific uptake of nanoparticles by cells needed to be reduced. We therefore continued to develop nanoparticles with lower overall surface charge within the liposomal platform.

B. Low Charge Vectors

Cell membranes consist of several membrane proteins that are negatively charged, such as that of the proteoglycans, rendering the cell membrane to be highly anionic. Electrostatic interaction with positively charged nanoparticles is the root of non-specific nanoparticle-cell membrane interactions. To minimise such non-specific binding, the zetapotential of the nanoparticles needs to be decreased. This can be achieved by decreasing the amount of cationic lipid in the nanoparticle formulation. Here, we reduced the amount of such cytofectins from 50% to 20%, whilst maintaining the lipid to pDNA ratio. The zetapotential of such vectors was reduced to 30% of that of the high charge vector, therefore decreasing the amount of non-specific uptake. Another advantage of the low-charged formulation is the reduction in nanoparticle size, where diameters of ~80nm were measured, compared to the 150nm diameter of high-charge nanoparticles (Fig 2). Satisfactorily, using low-charge targeted nanoparticles, an even further increase in transfection, up to 20 times higher was observed in comparison to non-targeted nanoparticles. Again, fluorescence microscopy gives indication of increased uptake by targeted vectors, a likely consequence of receptor-ligand interactions (Fig 3). To maximize the display of the targeting ligand, we continued by conjugating the peptide onto the distal ends of the extended PEG lipids.

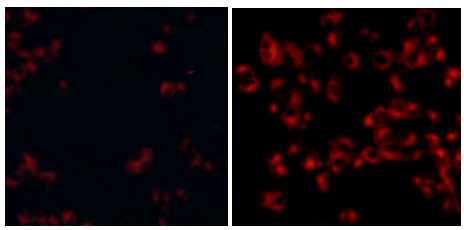

Fig. 3 Uptake of low charged vectors, decorated with (right) or without (left) 1 molar % of short peptide-lipid amphiphile at 60mins post-transfection. On DU145 cells, the targeted vectors show greater cell-associated fluorescence, indicating increased uptake of vectors due to receptor-selectivity.

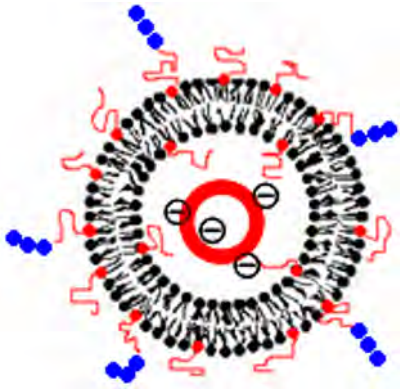

Fig. 4 Representation of the targeted delivery system for gene delivery, with peptide ligands (blue) extended from surface of the nanoparticle. The liposomal compartment consists of low mol% of cationic lipid, hence has lower overall surface charge. The red circle in the middle of liposome represents a circular plasmid.

C. Distal Peptide Conjugation

One of the major drawbacks of the u11 peptide-lipid amphiphile is the limited extension of the ligand on the vector surface. To improve receptor recognition, the presentation of the ligand should extend further from the vector surface, allowing improved docking into the target receptor's binding site (Fig 4). In our second method of targeted-nanoparticle preparation, we covalently conjugated the u11 peptide onto the distal end of functionalised PEGylated lipids, which are extended into the space surrounding the vector. In this method known as *post-coupling,* the distal ends of the PEGylated lipids were functionalised with a maleimide group. The maleimide functional group reacts readily with thiols, which required the modification of the u11peptide with an extra Cysteine amino acid before conjugation.

Again, transfection levels by targeted nanoparticles were higher, 30 times greater than that of the non-targeted particles, indicating the superior targeting efficiency of a low-charged nanoparticle with extended ligand presentation.

D. In Vivo siRNA Model

From the formulation studies and *in vitro* experiments, we learn that the nanoparticle platform on which the targeting ligands are presented is as important as the ligands themselves. Here, we study the ability of the optimised low-charge, non-targeted nanoparticles to induce protein knockdown in an *in vivo* cancer model.

Table 2- Summary of *in vivo* experimental conditions and results.

Tumour Type	Luciferase-expressing PC3-M-luc prostate cancer cells. Subcutaneous inoculation.
NP Size	80nm diameter
NP zeta potential	-0.9 mV
Dose	50 µg of anti-luciferase siRNA encapsulated. Administered on day 0.
% luciferase knockdown	75% on day 2, as monitored by IVIS.

Here we are administered nanoparticles containing anti-luciferase siRNA, where a reduction in luciferase protein is associated with a successful delivery and uptake of the nanoparticle at the tumour site. Using the optimised low-charge nanoparticle, a maximum of 75% reduction in luciferase activity was observed on day 2, indicating both the efficacy of the nanoparticle, plus its pharmacokinetic characteristics. The particle itself has high encapsulation efficiencies of over 90%, plus its near-neutral surface charges and small diameters are all favourable characteristics for successful delivery to tumours. Controls such as the injection of PBS only and injection of nanoparticles containing non-specific siRNA did not show a reduction in luciferase expression. These results indicate that the optimised nanoparticle is efficient as a functional delivery vehicle to tumour sites, hence potentially is an appropriate platform for ligand decoration to aid *in vivo* delivery.

IV. Conclusions

The results from our study shed light onto the factors contributing to the maximisation of a nanoparticle delivery vehicle's targeting effect. *In vivo* cancer studies also confirm the ability of such an optimised formulation to delivery genetic material. We conclude that a vector's stability, plus its surface zetapotential, along with the surface ligands' secondary structure and presentation, needs to be considered when developing a cancer-specific nanoparticle delivery vehicle.

BMSC Sheets for Ligament Tissue Engineering

E.Y.S. See[1], S.L. Toh[1] and J.C.H. Goh[2]

[1] Division of Bioengineering, National University of Singapore, Singapore
[2] Department of Orthopaedic Surgery, National University of Singapore, Singapore

Abstract — **The anterior cruciate ligament (ACL) has poor capabilities of healing. Currently, allografts or autografts are used to repair the injury site. But healing of the ACL following autograft or allograft reconstruction has been found slow. Thus, other methods like reconstruction of the ACL are being investigated. Most work in ligament tissue engineering has been done using a system of seeding biodegradable polymer scaffolds with single cell suspensions. The cell sources are mostly from Bone Marrow Derived Mesenchymal Stem Cells (BMSCs) or ligament fibroblasts. These cells would have to attach directly to the scaffolds and begin the process of proliferating, secreting ECM and other factors that would enhance the growth rate. This method is inefficient as many cells are lost during the seeding process due to the lack of ample site to adhere onto within the porous scaffold structure.**

When cells are cultured to confluence in vitro, they connect with each other through ECM and cell-to-cell adhesion molecules. With enzymatic digestion such as trypsinization, ECM proteins and cell-to-cell adhesion proteins are disrupted to allow the cells to be dissociated. Harvesting the entire cell sheet would avoid this disruptive process and preserve all ECM as well as cell-to cell adhesion proteins, as it does not experience the enzymatic dissociation process. With the help of the preserved ECM and cell-to-cell adhesion proteins, the cell sheet maintains cellular viability and functionality and can also adhere easily onto biodegradable scaffolds or other layers of cell sheets to form three-dimensional structures with suitable topology and mechanical properties. These unique aspects make the cell sheet technology a promising candidate for tissue engineering.

The proposed project intends to investigate the growth of a cell sheet beginning with BMSCs to study the collagen deposition, cell sheet viability, cell sheet thickness and gene expression to determine the suitability of BMSC sheets for ligament tissue engineering.

Keywords — **Bone Marrow Derived Mesenchymal Stem Cells, Cell Sheets, Ligament Tissue Engineering**

I. Introduction

Tissue engineering is based on the concept of using three-dimensional biodegradable scaffolds as a short term replacement for the extracellular matrix (ECM), and that the seeded cells would reform their native structure to take over the role of the scaffold as it degrades [1]. Current methods of seeding cells involve culturing the cells on tissue culture plastic (TCP) till sufficient numbers are obtained, followed by enzymatic digestion (trypsin) and finally seeding the single cell suspension onto the biodegradable scaffold [2,3]. This would involve the disruption of ECM and cell-to-cell adhesion proteins made by the cell. The single cell suspensions are then injected onto the scaffolds. The disadvantages of this method are that many cells are lost during the process of seeding onto the scaffolds as a large portion of the cells do not actually adhere to the scaffold but seep through the pores of the scaffold [4-6] and those that manage to adhere onto the scaffolds have to re-synthesize their own ECM again when they adhere to the new surface. In addition, the change in morphology and chemical makeup of the cells that leads to a loss of cellular activity is thought to be attributed to the disruption of the cellular membranes during trypsinization [7].

Research has been carried out on the development of a novel tissue engineering methodology to construct three-dimensional functional tissues by layering two-dimensional cell sheet without any biodegradable scaffold [8-10]. This method, although able to solve the problems faced by conventional cell seeding techniques, but is performed using terminally differentiated cells that have limited lifespan, poor differentiation potential and require long periods of time of culture to obtain a cell sheet with strong enough ECM that can be handled and manipulated without breaking apart.

Several studies have shown that BMSCs have a better proliferative capacity and collagen secretion as compared to terminally differentiated medial collateral ligament, anterior cruciate ligament and skin fibroblasts [11,12]. BMSCs have also been shown to differentiate towards the ligament-like lineage under mechanical stimulation [13], thus demonstrating the potential use of BMSCs for ligament tissue engineering.

The potential of BMSCs for ligament tissue engineering is clearly demonstrated, however, to the best of our knowledge, there has been no published data on BMSC sheets used for ligament tissue engineering. In this study, we set out to determine the cellular viability, collagen I deposition, cell sheet thickness and gene expression throughout the growth period of the BMSC sheet.

www.springerlink.com

II. Materials and methods

A. Isolation of Rabbit BMSCs

Rabbit BMSCs were obtained from whole bone marrow aspirates from New Zealand white rabbits and culture expanded according to procedures previously described [14]. Rabbit MSCs were isolated from fresh whole bone marrow aspirates from New Zealand White Rabbits (8 weeks old), culture expanded in low glucose culture medium containing Dulbecco's modified Eagle's medium (LG-DMEM; Gibco, Invitrogen, CA), 15% v/v fetal bovine serum (HyClone, Logan, UT), penicillin and streptomycin. Nonadherent cells were removed upon first passage of the cells. When primary MSCs became near confluent, they were detached using trypsin (0.25%) /1mM ethylenediamine-tetraacetic acid (EDTA) and replated at a 1:3 ratio. The second passage cells were then used for further study. All cell cultures were maintained at 37^{o}C in an incubator with 5% humidified CO_2. The cultures were replenished with fresh medium at 37^{o}C every 3-4 days.

B. Cell Seeding and Culture on TCP

BMSCs were seeded at a density of 3 x 10^5 cells/well in wells of a non-treated 6-well culture plate (NUNC, Denmark) The cells were grown in vitro in a 5% CO2 incubator at 37^{o}C with LG-DMEM supplemented with 15% FBS, till the cells reached 100% confluence (Week 0). Following that, the confluent cells were supplemented with 50μg/ml L-Ascorbic Acid (Wako, Japan) in 15% FBS LG-DMEM for another 3 weeks before the cell sheets were harvested and assays performed at weekly time points.

C. Analysis of Cell Sheet Viability

The viability of the cells present within the hyperconfluent cell layers was determined using the Alamar Blue (Invitrogen, CA) colorimetric assay. Briefly, the cells were incubated in medium supplemented with 20% (v/v) alamar blue dye for 1 h. One hundred microliters of medium from each sample was read at 570/600nm in a in a microplate reader (Sunnyvale, CA). Medium supplemented with 20% Alamar Blue dye was used as a negative control and the percentage of Alamar Blue reduction was calculated according to the formula provided by the vendor.

D. SDS-PAGE Collagen I and DNA Quantification

The hyperconfluent cell layers were washed twice with 1xPBS and digested with porcine gastric mucosa pepsin (2500 U/mg; Roche Diagnostics Asia Pacific, Singapore) in a final concentration of 0.25mg/mL. Samples were incubated at room temperature (RT) for 1h with gentle shaking followed by sonication of the solution until all cell fragments have broken up followed by 1hr incubation at RT. For samples that were not sonicated, they were incubated for 2h at RT. After the incubation step, the samples were neutralized with 0.1 N NaOH. The samples were analyzed by SDS-PAGE under non-reducing conditions described in [15] and normalized to the DNA content measured spectrophotometrically using the Hoechst 33258 method [16]. The fluorescence measurement of Hoechst 33258 dye was performed using a fluorescence plate reader (FLUOstar Optima, BMG Labtechnologies, Offenburg, Germany). Calf thymus DNA was used for construction of the standard curve for DNA quantitation..

E. Measurement of Cell Sheet Thickness

A homemade picrosirus red dye was made to stain the collagen fibres of the cell sheet. Briefly, 0.1% (w/v) Direct Red 80 (Fluka) was dissolved in concentrated picric acid. The solution was left to stand together with excess picric acid crystals overnight. Solution was filtered before use and added to the cell layers for 15mins to stain the collagen fibres. The dye was removed and washed thoroughly with 1x PBS before confocal microscopy (Olympus FluoView-Confocal Laser Scanning Microscopes, FV500*)*.

F. RNA Extraction and Real Time Reverse Transcription-Polymerase Chain Reaction (RT-PCR)

Total RNA was extracted using Trizol® reagent (Invitrogen, Grand Island, NY) and purified using the RNeasy Mini Kit (Qiagen, Valencia, CA) following the manufacturer's protocol. RNA concentration was determined using the NanoDrop (NanoDrop Technologies, Wilmington, DE) and complementary DNA synthesis was carried out using 100ng of total RNA according to the Manufacturer's protocol for SuperScript II reverse transcriptase with oligo(dT) primers. Real-Time PCR was done using 2μl of cDNA, 10μl of SYBR Green Master Mix (Qiagen, Valencia, CA) and the optimized concentration of primers, topped up to 20μl with nuclease free water. All reactions were performed on the real-time Mx3000P (Stratagene, CA, USA). The thermal cycling program for all PCRs was the following: 95ºC for 15 mins, followed by 40 cycles of amplifications, consisted of denaturation step at 94ºC for 15 s, an annealing step at 55ºC for 30 s and an extension step at 72ºC for 30 s. The genes analysed were Collagen Type I, Type III and Tenascin-C, with GAPDH as the housekeeping gene. The level of expression of the target gene, normalized to GAPDH, was then calculated using the 2^{Δ}Ct formula with reference to non-confluent BMSCs.

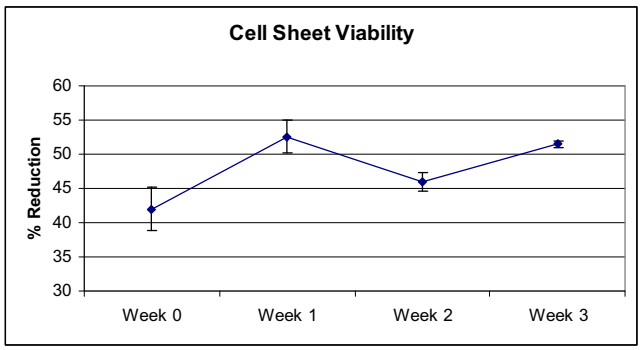

Fig 1. BMSC sheets do not show any trend when assayed with Alamar-Blue. Values are means ± standard deviation (SD) from analysis of duplicates of 3 independent experiments.

III. Results

A. Cell Sheet Viability

To investigate the viability of the cells within the BMSC sheet, the AlamarBlue assay was conducted on wells at a weekly interval (Fig 1). The results show no trend in the cell sheet viability.

B. Collagen I Quantification Normalized to DNA content

To determine the Collagen Type I deposition profile of the BMSC sheet, densitometry on SDS-PAGE of pepsin digests against a Collagen Type I standard was performed (Fig 2). The results show a general increase in Collagen Type I deposition on the cell layer with the most significant increase occurring during Weeks 2-3.

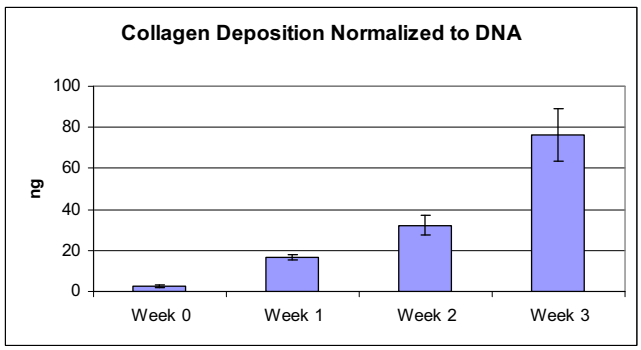

Fig 2. Increasing amounts of Collagen Type I deposition on cell layer. Most significant increase occurred during week 2-3. Values are means ± standard deviation (SD) from analysis of duplicates of 3 independent experiments.

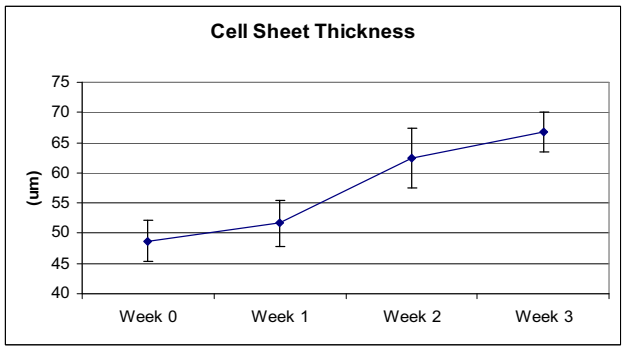

Fig 3. BMSC sheet thickness measured using a confocal microscope. Values are means ± standard deviation (SD) from analysis of duplicates of 3 independent experiments.

C. Measurement of Cell Sheet Thickness

To investigate the profile of the cell sheet thickness throughout the culture period, the thickness was measured using the z-direction slicing (Fig 3). The measurements obtained show a general increase in thickness up till week 3.

D. RNA Expression Profile of BMSC sheets

The effects on BMSCs in hyperconfluent culture conditions were examined by RT-PCR. We examined the expression of general ligament genes, namely Col I, Col III and Tenascin-C (Fig 4).

Col I mRNA expression showed an increase of around 2.5±0.3 fold during weeks 1 and 2 and dropped back to the basal level at week 3.

Col III mRNA expression showed an increase of 2.5±1.0 fold at week 2 and expression dropped to below basal levels at week 3.

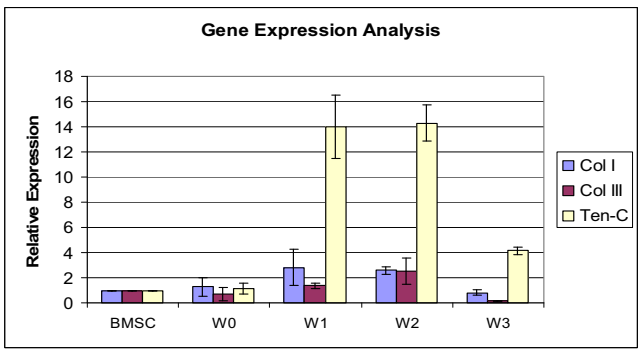

Fig 4. Relative gene expression of Collagen Type I, Type III and Tenascin-C with respect to P2 BMSCs. Values are means ± standard deviation (SD) from analysis of duplicates of 3 independent experiments.

IV. Discussion

The classical method of seeding single cells onto porous scaffolds encounters problems of adherence efficiency and re-synthesizing ECM of the tissue. These challenges make cell sheets an attractive alternative to alleviate these problems. BMSCs have also been shown to be better, in terms of cell proliferation and collagen secretion as compared to terminally differentiated fibroblasts for ligament tissue engineering. As such, BMSC sheets might prove to be a better cell source for tissue engineering of ligaments.

This study was designed to take a closer look at the formation of the BMSC sheet, to determine the viability (Fig 1), collagen type I, III and tenascin-c gene expression (Fig 4) and collagen type I deposition (Fig 2) of BMSCs in a hyperconfluent in vitro environment and the growth profile of the cell sheet (Fig 3).

The results of this study demonstrate that BMSC sheets remain viable despite being in hyperconfluent conditions. This also suggests that the change in cell sheet thickness is caused by continuous ECM deposition rather than an increase in cell numbers. The results obtained from RT-PCR gene expression analysis are consistent with a previous study on the upregulation of collagen type I, collagen type III and tenascin-c gene expression in BMSCs [13] to indicate differentiation towards the ligament fibroblast lineage of the BMSCs. Tenascin-c is well documented to be upregulated by external forces in various tissues like skeletal muscle, tendon [17] and ligaments [13]. The increase of gene expression of tenascin-c might be due to inherent contractile forces present within the dense collagen rich ECM, which provide similar cues for the cells to upregulate mRNA expression of tenascin-c when subjected to external mechanical forces. This hypothesis is in agreement with earlier studies that a natural internal tension between the cells and the surrounding ECM is present throughout a tissue [18].

V. Conclusions

This study demonstrates the potential of BMSC sheets as an alternative cell source for ligament tissue engineering. Further studies are needed to determine if the BMSCs within the sheets are differentiating towards the ligament fibroblast lineage, and if placing these BMSC sheets on scaffolds and providing external mechanical stimulus would further enhance the suitability of BMSC sheets for ligament tissue engineering. Future studies on gene expression will also be needed to evaluate the expression level of the early phase induction genes of the other 3 mesenchymal lineages (Runx2, Sox9 and PPARγ2)

Abstract — **Although most in vitro studies indicate that silk is a suitable biomaterial for ligament tissue engineering, in vivo studies of implanted silk scaffolds for ligament reconstruction are still lacking, especially in a big animal. The objective of this study is to investigate anterior cruciate ligament (ACL) regeneration using mesenchymal stem cells (MSCs) and silk scaffold in a pig model. The scaffold was fabricated by incorporating microporous silk sponges into knitted silk mesh, which mimicked the structures of ligament extracellular matrix (ECM). In vitro culture already demonstrated that MSCs on scaffolds proliferated vigorously and produced abundant collagen. The MSCs/scaffold was implanted to regenerate ACL in a pig model. After 24 weeks, histology observation showed that MSCs were distributed throughout the regenerated ligament and exhibited fibroblast morphology. The key ligament ECM components including collagen I, collagen III, and tenascin-C were produced prominently. The tensile strength of regenerated ligament also met the mechanical requirements. In conclusion, the results imply that silk scaffold has great potentials in future clinical applications.**

Keywords — **Silk scaffold, MSC, ACL, Pig model**

I. Introduction

Anterior cruciate ligament (ACL) plays an important role in keeping the normal motion and stability of knee joint. The rupture or tear of ACL can cause significant instability, which subsequently leads to injuries to other ligaments and development of degenerative joint disease. Due to the limited capacity to regenerate, ACL heals poorly in response to the repair by suturing the injured tissue back together. So the grafts are required for ACL reconstruction. Now, over 100,000 ACL reconstructions are performed every year in the United States. The current grafts involve autograft, allograft and ligament prostheses. Despite great improvements in available therapies, there remain significant limitations. The autograft and allograft have drawbacks such as ligament laxity, donor site morbidity and pathogen transfer. While the ligament prostheses are fraught with complications including mechanical mismatch, poor tissue integration and foreign body inflammation. Recently tissue engineering has emerged as a promising strategy for the regeneration of injured ligament with similar biomechanical and biochemical properties [1].

The scaffold is one of key components in tissue engineering, which can influence cellular activities and resultant matrix formation. In recent years, silk has been increasingly studied as the scaffold for ligament tissue engineering due to its biocompatibility, slow degradability, and remarkable mechanical capability. It provides an excellent combination of lightweight, high strength and remarkable elasticity. In our previous work, we successfully regenerated ACL using knitted silk scaffold and mesenchymal stem cells (MSCs) in rabbit model. The scaffold was demonstrated to possess good mechanical strength and biocompability. It could facilitate nutrients transmission and tissue infiltration [2]. However, the tensile strength of scaffold is relatively low for potential clinical application. So in this study, we fabricate a kind of braided cord enhanced knitted silk scaffold and reconstruct ACL using it in porcine model. The objective of this study is to find whether ACL can be regenerated in porcine model using this enhanced knitted silk scaffold and MSCs.

II. Materials and methods

The knitted silk mesh was fabricated using raw silk fibers on a knitting machine. Then the knitted silk mesh was degummed to remove sericin thoroughly. The silk solution was prepared by dissolving sericin-free silk fibers into a ternary solvent system followed by dialysis. To prepare scaffold, the knitted sericin-free silk mesh was immersed in silk solution and freeze-dried for 24 h. The freeze-dried mesh was immersed in a methanol–water solution to induce β-sheet structural transition and then was carefully rolled up with a braided silk cord inside to produce a tightly wound shaft with 80mm in length and 5.5mm in diameter [3].

The 3.0×10^6 autologous MSCs were loaded on each scaffold and cultured in vitro over 8 h for cell adhesion before implantation. Eight pigs were used in experiment. ACL reconstruction was performed on right knee and contra lateral one without treatment was regarded as normal control. The lateral parapatellar arthrotomy was used to expose

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1512–1514, 2009
www.springerlink.com

the right knee joint. After the native ACL was excised, the tibial and femoral bone tunnels were created. Both ends of scaffold were sutured with polyester suture and passed through the tunnel. The two ends were fixed by sutures tied over screws in femur and tibia.

The pigs were sacrificed at 24 weeks postoperatively. The knee joints were firstly scanned with micro-CT to determine the mineralized tissue formation in bone tunnels. Thereafter, five specimens from each group were used for mechanical test. The tensile load and stiffness were compared among groups. The rest specimens (n=3) from each group were fixed in formalin, embedded in paraffin and sectioned. The slides were stained with hematoxylin and eosin (HE) and immunostained with antibodies against collagen I, collagen III and tenascin-C. All data were analyzed using SPSS 10.0 software and statistically significant values were defined as $p<0.05$.

III. Results

After 24 weeks, the gross findings revealed that regenerated ligament resembled the normal ACL in experiment group. The scaffold was filled and encapsulated by newly formed fibrous tissue. The color and luster of regenerated ligament were similar to that of native ACL.

The cross sectional images perpendicular to the longitudinal axis of knee joint were reconstructed with micro-CT. The newly formed mineralized tissue in the full length of bone tunnel could be examined by screening all slices of each sample. In experiment group, the consecutive micro-CT images showed there was no obvious mineralized tissue formation in tibial and femoral bone tunnels after 24 weeks. The HE and immunohistochemistry staining were performed to further examine the histological changes of regenerated ligament. After 24 weeks the MSCs were distributed uniformly throughout scaffolds and showed the morphology of fibroblasts with elongated nucleus in experiment group. The fibroblast-like cells spread, proliferated and produced abundant ECM on scaffolds. The regenerated tissue became much denser with time. The silk fibers of scaffolds degraded almost completely after 24 weeks. The experiment group demonstrated the hypercellular infiltration and abundant matrix production.

After 24 weeks, the immunohistochemistry staining for collagen I was strongly positive in newly regenerated tissue in experiment group. While the collagen III and tenascin-c was expressed at a low level. The results were similar to those of normal control.

The regenerated ligament recorded a maximum tensile load of 404.9±49.9N and a tensile stiffness of 57.5±9.4N/mm. They were 52.5% and 61.2% of normal ACL, respectively.

Table 1 Mechanical properties of regenerated ligament in experiment and control groups (mean±SD)

Sample	Maximum load (N)	Stiffness (N/mm)
Native ACL	770.1±105.2	93.9±15.9
Scaffold	398.8±69.5	58.5±16.8
Experiment group	404.9±49.9	57.5±9.4

IV. Discussion

This study demonstrates that ACL can be regenerated by implantation of silk scaffold and MSCs in large animal model. This novel scaffold comprises the microporous knitted silk mesh of out layer and braided silk cord of inner layer. The out layer can facilitate cells adhesion and tissue in-growth. The regenerated ligament shows similarities to the native ACL in ECM composition. The cells showed excellent infiltration and were homogeneously distributed throughout the implants. On the other hand, the inner cord is able to enhance the strength of scaffold especially in initial phase after implantation. After reconstruction the scaffold can keep proper tensile strength until the newly formed tissue becomes mechanically competent. The strength is comparable to withstand the forces associated with daily activities. Furthermore, the host knee joint serves as an autologous bioreactor, which can provide various cytokines and physiological cyclic loading on implants to induce the differentiation of MSCs [2, 4].

These preliminary results provide evidence that silk-based biomaterial is a promising scaffold for ligament tissue engineering. More data will show us the changes of implanted scaffold in detail after the whole experiment is finished.

Abstract — **Ligament-bone interface (enthesis) is a complex structure which comprises of ligament, fibrocartilage and bone. The fibrocartilage transformation adds significant insertional strength to the interface and makes it highly resistant to avulsion forces. Many ACL grafts cannot generate native interfacial region, leading to their failure. Co-culture has proved to be an effective way to generate new tissues in tissue engineering. Studies have found important signaling molecules in transduction pathway of chondrogenesis to be transmitted via gap junctions. We hypothesized that stem cells cocultured between ligament and bone cells would enable transmission of chondrogenic factors from bone/ligament cells to bone marrow stem cells (BMSCs) via gap junctions, resulting in their differentiation into fibrocartilage. To test this hypothesis, we studied to establish effective co-culture system. In this study, two set of co-culture (BMSCs and ligament cells; BMSCs and bone cells) were established. Confocal microscopy showed efficient dye transfer from bone/ligament cells into BMSCs. This was further confirmed and quantified by FACS, which showed a gradual temporal increase in the percentage of BMSCs acquiring Calcein. RT-PCR analysis showed that the bone cells-BMSC and the ligament cells-BMSC co-culture systems expressed higher amounts of collagen type-2, as compared to the various monocultures. The results proved the establishment of effective co-culture. The findings provide important information for the development of a more promising ligament-fibrocartilage-bone graft.**

Keywords — **enthesis, fibrocartilage, co-culture, gap junction**

I. Introduction

The anterior cruciate ligament (ACL) is the most commonly injured ligament in the knee joint, with a prevalence of about 1 per 3,000 among Americans [1]. The poor healing capacity of ACL requires reconstruction surgery to be performed in most cases. In current clinical practice, the most popular and successful surgical replacement for ACL are autografts involving the use of the bone-patellar tendon-bone grafts and hamstring tendon grafts [2, 3]. While patellar tendon grafts are more stable, they are often associated with post-operative knee pain [4]. The hamstring grafts result in faster recovery and less knee pain, but are often associated with donor-site morbidity [3]. Most grafts are mechanical inserted, thus they cannot generate native interfacial region, often leading to grafts ruptures occurring through or near the insertion sites [5].

Ligament-bone interface (enthesis) is a complex structure which comprises four zones: ligament, unmineralized fibrocartilage, mineralized fibrocartilage and lamellar bone [6]. The fibrocartilage transformation adds significant insertional strength to the interface and makes it highly resistant to avulsion. Injured ACL fail to regenerate the intervening fibrocartilage at the enthesis. While the exact mechanism of interface formation is still unknown, studies have attempted to regenerate the enthesis [7].So a tissue engineering approach to create a ligament-fibrocartilage-bone graft would be more promising than a ligament-alone construct in providing better graft integration and resulting stability.

Co-culture has been shown to be an effective way of engineering new tissues [8]. In a co-culture system, two or more cell types cultured in same environment are likely to interact with each other. Some studies have showed cellular interactions between different cell types contributed to tissue information in vitro. Of all kinds of different cell-cell communications, gap junction communication plays an important role because it directly connects the cytoplasm of two cells, allowing the transmission of various intracellular signals and messengers into the neighboring cells [9]. Important signaling molecules in the transduction pathway of chondrogenesis have been shown to be transmitted via gap junctions [8]. To generate enthesis, we hypothesize that stem cells co-cultured between ligament and bone cells would enable transmission of chondrogenic factors from bone/ligament cells to BMSCs via gap junctions, resulting in their differentiation into fibrocartilage.

II. Methods

A. Harvesting BMSCs from rabbits

BMSCs were isolated and cultured by established technique approved by NUS Institutional Animal Care and Use

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1515–1518, 2009
www.springerlink.com

Committee, National University of Singapore [10-11]. Briefly stated, bone marrow was aspirated from the iliac crests of anaesthetized adult NZW rabbits and collected into polypropylene tubes containing preservative free heparin (1000 units/ml). Nucleated cells were isolated by serial culture and subculture on tissue culture polystyrene. 85% confluent cells of 2nd and 3rd passage were used for experiments.

B. Establishing primary ligament and bone cell culture

The primary ligament cells and bone cells were explant-cultured by methods described elsewhere. Briefly stated, the anterior cruciate ligaments (ACL) of both joints and upper part of tibia were surgically removed from a 3 kg NZW rabbit under anaesthesia. ACL tissue was cut into 1mm×1mm slices and digested with 5 ml of 0.15% collagenase-I in 37^0C shaking bath for 6hrs. The bone tissue was cut into 2mm×2mm pieces and digested with 5ml of solution containing collagenase-I and II (0.15% each). The semi-digested ligaments and bone pieces were explant-cultured in 60mm petridishes with 10% Dulbecco's Modified Essential Medium (DMEM) containing 10%fetal bovine serum, 1% antibiotics under humidified conditions at 37 ºC and 5% CO_2.

C. Establishing co-culture

Two sets of co-culture were established, one set comprising bone cells and BMSCs and another set comprising ligament cells and BMSCs by mixing the bone/ligament cells with BMSCs at a numerical ratio of 1:10. The co-cultures were plated on 60-mm petri-dishes in duplicate.

D. Dye coupling experiment

BMSCs, bone and ligament cells were seeded into separate 60mm petridishes at a density of 4×10^5 cells. When confluent, bone and ligament cells were dual-stained; dual labeled cells would serve as dye-donors. Cells were first stained with DiI Red [5µl in 1ml supplemented DMEM] and incubated at 37°C, 5% CO2, 100% humidity for 30 mins. The cells were washed twice with normal DMEM medium followed by stained with Calcein-AM [10µl in 1ml supplemented DMEM: Gap-junction permeable dye]. The cells were then incubated at 37°C for 60 mins and washed twice with normal DMEM medium and trypsinized. BMSCs were trypsinized without labeling with any of the dye (recipient cells). A volume of 10µl (8000-10,000 cells) of each of bone and ligament cell suspension were mixed separately with 100µl (80,000-100,000 cells) of BMSCs (at a ratio of 1:10). Now each of the mixed cell suspension was plated on a 6-well plate and cultured at 37°C. After 24 hours of culture, the cells were observed for dye-transfer using a Olympus FV300 Confocal Laser Scanning Microscope.

E. Fluorescent Activated Cell Sorting

The co-cultures were also analyzed by flow cytometry using a previously described protocol [13]. Each of the co-cultured cell suspensions (prepared by the method described above) were plated and cultured on separate 60mm plates. Cells were trypsinized and resuspended in 1X PBS after 2hrs, 6hrs and 12hrs post-coculture and their fluorescence intensity was measured in a FACStar-Plus (Becton–Dickinson, Heidelberg, Germany) with a one-laser setup for an excitation wavelength of 488 nm. The emission of Calcein and DiI was determined after filtering with a 530/30-nm bandpass filter (FL1/calcein) and a 575/26-nm bandpass filter (FL2/DiI), respectively.

F. Quantitative Real Time Reverse Transcription-Polymerase Chain Reaction (RT-PCR)

BMSCs, ligament cells and bone cells in monoculture and Ligament-BMSC and Bone cell-BMSC cocultures were trypsinized and their total RNA extracted (RNeasy Mini Kit (Qiagen, Valencia, CA)). RNA concentration was determined using the S2100 Diode Array Spectrophotometer (Biochrom, Cambridge, CB) and cDNA synthesis was carried out using 80ng of total RNA and SuperScript II reverse transcriptase with oligo(dT) primers. Real-Time PCR was performed on a iQ® 5 (Bio-RAD, California, USA) using 4µl of cDNA, 12.5µl of SYBR Green Master Mix (Qiagen, Valencia, CA) and the optimized concentration of primers, topped up to 25µl with nuclease free water. The program for all PCRs was the following: 95ºC for 3 mins, followed by 35 cycles of amplification, consisting of a denaturation step at 95ºC for 12 s, an annealing step at 58ºC for 30 s and an extension step at 72ºC for 30 s. The genes analyzed were Collagen Type I, II and III, with GAPDH as the housekeeping gene.

III. Results

A. Dye coupling experiment

Confocal microscopy showed efficient dye transfer from bone/ligament cells into BMSCs (Figure 1).

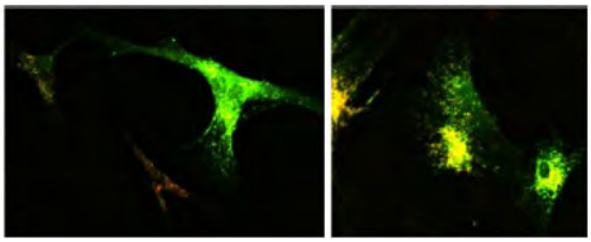

Figure 1: Confocal images showing dye transfer of calcein (green) from dual stained bone cells to BMSCs. Dual stained cells appear orange or have red flecks, while BMSCs appear purely green.

B. Fluorescent Activated Cell Sorting

FACS showed a gradual and progressive temporal increase in the percentage of BMSCs acquiring Calcein (Bone-BMSC: 2hrs-4.4%, 6hrs-10.4%, 12hrs-14.2%; Ligament cell-BMSC: 2hrs-4.3%, 6hrs-9%, 12hrs-13.8%; Figure 2).

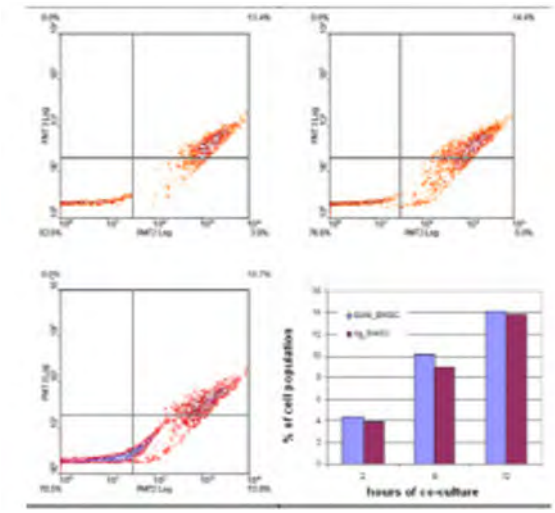

Figure 2: Gap-junction assay by flow cytometry in bone-BMSC coculture showing a gradual increase in recipient cell-pool on continued co-culture. X-axis: Calcein-AM; Y-axis: DiI Red

C. Gene Expression

Real time RT-PCR results showed that BMSCs, bone and ligament cells expressed nearly similar amounts of collagen type-2 when in cultured in monoculture systems. However in coculture systems, collagen type-2 expression was significantly upregulated, especially in the BMSC-Bone coculture system (6 fold increase, as compared to a 2 fold increase in BMSC-ligament coculture system; both compared against a bone-ligament coculture system; Figure 3).

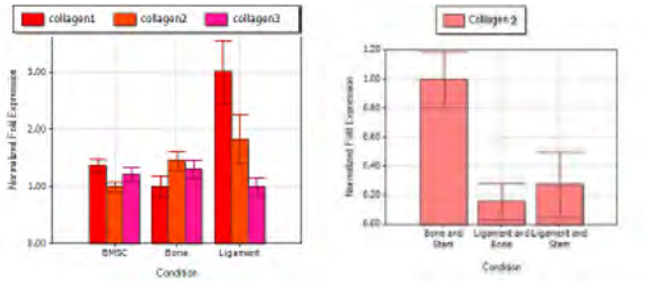

Figure 3: RT-PCR analysis of monoculture and coculture system. While BMSC monocultures have a low expression of collagen type- II, their co-culture with mature cells resulted in collagen type- II gene up regulation

IV. Discussion

A two-dimensional co-culture system of undifferentiated bone marrow stem cells and mature bone and ligament cells is presented. The co-culture system was shown to be functional, allowing the exchange of dyes from the mature donor cells into the stem cells. The establishment of the gap junctions in the co-culture was shown to be relatively rapid with about 14% of the recipient stem cells being stained positive within 12 hours, as demonstrated by the FACS results.

In conjuction with the gap junction permeable dye Calcein Green that was transferred into the recipient stem cells, paracrine signals responsible for initiating chondrogenic stem cell differentiation were also transmitted from the mature cells into the BMSCs. This was demonstrated by an upregulation of expression of the fibrocartilage-specific Collagen type-2, which is also found in the ligament-bone interface. In contrast, Collagen types 1 and 3 are the predominant collagens found in ligaments and bones [15].

Chonrogenic differentiation was more pronounced in the BMSC-Bone co-culture system, where a 6-fold higher upregulation was observed over the Bone-Ligament co-culture system. It was also observed that, in contrast, BMSCs, bone and ligament cells, in monoculture, expressed nearly similar amounts of collagen type-2. This implies that a co-culture system significantly influenced differentiation of BMSCs.

This study demonstrated the importance of cell to cell communication in the chondrogenesis process of BMSCs. Future work will focus on establishing a tri-lineage co culture system involving BMSCs with bone and ligament cells on a biomimetic scaffold to mimic the native interfacial environment to promote the chondrogenesis of BMSCs.

V. Conclusion

We have developed an effective co-culture system that enables transmission of chondrogenic factors through gap-junctions, helping in BMSC differentiation into a fibrocartilage lineage. Such a co-culture when translated on to appropriate scaffolds can generate ligament-bone grafts with the bone-ligament interface. Such bone-fibrocartilage-ligament grafts would be more promising than ligament-alone constructs to replace severely injured ligaments.

Effect of Atherosclerotic Plaque on Drug Delivery from Drug-eluting Stent

J. Ferdous and C.K. Chong

School of Chemical and Biomedical Engineering, Nanyang Technological University, Singapore

Abstract — **Atherosclerotic plaque formation due to lipid accumulation in the arterial wall is the major cause of stenotic coronary disease. To restore distal coronary blood supply and overcome restenotic events presented by bare wire stents, drug-eluting stent (DES) implantation is now commonly used to treat stenotic coronary disease. However, while its long-term outcome is still unavailable, early clinical results appear to be inconsistent. The use of computational models is believed to be important in understanding DES and to elucidate the delivery of drug and improve the efficacy of DES. The presence of plaque in the stented region is expected to affect drug pharmacokinetics related to DES. In this study, a 2-dimensional model which drug transfer was coupled with both luminal and transmural flows was presented to investigate drug deposition and distribution in the arterial wall. Paclitaxel was used as a model drug and its interaction with the binding sites in the tissue was treated as a reversible binding process. As predicted, the presence of plaque dramatically affects the local pharmacokinetics. Thick plaque absorbs more drugs and provides higher resistance to drug transfer in the arterial wall compared to thin plaque. Study on the effect of drug diffusivity in the plaque on drug deposition reveals that higher diffusion coefficient results in lower drug content in the arterial wall. Meanwhile, when drug partition coefficient in the plaque was varied within the range for paclitaxel, it showed negligible effect on drug deposition. In conclusion, the presence and property of plaque have an effect on the delivery of drugs in arterial wall and should be included in the modeling of drug delivery from a DES to improve the design of stent to achieve the best therapeutic outcome.**

Keywords — **Drug-eluting stent, atherosclerotic plaque, pharmacokinetics, computational model**

I. Introduction

Plaque formation in the arterial wall as a result of atherosclerosis reduces arterial lumen size and restricts distal blood flow and results. Balloon angioplasty followed by bare-metal stent implantation is a common mode of treatment. But its major drawback is restenosis. Drug-eluting stents (DES) are now widely used to mitigate restenosis. However, while its long-term outcome is still unavailable, early clinical results appear to be inconsistent. Therefore, a detailed study of the drug delivery system which is more physiologically realistic is expected to give a better insight about what is required to improve the efficacy of DES.

Physiological transport forces, drug physiochemical properties, local biological tissue properties and the design of stent are the main factors that govern the arterial wall local drug pharmacokinetics [1]. Using *in vitro* perfusion experiments it has been reported that both diffusion and convection play an important role on arterial drug transport [2,3], whereas Levin et al. [4] reported the impact of specific binding to intracellular proteins for arterial transport of paclitaxel, rapamycin and dextran. However, incorporation of all the above-mentioned issues in the experiment are difficult and hence computational modeling is an attractive alternative to predict the local pharmacokinetics related to DES. In earlier computational models, Hwang et. al. [5] showed the effect of physiological transport forces on drug pharmacokinetics in the arterial wall, neglecting the reversible binding of drug with tissues. The importance of binding of drugs by incorporating the reversible bound drug in the model was reported by Lovich et al. [6] and Shakrov et al. [7] assuming no transmural flow. But none of these studies have considered how the presence of atherosclerotic plaque affects the drug pharmacokinetics in arterial wall. This is expected to be an important an important issue because DES is deployed in the region laden with atherosclerotic plaque. Furthermore, it is important to note that local drug pharmacokinetics is directly related to vascular toxicity and efficacy of DES [8].

Previous study on the influence of thrombosis on drug pharmacokinetics from stent revealed that thrombus could affect the arterial drug uptake and thrombus composition altered the binding capacity and release of paclitaxel to the arterial wall. Moreover, the presence of atherosclerotic plaque also influences the transmural convection [9]. In addition, endothelium layer affects drug pharmacokinetics by altering transmural hydraulic flux as well [3]. In this study, a 2-dimensional (2D) model where drug transfer was coupled with both luminal and transmural flow and drug binding was treated as a reversible binding process to investigate the drug pharmacokinetics in the arterial wall as a result of DES deployment. Finally, how the nature of the plaque affects drug deposition in the arterial wall was also analyzed.

II. Methodology

A. Geometric model

A simple CardioCoil stent with circular strut was used in this study [10]. Although there are 11 struts each of 0.15 mm diameter and located 0.7 mm center-to-center distance, only 3 struts were used in this model to capture the physics better and reduce the computational overhead. The diameter of the coronary artery was considered 3 mm whereas the thickness of the arterial wall and drug-loaded polymer coating on the stent were 0.9 mm and 0.005 mm respectively. Plaque thickness was varied between 0.1 mm and 0.4 mm. Since the stent is axis-symmetric, a 2D model was considered which is shown in Figure 1.

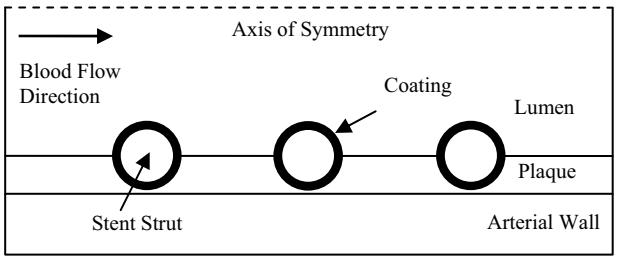

Fig. 1 2D schematic diagram of the stent (not to scale)

B. Model description

Blood flow dynamics in the lumen was described by the Navier-Stokes equation (Eq. 1) and continuity equation (Eq. 2) assuming blood as an incompressible, Newtonian fluid and the flow was laminar and steady:

$$-\mu_l \nabla^2 \mathbf{u_l} + \rho_l (\mathbf{u_l} \cdot \nabla)\mathbf{u_l} + \nabla \mathbf{p_l} = 0 \quad (1)$$

$$\nabla \mathbf{u_l} = 0 \quad (2)$$

where $\mathbf{u_l}$, $\mathbf{p_l}$, ρ_l and μ_l are, respectively, the luminal blood velocity, pressure, density and dynamic viscosity. On the other hand, transmural blood plasma flow inside the plaque and arterial wall was modeled by the Darcy's equation (Eq. 3) and continuity equation (Eq. 4):

$$\mathbf{u_i} - \nabla \cdot \left(\frac{K_i}{\mu_i} \mathbf{p_i} \right) = 0 \quad (3)$$

$$\nabla \mathbf{u_i} = 0 \quad (4)$$

where $\mathbf{u_i}$, $\mathbf{p_i}$ and μ_i are, respectively, the transmural blood plasma velocity, pressure, dynamic viscosity in i sub domain while i stands for plaque and arterial wall. K_i is the Darcian permeability coefficient.

Drug transport from the coating was modeled by the transient diffusion equation (Eq. 5):

$$\partial_t c_c + \nabla \cdot (-D_c \nabla c_c) = 0 \quad (5)$$

where c_c and D_c are the concentration and diffusivity of drug in the coating, respectively. A transient convection-diffusion equation (Eq. 6) was used to model the drug delivery in lumen:

$$\partial_t c_l + \nabla \cdot (-D_l \nabla c_l + c_l \mathbf{u_l}) = 0 \quad (6)$$

where c_l and D_l are the concentration and diffusivity of drug in the lumen, respectively. It is important to notice that only free drug, and not the bound drug attached to the binding sites, is transported through the plaque and arterial wall. Interaction between free and bound drug was characterized by a reversible reaction. Therefore, the free drug transport inside the plaque and arterial wall was modeled as a transient diffusion-convention-reaction equation (Eq. 7) :

$$\partial_t c_{f_i} + \nabla \cdot \left(-D_i \nabla c_{f_i} + \frac{\gamma_i \mathbf{u_i} c_{f_i}}{\varepsilon_i} \right) = -\alpha \left(c_{f_i} - \frac{c_{b_i}}{\kappa_i} \right) \quad (7)$$

where c_{f_i} and c_{b_i} are the free and bound drug concentration, respectively. D_i and κ_i are drug diffusivity and partition coefficient, respectively. γ_i is the hindrance coefficient and ε_i is the porosity of the arterial wall. α is the rate constant defined as the rate at which the binding sites adsorb drug [11]. Therefore, the bound drug concentration was modeled as:

$$\partial_t c_{b_i} = \alpha \left(c_{f_i} - \frac{c_{b_i}}{\kappa_i} \right) \quad (8)$$

C. Solution

All physical parameters and drug properties for this study were adopted from literature. Appropriate boundary conditions were carefully considered and assigned to solve all equations using a commercially available finite element (FE) based software COMSOL Multiphysics™, version 3.4. A total of 14,089 triangular mesh elements were used for the model. A sensitivity study was carried out based on the average velocity and average arterial wall drug concentration to ensure mesh and time step (used by the solver to solve transient equations) independent solution. For analysis of results, drugs in the tissue, expressed as a fraction of the initial amount of drug in the coating drug and concentration variation (CV) were used.

III. Results

As expected, the presence of plaque affects the drug deposition and as the thickness of the plaque increases, the total amount of paclitaxel in the arterial wall decreases, as shown in Figure 2(a) and Figure 3(a). Free paclitaxel increases in the initial stage after stenting but within 12 hours it started to decrease as it moves towards the perivascular wall. Bound paclitaxel in general increases until 24 hours and then starts decreasing at very slow rate. 16.61% more drug is found for 0.1 mm thick plaque compare to 0.4 mm after 5 days. On the other hand, drug distributions for both free and bound paclitaxel are shown in Figure 2(b) and Figure 3(b), respectively. Although at the initial stage of stenting the drug distribution is highly non-uniform (data not shown), it becomes stable after 1 day. Meanwhile, the presence of plaque decreases the CV of drug in the arterial wall and hence minimum CV is found for 0.4 mm thick plaque which is 23.63 % and 72.46 % less than the CV of no plaque condition for free and bound drug, respectively.

Finally, a sensitivity analysis was done for paclitaxel diffusivity (D_P) and partition coefficient (K_P) in the plaque. The effect of D_P on drug deposition is given in Figure 4 where D_P is shown as a ratio to the drug diffusivity in the arterial wall. The results reveal that, the amount of free and bound drug increase with increasing D_P at the initial stage but decrease thereafter. After 5 days 43 % and 35 % more free and bound drug, respectively, were found when the ratio was changed from 0.1 to 10. On the other hand, while K_P was varied within the range for paclitaxel in the arterial wall, no significant change in drug deposition in the arterial wall was noticed (Figure 5).

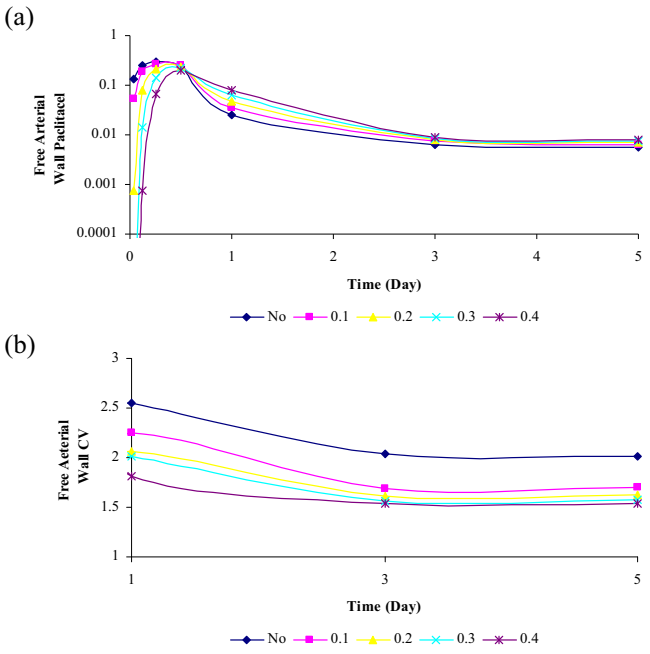

Fig. 2 Effect of plaque thickness on (a) amount and (b) CV of free paclitaxel in arterial wall

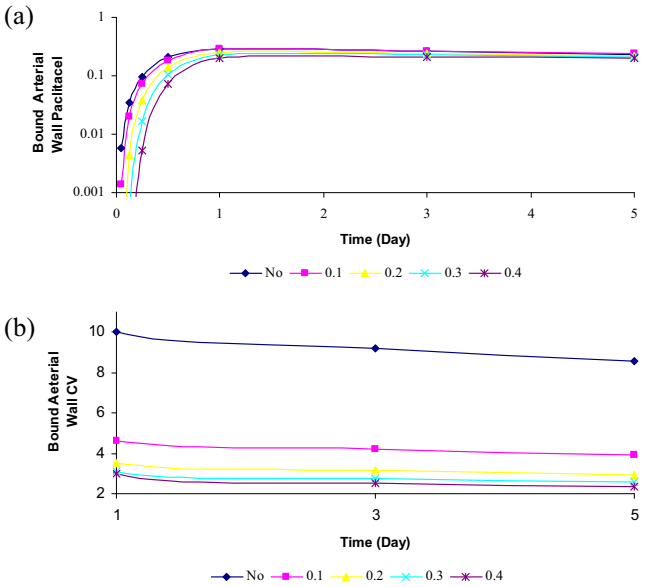

Fig. 3 Effect of plaque thickness on (a) amount and (b) CV of bound paclitaxel

IV. Discussion

Our results show that the presence of plaque dramatically affects the local pharmacokinetics of both free and bound paclitaxel in the arterial wall. First of all, the presence of plaque acts as a physical barrier to both drug transfer into the arterial wall and transmural hydraulic flux. Most importantly, the binding sites in the plaque absorb a substantial amount of drug. In addition, the endothelial layer also limits the drug transfer into the arterial wall as it acts as a barrier to transmural hydraulic flows for heparin and this should be more prominent for paclitaxel as convection plays an important role to paclitaxel drug transfer [2].

Study on the effect of D_P and K_P suggested that it is important to determine the physical properties properly inside the plaque. Higher D_P forces the drug to diffuse fast into the arterial wall and thus it enhances the drug loss from the perivascular wall as well. It also increases the luminal washout of drug from the plaque-lumen interface. Furthermore, the non-significant decrease trend in total arterial wall drug deposition due to increase in K_P indicates that more drug is available in bound form in the plaque which restricts

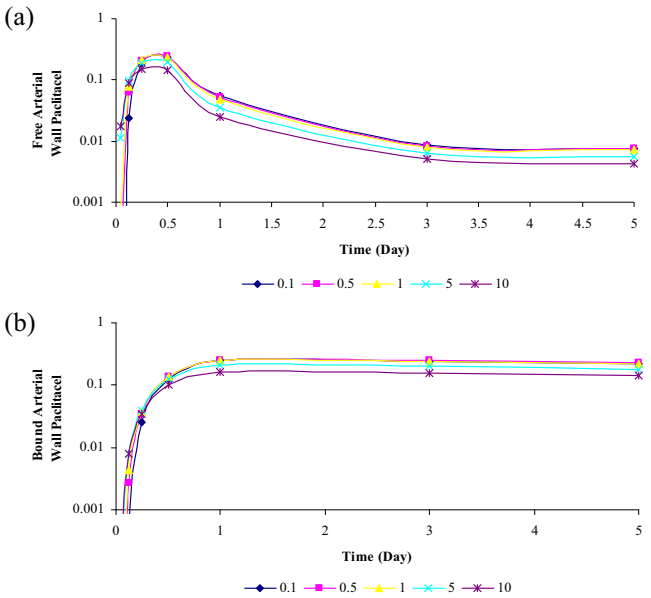

Fig. 4 Effect of paclitaxel diffusivity in plaque on arterial wall (a) free and (b) bound paclitaxel

the transport of free drug as well. These results are consistent with the findings reported earlier where increased drug diffusivity in the clot decreased arterial wall drug uptake and high drug binding capacity with clot delayed arterial uptake [12].

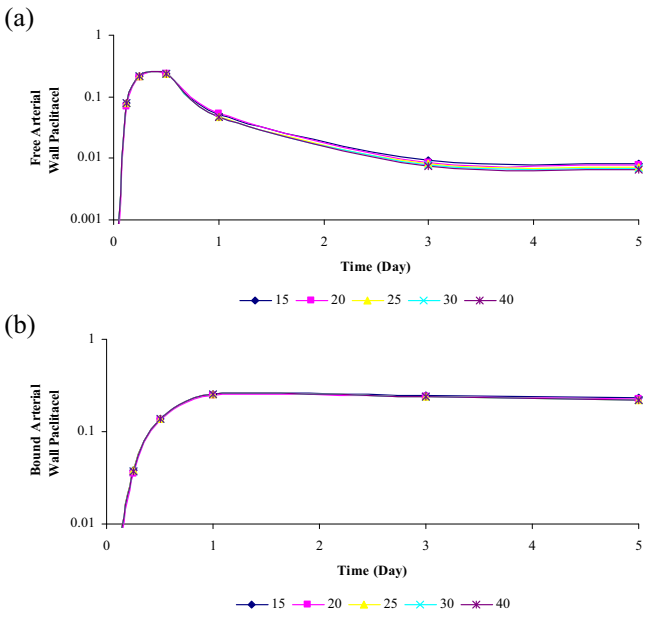

Fig. 5 Effect of paclitaxel partition coefficient in plaque on arterial wall (a) free and (b) bound paclitaxel

V. Conclusions

Drug pharmacokinetics in the arterial wall is shown to be affected by the presence of plaque and its thickness. As such, it is important to consider a model involving plaque in investigating drug delivery from DES to improve the design to achieve best therapeutic outcome. Based on the results using the simple geometry, it is expected that a more realistic 3-dimensional plaque geometry will give a better insight.

Perfusion Bioreactors Improve Oxygen Transport and Cell Distribution in Esophageal Smooth Muscle Construct

W.Y. Chan[1] and C.K. Chong[2]

[1]School of Mechanical and Aerospace Engineering, Nanyang Technological University, Singapore
[2]School of Chemical and Biomedical Engineering, Nanyang Technological University, Singapore

Abstract — **Mass transfer is a major issue for producing, in particular, thicker tissue constructs *in vitro*. Without the support of internal capillary network, oxygen supply is restricted to the superficial layer and the survival of cells deep within the construct could be threatened. In this study, oxygen was postulated as the limiting factor for cellular activity in developing tissue construct and their correlation was investigated. Single- and double-flow perfusion bioreactors were custom designed to provide a controlled tangential laminar flow at a flowrate of 0.545 ml/min over the surface of the tissue construct ($3.2 \times 2 \times 0.2$ cm^3 porous gelatin scaffold seeded with 2×10^6 cells/cm^3 of porcine esophageal smooth muscle cells). Gelatin scaffold of similar size and cell seeding was cultured in Petri dish and served as a static culture control for comparison. At day 5, oxygen profile in-situ was measured across the thickness of tissue construct while cell distribution and total DNA were analyzed. Bioreactors produced higher cell proliferation activity compared to static culture. Under static culture, cells were observed to populate near the surface of tissue construct. While single-flow bioreactor improved cell infiltration/migration in the scaffold, double-flow bioreactor improved further these cellular events and produced construct with more uniform cell distribution. These cell distributions appear to parallel that of oxygen distribution. In static culture, oxygen concentration dropped abruptly from the construct surface to a depth of about 1000 μm where it was maintained at a constant level in the core at low cell density but rose near the bottom surface. In the single-flow bioreactor, oxygen level dropped linearly from the top to the bottom surface of construct. In the double-flow bioreactor, oxygen level began to drop at about 2.5 mm above the construct surface but it was maintained at almost a constant level throughout the whole thickness.**

I. Introduction

Mass transfer is one of the major issues that have been a bottleneck to produce thicker tissue construct *in vitro*. Much of recent efforts attempted to pre-build a capillarial network *in vitro* by seeding capillary-forming cells (such as umbilical vein endothelial cells) together with growth factors for angiogenesis in order to provide a pathway to shorten the period of anastomosis to the host blood supply upon implantation; however, the anastomosis have shown to be limited [1]. For *in vitro* tissue engineering, evidence has shown that this network can improve oxygenation [2], but the effect of growth factor used to induce angiogenesis may have adverse effect on other cell types [1].

On the other hand, tissue engineering perfusion bioreactor has shown promises to improve the quality of tissue construct *in* vitro such as cell distribution and ECM deposition due to improved mass transfer with continuous flow of medium that increases convective transport [3-8]. However, the mechanism leading to these improved states has not been fully elucidated. One of the variables postulated to be important is the oxygenation of tissue construct. Oxygen is one of the critical chemical species in aerobic metabolism of mammalian cells. Below a certain oxygen level, hypoxic condition is induced and cells would adopt anaerobic metabolism for energy production which causes acidosis and subsequent cell death. *In vivo*, oxygen can be carried by erythrocytes which facilitate maintaining physiological level of oxygen in tissue. *In vitro*, tissue culture relies on gaseous oxygen dissolved in culture medium. Since oxygen is sparingly dissolved in water, oxygen supply would be severely limited in larger tissue construct with no vascular network. Therefore, it would be essential to study the importance of oxygenation in developing tissue construct. In this study, bioreactors with single- and double-flow perfusion were designed to study how oxygen transport (oxygen distribution) was improved in tissue construct and correlate construct oxygenation to the quality of tissue construct (cell distribution).

II. Method

Single- and double-flow bioreactors were designed and fabricated to allow medium flow across the top surface and both top and bottom surfaces of the tissue construct, respectively. The flow chambers were designed such that the flow profiles across the scaffold surfaces were fully- developed and laminar. Porcine esophageal smooth muscle cells (PESMCs) were isolated from pig esophagus and cultured in Dulbecco's Modified Eagle Medium (DMEM, HyClone) supplemented with 10% fetal bovine serum (FBS, HyClone), 1% antibiotic-antimycotic solution (Sigma) and 0.2% kanamycin (Sigma). Cells at p6 were seeded into $3.2 \times$

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1523–1526, 2009
www.springerlink.com

2×0.2 cm^3 porous gelatin scaffolds at 2 million cells/cm^3. A constant flow rate of culture medium at 0.545 ml/min was maintained by a peristaltic pump (Ismatec). Static culture of similar cell-seeded scaffolds served as a control. At day 5, oxygen distributions across the depth of constructs were measured in-situ within the bioreactor chamber and in Petri dish using oxygen microsensor (Unisense). Thereafter, the constructs were harvested and the total DNA was measured using Picogreen (Molecular Probes) while paraffin sections of tissue construct were prepared and stained in DAPI (Molecular Probes) and analyzed under fluorescence microscope (Carl Zesis). Serial images across the depth of constructs were taken from top to bottom surfaces. Images in vertical sequence were opened in ImageJ 1.40g, an open-source image processing program developed by National Institutes of Health, USA (http://rsb.info.nih.gov/ij/) and combined vertically using "Stack combiner" Plugin. A total of 20 segments (ROI) were created throughout the whole thickness of the construct using macros program developed in house. Cells were counted in each segment.

III. Results

A. O_2 distribution

O_2 distributions of PESMCs-seeded constructs cultured in Petri dish (static), single-flow and double-flow chamber were shown in Fig. 1. At day 5, all culture conditions, both under perfusion flow and static culture, resulted in decreasing trend in O_2 in the bulk medium phase.

At the construct surface, both static and single-flow culture resulted in similar interfacial O_2 level between 80% and 85% (at distance = 0 μm). Since the single-flow bioreactor has medium flow on the top side only, O_2 level was reduced monotonously with the depth and reached a minimum at the bottom side of the scaffold (59.5%). On the other hand, construct cultured in Petri dish was in suspension in the medium and diffusion can occur on the bottom side of the construct. It was found the O_2 level started to recover slightly from the core of the construct (at distance = 1000 μm) and reached a higher O_2 level (64.7%) at the bottom side. However, O_2 level at the bottom side was obviously lower than that at the top side which was closer to air-medium interface.

A completely different O_2 profile was found in double-flow bioreactor. Only one side of medium region was shown here since the profiles for both sides were identical. O_2 level dropped rapidly at 2.5-mm above the scaffold (based on the maximum gradient of 2.2×10^{-4} μm^{-1}), reaching 51.9% at the scaffold surface but this level was maintained across the depth of the construct. When the oxygenation level within the construct was compared with the highest level at the surface in each of the three cases, it was found that double-flow bioreactor resulted in the most uni-

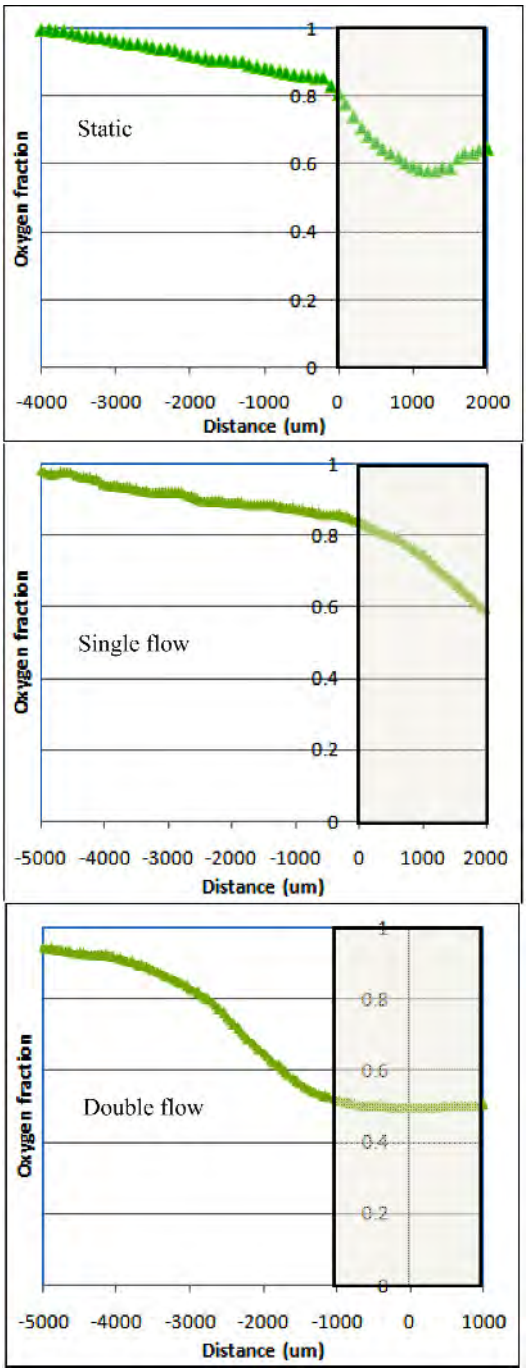

Fig. 1 Oxygen profiles for three culture conditions. Top: static, centre: single flow bioreactor and bottom: double flow bioreactor. The shaded regions indicate the constructs.

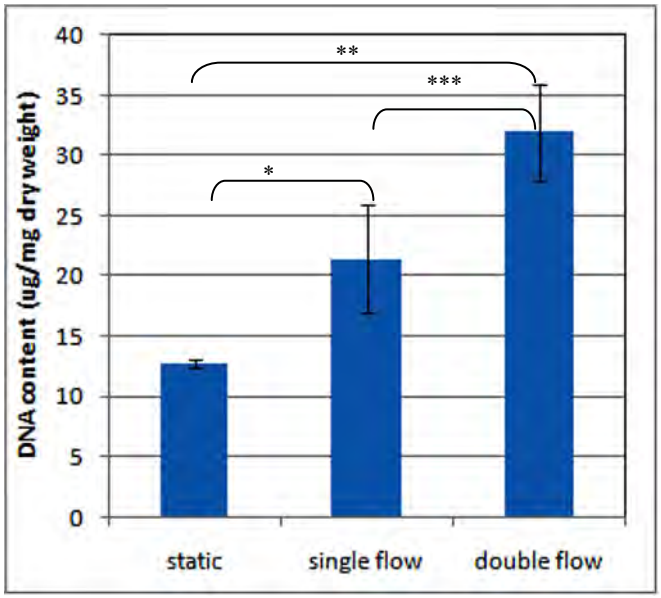

Fig. 2 Total DNA quantification

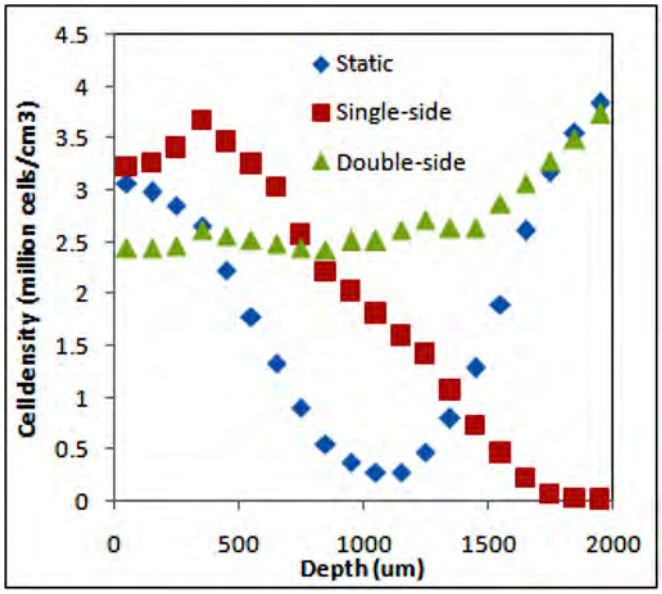

Fig. 3 Cell distribution

form oxygenation (only 4.2% difference) while the single-flow and static culture produced a difference of 28.9% and 28.2%, respectively.

B. Total DNA

In terms of cellularity of tissue construct, both bioreactor cultures resulted in significantly higher DNA contents compared to static culture ($p < 0.05$) while double-flow bioreactor was superior to the single-flow case ($p < 0.05$) (Fig. 2). 2.5-fold and 1.7-fold improvement of DNA contents were observed in tissue constructs cultured in double-flow and single-flow bioreactor after the 5-day period, respectively, compared to static culture.

C. Cell distribution

Three types of cell distribution patterns were observed in the 3 culture conditions (Fig. 3). Static culture resulted in a V-shaped profile with almost the centre (at 1000 μm) free of cells while the highest densities were found at both the top and bottom surfaces. Single-flow managed to maintain a cell density at high level up to about 500 μm and dropped monotonously thereafter. On the other hand, cell density in construct cultured in double-flow bioreactor was found to be relatively uniform across the thickness. When the cell number for each segment across the depth of construct was compared with those at the surface, the average difference was 10.4%, 60.5% and 58.2%, for double-flow, single-flow and static culture, respectively.

IV. Discussion

A. Macroscopic findings: Bulk medium O_2 level vs. total DNA

Many reported studies measured dissolved O_2 in the medium (or bulk flow) using blood gas analyzer to correlate with the outcome obtained in tissue construct (e.g. total DNA). Since this parameter is considered an average value of dissolved O_2 in a well-mixed medium, by averaging the O_2 level across the medium phase in this study, 77.6%, 91.3% and 81.1% were obtained for static, single flow and double flow conditions, respectively. Obviously, both bioreactors demonstrated improved oxygenation in medium by convective transport which in turn allowed a rather rough explanation for the increase in total DNA. This explanation was not exhaustive, however, since O_2 transport can adopt different regimes in bulk medium and construct, and an external improvement of oxygen transport cannot fully reflect the actual oxygenated state in the construct (internal oxygenation). Therefore, it is suggested that it would be more useful to study the internal oxygenation which is more crucial in cell growth within the construct as it provides a direct correlation between the oxygenation state and the cellularity and DNA contents of cells.

B. Microscopic findings: O_2 distribution-cell distribution

Three different profiles of O_2 distributions and cell distributions were observed in three culture conditions. It was

found that cell distributions followed closely the patterns of O_2 distribution, suggesting a strong correlation between these 2 parameters. The low cell regions observed in the core of the statically cultured construct and the bottom of the construct in the single-flow bioreactor were probably due to high O_2 demand required during the initial phase of cell attachment, resulting in low survival of cells in these regions. With better initial oxygenation as achieved in the double-flow bioreactor, cells in the core survived better and with uniform oxygenation over the culture period, cells were able to grow in a more uniform manner. However, the lower initial cellularity in some regions may adversely influence the fate of tissue construct as suggested in this study: (1) Cells which survived near the surface populated the scaffold faster and this could create a barrier for O_2 transport; (2) Cell growth could slow down due to cell-cell contact inhibition while cells at low density region could not grow due to the lack of cell-cell signaling leading to a cell-free region.

V. Conclusion

Three culture conditions (static, single-flow and double-flow bioreactors) were used to culture PESMCs-seeded construct. O_2 and cell distributions in these 3 conditions presented different profiles but these 2 parameters were highly correlated. It was shown that effective O_2 transport is important for the survival and uniform distribution of cells in developing tissue construct. The bioreactors designed in the study were able to improve and both the external (bulk medium) and internal (construct) oxygenation and hence the cellularity and quality of construct.

Determination of Material Properties of Cellular Structures Using Time Series of Microscopic Images and Numerical Model of Cell Mechanics

E. Gladilin[1], M. Schulz[1], C. Kappel[1] and R. Eils[1,2]

[1] German Cancer Research Center, Theoretical Bioinfomatics, Im Neuenheimer Feld 580, D-69120 Heidelberg, Germany
[2] University Heidelberg, BioQuant, Im Neuenheimer Feld 267, D-69120 Heidelberg, Germany

Abstract — **Determination of material constants is indispensable for quantitative description of mechanical properties of cellular structures. Since conventional methods of experimental cell mechanics are based on application of forces onto the cell boundary, intra-cellular structures are not accessible for direct measurements. In this work, we present an approach for estimation of canonic material constants (i.e. stiffness and compressibility) using times series of microscopic images and numerical model of cell mechanics. The proposed method is based on optical monitoring of the cellular deformation which can be triggered by any appropriate contacting or non-contacting technique affecting mechanical cell integrity. The presented experimental studies give examples of determination of material parameters of optically monitored cells whose deformation was induced by conventional micromanipulation and completely contact-free, using chemical agents.**

Keywords — **cell mechanics, material parameter estimation, contact-free measuring techniques, image analysis, numerical modeling**

I. Introduction

Numerous works have indicated the importance of mechanical factors to basic biological functions and processes in the cell [1-6]. Determination of canonic material constants, such as stiffness and compressibility, plays a key role in quantitative characterization of mechanical properties of normal and malignant cells [9]. Conventional approaches of experimental cell mechanics are based on micromanipulation techniques that employ application of controlled forces onto the cellular boundary [2,3]. Consequently, these methods provide information about the overall cell properties (e.g. stiffness of the whole cell) or those of its part which is directly accessible by the measurement (e.g. cell membrane). Probing mechanical properties of intra-cellular structures, which are not accessible for direct measurements, is not possible with conventional micromanipulation techniques. Meanwhile, modern microscopic imaging techniques, such as confocal laser scanning microscopy (CLSM), yield highly resolved 3D images of intra-cellular structures. Time series of 3D CLSM images depicting successive cell deformation under the impact of external forces provide valuable insights into mechanical behavior of cellular matter on the local scale and can serve for estimation of material parameters of constitutive models. In this work, we present an approach for determination of material properties of cellular matter which is based on analysis of time series of microscopic images and numerical modeling cell mechanics. The core idea of our approach consists in reformulation of parameter estimation problem as an image registration problem, i.e., material constants are determined as modeling parameters that minimize appropriately defined dissimilarity measures between computationally predicted and experimentally observed images. Based on optical monitoring of the cellular deformation, the proposed method can be used both in combination with and without conventional micromanipulation techniques. In the presented experimental studies, we give examples of application of this approach for determination of the Young's modulus (stiffness) and the Poisson's ratio (compressibility) of cells whose deformation was triggered by (i) uniaxial microstretcher and (ii) pure chemical inducement, using cytoskeleton-disrupting drugs.

II. Materials and methods

A. Elastomechanical Model of Cellular Matter

Based on previous observations [2,4], in the range of small deformations cellular matter can be approximated as a piecewise homogeneous, isotropic Hookean material characterized by the linear stress-strain law [8]

$$\sigma(\varepsilon) = \frac{Y}{1+\nu}\left(\varepsilon + \frac{\nu}{1-2\nu} tr(\varepsilon)\right) \qquad (1)$$

with two elastic constants: Y – the Young's modulus (material stiffness) and ν – the Poisson's ratio (material compressibility). Since the boundary value problem (BVP) in image-based analysis is typically formulated in a quasi-geometric form, i.e. both knowns and unknows are the displacements, definition of dimensionless modeling parameters is required. While the Poisson's ratio is a dimensionless quantity, the Young's modulus Y_i of i-th material can be substituted by the dimensionless *relative stiffness* Y_i/Y_1

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1527–1530, 2009
www.springerlink.com

which gives the ratio between Y_i and the stiffness of the reference material Y_1.

Due to the fact that the strain tensor ε in Eq. 1 is a nonlinear function of the displacement u

$$\varepsilon(u) = \frac{1}{2}(\nabla u + \nabla u^T + \nabla u \nabla u^T) \quad (2)$$

the equations describing the deformation of a linear elastic material are, in general, nonlinear with respect to u.

The deformation continues until the equilibrium between the external forces f and inner stresses σ is reached

$$\nabla \sigma + f = 0 . \quad (3)$$

Altogether Eq. 1-3 imply a parameter-dependent relationship between the external loads and the displacements in a deformed body.

For numerical solution of the elastostatic boundary value problems, the Finite Element Method (FEM) on tetrahedral grids was applied.

B. Image- and Model-based Parameter Estimation

Consider times series of images $I_t(x)$ depicting the successive deformation of an object in the optical field. Assuming that structural differences between each two images are due to deformations only, the consecutive time step represents the deformed configuration of the previous one, i.e.

$$I_{t+1}(x) = I_t(x + u) . \quad (4)$$

The displacement field u describing the volumetric deformation can be computed as a solution of the BVP defined by Eq. 1-3 and the boundary conditions, which are typically given in the form of the boundary displacements. Since the displacement field depends on material constants $u=u(Y, \nu)$, the problem of parameter estimation can be reformulated as an image registration problem which consists in finding an optimal set of material constants that minimizes a dissimilarity norm between computationally predicted and experimentally observed images. One of such dissimilarity norms is, for instance, the absolute image difference (AID):

$$AID_t(Y_i, \nu_j) = \| I_{t+1}(x) - I_t(x + u(Y_i, \nu_j)) \| \quad (5)$$

Determination of the minimum of Eq. 5 yields material constants for each pair of images from experimental time series, see Fig. 1.

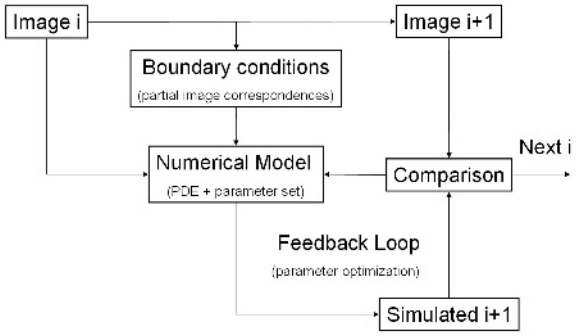

Fig. 1. Iterative scheme for image-based estimation of modeling parameters. Optimal set of modeling parameters for each time step corresponds to the minimum dissimilarity between computationally predicted and experimentally observed images.

C. Image Processing

Because of a number of natural and technical reasons, microscopic images are highly dynamic and exhibit a high level of statistical and structural noise. Consequently, the assumption of structural changes between each two time steps due to elastic deformations only, which was implied in Eq. 4, does not hold. The goal of image processing consists in reduction and possible elimination of non-elastic image differences by means of

- image denoising,
- rigid image registration,
- image enhancement and normalization.

In addition, images are used for the reconstruction of the object's geometry. For this purpose, images are binarized and iso-surface meshes corresponding to the outer boundary of the segmented regions are generated. Subsequently, triangulated surfaces are filled with unstructured finite element volumetric grids.

III. Results

Two experimental studies presented below demonstrate application of the above described framework for determination of material properties of cells whose deformation was induced (i) by uniaxial microstretcher and (ii) completely contact-free, using cytoskeleton-disrupting drugs.

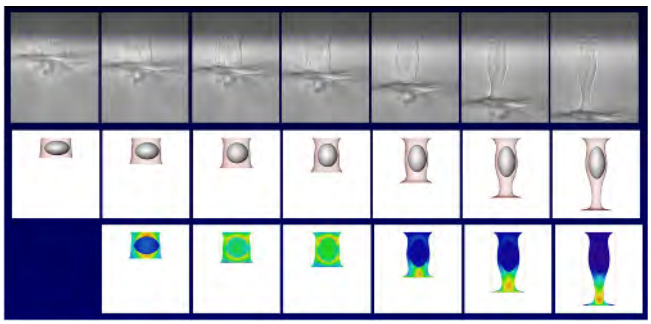

Fig. 2. Top row: experimental series of uniaxial cell stretchings. Middle row: geometrical models depicting successive numerical simulation of the cell deformation. Bottom row: 2D cut plane projections of the intracellular distribution of the mean strain. The color scale reflects the relative differences between low and high strains for each single deformation.

A. Simulation of Uniaxial Cell Stretching

In our previous work [7], we presented a study on determination of material parameters of a two-component model of uniaxially stretched cells. Fig. 2 gives an overview over iterative simulation of time series of cell stretchings including the prediction of the cell shape and distribution of intracellular strain. Starting from the initial geometrical model of the cell (Fig. 2 (middle row, left)), all subsequent time steps of the image sequence were computed from the previous steps. For each time step, optimal combination of material parameters (including the dimensionless ratio between the nuclear and cytoplasmatic stiffness Y_{cyt}/Y_{nuc} and the Poisson's ratio) was determined using the similarity measure which is based on conformity between computationally simulated and experimentally observed cell contours. At high stretching rates, additional assumptions about non-homogeneous distribution of material properties were made. The asymmetric deformation of lower and upper half of the cell could be explained as a result of asymmetric coating of microplates (fibronectin vs neutral substance). Time series of predicted material parameters show that progressive stretching lead to increasing stiffness and decreasing compressibility of the cell cytoplasm, see Fig 3.

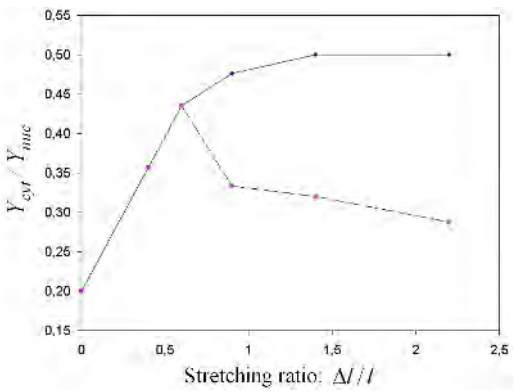

Fig. 3. Plots of numerically determined values for the relative stiffness of the cell cytoplasm probed in the middle of the upper (solid lne) and lower (dotted line) half of the cell as a function of the total cell elongation0.

B. Contact-free Investigation of Nuclear Mechanics

Investigation of mechanical properties of cell nuclei is important for epigenetics and medicine. Probing nuclear matter in living cells via conventional micromanipulation techniques is not possible. To enable image- and model-based analysis of nuclear mechanics, a contact-free induction of cellular deformation using cytoskeleton-disrupting drugs, such as Latranculin, was introduced (see Fig. 4). During the drug-induced deformation, 3D images of DAPI-stained nuclei were continuously acquired via confocal laser scanning microscopy. From large amount of acquired data, subsequences of images with high signal-to-noise ratio and small Z-shift were selected. These images were denoised and rigidly registered for further analysis of intensity differences that were caused by elastic deformations. Binarized images were used for generation of surface and volumetric models of 3D nuclei (see Fig. 5). Volumetric deformations were computed from correspondences between each two nuclear surfaces using a one-material model of nuclear matter based on Eq. 1-3. The goal of this study was to determine the nuclear compressibility, i.e. the Poisson's ratio. For this purpose, the nuclear deformation was computed for a number of sampling values of the Poisson's ratio varying in the range $0<\nu<0.5$. The optimal value of ν was obtained from the minimum of AID(ν) curves (Eq. 5). Fig. 6 shows the plots of AID(ν) for four consecutive time steps. Based on these findings the Poisson's ratio of $\nu=0.4 \mp 0.01$ was determined for the observed HeLa cell nuclei. This result is in good conformity with the literature values, e.g. [5,6].

IV. Conclusions

We presented an approach for determination of material properties of intra-cellular structures, which are inaccessible by conventional micromanipulation techniques, using time series of 3D images and numerical model of cell mechanics. The core idea of our method consists in reformulation of parameter estimation problem as an image registration problem, i.e., the optimal set of parameters corresponds to the minimum dissimilarity between computationally predicted and experimentally observed images. For induction of the cellular deformation, conventional micromanipulation or chemical agents, such as cytoskeleton-disrupting drugs, can be used. Further development of the method will focus on

automation of image processing and numerical solving techniques to enable widely unsupervised data analysis.

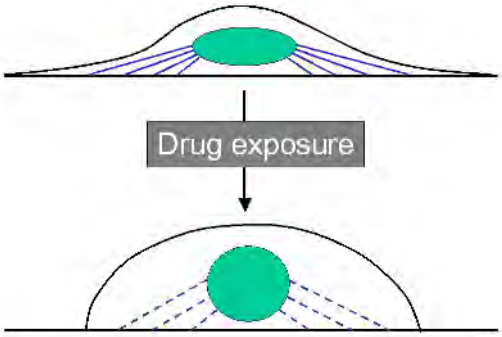

Fig. 4. Cytoskeleton-disrupting drugs induce uncontrolled deformations of cellular interior that yield a valuable source of information for image- and model-based analysis of nuclear mechanics.

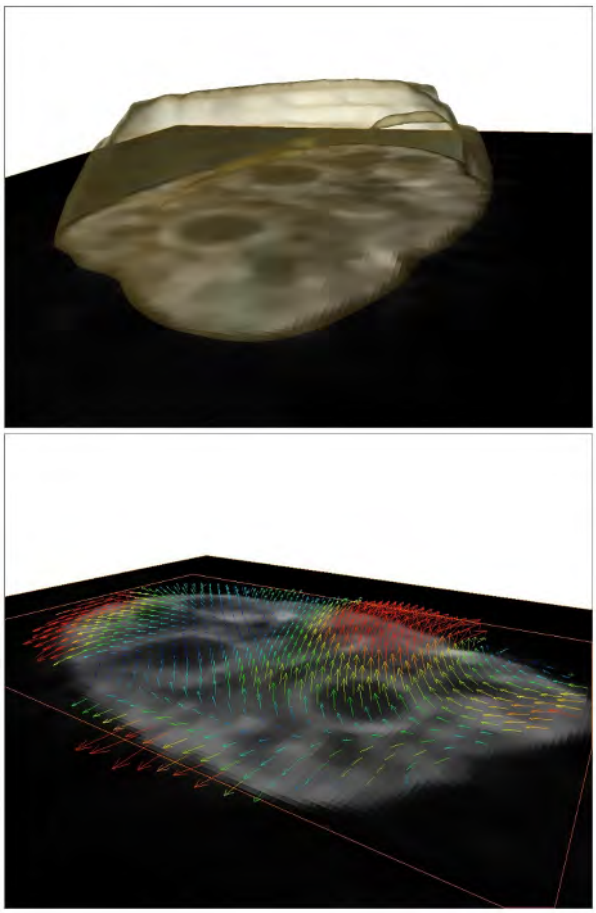

Fig. 5. Top: surface model of the HeLa cell nucleus generated on the basis of a 3D CLSM image. Bottom: volumetric displacement field computed from boundary correspondences between each two surfaces depends on the Poisson's ratio.

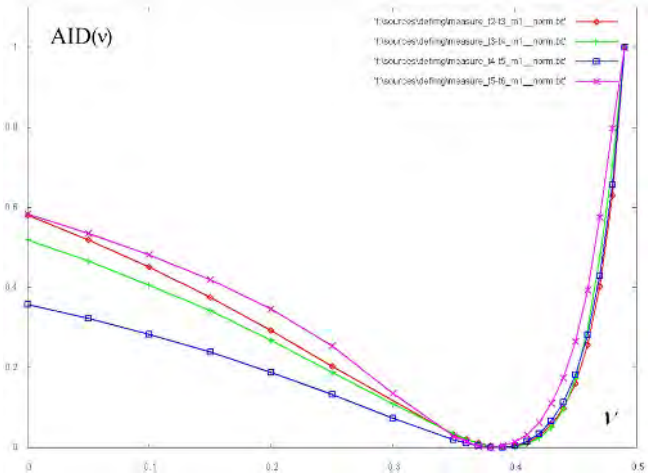

Fig. 6. Plots of the absolute image differences (AID) as a function of the Poisson's ratio for the four consecutive steps of image time series. All four curves exhibit a single minimum around $\nu=0.4$.

Analysis of a Biological Reaction of Circulatory System during the Cold Pressure Test – Consideration Based on One-Dimensional Numerical Simulation –

T. Kitawaki[1], H. Oka[1], S. Kusachi[1] and R. Himeno[2]

[1] Okayama University/Graduate School of Health Sciences, Okayama, Japan
[2] The Institute of Physical and Chemical Research (RIKEN), Saitama, Japan

Abstract — **Introduction: Arterial stiffness especially pulse wave shape index (Augmentation index: AIx) has attracted a great deal of attention as the predictor of the circulatory system condition. The AIx determined by the ratio of pulse pressure of reflection wave to progressive wave seem to show the change of reflection wave cause by the total peripheral vascular resistance. However, a phenomenon that progressive wave component increases and reflection wave component hardly changes during the cold pressure test (CPT) as a transient biological reaction. This phenomenon is hardly to explain only in the increase of the total peripheral resistance.**

Consequently, the mechanism of pulse wave change that attributes the reaction of the circulatory system was analyzed by using numerical simulation.

Method: The model of the systemic artery constructed two cylindrical tubes with taper. These cylindrical tubes denote a main aorta of systemic artery from central aorta to common iliac artery bifurcation and a brachial artery form aortic arch to the bifurcation of radial and ulnar artery, respectively. Following parameters were varied which correspond to the CPT load, heart rate: HR, stroke volume: SV, aortic stiffness: AS peripheral resistance: RT and arterial stiffness of brachial artery: BT.

Result: (1)A biological reaction of circulatory system during CPT is a complex reaction combined with not only peripheral artery but also heart or central aorta. (2)A biological reaction seems to be different by the short term CPT and by the long term CPT. We suspect that the change by the short term CPT may have caused β-effect and the long term CPT may have caused α-effect. (3)The pulse wave change phenomenon (especially change of AIx) during the CPT can be expressed using numerical simulation model combined with central aorta and brachial artery.

Keywords — **Circulatory system, sympathetic nerve, cold pressure test, numerical simulation, and augmentation index.**

I. Introduction

Arterial stiffness indexes, especially blood pressure pulse wave shape index (AIx: Augmentation Index), have received a lot of attention because they can indicate the risks for cardiovascular diseases [1]. The widely accepted index, AIx defined as the ratio between progressive wave coming from the heart (P1) and the reflection wave coming from at the periphery (P2) [1] described as Fig 1., is an index that is linked to *arterial stiffness* and *cardiac after load*, can be derived with the pulse wave analysis.

Generally, sympathetic nerve controls human cardiovascular system (heart artery etc.) by controlling the "Heart rate", "Heart contractility", "Arterial stiffness", "Peripheral resistance" etc. For example, load by cold pressure test (CPT) brings on the sympathomimetic reaction at heart and central artery by high heart rate and high heart contractility through the β1 receptor (β action). On the other hand, CPT also brings sympathomimetic reaction at peripherals by high arterial stiffness and high peripheral resistance through the α receptor (α action). Previous researches show that increased blood pressure and AIx during CPT [2], [3]. However, such AIx change mechanism poorly understood now.

In order to understand the basis of these indexes, it is necessary to understand the changes in the pulsatile waves in the systemic arteries. For this, numerical simulation models are very helpful, especially one-dimensional distributed constant models for the analyses of pressure wave propagations [4]. Accordingly, accurate pressure pulse waveform changes are analyzed by the construction of the numerical model which has the simple structure and that can analyze actual cardiovascular characteristic change.

In the present study, (1) continuous blood pressure waveforms were recorded, (2) the influence of sympathetic nerve controlling was analyzed and (3) change of cardiovascular mechanical character was calculated using numerical simulation model, due to investigate the AIx change mechanism during CPT.

II. Method

A. Experiment of CPT

Healthy volunteers (Age 21~34) were loaded by 2 types of CPT, during the measurements of continuous pulse wave-form measurement device (Omron HEM-910AI) at left wrist radial artery and every 50 seconds blood pressure (Omron HEM-8020-JE2) at right upper arm.

(1) Short term CPT: supine subject (n = 13) were loaded by cold bag on their ankles for 50 seconds three times.
(2) Long term CPT: seated subject (n = 11) were loaded by their right hand into cold water for 5 minutes.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1531–1534, 2009
www.springerlink.com

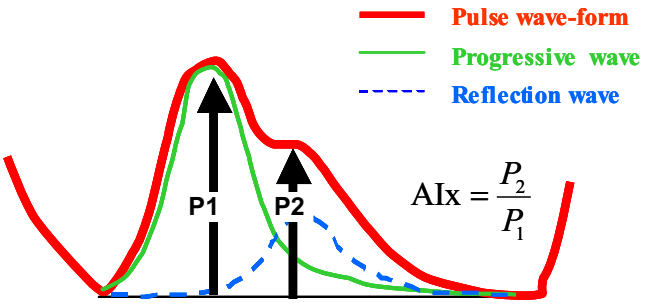

Fig. 1 Pulse wave-form and definition of AIx

The sensor output voltages corresponding to systolic pressure, reflection wave pressure and diastolic pressure were obtained beat by beat from pulse wave-form recorded by continuous pulse wave-form measurement device automatically. AIx were calculated by these output value and PPI (pulse to pulse interval) were determined by the intervals of diastolic pressure timing every beat.

B. Numerical Calculation

Assuming the fluid is axisymmetric, incompressible and there is no leak flow through the tube wall. The governing equation of continuity equation and momentum equation declare as follow [5]:

$$\frac{\partial A}{\partial t}+\frac{\partial Q}{\partial x}=0 \tag{1}$$

$$\frac{\partial Q}{\partial t}+\frac{\partial}{\partial x}\left(\frac{Q^2}{A}\right)+\frac{A}{\rho}\frac{\partial p}{\partial x}+f_t=0 \tag{2}$$

where A is the cross-section of the tube, Q is the mean sectional volume flow rate, p is the mean pressure, t is time, x is distance along the vessel axis, ρ is the fluid density, and f_t is the viscous resistance of oscillating flow.

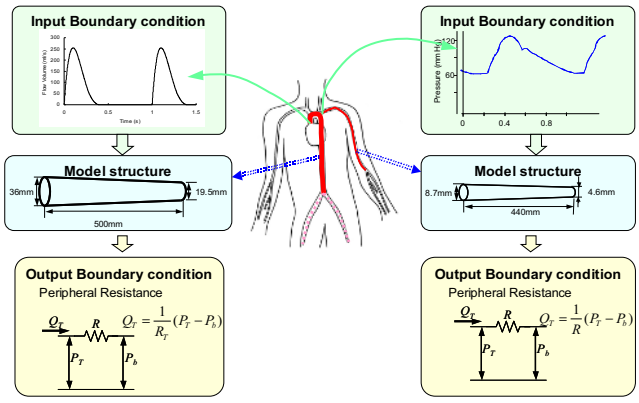

Fig. 2 Numerical Simulation model of cardiovascular system.

Substantively the relation between the transmural pressure and the internal radius of the arteries yield nonlinear curve [6]. The relation can be described with the following equation:

$$p = p_0 \exp\left(\beta\sqrt{(A-A_0)/A_0}\right) \tag{3}$$

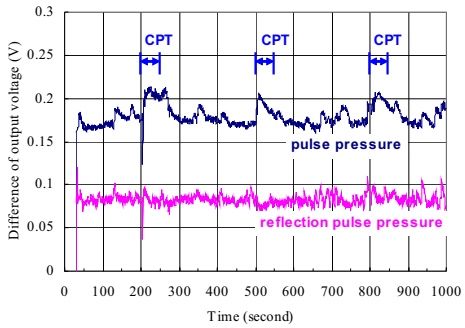
where p_0 and A_0 are reference pressure and cross-section, respectively, and the coefficient β is the stiffness parameter.

Numerical model structure were established by central aorta (from ascending aorta to bifurcation of common iliac artery) and brachial artery (from beginning of brachial artery to bifurcation site of radial artery and ulnar artery), referring to Fig. 2. The input pressure boundary condition of brachial artery was used by calculation result of central aorta.

The standard value of the model structure and mechanical parameter for the calculation was determined referring to literature data [7]. Parameter values were changed to correspond with the 2 types of CPT listed below.

(1) Short term CPT
  (i) HR: Increasing heart rate (=60/PPI) (+20%)
  (ii) SV: Increasing maximum flow rate (+20%)
  (iii) AS: Central arterial stiffness softening (-10%)
(2) Long term CPT
  (i) RT: Increasing peripheral resistance (+20%)
  (ii) BT: Increasing arterial stiffness of brachial artery (+10%)

III. Results and Discussions



A. Experiment of CPT

(1) Short term CPT

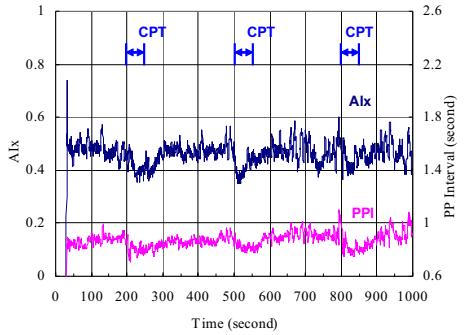


Figure 3 shows an example of time variation of short term CPT. The sensor output voltages of pulse pressure (= systolic pressure - diastolic pressure) and reflection pulse pressure (= reflection wave pressure - diastolic pressure) were shown in Fig. 3 (a), and time variation of AIx and PPI were shown in Fig. 3 (b), respectively. Pulse pressure increased during the short term CPT, because progressive wave component increased. In contrast, reflection pulse pressure is hardly changes. Consequently, AIx significantly decreased and PPI slightly decreased during the short term CPT.

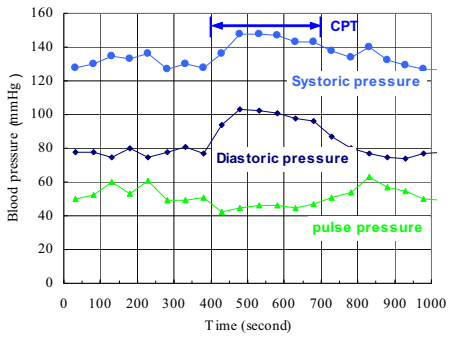
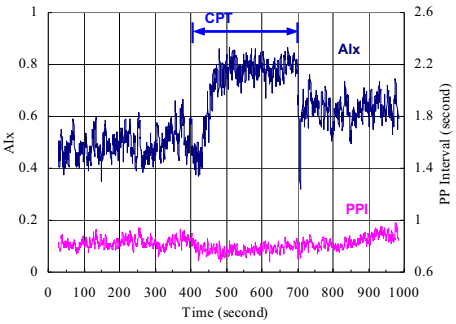
(2) Long term CPT

Figure 4 shows an example of time variation of long term CPT. Blood pressures (systolic pressure, diastolic pressure and pulse pressure) were shown in Fig. 4 (a), and time variation of AIx and PPI were shown in Fig. 4(b), respectively. Both of systolic pressure and diastolic pressure increased during the long term CPT. However pulse pressure



(a) Pulse pressure and reflection pulse pressure



(b) Time variation of AIx and PPI

Fig. 3 Experimental results (Short term CPT)

(a) Time variation of blood pressures.

(b) Time variation of AIx and PPI

Fig. 4 Experimental results (Long term CPT)

decreased the same time. AIx once decreased just started the load, and significantly increase during the long term CPT.

B. Numerical Calculation

(1) Short term CPT

Simulation results of pressure wave-forms of short term CPT were shown in Fig. 6 (a). (i)HR: Heart rate increasing cause progressive wave increasing, thus AIx and pulse pressure were decreased. (ii)SV: Increasing maximum flow rate cause mean pressure and AIx were increased. (iii)AS: Central arterial stiffness softening cause AIx and pulse pressure were decreased.

(2) Long term CPT

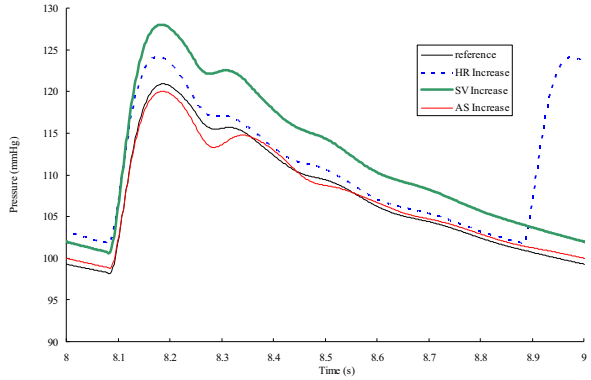
Simulation results of pressure wave-forms of long term CPT were shown in Fig. 6 (b). (i)RT: Peripheral resistance increasing cause AIx was increased and pulse pressure was decreased. In contrast, (ii) BT: increasing arterial stiffness of brachial artery causes both of AIx and pulse pressure were increased.

C. Comparison of calculation and experimental result.

(1) Calculation of parameter combination

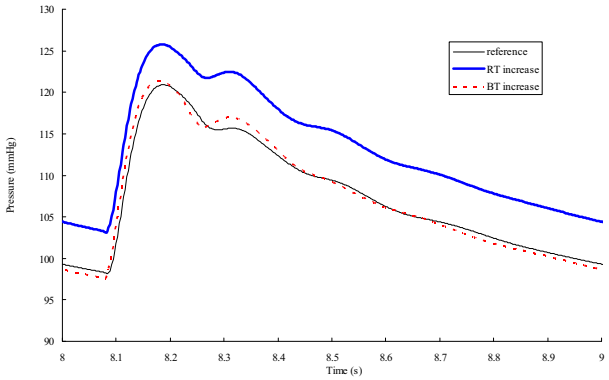
Combination parameter variations were calculated. Figure 7 (a) shows the calculation results among HR, SV and AS were varied simultaneously, in order to simulate the β reaction dominant response. As this result were same as human reaction of short term CPT (AIx and PPI were decreased, PP was increased). On the other hand, Fig. 7 (b) shows the results both RT and BT were varied, in order to simulate α reaction dominant response. This result were partially same as human reaction of long term CPT (AIx was increased).

(2) Discussion



According to the experimental and calculation results of AIx change by short term and long term CPT load, the cause of the AIx change was different in 2 types of CPT.

In short term CPT, heart contractility increasing just after the beginning of the load induced pulse pressure increasing and AIx decreasing, since β reaction dominant response.



By contrast, in long term CPT, increasing of peripheral resistance about one minute after the beginning of the load induced pulse pressure decreasing and AIx increasing, since α reaction dominant response.

IV. Conclusions

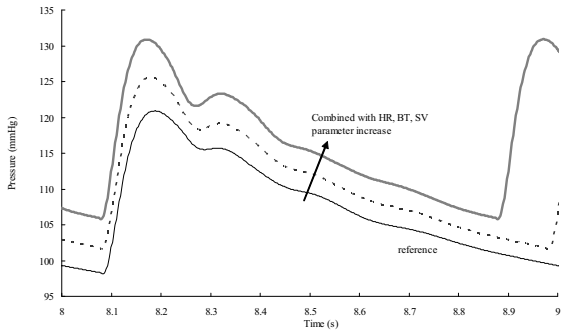
In order to understand the mechanism of pulse wave change and basis of AIx change, continuous pulse wave

(a) Short term CPT: correspond to β action dominantly

(b) Long term CPT: correspond to α action dominantly

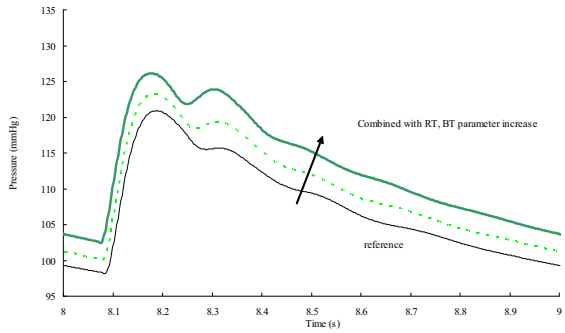
Fig. 5 Calculation results of single parameter variation.

were recorded during the 2 types of CPT, moreover waveform and AIx were analyzed by experimentally and numerically.



(1) A biological reaction of circulatory system during CPT is a complex reaction combined with not only peripheral artery but also heart or central aorta.

(2) A biological reaction seems to be different by the short term CPT and by the long term CPT. We suspect that the change by the short term CPT may have caused β-effect and the long term CPT may have caused α-effect.



(3) The pulse wave change phenomenon (especially change of AIx) during the CPT can be expressed using numerical simulation model combined with central aorta and brachial artery.

Identification of the Changes in Extent of Loading the TM Joint on the Other Side Owing to the Implantation of Total Joint Replacement

Z. Horak[1], T. Bouda[1], R. Jirman[2], J. Mazanek[2] and J. Reznicek[1]

[1] Czech Technical University in Prague, Faculty of Mechanical Engineering/Laboratory of Biomechanics, Prague, Czech Republic
[2] Charles University in Prague, 1st Faculty of Medicine/Department of Stomatology, Prague, Czech Republic

Abstract — **Temporomandibular joint is the most used joint of human body. Any defect of it has a significant influence on quality and style of life. If the TM joint is damaged, its treatment is very difficult and, in addition, it is impossible to replace fully this specific joint with a total replacement. In our opinion, the main reason is the method of implantation of existing replacements, when the whole range of masticatory muscles must be removed, and these results in significant change of mechanical loading of the whole system. The objective of this work was to create parametric computational FEM study comparing the effect of surgical procedure while implanting the total replacement of the TM joint on loading of the joint on the other side.**

Keywords — **temporomandibular joint, TMJ replacement, FE analyses, mechanical loading**

I. Introduction

Up to 60% of current population suffers from temporomandibular (TM) disorders. From the anatomy and mechanical point of view, the TM joint is a complicated bicondylar joint complex, which is one of the most loaded joints in human body. Its uniqueness lies in the fact that it is a coupled joint - two equal joints occur on one bone, the mandible, and so any movement or a dysfunction of one affects also the other joint.

Two types of replacement are used for reconstruction of TM joint. In the current clinical practice are used three types of total TM joint replacement: TMJ Concepts (TMJ Concepts Inc), The Christensen (TMJ Inc), and Lorenz (Biomet Inc). All three companies use similar construction of the replacement. The difference is in the type of movement that the replacements allow with their construction. The Christensen replacement allows only spherical movement of the condyle in the fossa, while the TMJ Concepts and Lorenz replacements allow rotation and sliding movement of the condyle in the fossa. The second type of movement is closer to the real situation of the physiologic temporomandibular joint movement. All three replacements have equal method of implanting the condylar type of the replacement [4-6], which is, in our opinion, essential for the end result of the correct function of the total replacement. When implanting the condylar part, the m. masseter is always resected over to the lateral surface of mandible, and in most cases also m. temporalis together with processus coronoideus mandibulae. Resection the m. temporalis with the processus enables easier rehabilitation of opening and resection m. masseter is necessary with regards to fixation of the condylar part of the replacement to the mandible. This method of fixing the replacement to the bone results cause radical change of force and kinematic both TM joints. Due to resection m. masseter and m. temporalis, the muscles on the other side must take over the force action needed for mastication, bite and stability of the whole system; however, this causes inadequate increase of loading on the TM joint on the other side.

The objective of this work was to create parametric computational study using FEM, analyzing the influence of used surgical procedures for implanting the temporomandibular joint total replacement on loading of the joint on the other side.

II. Materials and methods

The analysis of the effect of the method of implanting the TM joint total replacement was realized using the Finite Element Method (FEM). For the numerical simulations was build a simplified model of the mandible, inferior dental arch, both joint discs and fossa. The geometric model was designed on the basis of CT images of a healthy individual without obvious damage of the mandible and TM joint. The geometric models of the mandible and teeth were meshed with linear four-sided elements; the model of the disc was meshed with hybrid quadratic four-sided elements. The model of fossa was only represented by the lateral surface, which was reticulated by linear triangular shell elements as the fossa was considered as rigid body. The model was imported into the programme ABAQUS, in which the analyses were realized. The activity of muscles was modelled using 1D connector elements, which connected the beginning and tendon of the muscle and into which force was applied. The considered muscles were m. masseter, m. temporalis, m. pterygoideus med., and lat. All parts of the model were considered as homogenous isotropic materials, the parameters of individual material models are shown in Table 1.

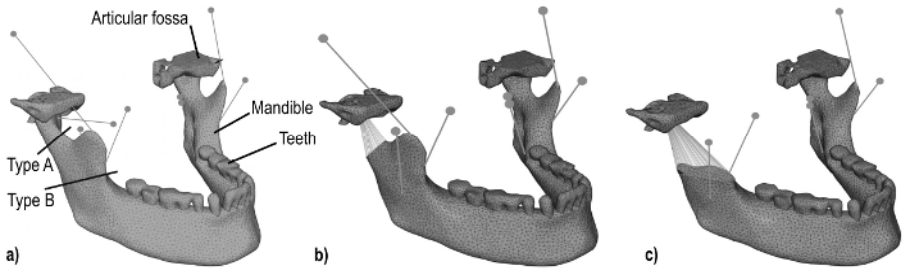

Fig. 1. a) FE Model of the mandible and TM joint with articular fossa. Muscles (CONNECTOR elements) are represented by the lines. The type of the condylar resection is showed by the lines on the right condyle, b) resection Type A1 and c) resection Type B1

The teeth were connected with the bone with TIE contact, which was also used for making the connection between the condyle of the mandible with the TM disc and connection between the TM disc and the fossa. Equal distribution of forces generated in muscles into the bone was realized by distributing coupling function. The reference points of the fossas, which were considered as rigid bodies, were fixed. The bite was simulated for three basic physiologic situations: bite on incisors I1, right and left first molar M1.

Table 1. Material properties of parts of model used in FE analyses of the TM joint.

Model parts	Material model description	Element type
Mandible	E=17 GPa, μ=0.30	C3D4
Tooth	E=21 GPa, μ=0.21	C3D4
TM disc	Money-Rivlin hyperelastic material C10=0.9, C01=9.10^{-4}, D1=1.10^{-5}	C3D10H
Fossa articularis	Rigid body	S3

The muscle forces generated by individual masticatory muscles were determined on the basis of physiologic cross sections of muscles and mathematical models presented in literature [1-3]. The magnitude of forces in muscles was determined on the basis of force ratio generated at the resulting bite force of 300N on the given tooth. The magnitude of maximum bite force considered in the model was picked with regards to clinical practice, where the patients with TM joint disorders have significantly reduced magnitude of this force [1]. The magnitude of bite force was considered as equal for all types of resection and the anatomical model. For the examined cases of bite, with maximum bite force requirement, it implies from the mathematical model [3] that from the group of considered muscles, m. masseter, m. pterygoideus med., and m. temporalis are fully activated.

There were modelled four simulations of the influence of the surgery while implanting the total replacement (see Fig.1): resection caput mandibulae while the m. pterygoideus lat. is removed (Type A1), resection of caput mandibulae with removing of m. pterygoideus lat. and m. masseter (Type A2), resection behind processus coronoideus mandibulae while m. temporalis and m. pterygoideus lat. are removed (Type B1), the last resection behind processus coronoideus mandibulae while m. masseter, m. temporalis and m. pterygoideus lat. are removed (Type B2). In the computational model, the total temporomandibular joint replacement was modelled as a spherical joint to which the surface created by the mandible resection is connected by distributing coupling function. The total replacement was modelled on the right side of the computational model and the results of the analysis were evaluated for the corresponding TM joint on the left side.

III. Results

The magnitude of TM joint loading was represented by the magnitude and components of the reaction force carried in the TM joint during bite. The values of the magnitude of loading on the TM joint for each type of resection were compared with the values of anatomical variation of the TM joint loading. The coordinate system, in which the results of the numerical analysis are presented, is right-angled Cartesian, where direction 1 (mediolateral), direction 2 (posterior – anterior), and direction 3 (craniocaudal).

From the results of the analysis listed in Table 2 for the bite on incisors (I1), increase of the reaction force and all its elements in the corresponding TM joint on the other side is obvious, for increasing size of the resection. This increase is most evident for direction 1, where the increase in all types of resection by Δ^{A1}=52.5%, Δ^{A2}=493.2%, Δ^{B1}=394.9%, Δ^{B2}=938.9% compared with the values obtained for the anatomic model. Also the increase of magnitude of loading in direction 2 is for each resection by Δ^{A1}=8.6%, Δ^{A2}=112.6%, Δ^{B1}=113.5%, Δ^{B2}=290.6%. The influence of the size of resection while implanting the TM joint replacement shows obviously also on the increase of the magnitude of loading in direction 3 is for each resection by Δ^{A1}=4.7%, Δ^{A2}=64.5%, Δ^{B1}=39.4%, Δ^{B2}=132.7%.

Type B2	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A

The same trend of the TM joint loading with regards to the size of resection is evident for bite on the first left molar (M1, i.e. bite on the molar neighbouring with the TM joint on the other side). The results of computation analysis are listed in Table 3 where the increase in individual types of resection by Δ^{A1}=33.3%, Δ^{A2}=523.8%, Δ^{B1}=319.0%, Δ^{B2}=1014.3%. The increase of magnitude of loading in direction 2 is for individual resections by Δ^{A1}=9.0%, Δ^{A2}=113.8%, Δ^{B1}=111.8%, Δ^{B2}=291.6%. The most important result is the magnitude of the reaction force and its components for the case Type A2 with removed m. masseter and for the case of resection Type B2. Here, the increase of the resulting reaction force by 503.3%, or 1107.9% respectively, is evident, while the increase of the medio-lateral component of the reaction R_1 is by 523.8%, or 1014.3% respectively, and the increase of the back-to-front component is by 113.8%, or by 291.6% respectively. From these values the stabilizing effect of m. masseter in medio-lateral direction is evident.

In the last variation of model loading, for the bite on the first right molar, it is possible to observe slight increase of reaction forces in the TM joint on the other side for the resection cases Type A2 and Type B1. The results of numerical analyses are listed in Table 4. The increase is most obvious for direction 1, where the increase for individual types of resection by Δ^{A1}=7.3%, Δ^{A2}=292.7%, Δ^{B1}=180.5%. Also increase of the reaction component is evident in direction 2: Δ^{A1}=0.6%, Δ^{A2}=4.1%, Δ^{B1}=44.7%. The influence of the size of resection while implanting the TM joint replacement will show also at the magnitude of reaction in the joint in direction 3: Δ^{A1}=1.6%, Δ^{A2}=12.6%, Δ^{B1}=2.6%. The biggest change can be observed for resection Type A2 at the medio-lateral component of reaction force, which changed by 292.7%, although the resulting reaction force changed only by 12.9%. For the resection Type B2, it was impossible to reach balance even when reducing the muscle force on the TM joint on the healthy side, or increasing the muscle force on the side of the implant.

From the afore-mentioned results of numerical simulations, the significant influence of the size of resection on loading the TM joint on the other side (independently of the place of bite) is evident when implanting the TM joint. The biggest increase of magnitude of the loading on the TM joint on the other side in general is evident for resection Type B2 (which is the most frequent when implanting the total replacement in clinical practice), in case of bite on the molar M1 on the other side (left) this increase of loading is 11-fold of the physiological loading!! The most significant

increase of TM joint loading is in medio-lateral direction, where the loading is 10-fold of the physiological loading. Moreover, when comparing the results for individual types of resection it shows that in order to keep the best function of the TM joint on the other side after implanting the total replacement, it is more important to retain the m. masseter than m. temporalis (Type A2 vs. Type B1). If m. masseter was resected, the total magnitude of loading on the TM joint for bite on incisors I1 is by 25% smaller, and for bite on the molar M1 on the other side is by 214% smaller!!

IV. Discussion and conclusions

From the executed analyses, it is evident that resecting m. temporalis, and especially m. masseter, for the existing method of implanting the TM joint total replacement, has fatal effect on loading of the joint on the other side. The biggest increase of the magnitude of loading the TM joint on the other side reaches the force component in medio-lateral direction and anterio-posterior direction, which causes significant increase of shear loading of the TM disc. This way of loading the TM disc, with regards to its function and structure, is most damaging. The increase of this way of loading is, in our opinion, the main cause of subsequent degeneration of the TM disc and surrounding structures in an originally healthy TM joint on the other side. From the results of the analyses it is clear that in case of implanting the TM joint replacement from the point of view of the smallest increase of loading the joint on the other side the most suitable is the size of resection Type A1 (retaining all muscles except m. pterygoideus lat.). On the other hand, the most used size of resection Type B2 (resection of m. masseter, m.temporalis, and m. pterygoideus lat.) is most devastating from the point of view of the TM joint on the other side. The variation of resection size Type A1 can be also regarded as the variation quantifying the loading of the joint on the other side only when replacing the TM joint. When comparing the remaining types of resection with Type A1, significant increase of loading on the TM joint on the other side is evident, and so clear conclusion is that resecting muscles has more significant effect on loading the TM joint on the other side while bite than the TM joint replacement with an implant.

In our opinion, the existing constructions of total TM joint replacement used in clinical practice (The Christensen, TMJ Concepts and Lorenz/Biomet) enable movement of the replacement close to real movement of the TM joint, but the way of connecting it to the mandible radically reduces their benefit for the patient.

In the numerical FE analysis, there were used simplified material models of biological tissue: elastic homogenous isotropic material (bone, teeth) and hyper elastic isotropic homogenous material (TM disc). Simplifying the used material models certainly has effect on the results of the completed FEM analyses, but with regards to the objective of this work this simplification is insignificant.

The results obtained from the executed computation FEM analyses of the effect of the implantation on the TM joint on the other side give us information for design of the construction of the TM joint implant, which would enable smaller surgery in the system of the masticatory muscles on the side of the implant, and at the same time, the possibility to make more delicate construction of the replacement. Such suitable change of the construction configuration of the TM joint replacement could reduce the loading on the TM joint on the other joint after implanting the total replacement, and thus, the benefit for the patient would be increased considerably.

Effects of Stent Design Parameters on the Aortic Endothelium

Gideon Praveen Kumar[1] & Lazar Mathew[2]

[1] Healthcare Practice, Frost & Sullivan (P).Ltd, Chennai, India
[2] School of Biotechnology, Chemical & Biomedical Engineering, VIT University, Vellore, India.

Abstract — **Vascular support structures are important tools for treating valve stenosis. A large population of patients is treated for valvular disease and the principal mode of treatment is the use of percutaneous valvuloplasty. Stent devices are proving to be an improved treatment method; these devices now account for 20% of treatments in Europe. This new technology provides highly effective results at minimal cost and short duration of hospitalization. Accurate and reliable structural analysis provides essential information to the design team in an environment where in vivo experimentation is extremely expensive, or impossible. This paper describes the design of vascular support structures (stents), to provide designers with estimates of the critical parameters which are essential to restore the functions of the endothelium of the Aorta during and after implantation without injuring it.**

Keywords — **Stent, Finite Element Analysis, Aorta, Coronaries, Blunt hooks**

I. Introduction

The treatment of stenotic valvular diseases consists of routine procedures in interventional cardiology. To date, the surgical approach is the only option to replace diseased cardiac valves [1]. Recently it has been shown that stenosis of mitral, aortic or pulmonary valves can be treated by percutaneous valve replacement and has recently opened new perspectives on transcatheter placement of cardiac valves. Aortic valve replacement generally has been accomplished by using a cardiac surgical procedure whereas endovascular procedures for valve replacement may provide an alternative to cardiac surgery. Percutaneous transluminal procedures have substantial benefits from the standpoints of health and safety, as well as cost. Such endovascular procedures require minimal invasion of the human body, and there is considerable reduction and, in some instances, even elimination of general anesthesia and intensive care unit stay. In Percutaneous replacement, the diseased valve is replaced by a biological valve via a catheter driven through the femoral artery to the aortic position. The valve is sutured to the stent, which is crimped into the catheter and is guided to the parent position of the aorta and deployed [2]. Thus it pushes the diseased valve aside and keeps the new bio-prosthetic valve in position. The stents that are used give adequate support and stability to the valve and also prevent the prosthesis from getting migrated either in the ante grade or retro grade direction [4]. These stents also help in preventing paravalvular leaks. With this view we have attempted to generate models to achieve proper stenting and placement of the prosthesis without migration, paravalvular leaks and obstruction of coronary blood flow.

II. Methods

A. Parametric Stent Designs

Stent geometries were uniquely defined using the following parameters.(a) Diameter of the aorta;(b) Distance between the aortic root and the coronary artery roots ;(c) Position of the coronary arteries;(d) Diameter of the coronaries;(e) Stent – Endothelium Mechanics. Keeping these parameters into consideration many stent models [Fig 1(a) – (c)] were designed to suit its requirement for percutaneous replacement. These parameters are extremely critical as shown in Fig 2.

The 3D geometry of the repeatable units of the stent was generated using SOLIDWORKS modeling Software. Using the repeating unit geometry of each stent design, solid models were generated. The unit consisted of 8 lips with two non crossing struts making a circular diameter of 16mm at the center and 18mm at the top and bottom as shown in Fig 3.The upper and the lower portions of the prosthesis has a high radial force, the upper portion flared to fix the stent firmly in the ascending aorta and the lower portion to expand against the calcified leaflets and to avoid recoil. The middle portion which bears the valve, is constrained and narrower to avoid obstruction of the coronary arteries. This varying diameter, as shown in Fig 1(c) at different parts of the stent creates the blunt hooks at either end of the stent. The port angle is 45 degrees with the two struts joining to form the circular stent. The stent design has a constant strut thickness of 0.5 mm and a height of 18 mm [7].

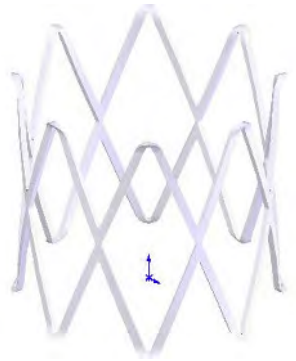
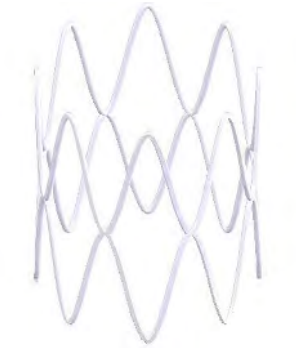
www.springerlink.com





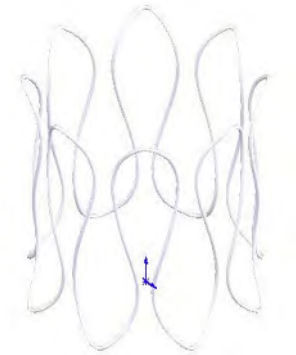


Fig. 1 (a) Model 1

(b) Model 2

(c) Model 3

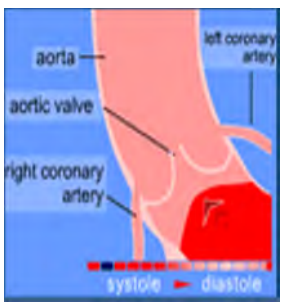

Fig. 2 Aortic valve and the coronaries

B. Material Model

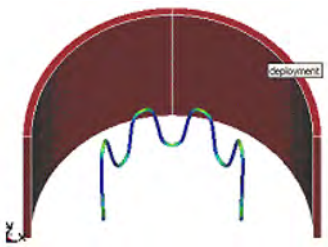
Stainless steel 316L was the material that was used for fabrication as it has a high strength to weight ratio and excellent biocompatibility when used in humans [6]. The material properties ideal for analysis are tabulated in Table 1.

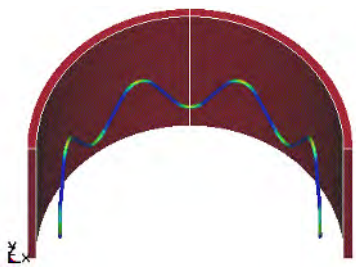
Table 1 316L Stainless steel – Properties

Material Name	316LStainless Steel
Young's Modulus (E)	201 GPa
Poisson's ratio	0.3
Yield stress	170 MPa

C. Mode of Analysis

The stent solid model was then meshed to form a cylindrical shape by transferring the nodal co-ordinates from a Cartesian co-ordinate system into a cylindrical co-ordinate system. In this way Finite element meshes were generated





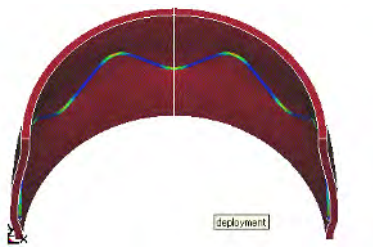


Fig. 3 (a) Stent fully crimped in the aorta

(b) Partially expanded Stent

(c) Stent expanding to fit into the aorta.

for the design. Free expansion analysis was done for the stent model using ANSYS finite element analysis software. Mechanical properties like crimping and re-expansion were studied. The models were subjected to finite element analysis with boundary conditions above the normal human blood pressure levels of 120/80 mm Hg The stent model seemed to withstand loads much more than that of the normal human pressure loads. The results of the designs are encouraging and would be published after patenting the model.

D. Stent – Endothelium Interaction

The stent – aortic endothelium mechanics was studied by placing the stent inside an aorta model. The stent was crimped and expended by applying various pressure ranges to understand its behavior inside the stent [Fig 3 (a), (b), (c)].

III. Results and Discussion

The stent models were designed, analyzed and its interaction with the aorta studied successfully. The dimension of the stent, such as the length can influence the deliverability, visibility and flexibility of the stent...Strut geometry is another important engineering aspect. We have come out with a design having 8 lips have 2 struts each given adequate gap between two adjacent struts. This gap between struts will enable the surgeon to place the stent in such a way that it doesn't obstruct the coronary blood flow which is situated just above the aortic valve. Furthermore the blunt hooks that are designed help the stent to take its position once it is implanted by the surgeon. The aorta took the shape of the stent as these blunt hooks got embedded into the endothelium of the aorta. This gave the stent a good fit into the aorta preventing it from getting migrated in either direction.

IV. Conclusion

Thus the effects of stent designs on the aortic endothelium were successfully evaluated.. However further analysis and studies are needed before these stents are fabricated and deployed. Animal experiments are being planned currently for this purpose.

Multi-Physical Simulation of Left-ventricular Blood Flow Based On Patient-specific MRI Data

S.B.S. Krittian, S. Höttges, T. Schenkel and H. Oertel

Institute for Fluid Mechanics, University of Karlsruhe (TH), Germany

Abstract — **Statistically, heart disease has been the major cause of death in the recent past, which emphasizes the need for computational heart models. In this context, the so-called KaHMo (Karlsruhe Heart Model) is specialized on the inner-ventricular blood flow and its influence on the overall heart conditions. Both healthy and diseased hearts are simulated in order to analyze characteristic flow patterns and pressure losses. The patient-specific fluid domain movement is realized by time-dependent geometries out of MRI data.**

However, in order to capture flow changes due to structural variations, a multi-physical simulation approach is of utmost importance. Consequently, the model extension KaHMo FSI includes macroscopic structural properties using a hyperelastic finite element composite. The partitioned code coupling strategy allows the combination of separated software packages specialized for both the fluid and structural domain respectively. The interaction of blood flow and constitutive behavior influences the interface movement for both relaxation and contraction. In this context, the energetic equilibrium between the computational fluid and structural domain requires kinematic and dynamic coupling conditions to be satisfied continuously.

The focus of this work is on the first application of patient-specific reference geometry for KaHMo FSI. The coupled flow simulation is compared to corresponding results from KaHMo's standard fluid domain movement. In order to validate the flow simulation itself a further test-case model is evaluated and compared to experimental flow measurements. A detailed understanding of hydro-elastic blood/soft-tissue interaction is important for future therapy planning.

Keywords — **patient-specific, heart model, fluid-structure interaction, implicit code-coupling, blood-flow analysis.**

I. Introduction

With a focus on the inner ventricular fluid mechanics, the so called KaHMo has been developed at the Institute for Fluid Mechanics, University of Karlsruhe (TH), Germany. The question arose whether a fluid stand-alone model is able to capture the influences on the inner ventricular flow pattern. Alternatively, a fluid-structure interaction (FSI) could have been taken into account. However, due to the lack of constitutive *in vivo* data, most FSI models are based on either generic data or *in vitro* measurements of animal hearts; a transformation onto a patient-specific human heart model cannot be undertaken. Consequently, KaHMo MRI is based on the time-dependent movement of the inner ventricular wall derived from patient-specific MRI images. Both healthy and diseased hearts can be investigated from a fluid mechanics point of view and important clinical indication criteria can be determined [3].

Nevertheless, for future generations of KaHMo the structural calculation will have to be taken into account again. Desperately needed *in vivo* data will become more and more available due to the continuous progress of MRI techniques. Therefore, the new KaHMo FSI represents the first step for replacing the time dependent wall movement by structural calculation. For this reason, a macroscopic composite model for the left ventricle has been generated.

Whereas the structural part is performed by the software package Abaqus 6.7-2, Fluent 6.3.26 is responsible for the flow calculation. The Fraunhofer-Institute for Algorithms and Scientific Computing (SCAI) provides the **M**esh-based **p**arallel **C**ode-**C**oupling **I**nterface MpCCI with explicit data exchange algorithms. However, blood/soft-tissue interaction requires stronger coupling mechanisms which are implemented within the new *"Implicit Coupling for KaHMo FSI"* module [2].

II. Models and methods

A. Geometry and model discretisation

The cardiac cycle can be divided into contraction and filling phase. Whereas the contraction phase is mainly dominated by the heart muscle itself, fluid-structure interaction effects play an essential role during the ventricle filling. This phase can be further divided into *rapid filling*, *late filling* and *atrium contraction.*

Figure 1 shows the starting CAD geometry derived from the MRI reference timeframe. The stress-free configuration is assumed to be located between late filling and atrium contraction. Whereas the solid domain is modelled by the endo- and epicardial surfaces, the fluid domain is described by the inner-ventricular wall only:

- The fluid domain penetrates the solid part at in- and outlet and is discretized by 200.000 tetrahedral cells.
- The structural model is discretized by 4.000 quadratic tetrahedral cells. The intersections at the in- and outlet area also form the spatial boundary fixation. Note, both endo- and epicardial surfaces bear muscle fiber information (Figure 2) as described in section *II.B*.
- Data exchange is performed at the common interface described by the fluid domain boundary and the endocardial surface, respectively.

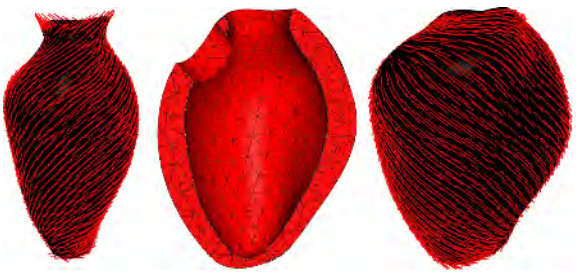

Fig. 2 Matrix (*middle*) with endo- (*left*) and epicardial fiber layers (*right*)

B. Material and composite approach

The composite model itself is based on a modified formulation of *Holzapfel*'s strain energy density function [1]:

$$W = \underbrace{c_1 \cdot \exp\left(c_2 \cdot (I_1 - 3)^2\right) + c_3 \cdot \exp\left(c_4 \cdot (I_2 - 3)^2\right)}_{matrix}$$

$$+ \underbrace{c_5 \cdot \exp\left(c_6 \cdot (I_4 - 1)^2\right)}_{fiber}$$

The invariant based formulation allows a mathematical separation into an isotropic matrix and a reinforced fiber direction and forms the constitutive basis of the partitions shown in Figure 2. The corresponding parameters (c_1-c_6) were estimated using simple shear test-data and a specialized least-square fitting procedure [4]. Muscle contraction is realized by a time-dependent fiber strain specification.

C. Coupling procedure

The overall KaHMo concept requires a partitioned modeling strategy for simulating the inner-ventricular blood flow. This allows the application of either the standard prescribed geometry movement or the novel *"Implicit coupling (for KaHMo FSI)"*. The latter uses relaxation procedures combined with an iterative time-step looping scheme (*see e.g.* [2]). For a given unknown vector f, i.e. load or spatial position, the relaxation function in *loop k* is represented by

$$f_{relax}^{k} = \omega^{k} \cdot f_{new}^{k} + \left(1 - \omega^{k}\right) \cdot f_{relax}^{k-1}$$

As soon as equilibrium between fluid and structure is reached the next time-step can be performed. The decision by which implicit coupling procedures should be applied depends strongly on physical properties (e.g. structural stiffness or fluid density) and the corresponding instability effects. Several validation test-cases proved that the load relaxation is most suitable for biomechanical applications.

D. Boundary condition

The interplay between heart muscle relaxation and the pressure boundary condition can be seen in Figure 3. However, the interface pressure itself depends on both static and dynamic pressure conditions. As the flow solution itself is a function of the pressure gradient the inlet and outlet pressure is regulated by the operating pressure only.

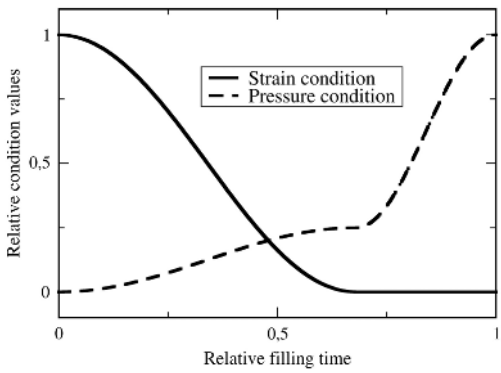

Fig. 3 Pressure condition and fiber strain during filling phase

III. Simulation results

For the first time the prescribed geometry movement of KaHMo MRT has been replaced by the calculated interaction of fluid and structure within KaHMo FSI. In order to evaluate the new simulation quality, both strategies need to be compared using the same patient-specific reference data. Having proved both strategies to be consistent, the coupled simulation of a validation experiment finally confirms the overall simulation approach.

A. Evaluation of model consistence

Using the patient-specific reference geometry shown in Figure 1, the measured cavity volume is compared to the simulated FSI-values in Figure 4. In spite of the simplified composite representation both results show the same characteristics (*ejection*, *filling* & *atrium contraction*), a good overall agreement and an ejection fraction of ~55%.

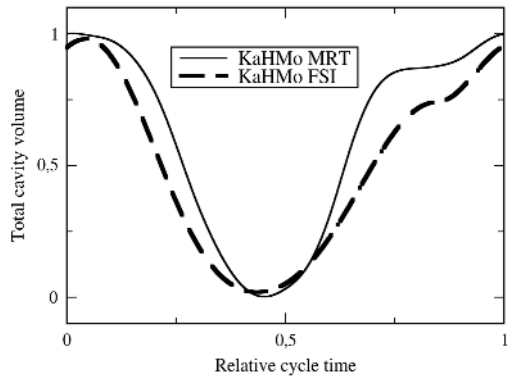

Fig. 4 Cavity volume measurement and coupled simulation result

Figures 5-7 show the characteristic time-frames during the ventricle filling phase. Both modeling approaches show the same temporal flow pattern development. The inflow jet during the rapid filling phase is accompanied by a ring vortex which grows asymmetrically with increasing cavity volume. Finally, the atrium contraction time-frame is characterized by the ring vortex turned clockwise in order to simplify the flow through the heart tip. The left vortex part now dominates the flow pattern and supports the blood outflow energetically during the up-coming ventricle contraction phase. As far as the coupling procedure itself is concerned the energetic equilibrium requires both kinematic and dynamic coupling conditions to be satisfied. Using an adaptive relaxation procedure, the energy residuum convergence tolerance is satisfied throughout the complete coupling process as shown in Figure 8.

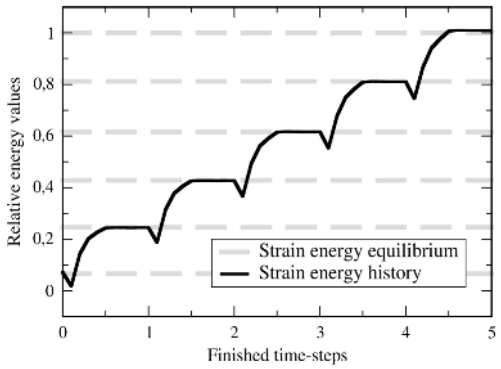

Fig. 8 Strain energy convergence history during filling phase

B. Flow field validation

In order to validate the general KaHMo flow pattern, an artificial ventricle device is used as validation experiment [5]. The silicon model is located within a pressure chamber which forces the ventricle to inflate or reject. Transparent materials enable the velocity flow field to be measured by PIV techniques. Both reference geometry and pressure distribution can be used as input for the FSI ventricle validation. Figure 9 shows one time-frame within the ventricle's filling phase and the overall flow patter agreement – both qualitatively and quantitatively.

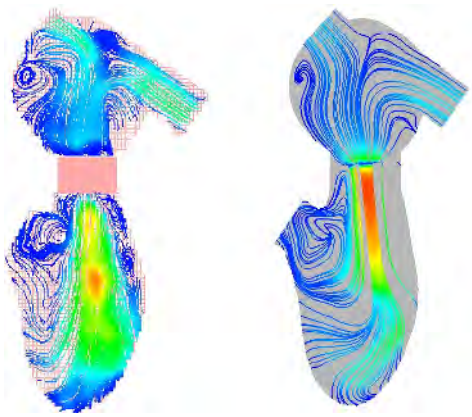

Fig. 9 Validation experiment (*left*) and KaHMo FSI (*right*)

IV. Conclusions

After having evaluated the flow field within a multi-physical simulated coupling validation, the *"Implicit Coupling (for KaHMo FSI)"* [2] was applied to an anatomical data set out of MR images for the first time. The comparison with the standard prescribed geometry movement shows a good agreement between the subsequent flow fields.

Although the prescribed geometry method guarantees a high level of patient-specific modeling, the definition of corresponding pressure boundary conditions is still a challenge. Within the fluid-structure interaction concept, however, the proof of energetic equilibrium always guarantees the structural deformation is due to the overall load condition and vice versa.

Current work includes the integration of MRI tissue information within more sophisticated material models. Structural changes (e.g. dead tissue) can be applied to the structural side and the corresponding flow pattern will be analyzed. Patient-specific dimensionless numbers e.g.

$$\Pi^{sys/dias}_{dynamic} = \left[\frac{E/\Delta V}{p}\right]^{sys/dias} \quad ; \quad \Pi^{sys/dias}_{static} = \left[\frac{E/\Delta V}{\rho u^{-2}}\right]^{sys/dias}$$

help to judge interaction effects for both systolic and diastolic functionality. $E/\triangle V$ represents the respective energy level per cavity volume related to the static/dynamic pressure. Consequently, KaHMo FSI and its multi-physical approach represents a further step towards cardiac modeling for *future therapy planning*.

Spinal Fusion Cage Design

F. Jabbary Aslani[1], D.W.L. Hukins[1] and D.E.T. Shepherd[1]

[1]School of Mechanical Engineering University of Birmingham, Edgbaston, B15 2TT, UK

Abstract — **A fusion cage is used to aid fusion of an intervertebral joint. To date, cages have been commonly made of materials (metals or polymers) that remain in the body. Post-operative complications with these permanent fixtures might be overcome by using biodegradable/bioabsorbable composite (BBC) cages. There are requirements for the BBC to be used as a cage material, including load bearing ability. The aim of this study was to evaluate the feasibility of using a BBC as a cage material. This composite would degrade gradually to be simultaneously replaced by bone. Post-operative complications are reduced as no foreign bodies remain within the patient and bone growth is unrestricted. The design of the cage has also been optimized based on BBC material properties. Cage features such as teeth and holes have been investigated to obtain a suitable cage design using BBC. Finite Element Analysis was carried out on cage concept models, using the material properties of BBC and polyetheretherketone (an existing cage material) for comparison purposes. The results, from an engineering view point, determined the feasibility of BBC as cage material.**

Keywords — **degradable polymers, bioactive glass, composite materials, fusion, spine.**

I. Introduction

Damage to intervertebral discs can lead to pain and immobility that may be treated surgically by fusion of the intervertebral joint using a bone graft [1, 2]. Fusion cages are often used to retain the graft bone [3]. To date, these cages are made of materials (polymer or metal) that remain in the body; the most common polymer in current use is polyetheretherketone (PEEK). These materials can lead to post-operative complications [4, 5] e.g. bone loss as a result of stress-shielding and adverse tissue reactions caused by corrosion [3, 4]. In this study, the feasibility of replacing the existing permanent materials with a biodegradable/bioabsorbable composite (BBC) was investigated. The design of an existing cage was modified and the stress distribution, when subjected to compression, was determined by Finite Element Analysis (FEA) using COSMOS Works (SolidWorks, Santa Monica, USA). The design features investigated were as follows:

- Slot and holes in the side (Figure 1)
- Teeth on the upper and lower surfaces (Figure 2)

The holes allow fluid transport to and from the cage interior, enabling hydrolysis of the BBC to occur from the inside as well as from the surface. Teeth may enable the cage to grip the vertebrae so that metal screws are not required to retain it in place. An insertion hole enables surgical instrumentation to be used to position the cage between adjacent vertebrae.

Resorbable polymers that have been used for implants include poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and poly(L-lactide co-D,L lactide) (PDLLA) [7-10]. Their degradation rates can be tailored to meet the requirements at the implant site. However, these polymers are too weak to meet the demands of load bearing implants [11]. Porous bioactive ceramics and silicate glasses may overcome this problem [12, 13], although they may be too stiff for some applications [14]. However, composites of a ceramic or glass with a polymer (i.e. BBCs) may be suitable for bioengineering applications [5]. In this study, a composite of PDLLA and bioglass-45S5 has been considered as a candidate material [14]. Results were compared with those for a successful existing cage that is manufactured from PEEK (Stalif C, Surgicraft Ltd., Redditch, UK).

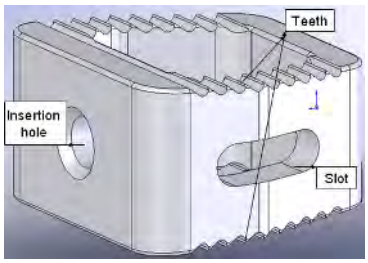

Fig. 1 Proposed fusion cage with slot

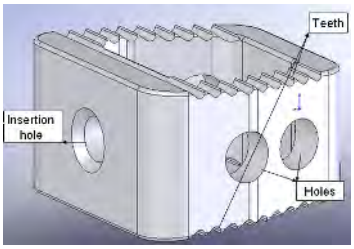

Fig. 2 Proposed fusion cage with holes

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1546–1549, 2009
www.springerlink.com

II. Material and Method

The cage was based on an existing design (Stalif C, Surgicraft Ltd., Redditch, UK) (Figure 3), where either a slot, or 1 to 20 holes, and 8 to 18 teeth were varied (Figures 4-5).

FEA was performed on the existing Stalif C and with the proposed BBC designs. The cage was loaded between two blocks whose properties mimicked those of cortical bone (Figure 6). Material properties for cortical bone, PEEK and BBC are given in Table 1. The total assembly was restrained from the bottom (to prevent movement) and a compressive (axial) force of 150 N [15] was applied to the top of the assembly, imitating the load experienced by the cervical region of the spine. The finest mesh size was used to solve the model in COSMOS Works.

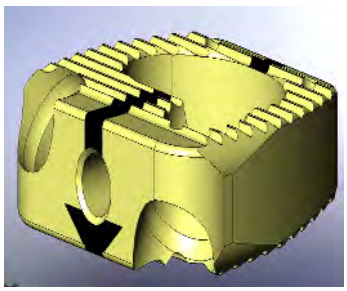

Fig. 3 Stalif C, Surgicraft

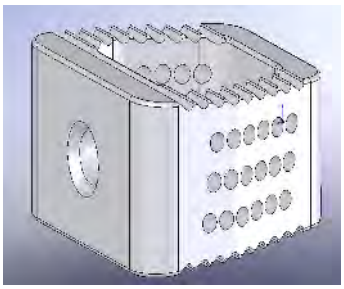

Fig. 4 Concept cage with maximum number of holes

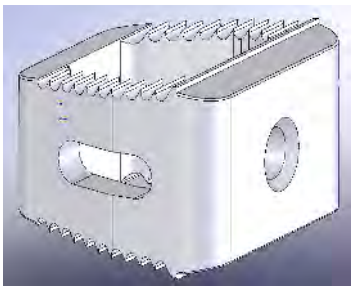

Fig. 5 Concept cage with maximum number of teeth

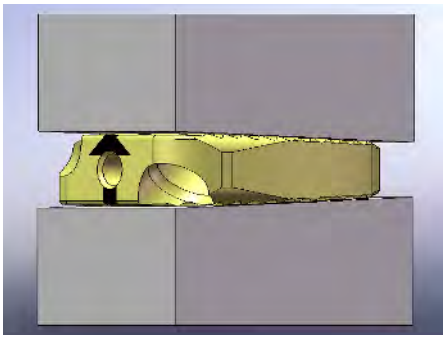

Fig. 6 Stalif C, with two boxes acting as vertebrae

Table 1 PEEK, BBC and cortical bone mechanical properties

Material	PEEK [16]	BBC [13, 17]	Cortical bone [18]
Young's modulus (GPa)	4	≈ 6	30
Poisson's ratio	0.4	0.4	0.3

FEA was carried out on each cage design to determine the maximum von Mises stress. This stress was then compared to the compressive strength of the material to determine the suitability of the concept model. The model was considered to be suitable when its maximum stress was less than the material compressive strength. For these cases, the maximum stress of the accepted model was then compared with the fatigue strength of a composite, with similar mechanical properties to BBC (hydroxyapatite-PEEK (HAPEX^{TM}) [18]), to determine the final step for suitability.

III. Results

The maximum stress for each cage design is given in Table 2. The proposed BBC cage, with maximum number of teeth (18 teeth), has a maximum stress value of 26 MPa, which is less than the maximum stress value of the current PEEK cage (32 MPa). The maximum stress was always seen at the tip of the teeth (Figure 7 and 8). Accordingly, the number of teeth has a direct effect on the maximum stress value; increasing the number of the teeth results in an increase in the maximum stress value. Nevertheless, this value was always significantly lower than the fatigue strength of the material used, resulting in an acceptable concept model for the next step. Also, the concept model with an increased number of holes (20 holes) had a maximum stress value of 13 MPa, for both BBC and PEEK, which is less than half of the maximum stress value of the

current cage (32 MPa), which also resulted in acceptance of the model for the next step.

HAPEX ^{TM} was chosen to compare the fatigue resistance of the concept models. It has a fatigue-life of between 24.6 – 32.4 MPa at 10^6 cycles [18-19]. All models in this study were acceptable, because their maximum stress value was less than the mentioned fatigue-strength.

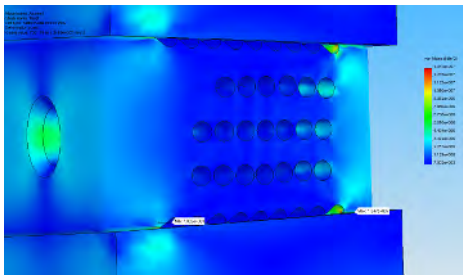

Fig. 7 Maximum stress on concept cage with maximum number of holes

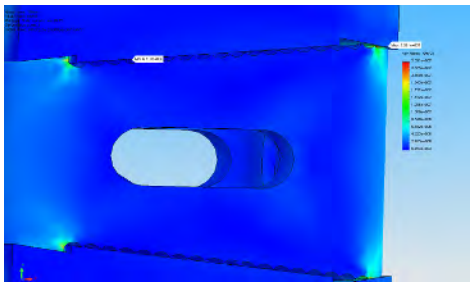

Fig. 8 Maximum stress on concept cage with maximum number of teeth

Table 2 Maximum stress comparison of existing and modified proposed cages with existing and proposal composite

Cage	Material	Material Compressive Strength (MPa)	Maximum Stress (MPa)
Stalif C	PEEK	118 [16]	32
Stalif C	BBC	140 [20]	32
Proposed cage (slot)	PEEK	118 [16]	16
Proposed cage (slot)	BBC	140 [20]	14
Proposed cage (20 holes – 8 teeth)	PEEK	118 [16]	13
Proposed cage (20 holes – 8 teeth)	BBC	140 [20]	13
Proposed cage (18 teeth – with slot)	PEEK	118 [16]	28
Proposed cage (18 teeth – with slot)	BBC	140 [20]	26

IV. Discussion

FEA has confirmed the feasibility of using a BBC as a cage material. A BBC, whose properties were used in the FEA, is biocompatible [14]. An increased number of holes and teeth are favourable in the cage design, because the teeth are able to retain the cage position and the holes allow fluid to pass through the cage, into the cage inner section. It is feasible to have up to 18 teeth and 20 holes in the design, without generating excessively high stresses in the cage.

The major limitation of this study was to use the fatigue strength of HAPEX^{TM} as a criterion for the success, or otherwise, of a BBC cage. This is a composite of a polymer (PEEK) with dispersed ceramic particles (hydroxyapatite) and so its fatigue properties could be very different from those of a BBC.

V. Conclusions

It appears feasible to design a BBC cage that is able to withstand a static compressive load up to 150 N. Further work is required to determine the fatigue properties of BBCs.

Comparison of Micron and Nano Particle Deposition Patterns in a Realistic Human Nasal Cavity

K. Inthavong[1], S.M. Wang[1], J. Wen[1], J.Y. Tu[1], C.L. Xue[2]

[1] School of Aerospace, Mechanical and Manufacturing Engineering, RMIT University, Australia

Abstract — **A computational model of a nasal cavity geometry was developed from CT scans and the simulation of the fluid and particle flow within the airway was performed using a Computational Fluid Dynamics (CFD) software. It was found that the deposition patterns for micron particles were highly dependent on the particle inertia and as a result, the majority of particles deposited in the anterior regions of the airway where a change in the flow streamlines was observed. In contrast the deposition for nano particles showed an even distribution of particles throughout the airway, driven by diffusion. Particle diameter was the most important parameter in determining what mechanism of deposition was most important.**

Keywords — **nanoparticle, nasal cavity, deposition, cfd**

I. Introduction

Nasal inhalation is a major route of entry into the body for airborne pollutants by which workers in occupational environments and the general population are exposed to. On the other hand, drug particles are deliberately sprayed into the nasal cavity in the event that the drug particles will deposit on the targeted sites for efficient drug delivery. Knowledge regarding particle deposition processes in the nasal cavity is important in aerosol therapy and inhalation toxicology. Experimental studies into aerosol deposition in the nasal cavity have been investigated in the past by a number of researchers [1-5]. In these studies, both micron or submicron particles were used exclusively and a comparison between the two types of particles was not performed.

Experimental methods performed on human subjects are limited due to the invasive nature and dangers associated with toxic aerosols. Computational simulations present another alternative to provide complementary data of submicron particle deposition for difficult and expensive experimental studies [6-8], while the study of micron particle deposition is not as notable in the literature. The deposition patterns for submicron and micron particles will inevitably be different due to the deposition mechanisms that each particle type experiences.

This paper presents a comparative study of the deposition of submicron particles, particularly the nanoparticles (1-10μm) and micron particles under different steady laminar flow rates by using the Lagrangian approach. The significance and influence of different force terms that are applicable to micron and nanoparticles are discussed and the local deposition patterns presented. A comparison of particle deposition patterns of the different particle types in the human nasal cavity is shown. The investigation in this paper was initiated due to the needs in health risk assessment on potentially toxic particles and the results are also applicable in targeted drug delivery with aerosols.

II. Method

A. Nasal Cavity Geometry Generation

A nasal cavity geometry was obtained through CT scans of the nose of a healthy 25 year old, Asian male, 170cm height, 75 kg mass as shown in Fig 1. The CT scan was performed using a CTI Whole Body Scanner (General Electric). The single-matrix scanner was used in helical mode with 1-mm collimation, a 40-cm field of view, 120 kV peak and 200 mA.

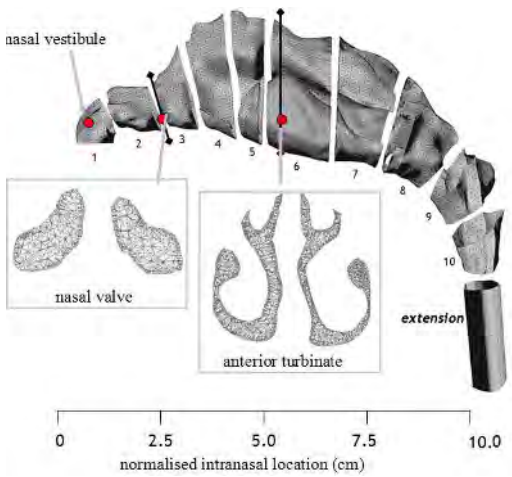

Fig. 1 Nasal cavity model used in the study which has been divided into ten separate sections named (Zone1 to Zone 10) for analysis of local deposition. Cross-sectional areas taken at the nasal valve and middle turbinate are shown with the computational mesh.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1550–1554, 2009
www.springerlink.com

The scans captured outlined slices in the *X-Y* plane at different positions along the *Z*-axis from the entrance of the nasal cavity to just anterior of the larynx at intervals of 1 to 5 mm depending on the complexity of the anatomy. The coronal sectioned scans were imported into a three-dimensional (3D) modeling program called GAMBIT (ANSYS Inc.) which created smooth curves that connected points on the coronal sections. Stitched surfaces were then created to form a complete computational mesh. An initial model with 82,000 unstructured tetrahedral cells was initially used to solve the air flow field at a flow rate of 10L/min. The model was then improved by cell adaptation techniques to refine the grid in order to achieve grid independence. The final grid consisted of 950,000 cells.

B. Numerical Procedure

The conservation equations of mass and momentum were solved through the commercial CFD code, FLUENT 6.3.

The equations were discretised using the finite volume approach with a third order accurate QUICK scheme while the pressure-velocity coupling was resolved through the SIMPLE method. Flow rates ranging from 4L/min to 15L/min were used. At these flow rates, the flow regime has been determined to be laminar [7, 9-11]. A quasi-steady flow rather than a cyclic unsteady flow was used based on the Womersley number, α and the Strouhal number, S which are 1.68 and 0.01 respectively.

Trajectories of individual particles can be tracked by integrating a force balance equation on the particle. This force balance involves the particle inertia balanced by forces acting on the particles, and can be written as,

$$\frac{du_i^p}{dt} = F_D + F_g + F_i \tag{1}$$

where F_d is the drag, F_g is the gravity term, and F_i is additional forces. For micronparticles, F_D is given by

$$F_D = \frac{18\mu_g}{\rho_p d_p^{\,2}} \frac{C_D \,\mathrm{Re}_p}{24} \left(u_g - u_p\right) \tag{2}$$

For nanoparticles, a form of Stokes' drag law [12] is available. In this case, F_D is defined as,

$$F_D = \frac{18\mu}{d_p^2 \rho_p C_c} \left(u_i^g - u_i^p\right) \tag{3}$$

Additional force terms F_i such as Brownian diffusion, Saffman's lift force and thermophoretic forces are applied.

III. Results

Velocity vectors within the nasal cavity airway are shown in Fig 2. The airflow enters the nostrils and immediately begins to accelerate as the vestibule narrows into the nasal valve. The flow increases at the nasal valve where the cross-sectional area is smallest and reaches a maximum (Figure 5a, b and c). Entering the atrium and the velocity decreases as the nasal cavity opens up. The flow remains along the middle and lower regions of the nasal cavity and close to the septum walls rather than diverging out towards the outer meatus. A region of recirculation appears in the expanding region of the cavity near the top (olfactory region) at cross-section A. At the nasal pharynx the velocity increases once more with a decrease in area. Low flow in the olfactory region may be a precautionary mechanism of the nose to prevent particles from damaging the olfactory nerves while still allowing vapor deposition for olfaction.

The inertial deposition of micron particles in the nasal cavity was normalized by using the inertial parameter, $I=Qd^2$, where Q is the air flow rate and d is the equivalent aerodynamic diameter. It is a convenient parameter that compares deposition against different flow rates and particle sizes at aerodynamic diameters. It is widely used for presenting particle deposition efficiencies, especially for in vivo data, where it is difficult to determine an adequate characteristic length for realistic human airways. Monodispersed particles in the range of 1-50μm were released passively into the nasal cavity with flow rates between 4-

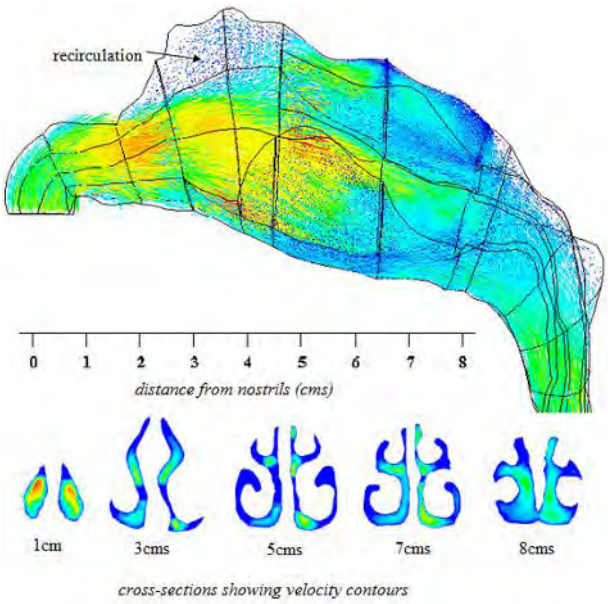

Fig. 2 Airflow patterns colored by velocity. Blue regions represent minimum velocity while red represents maximum velocities.

14L/min. The deposition of micron particles as a function of the inertial parameter is shown in Fig 3. The simulated micron particle deposition in the present nasal cavity model was compared with experimental data that used other nasal cast models.

Generally, the simulated data show reasonable agreement with the experimental data. Differences in deposition may be attributed to the inter-subject variability between the nasal cavity models, such as wider nasal replicate casts which can cause less deposition due to secondary flows [13].

The diffusional deposition of submicron particles (1 to 150nm) was simulated under a flow rate 10 L/min (Fig 4).

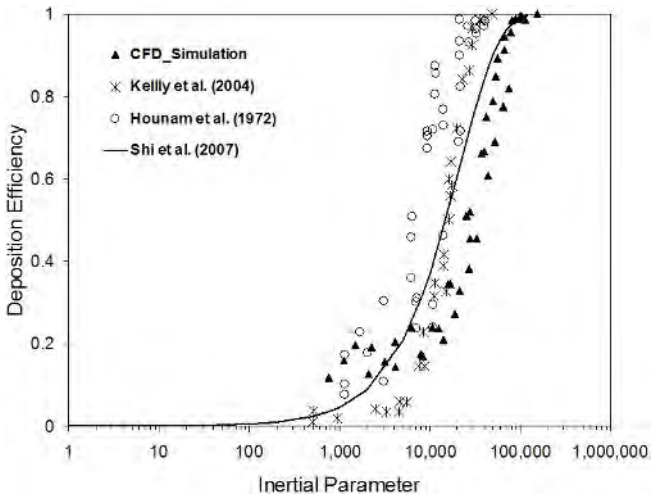

Fig. 3 CFD simulation results for total deposition of particles against Inertial Parameter compared with the experimental data.

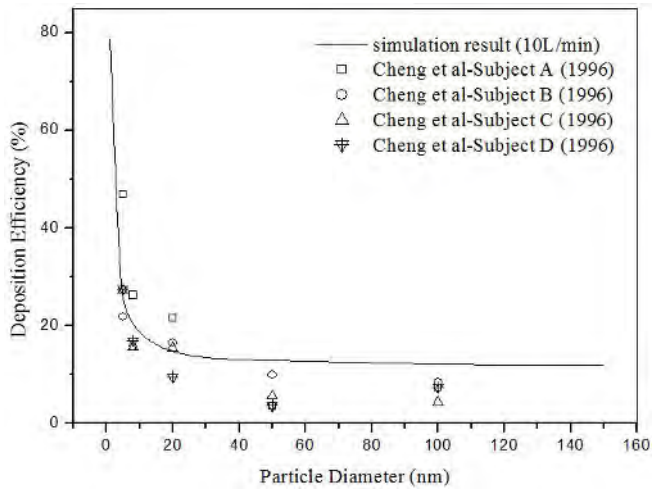

Fig. 4 Comparison between simulation and experimental data of nasal deposition efficiency for different nanoparticle size at a flow rate of 10 L/min

Comparisons of the simulated results were made with the available experimental data reported by Cheng et al. [2] for nasal cavities with different anatomical features. Here the solid lines correspond to the model prediction.

High deposition reaching 80% and nearly 100% were found for 1nm particles. High deposition by is found for particles up to approximately 50nm where particles that are larger provide little change in the total deposition. The deposition for 50nm or larger particles is approximately 10%. The comparisons with the data of Cheng et al. [2] show similar values. As discussed earlier, differences in the results may be attributed to anatomical variances in the nasal cavities used.

Local deposition patterns for a nano (1nm) and a micron particle (22μm) were compared, where the two particle types exhibited the same deposition efficiency. The discrete particles were tracked and the fate of each particle recorded. A particle was deemed to have deposited if its trajectory impacted onto the wall surfaces, otherwise the particle escaped through the outlet. The deposition pattern of a 22μm particle with the density of 1000 kg/m^3 (Fig 5a) shows most of the particles depositing in the anterior and middle regions of the nasal cavity. The upper region of Zone 2 (defined in Fig 1) is a 'hot spot' for deposition. This may be explained by the 90^o curve in the nasal geometry from the nostril inlet into the main nasal passage. The 22μm particles that were initially entrained in the flow path at the inlet are not able to change its flow direction because of the particle inertia, which leads to impaction in the upper region of Zone 2. The inertial impaction caused by the 90º bend is found again in the posterior region of the nasal cavity where the flow changes direction from the main nasal passage towards the larynx. A small hot spot for deposition is found near the nasopharynx. Other concentrated deposition sites are found

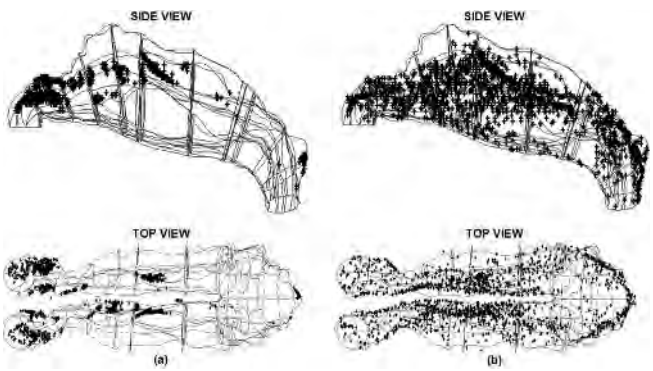

Fig. 5 Local deposition patterns of particles released uniformly from the nostrils for a flow rate of 10 L/min. (a) micron particle having a density 1000kg/m^3 and a diameter of 22μm (b) nanoparticle having a density 1000kg/m^3 and a diameter of 1nm. Both particles exhibit the sane deposition efficiency of 80%.

in the upper regions of the middle sections at Zones 4, 5 and 6. The flow field causes the particles to remain close to the septum walls and is pushed in an upwards direction where the local deposition sites are found.

The deposition pattern for a 1nm particle (Fig 5b) shows a different deposition pattern when compared with the 22μm particle, although the total deposition efficiency is the same (80%) for both particles. The deposited nano particles are distributed more evenly, not only in the entire nasal cavity, but also within each zone. The diffusion mechanism of deposition for 1nm particles disperses the particles in all directions.

The total deposition in the entire nasal cavity is quantified in terms of the total deposition efficiency (*TDE*) as:

$$TDE = \frac{\text{Number of deposited particles in the nasal cavity}}{\text{Number of particles entering the nasal cavity}}$$

The local deposition efficiency (*LDE*) is calculated for each of the ten subdivided zones presented in Fig 6. For better comparisons between the different zones, the *LDE* takes into account the zone surface area since the each zone exhibits different sizes.

$$LDE = \left(\frac{\text{Number of deposited particles in local region}}{\text{Number of deposited particles in the nasal cavity}}\right) \Big/ \left(\frac{A_{zone}}{A_{total}}\right)$$

Fig 6 shows the deposition fraction in each zone for the two particle types. The LDE normalised by the zone's surface area shows a high concentration of particle deposition for 22μm particles in zone 2. Besides the high concentration of deposited particles in Zone 2, the spread of deposited particles among the other zones are generally even, except for Zone 7 and 8 which has very little deposition. In comparison the deposition pattern for the 1nm particle shows a uniformly distribution of particle deposition.

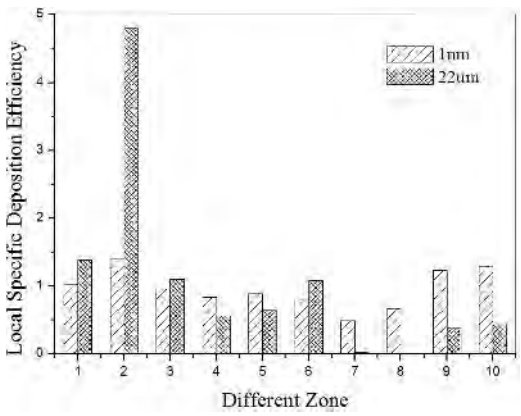

Fig. 6 Deposition patterns of 1 nm and 22 μm at inspiratory flow rate of 10 L/min. (density=1000 kg/m3, Total deposition efficiency=80%)

IV. Conclusion

A comparative study of the deposition of submicron particles and micron particles under different steady laminar flow rates by using the Lagrangian approach was presented. The significance and influence of different force terms that are applicable to micron and submicron particles were discussed and the local deposition patterns presented. It was found that the particle diameter has substantial influence on deposition patterns for both the micron particles and submicron particles. The total deposition efficiency of the micron particles increase as the particle diameter increases, while the inverse is true for submicron particles. Overall there is a difference in the local deposition patterns for micron and submicron particles. The major regions of deposition for micron particles were found to be at the anterior and middle parts in the nasal cavity while for submicron particles there was a uniform distribution of deposited particles.

Comparative Study of the Effects of Acute Asthma in Relation to a Recovered Airway Tree on Airflow Patterns

K. Inthavong, Y. Ye, S. Ding, J.Y. Tu

School of Aerospace, Mechanical and Manufacturing Engineering, RMIT University, Australia

Abstract — **Two computational models of the airway tree six generations deep were reconstructed from computed tomography (CT) scans from a single patient. The reconstructed models were used to investigate the effects of acute asthma on the airflow patterns, the pressure drop, and the implications it has on targeted drug delivery by using Computational Fluid Dynamics (CFD). Comparisons in the geometry found that bifurcation angles do not vary significantly between the two models; however small changes were observed which may be due to the physical scans of the patient taken at different times. The inhalation effort to overcome airway resistance in the asthma affected model was twice as high as that for the recovered model. It was also found that airflow patterns were significantly different between both models especially in regions where the effects of asthma were significant.**

Keywords — **asthma, airway, airflow, cfd, modeling**

I. Introduction

Experimental studies with human subjects have shown that patients with asthma have an effect on deposition of inhaled particles [1, 2]. Since the nature of in vivo studies is invasive CFD studies provide an alternative approach. However most of these computational studies have considered airflow patterns affected by tumors, and airway constrictions associated with chronic obstructive pulmonary disease (COPD) in localized subregions of the lung airways [3, 4]. The work by Longest et al.[5] however, included double bifurcation models of upper (G3–G5) and central (G7–G9) airways for a four-year-old child where the effects of asthma was modeled as a 30% constriction of the airway. In all the above studies, lung subregions of interest were reconstructed from Weibel [6]'s model and airway constrictions were modeled by decreasing the airway diameters artificially from experimental data.

Additionally the majority of airflow studies have been based on regular dichotomy airway models (symmetrical or idealized geometries) or lung segments (single, double and triple bifurcations) which lack realism and detailed flow structures. There have been a few studies that have studied an irregular dichotomy airway model [7, 8]. One advantage of using a realistic model is the inclusion of the effects of cartilaginous rings present in the trachea and early bifurcations. Two computational models of the airway tree six generations deep were reconstructed from computed tomography scans from a single patient. The first scan was taken a day after an acute asthma episode while the second scan was taken thirty days later when the patient had recovered.

II. Method

A. CT scans and Image Segmentation

The reconstruction of the airway was based on data obtained from CT scans of a 66 year old non-smoking Asian male (height 171 cm and weight 58 kg) using a helical 64 slice multidetector row CT scanner the day after hospital admission with an acute exacerbation of asthma. At the time, his lung function by spirometry (Spirocard, QRS Diagnostic, USA) showed severe airflow obstruction with a forced expiratory volume in 1 second (FEV1) of 1.02L (41% predicted). Data was acquired with 1-mm collimation, a 40-cm field of view (FOV), 120 kV peak and 200 mA. At baseline, 2 cm axial length of lung caudad to the inferior pulmonary ligament was scanned during a single full inhalation total lung capacity breath-hold, which yielded 254 contiguous images (slices) of 1-mm thickness with voxel size of 0.625 x 0.625. An identical protocol was used to acquire images following recovery 30 days later, when his FEV1 was measured at 2.27 L (91% predicted). The two computationally reconstructed models were then

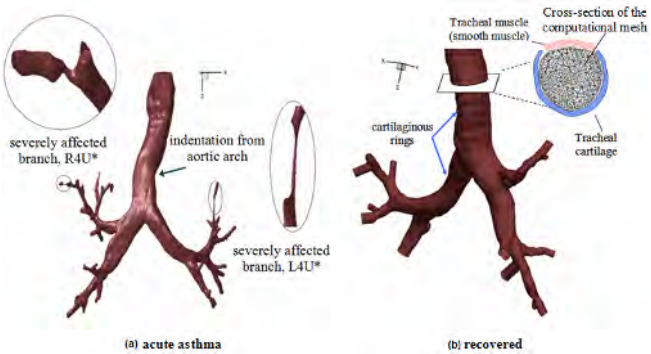

Fig. 1. (a) Front view of the acute asthma affected airway. (b) Reverse view of the recovered model showing the presence of the tracheal cartilage rings and the airway smooth muscle. *The naming convention for the branches is found in Fig.2.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1555–1558, 2009
www.springerlink.com

identified as the AA-model (acute asthma model) and the REC-model (recovered model).

To obtain the source data from medical images, the 'locally constrained watershed algorithm was used to address the issue of leakage during the image segmentation stage [9]. Leakage can occur when the wall of the airway that separates the surrounding tissues is relatively thin and noise present in the image causes the segmentation algorithm to "grow through" the wall. The resulting triangulated data points, (called cloud points) of the generated airway tree that lie on the airway surface are then fitted by applying the NURBS approach within the software Geomagic Studio and stored as an IGES file. Based on the IGES file, the commercial software CATIA (Dassault Systemes) was used to segment the model in terms of trachea, bifurcation and outlet. For the acute asthma model two branches were severely affected by the airway narrowing (Fig.2). These branches were modified and plugged at its ends which acted as a blocked airway. In terms of CFD modeling this was necessary as it is difficult to apply a suitable computational mesh on such small dimensional narrowed geometries.

B. Numerical Modeling

Using the meshing software GAMBIT 2.2 (Ansys Inc.), a mesh file was produced, which was then read into FLUENT 6.3 (Ansys Inc.). For this study the trachea was extended to allow the flow to develop naturally so that a more accurate inlet profile at the trachea was formed, rather than using a uniform profile. A flow rate of 15L/min was applied at the inlet, which corresponds to a Reynolds number of 1079. The low flow rate provides the advantages of simpler modeling by assuming a steady laminar flow. The flow regime has been considered as laminar or lightly transitional at flow rates of 28-30L/min (Re~2000-2500) [10, 11]. A steady flow was applied based on a variety of criteria such as the Womersley parameter, $\alpha = D/2(\omega/\nu_g)^{0.5}$ and the Strouhal number, $S = \omega D/u_{ave}$ where u_{ave} is the mean velocity, ω is the angular frequency of oscillation (=$2\pi f$), D is the diameter of the tube and ν_g is the viscosity.

Homogeneous outflow conditions were assumed where the mass flow was evenly distributed across each of the outlets. Furthermore, the outlets were artificially extended downstream given by, $L_{extension} = 0.05\,\mathrm{Re}\,D$ to obtain fully developed profiles and hence avoid any reverse flow that may be caused due to an abrupt end to the flow field. The computational model underwent grid refinement in order to achieve grid independence with the final model consisting of 1.3million cells.

The numerical schemes to solve the conservation equations of mass and momentum for the air flow under steady-state, isothermal, and incompressible conditions included the third-order accurate QUICK scheme for discretization, and the SIMPLE algorithm for the pressure–velocity coupling. The convergence criteria for the air flow properties (resolved velocities and pressure) were set at 10^{-5}.

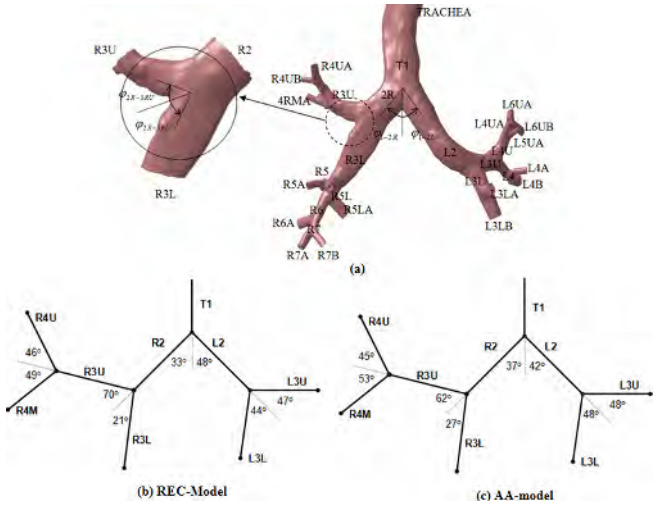

Fig. 2 (a) Bifurcation branch angle definition and diagram with branch name. Bifurcation angles with the main bronchial branches are given for the (c) Recovered Model and (d) the Asthma Affected model.

III. Results

A. Airway Geometry Comparison

The reconstructed model of the bronchial tree exhibits an asymmetric dichotomous branching pattern. The bifurcation at the carina produces the right main bronchus (R2, 41°) at a more obtuse angle than that of the left main bronchus (L2, 25°) measured by the interbronchial axis (centerline of the bronchus) with the long axis of the trachea. The sum of the two daughter branching angles (i.e. R2+L2 = 66°) form the tracheal carinal angle which compares with a mean value of 73° from a sample of 65 men and 55 women; age range 17–85 years; mean age 56 years [12] and 63° for a sample of 21 patients with an age range of 51-60 years [13]. Overall the bifurcation angles do not vary significantly between the AA-model and the REC-model, however small changes are observed which may be due to the scans which were taken of the patient thirty days apart where the positioning and inhalation may have differed.

Normalised velocity profiles (Fig.3) in the trachea and main bronchi were taken and compared with experimental data from a 3:1 scaled up acrylic plastic model of the human central airways [14]. The development of the profiles has been discussed in the publication by [14] and is not reported

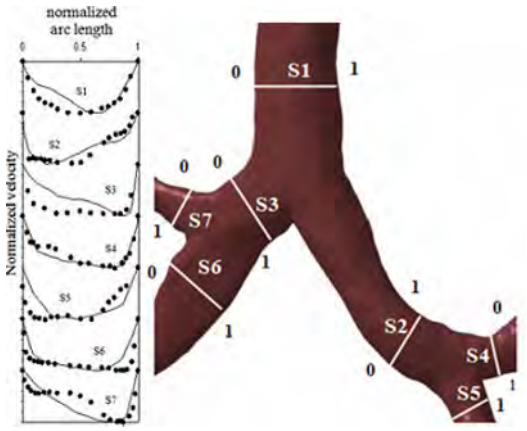

Fig. 3 Normalized axial velocity profile plotted as a function of the normalized arc length. The experimental data of Menon et al. (1984) are plotted as (●) for the corresponding locations.

here for brevity. However, local flow patterns are discussed in detail later in this report. The numerical results generally have good agreement with experimental results in terms of characteristic features. Some differences are found due to the inherent differences in the geometries used. For example at S1 the CFD results show a skewed velocity profile which is a result of the indentation from the aortic arch as well as the trachea cartilages. It can also observed that the tracheal bifurcation at the carina ridge produces a biased profile towards the inner walls of the subsequent daughter branches (S2, S3) due to the upstream flow momentum.

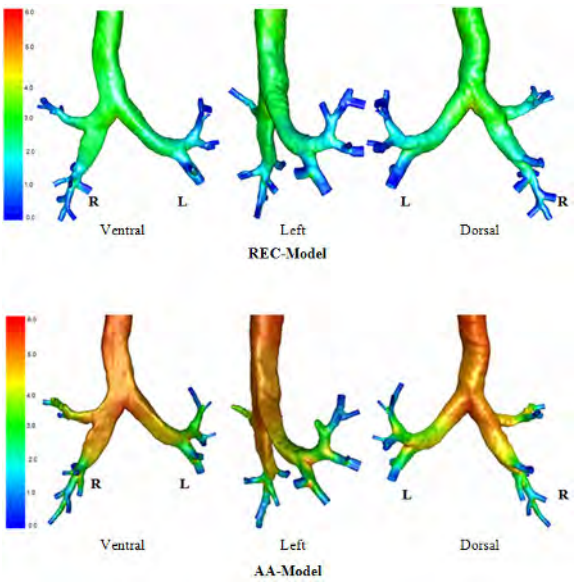

Fig. 4 Pressure contour plots. The pressure value is the pressure difference between the local regions with a reference pressure at the outlets.

B. Pressure Distribution

Contours of the total pressure in reference to the outflow pressure are shown in Fig.3. The required pressure difference at the inlet for the AA-model was 5.98 Pa, which is nearly twice the value for the recovered model (3.73 Pa). Along the main bronchus the pressure decreases steadily while there is a definite pressure drop from each main branch into the subsequent daughter branch. This is due to the bifurcation ridge where a local maximum occurs as a result of a build up of pressure, similar to a stagnation point. In the AA-model the constriction of some branches effectively reduce the number of flow paths by two as the constriction in L4U and R4U is so great that no flow passes through. Greater resistance is found in the AA-model because of the reduced cross-sectional areas in the AA-model.

C. Local Flow Features: Main Bronchus Bifurcation

Crossflow streamlines overlayed on contours of axial velocity at cross-sections a-a' to f-f' are shown in Fig.4. The cross-sectional views are taken from the upstream flow point of view looking downwards in the axial direction. The three cross-sections preceding the bifurcation (a-a', b-b', and c-c') depicts the flow before it bifurcates at the carina. Regionally the flow is concentrated on the left lateral wall due to the indentation by the transverse portion of the aortic arch. The streamlines are directed to the right side in response to the concentrated flow on the left wall. At b-b' the streamlines are moving towards the ventral side and at cc' just before the bifurcation, the flow begins to divide into the left and right side with ventrally. In the AA-model the axial contours are more evenly distributed. The effect of the aortic arch indentation is less significant, however after the indentation the streamlines are directed to the left side of the airway. Just prior to the bifurcation, the flow divides and the streamlines are moving more laterally than in the REC-model. Following the flow through the right main bronchus (d-d'), of the REC-model the bulk flow remains close to the inner wall side with the flow momentum shifting towards the outer wall as characterized by the streamlines. In the left main bronchus at e-e', the flow is found on the inside wall and a region of recirculation is present in the low axial flow region due to: i) the upstream velocity profile that is biased to the left side, ii) a more obtuse bifurcation angle that curves laterally producing a centrifugal acceleration, and iii) the critical carina geometry. The bifurcation of the left main bronchus into the upper lobe bronchus (L3U) occurs laterally, extending to almost the horizontal, while the lower lobe (L3L) is more directly in line with the main bronchus.

This leads to a high distribution of slow passing through the L3L. The AA-model shows some differences in airflow

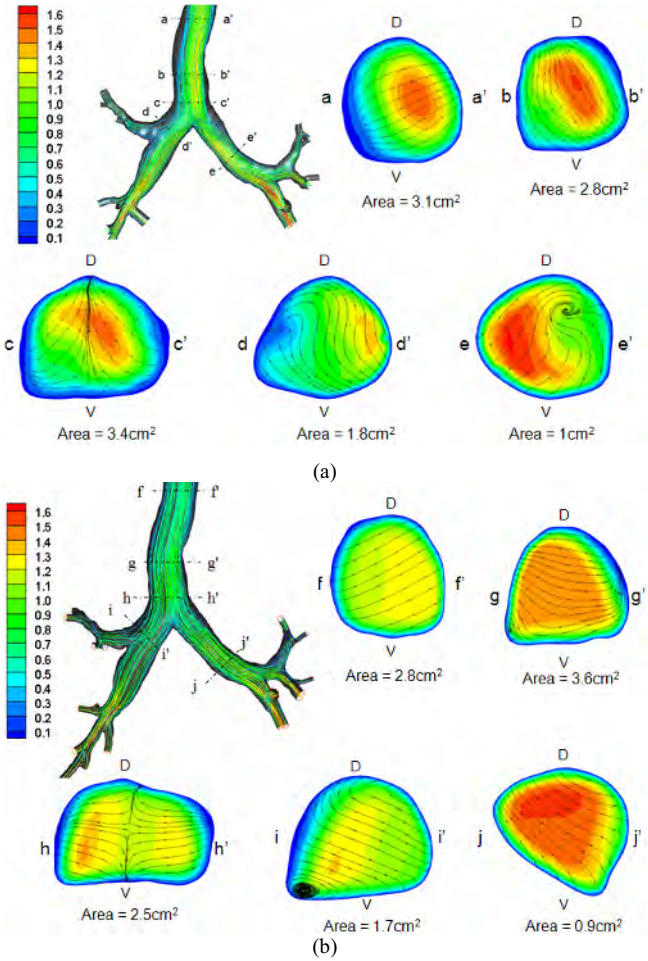

Fig. 5 Cross-flow streamlines overlayed onto axial velocity contour plots at specified cross sections in the main bronchi of the (a) REC-model (b) AA-model.

patterns particularly at i-i' and j-j'. The streamlines in left main bronchus (j-j') suggest that the flow is moving from the ventral to dorsal direction while locally the maximum axial velocity exists in the dorsal region. The main difference in the airway geometry is the presence of a narrowed rounded ridge on the ventral side. The geometry of the right main bronchus (i-i') has a flat ventral profile and high axial velocity is found more centrally in the cross-section. A region of recirculation appears in the left ventral region. It is interesting that recirculation regions are found within the first two branches after the carina for both models.

IV. Conclusion

It was found that bifurcation angles do not vary significantly between the AA-model and the REC-model, however small changes are observed which may be due to the scans which were taken thirty days apart where the positioning and inhalation may have differed. The required pressure difference at the inlet for the AA-model was 5.98 Pa, which is nearly twice the value for the recovered model (3.73 Pa). This suggests that during the period of an acute asthma episode, the work of breathing for the patient in order to achieve the same tidal volumes, is double compare to the recovered state, which can lead to respiratory muscle fatigue. Local flow patterns showed that the changes in the airway had significant influence on flow patterns. This is especially true in the region where the airway narrowing is most severe. This means that studies of therapeutic drug delivery in the airway should consider the effects of airway narrowing and not a recovered or a healthy airway.

Computational Analysis of Stress Concentration and Wear for Tibial Insert of PS Type Knee Prosthesis under Deep Flexion Motion

M. Todo[1], Y. Takahashi[1] and R. Nagamine[2]

[1] Research Institute for Applied Mechanics, Kyushu University, Kasuga, Japan
[2] Yoshizuka Hayashi Hospital, Fukuoka, Japan

Abstract — **3-D finite element model of a typical PS type knee prosthesis was constructed using its CAD data with use of a nonlinear spring model and an analytical load data for deep squatting. Stress analysis was then performed by an explicit finite element method under continuous deep flexion motion. It was shown that the equivalent stress on the Post surface rapidly increases due to the Post/Cam contact. Severe stress concentration is also generated on the surface. This kind of stress concentration may cause damage and failure of the Post. Wear analysis was also performed based on the results of the stress analysis and the classical wear theory. Wear depth was then estimated and the analytical result suggests that the developed FE model is useful for risk assessment of knee prostheses.**

Keywords — **Total knee arthroplasty, UHMWPE insert, Deep flexion, Wear, Finite element analysis**

I. Introduction

Total knee arthroplasty, TKA, is applied to patients with severe osteoarthritis as a final treatment to recover the function of the injured knee. In general, QOL of the patients is dramatically improved by obtaining knee movement without pain after TKA. Although the mobility of knee prosthesis is being improved through design modification, there are still some demands for knee prosthesis such as higher durability of tibial insert. It is therefore needed to understand the detail of movements of operated knee after TKA, and such information should be reflected to the design of knee prosthesis. It is however very difficult to understand the detail of TKA knee motion because of its complex movements characterized as a combination of flexion, rotation and roll-back. Fatigue fracture and severe wear of tibial inserts are sometimes reported, and they are thought to be strongly related to the stress states under such complex knee motions.

PS type knee prosthesis is known to be used in a typical type of TKA where anterior and posterior cruciate ligaments are removed. PS type prosthesis is characterized by the existence of Post-Cam structure to stabilize the knee movement through Post-Cam contact. In this type of prosthesis, failure and wear of the Post of the tibial insert are important problems and therefore, there is a demand for understanding the stress state of the tibial insert during knee motion. Under such circumstances, three-dimensional finite element method (FEM) has been utilized to characterize the 3D stress state of knee prosthesis.

In the previous studies of FEM simulations of TKA, most of them were aimed to analyze stress states under walking conditions with shallow flexions [1,2-5,8], and a few attempts have been made to analyze stress state under deep flexion [9-11]. The author's group recently developed simple 3D-FEM models using CAD data of knee prostheses clinically used, and investigated effects of deep knee flexion on the stress state of the tibial inserts [10-12].

In the present study, the FEM model was used to analyze a typical PS type knee prosthesis in order to characterize the stress state of the tibial insert under deep flexional motion. The model was also utilized to analyze the wearing process of the insert and then wear depth was compared with the stress state during flexional movement.

II. Finiteelement model

CAD model of a PS type knee prosthesis (Stryker Scorpio Superflex [6]) is shown in Fig.1. A 3D-FEM model consisting of femoral component, tibial component and tibial insert were constructed from the CAD data. Finite element meshed model is also shown in Fig.1. Tetorahedral elements were used, and the numbers of the nodes and the elements were 21958 and 89322, respectively. The tibial insert originally made from a thermoplastic polymer UHMWPE was assumed to be an elastic-plastic material and to follow the von Mises yield criterion. The bi-linear stress-plastic strain relationship experimentally obtained is shown in Fig.2 [7]. The metal femoral and tibial components were assumed to be rigid in order to reduce computational time. The friction coefficient between the femoral component and the tibial insert was chosen to be 0.04 [5]. It was assumed that the back surface of the tibial insert was perfectly connected to the top surface of the tibial component.

Reactional and frictional forces are generated on the contact surfaces of a TKA knee with PS prosthesis during flexional motion. In this TKA knee, these forces are balanced with the tensions of the soft tissues existing around the knee; as a result, for example, anterior-posterior move-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1559–1563, 2009
www.springerlink.com

ment (roll-back motion) occurs. In the present FEA model, a nonlinear spring model was utilized to express this movement [8]. Two spring elements were attached in the front of the tibial component and the two in the back as shown in Fig.3. The nonlinear force -displacement relation is given by

$$F = 0.18667d^2 + 1.3313d \quad (1)$$

where F and d are force and displacement, respectively. It is noted that this nonlinear relation was experimentally determined from a knee with removed anterior and posterior cruciate ligaments [8].

The axis of flexion was assumed to be located in the center of the circle which coincides with the shape of the condylar surface of the femoral component as shown in Fig.4. For the femoral component, only the displacement in the Z-direction was free and the tibial component was able to move freely only in the Y-direction. Load data used as the mechanical boundary condition was referred from Ref. 2 in which load data for rapid deep squatting was analytically obtained using 2 dimensional model of human knee considering muscular forces. The load F_N and F_T were applied to the femoral component in the vertical direction (Z-direction) and to the tibial component in the horizontal direction (Y-direction), respectively, as shown in Fig.4. The relationship between the load data and the flexion angle were shown with the body force used in the analysis in Fig.5.

Wear analysis was also performed on the basis of the stress analysis. From the classical wear theory, the wear

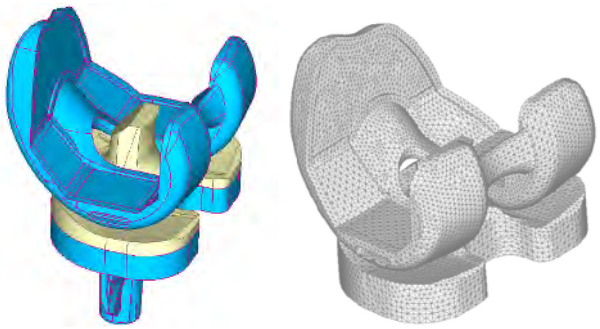

Fig. 1 CAD and FEM models of PS type knee prosthesis.

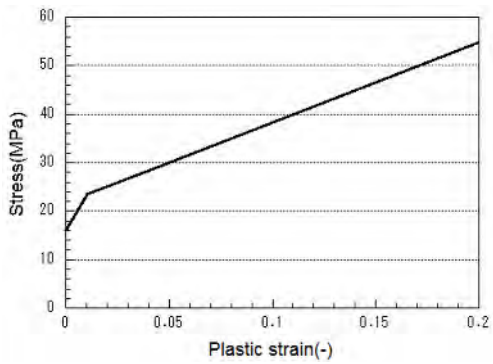

Fig. 2 Bi-linear stress-plastic strain relation.

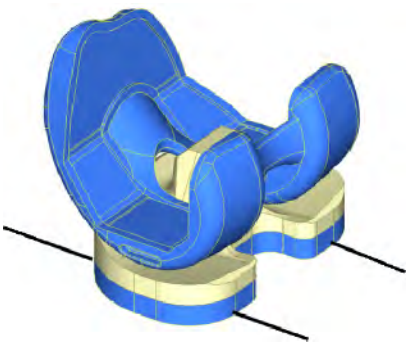

Fig. 3 Computational model with nonlinear springs.

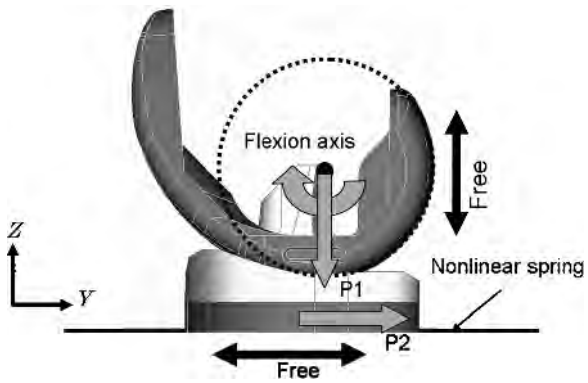

Fig. 4 Boundary conditions.

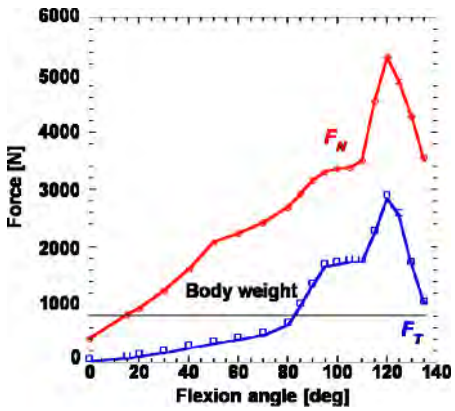

Fig.5 Force data used as mechanical boundary condition.

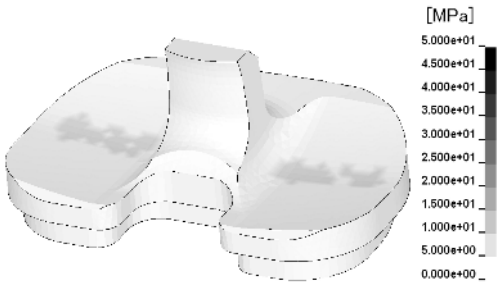
depth δ_{wear} after n increments can approximately be expressed as

$$\delta_{wear} = k\sum_{i=1}^{n} p_i |v_i| \Delta t \tag{2}$$

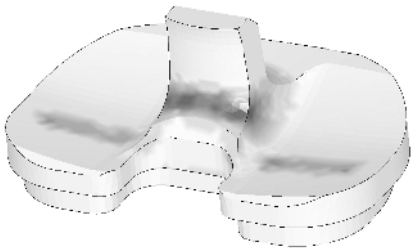
Where k is the constant, p_i the contact pressure, v_i the sliding velocity and Δt the time interval of an increment [13]. k was chosen to be $220\text{x}10^{-9}$ mm^3/Nm. v_i was assumed to be given by

$$|v_i| = \left[(v_{F-comp,z})^2 + (v_{F-comp,y} - v_{T-comp,y})^2\right]^{1/2} \tag{3}$$



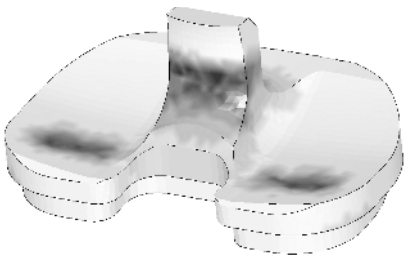
Where $v_{F\text{-}comp,z}$ and $v_{F\text{-}comp,y}$ are the z- and y-components of the maximum velocity of the femoral components on the contact region. $v_{T\text{-}comp,y}$ is the y-component of the maximum velocity of the tibial component. Δt was 0.01 msec in this analysis. p_i and the velocity components were evaluated from the stress analysis and then δ_{wear} was calculated by using Eqs(2) and (3).

A commercially available pre-processor FE-MAP was used to develop those 3D-FEM models including from the surface data, meshing and setting up of the boundary conditions. A commercial explicit finite element code LS-DYNA was then utilized as solver, and a post-processor LS-POST was used to analyze the results.



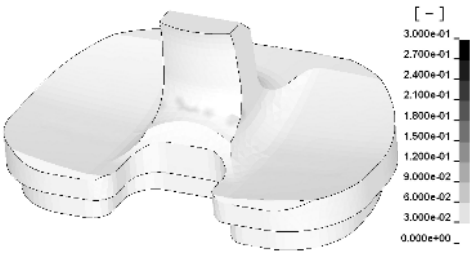
III. Results and Discussion

Von Mises equivalent stress distributions on the surfaces of the tibial insert at three different flexion angles are shown in Fig.6. At 45 deg, stress concentrations are only observed on the condylar surfaces. Contact between the Post and the Cam starts at about 65 deg, therefore, at 90 deg, stress concentrations appear on both the condylar and the Post surfaces. It is seen that the stress on the condyle increases with increase of flexion angle, and the stress on the Post is much higher than the condyle. At 135 deg, the stress further increases and the maximum value becomes about 51.2 MPa. Thus, the high concentrated stress much higher than the yield strength of UHMWPE may cause failure and wear of the tibial insert, especially, the Post.

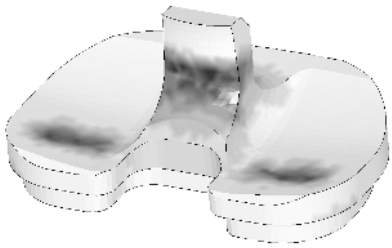


Equivalent plastic strain distributions at 90 and 135 degrees are shown in Fig.7. At 90 deg, plastic strain is distributed slightly on the Post. At 135 deg, plastic deformation region is dramatically extended and plastic strain is distributed on both the condyle and the Post. This result suggests that the tibial insert is plastically damaged under deep knee flexion and such plastic damage is accumulated under repeated flexions.

(a) 45 deg (σ_{max}=10.23 MPa)



(b) 90 deg (σ_{max}=32.68 MPa)



(c) 135 deg (σ_{max}=51.16 MPa)

Fig. 6 Equivalent stress distribution.

Distribution of wear damage is expressed by wear depth in Fig.8. At 45 deg, wear is distributed only on the center of the condyle. At 90 deg, the wear region on the condyle becomes larger and wear is also slightly distributed on the Post. The wear region on the Post becomes larger at 135 deg, and furthermore, wear is distributed on the rear part of the condyle in addition to the center. This clearly indicates that wear damage region extends from the center to the rear on the condyle as flexional motion progresses. It is thus noted that the wear analysis procedure developed in the present study may be able to predict wear damaged region that is different from the concentration regions of equivalent stress and plastic strain. Further study is needed to insure the validity of the wear analysis procedure.

IV. Conclusions

3D FEM model of PS type knee prosthesis clinically used worldwide was constructed from its CAD data. Stress state under deep knee flexion such as squatting was analyzed by using the explicit finite element method. Wear analysis was also performed based on the results of the stress analysis. The conclusions are summarized as follows:

(1) A simplified 3D-FEA model of PS type knee prosthesis for deep knee flexion analysis was developed by using nonlinear spring model and load data for deep squatting. High stress concentration due to the Post-Cam contact was reasonably expressed at deep flexion angles and furthermore, roll-back behavior was well simulated by introducing the nonlinear spring model.

(2) Stress concentration on the Post surface is very high, suggesting that failure and wear of the Post under repeated flexional motions.

(3) Wear depth is reasonably predicted by using the classical wear theory and the results of stress analysis. Wear is extensively generated on both the condylar and the Post surfaces.

Push-Pull Effect Simulation by the LBNP Device

J. Hanousek[1], P. Dosel[2], J. Petricek[1] and L. Cettl[1]

[1] Institute of Aviation Medicine/Department of Technical Development, Prague, Czech Republic
[2] Institute of Aviation Medicine/Department of Flying Safety, Prague, Czech Republic

Abstract — **LBNP (Lower body negative pressure) examination technique was initially applied in our case entirely as one of the possibilities for preliminary indirect individual estimation of the pilot's positive gravitational acceleration (+Gz) tolerance. At present LBNP exposition is also used as a method of drill in anti-g maneuvers and for the simulation of the so-called Push-Pull effect. Pilot's +Gz tolerance can be affected by in particular the Push-Pull phenomenon. It is characterized by the rapid and significant decrease of blood pressure values accompanied by a slower return to normality as a result of compensation reaction. The tolerance decrease to the +Gz acceleration turns up during flights in aircraft in situation of +Gz action after previous impact of the negative acceleration. Just the slower return of blood pressure to the standard value after its previous rapid decrease is very dangerous reality during flights. At this period pilot's performance is reduced and an impairment of the vision and G-LOC can occur.**

Keywords — **Pilot's ±Gz tolerance, LBNP examination, Push-Pull effect, blood pressure measurement, anti-g maneuvers.**

I. Introduction

Flights with alternating ±Gz acceleration in a cockpit of agile aircraft with high maneuvering capabilities invoke a cardiovascular response of the organism named a Push-Pull effect [1, 6, 8, 9]. This phenomenon is characterized by the rapid and significant decrease of blood pressure accompanied by a slower return to normality as a result of compensation reaction. Particularly the slower return of blood pressure to the standard value after its previous rapid decrease is a very dangerous factor during flights.

Our LBNP device was reconstructed in order not only to allow estimation of the +Gz tolerance level but also to find pilots with low tolerance to the Push-Pull effect. We developed the new LBNP examination method with the simulation of the Push-Pull effect that is an important training stage preceding pilots' centrifuge training. Blood pressure is a significant parameter reflecting the cardiovascular regulation level and it responds very sensitively to the LBNP exposure. Blood pressure changes during LBNP exposition correspond very well to in-flight Push-Pull effect [2, 3, 5, 6].

II. Materials and methods

LBNP examinations with a Push-Pull effect simulation consists of two stages following one by one. The first stage represents the Push-Pull simulation the second stage corresponds to the standard or so-called isolated LBNP exposure. Push-Pull effect is simulated by means of tilting LBNP device backwards to the −43° HDT (head down tilt) position. There is atmospheric pressure in the LBNP chamber. This first step corresponds to the plateau of microgravity. Pilots remain in this position throughout two minutes. Plus Gz load is created by the rapid LBNP exposition accompanied with a rapid return of the LBNP device to the vertical position. Negative pressure level has the value of −70 mmHg and this value is achieved in one second. The return of the device to the vertical position is accomplished also very rapidly, namely in two seconds. The exposition is finished at the end of the two minutes interval in case of sufficient tolerance. Otherwise, it is finished sooner, of course. The second stage is launched after a two minutes pause. The LBNP examination is accomplished again with one-step exposure to the negative pressure level of −70 mmHg with achievement of this value again in one second. Pilots are examined in the sitting position. As well as in the first stage the exposition is finished at the end of the two minutes interval in case of sufficient tolerance.

As mentioned above LBNP exposition is also used as a method of drill in anti-g maneuvers. A proper practical exercise of anti-g maneuvers is initiated before the end of exposure or upon an indication of cardiovascular system regulation insufficiency. This new LBNP examination method with the simulation of the Push-Pull effect is an important training stage before the demanding centrifuge training.

Blood pressure ranks among the essential physiological data measured during LBNP examinations. Blood pressure which stands for a significant parameter reflecting the cardiovascular regulation level in the orthostatic load responds very sensitively to the LBNP load. Physiological responses of the organism during LBNP examinations are rapid, and therefore measuring continuous finger blood pressure by means of a Portapres device proved to be advantageous [1, 2, 3, 5, 6, 7].

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1564–1568, 2009
www.springerlink.com

Since the finger blood pressure measured by the Portapres device is not always quite close to arterial pressures measured more upstream [4, 7], for example in the radial or brachial artery or in the aorta, we focus on the evaluation of blood pressure relative changes (related to the values before the exposure beginning).

In past we compared pilot's physiological responses to the LBNP, flight and centrifuge load. Physiological responses from the blood pressure and heart rate point of view are in an LBNP examination similar to the +3.5Gz in a human centrifuge and mostly correspond to the gravitational acceleration +4.5Gz during flights in aircraft [1, 2, 3]. At present we compared blood pressure responses of the isolated LBNP load to that of Push-Pull load.

III. Results

Blood pressure changes determine significant information about possible pilot's collapse state. The rapid blood pressure decrease comes into being very shortly after the LBNP exposure at the substandard result group. The rapid decrease of the systolic value is followed by pulse pressure decrease at the same time, too (Fig. 1).

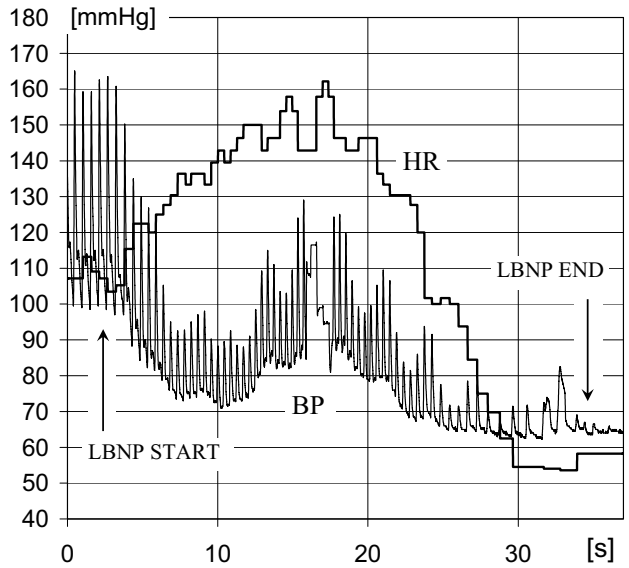

Fig. 1 Blood pressure (BP) and Heart rate (HR) behavior during an LBNP load with a substandard result.

This demonstration is also an occurrence of the bad combination, when systolic blood pressure value and pulse pressure decrease are followed by rapid heart rate drop.

Confirmation of different physiological responses under condition of the isolated LBNP load and Push-Pull load was the essential goal of the statistical evaluation. For this purpose the following blood pressure values (BP) were evaluated at the Czech Air Force pilots during both types of examinations and compared at initial 50 seconds intervals in both examinations:

- BPS0: systolic BP quiescent value just before an LBNP exposure beginning,
- BPD0: diastolic BP quiescent value,
- BPs: minimal attained systolic BP value at the 50s interval,
- BPd: minimal attained diastolic BP value,
- BPSM: maximal attained systolic BP value.

The following parameters (relative changes) were calculated:

- BPS0/BPs, BPS0/BPd, BPSM/BPS0.

The pairs of above listed data were compared for each pilot. All calculated values should be greater in the set with Push-Pull effect. The statistical test was designed to objectively prove that this claim stands good. A method for two independent stochastic selections was chosen, namely the Wilcoxon – White test that confirmed statistical significance on the level $p < 0.01$.

It must be emphasized that all examinations without exception showed a substantially greater blood pressure decrease (BPs and BPd) with its slower recovery to primary values in the phase of Push-Pull simulation in comparison with the isolated exposure. Relative maximal systolic blood pressure values (BPSM) exceeded in the phase of Push-Pull simulation these values achieved in the isolated exposure of all examinations with the good result (sufficient tolerance).

The above suggests that LBNP exposition is also used as a method of training of anti-g maneuvers both strain and breathing anti-g maneuvers. The typical example of the blood pressure changes in an instant of beginning of anti-g maneuvers is in Fig. 2. Such blood pressure improvement means that anti-g maneuvers were mastered well.

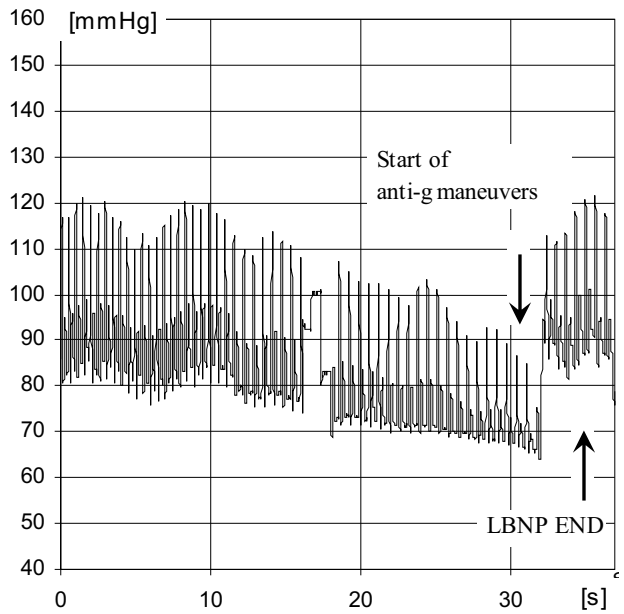

Fig. 2 Blood pressure behavior during an LBNP load with a standard result and with an exercise of anti-g maneuvers.

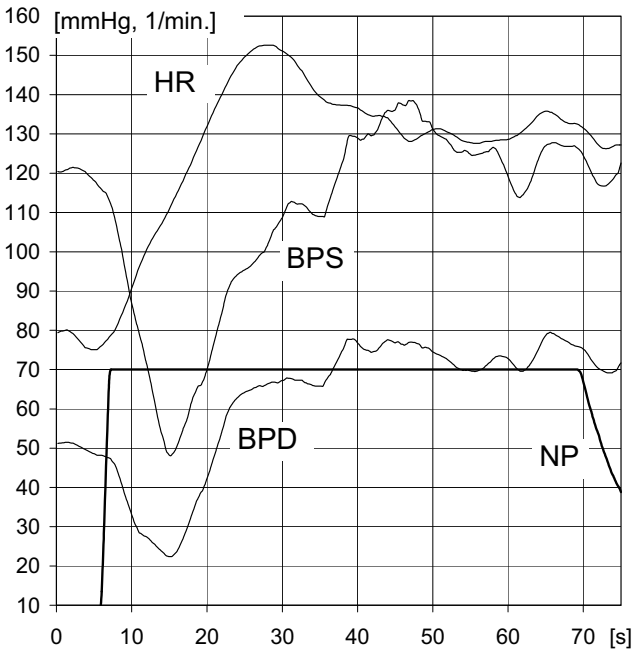

Fig. 3 Typical course of blood pressure (BP) and heart rate (HR) during LBNP exposure with Push-Pull simulation, where: BPS - systolic blood pressure, BPD - diastolic blood pressure, HR - heart rate, NP - negative pressure in the LBNP chamber.

IV. Discusion

An occurrence of sporadic extrasystoles in some cases is a typical manifestation of the cardiovascular system. The occurrence of sporadic extrasystoles can be seen in the pre-collapse state beginning but particularly after LBNP load ending (in an instant of blood volume regressive redistribution - rebound phenomenon). Arrhythmia haemodynamic consequence is immediately seen in continuous blood pressure signal.

A typical course of blood pressure and heart rate at pilots with sufficient cardiovascular regulation during LBNP exposure with the Push-Pull simulation we can see in Fig. 3.

The initial two-minute simulation of the -Gz load in the −43° HDT (head down tilt) position and viscera's shift evoke the enhancement of the parasympathetic nervous system. The rapid changeover to the vertical position and contemporaneous LBNP effect are vigorous orthostatic stimuli. However, reflective orthostatic compensatory mechanisms are weakened and decelerated in the situation of the increased vagotonia. At the same time their effect is significantly reduced. This contributes during first ten seconds of the +Gz simulation to the progressive blood pressure decrease. Heart rate rises up as the compensatory response. Then the blood pressure increase is relatively slow and the achievement of the initial value is only after other more then 20 seconds.

It results from Fig. 3 that +Gz tolerance of the examined subject was critically decreased at the beginning of this simulated +Gz load. It must be emphasized once again that the pilot's performance is considerably reduced during flights in the event of the Push-Pull effect occurrence.

A typical course of blood pressure and heart rate during the standard (isolated) LBNP exposure at the identical individual with sufficient cardiovascular regulation can be seen in Fig. 4 where again all parameters are the same as in Fig. 3. Slower decrease in blood pressure is characteristic of pilots with sufficient tolerance to the orthostatic load. Short-time systolic blood pressure rapid decrease can sometimes occur but it has only short duration.

It is evident in contrast to the previous figure that blood pressure decrease is indeed equally steep at the beginning of the LBNP load but this blood pressure decrease has shorter time duration. The return of blood pressure to initial values is faster than in case of Push-Pull effect. For reasons given the pilot's +Gz tolerance was in no way reduced.

Rapid blood pressure decrease immediately after an LBNP beginning is typical just in case of the insufficient orthostatic tolerance. The worst situation will arise when blood pressure decrease is followed by rapid heart rate drop (Fig. 1). Unless the LBNP exposure is finished the collapse state takes place immediately or very soon.

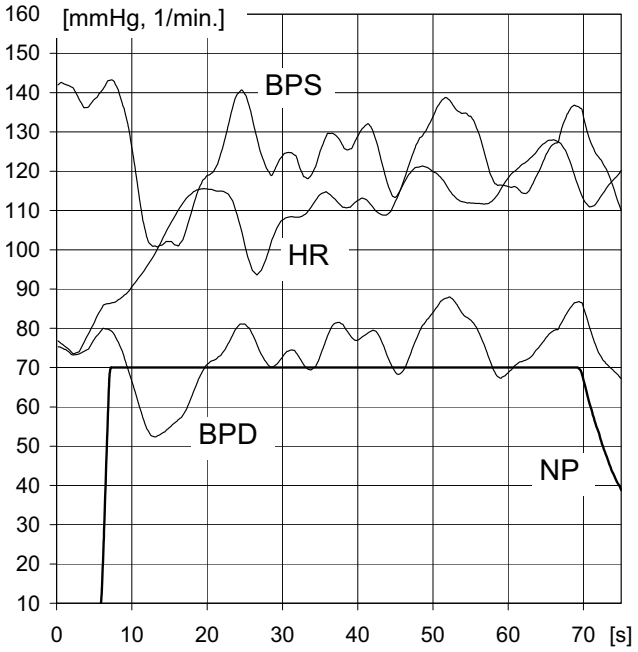

Fig. 4 Typical course of blood pressure and heart rate during standard LBNP exposure.

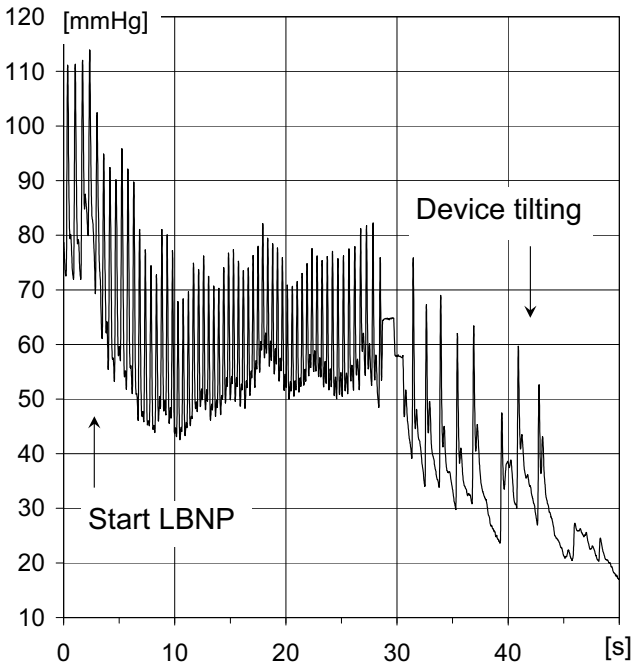

Fig. 5 Blood pressure course in the pre-collapse situation in Push-Pull load.

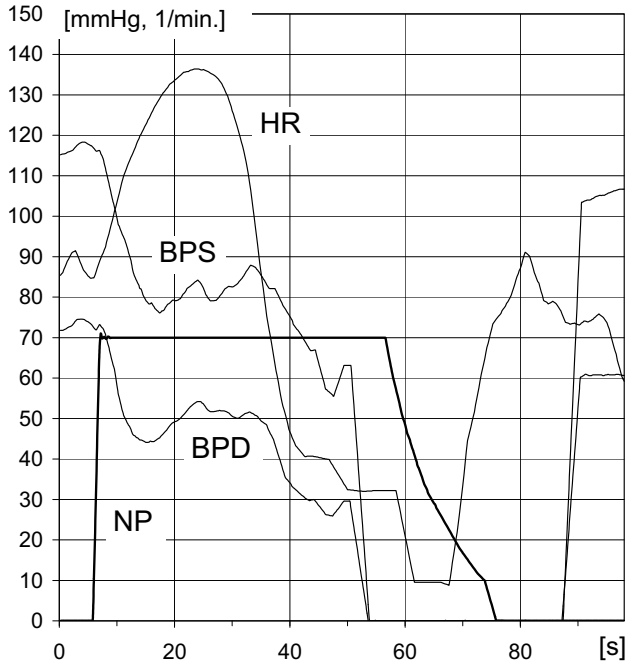

Fig. 6 Blood pressure and heart rate course in the situation of Push-Pull effect and in the event of insufficient tolerance.

Insufficient tolerance to the Push-Pull load brings often on the rapid onset of the collapse state (Fig. 5). The abrupt blood pressure decrease begins immediately after the negative pressure initiation. While heart rate soars during the first 15-20 seconds then in after 15-20 seconds it dramatically falls. The progress of the collapse state accompanied with blood pressure decrease to immeasurable values can arise in short time of the load. The situation in Fig. 6 was joined to the short-lasting (approx 10 seconds) asystolia and consequential bradycardia within the heart rate range of 25/min. to 10/min. The LBNP exposure was finished in 5 seconds from the beginning of the collapse state and the examined person was tilted backwards to the horizontal position. Heart rate soars again during leveling of the atmospheric pressure in the LBNP hypobaric chamber. As well primary value of blood pressure regenerates relatively quickly after the LBNP load ending.

V. Conclusions

The new developed LBNP examination method demonstrates better the impact of the Push-Pull effect on circulatory system efficiency. Negative influence of −Gz acceleration on +Gz tolerance during new examination method is evidently evincible.

Results of all examinations of the group of Czech Air Force pilots prove the statistically more significant decrease of blood pressure values in the phase of +Gz load. Subsequent recovery of cardiovascular parameters (blood pressure and heart rate) in the compensatory stage is delayed, too and it endangers pilots of black-out (G-LOC).

An LBNP exposition is also utilized as a method of drill in so-called anti-g maneuvers. A proper practical exercise of anti-g maneuvers in an LBNP load is initiated before the end of exposure or upon an indication of cardiovascular system regulation insufficiency. At this moment an LBNP exposure is finalized. An instantaneous blood pressure improvement is an indication of the successful mastery of this exercise. Well-timed and correct usage of anti-g maneuvers towards an overloading in highly agile and powerful aircraft is a fundamental assumption of the full exploitation of aircraft whole potentiality.

An Investigation on the Effect of Low Intensity Pulsed Ultrasound on Mechanical Properties of Rabbit Perforated Tibia Bone

B. Yasrebi[1] and S. Khorramymehr[2]

[1] Department of Biomedical Engineering, Islamic Azad University-Tabriz Branch, Tabriz, Iran
[2] Department of Biomedical Engineering, Islamic Azad University- Science & Research Branch, Tehran, Iran

Abstract — **Wide variety of studies in vivo experiments on animals have been shown that the most effective type of ultrasound waves to accelerate fracture healing in osteotomy procedure is LIPUS. In this study the authors investigate the effect of LIPUS on mechanical properties of healed perforated bone. Twenty-four white male New Zealand rabbits that have drilled the right tibia bone of them were used. The rabbits were divided in two groups: treatment and non treatment. The non treatment group was considered as control. The treatment group was exposed to LIPUS (30mW/cm2 spatial and temporal average, for 20 minutes/day). All of rabbits were divided into three parts according to timing (two, four and six weeks post drilling). Animals were killed in other weeks and mechanical properties (ultimate load and stiffness of bending) were measured. Results revealed ultimate load and stiffness were difference (P<0.05) on the treatment group in comparison to non treatment group after four weeks. The studies suggest that LIPUS stimulation could increase the new bone formation and mechanical properties. We concluded that LIPUS is most effective four weeks post drilling.**

I. Introduction

In this study we investigated the effect of Pulsed Low Intensity Ultrasound (PLIUS) on the heal rate of osteoperforated bones. After removal of a fixator, which is commonly used to immobilize long bone fractures, holes in the bone remained from removal of fixator pins or screws reduce the cross sectional area and consequently the mechanical strength of the bone. This may cause a new fracture at the hole site. A non-invasive method to enhance heal rate of perforated bones may reduce the time needed for recovery of the bone after removal of fixator pins and screws.

PLIUS has potentially important effects on the functional activities of connective tissue cells in vitro [1],[2]. The results of in vitro studies suggest that PLIUS lead to an increase in cytocolic Ca^{2+} and activation of calmodulin [3], and enhances the process of endochondral ossification where the soft callus is converted to mineralized hard callus [4].

A large body of evidence confirms the stimulatory effect of PLIUS on fresh fractures, nonunions, and other osseous defects such as osteotomies. It has been shown that PLIUS is highly efficacious in callus formation during rapid distraction osteogenesis [5], enhancement of osteogenesis at the healing bone-tendon junction [6], treatment of nonunion fractures [7], healing of complex tibial fractures in human [8], and distraction osteogenesis in case of delayed callotasis [9]. The effect of ultrasound on healing of osteotomies, as in vivo models of bone fracture, has also been emphasized [10],[11].

Thus far, the effect of ultrasound on healing of drilled osteoperforation is not clear. Repair at bone gaps is very sensitive to the gap size and shape, and wedge surface conditions [12],[13]. Size, shape and especially surface conditions of a hole drilled to a bone differ from that of gaps caused by natural fractures or osteotomies [14],[15],[16]. Therefore, the results of the effect of ultrasound in cases reported in the literature may not be directly applicable to osteoperforation healing. The present investigation is to clarify this effect.

II. Materials and Methods

Twenty-four mature New Zealand white rabbits weighting 2.0 ± 0.2 Kg were used. A two millimeter through medio-lateral hole was drilled at the midshaft of the right tibia of animals, using a standard dental drill (Minicraft, UK) at 30000 rev/min. Operated animals were randomly divided into PLIUS treatment group and placebo control group, and were euthanized at week 2, 4 and 6 postoperatively (n= 4, for each group and time point). During drilling, animals were anaesthetized using muscular injection of a mixture of Ketamin Hydrochloride 50 mg/ml and Xylazine 2% with a proportion of 1 to 5. They were given muscular injection of Prophylaxis Penicillin 800,000 U right after the surgery, and every 24 hours for two days.

Exogen™ 3000 (Smith & Nephew, USA), a standard ultrasound stimulator, was used to stimulate the osteoperforated site in PLIUS group (Gold and Wasserman 2005; Warden 2000). Ultrasound specifications were set to the intensity of 30 mW/cm^2, frequency of 1.5 MHz, and pulse

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1569–1571, 2009
www.springerlink.com

duration of 200 μsec, and were applied 20 minutes per day, 5 times per week [5],[9],[18]. Ultrasound treatment started one week postoperative and continued to the euthanizing day. Similar procedure was repeated for the placebo control group with the ultrasound apparatus at off position. All animals were kept at the same environment.

Every two weeks from the day of operation, 4 of the animals in each group were sacrificed and their right and left tibias were harvested. Samples were kept in normal saline solution. A standard three point bending tester (Zwick, Germany) was used to measure maximum force to break (in Newton) and maximum deflection (in millimeter) of each harvested tibia as measures of mechanical strength of bones. The measures in each operated tibia were normalized to the same measures in the contralateral tibia to reduce the variability effect. The two fixed stands in the bending tester were 8 centimeters apart, and the cross head applied the force right at the anterior side of the perforated site.

The method used was in compliance with the protocol established by the Care and Animal Use Committee of Iran University of Medical Sciences.

Mean value and standard deviation of mechanical measures were computed in each group. Kruskal-Wallis nonparametric test was performed to compare the means of the outcome measures in control and treatment groups. Mann-Whitney nonparametric test was used to compare the means of the measures between the control and treatment groups at each time point (SPSS, Ver. 13).

III. Results

Mean of normalized ultimate load and normalized stiffness increased as time point increased in the placebo control group and the PLIUS treatment group. Mean of normalized ultimate load and normalized stiffness were significantly higher in the treatment group than that in the control group at 4 and 6 week time points ($P<0.05$), but was not different at 2 week ($P>0.05$) (Table1 and Table2).

Table1: Average of Ultimate Load and Standard Deviation

Time / Group	Two Weeks after Surgery	Four Weeks after Surgery	Six Weeks after Surgery
Non Treated	0.76 ± 0.1	0.78 ± 0.07	0.89 ± 0.1
Treated	0.74 ± 0.16	0.91 ± 0.04	1.05 ± 0.06
P value	0.24	0.02	0.02

Table2: Average of Stiffness and Standard Deviation

Time / Group	Two Weeks after Surgery	Four Weeks after Surgery	Six Weeks after Surgery
Non Treated	0.87 ± 0.11	0.88 ± 0.09	0.98± 0.1
Treated	0.81 ± 0.14	1.01 ± 0.06	1.3 ± 0.1
P value	0.14	0.02	0.02

IV. Discussion

The positive effect of pulsed low intensity ultrasound on bone mechanical strength at osteoperforation sites was shown. This was concluded based on the results from an in vivo experimental study on rabbit tibia models, with the main outcome measures including ultimate load and stiffness in the osteoperforation sites.

The effect of ultrasound on wound healing and bone repair mechanisms has long been under investigation. Ultrasound causes a degranulation of mast cells resulting in the release of histamine. Histamine and other chemical mediators released from the mast cell are felt to play a role in attracting neutrophils and monocytes to the injured site. These and other events appear to accelerate the acute inflammatory phase and promote healing. In proliferative phase, ultrasound has been noted to affect fibroblasts and stimulate them to secrete collagen I. This can accelerate the process of wound contraction and increase tensile strength of the healing tissue.

The results of this study revealed considerable effect of PLIUS, at least following 6 weeks treatment, on bone mechanical strength in osteoperforations in rabbit tibia models. These findings are in agreement with the results from Claes et al. [18] who treated bone defects at the metatarsal bones of sheep with a segmental bone transport and then with low-intensity ultrasound using the same apparatus as ours. They showed significantly higher axial compression stiffness of callus tissue in the treatment group. Furthermore, Chan et al. [5] studied the effect of low intensity pulsed ultrasound on callus formation, and showed increased bone mineral content and volume of the mineralized tissue of distraction callus, and enhanced endochondral formation.

We, though, measured the bending stiffness of the healed bone which is very well related to the compressive stiffness.

Li et al. [3] and Unsworth et al. [4], based on the results of their in vitro studies, suggest that one of the mechanisms that low intensity pulsed ultrasound has on fracture repair is

to enhance the process of endochondral ossification where the soft callus is converted to mineralized hard callus. Our findings verify this implication due to the fact that heal rate was more quickly at the first 4 weeks of treatment, when callus mineralization is taken place.

V. Conclusions

The effect of pulsed low intensity ultrasound on the heal rate of osteoperforated bones in rabbit model was studied. It was found that PLIUS can enhance heal rates in osteoperforated bones. The heal rate is more rapidly at the first 4 weeks postoperatively. Ultrasound treatment may be used to shorten clinical treatment times after removal of pins or screws of bone fixators.

Influence of Cyclic Change of Distal Resistance on Flow and Deformation in Arterial Stenosis Model

J. Jie[1], S. Kobayashi[1], H. Morikawa[1], D. Tang[2], D.N. Ku[3]

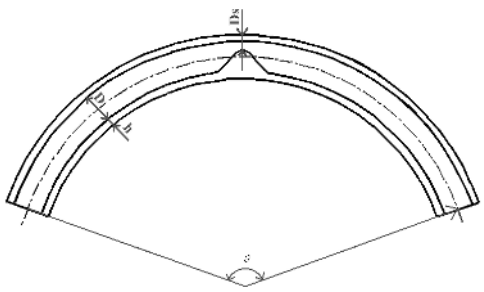
[1] Shinshu University, Japan
[2] Worcester Polytechnic Institute, USA
[3] Georgia Institute of Technology, USA

Abstract — **Blood flow through the constricted area of a severe stenosis is similar to that through a venturi or flow nozzle. In the contraction section, the blood can accelerate to high speed. In this situation, the external pressure may be greater than the internal fluid pressure, and atheroscrerotic plaque is compressed. The resultant compression may be important in the development of atherosclerotic plaque fracture and subsequent thrombosis or distal embolization. To examine the relationship between the flow and the deformation of coronary stenosis, we have developed curved stenosis models made of hydrogel that closely approximate the coronary disease situation, and performed flow experiments. Pulsatile flow was produced using a gear pump. The stenosis model was bent on a rubber support with ends that are pulled by a wire to change its curvature corresponding to curvature of the epicardial surface cyclically. In this study, we have developed the device of cyclic change of distal resistance of the stenosis model in sync with pulsatile flow, and applied to the flow experiment.**

Keywords — **Atherosclerosis, Coronary disease, Stenosis, Distal resistance, Biomechanics.**

I. Introduction

An increase in blood velocity on the distal side of stenosis causes a negative transmural pressure, and atherosclerotic plaque is compressed; furthermore, the stenosis may cause the collapse of artery which leads to the rupture of the plaque [1]. We have developed experimental stenosis models made of polyvinyl alcohol hydrogel (PVA) that closely approximate an arterial disease situation, and the characteristics of flow and deformation related to the changing geometry of stenosis and the existence of a lipid core were discussed [2-4]. To examine the relationship between the flow and the deformation of coronary stenosis, we have developed curved stenosis model, and performed flow experiments. The influence of flow and deformation on initial shape of stenosis models was discussed [5]. From the various experimental approaches, one can summarize some salient features of the intramyocardial coronary circulation as follows: The systolic inflow is low, sometimes even negative in early systole. The major part of the inflow is during diastole. The venous outflow is more evenly distributed with its major part in systole. In prolonged diastole, the inflow decreases almost linearly with the decrease in perfusion pressure and reaches a zero value at a relatively high pressure [6]. However the resistance of downstream the stenosis model for the previous experiment was constant in spite of the distal resistance of coronary artery is changed cyclically. In this study, we have developed the device of cyclic change of distal resistance of the stenosis model in sync with pulsatile flow, and applied to the flow experiment.



II. Methods

A. Stenosis model

During the experiment, stenosis model made of PVA hydrogel was used in a model for a diseased coronary artery. The polyvinyl alcohol hydrogel model is a more realistic stenosis model that shows thick stenosis and more compliant stiffness than the model made of silicone and latex [7]. This model is opaque, but its mechanical properties are similar to those of the coronary artery. The shape of stenosis model is similar to that of a sinusoidal curve. Figure 1 shows the shape of stenosis. The nominal stenosis severity *St* and eccentricity *Ec* of the stenosis model are given as follows:

$$St = (1 - Ds/D) \times 100\ [\%] \quad (1)$$

$$Ec = e/((D - Ds)/2) \times 100\ [\%] \quad (2)$$

($R \cdot \theta$=90mm, D=4mm, h=1mm, R=31.3mm, θ=2.9rad)

Fig. 1 Schematic representation of the curved stenosis model

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1572–1575, 2009
www.springerlink.com

B. Experimental setup

Figure 2 shows the experimental setup used. The PVA hydrogel stenosis model was fixed on rigid pipes and placed in a water tank. The water level was 14 cm from the center of the stenosis model (external pressure is approximately 10 mmHg). The upstream constant head reservoir was pressurized as the direct current component of pulsatile flow. The computer-controlled gear pump (MCP-Z, Ismatec) connected to the upstream tube served as the alternative current component of the flow. Upstream and downstream pressures were continuously measured using pressure transducers (SD 130, Toyoda Machine), which were placed at junctions between the rigid tube and the hydrogel, 50 mm upstream and downstream of stenosis. The working fluid used was water at room temperature with a kinematic viscosity ν of 0.01 cm^2/s. Flow rate was measured using an electromagnetic flowmeter (MagneW 3000FLEX, Yamatake), which was located outside the box 350 mm upstream and downstream of stenosis. Labview software (National Instruments) was used to operate, control and acquire data. The stenosis model was bent on a rubber support with ends that are pulled by a wire to change its curvature corresponding to curvature of the epicardial surface cyclically. The wire was driven by stepping motor to synchronize the phase with pulsatile flow. Figure 3 shows the cycle change of curvature. Sagittal section ultrasound images of the stenosis are made from the B-mode of a Duplex ultrasound scan. The valve and downstream constant head reservoir were set as the distal resistance of stenosis. As the device of cyclic change of distal resistance, we have used elastic PVC tube to change its cross sectional area. A rod driven by a linear motor pushes PVC tube which is the downstream side of the stenosis model. By periodical controlling the reciprocating movement of the rod, the distal resistance is changed cyclically. Figure 4 shows the reciprocating displacement of the rod. Frequency of reciprocating motion is 1 Hz. From 12 degree to 100 degree, the rod moves forward, at 100 degree, the PVC tube is mostly compressed. From 100 degree to 192 degree, the rod moves back along the same way, the PVC tube is released. The compliant rubber tube was used as the capacitance of intramyocardial coronary circulation.

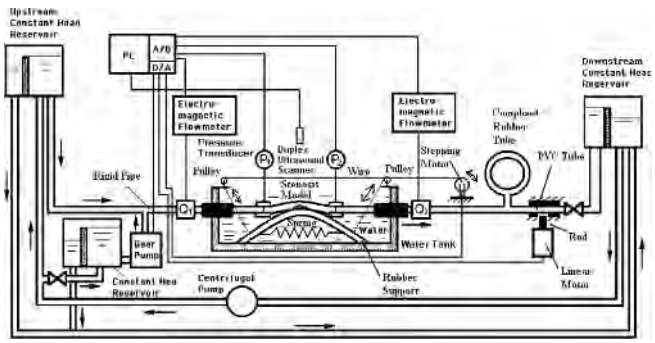


Fig.2 Experimental setup

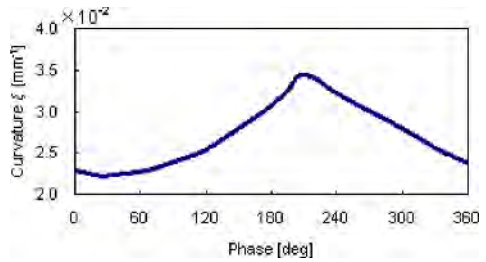

Fig. 3 Change of curvature in one cycle

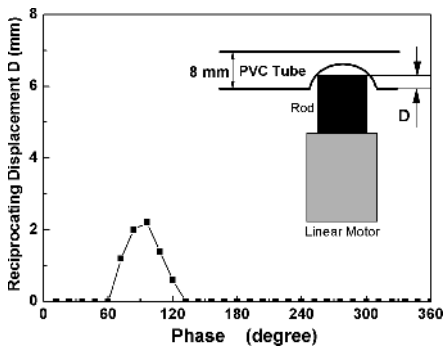

Fig. 4 Reciprocating displacement of the rod in one cycle

III. Results and Discussions

A. Change of distal resistance

We defined the distal resistance as following

$$R = P / Q \quad (3)$$

P is the downstream preassure and *Q* is the downstream flow rate. Figure 5 shows the distal resistance when rigid tube instead of the stenosis model. From 0 degree to 180 degree approximated the phase of systole, and from 180 degree to 360 degree approximated the phase of diastole. When the rod was not reciprocated, resistance was not constant, but when the rod was reciprocated, the resistance is increased in systole and reduced in diastole.

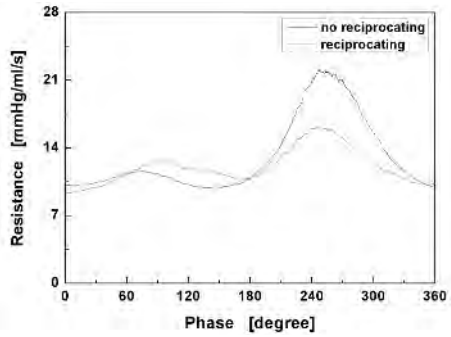

Fig. 5 Resistance in one cycle (P_{1avg} = 85 mmHg, P_{2avg} = 80mmHg)

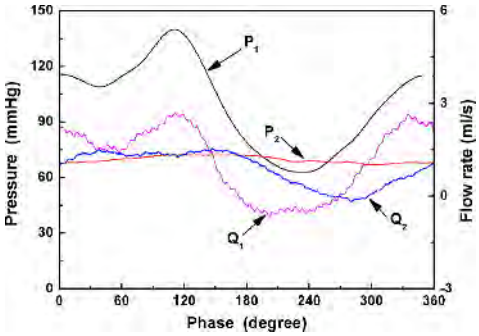
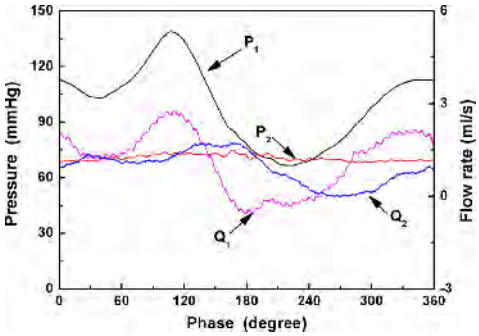


B. Flow and deformation

The following four conditions of curvature and rod reciprocating were selected for the experiment:



(a) Constant curvature and no rod reciprocating
(b) Cyclic change curvature and no rod reciprocating
(c) Constant curvature and rod reciprocating
(d) Cyclic change curvature and rod reciprocating

Figure 6 shows the measured upstream and downstream pressures and flow rates in one cycle for above conditions when stenosis model was used. P_1, P_2: upstream and downstream pressure, Q_1, Q_2: upstream and downstream flow rate. From Fig. 6(a) and (b), the flow is not changed obviously, some vibrations appeared in Fig. 6(b), this is caused by the wire to change the model's curvature. In Fig. 6 (c) and (d), the downstream pressure is increase from 70 degree to 100 degree, it is in accord with the phase for rod forward movement to compress the PVC tube. From 100 degree, the pressure began to decrease. This decrease process is longer than the rod backward movement, it is because a compliant rubber tube was put into the flow. This is similar to physiological coronary blood pressure. Compared Fig.6 (a) (b) with (c) (d), we observed the flow rates is increased from 180 degree to 360 degree.

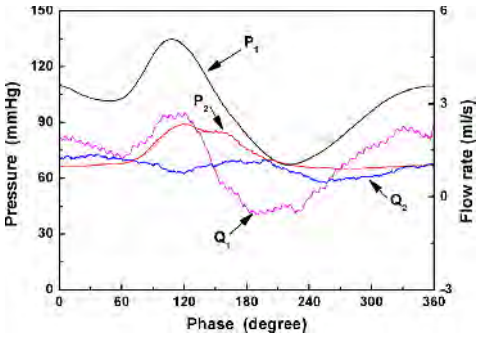


Figure 7 shows the sagittal section ultrasound images when the stenosis model is mostly expanded for above four conditions. The deformation of the stenosis was not changed obviously, because this stenosis (plaque portion) is homogeneous and stiffer than lipid rich plaque.

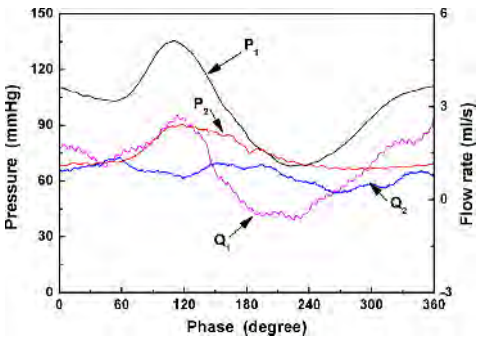

(a) Constant curvature and no rod reciprocating

(b) Cyclic change curvature and no rod reciprocating

(c) Constant curvature and rod reciprocating

(d) Cyclic change curvature and rod reciprocating

Fig. 6 Measured upstream and downstream pressures and flow rates in one cycle. (P_{1avg} = 100±40 mmHg, P_{2avg} = 70mmHg)

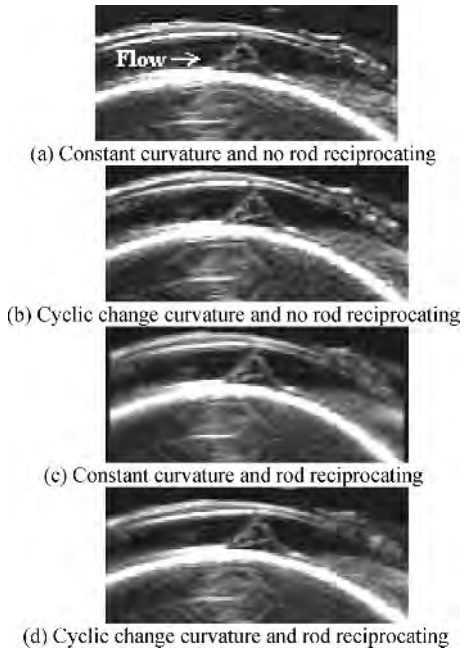

Fig. 7 Ultrasound images of sagittal section of the stenosis model

IV. Conclusion

In this study, we found that the cyclic change curvature does not effect the downstream pressure (average pressure, maximum pressure, minimum pressure) and flow rate (average flow rate, maximum flow rate, minimum flow rate) seriously. The cyclic change distal resistance is associated with an increase in maximum downstream pressure, minimum downstream flow rate and a decrease in maximum flow rate. But it can not influence the minimum downstream pressure, the average downstream pressure and average downstream flow rate. The phases of the maximum downstream pressure and the maximum flow rate were changed to be in accord with the change of distal resistance.

In the future work, more physiological experiment using more stiffer wall and soft plaque portion of the stenosis model that closer to human coronary artery, controlling more physiological coronary blood pressure (P_I), and accurate changing distal resistance and curvature will be performed.

Kinematics analysis of a 3-DOF micromanipulator for Micro-Nano Surgery

Fatemeh Mohandesi[1], M.H. Korayem[2]

[1,2] Mechanical Engineering Department, Iran University of Science and Technology, Tehran, Iran

Abstract — **In this paper; we have analyzed a robotic system, which is used in micro-nano surgery. This robot is a parallel robotic system with 3 degree of freedom. The scale of this robot is millimeter. The special characteristic of robot is having an additional link, which connects the spherical joint to moving platform. Here kinematics analysis and Jacobean matrix are investigated. In the section II an introduction to micro-nano surgery is stated. Section III involves the kinematics analysis, and in section IV Jacobean matrixes are explained.**

Keywords — **Micro-nano surgery, Direct Kinematics analysis, indirect kinematics analysis, Parallel robot, Jacobean Matrix**

I. Introduction

Micro-nano surgery is a kind of surgery in which the operational tools are in millimeter, micro or even nanometer. These tiny tools are carried by robotic systems. This robotic system here is a parallel manipulator, which has 3 degree of freedom. This manipulator has been used for handling and precise positioning of micro object. It's function was successful. In this paper, we have done kinematics analysis and found Jacobean matrix.

II. Micro-nano surgery

Micro-Nano surgery is the medical branch of nanotechnology. It can be divided into two separate parts: 1- doing the operation by nano robots, and the second: doing the operation by making surgerical tools in micro-nano scales. In here, the micro-nano surgery belongs to second group. This surgery is done by a surgeon who guides the tools by using joy sticks and sees the operation via cameras. Because of the difficulty of handling these tiny equipments, robotic systems are used for this purpose. Most of the time the master-slave robotic systems are used. Micro-nano surgery has many advantageous:

- Because of the tiny scale of the operational tools, the lacerations are shallow and they will be recovered very soon, so the duration of hospitalization decreases and then the cost of treatment decreases too.

- The mistakes which are caused by surgeon's tiredness, hands tremor, not enough experience and vision will vanish. Because the surgeon will be laid in a comfortable place and will do the operation easily.

- The pain, stresses in patient will reduced as, in some cases there is no need to anesthetize the patient.

-This surgery is used in tele-operation mode, so there will not be many people in the surgery room, specially in disease with high infections.

However, there are some disadvantageous too:

- High cost of stall and handling robotic systems.

- Training surgeons

- A supervisor engineer must be there, in order to repair the robotic system in case of deficiencies.

- Making the operational tools in micro-nano scale, because every surgery needs its own equipment.

The most important contention in this surgery is compost of surgeon's experience with stability and exactitude of robot.

III. Kinematics analysis

The configuration of the robot is shown in the figure 1. This robot is made up of a prismatic joint which is in the base, then a revolute joint, and then a spherical joint. A special characteristic of this robot is the existence of an additional link, which connects the spherical joint to moving platform. This links make the analysis more complicated. The geometry parameters of the robot according to the fig.1 are:

r: the radius of upper plate

R: the radius of fixed plate

d_i: the length of kinematics chain

T: rotation matrix which its arrays are as below:

$\begin{bmatrix} n_1 & o_1 & a_1 \\ n_2 & o_2 & a_2 \\ n_3 & o_3 & a_3 \end{bmatrix}$, this matrix shows the direction of moving plate.

X-y-z Euler angles of α, β, γ .

Vector p $\begin{vmatrix} p_x \\ p_y \\ p_z \end{vmatrix}$ which connects the centroid of upper plate to the centroid of fixed one. This vector indicates the location of moving plate.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1576–1579, 2009
www.springerlink.com

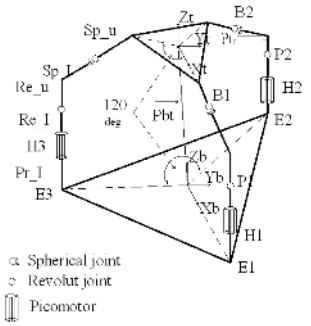

Fig.1 configuration of 3-PRS robot[2]

In direct kinematics analysis, the lengths of kinematics chains are known, and the purpose is finding position and orientation of moving platform. For this analysis, there are three groups of equations.

First group: equations which show the orthogonality of the matrix T. For this group we have 6 equations. These equations will be found in [1].

Second group: The revolute joint in all kinematic chains, imposes a constraint in moving. The second group equations are the constraints equations. Here 3 equations are got as:

$$P_y = -n_2 b_x + a_2 b_z \tag{1}$$

$$n_2 = O_1 \tag{2}$$

$$P_x = \frac{-1}{2}\left(O_2 b_x - n_1 b_x - 2a_1 b_z\right) \tag{3}$$

In which: b_x and b_z are the coordinates of spherical joints and are:

$$\begin{aligned} b_x &= r + sp_u\cos\theta_{tr} \\ b_z &= SP_U\sin\theta_{tr} \end{aligned} \tag{4}$$

Third group: These equations are related to the lengths of kinematic chains. The lengths of kinematic chains are found geometrically as:

$$\begin{aligned} d_1^{\,2} &= (p_x + n_1 b_x - a_1 b_z - R)^2 + (p_y + n_2 b_x - a_2 b_z)^2 \\ &+ (p_z + n_3 b_x - a_3 b_z)^2 \\ d_2^{\,2} &= (p_x - \frac{1}{2}n_1 b_x + \frac{\sqrt{3}}{2}o_1 b_x - a_1 b_z + \frac{1}{2}R)^2 + \\ &(p_y - \frac{1}{2}n_2 b_x + \frac{\sqrt{3}}{2}o_2 b_x - a_2 b_z - \frac{\sqrt{3}}{2}R)^2 + \\ &(p_z - \frac{1}{2}n_3 b_x + \frac{\sqrt{3}}{2}o_3 b_z - a_3 b_z)^2 \\ d_3^{\,2} &= (p_x - \frac{1}{2}n_1 b_x - \frac{\sqrt{3}}{2}o_1 b_x - a_1 b_z + \frac{1}{2}R)^2 + \\ &(p_y - \frac{1}{2}n_2 b_x - \frac{\sqrt{3}}{2}o_2 b_x - a_2 b_z + \frac{\sqrt{3}}{2}R)^2 + \\ &(p_z - \frac{1}{2}n_3 b_x - \frac{\sqrt{3}}{2}o_3 b_x - a_3 b_z)^2 \end{aligned} \tag{5}$$

For direct kinematics analysis, these 12 equations and 12 unknowns must be solved. But because of the nonlinearity of the equations, this is impossible and complicated. For this purpose we consider 2 Euler angels as knowns and find other parameters according to them. The table blow shows the result:

In all examples above, we considered the constant parameters as below:

$$\begin{aligned} &R = 40mm \\ &\theta = 5\,\text{deg}\,ree \\ &SP_u = 5mm \\ &r = 8mm \\ &d = 100mm \end{aligned} \qquad \begin{aligned} b_x &= 12.981mm \\ b_z &= 0.43577mm \end{aligned}$$

Tabel1-result of direct kinematics

α	β	T	P_x	P_y	P_z	γ
-3 degree	-3 degree	$\begin{bmatrix} -0/98992 & -0/00135768 & -0/14112 \\ 0/212725 & -0/989964 & -0/139708 \\ -0/139514 & -0/141311 & 0/980085 \end{bmatrix}$	-5.58025 mm	-78.9589, 83.4352 mm	-78.9589, 83.4352 mm	-0.0013741 degree
0 degree	0 degree	$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$	0 mm	9945.45, -9944.58 mm	9945.45, -9944.58 mm	0 degree
-3 degree	3 degree	$\begin{bmatrix} -0.989989 & 0.00271908 & -0.14112 \\ 0.0171957 & -0.990043 & -0.139708 \\ -0.140095 & -0.140736 & 0.980085 \end{bmatrix}$	-5.58023 mm	-78.9514, 83.4428 mm	-78.9514, 83.4428 mm	0.00274657 degree

The indirect kinematics analysis is much simpler than the direct one. In here the position and orientation of moving platform is known and the kinematic chains' length must be found. This can be easily done by equations (5). All analyses are done by "MATHEMATICA "software.

IV. JACOBEAN MATRIX

By Jacobean matrix the relations of velocities of moving platform and the joints or kinematic chains can be expressed. For this robot system, the input velocity is $\dot{q}$, which equals to $\dot{q} = [\dot{d}_1, \dot{d}_2, \dot{d}_3]$. The output velocity can be stated according to the velocity of the centroid of moving platform. A linear and an angular are considered as below" $\dot{x} = \begin{bmatrix} v_P \\ w_p \end{bmatrix}$. The Jacobean matrix is found from fig.2. An equation can be written based on vectors law:

$$\overline{OP} + \overline{Pb_i} = \overline{OE} + \overline{Eb_i} \tag{6}$$

By differentiating with respect to time form equation (6), the velocity is obtained:

$$V_P + w_P \times b_i = d_i w_i \times s_i + \dot{d}_i s_i \tag{7}$$

In the equation (7) b_i indicates the vector PB_i , s_i a unit vector in the direction of kinematic chains, w_i the angular velocity of i^{th} kinematic chain. The w_i is produced by the revolute joint, which is a passive joint and imposes constraint. So this velocity must be omitted form the equation. For this purpose, we do dot product the equation (7) by s_i. Then the equation becomes:

$$s_i.v_P + (b_i \times s_i).w_p = \dot{d}_i \tag{8}$$

By writing the equation (8) three times, for all kinematic chains, the Jacobean matrix can be extracted:

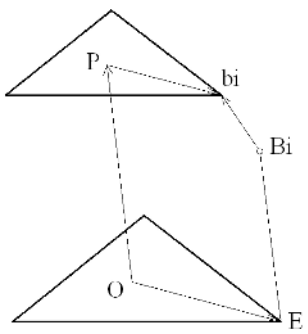

Fig.2 relation according to vectors law

$$\begin{aligned} &\text{i=1} \quad s_1.v_p + (b_1 \times s_1).w_p = \dot{d}_1 \\ &\text{i=2} \quad s_2.v_p + (b_2 \times s_2).w_p = \dot{d}_2 \\ &\text{i=3} \quad s_3.v_p + (b_3 \times s_3).w_p = \dot{d}_3 \end{aligned} \tag{9}$$

then the Jacobean matrixes will be :

$$J_x = \begin{bmatrix} S_1^T & (b_1 \times s_1)^T \\ S_2^T & (b_2 \times s_2)^T \\ S_3^T & (b_3 \times s_3)^T \end{bmatrix}_{3\times 6} \tag{10}$$

$$J_q = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}_{3\times 3} \tag{11}$$

In which Jacobean matrix J_x is called the direct kinematics Jacobean, and the J_q is called the inverse kinematics Jacobean matrix. If the robot is not in the singular configuration, the total Jacobean matrix will be as :

$$J = J_q^{-1} J_x \tag{12}$$

And the relation between the velocities is :

$$\dot{q} = J\dot{x} \tag{13}$$

The Jacobean matrix can be used in static, stiffness analysis. It is also used for finding the singularity points for a robot.

V. CONCLUSIONS

In the Inverse Displacement Solution (IDS), the position of actuators, according to the movement of platform is found. In the Forward Displacement Solution (FDS), position and orientation of the moving platform is determined, while the position of actuators is known. FDS analysis is very complicated and it is used in calibration, it is not used in control problems of robot. In the kinematics analysis these results are gained:

1- p_z is the only independent parameter among the six parameter [p_x p_y p_z α β γ]. This parameter did not appear in the constraint equations, which means it can be chosen separately from five other parameters, and also choosing these five parameters is completely independent from p_z.

2- Although this mechanism has 3 degree of freedom, but we can't assume all three angle Euler as given data. Just two from three angles must be known. Also for controlling the

mechanism, three parameters must be chosen, that one of them must be p_z. The two other parameters must be chosen from five remained parameters.

3- For each couple (p_x , p_y), two couples of Euler angles are existed, (α , β) and (- α, - β).For each given angle γ, the same couples are also existed. In the other hand:

$$\gamma=f_1(\beta,\alpha)=f_1(-\beta,-\alpha)$$

$$P_x=f_2(\beta,\alpha)=f_2(-\beta,-\alpha)$$

$$p_y=f_3(\beta,\alpha)=f_3(-\beta,-\alpha)$$

It means that in every point in robot workspace, a couple of Euler angles prevail that has the same γ. Two other angels are both positive and negative.

Stress and Reliability Analyses of the Hip Joint Endoprosthesis Ceramic Head with Macro and Micro Shape Deviations

V. Fuis[1], P. Janicek[2] and L. Houfek[1]

[1] Centre of Mechatronics – Institute of Thermomechanics Academy of Sciences of the Czech Republic and Institute of Solid Mechanics, Mechatronics and Biomechanics, Faculty of Mechanical Engineering, Brno University of Technology, Brno, Czech Republic
[2] Institute of Solid Mechanics, Mechatronics and Biomechanics, Faculty of Mechanical Engineering, Brno University of Technology, Brno, Czech Republic

Abstract — **The principal aim of this work is finding the reasons of the head's fractures because in the Czech Republic, some time ago, in vivo fracture of ceramic heads of total hip joint endoprostheses has been stated in a not negligible number of patients. The reliability of the ceramic head is based on the Weibull weakest link theory. The probability of the failure depends on the tensile stress values in the head, on the volume in which stress acts and on the material parameters of the used bioceramics (aluminium oxide). The stress analyses of the ceramic heads were realized using computational modelling - FEM system ANSYS under ISO 7206-5 loading. The maximum values of the tensile stress (the first principal stress) in the ceramic head are significantly influenced on the shape deviations of conical surfaces of the head and the stem cones. There are two types of the shape deviations – the first is macro deviations (different angle of the taper of the stem cone and the head cone), the second is micro shape deviations (the stochastic distribution of unevenness of cone contact surfaces). The macro and micro shape deviations of the cones were carried out using the IMS-UMPIRE measuring equipment.**

By computational modelling it has been proved that the character and the size of shape deviations on a conical contact area between the stem and the head of hip joint endoprosthesis have a pronounced influence on the character and the value of stress in the head and, hence, on the probability of the head's failure. Ignorance of this influence can lead to unforeseen failures of ceramic heads and thus to cast doubt on the trust-worthiness of a certain type of total hip joint endoprosthesis and of surgical treatment.

Keywords — **Total hip joint endoprosthesis, ceramics head, micro and macro shape deviations, stress, computational modelling.**

I. Introduction

One of the most frequently operated joints of the human body is the hip joint. In young patients, the operation is mostly aimed at reconstructing the joint's pathologically developed geometry. In older age, operations prevail in which the patients are provided with partial or total endoprostheses. These may be of different design solutions, with various materials being used in the endoprosthesis' individual parts. In a design solution which used ceramic heads, the destruction of the head has occurred *in vivo* – see Fig. 1. In one hospital of the Czech Republic, more than 1 % of applied endoprostheses had to be reoperated. That is why the state of stress and the reliability of ceramic heads of total endoprosthesis is being intensively analysed by means of computational modelling. Simultaneously, experimental modelling based on the strain gauges measurement is being conducted. These experiments are used to verify computational results.

Fig. 1 In vivo destructed ceramics head of the total hip joint endoprosthesis

II. Computational modelling

A. Problem situation

The failure of cohesion of ceramic heads of total hip joint prostheses has been stated in a not negligible number of patients. This applied to a structural model in which the head is connected with the metallic stem by a self-locking conical connection. The failure has taken place in particular in the endoprostheses made in the Czech Republic, however the failure of foreign-made endoprostheses has also been recorded. This problem situation required a solution in the

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1580–1583, 2009
www.springerlink.com

sense that the causes of this failure had to be established by means of a comprehensive analysis of reliability of ceramic heads of total hip joints endoprostheses.

The analysis of the head fracture surface orientation showed that the meridionally oriented fracture surfaces prevail – Fig. 1. Since ceramics is a material characterised by the limit state of brittle strength, the cohesion failure starting in directions perpendicular to the direction of the maximum principal tensile stress, then the stress responsible for the failure of head cohesion should be the hoop stress.

An effective method of solving the problem of reliability is computational modelling combined with experiment. For solving the strain/stress states in the head, the finite elements method was used, namely the ANSYS 11 program system.

B. Input parameters

The topology of the elements of the total hip joint endoprosthesis follows from Fig. 2 with the basic macro-dimensions of elements. Computational modelling of the strain/stress states in the head was implemented on a system whose elements were parts of the stem and the head.

In order to implement computational modelling of the impact of shape deviations of the cones of stems and heads of hip joint endoprostheses, which has a stochastic character, the measurement of these deviations was carried out using the IMS-UMPIRE measuring equipment. The quality of the measured contact surface of both cones can be expressed by macro-parameters (deviations) – the most important is angle of the taper of the head and the stem and straight line character), and micro-parameters (deviations) – local micro-unevenness of surface. As regards the inclination angles of the elements of ruled surfaces (degree of taper) one can say that the manufacturing documentation permits only an alternative in which the vertex angle of the head (angle α_h) is greater than the vertex angle of the stem (angle α_s) – Fig. 2 (the value of the angle α can be found from zero to 10'), and the circularity of the individual sections (perpendicular to the y-axis) is less than 10 μm. The measured micro shape deviations from the ideal conical shape for one cone of head are illustrated by the developed cones in Fig. 3. The micro shape deviations of the 3 stems cone are show in Fig. 4. The mentioned head with macro and micro shape deviations was put and loaded on all three stem cones.

The state of stress of the ceramic head of endoprosthesis can be strongly affected by the process of endoprosthesis implantation, when the surgeon fits the head on the cone of the stem. The fitting of the head on the cone of the stem is a random process, in view of the mutual position of the head to the stem (in sense of the head's slight turning around the y-axis, defined by angle β – Fig. 5). The question is, whether the local shape deviations of the cones, in case of random completing, can produce high tensile stresses that might reduce the reliability of the head. For this reason, a series of computations will be made for each pair and for various positions of the head towards the stem.

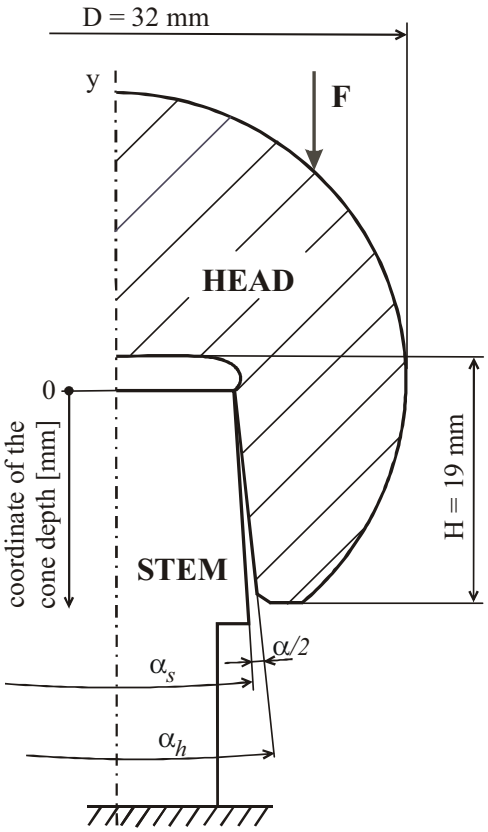

Fig. 2 Topology of the analysed system, macro shape deviation

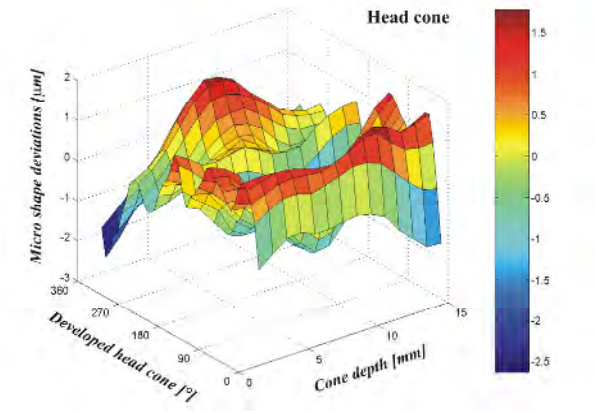

Fig. 3 Micro shape deviation of the head cone

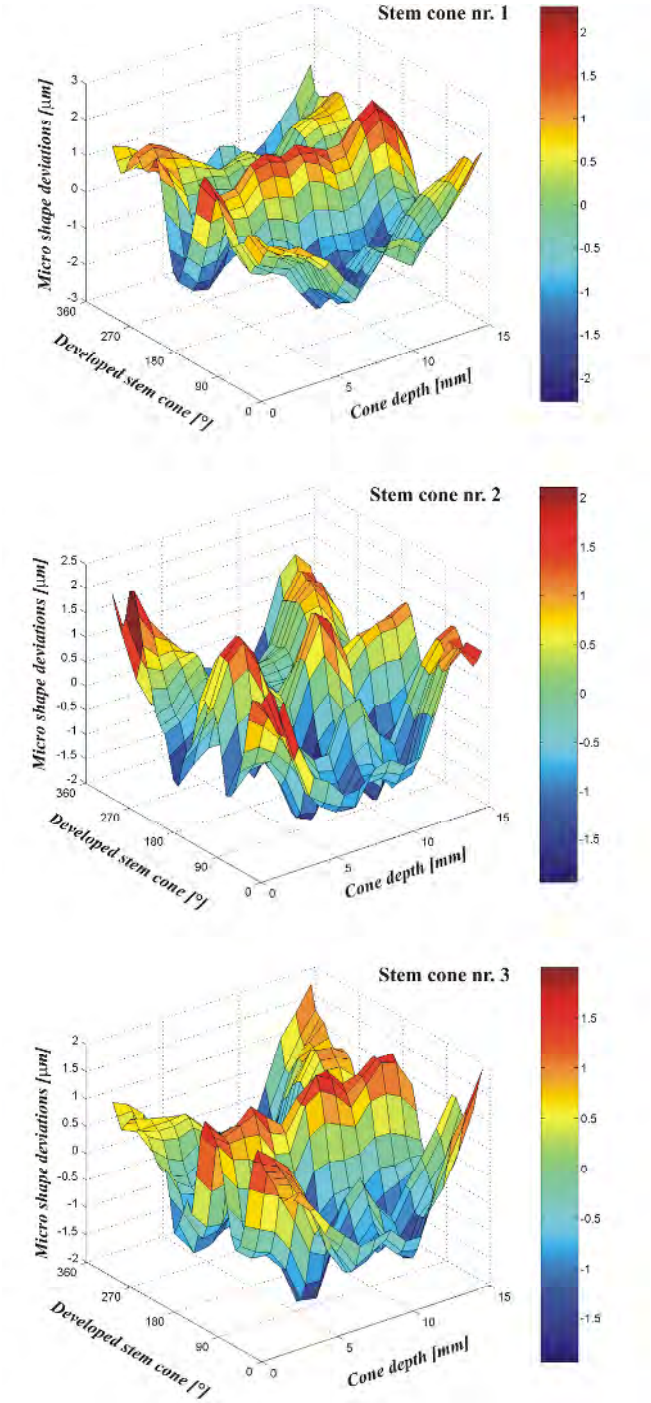

Fig. 4 Micro shape deviation of the stem cones

For computational analyses of the head's cohesion failure, the head was loaded with linear forces acting on a circle, the carrier of the resulting force *F* being identical with the axis of the stem, Fig. 2. This way of loading complies

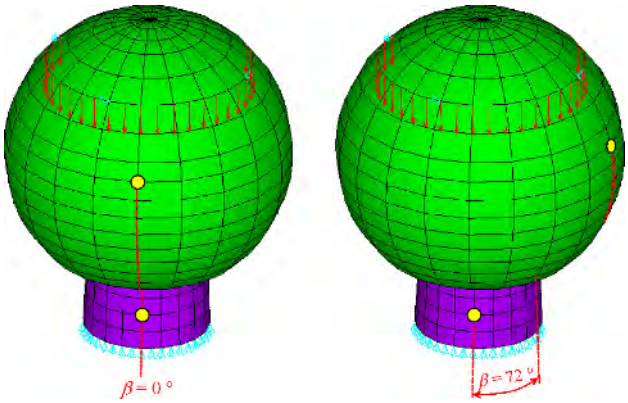

Fig. 5 Representation of various head to stem positions - angle β

with the ISO 7206-5 standard, according to which the reliability of ceramic heads is tested for failure of cohesion.

The material of the head and the stem was considered to be a linear isotropic continuum. The stem was made of steel and the following constitutive characteristics were taken into account in the calculation: E = 210 GPa μ = 0.3. The material of the head was ceramics on the basis of aluminium oxide Al_2O_3, for which the following constitutive characteristics were considered: E = 390 GPa, μ = 0.23. Contact between the head and the stem is modelled as elastic Coulomb friction with coefficient of friction f = 0.15 [1].

C. Results of the computational modelling

The negative behavior of the ceramics is the brittleness and therefore the tensile stresses in the ceramic head will be analysed in detail [2]. The distribution of maximum values of tensile stresses in the ceramic head (σ_{max}), in dependence on the value of the head's load, is shown in Figs. 6 - 8 for all analysed pairs (head pressed on the stem nr. 1 – Fig. 6, head pressed on the stem nr. 2 – Fig. 7 and head pressed on the stem nr. 3 – Fig. 8). The values σ_{max} for a given pair and for various positions of the head to the stem (various value of angle β) form a belt of relationships, the width or the height of which vary in the course of loading, and are related with the extent the dispersion of values σ_{max}. There are two limit macro shape deviations assumed (α = 0° – the cone tapper angle of the head and the stem is the same – blue curves, α = 10' (see Fig. 2) - limit value of the macro shape deviation – red curves) for each analysed pairs. For comparison, also an alternative was modelled taking into account only the deviation from the nominal degree of taper; in the diagrams it is represented by a broken lines and denoted VAR. 0 – α = 10' (variant assume only the macro shape deviation) and VAR. 0 – α = 0° (variant without macro and micro shape deviations – ideal cone).

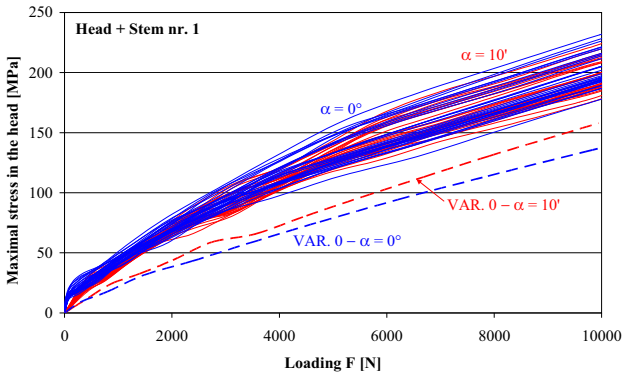

Fig. 6 Maximal head's stress curves during the loading for "Stem nr. 1"

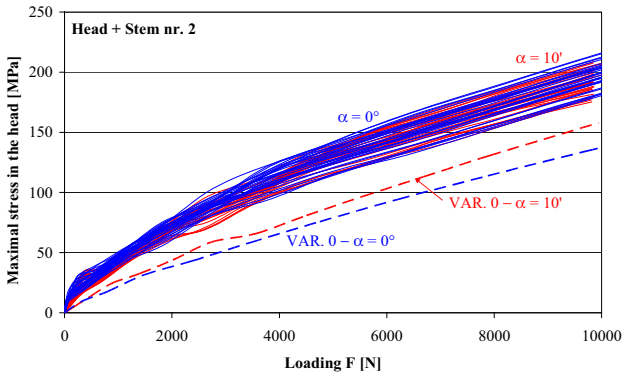

Fig. 7 Maximal head's stress curves during the loading for "Stem nr. 2"

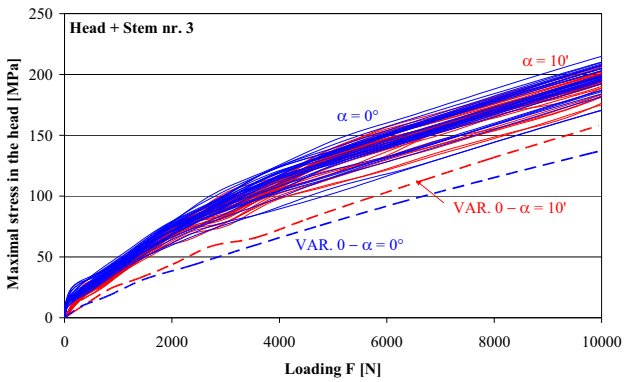

Fig. 8 Maximal head's stress curves during the loading for "Stem nr. 3"

The width of the belt of the σ_{max} curves in Figs. 6-8 (influence of the random position of the head on the stem cone) is similar for all analysed variants but the dispersion of the curves for variant with Stem nr. 2 is most equable (the maximal dispersion is about 40 MPa and the dispersion of the rest variants is higher – about 55 MPa).

The presence of the macro shape deviation without the micro shape deviations causes about 15 % increasing of the σ_{max} values (comparison of the VAR. 0 – α = 0° and α = 10').

The presence of the micro shape deviations or micro and macro shape deviations causes the increasing of the σ_{max} values from 27 % to 68 %. The width of the belt of the blue and red curves is very similar – the influence of the micro shape deviations is more significant than macro shape deviation.

III. Conclusions

By computational modelling it has been proved that the character and the size of micro and macro shape deviations on a conical contact area between the stem and the head of hip joint endoprosthesis have a pronounced influence on the character and the value of stress in the head and, hence, on the probability of the head's cohesion failure.

Abstract — **Pseudoelastic alloys have never been utilised in rehabilitation medicine yet. A compliant dynamic brace (EDGES) promoting spastic elbow relaxation was designed for clinical use and helped investigate the potentialities of pseudolastic NiTi in orthotics. Two post-stroke subjects wore EDGES for 1 week, at least 10h a day. No additional treatment was applied to the examined arm during this period or the following week. A great improvement of the resting position was observed in both patients as early as 3h after starting the treatment. During walking, EDGES did not constrain limb movements and was thus very well accepted by the patients. A slight decrease in elbow flexors spasticity was also observed in all subjects, but this effect disappeared 1 week after discontinuation, as did posture improvements. EDGES appears to be a good alternative to traditional orthoses in terms of acceptability and effectiveness in improving posture, and it could be very useful whenever short-term splinting is planned.**

Keywords — **Pseudoelastic alloys, spasticity, orthotics.**

I. Introduction

Pseudoelasticity is the unique ability of some alloys (typically Ni–Ti alloys) of recovering up to 8% of deformation fully. This behavior is due to reversible phase transformations occurring in the solid state [1], from austenite to martensite during loading and vice versa on unloading. Deformation and shape recovery occur through large plateaux along which stress remains constant. Besides their peculiar mechanical characteristics, pseudoelastic NiTi is very biocompatible and thus it is commonly utilized in biomedical applications. Rehabilitation medicine has never employed this material so far. In particular, the large deformability and low-stress shape recovery of pseudoelastic NiTi could be useful if applied to spastic contracted joints. Between 17% and 28% of post-stroke patients develop spastic contractures within the first 6 months after stroke [2]. Spastic muscles management commonly includes the use of static orthoses which achieve muscle relaxation through a sequence of constrained positions more and more stretched. This approach causes a number of problems: first of all, the spastic response elicited at every stretching step provokes great pain to the patients. Furthermore, static splinting does not allow for any movement of the constrained joint, which is not good for functional rehabilitation as it favours the insurgence of contractures and of learned non-use [3]. Moreover, post-stroke patients commonly show involuntary jerks or contraction patterns involving the spastic limbs, during which constraining movement can cause further pain. That is also the reason why traditional static orthoses are not very well accepted by the patients.

A compliant dynamic brace (EDGES, Fig. 1) promoting spastic elbow relaxation was designed for clinical use and helped investigate the use of pseudolastic NiTi in orthotics.

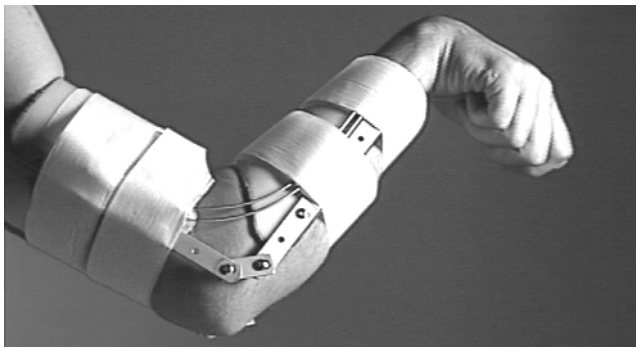

Fig. 1 The EDGES orthosis.

II. Material and methods

A. Material characterization

A commercial $Ni_{50.7}$-$Ti_{49.3}$ grade thermally-treated at 673K for 1h and water quenched was utilized for this application. Traction characterization was carried out on MTS 2/M thermo-mechanical test machine (MTS Systems, Eden Prairie, MN, USA), up to an engineering strain of 4%, at room temperature and the tensile stress-strain characteristic was recorded. The plateau values for this material were σ_m = 550MPa and σ_r = 240MPa.

Specially-designed grips mounted on the same test machine made it possible to carry out bending tests on the wire across the range 30°-220° (0° being wire straight). A 21cm long sample of wire (grip-to-grip) underwent two recorded deformation cycles across that range. The same sample was then manually preconditioned to bending between -180° and 180°, 50 times in the same bending plane of the test. Subse-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1584–1587, 2009
www.springerlink.com

quently, recorded continuous cyclic deformation was applied 10 times across the same range.

B. Orthosis design and characterization

The EDGES orthosis is made up of two thermoplastic shells modeled on a prototype human arm of average size. These are connected by a polycentric hinge at each side of the elbow joint. A variable number of NiTi wires can be laid into two tubular elements connected in parallel to the hinges. On putting on the brace, the shells are strapped on the upper arm and forearm by Velcro® bands (Fig. 1).

A test bench was designed and constructed as follows, to assess the quantitative static working capabilities of EDGES. An aluminum platform sliding in a finely controllable way along two horizontal guides holds the orthosis arm shell blocked by four screws. A crosshead is mounted horizontally between two vertical poles attached to the sides of the platform, so that it lies above the orthosis at a selectable distance from it. Two 0.03N/mm harmonic steel linear tension springs are pinned onto the crosshead at a suitable distance from the midline and attached to the sides of the orthosis forearm shell, keeping it aloft and tied. The springs are designed to balance the action of the orthosis NiTi wires (the orthosis weight being negligible in comparison). The test is conducted in the following manner: after 50 two-ways preconditioning manual bending cycles between -180° and 180° the orthosis is fixed to the test bench horizontally and almost completely extended. The platform and the crosshead are moved relatively to one another until the springs are at square angles to the orthosis connection bars; at this point a photograph is taken of the orthosis and springs from a sufficiently far distance that the parallaxis has neglectable influence on relative measures. Then, the platform and crosshead are moved again so that the springs, still at square angles to the orthosis bar, balance the force of the NiTi wires with the orthosis slightly more flexed; a new photograph is taken. The same thing is then repeated for increasingly flexed orthosis angles and then back towards extension. On post-processing the photographs, a point-wise hysteretic characteristic of orthosis corrective torque vs. orthosis angle can be obtained: the spring length (force) and the lever-arm (spring distance from the instantaneous centre of rotation) can be measured from the pictures taken at different flexion angles. Tests were conducted with the orthosis mounting 1 and 2 wires per side.

C. Clinical trials

Two patients (A and B) were chosen among the inpatients of the ward that were not under any other treatment on the elbow. Patient A was a 62 y/o male with left sensory-motor hemisyndrome, 6 years after an ischemic stroke, showing Ashworth 3 spasticity in the elbow flexo-extensors, full PROM and no AROM. Patient B was a 64 y/o female with left sensory-motor hemisyndrome, 9 years after an ischemic stroke, showing Ashworth 2 spasticity in the elbow flexors, full PROM and no AROM. Patients were treated according to ethical principles as approved by the hospital ethical committee and gave informed consent to undergo a period of treatment with EDGES.

Patients underwent general clinical assessment prior to the start of the treatment, which consisted in wearing EDGES continuously for the first 24h and as long as possible for the following week. A number of measurement were scheduled at T0 and 3h, 24h and 1 week after the initiation of the therapy. These included active and passive range of motion, spasticity on the Ashworth Scale, resting elbow position while sitting, standing and standing after walking. Elbow angles were assessed also via optoelectronic measurements, which allowed dynamical evaluation of patient-orthosis interaction. The same protocol was also repeated 1week after discontinuation of the therapy. Visual clinical assessment was carried out routinely every time an opto-electronic measurement was scheduled. Optoelectronic measurement protocol was based on 100Hz acquisition of the position of three IR reflecting markers (fixed on the shoulder, elbow and forearm) to track the elbow angle by eight IR cameras (Elite Gait Eliclinic - BTS, Garbagnate, Italy). During this trial the patients (initially sitting with the affected limb resting on their laps) were cued to relax the arm down along their sides, then stand up, relax the arm down again and finally start walking along the gangway. Acceptability of EDGES was also investigated using a visual scoring questionnaire proposed by Gracies et al [4].

III. Results

A. Bending characterization of NiTi wires and EDGES

Wire bending curves show a quasi-linear increase of force until the bent wire forms a pseudoplastic hinge where stress concentration induces detwinned martensite. At that point material resistance quickly drops towards a plateau value that is conserved at larger deformations. The backward path shows hysteresis but the general shape of the tracing is akin to the forward one. Stabilization occurs only after conditioning.

Fig. 2 reports the results of the bending tests conducted on the assembled orthosis. The corrective torque vs. angle characteristic of EDGES is non-linear and hysteretic in both trials. Sufficient corrective push is ensured also at lower

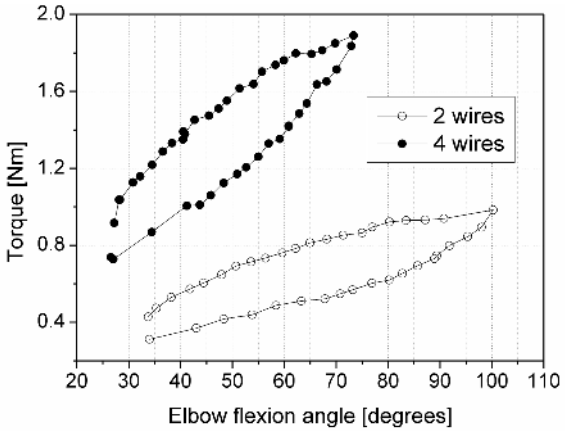

Fig. 2 Results of the bending tests on EDGES.

angles. The orthosis produces a moment increasing with angle in the 20°-80° range, after which it appears to reach a plateau at around 0.95Nm and 1.9Nm when equipped with 2 and 4 wires, respectively.

B. Clinical assessment

Variations of clinical conditions during the follow-up period were recorded and results are as in Table 1. It can be noted that the general trend, even in these very chronic patients, is definitely towards an improvement of elbow posture, which is already present at 24h and becomes more evident after 1 week. The decrease in spasticity obtained after 1 week of EDGES application is indeed a very interesting datum. All improvements appear to regress within 1 week of discontinuation.

Optoelectronic measurements show very nicely the time-course of elbow angle during the proposed clinical trials (Fig. 3). The quantitative analysis of movement confirms the general trend towards an increased elbow extension during therapy. Furthermore it is very interesting to observe that, while EDGES allows for wide movement of the elbow and does not impede flexing synergies during standing-up and walking, it is capable of reducing the amplitude of this

Table 1 Clinical follow-up: ROM and spasticity (without EDGES)

	Time	Sit	Stand	Walk	Relax	Ashworth
A	T_0	60°	50°	65°	50°	3
	3h	45°	45°	60°	50°	3
	24h	45°	50°	60°	50°	3
	1w	35°	40°	55°	40°	2
	1w after	50°	60°	65°	60°	3
B	T_0	70°	110°	100°	60°	2
	3h	30°	60°	70°	50°	1+
	24h	30°	30°	40°	30°	1
	1w	25°	30°	40°	20°	1
	1w after	65°	80°	95°	60°	2

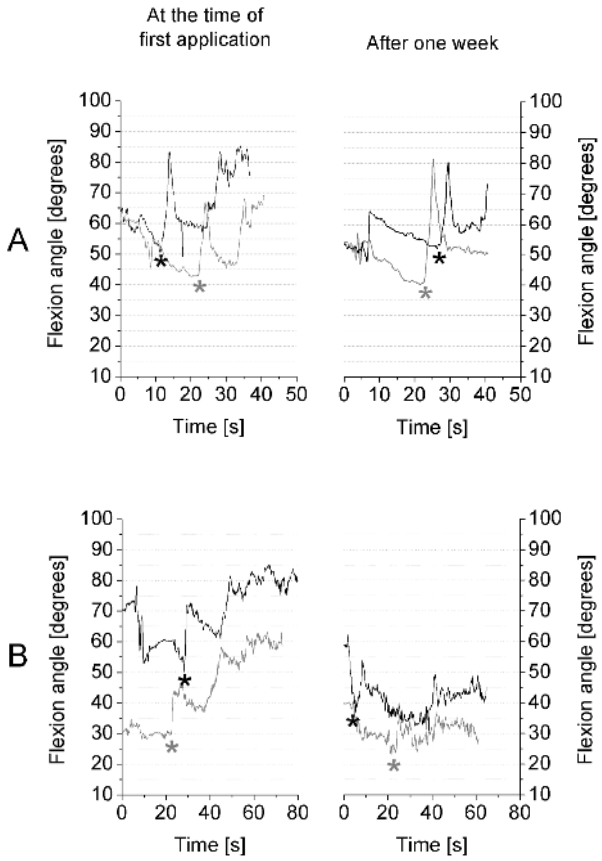

Fig. 3 Optoelectronic measurements on both patients wearing EDGES (gray line) and on removing it (black line). Star marks the "stand up" command. Elbow flexion following this point is a typical flexor synergic contraction. EDGES does not constrain this involuntary movement.

Table 2 Outcomes of Gracies' questionnaire for orthosis acceptablity

Question	A (1w)	B (1w)
How long did you wear EDGES today?	12 hours	18 hours
How did your arm feel while wearing EDGES?	7/10	8/10
Did you notice any changes wearing EDGES		
when walking?	Better	Better
when toileting?	No change	No change
when eating?	No change	No change
when dressing?	No change	No change
in ease of movement (muscle tone)?	Better	No change
in the confidence in your arm?	Better	Better
Would you wear EDGES for a few weeks if recommended?	Yes	Yes
Comments...	Some skin rash.	Cannot sit putting the arm on the lap

pathological movement. Patients' acceptation of EDGES was generally good after both 24 hours and 1 week of therapy (Table 2). Willingness to continue wearing it is preserved and only minor problems were observed, among which some light skin rash, that could possibly be avoided by a better lining than the present one. A particularly good result is in terms of improved ease of movement and confidence for the patient. It is interesting to notice that both patients reported walking better when they are wearing this elbow splint, possibly suggesting that improved confidence and decreased flexor synergies bring about greater stability.

IV. Discussion

The purpose of including pseudoelastic elements in a positioning brace is to provide a corrective torque across an angle as wide as possible such that it is not negligible even when the arm is almost fully extended. This principle is very innovative with respect to traditional orthotics, which is based on fixing the position of the limb and await tissue remodeling by relaxation. In the present work, a stable corrective force (and not a stable position) drives muscle stretching. This force ought to be sufficiently strong to produce tissue lengthening by *viscoelastoplastic creep* and not as strong as to impede arm movements. The values of corrective torque produced by EDGES, as measured from the bending tests (0.95Nm and 1.9 Nm), are considerably lower than maximal muscular flexor torques of around 50-75Nm [5], and somewhat less than the maximal passive-reflex torques, which are reported to be in the range 0.5-6Nm [6]. These measurements confirm that EDGES can stretch muscle while not constraining elbow position during voluntary movements or involuntary jerks. Clinical procedures carried out to assess the dynamical characteristics of EDGES when worn by spastic subjects, showed that even in this unoptimized version it can produce corrective loads in a stable manner for at least a week and that it does not constrain the elbow in a fixed position. This is clearly visible from the strong oscillations in arm position detected and shown in Fig. 3. Flexor synergies, which are a very common feature of post-stroke syndromes, cause involuntary arm flexion during some types of body movements (standing up, walking, …). Constraining devices can therefore be ill-tolerated in these circumstances. Acceptability of EDGES was on the other hand very good, suggesting that longer orthotic treatments with this orthosis can be attempted. Decrease in spasticity could be a wonderful result but it needs strong further evidence to be confirmed, as spasticity attenuation has never been conclusively proved in connection with orthotic treatment [7]. Relapse of ill-posture and spasticity after treatment discontinuation was absolutely expected, as 1 week is not a sufficiently long time to obtain plastic remodeling of human muscular and nervous tissues. Stabilized benefits could only be attended, should treatment be prolonged by several weeks. Reversibility of patients' conditions in the present clinical experiment suggests that EDGES is not harmful in a week's application.

V. Conclusions

A pseudoelastic positioning brace was designed and built based on commercial NiTi wires. Unconventional bending tests showed good cycling stability. Orthosis characterization demonstrated that it can generate corrective torques up to 0.95Nm and 1.9Nm when equipped with 2 and 4 wires, respectively. Clinical outcomes show improvement of patients' posture within 24h and further progress at 1 week. Spasticity appears to be decreasing during the first week, but this observation needs strong additional evidence to be confirmed. Patients' satisfaction was high, as was acceptability at both 24h and 1w. In conclusion, pseudoelastic NiTi is a suitable material for constructing elbow positioning braces that work on the principle of tissue lengthening by *viscoelastoplastic creep*. Other orthoses could be significantly enhanced with the use of pseudoelastic elements.

[3] Faculty of Engineering, Kyusyu Sangyo University, Fukuoka, Japan

Abstract — **Mechanical stress analysis of vertebral bone is required to determine compressive strength of vertebra for osteoporosis patients in clinical situation of orthopedics. Stress occurred in vertebrae depend on condition of musculoskeletal system of spine. Spine structure is mainly constructed of many vertebrae and flexible intervertebral disks, and it is unstable by itself under standing condition. Supporting by erector muscles and ligaments keep the spine standing condition, so that loading condition of each vertebra depend on the muscle and ligament forces. Biomechanical simulation of musculoskeletal model taking into account of muscle and ligament forces and intervertebral joint forces is necessary to determine the loading condition for vertebral stress analysis. Commercial software to deal with the musculoskeletal system, e.g. AnyBody Modeling System (AnyBody Technology Inc.), is available nowadays, and it has been applied to clinical, ergonomic or sport biomechanics problem.**

Spine kyphosis is often caused by compression fracture of osteoporotic vertebra, because shape of the fractured vertebra is sphenoidal with sharp anterior side of vertebral body. Spine kyphosis makes gravity center of trunk shift to anterior side, and then intervertebral joint moment due to trunk weight increase. Additional compression fracture is concerned at adjoining vertebrae to the fractured one in the kyphotic spine. In this study, musculoskeletal simulation model with spine kyphosis was created by using AnyBody Modeling System considering compensation posture due to kyphosis. Kyphosis patient used to have compensation posture to recover body balance and face up. Intervertebral joint forces and muscle forces of the model were computed, and then influence of the kyphosis on the intervertebral joint force at adjoining joints was discussed comparing between kyphosis and intact model. Furthermore, influence of the compensation posture on muscle forces related to spine was considered.

Keywords — **Biomechanics, Musculoskeletal Model, Spine, Kyphosis, Vertebral Compression Fracture**

I. Introduction

Recently, by the advanced computational mechanics technology, the mechanical analysis of the bone that reflected a complex structure and the material characteristic has been available [1]. The diagnosis of osteoporosis that considers strength of the bone according to the patient has been tried by using mechanical analysis technique. However, the loading condition and the boundary condition of the bone are not necessarily considered enough while progress of accurate modeling of bone structure and material properties. Spine structure is mainly constructed of many vertebrae and flexible intervertebral disks, and it is unstable by itself under standing condition. Supporting by erector muscles and ligaments keep the spine standing condition, so that boundary condition of each vertebra strongly depend on the muscle and ligament forces. It is important to give an accurate loading condition in which force of the muscle and the ligament is considered for mechanical analysis of vertebra on more clinical condition.

Spine kyphosis is often caused by compression fracture of osteoporotic vertebra, because shape of the fractured vertebra is sphenoidal with sharp anterior side of vertebral body. Spine kyphosis makes gravity center of trunk shift to anterior side, and then intervertebral joint moment due to trunk weight increase. Additional compression fracture is concerned at adjoining vertebrae to the fractured one in the kyphotic spine. Although such a change of the loading condition due to spine kyphosis can be easily expected, it is very difficult to evaluate load increase on each vertebra because of influences by the above-mentioned muscle and ligament forces.

In this study, musculoskeletal simulation model with spine kyphosis was created considering compensation posture due to kyphosis. Kyphosis patient used to have compensation posture to recover body balance and face up. Intervertebral joint forces and muscle forces of the model were computed, and then influence of the kyphosis on the intervertebral joint force at adjoining joints was discussed comparing between kyphosis and intact model. Furthermore, influence of the compensation posture on muscle forces related to spine was considered.

II. Analysis Method

A. The AnyBody Modeling System

Musculoskeletal model was developed using the simulation software the AnyBody Modeling System (AnyBody

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1588–1591, 2009
www.springerlink.com

Technology Inc.) [2]. This software handles model of human body mechanism, and the application area is medical, rehabilitation, ergonomic, sports or astronautical engineering, etc. By using the AnyBody Modeling System, we can develop 3-D musculoskeletal model by a script language called AnyScript. Model consists of segments regarded as bones or rigid elements, joints connecting segments, and muscle-tendon units having physiological characteristics. Drivers create posture and movement of joints. The AnyBody Modeling System calculates the joint and muscle forces from giving posture and external load by inverse dynamic analysis.

B. Analysis model

Analysis model was developed based on Standing Model (the AnyBody Research Project, Aalborg University, Aalborg, Denmark, http://www.anybody.aau.dk/repository) [3], which was human full body musculoskeletal model (Fig. 1).

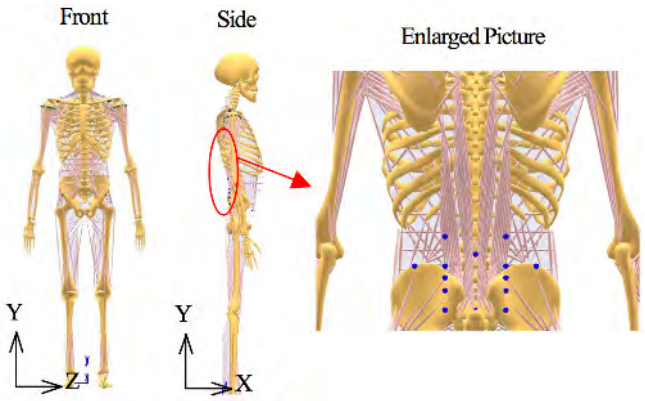

Fig.1 Full-body musculoskeletal model of the AnyBody modeling system.

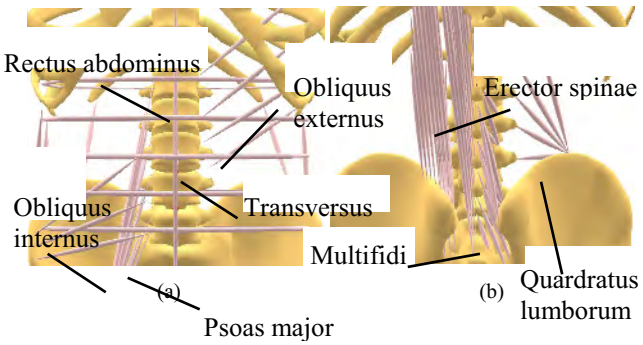

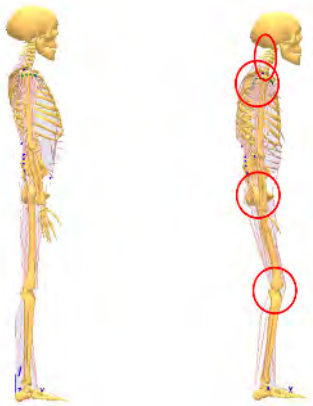

Fig.2 Trunk of model in (a) front view and (b) back view. Eight muscles are defined as trunk muscles.

Total number of muscle fascicles defined in this musculoskeletal model is 476. In trunk of model 158 fascicles were defined and divided into eight muscles (Fig. 2). Four abdominal muscles were included : rectus abdominus, transversus, obliquus internus and obliquus externus. Quadratus lumborum, psoas major, erector spinae and multifidi were defined as muscles of the lower-back [4].

Spine model is composed of nine segments : sacrum, five lumbar vertebrae, T12, T11 and a lumped thoracic part over T10. Spherical joint with three degrees of freedom was set between every vertebra from T10 to sacrum(Fig. 3). These intervertebral joint angles were varied in according to spinal alignment or posture [5]. Height of the model is set as 1.5m and weight is 50kg assuming a standard Japanese eldaly female.

(a) Healthy model (b) Kyphosis model

Fig.3 Standing posture of the normal healthy model and kyphosis model. Circles of the kyphosis model denote neck, glenohumeral, knee and hip joints which are changed from the healthy model by compensation.

Table 1 Change of joint angle of kyphosis model from normal model

Joint	Angle(°)
T11-T12	-20
Neck	+20
Knee	+20
Hip	+10
Glenohumeral	+10

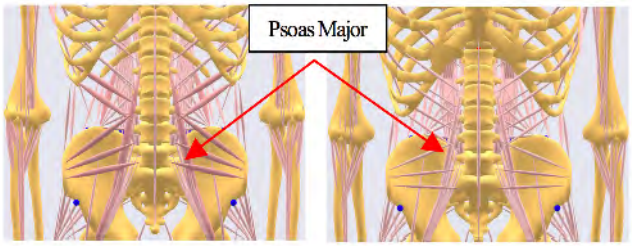
C. Kyphosis model

Assuming the case of compression fracture at 12th thoracic vertebrae where was favorite site of compression fracture caused by osteoporosis, we enforced to increase intervertebral joint angle of T11-T12 20 degree in flexion direction. And then, the compensation posture seen in the

kyphosis patient was set to the standing model. In the compensation posture, neck, knee, hip and glenohumeral joints were changed to make the face naturally turn to the front [6]. Fig. 3 shows standing posture of the normal healthy model and kyphosis model. Angle change of the joint is shown in Table 1.

D. Analysis condition

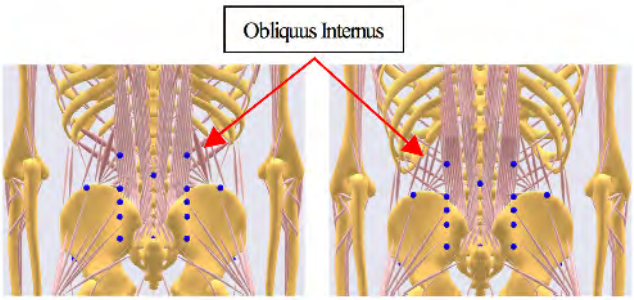
In the analysis, the muscular force and the joint force in each posture is calculated in the static condition. Min-max algorithm of AnyBody Modeling System is used in the muscular force calculation. The solution of the muscle recruited problem is minimization of the maximal muscle activity under constraints of the static equilibrium equations. Muscle activity means muscle force divided by the maximal isometric muscle force at each muscle's current working condition. The solution is equivalent to minimum muscle fatigue and it is computationally-efficient [2].



The self body weight and abdominal pressure were considered as external load to the body. The analysis was performed for the normal healthy model and the model taking the compensation posture, and their results were compared each other focusing on the trunk muscular force and vertebral joint force.

III. Analysis Result

A. Influence on trunk muscle



The trunk muscular forces are shown graphically in Fig.4 and Fig.5 for the normal healthy model and the kyphosis model. In the figure, muscular thickness correspond to magnitude of muscular force. Fig.4 shows front side of the models, and Fig.5 shows back side of the models. Psoas major that arrows in Fig.3 is displayed thicker than other muscles. Moreover, it is understood that arrowed obliquus internus is displayed thick in Fig.4. Relative large force occur in these muscles more than others muscles. A lot of thinner displayed muscles, that is smaller force muscles, exist in the kyphosis model in comparison with the healthy model. It is considered that the compensation posture set by this study has reduced a muscular force.

Fig. 6 shows force values of muscle bundles of the healthy model and the kyphosis model. It is observed that the muscle generate large force in the healthy model is obliquus externus, obliquus internus, psoas major, and transversus abdominis. It is thought that the posture of the upper part of the body is supported chiefly by these four muscles work when standing upright. Transversus abdominis muscle runs from lateral to anterior formed abdominal wall, its fibers running horizontally. So muscular force of transversus abdominis takes large value depending on abdominal pressure set here.

(a) Healthy model (b) Kyphosis model

Fig.4 Display of muscular force value of healthy model and kyphosis model in anterior view. Thickness of muscle line corresponds to magnitude of muscular force in the figure.

(a) Healthy model (b) Kyphosis model

Fig.5 Display of muscular force value of healthy model and kyphosis model in posterior view. Thickness of muscle line corresponds to magnitude of muscular force in the figure.

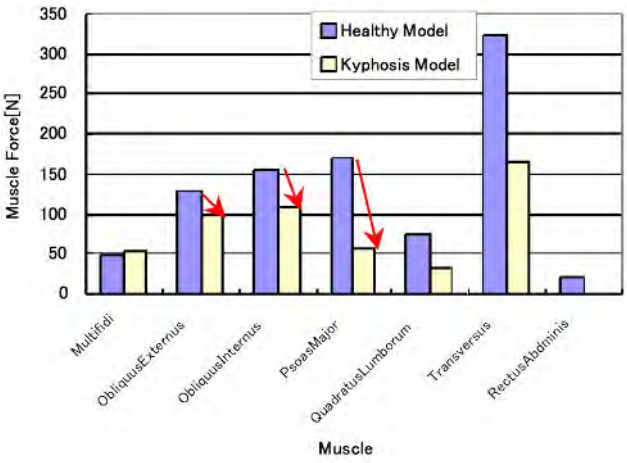


Fig.6 Muscular forces of healthy model and kyphosis model. Arrows show muscular forces related to spine erection with relative large difference between the healthy and the kyphosis model.

Four important muscles to keep upper body posture are focused in Fig.6, as comparing muscular force of the kyphosis model with the healthy model. A remarkable decrease in about 50% is observed with transversus abdominis, the value of 67% decreases in psoas major, 24% decreases in obliquus internus, and 31% decreases in obliquus externus as shown besides by the arrow in Fig.6. The trunk muscular forces decrease, as the compensation posture for the kyphosis due to vertebral compression fracture.

B. Influence on intervertebral joints

Intervertebral joint forces in axial direction are shown in Fig.7 for the healthy model and the kyphosis model. Force act on intervertebral joints tended to large in the joint on the tail side, and the joint force of L4-L5 is the largest in the lumbar vertebra. Force of all joints is larger in the kyphosis model than the healthy model. The compensation posture possible to make vertebral joint force increase. Especially, it rises greatly as shown by the arrow in the figure like 21% in L1-L2, 32% in T12-L1, and 33% in T11-T12. From Fig.6 and Fig.7, it was shown that the intervertebral joint forces in lumber spine increase although the trunk muscular forces decrease, when an osteoporosis patient has compression fracture at the 12th thoracic vertebrae and then takes the compensation posture for recovery body balance and view range. This causes the second compression fracture on another vertebra after occurring kyphosis by first compression fracture. Furthermore, it is considered that the second compression fracture happens easily to the adjacent vertebra of the 12th thoracic vertebra, because the increase ratio of the joint force is larger on the upper side of the 12th thoracic vertebrae assuming the fracture.

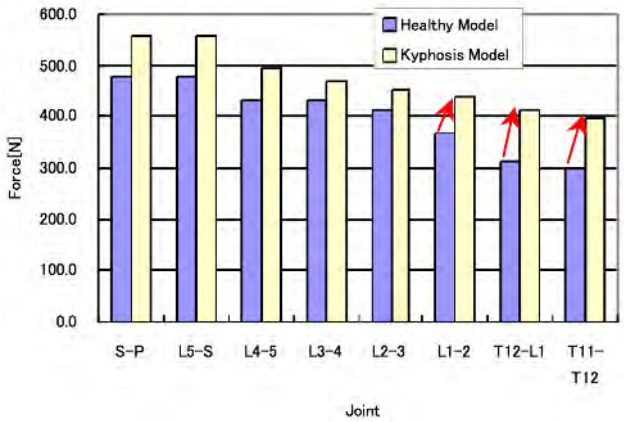

Fig.7 Comparison of the vertebral joint force along spine axis. Arrows show vertebral joint forces near fractured vertebra T12 with relative large difference between the healthy and the kyphosis model.

IV. Conclusions

To study the influence of the posture change by vertebral compression fracture in osteoporosis patient on loading condition of spine, muscular force of trunk and intervertebral joint force was calculated by using the musculo-skeletal model corresponding to normal posture and kyphosis posture. Deference of loading condition between the healthy model and the kyphosis model were considered and discussed. It was observed that mainly four trunk muscles in standing condition supported posture of upper body. In the kyphosis model with the compensation posture, although trunk muscular forces were reduced, intervertebral joint force increase in the maximum by 30% or more. It has been understood that risk of causing the second compression fracture rises further in the adjacent vertebra of the first fracturing vertebra. Thus, an important observation for considering about the risk of vertebral compression fracture in osteoporosis patient was obtained.

The Biomechanical Analysis of the Coil Stent and Mesh Stent Expansion in the Angioplasty

S.I. Chen[1], C.H. Tsai[2], J.S. Liu[2], H.C. Kan[1], C.M. Yao[1], L.C. Lee[1], R.J. Shih[1], C.Y. Shen1[1]

Abstract — **Percutaneous Transluminal Angioplasty (PTA) with stent is employed to treat the cardiovascular diseases in clinical to dilate stenotic arteries. There have been two types of stents (helical coil shape and traditional mesh shape) wildly used in angioplasty in the past few years. This research studied the biomechanical effects on the expansion behavior of these two different stents with balloon in the artery vessel. The commercial three-dimensional finite element method (FEM) based software was employed to perform all the computations in this study. Simulation results reveal that the pressure is delivered uniformly by the balloon, which leads the stenosed vessel to dilate. The dog bone effect is more obvious in the helical coil stent than the traditional mesh stent. The regions close to both ends of the stent exhibit large deformation and high shear stress values for both stent types. In the clinical practices, large deformation may cause stress concentration which leads to the damage of the vessel.**

I. Introduction

Cardiovascular diseases have been on the list of the top-ten leading causes of death in many countries in the past decade. It is a result of the narrowing and clogging of the arteries that cannot supply enough blood to heart. In the modern angioplasty, cardiologists apply stenting technology to restore normal blood flows in arteries where fatty deposits, or plaque formations, reduce the blood flow supply for patients with cardiovascular diseases. The balloon which is inflated by the pre-determined pressure pushes the stent radially outward against the vessel wall. Then the stent permanently expands the narrowing vessel to recover the continuous blood flow. There are currently several commercially available stent designs in the market [1]. A more detailed understanding of the mechanics may lead to significant improvement of the outcome on clinical medicine.

Finite element method (FEM) can help identify some valuable mechanical characteristics of stents, arteroes, and their interactions. So the numerical analysis has been proposed as an alternative approach to investigate mechanical properties of stents. Auricchio et al. [2] studied the biomechanical interaction between a balloon-expandable stent and a stenotic artery. Migliavacca et al. [3] investigated the effects of different geometrical parameters of a typical coronary stent on the mechanical performance. Lally et al. [4] assessed the effects of artery wall shear stress on two different stent designs using a balloon-stent model.

The purpose of this study is aimed at the biomechanical and interactive behavior of stent deployment system by the aid of FEM analysis. Two different stent designs (helical coil shape and traditional mesh shape) were considered to evaluate the stent deployment system. In order to fully understand the biomechanical effects of atherosclerotic artery during the inflating process, a 3D composite stent model, which consisted of the stent, balloon, and artery components, was generated for this study. In the stent expansion process, the characteristics of deformation, and stress distribution were investigated using the FEM approach.

II. Materials and methods

The full model of the stent deployment system proposed in this study was composed of three parts: stent, balloon and artery as shown in Fig. 1. All of the finite element models in this study were created by the commercial package of ANSYS 11.0 (ANSYS, Canonsburg, PA, U.S.A). A widely used mesh stent type [5] and a helical coil type stent were chosen in this study [6]. Both the helical coil stent and traditional mesh stent models had the length of 21mm, outer diameter of 2.06mm and thickness of 0.05mm. A grid convergence test was performed to ensure the necessary grid density for all the computations. There were 29112 nodes and 13184 elements in coil stent model, and 69953 nodes and 26628 elements in mesh stent model with tetrahedral elements were shown in Fig. 2. The balloon model had length 21mm and thickness 0.05mm. Artery and balloon were modeled as the cylinder with 30mm in length and 2.1mm in inner diameter, and the thickness of artery wall was 0.5mm. The balloon expanding full models of the coil and mesh stents were shown in Fig. 1. There were 11555 nodes and 7797 elements in the balloon component, and 35855 nodes and 37715 elements in the vessel component with hexahedral element.

www.springerlink.com

Fig. 1. The balloon-expanding full model with the coil and mesh stent system

Fig. 2. The three-dimensional grid models of the coil stent and mesh stent

In the analysis model, all material properties were assumed to be homogeneous and isotropic. The material of the stent was assumed to be 316L stainless steel and was described as a bilinear isotropic hardening with Young's modulus 196 GPa, Yield stress 205 MPa, Tangent modulus 692 MPa and Poisson's ratio 0.3 [7]. The Young's modulus of the balloon and vessel were 30.1 MPa and 1380 MPa, respectively, and the Poisson's ratio were all 0.499 [8]. Implicit nonlinear large deformation analysis was performed in ANSYS 11.0. The surface-to-surface contact elements were used to perform the loading transfers between the balloon and the stent, and between the stent and the vessel. The friction coefficient was set as 0.3. Both ends of the vessel model were fixed for all DOF (Degree of Freedom), and the uniform pressure was loaded from 0 to 10 MPa in the balloon inner surface, which was treated as the boundary condition.

III. Results and Discussion

From the simulation results, the deformed shapes of the stent and balloon components with coil and mesh stent were shown in Fig. 3. The balloon delivered the pressure uniformly, which led the stenosed vessel to dilate. It is noted that the dog-boning effect is not very obvious at the both ends of the helical coil stent and mesh stent. This is because the vessel component is included in the analysis and resists partial dog-boning effect from the stent at the both ends. It is observed from Fig. 3 that the dog bone effect is more evident in the helical coil stent than the mesh stent. The deformation at both ends of the coil stent is larger than these of the mesh stent. It indicates that the geometric structure of the helical coil stent is weaker than mesh stent at the both ends of the stent. Figure 4 illustrates the von-Mises stress distribution contours for both the helical coil and mesh stent models at large deformation (fully expanded) stage. Figure 5 demonstrates that the von-Mises stress concentrates in the large deformation region of the vessel for the helical coil stent model. The high stress levels may result in the lesion in the vessel wall during the stent expansion stage.

Effect of Airway Opening Pressure Distribution on Gas Exchange in Inflating Lung

T.K. Roy, MD PhD[1]

[1] Division of Critical Care, Dept of Anesthesiology, Mayo Clinic, Rochester MN USA

Abstract — **Pathophysiological alterations in lung mechanics commonly occur in critically ill patients and can result in impaired oxygenation and ventilation. The process of recruitment as the lung inflates involves the progressive opening of airways resulting in increasing amounts of alveolar volume available for gas exchange, and is modeled in this study using avalanche dynamics. Here we employ a symmetric 10-generation tree to represent the region of the lung participating in gas exchange along with a simplified model of pulmonary microvascular blood flow through an accompanying vascular network. The model is used to obtain the mean oxygen saturation during lung inflation under normal conditions as well as those simulating increased threshold opening airway pressures. For the values of parameters used, the oxygen saturation calculated for a uniform distribution of opening pressures is found to be 3.6% higher as compared to simulations performed using a generation-dependent distribution of opening pressures with higher opening pressures in smaller airways. In both cases, blood flow is assumed to be constant and the effects of gravity are not considered. Future work will include the effect of regional heterogeneity in lung mechanics on gas exchange. The ultimate goal of this work is to develop optimal ventilation strategies to minimize ventilator induced lung injury and improve gas exchange in critically ill patients.**

Keywords — **Pulmonary mechanics, gas exchange, avalanche dynamics, ventilation-perfusion matching, critical illness.**

I. Introduction

Critically ill patients are often affected by alterations in pulmonary mechanics caused by changes in airway elasticity and resistance [2]. Optimizing oxygenation and ventilation in these patients requires a quantitative understanding of ventilation/perfusion matching in the regions of the lung available for gas exchange. As the lung inflates, the increasing alveolar volume available for this purpose can be modeled using avalanche dynamics [3]. The purpose of this preliminary theoretical study is to assess the effect of two different laws governing airway opening pressures on oxygenation over the respiratory cycle.

Airway opening as governed by avalanche dynamics requires the assignment of opening pressures to each segment in the tree structure used to model the airway. In this study, a symmetric tree structure is employed to represent the portion of the tracheobronchial tree that participates in gas exchange. A simplified model of pulmonary microvascular blood flow through an accompanying vascular network is used to obtain the mean oxygen saturation during lung inflation under normal conditions as well as those simulating increased threshold opening airway pressures; specifically, a uniform distribution of airway opening pressures is compared to a generation-dependent distribution of airway pressures with higher pressures corresponding to smaller airways.

II. Methods

A symmetric 10-generation tree was modeled using Mathematica 6.0 (Wolfram Research, Champaign IL, USA) to represent the region of the lung available for gas exchange. The presence of an accompanying vascular network with specified inlet PO_2 was assumed and gas exchange was assumed to take place in the alveoli, defined as the terminal segments of the tree. These calculations were performed in accordance with the following assumptions.

A. Airway Opening

Lung inflation was simulated using avalanche dynamics following the assignment of airway opening pressures to each segment of the tree structure. For the reference case, normalized opening pressures $P_{i,j}$ (corresponding to segment j of generation i) were selected from the uniform distribution U(0,1). Generation-dependent opening pressures were calculated according to:

$$P_{i,j} = 1 - P^{1+\ln(i+1)} \quad (1)$$

where P represents a value selected from the uniform distribution U(0,1). Pseudorandom numbers in this range were generated using the Mathematica function `RandomReal`. Following the tenets of avalanche dynamics, the pressure at the initial (root) segment was gradually increased in small increments to simulate lung inflation. Connected segments with opening pressures less than or equal to the pressure at the inlet were progressively opened as the inlet pressure was increased [1, 4]. Terminal segments (alveoli) that were in communication with the root segment were assumed to participate in gas exchange as detailed in Section B.

Table 1 Parameter Values

Parameter	Value	Units
Pulmonary artery PO_2	40	mmHg
Inspired PO_2	100	mmHg
P_{50}	27	mmHg
n	2.6	–

B. Gas Exchange

Gas exchange was modeled with the assumption that oxygen tension would rapidly equilibrate across the alveolar-capillary membrane. The pulmonary venous oxygen tension was therefore calculated as the weighted average of the oxygen tension of venous blood in contact with unopened alveoli (representing shunt fraction) and the oxygen tension of blood in contact with alveoli open to the root segment. The Hill equation was used to convert between oxygen tension (PO_2) and oxygen saturation (SO_2):

$$SO_2 = PO_2^n / (PO_2^n + P_{50}^n) \quad (2)$$

Pulmonary venous oxygen saturation was integrated over the inspiratory phase to provide a mean measure of oxygenation during lung inflation. Parameters used in the simulation are listed in Table 1.

III. Results and Discussion

The model was used to obtain the mean oxygen saturation during lung inflation under normal conditions as well as those simulating increased threshold opening airway pressures. For the values of parameters used, the oxygen saturation calculated for a uniform distribution of opening pressures was found to be 3.6% higher as compared to simulations performed using a generation-dependent distribution of opening pressures with higher opening pressures in smaller airways. Figure 1 shows pulmonary venous oxygen saturation as a function of normalized inlet pressure for the reference case (dashed blue line). The utilization of generation-dependent opening pressures delays opening of alveoli, resulting in a higher shunt fraction during more of the inspiratory cycle (solid purple line). This phenomenon is illustrated in Figure 1 and results in a lower mean saturation when averaged over the inspiratory cycle as compared to the reference case. This simulation clearly demonstrates the influence of alterations in pulmonary mechanics on gas exchange frequently seen in critically ill patients.

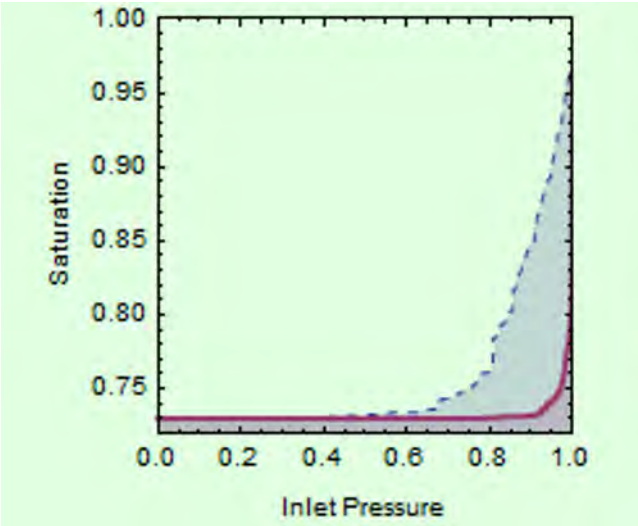

Fig. 1 Variation of pulmonary venous saturation during inspiration

IV. Conclusions

The purpose of this preliminary study was to assess the impact of generation-dependent opening pressures on oxygenation of blood flowing through the pulmonary vasculature. As expected, the oxygen saturation was seen to be higher with uniform opening pressures as compared to the case where higher opening pressures were assigned to smaller airways. Future studies will incorporate heterogeneity in the airway and vascular tree structures, airway and alveolar wall tissue elasticity, a more detailed model of gas exchange across the alveolar-capillary membrane, and incorporation of gravity effects. The ultimate goal of this work is to develop optimal ventilation strategies to minimize ventilator induced lung injury and improve gas exchange in critically ill patients.

Artificial High – Flexion Knee Customized for Eastern Lifestyle

S. Sivarasu[1] and L. Mathew[2]

[1] Ph.D Scholar, SBCBE, VIT University, India
[2] Dean, SBCBE, VIT University, India

Abstract — **Total Knee Arthroplasty has been an end term surgical procedure for pain relief and movement restoration in knee joint with Arthritis. The procedure has been followed for more than 5 decades. The performance of the joint after the procedure is dependent on the implant design. The emphasize for customized joint design for the eastern world has be in the discussion for a while now, mainly owing to the economic growth surrounding the eastern countries like China and India. Also the arthritis estimates show that the probable increase in the procedure numbers in the coming years.**

The requirement of eastern world for their lifestyles is the provision to sit on the lower platform. This means that the flexion-extension requirement of the implant is over 120 degrees. More over the activities like squatting would require mild inner rotation in the implant, so a Rotating platform design is considered for the knee design.

A multi radii design with an extended condylar portion is considered for the femoral component design. The inner profile is maintained such that it can be used with standard zigs that are used in TKS. The inner structures are of the component are design such that it enhances bone growth even after the implantation. Based on the tibial component design two final models were derived.

The models were subjected to Finite Element Analysis [FEA]. Design corrections were made with the FEA results. The models were then subjected to AdamsView motion analysis and Jack Motion Analysis. The range of motion of the models was verified to be over 120^{o}. The research is aimed in designing a knee with over 135 degrees of range of motion.

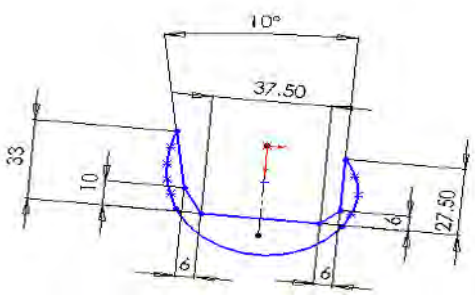
Keywords — **Total Knee Arthroplasty, Artificial Knee, High Flexion Knee, Squatting, Finite Element Analysis**

I. Introduction

The joint replacement surgeries are doubtlessly the gift of science and technology for human welfare. The history of joint replacement begins way back in the late 60's. Initially from the Hip, then to Knee and now shoulders, ankle elbow and almost all the joints are replaced nowadays.

The knee replacement procedures had been followed for almost 50 years in the surgical procedure called the Total Knee Replacement [TKR] or the Total Knee Arthroplasty [TKA]. Here the cartilages and the bones surface which are degenerated by arthritis are removed and replaced with the metal components either by cemented or Cementless procedures. The metal and the Polyethylene components are all together called the Artificial Knee. [1][2][3]

II. Design of the Artificial Knee:



The components in the artificial knee are,

- The Femoral component
- The Tibial component
- The Patellar component
- The PE Insert

The design of each components of the artificial knee is shown below. The design emphasis is given on the femoral component as that's the only component involved in the major movements. Where as the rest of the components act mainly as supporting structures.

A. The Femoral component design:

The femoral component being the key factor in the flexion range determination of an artificial knee needs extreme care in its design and evaluation. The ideal femoral component would be the replica of the natural femur, but owing design constrains few modifications are made on the design. [1][2][4]

Developing from the base design we get the 3-D model of the femoral component. Fig. 2

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1597–1599, 2009
www.springerlink.com

Fig.2 Femoral component models.

The existing multi-radii design by its own has a range of over 135 degrees. To allow this range corrections are made on the posterior of the PE insert for the free movement of the femoral component over the insert. The rise in the PE is shelved and seen to that the rolling and gliding is continuous.[1][2]

Design parameters such as the single- radii or a multi radii design were initially compared. The multi radii design offers better range of motion that the single radii design. These tests were done using the ADAMS simulation works. The movements were defined by an equation and they were allowed to move. The results suggested that the multi radii design not only supports the rolling but also the gliding action as in a natural knee unlike the single radii design. [1][2][5]

The radius of the arc of the condyles of the femoral components, have better stability if they are away from each other and have better range of motion if they are towards each other. But trying to get a balance between the movement and the stability the medical lines were selected for the condlyar arc.[6]

The arc of the femoral components condyles in the posterior side, i.e. the part where the femoral component rests during the high flexion, is has a curivical end than the regular stunt end. This enhances the range of motion. This also means the extension of range of motion by another 10 to 15 degrees [1][2][7]

III. The Final Designs

A. The final designs:

The two proposed 2 new designs for the eastern lifestyles.Fig.3 and Fig.4

Fig.3 Model – I : Regular conical Insert

Fig.4 Model–II: Peg Restrainer for the PE insert

B. Analysis of the Design:

The design is subjected to Finite Element Analysis [FEA]. Owing the FEA results the corrections were made in the designs. The models were also subjected to motion analysis to determine the flexion- extension range. Both the results of the FEA and motion analysis are key factors in the design of the implant. [8]

C. Results of the Analysis:

The models were subjected to finite element analysis with load conditions above the normal human load levels. For example for the Tibial component, the maximum load

subject would be around 6 times the body weight. i.e., 6* 65 [average Weight] = 390Kgs. But for the same condition, the models were tested with a load of around 450-500 Kgs. The results of the designs would be published after the patenting of the model. However the results have been good enough to move the model for fabrication.[1][2]. The AdamsView motion analysis shows that the models when subjected to motion undergo a flexion of up to 130°.

IV. Discussion

Fig.5 below illustrates the flexion – extension range of the normal knee

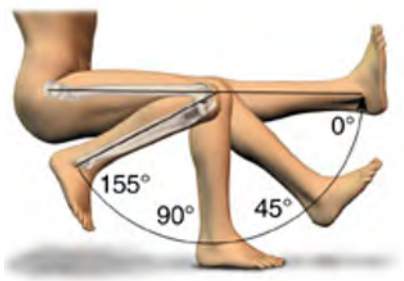


Fig.5 Flexion – Extension Range of the Knee.

The normal artificial knee designs that are available in the market are designed with consideration on the western population. Most of these implants have a design restriction upto 90degrees. The normal activity of an average eastern world population lies around 100 degrees. The existing design thus cannot be used in these applications. How ever these new design that are proposed can give the comfort of semi-squatting as they provide flexion extension range of around 120 degrees. This is validated with the AdamsView simulation results.

V. Conclusions

Fixing the components and making one component to glide over the other achieved the existing range of 130 degrees. This movement is defined by an equation. However, the movements restricted to 130 degrees strictly by the restriction of the condyles of the femoral components. The change in this section will definitely help us reach 140 degrees.

Biomedical Engineering Analysis of the Rupture Risk of Cerebral Aneurysms: Flow Comparison of Three Small Pre-ruptured Versus Six Large Unruptured Cases

A. Kamoda[1], T. Yagi[1,2], A. Sato[1], Y. Qian[1], K. Iwasaki[1], M. Umezu[1], T. Akutsu[3], H. Takao[4], Y. Murayama[4]

Abstract — **A relationship between blood flows in cerebral aneurysms and their rupture remains obscure. In clinical practice, the size of aneurysms is one of the important factors for determining a strategy of treatment, but in our database three small aneurysms became ruptured during follow-up. Here, we aim to study their pre-ruptured hemodynamics, and differentiate them with those of six large unruptured aneurysms. All the aneurysms occurred in internal carotid artery, and their mean sizes were 6 and 10.8 mm for pre-ruptured and unruptured cases, respectively. We reproduced their replica as a patient-specific elastic model using clinical images obtained by digital subtraction angiography and a series of rapid prototyping techniques. Flows were reproduced *in vitro* using a cerebral flow simulator, and visualized by Time-resolved Particle Image Velocimetry. All pre-ruptured cases showed the collision of an incoming flow at a distal neck, and formed a prominent jet stream directing towards the aneurismal head. In contrast, none of unruptured aneurysms had such a marked impingement, and their flows were most likely characterized by swirling patterns. All unruptured cases occurred in a twisted vessel, or carotid siphon, whereas pre-ruptured ones were located downstream whose geometries consisted of a simple curvature. These findings suggest that internal carotid artery has a regional dependency of the risk of aneurismal rupture. Furthermore, the presence of jet streams for small-sized aneurysms may be a substantial indicator of the rupture and immediate treatments.**

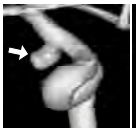
Keywords — **cerebral aneurysm, rupture, PIV, hemodynamics**

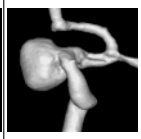
I. Introduction

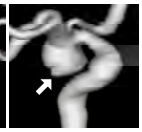
The rupture risk of cerebral aneurysm is diagnosed by several factors including size and geometry. The occurrence rate of the rupture is only about 0.5 % per year [1], but it leads to subarachnoid hemorrhage that has a significant impact on the life of patients since its mortality rate reaches up to 50 % [2]. Currently, about 85 percents of subarachnoid hemorrhage were estimated to be caused by the aneurismal rupture. Thus, there is a significant demand for the risk management of rupture.

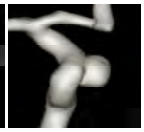
It is widely believed that hemodynamics in aneurysm may be related with its rupture. Wall shear stress (WSS) is one of the key parameters in regulating the remodeling of blood vessels. Likewise, some researchers utilized the WSS to assess the risk of aneurismal rupture, but there is as yet a reliable correlation between them [3, 4]. Indeed, there are even varying magnitudes of the WSS observed in an individual aneurysm, which in turn hampers to compare the value with others.

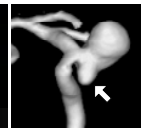
Cebral and colleagues studied the flows in aneurysms with a wide variety of anatomy, namely lateral, bifurcation, and terminal types, using computational fluid dynamics (CFD) [5]. In doing so, they assumed the vessel wall acted as a solid boundary. They observed varying patterns of inflow jets among ruptured and unruptured cases, and reported that the former more likely had small impingement regions and narrow jets.

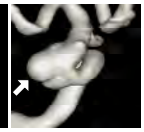












Until now, we observed the rupture of three small-sized lateral aneurysms in internal carotid artery during follow-up. In the present paper, we compare the flows with those of large-sized six aneurysms from the similar anatomical location. The flow analysis comprised a patient-specific elastic replica and an *in vitro* flow visualization using Time-resolved Particle Image Velocimetry (PIV). This paper aims to clarify the differentiation of flows between pre-ruptured and unruptured cases and to better understand the mechanism of the aneurismal hemodynamics in an effort to establish the risk management of rupture.

II. Method

Table 1 summarizes data of aneurysms studied. Three-dimensional digital subtraction angiography done by interventional neuroradiologists determined geometries of aneurysms including parent vessles. Fig.1 shows anatomical locations of aneurysms. The mean size and age of three pre-ruptured cases were 6 mm and 67 years, while counterparts of six unruptured cases were 10.8 mm and 62.7 years. Vascular geometries were reproduced as a patient-specific

Fig.2 Patient-specific elastic models of aneurysms. These models are made of transparent silicone rubber.

replica (Fig.2). These aneurysm models were made of a transparent silicone rubber using rapid prototyping techniques including stereolithography and lost-wax casting. The mechanical property of the models was standardized by incremental distensibility, which had a value of $1.4\pm0.4\times10^{-3}$ 1/mmHg, approximately corresponding to that of anterior cerebral artery of healthy individuals [6].

Then, the aneurysm model was set in a pulsatile flow simulator (Fig.3). The mean flow rate was adjusted to 330 mL/min at a pressure of 120/80 mmHg, a heart rate of 70 bpm, and a systolic fraction of 35 %. The working fluid was a mixture of glycerol and water with a fraction of 46 and 54 %, respectively, which had a density and kinematic viscosity of 1100 kg/m^3 and 3.7 cSt, respectively. The fluid was seeded by fluorescent tracer particles with a density of 1100 kg/ m^3 and a mean size of 15 μm (Fluostar, EBM corp., Tokyo).

Then, Time-resolved PIV measurements were carried out. A long-pass fluorescent filter eliminated the scattered light from the laser with a wavelength of 532 nm and selectively passed the fluorescent light with a wavelength of 580 nm.

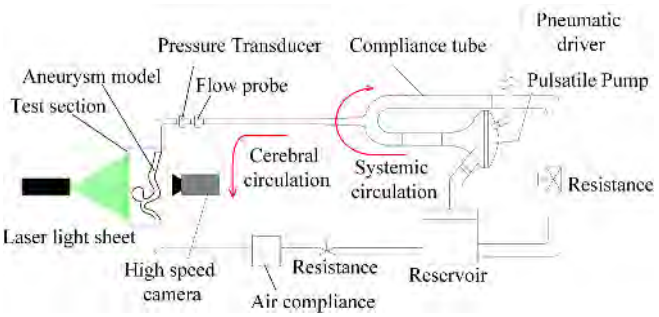

Fig.3 In vitro cerebral vascular flow simulater

This fluorescent PIV technique was found to be significantly useful for the accurate measurement of aneurismal flows. PIV measurements were repeated in multiple planes to cover the whole part of aneurysms.

III. Results and Discussion

Flow characterization revealed that flow patterns were classified by three types for aneurysms studied. Jet type was characterized by a jet flow, which was defined to have a flow collision at the distal neck and a separated flow directing towards the head of aneurysm. The all pre-ruptured cases exhibited such phenomena with jet velocities reaching 1 m/s approximately. Fig.4 summarizes the representative pattern of the jets observed during peak phase. The incoming flow in the parent vessels collided with the downstream sides of the aneurismal necks, and then the separated flow formed the intra-aneurismal jet. There are no marked differences observed for the cyclic changing of flow patterns. Swirl type was characterized by a swirling flow which was most likely observed in the unruptured cases. Fig.5 shows the representative inflow patterns for the unruptured cases. Incoming flows did not show a marked collision to the neck, and the flows in the parent vessels rather entered the aneurysms more smoothly. In order to understand the flow structures in three-dimensions, PIV measurements were made in orthogonal planes (Fig.6). It was found that the flows were more likely characterized by swirling flows rather than jet flows. Branch type was characterized by multiple flows because of the presence of blebs. All the blebs showed the distinct low velocity of the order of 0.1 m/s or less.

Table 2 summarizes the characterization of flow patterns. Distinct vascular geometries caused varying patterns of aneurismal hemodynamics. Most of unruptured cases were located in carotid siphon whose geometries were characterized by strong twisting shapes. On the other hand, all pre-ruptured cases were at the downstream, where the vessel consisted of smooth curvature without twisting. The twisting vessel generated a tangential inflow into the neck plane, resulting in the formation of a swirling flow. In terms of fluid dynamics, a jet flow tends to become more unstable

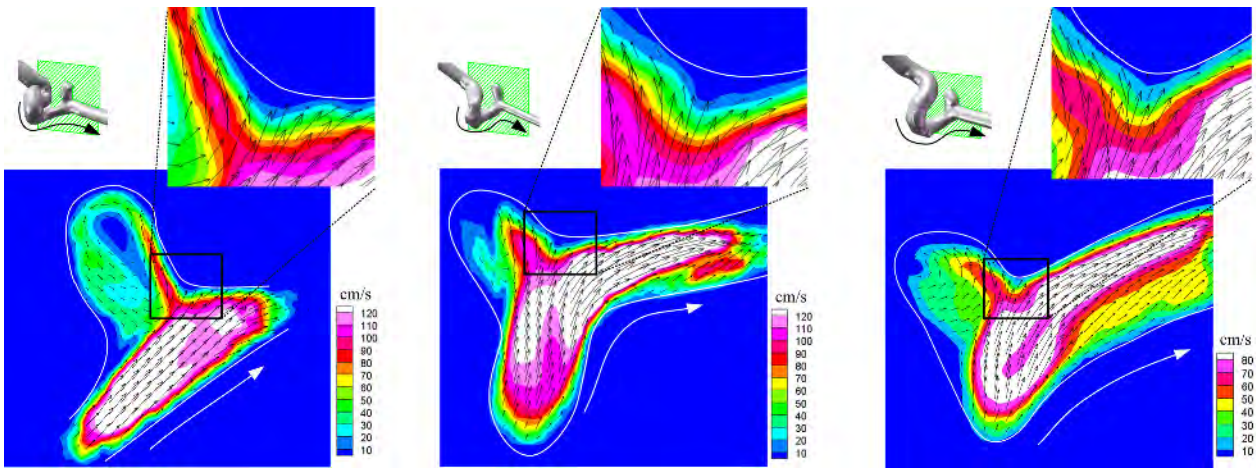

Fig.4 Aneurismal jets observed during peak phase in all pre-ruptured cases (left: case1, center: case2, right: case3). The flows in the parent vessels collided with distal sides of the aneurismal necks, and then the breakup of the flow led to form the jets. Schema shows measurement planes.

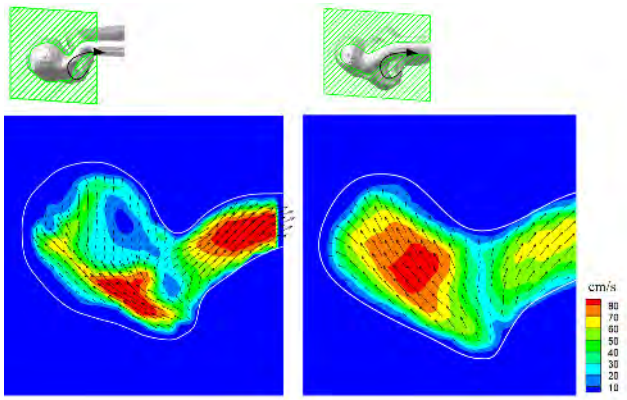

Fig.5 Comparison of inflow patterns in unruptured cases (left: case4, right: case5)

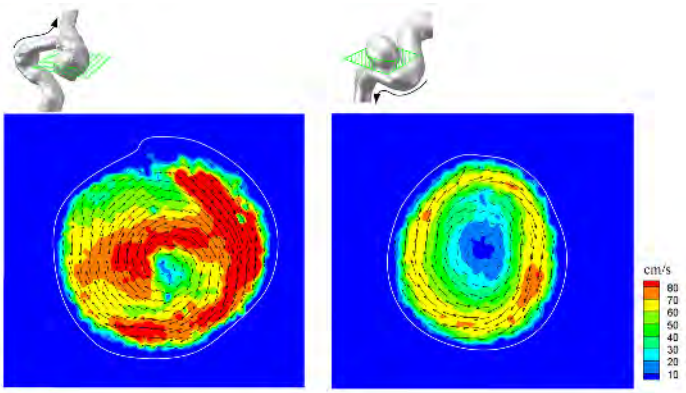

Fig.6 Swirling flow patterns observed in unruptured cases (left: case6, right: case7)

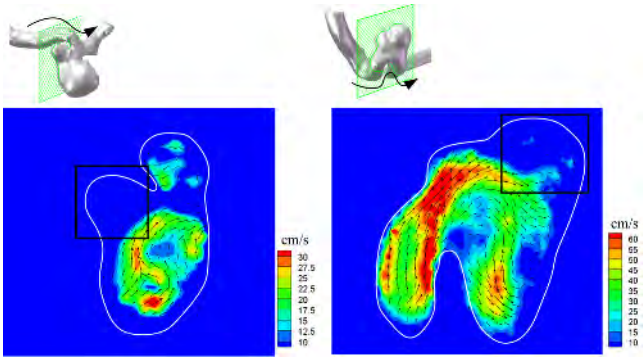

Fig.7 Multiple flows observed in unruptured cases (left: case8, right: case9). These cases harbor blebs (black frame).

Table 2 Flow patterns in aneurysms studied. Inflow patterns are described in parentheses. Case1, 2 and 3 have impinging flow as indicated by red arrow.

Flow pattern	Case							
Jet Type (collision)	Case 1		Case 2		Case 3			
Swirl Type (smooth inflow)	Case 4		Case 5		Case 6		Case 7	
Branch Type (smooth inflow)	Case 8		Case 9					

owing to an adverse pressure gradient and more often generates high WSS than the swirling flow. As a result, our data may indicate that there is a varying degree of rupture risk of aneurysm in internal carotid artery. By considering that the pre-ruptured aneurysm had the rather small size, it is suggested that the presence of a jet flow may be a substantial indicator of the rupture of a small-sized aneurysm.

IV. Conclusions

This study showed that there is an interesting trend in the relationship between aneurismal hemodynamics and rupture. The flows studied were classified into three types characterized by Jet, Swirl and Branch Type. Varying flow patterns attributed to the anatomical location in internal carotid artery. The simple curvatures of the parent vessels promoted colliding flows at the distal sides of aneurismal necks, resulting in the strong aneurismal jets. The swirling flows observed in the unruptured cases were caused by the twisting vessel which is called carotid siphon. The blebs on aneurysms made a distinct low velocity in contrast to that of the mainstream. It was suggested that aneurismal jets may play a key role for the risk management of the rupture, and can be characterized according to the anatomical configuration of the aneurysm and parent vessel.

Metrology Applications in Body-Segment Coordinate Systems

G.A. Turley[1] and M.A. Williams[1]

[1] WMG: Innovative Solutions, School of Engineering, The University of Warwick, Coventry, UK

Abstract — **The location and stability of a surgical implant is a critical factor for a successful clinical outcome. This is dependent upon being able to define the position of an implant in relation to its mating bone or body-segment. Advances in the surgical process require definition of body-segment coordinates to be robust which is influenced by the references these coordinate frames are derived from. This paper presents preliminary findings in the use of metrology tools and techniques to register bone landmarks in an accurate and repeatable manner and address whether the establishment of a body-segment coordinate frame can aid in implant positioning.**

Keywords — **Body-Segment Coordinates, Implant Bone-Alignment, Metrology.**

I. Introduction

The surgical process has emerged as a field which has seen the exploitation of sophisticated technologies, often having to embrace adapted principles from other industries. This has led to a closer integration with the engineering community and produced cross-disciplined research increasing the depth of knowledge available to the surgeon to diagnose, treat and rehabilitate their patients using more customized approaches [1]. An area that can have a significant impact upon the success of the surgical intervention is the location and stability of the surgical implant in orthopedic surgery [2]. However, the clinical outcome of the location and orientation of the endo-prosthesis is still affected by surgeon-handwork and implant-bone alignment [3]. This highlights a gap in knowledge between the engineering and healthcare community and provides a focus for this paper.

II. Biomechanical coordinate frames

The location and stability of a surgical implant is influenced by how well the endo-prosthesis and bone can be dimensionally aligned and is therefore intrinsically a biomechanical problem. In biomechanics it is important that factors such as motion, location and orientation are expressed where possible in clinical terms to ensure meaningful comprehension by the healthcare community, which requires relating findings and expressing them in an anatomical coordinate frame shown in Figure 1 [4].

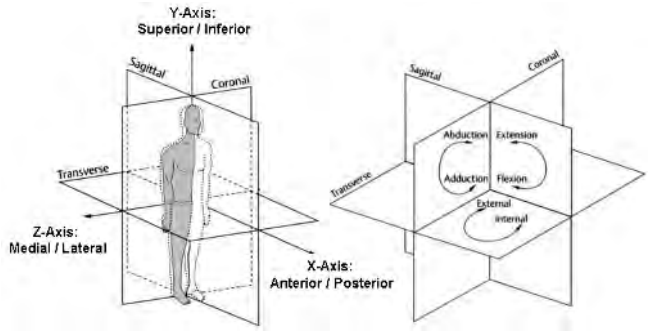

Fig 1 The Anatomical Coordinate Frame

Biomechanical assessment uses the principles of rigid-body mechanics, which regards the distances between points on a moving segment to be invariant [5]. A rigid-body has six degrees of freedom which are used to describe the location and orientation of a body-segment [6, 7]. Using Figure 1 there are three translational degrees of freedom which occur along the x, y, z axes and three rotational degrees of freedom which occur about these axes.

In orthopedic biomechanical application such as gait analysis and arthroplasty procedures involving endo-prosthesis the relative position of one body-segment to another is critical to ascertain the joint characteristics [8]. To be able describe joint characteristics in a biomechanical context two classes of coordinate frames are used. Body-segment coordinate frames which refer to the local coordinate system of a particular bone and joint coordinate systems which are used to define the relationship between two body-segments of a joint, for example the humerus and the scapula which are the mating bones within the shoulder joint system [9]. This paper will focus upon the use of body-segment coordinate frames in the application of aligning a hip endo-prosthesis with a femur using dimensional metrology tools and techniques.

III. Research problem

A body-segment coordinate system relies on establishing a cartesian coordinate frame for a bone segment [9, 10]. Advances in the surgical process require definition of body-segment coordinates to be robust which is influenced by the references these coordinate frames are derived from [11].

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1604–1607, 2009
www.springerlink.com

Using rigid-body principles to define a body-segment coordinate system, three location parameters and three orientation parameters are required to form a cartesian coordinate system [6]. Therefore, a minimum of three non-collinear points or landmarks are necessary to construct a body-segment reference frame [12, 13].

One of the major sources of error in a study or clinical analysis using body-segment coordinate frames is the registration of landmark information. This registration is influenced by two significant factors, being able to palpitate or digitize exactly the same reference point location on a bony prominence in a repeated manner and the limited accuracy of the measurement devices used to register the landmarks [14, 15]. Coordinate frames are also influenced by variability in the bone morphology and the fact that the rationale behind the selection of landmarks do not consider the increased anatomical stability that some landmarks have with regard to others [4, 13, 16].

The issues highlighted in the previous paragraph present certain research problems which the initial work presented in this paper purports to begin to address. These research problems have been detailed:

- Can metrology tools and techniques be used to register bone landmarks in an accurate and repeatable manner?
- Can the establishment of a body-segment coordinate frame aid in the positioning of an endo-prosthesis?

IV. Methodology

The research problem presented in the previous section is sought to be addressed by the use of a Coordinate Measuring Machine (CMM) to register bone landmarks on a model femur. A CMM is a computer numerically controlled (CNC) measurement system, which with the aid of a probing device can detect the spatial coordinates of an artifacts surface. Two probing systems will be used in this experiment, a touch-trigger probe and a non-contact laser-scanning probe. The touch-trigger probe is a tactile sensing element whose displacement can be sensed throughout the three dimensional workspace of the CMM. It interacts with the workpiece through probing the artifact surface, recording the x, y, z position and its i, j, k direction [17].

Laser-scanning consists of defining a numeric representation of an artifacts surface through sets of 3-D points [18]. It can gather up to 19,200 points per second, utilizing an image sensing camera and a focused laser line to gather points using a process known as active triangulation [18, 19]. This allows surface topology to be determined without having to contact the objects surface.

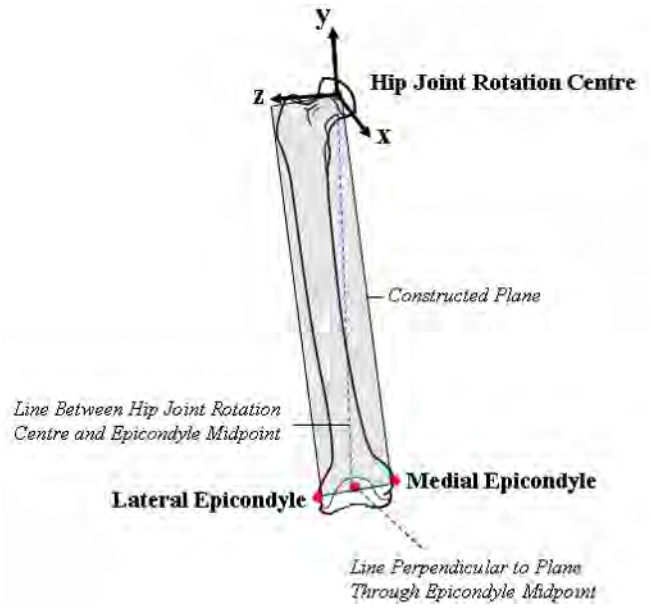

Fig 2 Femur Body-Segment Coordinate Frame

The two probing technologies that are going to be used during this experiment are the Renishaw TP20 touch-trigger probe and the Metris LC50 laser-scanning probe, both these probes will be mounted to a Metris HC-90 Horizontal CMM arm. When mounted to the CMM the touch-trigger probe has a quoted repeatability of 6μm while the laser-scanning probe has a repeatability of 15μm.

The laser-scanning probe was first used to take a scan of the model femur in the CMM global coordinate frame. The generated point cloud was then used to provide coordinate data for the three reference landmarks for the femur shown in Figure 2. This was made possible through visualizing the point cloud within the CAD environment so that the femur could be aligned to pick out the most medial and lateral points of the medial and lateral femoral epicondyles (FE) respectively and fit a sphere through the femoral head to determine the hip joint centre of rotation (HRC). These are the recommended landmarks proposed by the International Society of Biomechanics (ISB) [20]. The touch-probe was then fitted and programmed to measure the FE's and 30 points on the femoral head to calculate the HRC. A body-segment coordinate system was then established by constructing a line between the HRC and the midpoint of the FE's. A 3-point plane was then constructed from the landmark features and a line projected perpendicular from this plane through the midpoint of the FE's. The global reference system of the CMM was translated so that its origin coincided with the midpoint of the FE's and a 3-axis Euler rotation sequence [21] was then applied to rotate the global frame so that the y-axis aligned with the line between the

HRC and the midpoint of the FE's and the x-axis aligned with the other constructed line. This left the z-axis pointing positively in the right-lateral direction. A further translation of the origin was applied so that it was coincident with the HRC. This established a body-segment coordinate system that was both congruent with the ISB recommendations and anatomically representative.

The original point cloud was imported while the body-segment coordinate frame was being constructed which allowed the initial laser scan to be transformed into the femoral reference frame. The coordinate data for a further six landmarks could then be determined using the same methodology as was used for selecting the three reference landmarks. These were then programmed to be measured ten times using the touch-trigger probe, measuring the reference landmarks and reconstructing the femoral reference frame each time from the CMM global coordinates. This provided a test for the robustness of the body-segment coordinate system and for the repeatability of landmark digitization.

A model endo-prosthesis was then measured by the touch-trigger probe. Features were selected from the endo-prosthesis that permitted a coordinate frame to be constructed that was congruent with the body-segment coordinate frame of the femur, shown in Figure 3. A laser-scan was then taken in this coordinate frame so that both the endo-prosthesis and the femur could be analyzed in the CAD environment. A finite element mesh was generated from each point cloud and the axes of the implant coordinate frame were then aligned with the femoral coordinate frame to allow the helical or screw angle between the coordinate axes to be calculated so that congruence could be assessed. Once the endo-prosthesis axes were fully aligned with that of the femur the positioning of the implant could be evaluated. The results of this experiment are presented in the following section.

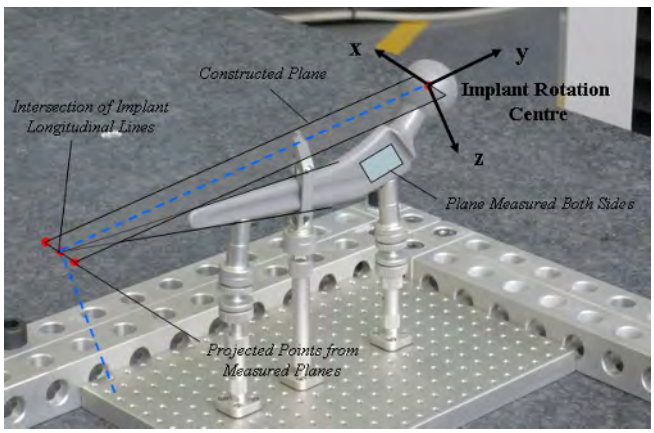

Fig 3 Endo-Prosthesis Coordinate Frame

V. Results

The CMM touch-trigger measurement results for the digitization of the six non-reference femoral landmarks have been presented in Table 1. Due to the probing directions of the landmarks being different, the measurement axis which produced the worst repeatability reading for each landmark has been presented. This axis coincided with the significant axis of evaluation for all landmarks. The table shows that the reference landmarks selected could be re-measured to produce a robust alignment frame which can digitize in a repeatable manner bone landmarks.

Table 1 Repeatability of Landmark Measurements

Landmark	Axis	Repeatability (μm)
Fovea Capitis	Y	6.71
Superior Point of Greater Trochanter	Y	1.95
Lateral Point of Greater Trochanter	Z	5.69
Superior Point of Lesser Trochanter	X	5.42
Superior Point of Medial Condyle	Y	3.46
Superior Point of Lateral Condyle	Y	2.59

The construction features of the body-segment coordinate frames for both the femur and the endo-prosthesis were examined in the CAD environment. The datum axes were aligned by applying a 3-axis Euler rotation sequence from which a helical angle of 6.62º was calculated which represented the deviation between the two coordinate frames. This is within the 10º angle bearing limit defined as deviating significantly from the frame of reference [11]. As well as the congruence of the axes being examined the endo-prosthesis positioning could also be visually evaluated. Figure 4 provides a schematic of the implant and femoral position relative to each other.

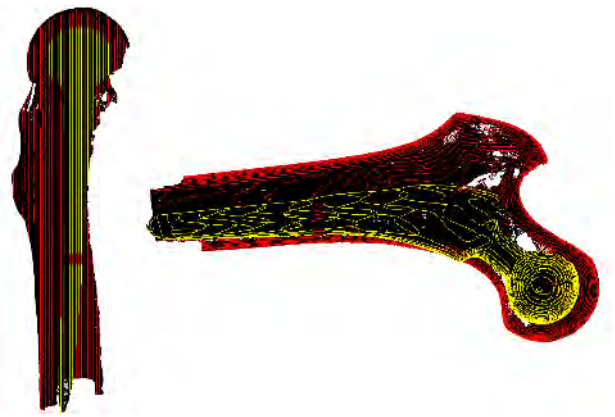

Fig 4 Schematic of Implant Positioning

Reviewing the schematic although professional clinical assessment is required, it is clear that the implant protrudes from the femoral surface and is situated so that only a thin bone wall thickness is holding the implant in place. The schematic does show however that the implant positioning does maintain the hip joint rotation centre. However, because of the limitations detailed, it can be asserted that the recommended femoral body-segment coordinate frame is not suitable for the surgical positioning of this design of endo-prosthesis.

VI. Conclusions & further work

The preliminary work presented in this paper has shown that metrology tools and techniques can be used to register bone landmarks in an accurate and repeatable manner. Also, an endo-prosthesis reference frame was established that was congruent with the recommended femoral body-segment coordinate frame [20], although the functionality with regard to implant positioning can be questioned.

The degree of congruence between the two coordinate systems will vary with bone morphology and pathology particularly considering the distance of the two reference femoral epicondyles away from the functionally important hip joint rotation centre. Therefore, the suitability of other more proximal landmarks is proposed to be investigated. The preliminary investigation has scope to expand the research with regard to the role of biomechanical coordinate frames in surgical implant positioning. The items below present a summary of this future scope:

- To use metrology tools and techniques to provide a traceable calibration route to improve the accuracy and repeatability within the surgical field;
- To incorporate the visualization techniques presented into the digital templating process, to include features such as landmark recognition and registration and bone cutting angles;
- To incorporate both body-segment coordinate and joint coordinate frames in the dimensional assessment of endo-prosthesis and design of surgical fixtures.

Finite Element Modeling Of Uncemented Implants: Challenges in the Representation of the Press-fit Condition

S.E. Clift

Centre for Orthopaedic Biomechanics, University of Bath, UK

Abstract — **The primary stability of uncemented orthopaedic implants is dependent upon the production of a stable mechanical environment at surgery. Excessive movement between the prosthesis and the surrounding bone can lead to the formation of fibrous tissue instead of a direct bond with the bone. The establishment of an interference fit at surgery, called a press-fit, is widely used to limit such interfacial movement. Although this technique is very successful, bone fracture at surgery can occur if too high a fit is attempted. The question therefore arises as to what is the minimum level of interference that will help provide the mechanical environment in which osseointegration can occur. Computational approaches, such as the finite element methodology, are currently being explored in order to inform this discussion by identifying the characteristics of the mechanical environment which have most effect.**

Keywords — **press-fit, finite element, bone relaxation, uncemented implants.**

I. Introduction

A variety of techniques are used to secure orthopaedic implants to bony tissue. Cemented implants typically use a PMMA bone cement to promote a mechanical interlock with the surrounding bone, whereas the design of uncemented implants requires a direct bond to be established between the implant and the adjacent bone.

Critical to the production of this direct bond (termed 'osseointegration') is the minimization of interfacial slip. There are two contributions to the level of interfacial slip; one is the cyclic interfacial displacements caused by physiological loading, termed micromotion or dynamic motion, and the other is the subsidence of the prosthesis (Figure 1, Bühler et al [1]). High levels of micromotion (in excess of 150 microns) have been shown to lead to the formation of a fibrous tissue layer whereas lower levels of micromotion (40 microns or less) have been associated with osseointegration (Jasty et al [2]).

One way of reducing micromotion is via an interference fit between the bone and the implant, established at surgery by under-reaming. This interference fit must not be so large as to cause the femur to fracture (Davidson et al [3]), nor small enough to fail to limit micromotion. A further influence on the magnitude of the interference fit is produced by the stress relaxation of the bone.

This paper contains a review of the contribution and potential of finite element analysis to inform the choice of the magnitude of the interference fit.

II. Methodology & results

The key issues concerned with finite element model development of uncemented implants are considered below:

Specimen specific materials properties:

Specimen specific materials properties are now routinely used in computational orthopaedic biomechanics. Both bone geometry and the variation in mechanical properties are typically derived from CT scan data (eg [4]). An open access set of such scan data has been made available by The National Library of Medicine Visible Human Project (http://www.nlm.nih.gov/research/visible/visible_human.html). This dataset has the advantage that predictions can be more readily compared with those from other investigators. The big disadvantages are that the bones in question are obviously not available for experimental validation and, of course, no clinical outcome is associated with them. It is also important to be cautious about conclusions drawn from the analysis of a single bone [5].

Despite the popularity of such sophisticated representations of geometry and materials properties, they may not be the best choice for all types of investigation. Understanding can still be advanced with 2D/axisymmetric models as in the study of Shultz et al [6].

Hounsfield units to bone density, bone density to mechanical properties:

Bone density is represented in medical CT scanning by the Hounsfield Unit (HU) parameter, a measure of the local attenuation of the X-ray signal. This can be correlated to bone mineral density by including a hydroxyapatite "phantom" of known properties in the scan. Complete bones can be mapped in this way. The medical CT scanning technique does not provide any quantitative information on bone ar-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1608–1610, 2009
www.springerlink.com

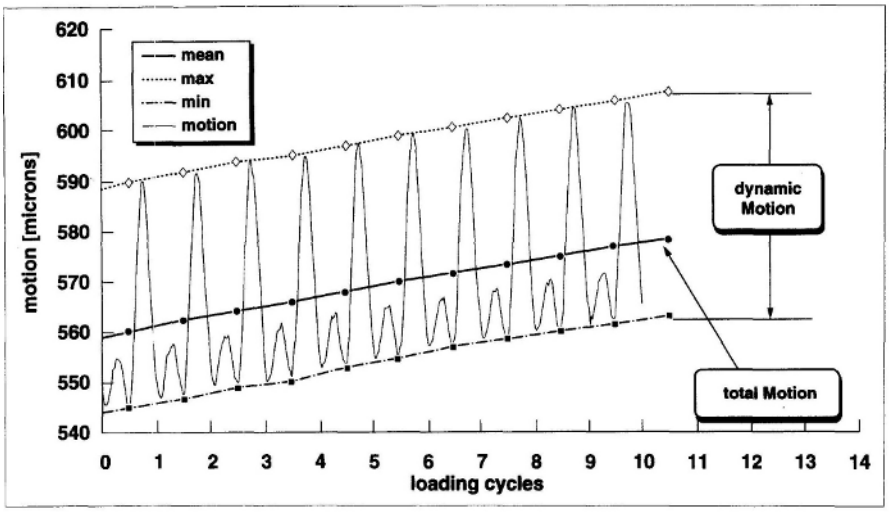

Figure 1: Definitions of dynamic motion (micromotion) and total motion (subsidence) taken from Bühler et al [1]. Figure reproduced with the kind permission of Elsevier.

chitecture, for this micro-CT scanning is needed. In contrast, micro-CT scanning is currently only able to deal with relative small specimens (with a maximum size of several centimetres) and so cannot map a complete long bone, for example. Thus whole bone finite element models to date are based on the information available in medical CT scanning. Particularly challenging is the process of calculation of appropriate materials properties for the bone from the mesure of density and many relationships have been proposed to account for this [7].

Friction

The presence of friction is essential to the minimization of micromotion (Kuiper & Huiskes [8]). Careful use of face-to-face contact elements incorporating Coulomb friction models have been shown to produce good agreement with experiments on composite femurs (Viceconti et al [9]). The properties assigned to the contact elements, in particular contact stiffness and convergence tolerance, can have a considerable influence on the predictions of micromotion (Bernakiewicz et al [10]). Non-linear models of friction have also been developed and validated against simple contact geometries (Dammak et al [11]) and successfully used in comparison with femoral micromotion experiments (Figure 2 [12]). Predictions from Abdul-Kadir et al [12] suggest that magnitudes of interference fit as low as 50 microns may be sufficient to produce the mechanical environment in which osseointegration can occur.

Bone relaxation

Stress relaxation in bone has been demonstrated by Shultz et al [6] to have a dramatic effect on the magnitude of the interference fit established at surgery. Using a validated finite element model, they explored the variation of three levels of initial interference fit with time (Figure 3 [6]). Rapid decay in contact pressure was observed, with predictions for levels of interference fit in excess of 0.1mm approaching that of 0.1 mm within the first 30 minutes. The lowest magnitude of interference fit examined, that of 0.01mm, appeared not to be significantly influenced by bone relaxation.

III. Future Questions

Validated finite-element models of the interference fit condition offer the possibility of investigating many clinically relevant situations, including:

- Partial bone-stem contact
- Varying levels of interference fit at different locations
- Non-uniform friction
- Bone stock loss associated with revision surgery
- Effect of variation in prosthesis positioning on micromotion
- Effect of local variations in bone density.

Abstract — **The purpose of this study was to develop a detailed 3-Dimension mandibular model with dental implants on the basis of CT data and to conduct stress analysis to characterize the effects of the material type of prosthesis on stress/strain distribution in the mandibular bone. Three types of materials, a polymer and two metals, with different elastic properties were chosen as the prosthesis materials. The analytical results showed that the Mises equivalent stress and equivalent elastic strain along the circumference of the implant at distal side were much higher than in the anterior region. It was also shown that the stress/strain concentration at the bone increased with decreasing the prosthesis stiffness. The stress/strain concentration observed in the circumference of the implants could be the driving force for loosening and fracture of the implants.**

I. Introduction

Recently, dental implant operation is known to be one of the most effective treatments for tooth less jaw bones [1]. It is clinically important to understand the mechanical effects of implants on mandibular bones because such mechanical interactions between implants and bones are thought to be related to biological bone resorption around implants and safety and durability of implants themselves. It is actually reported that the majority of the long-term convalescence after implant surgeries is strongly affected by mechanical factors [1].

Experimental studies using animal and model bones have been performed to characterize the mechanical interactions between implants and jaw bones, however, in general, deformation behavior of the surfaces of the implants and bones is only measured by, for example, strain gage methods and it is very difficult to characterize the stress state inside of the implants and bones. On the contrary, the stress state of implants inserted into jaw bones can be analyzed by computational analysis such as the finite element method (FEM). Two-dimensional and simplified three-dimensional models were mainly used in the previous implant analyses by FEM [2,3].

Recent years, three-dimensional detailed human tissue models are developed by using digital images of X-ray CT and MRI and stress analysis of these models are performed by FEM. This kind of computational technique is expected to be one of the most convincing methods that can be used to understand the mechanical conditions of bones under real situations in the field of biomedical engineering. This technique has also been applied to jaw bones [4].

In the present study, a detailed 3D-FEA model of a mandibular bone without teeth was developed from a series of CT images, and then All-on-4 dental implant model consisting of four implants, prosthesis and artificial teeth was attached to the bone model. FEA of the model was then performed to characterize the effects of the implants on the stress and strain states of the mandibular bone.

II. Development of computational model

A two-layer mandibular model consisting of cortical and cancerous bones was developed from X-ray CT images of a human skull. From each of the CT images, the outlines of the cortical and cancellous bones were extracted and accumulated to construct three dimensional bone shapes. The 3-D bone models of the cortical and cancerous were firstly expressed as two crowds of points by the image analysis software ISEC2. Surface data of the bone models were then constructed by polygons from the point data by using Rapid Form 2004. Solid data of the bone models were build up from the surface data by using the pre-post processor FEMAP for FEA. The Mandibular model was finally constructed by combining the solid models of the cortical and cancerous bones.

All-on-4 generally consists of four implants, prosthesis and artificial teeth. An implant model was constructed as a cylinder of 4 mm diameter. Two implants were embedded into the anterior side of the mandible, and two were also embedded into the distal side. The implant embedded into the molar part was inclined at 45 degree. A simple model of prosthesis fixed on the implants was constructed on the basis of the shape of the mandible. Artificial teeth models constructed from CT images were attached on the top of the

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1611–1614, 2009
www.springerlink.com

prosthesis. The All-on-4 model attached to the mandibular bone is shown in Fig.1.

Meshed model and boundary conditions are shown in Fig.2. 4-node tetrahedral elements were used and the numbers of elements and nodes were 174672 and 49710, respectively. Cortical and cancellous bones, implant, prosthesis and artificial teeth were assumed to be linear elastic and the material constants used in the analysis are shown in Table 1 [5,6]. The material of the prosthesis was chosen to be acrylic resin, titanium or Co-Cr alloy in order to assess the effect of Young's modulus of the prosthesis. The implant and the artificial teeth were assumed to be made from titanium and ceramics, respectively. All of the interfaces were perfectly connected. Forces generated by four kinds of masticate muscles were considered to be acted on the mandible and the directions of the muscles were determined based on CT images and Ref.4. The heads of mandible were able to move only in the horizontal direction (the Y-direction). The top-surface nodes of the artificial teeth were perfectly fixed to express firm biting condition [7]. Distributed loads were also applied to the nodes close to the heads of mandible in order to avoid stress concentration at the fixed nodes on the heads.

III. Results and Discussion

Equivalent stress distributions in the bone tissues surrounding the left-hand implant are shown in Fig.3. Stress concentration was observed on the cortical bone surrounding the neck of the molar implant. The obvious change of stress concentration at the interface region between the cortical and cancellous bones is typical behavior in the computational model assuming simple two-layer model. Pass-plots of equivalent stress along the bone tissues surrounding the front and the molar implants are shown in Fig.4. For both the implants, equivalent stress sharply rose up as transferring from the cancellous and the cortical bone. Equivalent stress in the metallic prosthesis model tends to be higher than that in the acrylic prosthesis, and such difference is mainly seen on the cortical bone for the surrounding of the molar implant; on the contrary, on the cancellous bone for the surrounding of the frontal implant.

Equivalent strain distributions are shown in Fig.5. Path plot of equivalent strain along the surrounding bone tissues are also shown in Fig.6. Equivalent strains are concentrated in the surrounding bones of the molar and the frontal implants. Effect of the Young's modulus of prosthesis is clearer on strain than on stress, and the strain is much larger in the metallic implants than in the acrylic.

In the present model, the mandible tries to be deformed by muscle forces, however, restricted by the fixed artificial teeth. For the case of prosthesis with low Young's modulus, the resistance to the deformation of the mandible is small, as a result, equivalent stress and strain become low in the surrounding bone of the left-hand implant. On the other hand, for the case of a prosthesis with high Young's modulus, deformation of the entire prosthesis is relatively small and hence the resistance to the deformation of mandible becomes large, as a result, equivalent stress and strain increase in the surrounding bone of the left-hand implant.

The developed mandibular model was effectively used to characterize the stress/strain distributions within the bone tissues, especially in the surroundings of the implants under firm masticate condition. This mechanical information is thought to be a good guideline to predict bone absorption in the vicinity of implants and failure of All-on-4 implant system.

IV. Conclusions

A 3-D model of a mandibular bone with All-on-4 implant system was developed to investigate the mechanical interaction between bone and implants under biting condition. The two-layer mandible model was constructed from X-ray CT images, and then the All-on-4 system consisting of four implants, prosthesis and artificial teeth was attached to the mandible. Finite element analysis of the model was performed under a boundary condition considering four kinds of masticate muscles. Effects of the prosthesis stiffness on the stress/strain states in the mandibular bone was characterized on the basis of the FEA results. Stress/strain concentrations were clearly recognized in the surrounding bone of the implants, and the degree of such stress concentration became higher as the Young's modulus of the prosthesis increased.

Abstract — **We found that the level of CD3+4+8+T-cells was normal in peripheral blood of RA patients. Otherwise an amount of CD3+4-8-, CD3-4+ and CD3-8+ subpopulations was increased in 10 patients and level of CD10+ cells (24%) in 2. We found also significant imbalance of CD3+4+8- and CD3+4-8+ mature T-cells in all RA patients The level of CD3+4+ 5-40-fold exceeded the level of CD3+8+. The 24-hour incubation of RA patient's lymphocytes with human TEC culture and TEC supernatant could influence upon T-cell receptor phenotype. We found tendency to increase of CD3 after the incubation in all patients. Otherwise the dynamic of CD4 and CD8 was different. In 4 cases we saw the moderate decrease of CD4 expression and increase of CD8. But in 9 cases the imbalance of CD3+4+ and CD3+8+ subpopulations increased after cultivation due to progressive CD8 expression diminution. The above mentioned facts allowed us to suppose the heterogeneity of T-cell selection disturbances in RA**

Keywords — **Rheumatoid Arthritis, T-lymphocytes, Pathology of Thymic Selection**

I. Introduction

Investigation of mechanisms, by which T-cells acquire tolerance for self-antigens, remains one of the important problems of basic and clinical immunology, in particular, in the correction of autoimmune diseases. Specific recognition of autoantigen by autoantibody or T-cell receptor (TCR) in context of HLA-II receptor by "forbidden" cell clones is now the main concept of autoimmunity phenomena. This concept can properly explain the debut and pathogenesis of organ-specific autoimmune diseases such as I-type diabetes mellitus. Otherwise systemic autoimmune diseases (SAD) are characterized by polyclonal activation of T and B-cells targeted to different antigens [1]. Even in Rheumatoid arthritis (RA) (not to mention progressive systemic sclerosis, sarcoidosis or psoriasis) the identification of specific autoantigen remains disputable. So the investigation of pathogenic role of non-TCR-dependent T-lymphocyte activation in SAD could be crucial. Moreover numerous reports give evidence that among the peripheral blood lymphocytes (PBL) or in inflamed tissues in SAD patients are T-cells with unusual "thymocyte-like" phenotype enriched by adhesive receptors. These cells have increased activation properties [2]. The aim of the work was to prove our hypothesis on T-lymphocyte positive selection disturbance in RA and to investigate PBL phenotype before and after co-cultivation with human thymic epithelial cells (TEC).

II. Materials and metnods

We analyzed the phenotypic features of PBL in 21 patients with definite RA and 12 healthy donors The PBL phenotype was studied by anti-CD3-PE, anti -CD4-PE, anti-CD8-FITC, anti-CD10, anti-CD69, anti-CD71, anti-CD34 monoclonal antibodies (Becton Dickenson) using the method of laser flow cytometry with double and triple-color monoclonal antibody scanning. The lymphocyte-thymic epithelial cells adhesion phenomenon was studied in co-culture of PBL and human TEC. Cultures were incubated at 37°C for 20 min with subsequent centrifugation and new incubation at -4°C for 30 min. The results were estimated by accounting of TEC-lymphocytes "rosette-forming" complexes in samples after glutaraldegide fixation. The T-cells receptors dynamics studied in 24-hour lymphocyte-TEC and T-lymphocyte-TEC supernatant co-cultivation in sterile conditions at 37°C T-cells phenotype was studied by flow cytometry before and after cultivation.

III. Results

Peripheral blood lymphocytes phenotype in RA patients. At the first stage of investigation the main object of our research was the population of CD3+4+8+T-cells with phenotype similar to early thymic emigrants. But during the research work we found that the level of CD4+8+T-cells among the PBL of RA patients was about 2 – 3% Only three patients demonstrated CD3+4+8+ amount more than 5%. Otherwise an amount of CD3-4+ and CD3-8+ subpopulations was increased in 10 investigated patients in general. In three patients we found high level of unusual CD3-4+ lymphocytes (6,0%, 1,1% and 42,8%). See Fig.1. The phenotype and function of these cells is subject for our

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1615–1618, 2009
www.springerlink.com

future investigations. For identification possible maturation impairment in RA-PBL we also investigated markers typical for early stages of T-cell maturation (CD10, CD71, CD98, CD34). The increased level of CD10+ cells (24%) was found in 2 patients. The expression of others molecules was non significant. We also didn't found γδTCR+T-cells among the PBL of our patients. The marker of spontaneous activation CD69 was expressed on 5-6% RA-PBL. The investigation of mature T-lymphocytes subpopulation showed significant imbalance of CD3+4+ and CD3+8+T-cells in all RA patients The level of CD3+4+ 5-40-fold exceeded the level of CD3+8+. Only 2 patients had normal (1,5 – 2) rate of CD3+4+/CD3+8+ balance.

Lymphoid cells-thymic epithelial cells adhesion Phenomenon of human thymocytes and human TEC adhesion during the cultivation "in vitro" is well-known. In our case human thymocytes bound almost 75 %TEC in co-culture whereas lymphocytes of healthy donors had minimal adhesive activity binding 11,75+2,9%TEC. RA PBL bound 28,2+4,2%TEC.(PBL of some patients bound more than 32%TEC) forming rosette-like structures. See Fig.2. The pretreatment of lymphocytes by anti-CD2 reduced adhesion. This fact allowed us to identify cells sticking to TEC as T-lymphocytes. We didn't find the difference in adhesion properties of PBL between "classical" and nodular variant of RA but as we reported earlier [3], PBL-TEC adhesion in sarcoidosis patients was lower (13,4+2,3TEC) than in RA.

The 24-hour incubation of RA patient's lymphocytes with human TEC culture and TEC supernatant We found that 24-hour incubation of RA patient's lymphocytes with human TRC culture and TEC supernatant could influence upon RA-PBL T-cell receptor repertoire. During the incubation with TEC culture there was a tendency of increase of CD3 in all patients. See Fig.3. Otherwise the dynamic of CD4 and CD8 was different in different co-cultures. In 4 cases we saw the moderate decrease of CD4 expression and increase of CD8 which lead to CD3+4+/CD3+8+ balance normalization. But in 9 cases the imbalance of CD3+4+ and CD3+8+ subpopulations increased after cultivation due to progressive CD8 expression diminution. Amounts of CD3+4+8+, CD10+, and CD69+ T-cells didn't change after the incubation but there was 1,5-4-fold increase of HLA-DR expression. Receptor dynamics picture during the PBL incubation with TEC supernatant was typologically similar to described results of PBL-TEC incubation but much less evident. The different dynamics of CD3+4+ and CD3+8+cells level during the incubation with TEC (the tendency of normalization of its balance in one part of patients and aggravation of imbalance in other part) permits us to suppose phenotypic heterogeneity of these cells in particular the different density of CD3, CD4 and CD8 receptors.

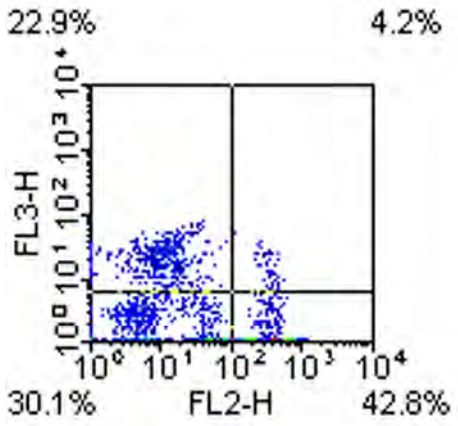

Fig. 1. CD3-4+ subpopulation (42,8%) among the RA-PBL in patient B. CD4PE(FL2) CD3PE(FL3)

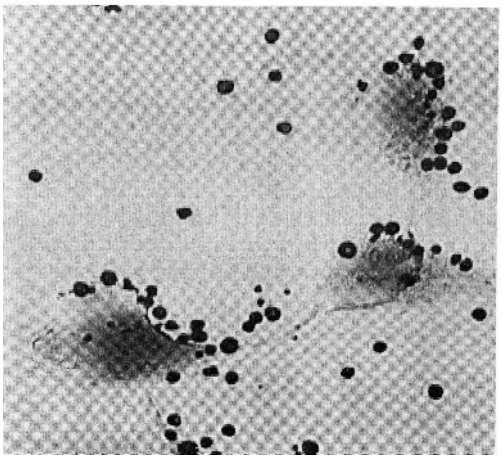

Fig. 2. RA PBL tropism to Thymic Epithelial Cells culture

IV. Conclusions

Thus, the data testify, the rising of level of PBL carrying features of cellular dysmaturity in some of our patients. Evident tropism of RA PBL to human TEC, the marked imbalance of CD3+4+/CD3+8+ subpopulations and moreover the presence of CD3-4+ and CD3-8+ cells in PBL can give evidence of thymic or postthymic T-cell selection abnormality in RA. The 24-hour incubation of RA patient's lymphocytes with human TEC culture and TEC supernatant could influence upon T-cell receptor phenotype causing in some cases normalization in other cases aggravation ob main T-cells subpopulations imbalance/ The particular interest for future investigations represents the phenotype and function of CD3-4+ population. Now we could assume the similarity of these cells to $CD3^{low}4+$ T-cells.

The results of the present work permits us to summarize and generalize the role of immature T-clones with low density of CD3 and the breakdown of thymic selection processes in the pathogenesis of systemic and organ-specific autoimmunity. Autoimmune mice, homozygous for the "Ipr" gene develop a profound lymphadenopathy resulting from the accumulation of anti-Ia-reactive $\alpha\beta TCR^{+}CD3^{low}4\text{-}8\text{-}B220^{+}$ T-cells in peripheral lymphoid tissues. The majority of investigators propose the connection between these autoreactive cells and the manifestations of SLE-like syndrome in Ipr-mice [4]. Adult Ipr thymuses were found to contain an immature population of thymocytes, phenotypically identical to the peripherally accumulating $\alpha\beta TCR^{+}CD3^{low}4\text{-}8\text{-}B220^{+}$ T-cells. Evidence is presented that some of these Ipr-precursor cells are capable of intrathymic differentiation, whereas the vast majority are exported unchanged to the lymph nodes, probably due to progressive atrophy of the thymic cortex in Ipr-mice. On the other hand the MHC class II antigen expression is enhanced on macrophages, dendrite cells, proximal tubular cells and precedes overt glomerular lesions and proteinuria**.** In human SLE activated $CD3^{low}4\text{-}8\text{-}$ cells can augment the production of pathogenic anti-DNA-antibodies by 30-fold. Progressive atrophy of thymic cortex in Ipr-mice probably can lead to ineffectiveness of cortical stage of T-cell selection and compensatory induction of immature T-cell expansion in peripheral lymphoid tissues [1].

The synovial membrane of patients with rheumatoid arthritis and seronegative arthropathies (Reiter-syndrome) displays a selective expansion of a specific population of $\gamma\delta^{+}TcRCD3^{low}4\text{-}8\text{-}$ T-cells. The density of CD3 molecules in these cells is significantly lower than in peripheral blood T-lymphocytes. The selection and pathways of development of $\gamma\delta^{+}$TcR T-cells are poorly investigated. Their localization in skin, mucosal and synovial membranes, high adhesive and secretor activity permits us to assume their role as triggers of autoimmune inflammation in places of their accumulation [5].

Psoriasis is a disease of activated keratinocyte. "Products of activated keratinocytes change the function of T-cells that, in turn, produce factors, perpetuating the process of keratinocytic activation."[6]. Activated keratinocytes can induce mononuclear cell proliferation via MHC-class I and U-independent mechanism. It is possible that these proliferating cells are MHC-unrestricted $\gamma\delta^{+}$TcR T-clones with high adhesive activity. Perhaps the different endothelial adhesive molecules expressed in different skin diseases of unknown etiology account for the distinct composition of the inflammatory infiltrate.

The character and consequence of T-cell-keratinocyte interactions and $\gamma\delta^{+}$TcR T-cell expansion in psoriasis reflects the early events of thymic maturation of γδTcR+ thymocytes in subcapsular zone of the thymus before their emigration to the periphery. The severe exacerbation of psoriasis and Reiter-syndrome in HIV-infected patients can be connected with the depletion of $CD4^{+}$ mature T-cells, selectively infected by HIV and compensatory induction of thy-

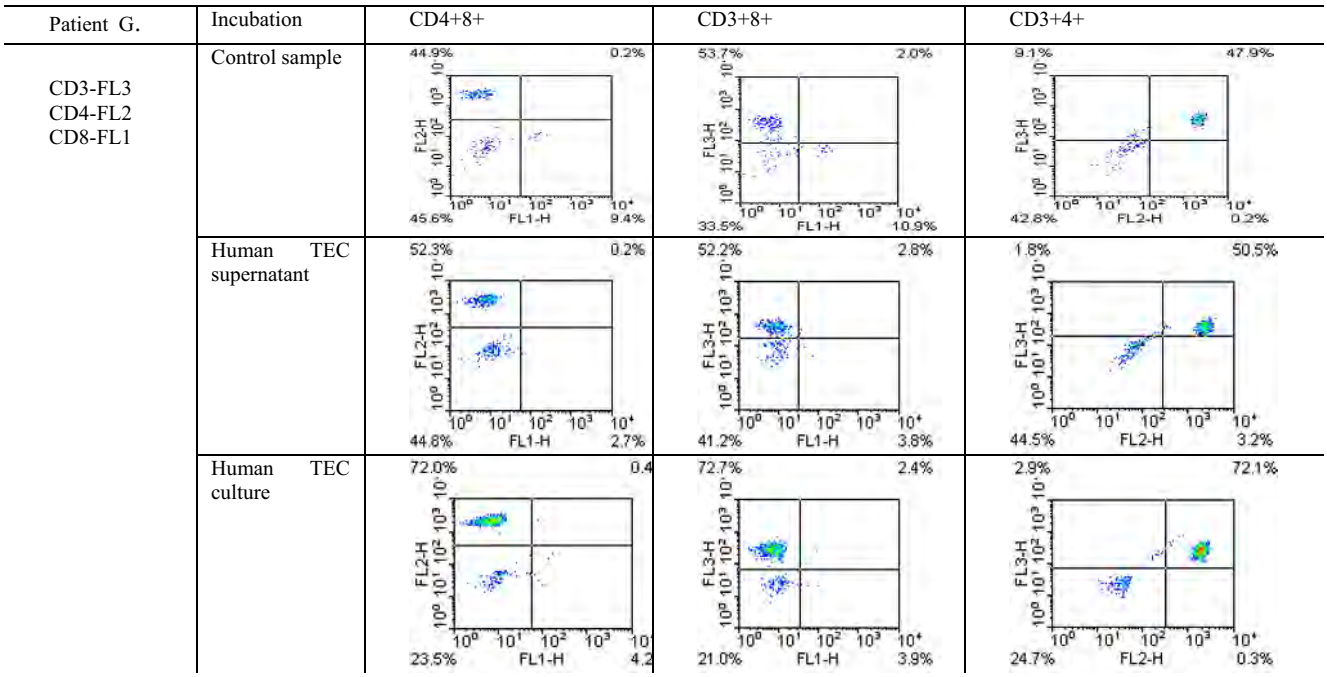

Fig. 3. Dynamics of RA peripheral blood T-lymphocytes phenotype during the 24-hour incubation with human TEC supernatant and human TEC culture.

mus-independent T-cell development, in particular, $\gamma\delta^{+}$TcRCD3^{low}4"8" T-cell expansion in skin. Myasthenia gravis is the disease of the nervous system with the development of autoimmune reaction to cholinoreceptor. There was established the relationship between the disease relapse and the increase of the number of circulating $CD3^{+}4^{+}8^{+}$ T-cells with cortico-medullary-like phenotype [1]. The findings of thymic alteration (thymoma) in about 80-90% of myasthenia patients stress a central role for the thymus in the pathogenesis of myasthenia gravis. Neoplastic epithelial and myoid cells in malignant thymoma, complicated by myasthenia contain only incomplete cholinoreceptors, of cholinoreceptor-like molecules. Thymomas with immature epithelial cells predominantly express immature thymocyte phenotype [7]. These abnormalities can reflect abnormal thymic epithelial maturation, ineffectiveness of medullar stage of thymic T-cell development. Abnormal expression of low-immunogenic determinants of cholinoreceptor in the thymus can lead to the breakdown of negative selection of autoreactive $CD3^{+}4^{+}8^{+}$ T-clones in cortico-medullary zone of thymus gland, their cytotoxic activity in the nervous system.

In this context is also interesting to discuss attempts of experimental induction of autoimmune systemic diseases in BN-rats with thymic cortex depletion, using $HgCl_2$, and organ-specific autoimmune diseases in mice BALB/c with thymic medulla atrophy after the exposition of cyclosporine A [1]. Experimentally-induced autoimmune syndromes demonstrate regularity: atrophy of thymic cortex in systemic autoimmunity leads to enhanced expression of la-antigens and adhesive receptors in peripheral lymphoid tissues and to expansion of immature T-cell clones with anti-Ia-reactivity and low density of CD3, at the same time, degenerative processes in thymic medulla in organ-specific autoimmune diseases result in defects of negative T-selection and hyperactivity of "medullar-like" autoreactive cytotoxic T-clones. Degenerative processes in the thymic stroma (pathology of thymic microenvironment) as a potential cause of T-cells selection ineffectiveness also occur in various autoimmune diseases. In this way identification of activated "anti-self" T-clones with unusual "immature" phenotype and MHC-antigens expression in the foci of autoimmune inflammation permits us to assume the compensatory induction of positive and negative T-selection in peripheral tissues and tissue damage by auto reactive clones Careful investigation of the thymes microenvironment pathology of subcapsular and cortical zones in systemic autoimmune diseases (especially in SLE psoriasis, rheumatoid arthritis) on the one hand, and investigations of cytoarchitectonics disturbances in thymic medulla in organ-specific autoimmunity on the other hand, makes it possible to re-think the pathogenesis of autoimmune diseases, their combinability and transformation, and allows us to develop new principles of immunocorrection.

Axial and Angled Pullout Strength of Bone Screws in Normal and Osteoporotic Bone Material

P.S.D. Patel[1], D.E.T. Shepherd[1] and D.W.L. Hukins[1]

[1] School of Mechanical Engineering, University of Birmingham, Edgbaston, B15 2TT, UK

Abstract — **Orthopedic surgery often involves the use of bone screws to stabilize fractures. Screw fixation can be extremely difficult in osteoporotic (OP) bone because of its compromised strength. Pullout strength is commonly used to measure screw fixation strength. In this study, axial and angled screw pullouts (ranging from 0° to 40°) were performed on 0.09 g.cm^{-3}, 0.16 g.cm^{-3} and 0.32 g.cm^{-3} polyurethane (PU) foam. The PU foam was used to model different levels of low density human cancellous bone, including OP bone. Screw pull-out tests were conducted under displacement control at a rate of 0.1 mm.s^{-1}. Load and displacement values were recorded; the maximum load during screw pullout was defined as the pullout strength of the screw. Two different titanium-alloy bone screws were used to test for any effect of thread type (i.e. cancellous or cortical) on the screw pull-out strength. Failure of screw fixation was observed from the stripping of the internal screw threads within the PU foam. Compared to the cortical screw, the cancellous bone screw had the highest pullout strength under almost all conditions of pullout angle and PU foam density. For both screws, the pullout strength increased with increasing PU foam density. Results indicate that the PU foam density, rather than the screw angle or thread type, is the most influential factor affecting screw pull-out strength. These findings are important in understanding the behavior of screw fixation and screw failure within an OP bone model.**

Keywords — **bone screw, cancellous bone, osteoporosis, screw pullout, polyurethane foam.**

I. Introduction

Osteoporosis is a bone disease in which bone resorption exceeds bone deposition, resulting in bone loss [1]. The associated reduction in bone quality often leads to bone fractures, which in turn leads to the need for fixation of implants to aid repair. Bone screws are commonly used in orthopedic implants for internal fracture fixation. Pullout strength can be used to measure screw fixation strength. To date, work on screw pullouts has focused mainly on axial pullouts in cadaver bone [2-4], animal bone [5-7] and in artificial materials mimicking the properties of human bone [5, 7, 8]. Few studies in the literature report screw pullouts from non-augmented/untreated osteoporotic (OP) bone [9].

In part, this is due to the contraindicative use of bone screws in OP bone, which generally has less tissue to engage with the screw thread compared to normal bone. However, there may be a need to use screws in OP bone, such as for fusion cages in the human spine and for the effective repair of fractures involving OP bone. Another reason is because of the widespread variability in the mechanical properties of normal and OP human bone, which makes it difficult to compare screw performance. In this study, the problem of variability was overcome by using polyurethane (PU) foams of different densities to represent normal and OP bone. For OP bone, multiple sites of screw fixation are often used, which means that screws can be placed at various angles. The objective of this study was to determine how the pullout strength of a bone screw is affected by the following factors: (i) screw pullout angle, (ii) screw thread type and (iii) the density of PU foam, representing different densities of bone.

II. Materials and Methods

A. PU Foam Samples

PU foams, of three different densities, were used in this study. Closed cell PU foam of density 0.16 g.cm^{-3} and 0.32 g.cm^{-3} (American Society for Testing and Materials, ASTM, Grade 10 and Grade 20) [10] was used to model low and medium density cancellous bone respectively. Open cell rigid PU foam of density 0.09 g.cm^{-3} was used to model very low density cancellous bone. A previous study by the authors had found that the 0.16 g.cm^{-3} PU foam may prove suitable as an OP cancellous bone model when fracture stress is of concern. The authors found that 0.16 g.cm^{-3} PU foam is a good alternative for in-vitro testing because it has compressive Young's modulus and yield strength values similar to OP bone that has also been tested in compression [11]. All PU foams were purchased in block form, with dimensions 130 × 180 × 40 mm, from Sawbones® Europe AB, Malmö, Sweden. The foam densities were supplied by Sawbones® Europe AB. For this study, PU foam test blocks, with dimensions 45 × 60 × 40 mm, were prepared using a cutting saw.

www.springerlink.com

B. Screw Pullout Testing

A cancellous bone screw, 6.5 mm diameter × 30 mm length, and cortical bone screw, 4.5 mm diameter × 30 mm length, were used to test for any effect of thread type on the screw pullout. Both screws were made from medical grade titanium alloy, Ti-6Al-4V. Pilot holes of 3.5 mm diameter, for the cancellous bone screw, and 3 mm diameter, for the cortical bone screw, were drilled into a PU foam test block before screw insertion. Each screw was inserted into the PU foam through a pullout fixture that was tailor-made to the desired angle of pullout (Figure 1). The pullout fixture, engaged with the bone screw head, was then attached to the actuator of an ELF3300 materials testing machine (Bose Corporation, ElectroForce Systems Group, Minnetonka, MN, U.S.A.). The bottom part of the test set-up, involving the PU foam block, was placed in a tailor made chamber attached to a platform on the machine's load cell (Figure 1).

Screw pullout was conducted under displacement control at a rate of 0.1 $mm.s^{-1}$. Load and displacement values were recorded and the maximum load generated during screw pullout was defined as the pullout strength of the screw [12]. Six pullout tests were performed for each condition of screw pullout angle (0º, 10º, 20º, 30º, 40º), screw type (cancellous screw thread, cortical screw thread) and PU foam density (0.09 $g.cm^{-3}$, 0.16 $g.cm^{-3}$, 0.32 $g.cm^{-3}$). The same cancellous and cortical screw was used for all tests because of the comparatively low strength of the screw host material (PU foam) to the metallic bone screws.

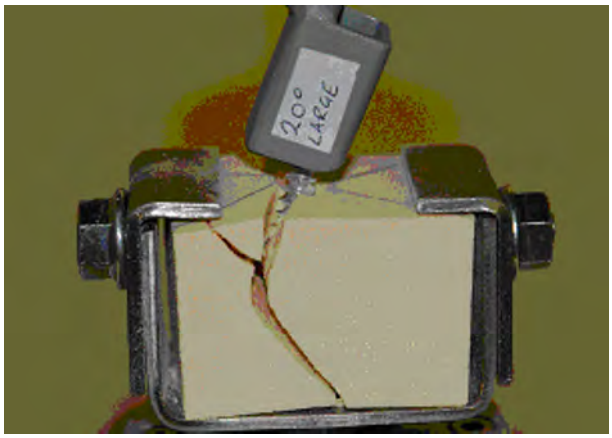

Fig. 1 20º pullout of a cancellous bone screw from PU foam used as a model for OP and normal bone (according to the PU foam density).

III. Results

Tables 1 and 2 show the mean and standard deviation of screw pullout tests for the cancellous and cortical bone screws respectively.

Table 1 Ø 6.5 mm Cancellous screw pullout mean ± standard deviation (N)

Screw Pullout Angle	0.09 $g.cm^{-3}$ PU foam	0.16 $g.cm^{-3}$ PU foam	0.32 $g.cm^{-3}$ PU foam
0º	12.8 ± 2.3	356.7 ± 50.1	1145.3 ± 55.4
10º	22.0 ± 10.6	401.5 ± 22.6	1524.5 ± 66.7
20º	20.7 ± 8.9	354.3 ± 7.5	1033.1 ± 45.0
30º	21.6 ± 6.9	390.6 ± 27.2	1130.8 ± 72.0
40º	21.4 ± 2.9	330.3 ± 37.1	776.3 ± 96.6

Table 2 Ø 4.5 mm Cortical screw pullout mean ± standard deviation (N)

Screw Pullout Angle	0.09 $g.cm^{-3}$ PU foam	0.16 $g.cm^{-3}$ PU foam	0.32 $g.cm^{-3}$ PU foam
0º	10.4 ± 3.2	115.1 ± 26.5	1081.1 ± 72.0
10º	5.3 ± 3.3	209.6 ± 40.8	940.5 ± 84.2
20º	19.0 ± 7.3	288.9 ± 31.5	967.6 ± 25.9
30º	21.1 ± 5.3	246.4 ± 28.7	827.0 ± 33.7
40º	16.5 ± 8.4	184.0 ± 16.6	793.7 ± 81.2

Statistical comparisons were made using MINITAB® Release 14.1 Statistical Software (Minitab Inc., Pennsylvania, USA). Normality of the distributions was assessed using the Anderson-Darling test. Analysis of variance (ANOVA) and Tukey's Honestly Significant Difference comparison tests showed that the cancellous screw had a significantly higher pullout force than the cortical screw ($p<0.05$). For both screws, pullout strength increased with increasing PU foam density, which was found to be statistically significant ($p<0.05$).

Significant differences ($p<0.05$) were also detected for angled screw pullouts between the following angles: 0º > 40º; 10º > 0º, 20º, 30º, 40º; 20º > 40º; 30º > 40º. No significant differences ($p>0.05$) were detected in screw pullout force between the following angled pullouts: 0º and 20º; 0º and 30º; 20º and 30º.

Regression analysis showed a high correlation (R^2 = 0.8902) between the mean cortical screw pullout force and pullout angle in the 0.32 $g.cm^{-3}$ PU foam, which was found to have a significant relationship ($p<0.05$). No other significant relationships ($p>0.05$) existed between the mean screw pullout force and angle for all remaining test conditions.

IV. Discussion

This study has accounted for several factors affecting screw pullout, by systematically varying the screw type, host material density and screw pullout angle. A possible explanation for the increased cancellous screw pullout, compared to cortical screw pullout, is that the PU foam test material has been designed to mimic human cancellous bone, making the cancellous screw thread more favorable to its host material.

Results for the angled screw pullouts suggest that only screws placed axially or up to a 10º angle may increase its holding power. Angled pullouts at 20º, 30º and 40º show mixed results and may marginally improve screw holding power compared to screws placed at less than 20º. However, as the regression analysis between pullout force and angle has shown, this is not so clear-cut.

Three different densities of PU foam were used to model OP (0.09 g.cm^{-3} and 0.16 g.cm^{-3} foam) and normal (0.32 g.cm^{-3} foam) human cancellous bone. The foam is an acceptable model for cancellous bone and has been used in several studies to investigate orthopedic devices [13, 14]. For both screws used in this study, the screw pullout force decreased with increasingly OP bone material. Lower screw pullout strength was also reported in OP bone material compared to normal bone material for self-tapping bone screws [15].

In this study, failure of screw fixation was observed from the stripping of the internal screw threads within the PU foam. The literature reports the following relationship to predict the shear failure force necessary to strip the internal threads formed in PU foam [13, 16, 17]:

$$F_S = S \times A_S = S \times \{L \times \pi \times D_{major}\} \times T \quad (1)$$

where:

F_S = predicted shear failure force (N)

S = material ultimate shear stress (MPa)

A_S = thread shear area (mm^2)

L = length of thread engagement in material (mm)

D_{major} = major diameter (mm)

T = Thread Shape Factor (dimensionless) $= (0.5 + 0.57735\, d/p)$

d = thread depth (mm) $= (D_{major} - D_{\min or})/2$

$D_{\min or}$ = minor (root) diameter (mm)

p = thread pitch (mm)

Based on this formula, the predicted shear failure forces for axial screw pullout were calculated as shown in Table 3. Predictive values for 0.09 g.cm^{-3} PU foam could not be calculated because the ultimate shear stress of this open cell foam was unknown. Table 3 shows that the formula can be useful in approximating screw pullout force in a given material, especially for the 0.32 g.cm^{-3} PU foam, which showed a close match between predicted and experimental results for the cortical screw.

Table 3 Comparison of the mean axial screw pullout results with calculated theoretical values

PU foam density (g.cm^{-3})	Predicted shear failure force (N)		Experimental mean axial screw pullout force (N)	
	Cancellous screw	Cortical screw	Cancellous screw	Cortical screw
0.16	604	405	357	115
0.32	1622	1090	1145	1081

Equation 1 demonstrates the important relationship between bone shear strength and screw pullout strength. A study on bovine cancellous bone, tested in pure shear, found the following relationship between shear strength, S (MPa), and apparent density, ρ (g.cm^{-3}) [18]:

$$S = 21.6\rho^{1.65} \quad (2)$$

Using the average material property data provided for the PU foams used in this study, a similar relationship was derived between shear strength and apparent density:

$$S = 21.5\rho^{1.42} \quad (3)$$

Similarly, the shear strength and apparent density of unicellular PU foam has been demonstrated to have the following relationship [13]:

$$S = 23.9\rho^{1.54} \quad (4)$$

Equations 2, 3 and 4 are very similar and justify the use of PU foam, of various densities, to mechanically simulate the relative shear strength properties of bone. This is beneficial for screw pullout testing from low density PU foam, which would be able to model the shear strength of OP bone, as has been performed in this study.

V. Conclusions

This study has analyzed pullouts of cancellous and cortical screws at 0º, 10º, 20º, 30º, 40º angles in 0.09 g.cm^{-3}, 0.16 g.cm^{-3}, 0.32 g.cm^{-3} PU foams, to determine how screw pullout is affected in an OP bone material, defined in the authors' previous study, compared to normal bone. The mean screw pullout force decreased with increasingly OP bone material. The cancellous bone screw demonstrated higher pullout forces than the cortical screw. Screws placed

at 0º and 10º angles showed greater holding power than screw placement at 20º, 30º and 40º angles.

Experimental Characterization of Pressure Wave Generation and Propagation in Biological Tissues

M. Benoit[1], J.H. Giovanola[1], K. Agbeviade[1] and M. Donnet[2]

[1] Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland
[2] E.M.S. Electro Medical Systems S.A., Switzerland

Abstract — **Aim of the study: This work develops a measurement technique for pressure waves in soft tissues. It aims at characterizing, understanding and modeling the generation and propagation of pressure waves in soft tissues, with a view towards medical applications for the treatment of various tissue pathologies.**

Description of methodology and salient results: First, Hopkinson bar techniques have been adapted to measure the waves emitted by an impact generator, transmitted through the material and reflected at the interfaces. Simulations with an explicit FEM software reproduce the measured data well. Secondly, flexible PVDF gages have been calibrated for measurement of wave propagation in soft tissues. Although PVDF gages have acoustic impedance similar to that of soft tissues, they act nevertheless as foreign inclusion and perturb the measurements. To deal with this problem, we apply an hybrid experiment-FEM simulations technique to interpret the PVDF gage records and extract reliable pressure data. Results are applied to the design of biomedical devices for the Extracorporeal Shock Wave Therapy (ESWT).

Conclusion: Adapted Hopkinson bar technique coupled with FEM simulation can predict pressure wave emitted, transmitted and reflected at the interfaces of an impact generator. PVDF flexible gages are a promisisng technique for measuring wave propagation in soft tissues and can serve to calibrate appropriate nonlinear viscoelastic constitutive models for soft tissues. This work contributes to improve the scientific knowledge of the healing effect of shockwaves for different pathologies by providing a well characterized mechanical wave input in the treated tissues.

Keywords — **pressure waves, Hopkinson bar, soft tissues, PVDF gages, explicit FEM simulation, inclusion, ESWT**

I. Introduction

Treating tissue pathologies such as tendinitis with pressure waves is increasingly popular. In order to understand and optimize the effect of pressure waves in clinical applications, medical results must be correlated with well characterized mechanical stimuli. This paper presents preliminary results of work aimed at characterizing pressure waves propagating in biological tissues. Difficulties of this study include primarily the non-linear viscoelatic nature of biological tissues and the accurate measurement of pressure waves in these complex tissues.

Our approach to these problems is based on a hybrid experimental-numerical method. The elastic wave produced by an impact generator is first characterized by using a Hopkinson bar and simulated with an explicit FEM software. Wave propagation in tissues is then measured using PVDF gages and then simulated with a calibrated Ogden model. The simulation capability can then serve to make predictions of wave energy delivered in various impactor and tissue configurations.

Many authors have published results using PVDF gages for the measurement of wave propagation at the interface between solids, using gas shock tubes [1], or as a pressure sensor [2]. Some gages have shown creeping problems, pyroelectric effects, humidity dependence and dielectric relaxation, which have been highlighted and partially solved [2], [3]. In addition O.A. Shergold and al [4] have published split Hopkinson pressure bar measurements and simulations of the stress-strain response of pig skin at high strain rates. The specific aim of the work presented here is to develop a measurement technique for wave propagation in soft tissues using PVDF gages.

II. Experiments

A. Measurements of the waves generated by an impact generator using a Hopkinson bar

The pressure bar technique has been developed by Kolsky [5]. Here we use the original Hopkinson bar arrangement consisting of a cylindrical bar which is suspended in a horizontal position by wires so that it can freely translate in a vertical plane. It is instrumented with 4 strain gages mounted in a Wheatstone bridge. A wave generation device impacts and transmits pressure wave in the Hopkinson bar (see fig. 1). Systematic measurements are performed for several impact speeds.

www.springerlink.com

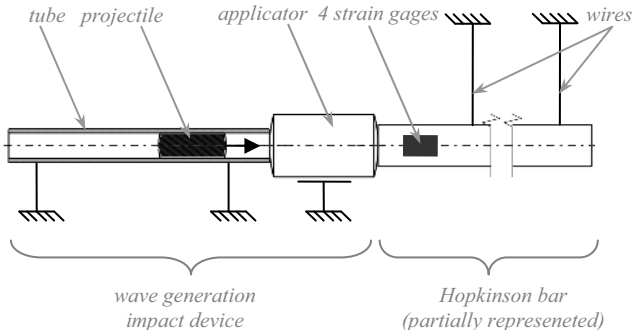

Figure 1: sketch of impact generator and Hopkinson bar used to characterize pressure waves generated on head of applicator

B. In vitro measurements of wave propagation in soft tissues using flexible PVDF gages

In our experiments, we perform measurement with PVDF gages from Piezotech SA company. Theses gages are manufactured by a patented poling process and show strong stability of the calibrated parameters. They provide nano-second time-resolved stress measurements and reproducible response, independent of the loading path up to *20MPa*.

In order to measure the traction and tension stress without undesirable bending contribution, PVDF gages are mounted on poly4-methyl-1-pentene polymer (TPX) supports with a cyanoacrylate glue.

A sketch of the electric wiring of the gage is show on figure 2: the PVDF gauge is regarded as a current source; it is mounted in parallel with a *50 Ohm* resistance (input impedance of an oscilloscope).

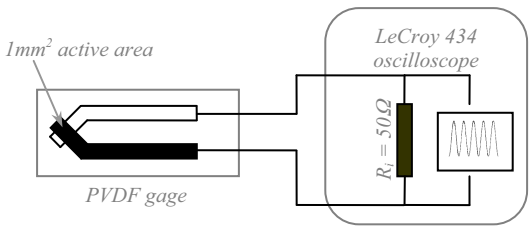

Figure 2: PVDF gage electric wiring

The signal measured by the oscilloscope is first converted to current and a fictitious offset is removed by subtracting the average of the complete signal.

Charge Q is calculated by integrating the baseline-corrected current I over time:

$$Q(t) = \int_0^t I dt \tag{1}$$

Stress σ_{33} depends linearly on the charge Q, the active surface of the gage S, and the calibration factor d_T:

$$\sigma_{33}(t) = \frac{Q(t)}{d_T S} \tag{2}$$

A sketch of the test arrangement for pressure wave measurements in bio-tissues is shown on figure 3 : the impact generator described above is applied on a core-sample of soft tissue confined in a PMMA tube and backed with silicone rubber. A spring applies a *0.016MPa* pre-stressed to the whole system. Samples of skin and of fat of a pig serve as soft tissues. Frozen samples of pigs killed less than 24 hours before the tests are cored to the desired dimensions. Preliminary measurements were performed on unfrozen samples, for several impact speeds.

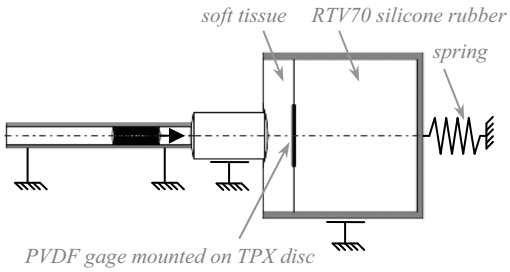

Figure 3: Sketch of the measurement unit

C. Foreign inclusion problem

In our measurements, PVDF gages are inserted inside soft tissues and act as foreign inclusion that modify the propagating pressure wave they are supposed to measure. Part of the wave is reflected at the interface between the tissue and the gage and part of it is transmitted through the gage.

Comparison of results of simulations with and without the gage inclusion provides a method to evaluate the measured signals and extract reliable pressure data.

III. Results

A. Wave propagation in the Hopkinson bar

FEM simulation using ABAQUS/Explicit and measurement of pressure waves propagated in the Hopkinson bar are performed for several impact speeds. As shown in Fig-

ure 4 for a test at an impact speed of *15m/sec*, simulations are in good agreement with measured data.

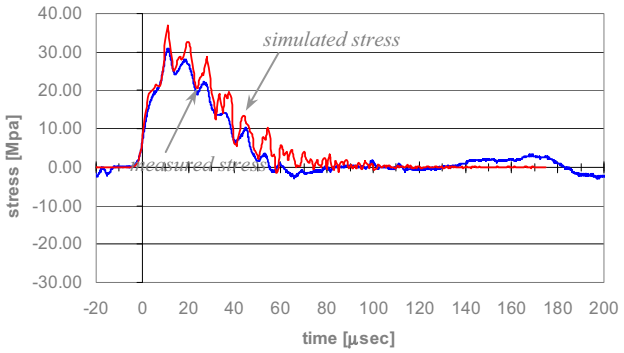

Figure 4: stress measured and simulated record for an impact speed of *15m/sec*

These results show that the Hopkinson bar is a good system for characterizing the waves emitted by the impact generator. First, the good agreement between measured data in the Hopkinson bar and FEM calculations validates the simulation method. Secondly, FEM simulation can predict pressure wave emitted, transmitted and reflected at the interfaces and allows calculating the waves generated and propagated in the projectile, the applicator and on the head of the impact generator. It allows characterizing the impact generator and can be used for any other device generating pressure waves by impact.

B. Wave propagation in water

Measurement and FEM simulation of wave propagation in water have been performed using PVDF gages. The reliability of pressure wave simulations in water has been demonstrated by many previous studies. Figure 5 shows a good correlation between measured and simulated data.

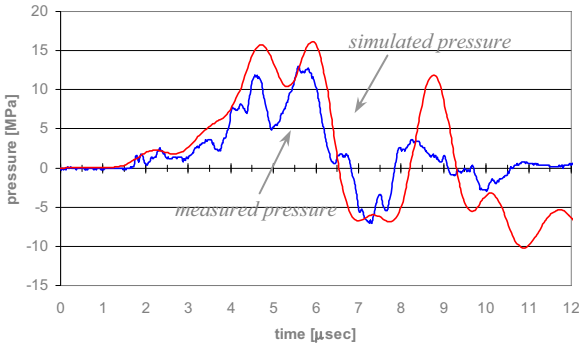

Figure 5: measured and simulated stress waves in water at *1mm* from the head of the impact generator – impact speed *25m/sec*

The agreement between measurements and simulations, that serve as reference, demonstrate that the PVDF gage is a reliable technique for measurement of wave propagation in water.

C. Wave propagation in soft tissues

A constitutive model is required to simulate the behavior of soft tissues exposed to stress waves. The Ogden model for an isotropic, hyper-elastic solid is calibrated here to describe the constitutive behavior of skin and fat from pig. Figures 6 and 7 show preliminary measurements and simulations made on the skin and the fat of a pig. Samples are about *3mm* thick; impact velocity is *9m/sec.* We performed multiples impacts at the same location of the same sample to establish repeatability.

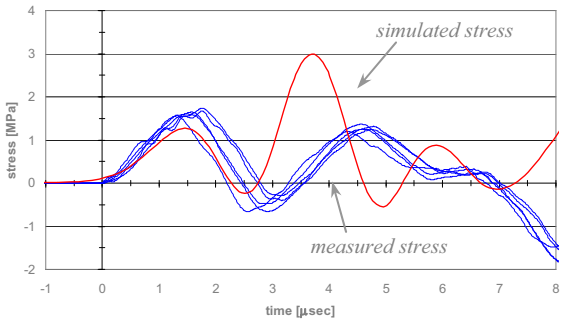

Figure 6: and simulated stress waves in the skin of a pig – thickness *3mm* – impact speed *9m/sec*

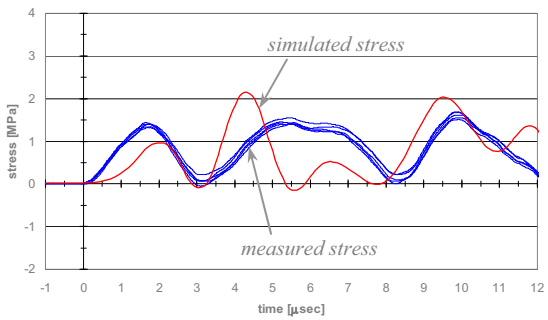

Figure 7: measured and simulated stress waves in the fat of a pig – thickness *3mm* – impact speed *9m/sec*

These results demonstrate repeatable measurements on a single sample. Variability between samples is mainly observed on the amplitude of the signal but not on the period. On the other hand, simulations with an Ogden model do not fit the measured pressure profiles well for each impact velocity. Therefore, the Ogden model does not seem suitable

for simulations of the high rate behaviour of biological tissues subjected to elastic waves.

IV. Discussion and conclusion

The work reported here leads to the following conclusions. First, measurements performed on the Hopkinson bar characterize the impact generator and validate the use of numerical simulation method to predict wave generated and propagated in metallic parts. Secondly, PVDF gage is a reliable technique for measurement of wave propagation in soft tissues.

These preliminary results show that more measurements and simulations are necessary to characterize wave propagation in soft tissues. Future measurements will permit to describe in details reproducibility on a single sample and variability of different samples. Measurements on a known elastic medium will differentiate the contribution of the PVDF gage from the behaviour of the soft tissue. Moreover, another constitutive model should be developed and calibrated to better simulate the behaviour of soft tissues loaded by pressure waves.

Finite Element Analysis into the Foot – Footwear Interaction Using EVA Footwear Foams

Mohammad Reza Shariatmadari

School of Enginneering, University of John Moores, Liverpool, UK.
Web: www.ljmu.ac.uk***, Email:*** m.r.shariarmadari@2005.ljmu.ac.uk

Abstract — **Diabetic ulcers are the most common foot injuries leading to lower extremity amputation. Early detection and appropriate treatment of these ulcers may prevent up to 85 percent of amputations [1-3]. One of the most important defence in pressure off-loading and preventing recurrent ulcers is the proper footwear or *orthotic* intervention [4-7]. In order to achieve that, a biomechanical knowledge of forces and pressures under the foot play an important role in the assessment and treatment of various foot pathologies, and patients who are at risk or are experiencing variety of foot problem.**

The current study uses test material data and FEA to investigate the foot - footwear interaction and performance of two EVA footwear foams subjected to quasi - static and dynamic compressive loading. The aim is to obtain the peak stresses in the foot in the situation such as standing, walking, running and jumping. These stresses are very useful as they will enable to design suitable orthotic footwear, to reduce the amount of stress in the foot for those individuals such as diabetes.

Keywords — **EVA Foam, Cowper Symonds, Finite Element Analysis, Footwear**

I. Introduction

The foot is a mechanically complex structure of immense strength and it can sustain enormous pressure. Biomechanics is the study of the human body's movement during walking, running and sports, and the effects that outside influences have on the motion of the body [8]. The foot functions as a link in a biomechanical kinetic chain, where movement at one joint influences movement at other joints in the chain [9].

The quasi – static and dynamic footwear foams characteristics are necessary to obtain by the experimental / analysis to ensure that the suitable footwear is designed according to the needs of individuals and to prevent the injuries to the lower extremity. Based on the existing literature, there is inadequate high strain rate material data for footwear (orthotic intervention) to simulate different situations such as walking, running and jumping.

One of the most versatile footwear products on the market is EVA and stands for Ethylene Vinyl Acetate [10]. When formulated into a closed cell foam product, it takes on the following characteristics [11],

- good weather and chemical resistance
- low water absorption
- good acoustic properties
- oil resistance
- high energy absorption
- environmentally friendly, safe disposal by recycling, dumping or incineration

Quasi - Static and Dynamic compression loading tests were carried out on two grades the most commonly used EVA foam materials at the loading rates of 0.01, 0.1, 1 and 2 m/s, using a high speed testing machine.

Finally, axisymmetric Finite Element (FE) foot and footwear models were developed using the test material data to calculate the maximum pressure in the foot.

The results were and showed a good trend of variations of force – displacement with loading rates. As the loading rate increased, the forces in the foot increased.

II. Materials and methods

A Footwear Material Testing

Static and Dynamic compression loading tests were carried out on two grades the most commonly used EVA foam materials at the loading rates of 0.01, 0.1, 1 and 2 m/s, using a high speed testing machine. The foam specimens were dimensioned at Length=50 mm, Width=50 mm and Thickness= 20 mm.

The testing scheme was adapted from ASTM D575-91, standard test methods for rubber properties in compression [12].

B Stress – Strain Behavior of Footwear Foams

The Stress-strain behavior of the EVA foams for the varying speeds of 0.01, 0.1, 1 and 2 m/s are shown in Figures (1 - 2).

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1627–1630, 2009
www.springerlink.com

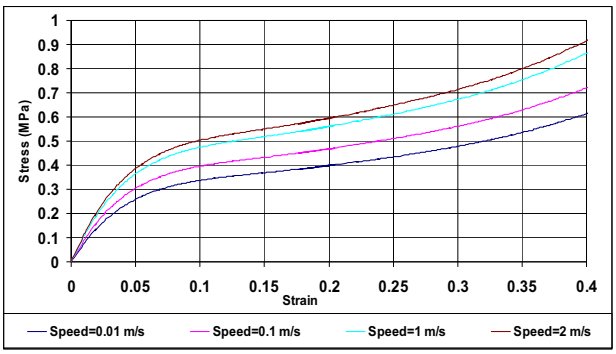

Fig. 1 Material Data for Low Density EVA Foam

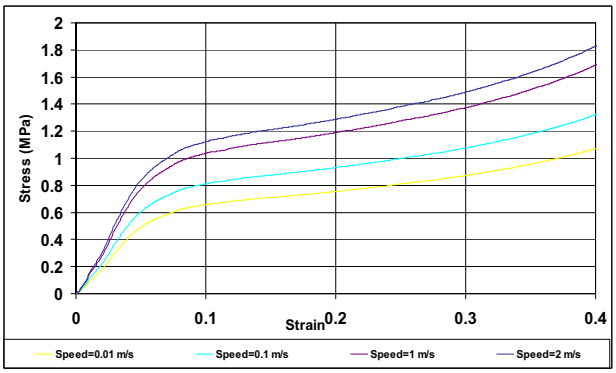

Fig. 2 Material Data for Medium Density EVA Foam

C Finite Element Analysis

A simplified foot – footwear FE model was adapted from Verdejo et al. [13], see Figure (3). The calcaneus geometry was simplified to have a vertical axis of rotational symmetry. The geometry of its lower projection was simplified as a hemisphere of radius 15 mm attached to the end of a 20 mm vertical cylinder of radius 15 mm. The heel pad outer geometry was taken to be a vertical cylinder of radius 30 mm: the lower surface was spherical with radius of curvature of 40 mm, typical of a foot; a smooth blend was made between this surface and the vertical cylindrical surface. The minimum heel pad thickness was taken as 12 mm. When the EVA foam was present, it was taken as a vertical cylinder of radius 35mm and height 22 mm with flat upper and lower faces. The simple FE foot was modeled with and without the footwear foam.

Eight nodded axsymmetric elements (CAX8RH) were used to mesh the bone, heel pad and the foam mesh. Convergence tests were carried out to determine a suitable mesh density for the model.

The models were subjected to compression by applying a prescribed displacement on the bone. The table was fully fixed while the upper calcaneus boundary was ramped down by 10 mm. The coefficient of friction between the heel pad and the foam or support table was taken as 1.0.

The static and dynamic foam material models were taken from the tests carried out on two grades of EVA foams.

The hyperfoam model in Abaqus [16] uses the Ogden strain energy function as shown in Eqs (2 & 3)

$$U=\sum_{i=1}^{N}\frac{2\mu_i}{\alpha_i^2}\left[(\hat{\lambda}_1^{\alpha_i}+\hat{\lambda}_2^{\alpha_i}+\hat{\lambda}_3^{\alpha_i}-3)+\frac{1}{\beta_i}\left((J^{el})^{-\alpha_i\beta_i}-1\right)\right] \quad (2)$$

where

$$\beta_i=\frac{\nu_i}{1-2\nu_i} \quad (3)$$

where N is a material parameter, μ_i, α_i and β_i are temperature dependent parameters. λ_I are the principal extension ratios.

The material properties for the soft skin, bones and rigid table are defined as in Table (1).

Table 1 Foot Material Properties

Component	Young's Modulus	Poisson Ratio
Bones [17]	7300.0 MPa	0.3
Rigid Table / Plate [18]	209E+09 Pa	0.43
Soft Skin [19]	14.3 kPa	7.3

The displacement was monitored at the upper calcaneus boundary (as shown in Figure 3) and the reaction force was determined from the constraints.

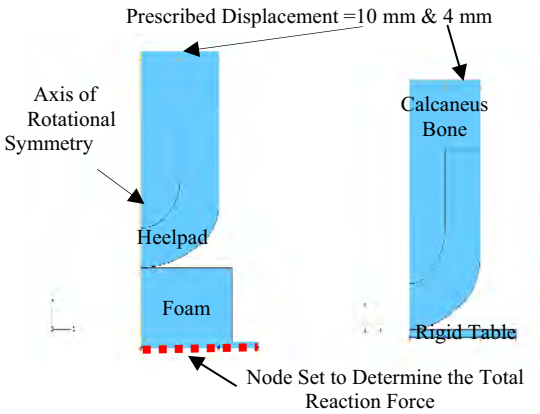

Fig 3 FE Assembly Models of Calcaneus Bone, Heel Pad (Skin), Rigid Table and (a) with Foam (b) without Foam

Figure (4) show the vertical stress, S_{22} contours and the deformed shapes of the foot – footwear and foot – table models under static loading of around 500 N.

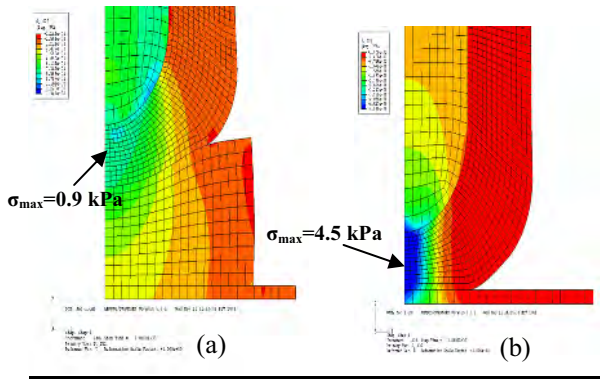

Fig. 4 Deformed Contours of Vertical Compressive Stresses (S_{22}) of Bone and Heel Pad on a Flat Rigid Table (a) with Shoe (b) without Shoe

The quasi-static and dynamic material data for low and medium density EVA foams were used in the foot – footwear FE model shown in Figure (3). Figure (5) details the FEA force-displacement at the interface between the foam and soft skin when using results for low and medium density EVA foams at different loading rates.

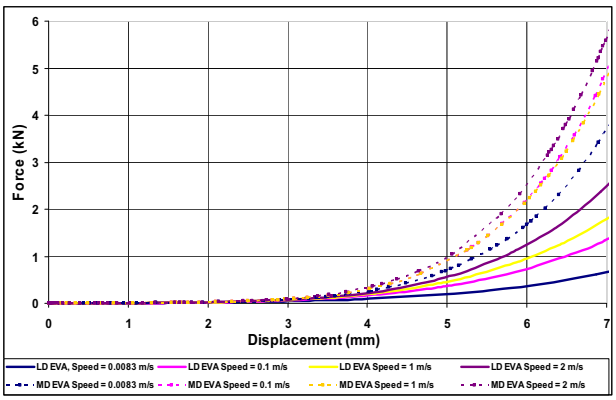

Fig. 5 FE Force – Displacement for Low and Medium Density EVA Foams Using Quasi – Static and Dynamic Test Material Data

Figure (6) shows the force versus displacement curves obtained from literature [14 & 15] and current FEA results for both heel / rigid table and heel / foam / rigid table models.

III. Conclusions

The footwear foam materials of varying densities were compressed up to 50% of their initial thickness at speeds ranging from 0.01 to 2 m/s. As can be seen from Figures (1 & 2), increases in foam density and the rate of loading results in increased stiffness and subsequently increased stress at constant strain. The figures also show the non-linear material characteristics with the foams stiffness changing with increasing strain.

- For a 40% strain of the medium density foam, the stress for quasi - static loading was found to be 0.53 MPa. The loading rates were then increased to the dynamic levels of 0.1, 1 and 2 m/s. As a result the stresses increased to 0.6, 0.98 and 1.12 MPa respectively for the same strain of 0.4.
- With respect to the accuracy of the test material data, the tests were repeated and satisfactory results were obtained at the quasi-static loading rate. The high speed testing machines exhibited more sensitivity as the loading rate increased which resulted in poor repeatability.

The non-linear large deformation problem of foot – footwear interaction was analysed by developing a simple FE model to find the maximum stresses in the foot, with and without footwear. The following conclusions were drawn:-

- It was found that most of the deformation occurs by flattening of the lower surface of the heel pad.
- The deformed heel pad does not decrease much in thickness while the foam becomes increasingly concaved. The maximum stresses in the foot occurred at the left hand side of the contact area as shown in Figure (4).

- The reaction forces were found to be 500N and 452N for 10 mm and 4 mm prescribed displacements with and without footwear foams respectively using the material data from [13]. As can be seen in Figure (4) the stresses are reduced in the foot from 4.5 kPa (without shoe) to 0.9 kPa (with the shoe) at this load.

Furthermore, the quasi – static and dynamic test material data for the two other types of low and medium density EVA foams were used in the foot and foam FE model to calculate the stresses in the foot. Figure (5), shows an expected trend of force - displacement behavior with loading rates. The comparisons made between these two different foam grades revealed that,

- the density of the footwear foams is an important factor in the peak forces produced in the foot. The compressive forces were lower with low density EVA foam because the material is soft and more resistant to bottoming out than higher density foams. Low density EVA foam reduces pressure by distributing body weight forces over a larger area of the foot and the pressure decreases as area increases for the same force.
- For 7 mm displacement, the maximum compressive forces in the contact area between the heel pad and the foam for the static loading was found to be 607 and 3416 N for low and medium density foams respectively (see Figure 5). The loading rates were then increased to the dynamic levels of 0.1, 1 and 2 m/s, which resulted in the maximum contact forces to increase further to 1328, 1788 and 2368 N and 4763, 5570 and 5777 N for low and medium high density foams respectively. Therefore, the loading rate was found to be another key factor in the forces acting on the foot as the higher the loading rate is, the higher the contact forces were found to be. The displacements were lower at higher loading rates due to rapid air loss in the foam materials.
- Any increase of the contact area between the heel pad and the foam was found to have direct effect in reducing peak pressure on foot.
- Density of foam and strain rate affect forces generated in foot.

Age Effects On The Tensile And Stress Relaxation Properties Of Mouse Tail Tendons

Abstract — **Tendons are known to exhibit complex mechanical behavior when transferring forces from muscles to bone. This nonlinear mechanical response varies with age due to the presence of degenerative effects which is attributed to the structural changes and interactions observed in each hierarchical level of the dense connective tissue.**

In this study, mouse tail tendons were excised from the C57BL6 mice to evaluate the age effects on tensile and stress relaxation properties. Uniaxial tests were performed on two age groups: 1-month-old and 8-month-old. The extension rate effects on the ultimate tensile strength (UTS) and modulus were evaluated. The stress decay and relaxation rate were also analyzed. Polynomial function and power law were used to evaluate the modulus and the relaxation rate respectively.

The extension rate effect on the UTS and modulus were significantly different for the younger group but the difference were not observed on the older group. Furthermore, the failure modes were observed to be complete for the younger group and non-uniform for the older groups when rupture sites were observed. The younger group demonstrated a faster relaxation as compared to the older group. These results suggested that the physiological changes which take place due to aging provide quantitative evidence of changes in the mechanical properties of tendons. Future work on other age groups are in progress.

Keywords — **extension rate, tendon, mechanical properties, age**

I. Introduction

Tendons are dense connective tissues that are responsible for transferring forces from muscles to bone. Compared to ligaments, which connect bone to bone, the functional forces of tendons are higher and they act as springs to store elastic energy for energy–efficient locomotion without an extended length of the muscle between origin and insertion [1, 2]. In response to mechanical loading, the living tissues metabolize and change their structural properties; the structural change involved the interaction between the collagen type I fibers, fibrils, molecules and non-collagenous extracellular matrix (ECM) present in the multi-unit hierarchical tendon structures. This ability of tendons is known as tissue mechanical adaptation: a condition which tendons are capable of withstanding different levels of mechanical load [3, 4]. However, as ageing takes place, the tendon physiological developments are affected. The changes include the type of cross-links, proteoglycan density, fibril distribution and water content, which suggest that ageing can, indeed, influence the mechanical properties of tendons [5-9].

The strain rate effects on the mechanical properties soft tissue have been extensively explored for sports biomechanics purposes [10-14]. However, age-related strain rate effect has yet to be widely examined [15-17]. Based on current knowledge, strain rate effects on mouse tail tendons is limited to 3-week-old and 8-week-old [8]. This article highlights 1-month-old and 8-month-old results as part of a wider study to examine the age-related mechanical properties from 1-month-old to 36-month-old mouse tail tendons. The extension rate effect on tensile properties as well as the viscoelastic properties of both age groups shall be examined.

II. Methods

Three C57BL/6 mice from each age point, 1.0-month-old (1MO) and 8.0-month-old (8MO), were euthanized with a lethal does of carbon dioxide under the protocol approved by the Institutional Animal Care & Use Committee. The intact tails were wrapped in a Phosphate Buffer Saline (PBS, pH 7.2) soaked gauze, sealed in a plastic bag and stored in a -20 ˚C freezer until needed.

Before mechanical testing, the preserved mice were thawed under room temperature for three hours. The dissection procedures were conducted cautiously to minimize damage. The middle portion of each retrieved tendon was sectioned to approximately 15 mm in length for the tensile and stress relaxation tests (Fig. 1). The trimmed tendon was then pasted across the length of a thin framed template using cyanoacrylate adhesive. The purpose of the template is to prevent any premature damages to the tendon specimen during the handling process. The two sides of the template were trimmed off before loading.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1631–1635, 2009
www.springerlink.com

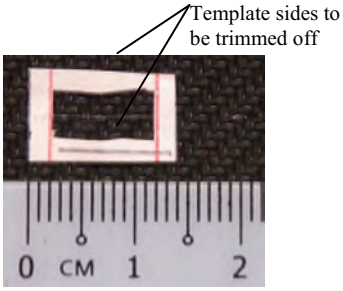

Fig. 1 A template with mouse tail tendon pasted on using cyanoacrylate adhesive. Each tendon was trimmed to approximately 15 mm in length for mechanical testing.

A. Mechanical Testing

Each tendon-on-template was mounted onto the grips of a custom-made horizontal tensile test device, which is immersed in PBS to avoid specimen dehydration. The tensile device was equipped with a force sensor of 450g in capacity (model: UF1, LCM Systems, UK) and a linear displacement transducer (model: CDP-M, Tokyo Sokki Kenkyujo, Japan) which measures the grip-to-grip displacement. A motor controller was incorporated to subject the specimen to a constant extension rate. With the assumption that each mouse tail tendon has a circular cross-section, the mean diameter (d) of each tendon was determined by conducting measurements at eight different locations along the central segment of the mounted tendon under bright field microscopy using NIS-Elements (model: TS100, Nikon). The nominal cross-sectional area (A) was then calculated using $A = \frac{\pi d^2}{4}$.

The tail tendon specimens, 1.0-month-old (1MO_T, n = 65) and 8.0-month-old (8MO_T, n = 57), were subjected to extension rates of 0.05, 0.5 and 1.0 mm/s from a relax state till ruptured (Table 1). No preconditioning or preloading was performed. The force generated from stretching the sample and relative displacement between the grips were measured using the force sensor and displacement transducer respectively and the data of both properties were collected at a rate of 100 Hz. The displacements and loads observed were normalized to strain and stress respectively. Each stress-strain data set was then fitted with a 5th polynomial function using a least–squares curve fit (Fig. 2). The modulus of the tendon specimen was deduced as the first derivative of the polynomial at the inflection point of the linear region [8]. The ultimate tensile strength (UTS) of each tendon specimen was also determined.

The stress relaxation was performed by loading each of the 1-month-old (1MO_SR, n = 18) and 8-month-old (8MO_SR, n = 18) tendon specimens to approximately 2 to

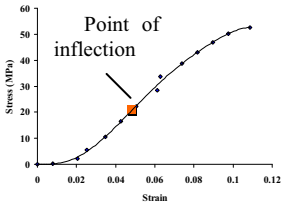

Fig. 2 Typical stress-strain data plot of 8MO_T tail tendon specimen fitted with a 5th order polynomial. Modulus was calculated as the gradient of the polynomial at its inflection point (square).

Table 1 The extension rates expressed in terms of strain rates for mechanical properties tests. The values are expressed in mean ± standard error.

Extension Rate (mm/s)	Strain Rate of MTT (%/s)	
	1-month-old (n = 65)	8-month-old (n = 57)
0.05	0.457 ± 0.005	0.460 ± 0.007
0.50	4.280 ± 0.0526	4.504 ± 0.074
1.00	8.960 ± 0.110	8.811± 0.116

5 % strain with a displacement rate of 0.05mm/s [18, 19]. The applied strain level coincides with the linear region of the load-displacement curve. The decay of the induced load with respect to time (t) was recorded at a rate of 10 Hz for 20 minutes. The stress relaxation curves of each age group was fitted using the power law, $\sigma = At^s$, where A is an arbitrary constant and s is defined as the stress relaxation rate [19]. The unknown values, A and s, are determined by performing a log-log plot.

B. Scanning Electron Microscopy

The ruptured and the non-tested tail tendons were fixed in 2.5% glutaraldehyde in PBS for 15 hours at room temperature. Next, the tendons were dehydrated through a series of ethanol solutions then followed by critical point drier (Model: CPD030, Baltec, Germany). The dried specimens were then pasted onto aluminum sampler holders and sputter coated with gold (model: JCF-1600, JEOL, USA).

Finally, the fiber level studies were conducted by mounting the sampler holder onto the scanning electron microscope platform (model: JSM-5600-LV, JEOL, USA).

C. Statistical Analysis

The data collected were analyzed with one-way ANOVA to detect the significance differences for the tail tendon diameters, strain rate effects on each age group and stress

relaxation properties between the two age groups, . The tensile strengths and moduli were compared to evaluate the strain rate effects for each age group while the percentages in stress decay and relaxation rate were used to observe the differences between both age groups.

III. Results

This study aims to evaluate the extension rate effects on the mechanical properties of 1-month-old and 8-month-old mouse tail tendons. When comparison was made between the diameters of the two age points (Table 2), significance differences was observed ($P < 0.05$). Fig. 3 shows the SEM images of 1MO and 8MO tail tendons respectively. It can be observed that the 1MO collagen fibers appeared as wide bundles while the 8MO tendons are composed of narrower collagen bundles.

The UTS and modulus was significantly different ($P < 0.05$) over the range of extension rates for 1MO (Table 3). For 8MO_T, there was no significant difference observed for both properties ($P > 0.05$), except for the UTS and modulus at higher strain rate ($P < 0.05$) (Table 4). The ruptured sites are illustrated in Fig.3. The fracture sites of 1MO_T were observed to differ between the extension rates; the fibers ruptured into thicker bundles at lower extension rate and demonstrated narrower fibers strands as the extension rate increases. Although there is no observable extension rate effect on the fracture sites for 8MO_T, it was noticed that the ruptured mechanisms shared similar localized failure as 1MO_T specimens strained at 0.5 and 1.0 mm/s.

The percentages of stress relaxed were obtained as 75.77 ± 14.30 % and 41.36 ± 11.72 % for 1MO_SR and 8MO_SR respectively (Table 5). Difference between both age groups was statistically significance ($P < 0.05$). In addition, the power law, fitted onto the log-log plot of stress relaxation curve, revealed significance in the stress relaxation rate between both age groups ($P < 0.05$). The s values, which define the stress relaxation rates, were 0.243 ± 0.150 and 0.109 ± 0.067 for the younger and older age groups respectively.

Mice Group	*A*	*s*
1MO_SR	30.87 ± 4.69	0.24 ± 0.04
8MO_SR	27.39 ± 4.26	0.11 ± 0.02

IV. Discussion

The age effect on the mechanical properties of 1-month-old and 8-month-old mouse tail tendons was conducted. Firstly, comparison of the diameters of both age groups indicated significant difference and the younger specimens were observed to be composed of thicker bundles of collagen fibers as compared to the older specimens.

Next, the extension rate effect on the two age points was also investigated. 0.05, 0.5 and 1.0 mm/s were the extension rates used to subject the tendon specimens to rupture. Significant difference was detected on the UTS and modulus on 1MO_T for the extension rate ranges. 8MO_T, generally, was not affected by extension rate; only the UTS and modulus at higher extension rate displayed significant difference. Furthermore, the extension rate sensitivity for 1MO_T was found to be significant when the rupture sites were taken into consideration. The failed portions were observed to be complete for 1MO_T specimens subjected to 0.05 mm/s and the damage was noticed to be more localized as the extension rate increases. This observation is consistent with that of *Kastelic et al* who conducted the study using x-ray diffraction and suggested that failure mechanisms may have occurred in the interfibrillar level [16]. 8MO _T mainly showed localized failures for all the extension rates tested. *Robinson et al* and *Haut et al* suggested that proteoglycan such as decorin which may play a possible role in defining the failure difference between the two age points strained at 0.05 mm/s [8, 15]. In addition, 1MO_T and 8MO_T which are characterized with enzymic and glycated cross-links between the collagen molecules respectively. Glycated cross-links, which are known to be mechanically stronger than enzymic cross-links, may have contributed to the localized damage and thus possible shear effects [6].

Stress relaxation data was presented in terms of stress decay as well as stress relaxation rate. 1MO_SR demonstrated higher relaxation decay and rate as compared to 8MO _SR. Lower water content and decorin exhibited by older specimens was suggested to decrease strain-rate sensitivity as well as viscoelastic behavior. Conversely, *Elliot et al* and *Johnson et al* found that younger patellar tendons tend to exhibit slower relaxation with the support that the higher water binding effects of decorins may have resulted in friction during the processes of collagen molecule interactions [20, 21].

V. Conclusion

This study examined the extension rate effects on the tensile properties and stress relaxation properties of 1-month-old and 8-month-old mouse tail tendons. The extension rate effects on the tensile strength and modulus were significantly different for the younger group but the difference were not observed on the older group. Future work shall focus on more age groups.

Do trabeculae of femoral head represent a structural optimum?

H.A. Kim[1], G.J. Howard[1], J.L. Cunningham[1]

[1] Department of Mechanical Engineering, University of Bath, UK

Abstract — **This paper presents a numerical investigation in the influence of loading on the trabecular architecture of a femoral head using structural optimization. Previous literature has shown that structural optimization can be used to simulate the response of bone to external loading conditions, in the cases of os-calcis and vertebrae of which the loading conditions may be considered relatively simple. The geometry of a typical femoral head is modeled in the two-dimensional finite element environment with 8-noded quadrilateral elements. Three load cases were considered: 1) the single leg stance phase of gait; 2) the extreme of abduction experienced on a daily basis; 3) the extreme of adduction experienced on a daily basis. These were chosen to give an insight into the influence of difference loading conditions on various architectural features of the femoral head. The results obtained from structural optimization applied to investigate the effects of frequency of load cases suggests that the frequency of load cases is not directly proportional to their influence on the trabecular architecture. The paper also presents some preliminary results, using the same technique, of the influence of a prosthetic femoral stem on the architecture of the surrounding trabecular bone.**

Keywords — **bone, femoral, trabeculae, remodeling, optimization.**

I. Introduction

The well-defined internal architecture of trabecular bone has been thought to represent an optimum biological response to its mechanical environment. Structural optimization has hence been used to investigate the bone structure and the remodeling mechanism [e.g. 1, 2].

Structural optimization considered in this context is sometimes referred to as topology optimization, the shape of the boundaries that defines a design is optimized as well as the number of boundaries, i.e. creating holes. It typically considers design problems in a continuum environment such as Fig. 1, where the continuum domain is represented by Ω enclosed by a boundary, Γ, with body forces, f, the boundary traction, t on $\Gamma_t \subset \Gamma$, and support on $\Gamma_u \subset \Gamma$. The optimization problem is formulated as a material distribution problem where the design variable, x_i is either present or absent, $x_i \in \{1,0\}$. The implementation typically employs the presence or absence of finite elements as a design variable [3].

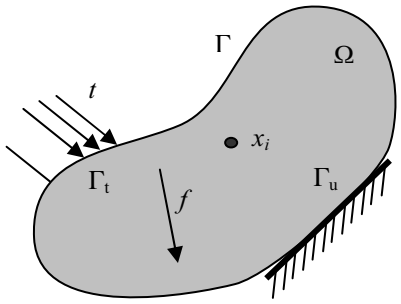

Fig. 1 Generalised two-dimensional continuum domain

Such material distribution problems commonly employ continuous material density distribution to represent the structural architecture. Whilst this offers a general understanding of the optimum configuration, the structural details are often unclear or limited, particularly for more complex geometries with multiple loading conditions. In addition, a recent study has shown that a continuous optimum solution may be significantly different from the discrete optimum solution [4].

This paper aims to investigate the influence of loading conditions on typical femoral head trabecular architecture using a discrete topology optimization strategy and understand the role(s) of various key features. It will also show preliminary results from applying structural optimization to study the trabecular remodeling response to the presence of a hip prosthesis.

II. Finite element modelling of femoral head

A. Geometry

The femoral head is modeled by an artificial cut across the proximal diaphysis, Fig. 2. A representative 2D section of the mid-frontal plane of the proximal femur was created in Solid Edge® [4]. The geometry was based upon that used by Jacobs et al. [5] and the internal area was fully populated in order for optimization to determine the optimum configuration. The femur geometry was meshed using 7,056 8-node quadratic isotropic plate elements in ANSYS® [6]. An elastic modulus, E = 20GPa and a Poisson's ratio, υ = 0.3 were specified for all the elements.

www.springerlink.com

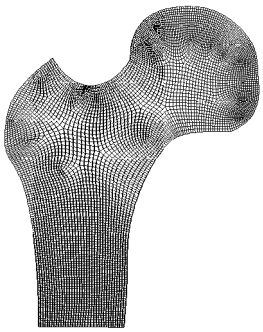

Fig. 2 Finite element model of a femoral head

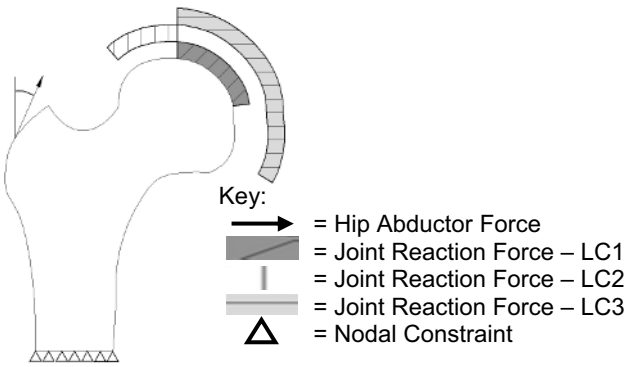
A row of two-element thickness was defined around the external boundary of the femur model. These perimeter elements were excluded from the optimization process to prevent changes to the geometry of the femur, thus the optimization routine considered only the internal trabecular structure.

B. Boundary and loading conditions



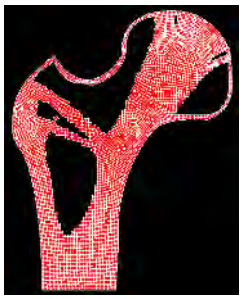


Fig. 3 Loading and boundary conditions

Table 1 Magnitude of load cases

	Joint reaction		Hip abductor	
	Force (N)	Pressure (MPa)	Force (N)	Orientation (°)
LC1	2317	36.07	703	24
LC2	1158	34.48	351	8
LC3	1546	16.57	468	35

A set of three load cases representing typical activities performed on a daily basis was considered, [8]. Fig. 3 depicts the load cases, where load case one (LC1) represents the single leg stance phase of gait whilst load cases two (LC2) and three (LC3) represent the extremes of abduction and adduction respectively, Table 1. In each case a pressure load was applied across an area of the femoral head to represent the joint reaction force and a point load applied at the greater trochanter to represent the hip abductor force.

The line of nodes which formed the distal boundary was fully constrained against translation and rotation in all directions as shown in Fig. 3.

(a) LC1

(b) LC2

(c) LC3

Fig. 4 Optimum solutions for each load case

III. Application Optimization

The structural optimization problem is to minimize the product of compliance and volume, as written in a discrete form in (1).

$$\text{Minimize } C(x_i, u_i)\, V(x_i) \tag{1}$$

where C denotes total compliance and V is the total volume of the design [4]. This problem is solved using Evolution-

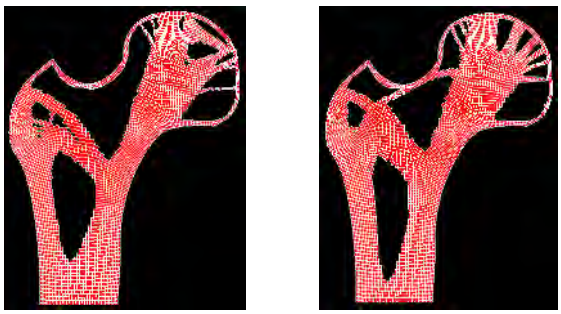
ary Structural Optimization (ESO) [3], using the elemental von Mises stress as sensitivities computed by the finite element method.

A. Application of each loading condition

Three optimization runs were first carried out for each loading condition, and the solutions with a 35% volume reduction were obtained, Fig. 4.

The results for LC1 show the development of a thick band of elements extending from the surface of the femoral head into the medial cortex of the diaphysis akin to the primary compressive trabeculae. A cavity was formed in the middle of the metaphysis similar to the proximal end of the medullary cavity. A void was also created on the medial side of the femoral head, similar to Babcock's triangle and around the area where Ward's triangle is found.

The application of LC2 led to a strut akin to the primary tension trabeculae running from the lateral cortex of the diaphysis, around the superior edge of the position of Ward's triangle into the lateral side of the femoral head. A band of elements also ran from the femoral head into the medial cortex of the diaphysis, supporting the prediction of the primary compression trabeculae in LC1.



The results of LC3 again predicted a band of elements similar to the primary tension trabeculae although in this case originating from the point of abductor force application at the greater trochanter.

B. Simultaneous Application of Loads

The multiple load cases were considered again by applying all load cases simultaneously. Two optimization runs were conducted with and without accounting for the frequency. As the load cases are applied simultaneously, the frequency of load cases 3:1:1 is simulated by multiplying the magnitude of LC1 by 3, and the solutions are displayed in Fig. 5.

Fig. 5(a) shows that the application of the load case of 3:1:1 ratio led to an unrealistic internal structure with many morphological similarities to that predicted by the application of LC1 only, Fig. 4(a). Again a thick strut was predicted in the femoral head which extended distally into the medial cortex of the diaphysis. A void was created which encompasses the area where Ward's triangle is typically found but extended too far in both the medial and lateral directions. This was largely due to the lack of tensile stress resulting from the low magnitude of LC2 in this case. The low magnitude of LC2 also resulted in the medullary cavity like void to be translated in a proximal direction.

Fig. 5(b) shows that the application of the three load cases simultaneously as given in Table 1 produced a structure in which the major morphological characteristics of the proximal femur may be identified. A thick strut runs from the surface of the femoral head into the medial cortex of the diaphysis representative of the primary compressive trabeculae. The cortical bone lining the diaphysis can be identified either side of a void representative of the medullary cavity. The boundary conditions at the cut across the diaphysis have prevented the medullary cavity from extending further in the distal direction at this point. Further voids representative of Ward's triangle and Babcock's triangle are identified. The area where the primary tensile and secondary compressive trabeculae cross can be seen superior to the medullary cavity. The primary tensile trabeculae can also be seen to extend around the superior boundary of Ward's triangle into the femoral head.

(a) 3:1:1 frequency (b) equal frequency

Fig. 5 Optimum solutions for multiple load cases applied simultaneously

IV. Trabecular Remodeling of Femoral Head in Response to the Presence of Prosthesis

The finite element model of the femoral head of Fig. 2 was modified to incorporate the femoral component of a non-cemented hip prosthesis. The length of the diaphysis was increased to encase the full length of the femoral component of an Exeter style implant. 10,187 8-node quadratic plate elements were used. The prosthesis was also not allowed to be modified. All three load cases were applied simultaneously at equal frequency. Fig. 6 depicts the von Mises stress contour plot of the initial model where Young's modulus of the prosthesis was given as 210GPa.

The optimum solution is depicted in Fig. 7, where high bone resorption is apparent. This is because the stiffness of the prosthesis is significantly greater than that of the bone, hence attracting a greater level of the applied load. This can be seen in Fig. 6 where the von Mises stress of the prosthesis is greater than that in the bone. This low stress and strain level leads to the high bone resorption seen in the solution of Fig. 7, which is consistent with the previous findings [10].

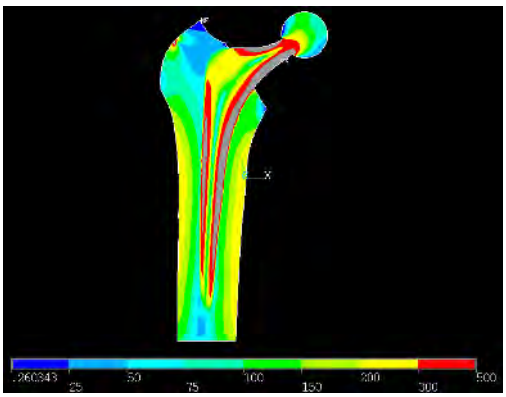


Fig. 6 Von Mises stress distribution of femoral head model with prosthesis

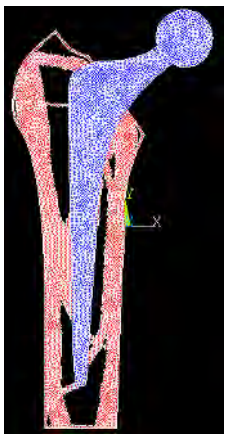

Fig. 7 Optimum solutions for trabecular remodelling around prosthesis

It is also noted that the morphology of the optimum solution is considerably different from the original trabecular orientation of Fig. 5. This suggests that the original architecture is far from the optimum for the new load distribution in the presence of prosthesis. Whilst the original trabecular architecture represents the optimum load carrying structure, the presence of the prosthesis significantly alters the load path and the existing trabeculae no longer represent the optimum solution.

V. Conclusion

It was shown that the application of loads representative of a single activity only was not capable of predicting the full range of morphology characteristic of the proximal femur. However, the results have shown that the range of morphology observed in the femur is in fact created by a range of loads representative of different activities. The application of the three load cases individually allowed the origin of different morphological features to be identified. Whilst the three load cases considered in this study are the common load cases in existing literature, the first two load cases were observed to have dominant influence on the structural morphology.

When the multiple load cases were considered, it was found that structural optimization produced the most realistic results when all load cases were applied simultaneously. This supports the observations from previous studies that bone retains the memory of the applied mechanical loading history [9] and the local strain status may not immediately return to its original status upon removal of a load case. Furthermore, the frequency of the load cases did not appear to have a significant influence on the morphological definition of femoral head trabeculae.

The preliminary results of trabecular remodeling response to the presence of prosthesis shows a high level of bone resorption due to the considerably greater stiffness of the propsthesis relative to that of the bone. The optimum solution suggests that the presence of the prosthesis alters the load paths significantly and that the original trabecular architecture may no longer represent an optimum structure. However further studies are required to consider the contact of the bone and prosthesis surfaces in order to gain a more comprehensive understanding of the remodeling response.

Gender and Arthroplasty Type Affect Prevalence of Moderate-Severe Pain Post Total Hip Arthroplasty

J.A. Singh[1,2], S.E. Gabriel[2] and D. Lewallen[1]

[1] Minneapolis VA Medical Center & University of Minnesota, Rheumatology, Minneapolis, MN, USA
[2] Mayo Clinic School of Medicine, Health Sciences & Orthopedic Surgery, Rochester, MN, USA

Abstract — **Objective: To investigate the impact of gender, age and arthroplasty type (primary vs. revision) on prevalence of moderate-severe hip pain.**

Methods: Using an Institutional Total Joint Registry, we identified a cohort of patients who underwent primary of revision THA from 1996-2004 and responded to the follow-up questionnaires. We compared the prevalence of moderate or severe hip pain based on arthroplasty type, gender and by age (<60, 61-70, 71-80 and >80 years). Results based on gender and type of arthroplasty were analyzed by comparing proportions and based on age by using Chi-square tests, considering a p-value<0.05 significant.

Results: Moderate-severe pain was less prevalent following primary vs. revision THA at 1-year (5.5% vs. 9.8%, p<0.001), and 2-years post-surgery (7.5% vs. 16.3% vs.; p<0.001). The prevalence of moderate-severe pain at 1-year post-arthroplasty was similar for women and men, both primary THA and revision THA: 6.3% vs. 4.6%, p=0.13; and 11.8% vs. 7.3%, p=0.058, respectively; and in revision THA at 2-years: 17.7% vs. 14.7%, p=0.068. However at 2-years, more women than men had moderate-severe pain in primary THA group: 8.8% vs. 6.6%, p=0.042, respectively.

Age had a significant impact on prevalence of moderate-severe pain after 1- and 2-years after primary THA with lower prevalence of pain in 61-70 yr age group compared to other age categories (p=0.01 and p<0.001), but did not have a significant impact on prevalence of moderate- severe pain post-revision THA (p=0.406 and p=0.397, respectively).

Conclusions: Moderate-severe pain was more prevalent in women with primary THA at 2-years, but not at 1-year. This might suggest that factors not directly related to surgery such as anatomical and biochemical differences, bone remodeling, differences in recovery of strength and endurance, activity level or comorbidities may play a role in these differences and need further study.

Keywords — **Pain, Hip Arthroplasty, Predictors, Gender, Age.**

I. Introduction

Total Hip Arthroplasty is a very common surgery for the treatment of end-stage arthritis. It leads to pain relief, improvement in function and quality of life. It has been termed "the operation of the century" [1].

Approximately 208,600 THA were performed in the U.S. in 2005 [2]. It is estimated that demand for primary THAs will grow by 174% to 574,000 by 2030 [2]. Most studies show that THA is very successful in relieving pain. A population-based survey of random sample of 5,500 subjects >65 years old in UK showed that 26% of patients who received THA more than an year ago still complained of some pain in the operated hip [3].

Many factors have been reported to be associated with pain outcomes after THA. Patient expectation of complete relief from after surgery was associated with better improvement in pain and function 6-months after hip and knee arthroplasty [4]. Patients with lower comorbidity were found to have better outcomes after revision hip arthroplasty [5]. Preoperative pain was a predictor of post-operative severity in patients with revision THA [5] and primary THA [6,7]. Older age [6,8] and postoperative low back pain [6] are associated with worse functional outcome 3.6 years after THA. Pre-operative function predicted post-operative pain and function outcomes in a group of patients undergoing knee and hip replacement [7]. Most studies either did not examine gender or found that it was not a significant predictor of outcomes after THA [8].

In this study, our aims were to assess whether: (1) male gender, older age and lower pre-operative pain were associated with a lower risk of moderate-severe pain 1- an 2-years after primary THA; (2) these associations were independent i.e., the associations remain significant in multivariable-adjusted analyses; and (3) gender, age and pre-operative pain are associated with moderate-severe pain 1- an 2-years after revision THA.

II. Methods

A. Study Cohort

Total Joint registry at the Mayo Clinic has been collecting revision data on all patients who undergo hip or knee arthroplasty since 1969 and pain and functional data since 1993. For this study, we identified all patients who underwent primary or revision Total Hip Arthroplasty (THA) patients from 1996-2004 that responded to a validated mailed questionnaire or completed a questionnaire during

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1640–1643, 2009
www.springerlink.com

clinic visit at 2-, and 5-years post-THA. For the patients who did not return questionnaires, or return for their follow-up visit, the trained staff administered pain an function questionnaires.

B. Outcomes and Predictor Variables

Hip Pain was assessed with a single question: "Do you have pain in the knee in which the joint was replaced? ". Patients were asked to select one of the following four responses: None, Slight, Moderate, Severe/marked. For the analyses, moderate and severe pain categories were combined.

The main predictors of interest were gender (women vs. men), age (categorized as ≤70 years or >70 years) and pre-operative pain severity (categorized as moderate-severe pain vs. other categories). Age categorization was based on similar categorizations in the previous studies and based on clinical decision of the orthopedic surgery expert.

C. Statistical Analyses

We conducted separate logistic regression analyses separately for primary and revision THA at 1- and 2-year follow-up periods. Univariate logistic regression analyses assessed the association of gender, age or pre-operative pain severity with post-operative moderate-severe pain. Multivariable-adjusted logistic regression analyses adjusted for age, gender and pre-operative pain severity simultaneously. We present odds ratios (OR) with 95% confidence intervals (CI). A p-value <0.05 was considered statistically significant.

III. Results

There were 4,713 primary THA at 2 years with data and 1,839 revision THA at 2 years with data. For the primary THA, there were 1,477 men and 1,605 women at 1-year; 2,326 men and 2,387 women at 2-years. For revision THA, 595 were men and 476, women at 1-year; 839 were men and 1,000 women at 2-years.

Moderate-severe pain was less prevalent following primary vs. revision THA at 1-year (5.5% vs. 9.8%, p<0.001), and 2-years post-surgery (7.5% vs. 16.3% vs.; p<0.001).

A. Univariate and Multivariable-adjusted predictors of Moderate-severe pain 1-year after Primary THA

At 1-year after primary THA, none of the variables were significantly associated with the outcome, moderate-severe pain (Table 1).

Table 1 Univariate Predictors of Moderate-severe pain at 1-year after Primary TKA

	Odds Ratio	95% CI	p-value
Age ≥70 (vs. <70)	1.35	0.86, 2.12	0.19
Men (vs. women)	0.73	0.46, 1.15	0.17
Moderate-severe pre-op pain	1.60	0.38, 6.75	0.52

CI, Confidence Interval

Table 2 Multivariable-adjusted Predictors of Moderate-severe pain at 1-year after Primary TKA

	Odds Ratio	95% CI	p-value
Age ≥70 (vs. <70)	1.34	0.77, 2.35	0.30
Men (vs. women)	**0.56**	**0.30, 0.98**	**0.04**
Moderate-severe pre-op pain	1.52	0.36, 6.49	0.57

CI, Confidence Interval

Multivariable-adjusted analyses found no associations of age or pre-operative pain with post-operative moderate-severe pain at 1-year after primary THA. Men were significantly less likely to report moderate-severe pain than women, after adjusting for differences in age and pre-operative pain severity (Table 2).

B. Univariate and Multivariable-adjusted predictors of Moderate-severe pain 2-years after Primary THA

In univariate analyses, age ≥70 was associated with significantly higher odds of moderate-severe pain two years after primary THA compared to those younger than 70 years (Table 3).

The age association noted in univariate analyses was confirmed in multivariable-adjusted analyses (Table 4). Men were significantly less likely to report moderate-severe pain compared to women. Pre-operative pain was not significantly associated with pain outcomes.

Table 3 Univariate Predictors of Moderate-severe pain at 2-year after Primary TKA

	Odds Ratio	95% CI	p-value
Age ≥70 (vs. <70)	**1.41**	**1.11, 1.80**	**0.005**
Men (vs. women)	0.83	0.65, 1.06	0.14
Moderate-severe pre-op pain	1.29	0.63, 2.66	0.49

CI, Confidence Interval

Table 4 Multivariable-adjusted Predictors of Moderate-severe pain at 2-years after Primary TKA

	Odds Ratio	95% CI	p-value
Age ≥70 (vs. <70)	**1.41**	**1.03, 1.92**	**0.03**
Men (vs. women)	**0.71**	**0.52, 0.98**	**0.04**
Moderate-severe pre-op pain	1.21	0.58, 2.49	0.61

CI, Confidence Interval

C. Univariate and Multivariable-adjusted predictors of Moderate-severe pain 1-year after Revision THA

In univariate analyses at 1-year after revision THA, none of the variables were significantly associated with the outcome, moderate-severe pain (Table 5).

Multivariable analyses did not find any significant differences by age, gender or pre-operative pain severity.

Table 5 Univariate Predictors of Moderate-severe pain at 1-year after Revision TKA

	Odds Ratio	95% CI	p-value
Age ≥70 (vs. <70)	1.04	0.61, 1.77	0.86
Men (vs. women)	0.59	0.34, 1.02	0.07
Moderate-severe pre-op pain	2.5	0.93, 6.69	0.08

CI, Confidence Interval

Table 6 Multivariable-adjusted Predictors of Moderate-severe pain at 1-year after Revision TKA

	Odds Ratio	95% CI	p-value
Age ≥70 (vs. <70)	1.56	0.76, 3.27	0.24
Men (vs. women)	0.49	0.22, 1.08	0.08
Moderate-severe pre-op pain	2.49	0.93, 6.64	0.07

CI, Confidence Interval

D. Univariate and Multivariable-adjusted associations for Moderate-severe pain 1-year after Revision THA

Pre-operative pain severity was significantly associated with post-operative pain severity at 2-years after revision THA. Age and gender were not associated.

Multivariable-adjustment did not attenuate the strength of association of pre-operative pain severity with post-operative pain severity at 2-years post-revision THA.

Table 7 Univariate Predictors of Moderate-severe pain at 2-years after Revision TKA

	Odds Ratio	95% CI	p-value
Age ≥70 (vs. <70)	1.10	0.86, 1.42	0.45
Men (vs. women)	0.79	0.63, 1.02	0.07
Moderate-severe pre-op pain	**2.22**	**1.34, 3.66**	**0.002**

CI, Confidence Interval

Table 8 Multivariable-adjusted Predictors of Moderate-severe pain at 2-years after Revision TKA

	Odds Ratio	95% CI	p-value
Age ≥70 (vs. <70)	1.02	0.70, 1.50	0.91
Men (vs. women)	0.79	0.54, 1.16	0.23
Moderate-severe pre-op pain	**2.21**	**1.33, 3.65**	**0.002**

CI, Confidence Interval

IV. Discussion

In this study of a large number of THA patients, we noted a significantly higher prevalence of moderate or severe pain in women (vs. men) at 1 and 2 years post primary THA and at 5-years post Revision THA. We also found the patients with moderate-severe pain pre-operatively had more moderate-severe pain at 2- and 5-years after revision THA, but not after primary THA. Older patients had more moderate-severe pain at 2 years post-primary THA.

Our study has several strengths and limitations. Strengths include a large sample size, use of multivariable-adjustments, ability to adjust for pre-operative pain severity, and follow-up up to two years. We presented analyses for both primary and revision THA. Our study has limited generalizability, since it is a single-center study and patients are predominantly Caucasians. Non-response bias due to approximately only half of those with post-operative questionnaires having pre-operative assessments also limits generalizability. Residual confounding due to BMI, comorbidity etc in possible. We were unable to examine other important predictors of pain after THA including psychological distress, depression or anxiety. A longer follow-up would make these findings even more interesting. A study of 5-year outcomes controlling for additional variables is underway.

These findings have important implications. It is not clear from the published literature whether gender is a predictor of pain outcomes after primary THA. Studies in primary THA found no gender association [8], while a study in patients with revision THA reported worse outcomes in women [9]. We found that female gender was associated with worse pain outcomes in primary THA both at 1- an 2-years, but not in revision THA patients. Our study had a larger sample size than previous studies, used a single pain question as opposed to WOMAC or Hip society scores in the previous studies and performed multivariable-adjusted analyses after controlling for pre-operative pain differences and age. Holtzman et al. found that women had worse pain and function than men at the time of the THA and at one year after THA [10]. Comorbidities and pre-operative status explained the post-operative differences only partially.

An interesting finding was that of association of pre-operative pain severity with post-operative moderate-severe pain at both 1- and 2-years in patients with revision, but not primary THA. This is an interesting finding since we had a far larger sample for primary than revision THA, yet associations were significant in revision THA. This implies that different factors predict pain outcomes after primary vs. revision THA. This is a new and important contribution to the existing literature in the area of patient-reported outcomes.

In summary, in this study of a large number of THA patients, we noted a significantly higher prevalence of moderate or severe pain in females (vs. male) at 1 and 2 years post primary THA and at 5-years post Revision THA. We also found the patients with moderate-severe pain pre-operatively had more moderate-severe pain at 2- and 5-years after revision THA, but not after primary THA. Older patients had more moderate-severe pain at 2 years post-primary THA.

V. Conclusions

Age and female gender predict the risk of moderate-severe pain after primary THA and higher pre-operative pain severity predicts moderate-severe pain after revision THA. Further studies need to examine if risk stratification is possible based on these factors.

Quantification of Polymer Depletion Induced Red Blood Cell Adhesion to Artificial Surfaces

Z.W. Zhang and B. Neu

Division of Bioengineering, School of Chemical and Biomedical Engineering, Nanyang Technological University, 70Nanyang Avenue, Singapore 637457.

Abstract — **Cell-cell interactions are governed by interplay of various cell-receptor-mediated interactions and non-specific forces, with non-specific forces such as electrostatic repulsion often allowing or preventing cells approaching close enough to establish adhesion via lock and key forces. One non-specific force that has only recently been suggested as being important for cell-cell interaction is macromolecular depletion interaction. Polymer depletion occurs at cell surfaces if adsorption energy is low, and if depletion zones of adjacent surfaces overlap; osmotic forces move fluid away from the intercellular gap and cell-cell attractive forces develop. In this study interference reflection microscopy (IRM) was employed to study red blood cell (RBC) adhesion to glass surfaces in the presence of dextran in order to elucidate and quantify the underlying mechanism. Our results indicate that adhesion is markedly increased in the presence of dextrans with a molecular weight above 70 kDa. The calculated adhesion energies varied between 0.1 and 1 μJ/m2 and the bell-shaped relation between adhesion energy and both polymer molecular mass and concentration was in qualitative and quantitative agreement with a theoretical depletion model. A strong suppression of membrane undulations was also observed. In overview, our results indicate that depletion interaction plays a significant role in RBC adhesion via initiating close contacts. The results suggest the importance of depletion forces for RBC interactions and its relevance to a wide variety of cell-cell and cell-surface interactions.**

Keywords — **IRM; Depletion interaction; Red blood cell; Dextran**

I. Introduction

During the past few decades, the adhesion of red blood cells (RBC) to other cells and to surfaces has been studied quite extensively due to at least two reasons: 1) Abnormal adhesiveness to other RBC and to endothelial cells has been linked to several diseases such as sickle cell anemia or diabetes mellitus [1, 2]; 2) Red blood cells are relatively simple, easily obtainable cells thus making them logical choices to study the fundamentals of cell interactions in the circulation or with biomaterials. It is clear that various non-specific forces (e.g., electrostatic) and specific forces (e.g., cell adhesion molecules) govern RBC and other cell adhesion to cells or surfaces. While prior studies have described several aspects of RBC adhesion in normal and pathologic states, none appears to have considered depletion interaction as a non-specific force for cell-surface adhesion. Conversely, depletion mediated interactions are commonly considered in the general field of colloid chemistry, and several previous reports have dealt with the experimental and theoretical aspects of depletion aggregation, often termed depletion flocculation [3-7].

More recently, depletion interaction as an attractive force in polymer-induced RBC aggregation has been considered, with results indicating that polymer depletion plays a major role in reversible aggregation of RBC [8, 9]. Such findings are of basic science and clinical interest, in that reversible RBC aggregation is an important determinant of the in vitro rheological behavior of blood as well as of in vivo blood flow dynamics and flow resistance [10, 11].

A depletion layer develops near a surface in contact with a polymer solution if the loss of configurational entropy of the polymer is not balanced by adsorption energy. Within this layer the polymer concentration is lower than in the bulk phase. Thus, as two particles approach, the difference of solvent chemical potential (i.e., the osmotic pressure difference) between the intercellular polymer-poor depletion zone and the bulk phase results in solvent displacement into the bulk phase and hence depletion interaction [5]. Due to this interaction, an attractive force develops that tends to minimize the polymer-reduced space between the cells, thus resulting in flocculation or aggregation. The existence of depletion layers at the RBC surface has been confirmed via electrophoresis studies of cells in various polymer solutions [8, 12, 13], and the energetics of RBC interaction in neutral polymer solutions and the effects of the "soft or hairy" RBC membrane glycocalyx have been reported [9].

To gain a better understanding of this depletion interaction and the physical basis for RBC adhesion to other surfaces, the adhesion of RBC is evaluated by quantitative reflection interference contrast microscopy (IRM). IRM is a powerful tool which allows visual examination of cell/surface contact and separation in real time. It enables dynamic analysis of surface topologies and local membrane-

www.springerlink.com

substrate distances of adherent cells to measure adhesion forces[14]. To quantify the depletion interaction between RBC and coverslip, a theoretical model was established to determine the height profile of RBC at the contact area, and cell-surface affinity was quantified by Young's equation, and this depletion affinity was then compared to the theoretical model. The study here involved sedimentation of normal human red blood cell onto a BSA coated round glass coverslip in the presence of different neutral polymer. Cell adhesion dynamics, membrane undulations, and adhesion energies were quantified as a function of polymer molecular mass and concentration.

II. Materials and Methods

A. RBC preparation

Blood was obtained by thumbnail puncture using a sterile lancet and used within 4h. RBCs were separated from whole blood by centrifugation at 1,000g for 5min, and washed 3 times in isotonic PBS, following that, they were re-suspended at about 0.1% hematocrit in PBS or various dextran solutions.

B. Coverslips preparation

The details has been described previously[15]. Round glass coverslips (25mm diameter) were immersed in nitric acid(65%, Sigma Aldrich)overnight, then they were washed with distilled water and coated with 4% APES in anhydrous acetone (Sigma Aldrich) for 4min. These aminated coverslips were stored in a dust-free plastic chamber until use. 2% BSA (w/v) was incubated with the coverslips for 2 hours at room temperature and rinsed gently with PBS and placed on the holder.

C. Interference reflection microscopy (IRM)

The effects of various dextran suspensions on the interface between settled RBC and the flat glass surfaces were quantified via IRM (Figure 1). In this method, darker areas of the image indicate decreasing distances between the cell and the flat surface [16]. Our IRM setup is based on an Olympus IX71 inverted microscopy equipped with a Zeiss Neofluoar 63 ×/1.25 Antiflex oil immersion objective. Light from 100W high-pressure mercury arc lamp is filtered with a 546.1nm band-pass filter (dv=5nm, 85%, Omega, USA). The contrast in reflection interference microscopy is enhanced by suppressing stray light with the antiflex technique[17].

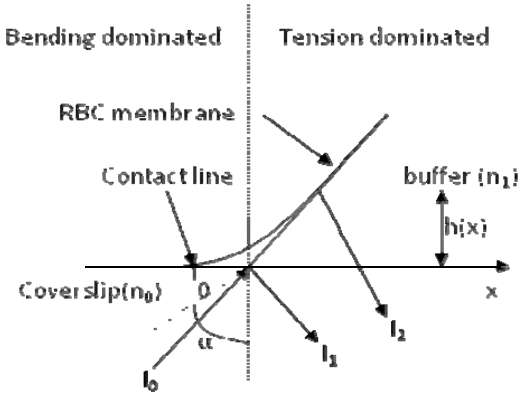

Figure 1 Principle of IRM

D. Data analysis

The details of quantitative IRM has been described elsewhere [18]. Briefly, the cell contour at contact area can be obtained by an arccosine transformation of the intensity:

$$h_{(x)}=\frac{\lambda}{4\pi n}[\arccos\frac{2I_x-(I_{\max}+I_{\min})}{I_{\max}-I_{\min}}] \quad (1)$$

Where λ is the wavelength (546.1nm), $I_{\max}$ and $I_{\min}$ are the maximum and minimum intensities for adjacent wave respectively and n is the reflective index of the solution ($n\approx$ 1.34).

Both the contact angle α and capillary length λ can be obtained by doing a linear least squares fitting to the tension dominated region (see Figure 2) [19]:

$$h(x) = \alpha \cdot (x - \lambda) + \alpha \cdot \lambda \cdot e^{-x/\lambda} \ (x \geq 0) \quad (2)$$

By using Young's equation:

$$W=\gamma(1-\cos\alpha) \quad (3)$$

the adhesion energy can be determined, where $\lambda=(\kappa/\gamma)^{1/2}$, with γ being the surface tension and κ the bending elastic modulus of RBC ($\kappa=1.8\times10^{-19}$J) [20].

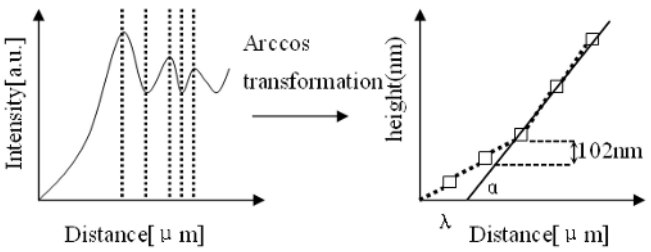

Figure 2 Reconstruction of height profile at contact area

III. Results

A. Red blood cell adhesion dynamics

A typical scenario of RBC adhesion in the presence of dextran is shown in Figure 3. In these studies RBC were suspended in various dextran solutions and allowed to settle and examined by IRM; a darker appearance of the contact area between the cell and the glass slide indicates closer proximity [21]. In dextran-free PBS and in solutions containing dextran 40 kDa the area of close contact stays rather small, with the cells appearing as rings due to close contact only at the peripheral rim of the biconcave RBC. The appearance of the cells changes with the addition of dextran 70 kDa and 500 kDa, such that cells begin to flatten with increased contact area.

In PBS or in dextran solutions containing dextran of molecular weights of 40kDa or less no significant adhesion energy could be determined. Above molecular weights of 40 kDa the adhesion energy showed a bell shaped dependence on the polymer concentration with the maximum adhesion around 4g/dl. The measured energies were all between 0.1-1 $\mu J/m^2$.

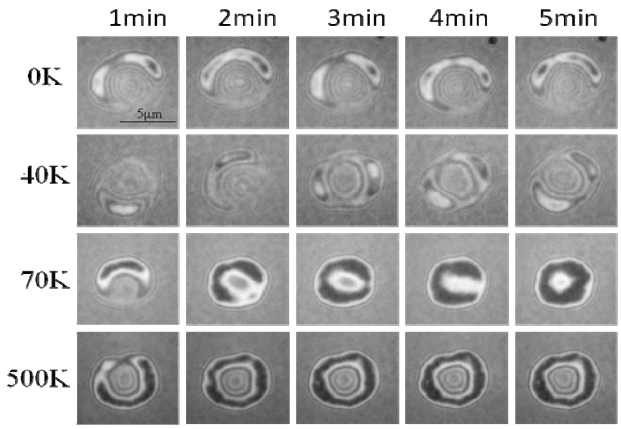

Figure 3 A series of IRM images for RBCs suspended in PBS, 1g/dl dextran40k, 0.5g/dl dextran70k and 0.5g/dl dextran500k

B. Suppression of membrane undulations

Undulation is a unique feature of biological membranes due to thermal excitation. If RBC were suspended in PBS, they showed pronounced membrane undulations, whereas the addition of dextran 70K (2g/dl) lead to a strong suppression (Figure 4). From these results, we can infer that membrane undulation was hindered by high molecular mass dextran.

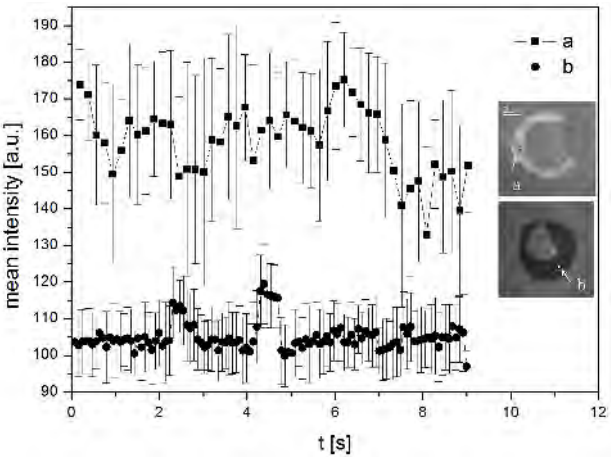

Figure 4 Comparison of the membrane undulation for PBS, 70k (2g/dl), a and b are 1x1 pixels.

IV. Discussion

In this study, we used the neutral polymer dextran to induce cell adhesion. The results presented above clearly illustrate the impact of 70 kDa and 500 kDa dextran on RBC-surface interactions. We conclude that our results are in agreement with the hypothesis that RBC adhesion can be significantly enhanced by neutral polymer induced depletion interaction, with the extent of this effect determined, in part, by polymer molecular size. As shown small dextran had no effect on cell adhesion: it is too small to establish a meaningful depletion layer, with the depletion layer of this small dextran buried within the cell's glycocalyx. Thus, before this thin depletion layer could lead to any attractive interaction, glycocalyx factors (e.g., steric interaction and electrostatic repulsion) prevent adjacent surfaces from becoming sufficiently close. However, for larger dextrans, the depletion layer reaches beyond the glycocalyx, thus leading to the observed impact on cell adhesion.

V. Conclusion

In summary, our findings provide important new insights into the stabilization and destabilization of blood cells in plasma like-suspensions. Further, we suggest that our findings may have physiological and biomedical implications. For example, in pathological conditions large differences in RBC interaction have been observed and our recent understanding of red cell aggregation suggests that these differences are likely due to altered depletion forces between these cells [22, 23]. Age-separated human RBC also exhibit marked differences in affinity, with older, denser cells hav-

ing 3-fold greater affinity than younger, less dense cells in both plasma and polymer solutions [9]. Thus it may be useful to utilize these altered depletion forces for biotechnological applications such as cell separation, and to consider them when looking at the biocompatibility of scaffolds or other biomaterials. While the experimental system used herein represents a rather simple *in vitro* model, our results also suggest possible *in vivo* significance of depletion forces cell on adhesion (e.g., RBC, white cell or platelet interactions with endothelial cells): depletion interaction may help promote cell contact, thereby allowing more-specific adhesive mechanisms to take place.

Abstract — **Wide variety of studies in vivo experiments on animals have been shown that the most effective type of ultrasound waves to accelerate fracture healing in osteotomy procedure is LIPUS. In this study the authors investigate the effect of LIPUS on mechanical properties of healed perforated bone. Twenty-four white male New Zealand rabbits that have drilled the right tibia bone of them were used. The rabbits were divided in two groups: treatment and non treatment. The non treatment group was considered as control. The treatment group was exposed to LIPUS (30mW/cm2 spatial and temporal average, for 20 minutes/day). All of rabbits were divided into three parts according to timing (two, four and six weeks post drilling). Animals were killed in other weeks and mechanical properties (ultimate load and stiffness of bending) were measured. Results revealed ultimate load and stiffness were difference (P<0.05) on the treatment group in comparison to non treatment group after four weeks. The studies suggest that LIPUS stimulation could increase the new bone formation and mechanical properties. We concluded that LIPUS is most effective four weeks post drilling.**

I. Introduction

In this study we investigated the effect of Pulsed Low Intensity Ultrasound (PLIUS) on the heal rate of osteoperforated bones. After removal of a fixator, which is commonly used to immobilize long bone fractures, holes in the bone remained from removal of fixator pins or screws reduce the cross sectional area and consequently the mechanical strength of the bone. This may cause a new fracture at the hole site. A non-invasive method to enhance heal rate of perforated bones may reduce the time needed for recovery of the bone after removal of fixator pins and screws.

PLIUS has potentially important effects on the functional activities of connective tissue cells in vitro [1],[2]. The results of in vitro studies suggest that PLIUS lead to an increase in cytocolic Ca^{2+} and activation of calmodulin [3], and enhances the process of endochondral ossification where the soft callus is converted to mineralized hard callus [4].

A large body of evidence confirms the stimulatory effect of PLIUS on fresh fractures, nonunions, and other osseous defects such as osteotomies. It has been shown that PLIUS is highly efficacious in callus formation during rapid distraction osteogenesis [5], enhancement of osteogenesis at the healing bone-tendon junction [6], treatment of nonunion fractures [7], healing of complex tibial fractures in human [8], and distraction osteogenesis in case of delayed callotasis [9]. The effect of ultrasound on healing of osteotomies, as in vivo models of bone fracture, has also been emphasized [10],[11].

Thus far, the effect of ultrasound on healing of drilled osteoperforation is not clear. Repair at bone gaps is very sensitive to the gap size and shape, and wedge surface conditions [12],[13]. Size, shape and especially surface conditions of a hole drilled to a bone differ from that of gaps caused by natural fractures or osteotomies [14],[15], [16]. Therefore, the results of the effect of ultrasound in cases reported in the literature may not be directly applicable to osteoperforation healing. The present investigation is to clarify this effect.

II. Materials and methods

Twenty-four mature New Zealand white rabbits weighting 2.0 ± 0.2 Kg were used. A two millimeter through medio-lateral hole was drilled at the midshaft of the right tibia of animals, using a standard dental drill (Minicraft, UK) at 30000 rev/min. Operated animals were randomly divided into PLIUS treatment group and placebo control group, and were euthanized at week 2, 4 and 6 postoperatively (n= 4, for each group and time point). During drilling, animals were anaesthetized using muscular injection of a mixture of Ketamin Hydrochloride 50 mg/ml and Xylazine 2% with a proportion of 1 to 5. They were given muscular injection of Prophylaxis Penicillin 800,000 U right after the surgery, and every 24 hours for two days.

Exogen™ 3000 (Smith & Nephew, USA), a standard ultrasound stimulator, was used to stimulate the osteoperforated site in PLIUS group (Gold and Wasserman 2005; Warden 2000). Ultrasound specifications were set to the intensity of 30 mW/cm^2, frequency of 1.5 MHz, and pulse

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1648–1650, 2009
www.springerlink.com

duration of 200 μsec, and were applied 20 minutes per day, 5 times per week [5],[9],[18]. Ultrasound treatment started one week postoperative and continued to the euthanizing day. Similar procedure was repeated for the placebo control group with the ultrasound apparatus at off position. All animals were kept at the same environment.

Every two weeks from the day of operation, 4 of the animals in each group were sacrificed and their right and left tibias were harvested. Samples were kept in normal saline solution. A standard three point bending tester (Zwick, Germany) was used to measure maximum force to break (in Newton) and maximum deflection (in millimeter) of each harvested tibia as measures of mechanical strength of bones. The measures in each operated tibia were normalized to the same measures in the contralateral tibia to reduce the variability effect. The two fixed stands in the bending tester were 8 centimeters apart, and the cross head applied the force right at the anterior side of the perforated site.

The method used was in compliance with the protocol established by the Care and Animal Use Committee of Iran University of Medical Sciences.

Mean value and standard deviation of mechanical measures were computed in each group. Kruskal-Wallis nonparametric test was performed to compare the means of the outcome measures in control and treatment groups. Mann-Whitney nonparametric test was used to compare the means of the measures between the control and treatment groups at each time point (SPSS, Ver. 13).

III. Results

Mean of normalized ultimate load and normalized stiffness increased as time point increased in the placebo control group and the PLIUS treatment group. Mean of normalized ultimate load and normalized stiffness were significantly higher in the treatment group than that in the control group at 4 and 6 week time points ($P<0.05$), but was not different at 2 week ($P>0.05$) (Table1 and Table2).

Table1: Average of Ultimate Load and Standard Deviation

Time / Group	Two Weeks after Surgery	Four Weeks after Surgery	Six Weeks after Surgery
Non Treated	0.76 ± 0.1	0.78 ± 0.07	0.89 ± 0.1
Treated	0.74 ± 0.16	0.91 ± 0.04	1.05 ± 0.06
P value	0.24	0.02	0.02

Table2: Average of Stiffness and Standard Deviation

Time / Group	Two Weeks after Surgery	Four Weeks after Surgery	Six Weeks after Surgery
Non Treated	0.87 ± 0.11	0.88 ± 0.09	0.98± 0.1
Treated	0.81 ± 0.14	1.01 ± 0.06	1.3 ± 0.1
P value	0.14	0.02	0.02

IV. Discussion

The positive effect of pulsed low intensity ultrasound on bone mechanical strength at osteoperforation sites was shown. This was concluded based on the results from an in vivo experimental study on rabbit tibia models, with the main outcome measures including ultimate load and stiffness in the osteoperforation sites.

The effect of ultrasound on wound healing and bone repair mechanisms has long been under investigation. Ultrasound causes a degranulation of mast cells resulting in the release of histamine. Histamine and other chemical mediators released from the mast cell are felt to play a role in attracting neutrophils and monocytes to the injured site. These and other events appear to accelerate the acute inflammatory phase and promote healing. In proliferative phase, ultrasound has been noted to affect fibroblasts and stimulate them to secrete collagen I. This can accelerate the process of wound contraction and increase tensile strength of the healing tissue.

The results of this study revealed considerable effect of PLIUS, at least following 6 weeks treatment, on bone mechanical strength in osteoperforations in rabbit tibia models. These findings are in agreement with the results from Claes et al. [18] who treated bone defects at the metatarsal bones of sheep with a segmental bone transport and then with low-intensity ultrasound using the same apparatus as ours. They showed significantly higher axial compression stiffness of callus tissue in the treatment group. Furthermore, Chan et al. [5] studied the effect of low intensity pulsed ultrasound on callus formation, and showed increased bone mineral content and volume of the mineralized tissue of distraction callus, and enhanced endochondral formation.

We, though, measured the bending stiffness of the healed bone which is very well related to the compressive stiffness.

Li et al. [3] and Unsworth et al. [4], based on the results of their in vitro studies, suggest that one of the mechanisms that low intensity pulsed ultrasound has on fracture repair is

to enhance the process of endochondral ossification where the soft callus is converted to mineralized hard callus. Our findings verify this implication due to the fact that heal rate was more quickly at the first 4 weeks of treatment, when callus mineralization is taken place.

V. Conclusions

The effect of pulsed low intensity ultrasound on the heal rate of osteoperforated bones in rabbit model was studied. It was found that PLIUS can enhance heal rates in osteoperforated bones. The heal rate is more rapidly at the first 4 weeks postoperatively. Ultrasound treatment may be used to shorten clinical treatment times after removal of pins or screws of bone fixators.

Integrative Model of Physiological Functions and Its Application to Systems Medicine in Intensive Care Unit

Lu Gaohua and Hidenori Kimura

Brain Science Institute, the Institute of Physical and Chemical Research (RIKEN), Nagoya, Japan

Abstract — **Systems medicine characteristic of simultaneous management of various physiological functions by various medical specialists, while taking the best use of various medical apparatus, has not been completely realized in the current intensive care unit (ICU). In order to improve such systems medicine from viewpoint of biomedical engineering, an integrative model of physiological functions is developed to simulate clinical management of patient under brain hypothermia treatment (BHT), which is considered as a representative of systems medicine. The model consists of the biothermal regulatory, circulatory and respiratory dynamics, as well as the pharmacokinetics of diuretic and sedative. The model is validated by similarity between model simulation results and clinical data. Then the model is used to simulate clinical management concerning the simultaneous control of therapeutic cooling, minute ventilation, diuretic and sedative infusion. Theoretical discussion would benefit the integration of various medical apparatus and the collaboration among various medical specialists in the current ICU.**

Keywords — **Systems medicine, intensive care medicine, brain hypothermia treatment, model, control.**

I. Introduction

Systems medicine carried out in the intensive care unit (ICU) consists of an integration of various diagnostic and therapeutic equipments, as well as an active teamwork of various medical specialists, for the sake of simultaneous management of various physiological functions of the patient [1]. However, systems medicine has not been completely realized in the current ICU. One of the difficulties in realizing systems medicine is the collaboration among the varying disciplines remains a common problem, mainly because different medical subspecialists only manage their own "organ" of expertise [2]. Another difficulty is various medical equipments function alone in the clinical practice, as they are produced independently by various makers.

In order to improve systems medicine from viewpoint of biomedical engineering, a mathematical model is developed to simulate the systemic management of various physiological functions of patient under brain hypothermia treatment (BHT), which is considered as a representative of systems medicine of acute disease in the ICU. The intracorporeal integration of physiological functions, such as the biothermal regulatory, circulatory and respiratory dynamics, as well as the pharmacokinetics of diuretic and sedative, are modelled together with the extracorporeal integration of various medical treatments, including therapeutic cooling, mechanical ventilation, diuretic and anaesthetic infusion. The model is validated by the similarity between model simulation results and clinical data. Then, the model is used to simulate the simultaneous control of intracranial temperature and pressure, minute ventilation and sedative infusion during the therapeutic hypothermia. Model development and simulation results are reported in this paper.

II. Model Development

A. Systems medicine of therapeutic hypothermia

As an intensive care carried out in the ICU, BHT protects the damaged brain from the secondary neuron death [3]. Although protective to neuron, hypothermia is invasive to the body. Therefore, all physiological functions of the patient should be cared intensively. In particular, the patient under therapeutic cooling should be sedated deeply for a stable management of the circulation, respiration and metabolism and so on. Some specific targets include cooling the brain temperature at about 34°C, depressing the intracranial pressure below 20 mmHg, decreasing the minute ventilation to avoid hyperventilation and putting the patient under suitable sedation [3].

Realization of systems medicine in the clinical practice of BHT requires an integration of medical equipments, such as the cooling blanket, mechanical ventilator and various

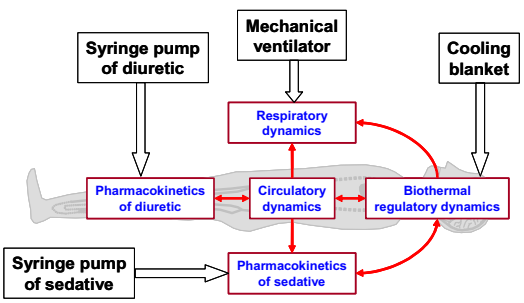

Fig. 1 Systems medicine of therapeutic hypothermia

www.springerlink.com

syringe pumps of diuretic and sedative, as shown in Fig. 1. In order to improve such systems medicine, it is desired to quantitatively analyze the interactions among various physiological functions, including the biothermal regulatory, circulatory and respiratory dynamics, as well as the pharmacokinetics of diuretic and sedative. For this purpose, an integrative model of various physiological functions is first developed for simulation of clinical systemic management of hypothermic patient.

B. Model structure

As shown in Fig. 2, the integrative model developed in this study owns a compartmental structure. It consists of 6 parallel segments, that is, the cranial, the cardiocirculatory, the pulmonary, the visceral, the muscular and the residual segment. Each of the latter 4 segments is divided into 2 compartments to represent the mass and the capillary blood. The cranial segment is composed of 3 compartments, brain mass, brain blood and cerebral spinal fluid (CSF). The cardiocirculatory segment comprises no mass compartment, but 2 blood compartments of the arterial and venous parts. All blood compartments are correlated together via blood flow allocation.

All physiological functions in the body are considered as passive systems without inherent neuronal regulation of biothermal, cardiocirculatory and respiratory dynamics, since the hypothermic patient is generally sedated deeply for stable management in the ICU. Alternatively, it is considered that extracorporeal feedback loops are formed via medical diagnosis and treatment.

Various medical equipments applied to the human body are considered as ambient input to the integrative model. In particular, the mechanical ventilator determines minute ventilation to the lung mass compartment, while diuretic and sedative are infused into the venous part of the cardiocirculatory segment via syringe pumps. Therapeutic cooling induced by the cooling blanket is modelled by temperature-adjustable surrounding to the muscular segment.

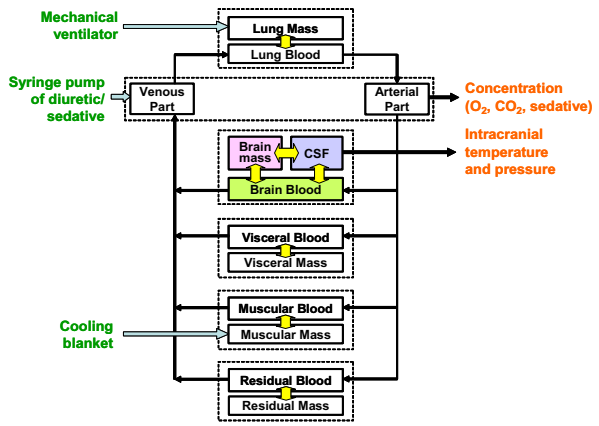

Fig. 2 Compartmental structure of integrative model

All equipments mentioned previously are tuned independently in the clinical practice. Such independency is an obstacle to realization of systems medicine in the ICU. The current paper aims to provide some hints on their integration based on the integrative model.

C. Governing equation

Based on the conservation law of energy and mass, the dynamics of temperature, hydro-static pressure and concentration of respiratory gases (O_2 and CO_2) or drugs (diuretic and sedative) in all compartments are described mathematically. In particular, a unified form of governing equation, as given by equation (1), on account of the analogy of temperature, hydrostatic pressure, respiratory gas and drug concentration. That is,

$$d(CX)/dt = q_{in} - q_{out} \tag{1}$$

where C denotes thermal capacity in the biothermal regulatory dynamics, compliance in the circulatory dynamics, distribution volume in the respiratory dynamics and the pharmacokinetics. X is temperature, hydrostatic pressure and concentration of respiratory gas or drug in the targeted compartment. The left hand side means the storage rate of energy or substance (water, gas, diuretic or sedative). q_{in} and q_{out} on the right hand side are the rate of energy or substance in and out, respectively, with respect to the targeted compartment.

D. Interaction mechanism

As shown in Fig. 1 and 2, blood flow of the circulatory dynamics transports heat, respiratory gases and various drugs throughout the body. Therefore, the biothermal regulatory dynamics, the respiratory dynamics and the pharmacokinetics of diuretic and sedative are combined together with the circulatory dynamics via the circulating blood flow.

At the same time, various physiological and pharmacodynamical mechanisms help integrate the targeted five dynamics together. The major physiological interaction mechanisms are the temperature dependency of metabolism, permeability at the interface of capillary bed, hemoglobin-oxygen dissociation, diuretic and sedative clearance. As a pharmacodynamical interaction mechanism, the thermoregulatory threshold of the biothermal regulatory dynamics is considered to be linearly dependent on the arterial concentration of sedative.

E. Parameter setting

Simulating the integrated system requires values of various kinetics constants, including thermal capacity, distribution volume, compliance, permeability coefficient, blood or lymph flow, metabolic generation or consumption, drug clearance, as well as the initial value of temperature, hydrostatic pressure and concentration of respiratory gases. Obviously, it is impossible to obtain all values in one patient.

For theoretical discussion, some data are given to the integrative model on the base of literature while some data are given on the base of extrapolation. Several data are assumed and revised through model verification and/or validation and through model improvement. Various data of the biothermal regulatory system, the respiratory system, the circulatory system, the pharmacokinetics of diuretic and sedative (mannitol and propofol in this study) are available in the previous reports [1], [4-6].

Taken together, the integrative model consists of a compartmental structure and a representative governing equation, together with various interaction mechanisms and physiological parameters. Medical treatments are considered as adjustable input to the model.

F. Model validation

Partial model of the biothermal regulatory dynamics, the circulatory dynamics and the pharmacokinetics of diuretic or sedative are estimated separately, based on the similarity between the model simulation results and the clinical data concerning brain temperature in response to step cooling, the time course of intracranial pressure, as well as the intracranial concentration of diuretic or sedative, in response to bolus injection and/or to periodic infusion of diuretic and sedative. Furthermore, various properties of the respiratory part of the integrative model are qualitatively compared well with the general knowledge or quantitatively with the experimental data reported in literature.

III. Model application

A. Simulation setting

The integrative model is used to simulate the clinical management of therapeutic cooling, minute ventilation, diuretic and sedative infusion. For this purpose, the model is first introduced to mimic a real hypothermic patient characteristic of intracranial hypertension (intracranial pressure is about 25 mmHg).

On one hand, the desired intracranial pressure in the clinical BHT is the normal value in healthy adults, 10 mmHg assumed in this study. Mannitol is infused as a diuretic to depress the increased intracranial pressure.

On the other hand, the desired brain temperature is a curve abstracted from the practical management of BHT. The total course is 120 h or five days. First, brain temperature is cooled down at a constant rate. The hypothermic brain temperature of 33.5°C is achieved in 8 h and maintained up to 48 h. Then, brain temperature is increased deliberately up to 36.5°C within two days and it is maintained at that temperature for one more day. Temperature of the cooling blanket is tuned to control the brain temperature.

Both the mannitol infusion and the ambient cooling are controlled by PID controllers developed in this study, while taking the decoupling control of brain temperature and intracranial pressure into consideration.

At the same time, management of respiration seeks to stabilize the arterial CO_2 near its nominal value (40 mmHg) through controlling the minute ventilation during hypothermia, based on a linear relationship between cooling temperature and minute ventilation, which is also developed in this study.

Furthermore, a pharmacodynamic relationship between the temperature threshold of thermoregulatory reaction (the core temperature triggering vasoconstriction or shivering) and the blood propofol concentration is used to combine the biothermal regulatory dynamics with the propofol kinetics.

Altogether, the targeted five dynamics, that is, the biothermal regulatory dynamics, circulatory dynamics, respiratory dynamics, diuretic kinetics and sedative kinetics, as shown in Fig. 1, are simultaneously enrolled in this simulation setting. All controllers are available in the previous reports [1], [4-6].

B. Simulation results

Simulation results are summarized in Fig. 3.

It was shown that the brain temperature of the model could be cooled to follow the desired temperature curve almost perfectly. The suggested cooling temperature is physically realizable and physiologically acceptable.

At the same time, simulation results showed that the intracranial pressure of the model could be decreased to the reference, via a dynamic infusion of mannitol.

Simulation result of the respiratory dynamics supported the clinical notion that the minute ventilation should be reduced with reference to the therapeutic cooling for stabilization of arterial CO_2.

Simulation result of the propofol kinetics suggested a novel possibility of propofol infusion in BHT. In particular, it was shown that propofol would be unnecessary during the first 2 hours and the last 30 hours.

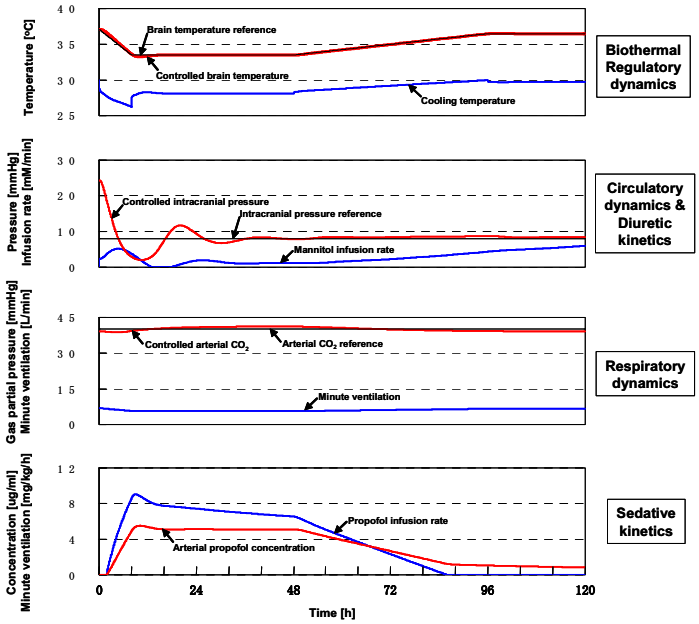

Fig. 3 Simultaneous management of the targeted five dynamics

All simulation results are consistent with the clinical knowledge. Simulation results particularly demonstrated possibility of tuning the mechanical ventilator, as well as the syringe pumps of diuretic and sedative, with respect to the cooling blanket.

IV. Conclusions

The developed integrative model provides the first framework of modelling various physiological functions simultaneously at the organ level in the human body. Actually, the biothermal regulatory dynamics, the circulatory dynamics, the respiratory dynamics, and the pharmacokinetics of diuretic and sedative are modelled in the same compartmental structure and in the same governing equations. These targeted dynamics are integrated through the circulating blood flow, together with the temperature-dependency mechanisms of various physiological functions.

As exemplified in the simulation using the integrative model, the present model succeeds in providing a holistic perspective of various physiological functions of patient under BHT. Simulation results inspire the medical staffs to tune various medical equipments based on the integrative model. Such theoretical discussion gives hints on integration of medical equipments for systems medicine. Also, it would benefit the collaboration among various medical specialists, not only in the BHT but also other intensive care carried out in the current ICU.

A Brain-oriented Compartmental Model of Glucose-Insulin-Glucagon Regulatory System

Lu Gaohua and Hidenori Kimura

Brain Science Institute, the Institute of Physical and Chemical Research (RIKEN), Nagoya, Japan

Abstract — **In order to demonstrate the relationship between brain glucose homeostasis and blood hyperglycemia in the diabetes, we develop a mathematical model of glucose-insulin-glucagon (GIG) regulatory system consisting of the peripheral GIG interaction and the central brain-endocrine crosstalk. Firstly, the body is approximated compartmentally. Then, the peripheral interactions among the glucose dynamics, insulin dynamics and glucagon dynamics are described mathematically, together with a feedback control loop describing the central brain-endocrine crosstalk for the control of brain glucose homeostasis. Furthermore, the effects of long-term severe stress and the effects of blood-brain barrier (BBB) adaptation to dysglycemia are taken into consideration. The model is validated by comparing model simulation profiles with clinical data concerning the GIG regulatory responses to bolus, durational and continuous glucose infusion. On account of the simulation results of the effects of long-term severe stress and BBB adaptation on the generation of blood hyperglycemia, it is proposed that blood hyperglycemia in the diabetes is an outcome of the control of brain glucose homeostasis.**

Keywords — **Brain glucose homeostasis, glucose-insulin-glucagon (GIG) regulatory system, diabetes, model, simulation.**

I. Introduction

Because of the importance of providing a continuous energy resource of glucose to the brain, the body has developed an elaborate glucose-insulin-glucagon (GIG) regulatory system to maintain the glucose concentration in the blood and the glucose delivery to the brain when blood glucose levels fall or raise out the euglycemic boundaries. Resultantly, the varying range of brain glucose is much smaller than that of blood glucose during blood euglycemia [1]. For example, it was observed in rats that an increase of 50 mg/dl in the blood glucose level from its baseline only caused 10 mg/dl increase in the brain glucose level [2]. Clinically, it is known in the diabetic patients that chronic hyperglycemia does not alter brain glucose concentrations, compared with the healthy subjects [3]. These physiological facts stimulate us to propose that the ultimate goal of GIG regulatory system, which consists of the peripheral GIG interaction and the central brain-endocrine crosstalk, is not the homeostasis of glucose concentration in the blood, but the homeostasis of glucose concentration in the brain.

Although the neuronal and/or hormonal regulation of blood glucose homeostasis through the brain has been a target of some qualitative studies, brain glucose homeostasis has not been studied theoretically [4]-[6]. Several mathematical models of the GIG regulatory system are used for theoretical and clinical applications for diabetes control [7], [8], but, no theoretical model has been developed to discuss the relationship between the brain glucose homeostasis and the diabetes.

Main purpose of this paper is to demonstrate the relationship between the brain glucose homeostasis and the blood hyperglycemia in the diabetes. A brain-oriented compartmental model is developed to describe the GIG regulatory system, while effects of long-term severe psychological stress and effects of blood-brain barrier (BBB) adaptation to dysglycemia on the generation of blood hyperglycemia are taken into account. Modelling and preliminary simulation results are reported here.

II. Model description

A. Model structure

The body is divided into 9 segments (Fig. 1). The cranial segment consists of 3 compartments, brain mass, blood and cerebrospinal fluid (CSF). The cardiocirculatory segment is composed of arterial and venous compartments. Each of the other 7 extracranial segments comprises a mass compartment and a blood compartment. All blood compartments are linked via blood allocation. Based on the anatomy of hepatic portal vein, blood flows from the pancreas and gut segments enter the liver segment and then join the systemic circulation, together with the hepatic arterial blood flow.

From the viewpoint of systems control, the cranial segment is considered as the controlled object of brain glucose homeostasis while all extracranial segments as the actuator characteristic of the peripheral GIG interaction.

Feedback control loop corresponds to the central brain-endocrine crosstalk. The afferent signals are mainly generated by the central glucosensing neurons and integrated by the hypothalamus (controller). Various efferent signals are affected by the stress before regulating the hepatic glucose production and pancreatic hormonal secretion.

www.springerlink.com

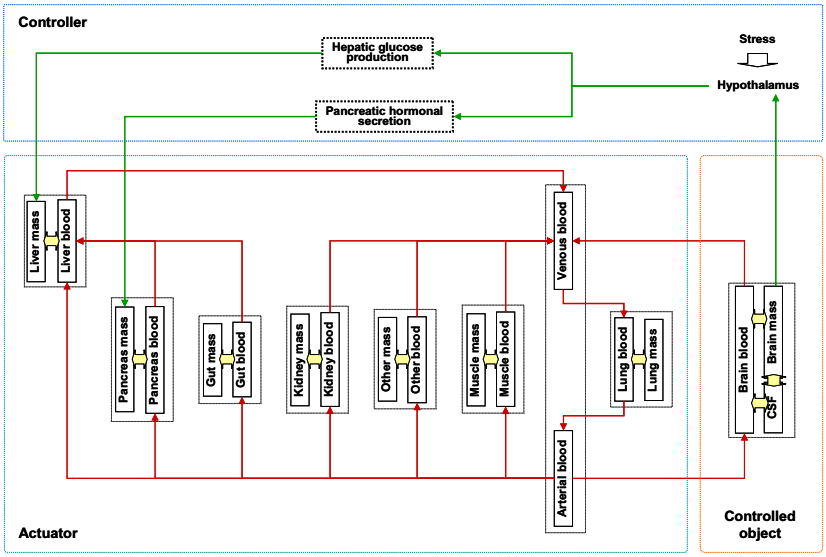

Fig. 1 Compartmental structure of the model

B. General governing equation

Applying the mass conservation law, the dynamics of glucose, insulin and glucagon could be described representatively as follows,

$$\begin{aligned} V\,dG/dt = {} & (1+stress)(1+\gamma)g_{hgp}(G,I,E) + g_{infusion} \\ & + g_{permeation} - g_{brain}(G) - g_{red\ cell}(G) \\ & - g_{urine}(G) - g_{periph}(G,I) \end{aligned} \tag{1}$$

$$\begin{aligned} V\,dI/dt = {} & (1-stress)(1-\beta)i_{beta}(G,I,E) + i_{infusion} \\ & + i_{permeation} - i_{periph}(G,I) \end{aligned} \tag{2}$$

$$\begin{aligned} V\,dE/dt = {} & (1+stress)(1+\alpha)e_{alpha}(G,I) \\ & + e_{permeation} - e_{periph}(E) \end{aligned} \tag{3}$$

where G, I and E denote the concentrations of glucose, insulin and glucagon, respectively. V is distribution volume. *stress* denotes positive variable of stress. $g_{hgp}(G, I, E)$ describes hepatic glucose production, which is dependent on concentrations of glucose, insulin and glucagon in the hepatic mass. Similarly, i_{beta} and e_{alpha} describe pancreatic insulin and glucagon secretions, depending on the local concentrations of glucose, insulin and glucagon in the pancreatic mass. $g_{infusion}$ and $g_{permeation}$ are rate of infusion and permeation of glucose, respectively into the targeted compartment. The same are $i_{infusion}$ and $i_{permeation}$. g_{periph}, i_{periph} and e_{periph} denote glucose utilization and hormonal clearance. In formula (1), g_{brain} and $g_{red\ cell}$ describe insulin-independent glucose metabolism by the neuronal cells in the brain mass compartment and by the red cells in the arterial compartment, respectively. g_{urine} denotes glucose discard from the kidney mass compartment if hyperglycemia. γ, β and α are the efferent signals. They are given as follows,

$$r = k_r e, \quad \beta = k_\beta e, \quad \alpha = k_\alpha e \tag{4}$$

$$e = (G_{brain} - G_{brain0}) + k_i(I_{brain} - I_{brain0}) + k_g(G_{liver} - G_{liver0}) \tag{5}$$

where e denotes the controlled error. k_γ, k_β, k_α, k_i and k_g are parameters characteristic of the brain-endocrine crosstalk.

It should be pointed out that, not all terms appear in all compartments. For example, g_{brain} occurs only in the brain mass compartment.

C. Modelling of blood-brain-barrier (BBB) adaptation

The glucose transport across the BBB is described the following Michaelis-Menten equation,

$$g_{permeation}^{BBB} = \frac{T_G G_{blood}^{brain}}{C_{G0} + G_{blood}^{brain}} \tag{6}$$

where T_{G0} denotes maximal glucose transport rate and C_{G0} denotes Michaelis constant.

Clinical observations suggest the maximal glucose transport rate is glucose-dependency [9]. Therefore, a first-order process is assumed to describe such BBB adaptation as follows,

$$T_G = \begin{cases} T_{G0} & (G_{blood}^{brain}\ within\ euglycemina) \\ T_{G0} - \Delta T_G & (G_{blood}^{brain}\ without\ euglycemina) \end{cases} \tag{7}$$

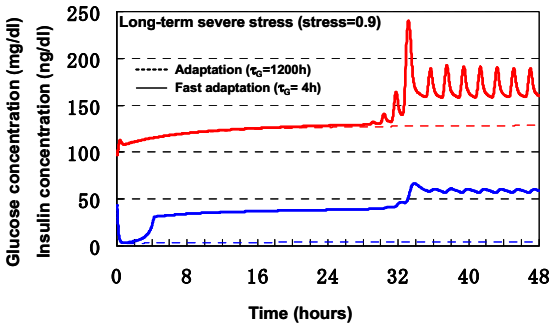
$$\frac{\Delta T_G(s)}{\Delta G(s)} = \frac{k_G}{1+\tau_G s} \tag{8}$$

where ΔT_G is the response of T_G with respect to hyperglycemia. k_G and τ_G are gain and time constant, respectively. s is LapLace operator.

III. Model validation

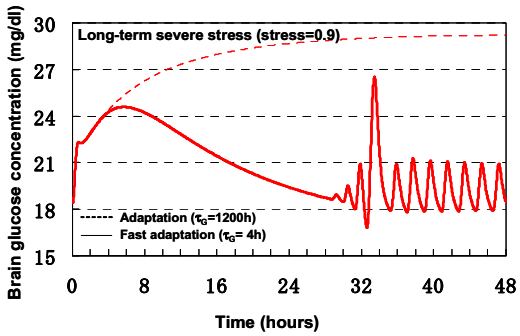
After tuning the values of physiological and physical parameters, mainly by trail and error, the simulation profiles obtained from the compartmental model are consistent well with the clinical data. In particular, it is shown that the current model is appropriate in describing the GIG regulatory responses to bolus, durational or continuous glucose infusion (data not shown due to space limitation).

IV. Model application



In order to demonstrate the relationship of brain glucose homeostasis and blood hyperglycemia in the diabetes, stress-induced hyperglycemia and BBB adaptation to such hyperglycemia are simulated in the model.

For this purpose, long-term severe stress (*stress*=0.9) is assumed in the simulation. Time constant in formula (8) is assumed to be 4 h in the model, although it may be some years in the clinical practice. Such an assumption of short time constant is due to time limitation of computer simulation. Therefore, the simulation results (solid line in Fig. 2) should be considered as fast-forward of the responses (broken line in the same figure).



As shown in Fig. 2, with a fast BBB adaptation, a hyperglycemic steady-state of blood glucose was generated, while the brain glucose was maintained within the euglycemic range. Both the concentration of blood insulin and that of blood glucagon were higher than their basal values, while the ratio of glucagon to insulin was elevated (data not shown). Therefore, the current model simulated an abnormal state similar to the diabetes, which is characteristic of hyperglycemia, hyperinsulimia and hyperglucagonemia.

The simulation results are consistent well with clinical knowledge. As reviewed by Jiang and Zhang [10], the absolute levels of glucagon or the ratios of glucagon to insulin are often elevated in various forms of diabetes in both animal and human subjects. The same authors also pointed out that, chronic hyperglucagonemia was correlated with and was partially responsible for increased hepatic glucose production and hyperglycemia in type 2 diabetes. On account of physiological fact that stress increases glucagon secretion, it is reasonable to consider stress is one of the causes of hyperglycemia in the diabetes.

As shown in Fig. 2b, with the assumed proportional feedback control, brain glucose homeostasis was realized

(a) blood concentrations of glucose and insulin

(b) brain glucose concentration

Fig. 2 Effects of long-term severe stress and BBB adaptation

during blood hyperglycemia. In particular, the brain glucose is at euglycemic level while blood glucose is at hyperglycemic level. The simulation result is consistent with clinical observation that chronic hyperglycemia in diabetic patients does not alter brain glucose concentrations, compared with the healthy subjects [3].

Simulation results demonstrate that BBB adaptation would contribute to the generation of blood hyperglycemia and the maintenance of brain glucose under stress. Both the gain and the time constant of BBB adaptation to dysglycemia are of importance. On account of their dependence on individual, it is reasonable to speculate that a person with large gain and short time constant would be sensitive to stress-induced hyperglycemia and give rise to diabetes.

V. Discussion

A. Importance of brain glucose homeostasis

The brain is one of the major organs that need continuous energy resource of glucose. Maintenance of constant glucose concentration in the brain is of supreme importance due to the physiological facts that the brain is uniquely dependent on the availability of glucose, and that dysglycemia, either hypoglycemia or hyperglycemia, would damage its function.

Obviously, not only in the healthy but also in the diabetics, the brain glucose concentration is maintained constant. Various physiological facts suggest the maintenance of constant glucose level in the brain is more important than that in the blood. Therefore, it is hypothesized that the ultimate goal of GIG regulatory system is not the blood glucose homeostasis, but the brain glucose homeostasis.

Whereas the relations among the brain, glucose homeostasis and diabetes have been qualitatively recognized in experimental animals and in clinical patients, no theoretical analysis is available on the relationship between brain glucose homeostasis and blood hyperglycemia in the diabetes. To the best of our knowledge, it is the first paper that targets on the control of brain glucose homeostasis to provide a theoretical framework of discussing the roles of brain contributing to the generation of hyperglycemia in the diabetes.

B. Role of BBB adaptation in the diabetes

To maintain the brain glucose homeostasis, glucose transport from the blood to the brain should be regulated accurately, according to short-term and long-term states of blood glucose. Actually, the BBB helps govern the brain glucose homeostasis through temporary and permanent mechanisms. It is considered that, the former is the BBB semi-permeability of glucose, a physical filter with respect to sharp variations in the blood glucose levels, while the latter is the BBB adaptation, which is a physiological response to chronic hypoglycemia or hyperglycemia.

It has been shown by simulations using the model that the BBB adaptation, together with the long-term severe stress, contributes to the blood hyperglycemia. A vicious spiral of blood hyperglycemia and BBB adaptation would exist in the diabetes. However, such an interaction should be considered as a self-protective mechanism of the brain.

It is considered that control of brain glucose homeostasis requires increasing blood glucose levels if BBB glucose transport is depressed owing to BBB adaptation. If not, the brain would be short of glucose, as seen in “insulin shock”, where the blood glucose is controlled euglycemically by exogenous insulin injection while the glucose transport across the adapted BBB is not improved.

Therefore, it is reasonable to consider that the blood hyperglycemia observed in the diabetes would be one of the controlled results of the brain glucose homeostasis through the permanent BBB adaptation mechanism. Also, as a suggestion, re-modification of BBB adaptation in the diabetes, with either pharmacokinetic or genetic measures, would be a possible strategy on clinical control of blood hyperglycemia in the diabetes.

VI. Conclusions

Various physiological facts suggest brain glucose homeostasis, but not blood glucose homeostasis, is the ultimate goal of glucose-insulin-glucagon (GIG) regulatory system developed in the body. A brain-oriented compartmental model was developed in this paper to analyze the relationship between brain glucose homeostasis and blood hyperglycemia in the diabetes. The effects of BBB adaptation to dysglycemia, as well as the effects of long-term severe stress, on the generation of blood hyperglycemia were simulated in the model. It was shown that both long-term severe stress and BBB adaptation contribute to blood hyperglycemia. Preliminary simulation results demonstrate that blood hyperglycemia in the diabetes is an outcome of control of brain glucose homeostasis.

Linkage of Diisopropylfluorophosphate Exposure and Effects in Rats Using a Physiologically Based Pharmacokinetic and Pharmacodynamic Model

K.Y. Seng[1], S. Teo[1], K. Chen[1] and K.C. Tan[2]

[1] Bioengineering Laboratory, Defence Medical & Environmental Research Institute, DSO National Laboratories, 27 Medical Drive, #09-01, Singapore 117510, Republic of Singapore
[2] Department of Electrical and Computer Engineering, National University of Singapore, 4 Engineering Drive 3, Singapore 117576, Republic of Singapore

Abstract — **Organophosphate (OP) exposure can be lethal at high doses while lower doses may impair cognitive performance. Diisopropylfluorophosphate (DFP) is an OP insecticide. The biological response of DFP is primarily mediated through its effects on B-esterases, including acetylcholinesterase (AChE). By binding to AChE, DFP inhibits the function of AChE, resulting in the accumulation of the neurotransmitter acetylcholine at synapses. A model capable of predicting the relationship between DFP exposure and the resultant inhibition of AChE would be useful in risk assessment and the design of medical countermeasures against exposure to B-esterase (B-EST) inhibitors. In the present study, we modified a previously-described physiologically based pharmacokinetic and pharmacodynamic (PBPK/PD) model for the effect of DFP on (B-EST) activity by the usage of more widely accepted physiological data and description to more accurately simulate the physiological condition. In addition, we edited the mathematical formulas describing the relevant chemical reactions between DFP and B-EST to improve the theoretical model. For model verification, we compared AChE recovery data measured in vivo in male Wistar rats after single and multiple subcutaneous dosages of DFP with our model predictions. Our results showed a closer fit to the experimental data of AChE activity in contrast to the original PBPK/PD model after single and multiple injections of DFP in rats. The results supported the common hypothesis that distinct regeneration-dominated and synthesis-dominated phases of AChE recovery likely occurred during the experiments. Simulation results from the updated model also highlighted the crucial transition time period where additional experimental results would be most helpful in confirming the kinetics of B-EST dissociation and resynthesis.**

Keywords — **PBPK/PD model, diisopropylfluorophosphate, organophosphate, AChE inhibition, rat.**

I. Introduction

Diisopropylfluorophosphate (DFP) is a member of a class of organophosphate (OP) insecticide that inhibits B-esterases (B-ESTs), including acetylcholinesterase (AChE). Mortality associated with DFP poisoning is primarily due to its inhibition of AChE activity. The toxicological mode of action of a chemical is but one of the pieces needed in the risk assessment together with knowledge of differences in physiology, metabolism and disposition between species [1]. By integrating physiological, metabolic and biochemical information, physiologically based pharmacokinetic and pharmacodynamic (PBPK/PD) modelling is capable of predicting the relationship between OP exposure and resultant toxic effects. A PBPK/PD model is amenable to various forms of toxicokinetic extrapolations including interspecies (rodent to human), high to low dose, duration (acute to chronic) and from the average human to potentially susceptible subpopulations [2].

A PBPK/PD model to quantify the relationship between DFP and the inhibition of B-ESTs – comprising AChE, butyrylcholinesterase and carboxylesterase – in the rat has been previously published by Gearhart et al. [3,4]. In this study, we present an augmented version of this model by the usage of more widely accepted physiological data and the inclusion of the hepatic portal vein to more accurately simulate the physiological condition. We parameterised the PBPK/PD model by using reference physiological parameter values, partition coefficients and biochemical constants that were determined based on reported experiments and optimised by manual adjustment until the best visual fit of the simulations with the experimental data were observed. We verified the model by simulating the dynamic response of B-EST inhibition *in vivo* after single and multiple oral dosages and comparing simulated results with experimental results.

II. Methods and materials

A. PBPK Model

Our PBPK model was modified from [3,4]. In our revised model, the (1) venous blood pool (VEN); (2) arterial blood pool (ART); (3) lungs (LU); (4) brain (BR); (5) liver (LI); (6) kidneys (KI); (7) rapidly-perfused tissues (RPT); (8) slowly-perfused tissues (SPT); (9) fat (AD); (10) heart (HE) and (11) diaphragm (DIAP) compartments were included. We assumed that the rate of DFP transport into the tissue was limited by blood flow while diffusion within

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1659–1662, 2009
www.springerlink.com

each tissue was instantaneous [5]. In Table 1, we summarised the physiological parameters of our model.

Table 1 Physiological parameters used in our PBPK model.

B. Model for Reaction between DFP and B-EST

DFP inhibits B-EST by binding to it forming a complex. As shown in Fig. 1 for AChE, the inhibited complex can either be degraded by aging, or can spontaneously dissociate to regenerate free B-EST.

In all compartments besides the AD compartment, we assumed that the baseline synthesis and degradation of B-ESTs followed zeroth-order and first-order rate constants respectively, and that these rate constants were unaffected by the introduction of DFP. We assumed that B-EST enzymes were not available in the AD compartment. In addition, our model contained equations to describe A-esterase-mediated hydrolysis [Parkinson, 1996] of DFP to diisopropylphosphoric acid (DIP) in the ART, VEN, BR, LI, KI, RPT and HE compartments.

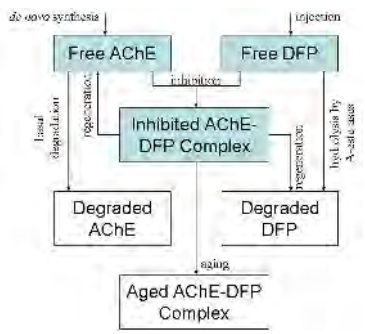

Fig. 1 Chemical reactions between DFP and AChE. Shaded compartments indicate pools whose concentration were tracked in the model.

C. Model Parameterisation

The partition coefficients as well as the Michaelis-Menten constant (K_m) that characterised the metabolism of DFP to DIP in our PBPK/PD model were adapted from [3,4] and shown in Table 2. In addition, we calibrated our model by referencing the authors' parameters for bimolecular inhibition (K_{inb}), synthesis (K_{syn}), degradation (K_{deg}), regeneration (K_{reg}) and aging (K_{age}).

Table 2 Physicochemical parameters used in our PBPK model.

Parameter	Rat
Partition coefficients for DFP

D. Model Calibration and Validation

For model calibration purposes, the simulation of our parameterised PBPK/PD model was compared with the experimentally measured activity of AChE in the brain and blood of male Wistar rats after single subcutaneous administration of 0.7 mg DFP/kg. Next, we applied the calibrated PBPK/PD model for the rat to the repeated dosing condition (first dose of 1.1 mg DFP/kg followed by 11-time repeated administration of 0.7 mg DFP/kg every 48 hours) [6,7].

III. Results and Discussion

A. Two-Phase Kinetics of AChE Recovery

From the experimental data on the time courses of unbound AChE concentration in rodents following DFP exposure [6,7,8], we noted that the recovery of AChE exhibited two distinct kinetic phases. This biphasic phenomenon, also reported by Mason [9], was exemplified by an early short-duration phase showing rapid recovery and a later long-duration phase with a slower rate of recovery. Since free AChE could be formed either by *de novo* synthesis or by dissociation of the AChE-DFP complex, we hypothesised that each kinetic phase was likely due to one of the two mechanisms dominating the recovery of AChE. As a consequence, we optimised K_{syn}, K_{deg}, K_{reg} and K_{age} (beginning from their initial values in Table 2) so as to fit the model simulation with the experimental data.

B. Model Calibration

In Table 3, we showed the values of K_{syn}, K_{deg}, K_{reg} and K_{age} that resulted in the best model fit of the experimental data in rat.

Table 3 Optimised biochemical parameters in our model

Rate constants	Brain compartment	Others
K_{syn} (mole/h)	1.4 E^{-12}	7.6 E^{-13}
K_{deg} (1/h)	0.01	0.04
K_{reg} (1/h)	0.036	0.72
K_{age} (1/h)	0.132	0.658

We compared simulations of the AChE recovery by our parameterised model with the experimental data for AChE recovery in the brain and blood of male rats after single subcutaneous administrations of DFP. As shown in Fig. 2, our model simulation results correctly captured the profiles of the recovery of AChE with respect to time (unbound AChE concentration as a fraction of the total AChE concentration).

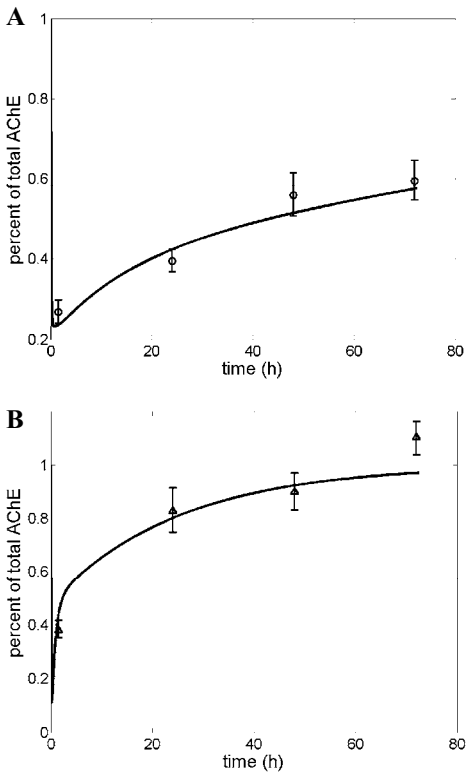

Fig. 2 Recovery of AChE in the brain (A) and blood (B) of rats after single 0.7 mg DFP/kg subcutaneous administration. Each datum represents mean ± standard error (data from [6,7]). Solid line indicates our model simulation results.

Our model simulations also indicated that the transition between the regeneration-dominated to the synthesis-dominated phases occurred between 1.5 to 3 hours after injection of DFP in rats. Because the experimental data for AChE activity in rat brain and blood contained only two measurements during the first 24 hours (at 1.5 and 24 h), our adjustment of the rate constants was based on a small volume of information. These predictions can be verified when more experimental data becomes available. Despite this, the shape of the simulated AChE recovery fuelled the postulation that distinct regeneration-dominated and synthesis-dominated phases of AChE recovery likely occurred during the in vivo experiments. These observations suggested that our revised model replicated the pathophysiological conditions in the animal models better than [3,4]. Hence, the physiological and adjusted physicochemical parameters listed in Tables 1 and 2 were considered appropriate for modelling the current data.

C. Model Validation

Following the calibration exercise, our model of DFP disposition and response for the rat was applied to the multiple dosing experiment. Our results showed that the PBPK/PD model was able to obtain a generally close fit to the experimentally-measured recovery of soluble AChE in rat brain [6], as shown in Figure 3A. The temporary levelling off of experimentally measured AChE recovery at 0.8 from 8 to 28 days after the last dose may indicate that other mechanisms may have occurred that caused a temporary alteration of the equilibrium AChE concentration. Similarly, as shown in Figure 3B, our calibrated model achieved a close fit to the recorded recovery of AChE activity in rat blood [7]. However, the overshoot observed in experimental data at 3 and 35 days after the last dose may likewise indicate the presence of other mechanisms or reactions that affect the recovery of AChE activity, which we did not model in the present numerical simulation exercise.

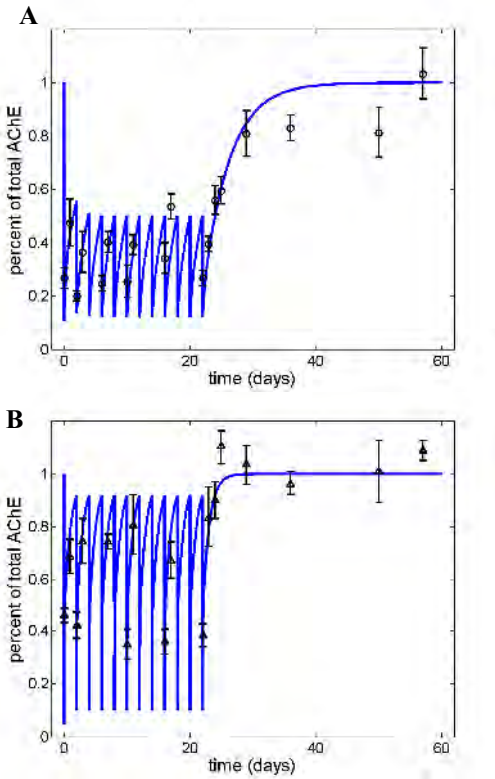

Fig. 3 Recovery of AChE in the brain (A) and blood (B) of rats after subcutaneous injections of DFP every other day for 22 days. Each datum represents mean ± standard error (data from [6,7]). Solid line indicates our model simulation results.

IV. Conclusions

In the present study, we augmented a previously-described PBPK/PD model for DFP dosimetry and response by adding additional components and using alternative parameter values to more closely replicate the physiology of the animal model. In addition, by adjusting the rate constants used in the model, we achieved a closer fit of the simulated kinetics to experimental data than previously described. As a result of the improved simulation, we predicted that B-EST inhibited by DFP exhibits two distinct kinetic phases in its recovery in rats, and that additional experimental measurements during the transition period would allow a better estimation of the rate constants of the individual chemical reactions. We have ongoing efforts to extrapolate this model to predict human response.

Acknowledgment

We thank Dr. Jeffery M. Gearhart for his insightful discussion in developing this PBPK/PD model. We are grateful for Dr. Teoh Eu Jin and Mr. Douglas Goh for assistance in implementing initial versions of the model equations. This work was supported through a grant from the Ministry of Defence in Singapore

Blood Flow Rate Measurement Using Intravascular Heat-Exchange Catheter

Seng Sing Tan and Chin Tiong Ng

Nanyang Polytechnic, Singapore, Singapore

Abstract — **During treatments for patients with coronary artery diseases, continuous cardiac out measurement is essential to provide feedback and monitor any improvements in the vascular system. This paper presents a new possible approach to measure the cardiac output using an intravascular heat-exchange catheter. In order to measure the blood flow rate, the catheter is inserted into a blood vessel and a heat-transfer element attached at the distal end is positioned at a desired location to enable heat transfer from the blood to the cooling fluid in the element. The outlet temperature change of the cooling fluid occurs during the heat-exchange process and is monitored by thermal-sensors to determine the cardiac output and any substantial change of the cardiac output. A preliminary experimental study demonstrated an essential relationship, which can be used to determine the cardiac output from the measurement of the outlet temperature of the cooling fluid alone, without the need to determine the temperature change at the down stream of the blood flow. It also has an advantage of not injecting any auxiliary liquid or dye into the blood flow. Thus, it allows repeated measurement and does not affect the composition of blood stream. Furthermore, it does not warm up the blood flow. Therefore, it avoids any possible adverse effects caused by heating in the vascular system. This current approach is useful in monitoring any continuous improvement and providing feedback in the stenting surgery operation, bypass operation or any treatment related to atherosclerosis.**

Keywords — **Heat Exchange, Catheter, Blood Flow Rate, Intravascular, Cardiac Output.**

I. Introduction

Chronic coronary artery diseases obstruct the blood flow supplying oxygen-rich blood to the heart by forming plaques on the inside walls of coronary arteries. The standard treatments for coronary artery diseases include the balloon angioplasty. The balloon angioplasty compresses the fatty plaques onto the artery walls, often followed by a coronary stent implant [1]. The other standard treatments for coronary artery diseases are atherectomy, medication and bypass surgery to restore normal blood flow rate. Thus, it is essential to monitor closely the real-time blood flow rate during these treatments.

There are many different techniques to measure the continuous cardiac output [2]. This study explores a new approach using an intravascular heat-exchange catheter to determine blood flow rate or cardiac output. The catheter comprises a catheter tube with a flexible closed-loop heat-transfer element disposed at the distal end. The process comprises steps of placing a catheter at a desired location within a blood vessel, acquiring the temperature of the fluid passing through the heat-transfer element and the temperature of the blood flowing over the element. The acquired information is then used to determine the blood flow rate. A preliminary experimental study was conducted to demonstrate that the mass flow rate of blood can be expressed in term of the outlet temperature of the fluid leaving the heat-transfer element. The study showed that an essential relationship can exist. The expression derived can be used to determine the cardiac output and any substantial change of the cardiac output from the measurement of the outlet temperature of the cooling fluid alone.

II. Background

Coronary artery disease is a chronic disease, which impedes or blocks the flow of oxygen-rich blood to the heart through the coronary arteries. This obstruction is caused by a disease known as atherosclerosis, which is sometimes also called blockage of the arteries, narrowing of the arteries and hardening of the arteries. The first goal for treatment of atherosclerosis is to restore as much blood flow as possible through the affected portion of the vascular system and reduce the risk of a plaque rupture, which can result in a heart attack or stroke.

Balloon angioplasty and atherectomy are a few standard treatments based on catheter-based procedures for coronary artery disease. The goal of balloon angioplasty is to make more room for blood to flow through the artery. Coronary stents are often implanted after a balloon angioplasty and/or atherectomy. Stents may be placed in arteries and veins throughout the body to restore normal blood flow. The improved blood flow can lead to an improvement in cardiac function. Thus, measuring blood flow rate is an essential feature in these treatments so as to provide feedback and monitor the changes in the flow rate. Otherwise, based on other indirect methods of observing the patients' response would compromise the success of the treatments in the absence of this important measurement.

Attempts to measure blood flow rate or cardiac output in the prior arts have taken different principles and forms.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1663–1666, 2009
www.springerlink.com

One of the well-known techniques is to include a heating element in the catheter together with other sensors and controls. By heating a segment of blood indirectly with the heating element such as an electric resistance heater, the temperature deviation of blood could be monitored as a function of time at a location downstream from the location at which the heating element is placed. The blood flow rate is then measured by the area under the thermodilution curve based on Stewart-Hamilton Principle [2, 3]. However, the heating could result potential injuries and other adverse fever responses from the body. Another technique avoiding the adverse heating effect is to inject a bolus of saline liquid into the blood stream, where the saline liquid has a lower temperature than that of the blood [4]. The blood flow rate is then determined using the similar thermodilution analysis. Other similar technique sometimes used in place of an injected cold bolus is to include injecting indicator dye into the blood vessels to enhance X-ray images. The blood flow rate can be then determined by the dye-dilution curve. However, in the latter two cases, alien materials have been introduced into the blood flow. They are subjected to important drawbacks as they could result in excessive fluid infusion into the patient and cause safety concerns. Excessive infusion in turn can increase the risk of congestive heart or kidney failure in certain patients [5]. Other techniques include the Flick method and the Doppler ultrasound method. The former measures the blood-oxygen content and the oxygen consumption rate which requires the patient to be in a steady state in which cardiac output does not change significant, while the latter uses a Doppler probe which measurements are troublesome and inaccurate as it is sensitive to its orientation although the method is noninvasive. Therefore, there is an existing need for processes and apparatus that can measure continuous cardiac output easily, effectively and safely.

III. Apparatus and Approach

A. Proposed Measuring Device

In this study, a newly designed measuring device (patent pending) consists of a heat-transfer element together with thermal-sensors adaptable to a catheter for measuring blood flow rate as shown in Fig. 1. The catheter comprises a catheter tube with a heat-transfer element attached at the distal end for conducting the heat-exchange between the cooling fluid flowing inside and blood flowing outside.

The heat-transfer element is a flexible closed-loop heat exchanger, made of metallic capillary tubing coiled into a spring-like configuration not more than 5mm outside diameter. The catheter has at least three lumens. Two of them are used for consistent supply of heat-exchange fluid cooler than the blood temperature to the heat-transfer element, while the third is for delivering out electronic signals from thermal-sensors through a temperature monitoring port at the proximal end of the catheter to monitor the temperatures with a data logger. The catheter proximal end also has a cooling fluid inlet port for introducing the cooling fluid into the catheter and an outlet port for discharging the cooling fluid from the catheter

B. Application

In an operational application, the flexible catheter is inserted into a blood vessel through the vascular system of a patient to place the distal tip of the catheter at one desired location in a blood vessel where the blood flow rate measurements are needed. A cooling fluid is then pumped through the catheter to the distal tip, where a flexible closed-loop heat-transfer element is positioned to enable heat transfer between the cooling fluid and the blood. The

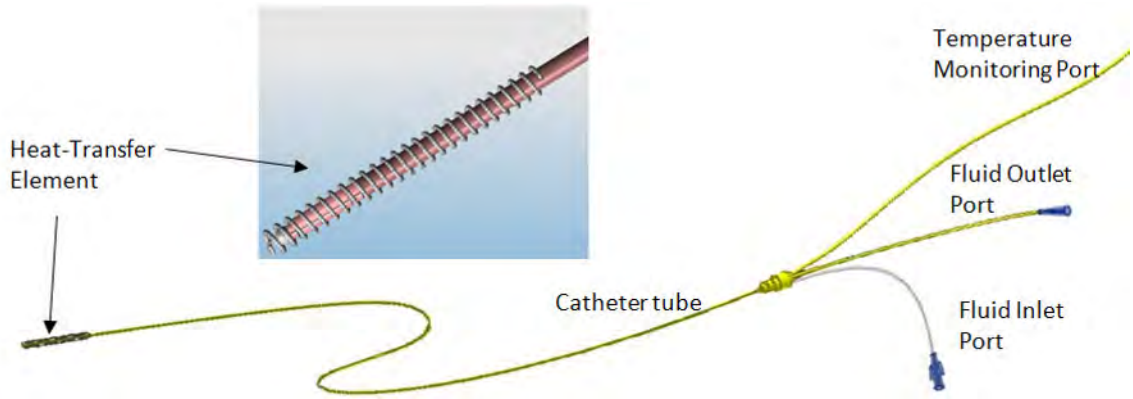

Fig. 1 Heat Exchange Catheter

heat-transfer element absorbs heat energy from the blood flowing over the heat-transfer element in the blood vessel. By having a very large surface area of the heat-transfer element and a relatively lower mass flow of the fluid in the heat-transfer element with respect to the blood flow rate outside the heat-transfer element, a small amount of heat energy could effectively transfer to the cooling fluid in the heat-transfer element, thereby creating an elevated temperature suitable to determine the cardiac output or the blood flow rate. Once an empirical relationship between the temperature parameter and the blood flow rate is established for a specific heat-transfer element, merely measuring the temperature change leaving the heat-transfer element enables cardiac output or the substantial change of the cardiac output, to be determined through this relationship without the need for introduction of an auxiliary liquid into the patient's blood.

C. Experimental Setup

The blood-flow-rate measurement device was first being placed into a rubber tube, which could simulate any portion of the patient's vascular system. One end of the rubber tubing was being placed into the hot-water bath maintained at a certain temperature. A Peristaltic pump was used to circulate the warm fluid through the tubing. The flow created by the water pump simulated the cardiac output or blood flow rate. An electrical pump fixed with a syringe containing cold water was attached to the fluid inlet port of the catheter to supply cooling fluid at a fixed rate into the heat exchanger attached at the distal end of the catheter. The schematic representation of the experimental setup is shown in Fig. 2. The electrical signals for the thermocouples were connected to a data logger to monitor the temperature of the cooling fluid flowing in and out of the heat exchanger and the warm fluid flowing over the heat exchanger in the rubber tube.

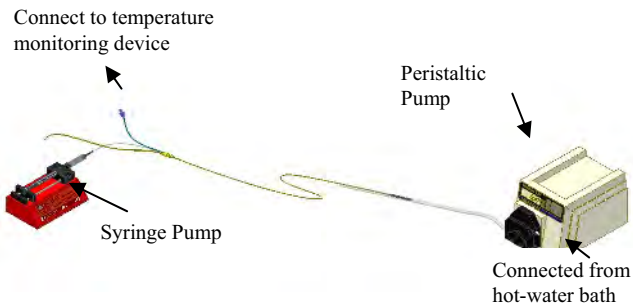

Fig. 2 Schematic Diagram of Experimental Setup

In this feasibility study, the flow of the cooling fluid was set at the rate of 5ml/min. In order to simplify the setup, the cooling fluid was maintained at room temperature (27°C) while the hot-water bath was controlled at 55°C. When the flow rate of the warm water varied from 180ml/min to 1170ml/min at different intervals, the temperatures measured through the data logger were recorded. The results were tabulated and presented graphically to analyze the relationship between these two parameters.

IV. Observation and Results

The results showed that the outlet temperature of the cooling fluid increased gradually from 36.8°C to 42.8°C, as the flow rate of the warm fluid flowing outside the heat exchanger increased from 180ml/min to 1170ml/min. The outlet temperature increased significantly at the beginning when the warm fluid flowed at a lower rate. When the warm fluid flowed much faster, the outlet temperature went up as well, but the rate of temperature increase was not as significant. As shown in Fig. 3, it demonstrated that there is a good relationship between the warm water flow rate and the outlet temperature of the cooling fluid. By fixing an appropriate flow rate and the inlet temperature of the cooling fluid, an empirical expression could be formalized to represent the relationship. Such expression representing for the specific heat-exchange catheter could be useful in tabulating the cardiac output based on the outlet temperature of the cooling fluid alone. Alternatively, a mathematical expression could be developed through the theory of thermodynamic.

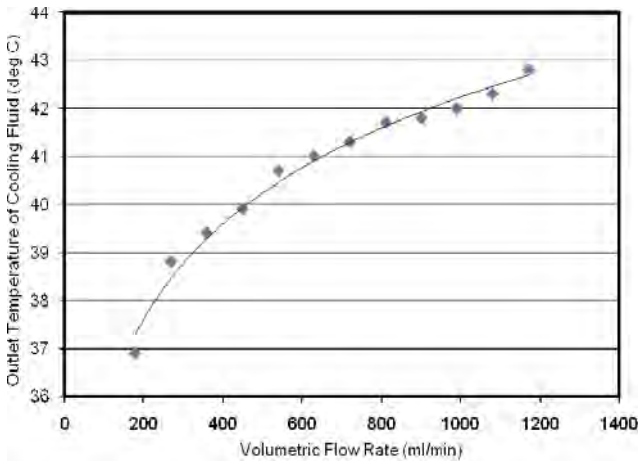

Fig. 3 Graph of Outlet Fluid Temperature vs. Volumetric Flow Rate

V. Analysis and discussion

As compared to thermodilution methods employing indirect heating of blood using surface heating electrical resistance heaters, the method used in this study does not heat the blood flow. Thus, it avoids the adverse effects caused by the use of surface-heating electrical-resistance heaters. It only transfers only a small amount of heat energy from the blood stream to the fluid in the heat-transfer element, thereby creating an elevated temperature suitable to determine the cardiac output or the blood flow rate.

In addition, it does not inject any auxiliary liquid or dye into the blood flow; thus it allows repeated measurement and does not affect the composition of blood stream, unlike dye dilution or conductivity dilution techniques. It could be used on a given patient with increased frequency over relatively long periods of time. Such approach is less likely to result unfavorable response by the body system of the patient. Furthermore, it also does not need to know the temperature change between the up and down streams of the blood flow. As such the apparatus can be shorter and much miniaturized.

VI. Conclusions

In conclusion, this study offers many benefits in the following areas:

1. The method used in the proposal to determine the cardiac output requires only measurement of the temperature of the fluid in the heat-transfer element, without the need to know the temperature change between the up stream and down stream of the blood flow.

2. The method does not affect the composition of the blood stream, unlike dye dilution or conductivity dilution techniques.

3. The approach used in this proposal unlike techniques involving injection of auxiliary liquid, allows repeatability of procedures which could be used on a given patient with increased frequency over relatively long period of time.

4. As compared to thermodilution method, which employs indirect heating of blood using surface-heating electrical-resistance heaters, the current approach extracts a small amount of heat energy from the blood to evaluate the cardiac output. This approach does not have any adverse effect to the vascular system and unlikely to have unfavorable consequences to the patient.

5. The current approach to determine the flow in a narrow channel is unique and could have many applications such as in food industries or chemical plant, besides life science applications, as it does not contaminate or affect the properties of the flowing fluid.

Mechanical and Electromyographic Response to Stimulated Contractions in Paralyzed Tibialis Anterior Post Fatiguing Stimulations

N.Y. Yu[1] and S.H. Chang[2]

[1] Department of Physical Therapy, I-Shou University, Kaohsiung County, Taiwan
[2] Department of Occupational Therapy, I-Shou University, Kaohsiung County, Taiwan

Abstract — **Muscle fatigue is one of the most important problems resulting when functional electrical stimulation is implemented. After muscle fatigue, the manifestation of post fatigue recovery process is hence necessary for the external control of electrically elicited muscle contractions. Thirteen able-bodied young adults were recruited for this study. For inducing muscle fatigue, a modified Burke fatigue protocol was delivered to activate the tibialis anterior for 4 minutes. Before and after the modified Burke fatigue protocol, a series of pulse train with three pulses of 1 Hz and 7 pulses of 20 Hz of stimulation frequency, were delivered to induce 3 twitches and a fused contraction at 1, 3 and then followed every 5 minutes for 60 minutes. When the muscle was stimulated, the stimulus-response EMG and the generated ankle dorsiflexion torque were collected for further analyses. This study found the recovery process of muscle fatigue could be modeled by a first order exponential equation. The properties in twitched and tetanic contraction were found to be different. The recovery process was found faster in tetanic muscle contraction. The disassociation between mechanical and myoelectric activities was found in the recovery process, especially in the twitch contraction. These findings will help researchers and clinicians predict the muscle force and permit a better adjustment of the stimulation parameters.**

Keywords — **muscle contraction, muscle fatigue, recovery, low frequency fatigue, potentiation.**

I. Introduction

Fatigue is a major challenge for continuing an ongoing movement induced by electrical stimulation. Most of the researchers found that when muscle is fatigued, the torque frequency curve will shift to the right, i.e., to a same level of the force output, but that the frequency must be increased [1][2]. The recovery of contractile speed caused the tetanus's failure to fuse in lower frequency stimulation, whereas the tetanus torque became less depressed in higher frequency stimulation [1]. This phenomenon is termed as low frequency fatigue (LFF). In addition, potentiation is one important mechanical characteristic and also considered a competing process in which repetitive stimulation of a fatigued muscle yields augmentation of peak force [3]. Our aim was to observe whether these two phenomena occur in the recovery process and to determine the main feature of potentiation in post fatigue paralyzed muscles.

From physiologic aspects, many studies have investigated the evoked EMG of the stimulated muscle during the fatiguing process. It is tempting to use EMG as an indicator of muscle state. The close correlation between muscle force and amplitude of stimulus-evoked EMG indicates the possibility that the EMG signal can directly provide information for monitoring electrically-elicited muscle contraction, and as control signals for compensating for the decrease of muscle force due to fatigue [4]. The temporal features have also been used to quantify the muscle fatigue process, including: latency, rise time to peak (RTP), and PTP duration (PTPD) as well as frequency characteristics. Both temporal and frequency features were presumably related to the propagation velocity of the motor unit action potential in muscle fibers. Most of the results showed a decrease in muscle fiber conduction velocity during the muscle fatigue process [5]. For the recovery process, Shields et al., proposed a result of their study on paralyzed soleus muscles [6]. They found that after 5 min from the cessation of electrical stimulation, the evoked EMG had almost returned to its original features, but the recovery of muscle force was not so significant. According to their study, if the evoked EMG can be a fatigue indicator, it is true only when the recovery process does not start, or other factors may exist contributing to the varying relationship between EMG amplitude and the muscle contraction force during the recovery process.

The aim of this research is to characterize the muscle recovery processes by observing the twitch and fused isometric contractions. In addition to contractile activity, a recovery manifestation constituted from myoelectric activities is also necessary for reflecting the condition of the stimulated muscles. The relationship between myoelectric parameters and the recovered force measurements were analyzed to examine the condition of excitation-contractile coupling.

II. Methods

A. Subjects

Thirteen spinal cord injured subjects (11 male and 2 female, 26-43 years, 63-85 kg and 1.62-1.84 m) with mean ± SD age of 35.0±7.3 years were recruited for this experiment. The average time post-injury was 4.3±2.68 years. The neurological levels of the subjects are between T4 and T11 and with no or little spasticity in the lower limb muscles. The local Ethics Committee approved the experimental procedures, and all subjects signed an informed consent that was approved by the Human Subjects Review Board of I-Shou University.

B. Experimental Setup:

During the experiment, each subject lay on a long bench with his or her hip and knee joints fixed in a 0° flexion. The tibialis anterior was stimulated by a Grass electrical stimulator (S8800) and constant-current unit (CCU1 A, Grass Instrument, Quincy, MA) using 300 μs, 20-Hz square-wave pulses. For inducing muscle fatigue, current with supramaximal amplitude was applied to the tibialis anterior with the subject lying on the bench with the lower leg fixed on a testing device, as shown in Figure 1.

To detect the muscle force output, the generated ankle dorsiflexion torque representing the force output of the tibialis anterior can be collected from the analogue output of the torque sensor (TP-10KMAB/CB, Kyowa). To detect the evoked EMG, surface electrodes with a 2-cm inter-electrode distance (Norotrode 20, Myotronics-Noromed, Inc.) were applied on the stimulated muscle. They are bipolar Ag-Ag chloride surface electrodes with a 7 mm diameter and fixed 20 mm inter-electrode distance.

Surface EMG was amplified (Model 12A14 DC/AC Amplifier, Grass Medical Instruments) with a gain of 1000, and passed through a frequency window of 3-3k Hz (Neurodata Acquisition System, Model 12, Grass Medical Instruments). The EMG signal was sampled at a rate of 5k Hz stored on computer disk for later analysis using Matlab (Mathwork Co., Natick, Mass.) signal processing software. A hardware blanking with a sample and hold design was used for stimulus artifact suppression. This hardware-based blanking circuit is triggered by a synchronous pulse from the stimulus pulse itself.

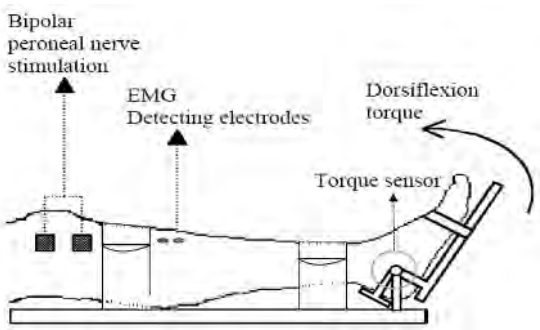

Figure 1: Schematic presentation of testing device.

C. Experimental Protocols:

The recovery tests were performed in the right lower legs of all of the subjects. Supra-maximal electrical stimulation (determined by the maximal peak to peak amplitude of the evoked EMG) was delivered to induce muscle fatigue. A modified Burke fatigue protocol was delivered for 4 min, which activated the tibialis anterior every second for 0.33 sec using a 20 Hz stimulation frequency. Before the fatigue protocol, 3 pulses with 1 Hz and 7 pulses with 20 Hz of stimulation frequency were delivered to induce 3 twitches and 1 fused contraction for the collection of the initial baseline data. Immediately after the fatigue protocol, the same testing protocol was delivered to the muscle in 1, 3 and 5 minutes, and then every 5 minutes for 60 minutes. At the same time, the twitch and tetanic force, as well as the stimulus-evoked EMG, were collected for the off-line analyses.

D. Data Analyses:

In every test of the experiment, every 3 consecutive twitches were averaged together to represent a single twitch. The peak torque (PT) in the twitch and fused contractions can be obtained by finding the maximal value in the array of torque data. For measuring the total activation produced by twitch or tetanus, the torque-time integral (TTI) was also computed. For observing the myoelectric activities, the stimulus-evoked EMG of the stimulated muscle was studied during the recovery process. Peak-to-peak amplitude (PTP) and the other characteristics, such as root mean square (RMS) and temporal parameters, including rise time to peak (RTP) and PTP duration (PTPD), were used to quantify the recovery process of the myoelectric activities.

The measured parameters of twitch or fused contractions were plotted in correspondence with the elapse of recovery time. The plotted curves were fitted by a function for characterizing the recovery process. The recovery process was characterized empirically by an exponentially asymptotic curve:

$$Y = A(1 - e^{-\tau_0 t}) + M_0$$

where Y is the predicted value of torque output, t is the elapsed time, τ_0 is the time constant, M_0 is the initial value of torque output in the recovery process, and A is a scaling

parameter for recovering the normalized data to its original value. A nonlinear curve fitting technique was used to find the optimal parameters such that error could be reduced to a minimum by using the Nelder-Mead simplex algorithm. After the normalization, the recovery processes from muscle fatigue could be analyzed by comparing the time constant of the measurements of the evoked EMG and torque output.

E. Statistical Analyses:

Repeated measures of ANOVA were utilized to compare the difference of time constant between EMG and mechanical parameters. If significant main effects were observed, Bonferroni post-hoc tests were performed. For observing the relationship between EMG and the recovered force, a series of correlation analyses was conducted.

III. Results

A. General manifestation of recovery processes

As depicted on Figure 2, the torque output of ankle dorsiflexion was found to have diminished after modified Burke fatigue protocol. After about 5 minutes post stimulation, the torque output of stimulated muscle was found to have increased to about one half of the initial amplitude. After about 10 minutes, the output increased, approaching 60% of the initial amplitude. In the observation of force development of a single twitch, the rise time to peak torque was delayed until about 10 minutes of time had elapsed. The twitch contraction time was prolonged at around 1 to 5 minutes after fatigue stimulation. After that, the twitch contraction time returned to its initial value.

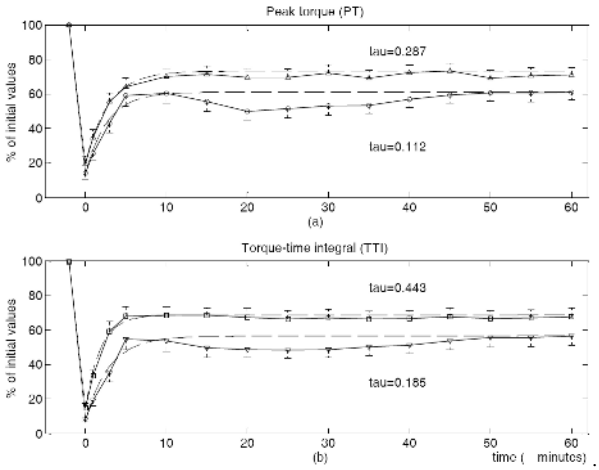

Figure 2. (a) PT and (b) TTI of twitch (-○- and -∇-) and tetanic (-Δ- and - -) contractions. Data, expressed as percentage of initial values, are means+SE or means-SE.

B. The Recovery Processes of Muscle Fatigue

The data on the recovery process were fitted empirically by an exponentially asymptotic curve. After all of the measuring parameters had been fitted, the time constants were extracted. The respective mean and standard error of recovery time constants are Twitch PT (.112±.034), Twitch TTI (.185±.060), Tetanic PT (.287±.033), and Tetanic TTI (.443(.056). Figure 2 shows the changes of biomechanical measurements in the recovery processes. Repeated measurements of ANOVA showed significantly different changing speeds within biomechanical parameters ($F= 15.23$, $p<0.001$). In the comparison of recovery speed between contraction types (twitch vs. tetanus), and the curves in twitch contractions, a significantly faster rising speed can be found in tetanic PT ($p=0.002$) and TTI ($p=0.028$). In the comparison of recovery speed between PT and TTI, the latter was found to be faster than the former in tetanic contraction ($p=0.01$) but was not found in twitch contraction ($p=0.469$).

Repeated measures of ANOVA showed significantly different changing speeds within myoelectric measurements ($F= 2.90$, $p<0.05$). The respective mean and standard error of recovery time constants of myoelectric parameters are EMG PTP (.191(.047), EMG RMS (.293(.073), EMG RTP (.255(.091), and EMG PTPD (.468(.069). Figure 3 shows the changes of myoelectric measurements in the recovery processes. Significant difference was only found in the comparison of recovery process between EMG PTPD (fastest) and EMG PTP ($p<0.05$). Except for this, no significant difference was found in the comparison between, or within, amplitude and temporal parameters.

Figure 3 depicts and illustrates the correlation coefficients between myoelectric and biomechanical parameters.

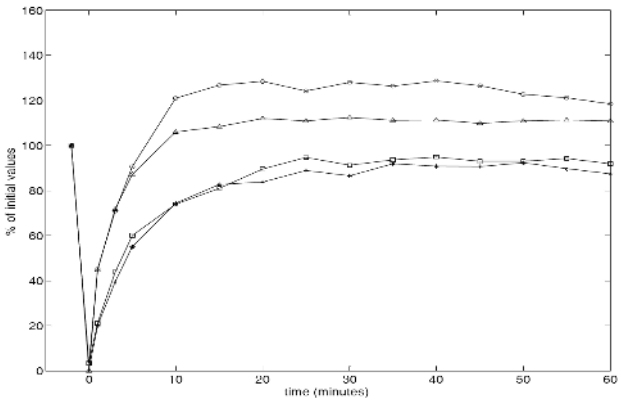

Figure 3. The recovery processes of EMG parameters of the stimulated muscles EMG PTP (-*-), RMS (- -), EMG RTP (-○-), EMG PTPD (-Δ-). In order to aid the visualization of a comparison with the amplitude parameters, the temporal parameters (EMG RTP and PTPD) were inversed first, and then normalized by the initial values.

Two major findings can be noted on the Figure. In general, the EMG parameters correlated more strongly with tetanic than with twitch ones. Among 4 myoelectric parameters, the EMG PTPD has the highest correlation coefficients with parameters of tetanic contraction (r=-.77 in tetanic PT and r=-.75 in tetanic TTI) but lower correlation coefficients with twitch ones (r=-.44 in twitch PT and r=-.48 in twitch TTI). In contrast to EMG PTPD, the other temporal parameter (EMG RTP) has the lowest correlation coefficients with tetanic PT (r=-.55) and tetanic TTI (r=-.59) and lower correlation coefficients with twitch PT (r=-.47) and twitch TTI (r=-.47). The EMG amplitude parameters also have strong correlations with parameters of tetanic contraction (r=.61 to r=.63), but only moderate correlations with twitch ones (r=.44 to r=.52).

IV. Discussions & conclusions

The present study was the first to investigate the recovery process from electrically induced muscle fatigue on the myoelectric and contractile activities for human paralyzed tibialis anterior muscles. After 10 min of rest, the peak torque of single twitch rises to about 60% of the original value. In tetanic contraction, also after about 10 min of rest, the PT and TTI recovered with a faster speed, and reached about 70% of the original value. Pertaining to the fast recovery rate in tetanus, a similar study reported by Shields et al. observed the differential responses between the twitch and the tetanus during the recovery process and also found some preferential recovery at tetanus that is not present at twitch contraction [1]. They suggested that there is a complex interplay between optimal fusion created from contractile speed slowing and excitation/contraction coupling (ECC) compromise. Even if the full recovery of the contraction speed does not prevent greater recovery of the tetanus, it suggests that other factors contribute the faster recovery of tetanic force. From the result of a preferential loss of force at low frequency of stimulation (1 Hz), low frequency fatigue (LFF) can also explain some of this disassociation between twitch and tetanic recoveries. Although 20 Hz is also considered a lower frequency, muscle force recovery differed in varied stimulation frequencies, indeed suggesting the existence of LFF. Much higher frequency (ex. 30 or 50 Hz) would be expected to have a faster and more forceful recovery after fatiguing stimulation. For verification, future works are suggested on studying the recovery rate of muscles activated by higher stimulation frequency.

Post-fatigue potentiation, as reported by previously similar studies, is also considered to be an important factor to counteract the impaired ECC at the same time. Many studies have shown that potentiation occurs most readily in muscles that consist of primarily fast-twitch fibers [7]. After spinal cord injury, the gradual transformation is believed in chronically paralyzed muscle from a primarily slow muscle with type I fibers to a fast muscle with mainly type IIb fibers [8], such as would be expected in muscles observed in this study. Surface electrical stimulation is considered a rather random phenomenon, with both fast and slow fibers being activated. The mechanical response depends on a muscle's architecture and relative proportion of fast and slow fibers. As found in this study, the fast relaxation rate between ~5 and ~10 min of post fatigue implicates the predominate activation of fast muscle. Since, as reported by previous studies, potentiation is preferential in type II muscle fibers, the predominant activation of type II muscle fibers also explained the existence of potentiation.

EMG amplitude has been suggested for use as a fatigue indicator for feedback control in FES application [4]. However, this study also found that disassociation occurred during the recovering processes between mechanical and myoelectric measures. From the results of the present study, the EMG PTPD which correlated more with the recovering tetanic force might be more suitable for the application of monitoring the recovery of electrically induced muscle fatigue. However, since the complete recovery of muscle force follows the full return of EMG parameters, an adaptive tuning of gain and offset of EMG utilities in monitoring or predicting the stimulated force, is therefore necessary to compensate for this dissociation.

Abstract — **This study considers the momentum transport and oxygen transfer in a modified stirred tank bioreactor. The design is novel in the sense that the impeller is positioned above the culture medium (instead of being suspended inside it). This design has potential benefits of enhanced gas transfer, reduced possibility of contamination, and better access to the culture medium. Computational fluid dynamics modelling is used to simulate the gas and fluid flow in the bioreactor. A rotation rate of 60 to 240 rpm (corresponding to the laminar regime) was adopted. Results show that the flow in the medium is swirl-dominant with an induced secondary flow in the meridional plane consisting of a steady and robust recirculation bubble. As the Reynolds number is increased beyond ~427, we observe the formation of an additional smaller toroidal-bubble at the bottom wall. This bubble bears some resemblance to the vortex breakdown topology commonly found in confined swirling flows. In terms of the oxygen distribution, oxygen transfer from the gaseous phase into the culture medium is enhanced through forced diffusion taking place across the air-medium interface. For the Reynolds number range studied there is clear dominance of convection over diffusion in the transport of oxygen from the air-medium interface and throughout the culture medium.**

Keywords — **bioreactor, computational fluid dynamics, oxygen concentration, tissue engineering**

I. Introduction

Research in the area of bioreactor process hardware technology in biomedical engineering continues to receive prominent attention ([1],[2]), particularly in relation to the industrial-scale production of mammalian cell lines. While the use of bioreactors has been fairly well established in certain industries (e.g., wastewater, food processing, etc), it remains important to consider the physiological requirements of mammalian cells toward the *in-vivo* condition. Two critical physiological parameters relevant to larger bioreactor volumes with high tissue densities, include oxygen transfer and mechanically-induced shear at the cell walls.

The adverse susceptibility of animal cells to high levels of shear has been well described [3] and significant efforts have also been made to improve the efficiency of oxygen diffusion [4]. While it is accepted that methods such as agitation or gas sparging can enhance oxygen diffusion and nutrient transfer, this often comes at the expense of increased levels of shear [5]. Therefore a well-correlated relationship between the mechanical stimulation of a bioreactor and the oxygenation requirements of particular cell type remains crucial in bioreactor optimization studies.

The objective of this study is to computationally model in detail the transport of momentum and oxygen taking place in a novel small-scale bioreactor in which the culture medium is agitated by an aerial impeller that is positioned directly above it (see Figure 1a). This study forms a part of

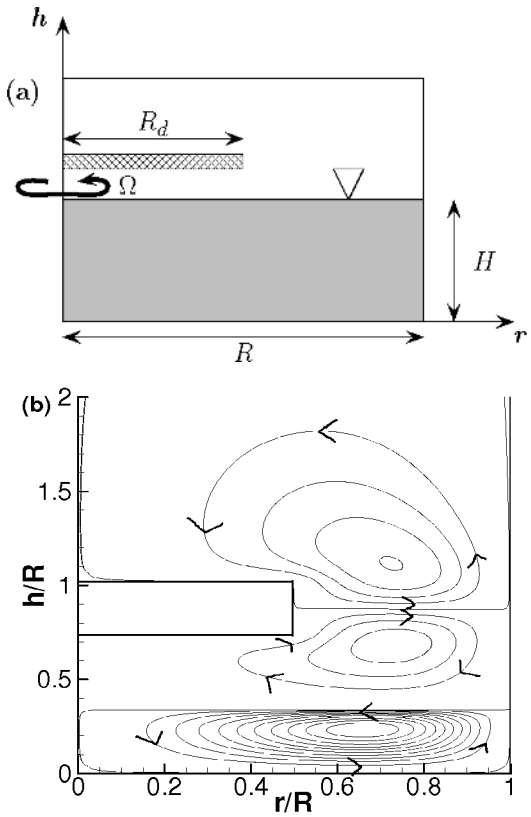

Figure 1: (a) Schematic of the aerial bioreactor in the meridional plane, (b) representative streamlines of the flow.

www.springerlink.com

ongoing investigations by biological engineers at Monash University, to investigate the feasibility and practical application of laminar stirred-tank bioreactors for cell and/or tissue culture. From a fluid dynamics perspective, characterization of the flow in a laminar bioreactor based on a lid-driven cylinder have been performed extensively, both experimentally and numerically ([6],[7],[8]). The design itself was originally based on explorations of the possibility of applying vortex breakdown theory to provide a controlled, low-shear and well-mixed environment within the bioreactor chamber.

In terms of cell culture, two prototype configurations in which the laminar bioreactor concept have been successfully tested are 5~ml cylindrical vessels with a partially-submerged disk [9], as well as a non-submerged disk [10].

In this study, the latter configuration (see Figure 1) is considered in further detail. An instantaneous snapshot of the streamline pattern highlighting the induced secondary flow in both the gaseous and aqueous phases is shown in Figure 1b. Note that the results and discussion will be mainly confined to the aqueous phase, e.g., the culture medium in the remainder of the paper. Specifications of the rig and flow are shown in Table 1. The Reynolds number is based on the rotation speed of the impeller, radius of the impeller, and the physical properties of *air*.

Table 1: Specifications and aspect ratio (AR) of the bioreactor

Parameter	Range
Cell consumption of oxygen	1.0-1.2*10^{-17} mol O_2/cell.s
Cell density	5*10^{10} cells/m^3
Cylinder radius, R	17.65 mm
Fluid height, H	6 mm
Fluid density, ρ	998 kg/m^3
Impeller radius, R_d	15.43 mm
Impeller thickness	5 mm
Impeller height (from base)	13 mm
Impeller speed	60-240 rpm
Bioreactor AR, H/R	0.339
Impeller AR, R_d/R	0.872
Reynolds number, Re	183-731

II. Numerical methods

The commercial CFD software package, FLUENT, is used to simulate the flow and oxygen transport in the aerial bioreactor. The unsteady solver is used whereby the incompressible Navier Stokes equations (INSE) are temporally marched from initially zero flow to steady state. The axisymmetric form of the INSE are solved on the meridional plane (see Figure 1) with the assumption of axisymmetry. The volume-of-fluid (VOF) technique is used to model the air/culture-medium interface.

As expected for a CFD investigation, a series of meshes was tested to ensure the flow is well resolved. In terms of spatial resolution, the grid points were concentrated around the impeller and cylinder walls. While it is largely anticipated that the inter-phase boundary would remain flat (given that the Froude number is << 1), nevertheless particular attention was paid to resolving the interface boundary to prevent the development of non-physical oscillations. Further details on the numerical techniques used in this study can be found from [7] and [8].

III. Results and discussion

Figure 2 shows steady-state plots of the normalized streamfunction in the meridional flow at three rotation speeds. As seen in Figure 1b, there is a clockwise induced recirculation region in the gaseous phase lying directly underneath the impeller. The centrifuging effect of the air induces a counter-clockwise recirculation bubble in the culture medium. The concentration of the streamlines at the radial location of r/R ~ 0.7-0.8 along the interface boundary suggests significant transport of angular momentum across the air-medium interface.

As the rotation speed is increased, it is observed that an initially narrow and weaker bubble rotates in the opposite direction is formed, being located at the bottom wall. Similar to the situation found in confined swirling flows undergoing vortex breakdown [11], this bubble is located along the axis of rotation. Figure 2c shows that while the main recirculation region remains relatively steady from Re=180 to 240, a widening of the *narrow* bubble can be observed. The number of streamlines inside the bubble indicates an increase in the circulation of the fluid. In addition, the stagnation point of the bubble also moves upwards towards the air-medium interface.

Figure 3 shows the steady-state normalized dissolved oxygen (DO) concentration in the medium phase at three rotation speeds. The dissolved oxygen (DO) clearly shows a strong association of oxygen transport with the dominant counter-clockwise recirculation pattern of the flow. Figure 3a shows that the presence of DO at the base (where cell colonies are expected to congregate in practice) is convection-dependent. In contrast, transport via diffusion is much weaker, judging by the relatively low concentration of DO at the centre of the main recirculation region. At the lowest speed of 60 rpm, it is observed that the oxygen concentration is concentrated mainly along the axis of rotation. Note that the diffusivity of oxygen is approximately 500 times

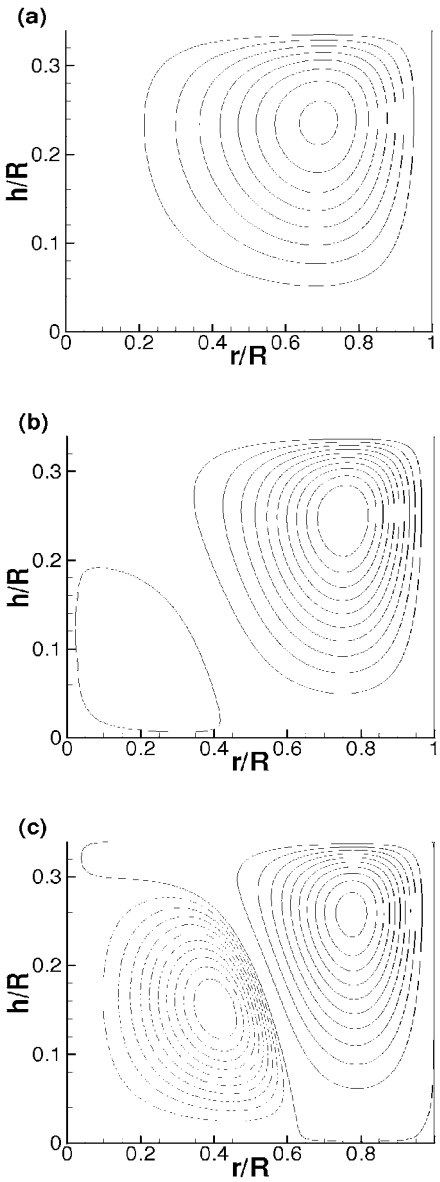

Figure 2: Normalised streamfunction for impeller rotation speed of (a) 60 rpm, (b) 180 rpm, and (c) 240 rpm. The solid lines represent the clockwise rotation with range of 0-1*10-5, while the dashed-dot lines represent the counter-clockwise rotation with range of -8*10-5-0. The intervals are equi-spaced.

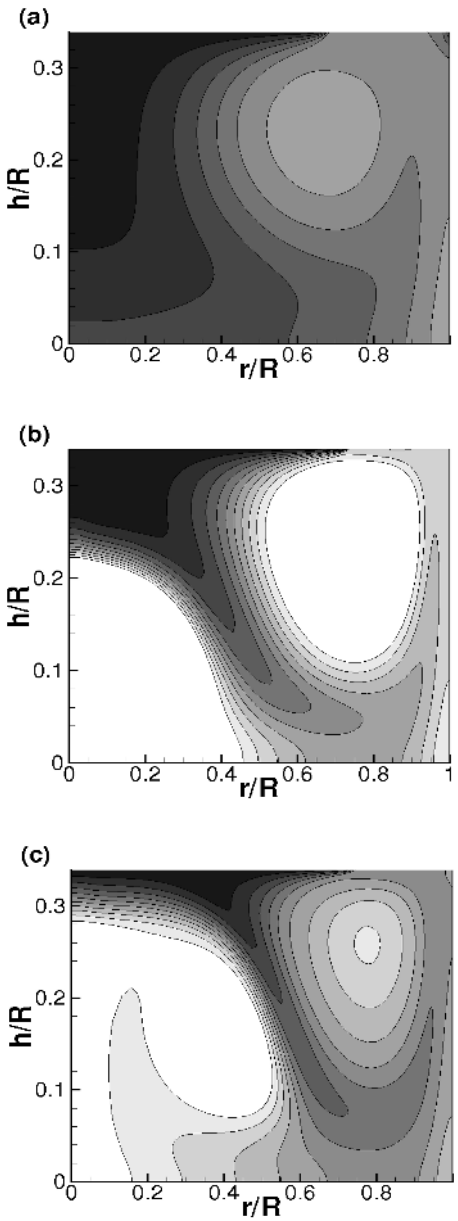

Figure 3: Normalised dissolved oxygen (DO) concentration in the medium phase for impeller rotation speed of (a) 60 rpm, (b) 180 rpm, and (c) 240 rpm. The range is the same for each plot: 0.993 < DO < 1.0.

lower than the kinematic viscosity of water. The induced flows within the fluid medium clearly indicate the flow is driven by convection, hence the transport of oxygen will clearly be dominated by advection by the flow for the chosen operating condition range.

As the rotation speed is further increased resulting in the appearance of the axial bubble, there are two distinct regions of low DO concentration, which correspond to the respective centres of the main recirculation zone and the axial bubble (refer to Figure 3b). The streamfunction plot shown in Figure 2b suggests that oxygen from the interface is mainly convected within the medium along a narrow path with negligible diffusion across the streamlines. In contrast, Figure 3c shows an overall improvement in the oxygen diffusion to the two recirculation zones as Re is increased. However, the oxygen concentration within the second bub-

ble remains lower as it is relatively weaker in comparison to the main recirculation region.

IV. Conclusions

In this study, computational modelling of the flow and oxygen transport in a small-scale stirred tank bioreactor that is driven by an aerial disk has been performed. The results show that oxygen diffusion across the air/culture-medium interface is enhanced by advection of the oxygen rich interface fluid by the induced secondary flow in the culture medium. In addition, this study has provided some insight into the development of the vortex breakdown bubble (commonly found in confined swirling flows) and the resulting effect of the presence of the bubble to the overall oxygen transport within the bioreactor chamber.

Abstract — **Fenestrated stent grafts are becoming widely used in clinical practice to treat patients with complicated aortic aneurysms, with short to mid-term satisfactory outcomes being achieved. However, long-term results are yet to be determined. One of the main concerns about the safety of fenestrated repair is the patency of fenestrated renal arteries and subsequent renal function. The purpose of this study is to investigate the hemodynamic changes in patients treated with fenestrated stent grafts using a two-way fluid-structure interaction. 4 patients undergoing fenestrated stent graft repair were selected for inclusion in our analysis. All of the fenestrated renal arteries remained patent after implantation of stent grafts with one patient developing post-procedural complication, endoleak. Our results showed that with insertion of fenestrated stents into the renal arteries with variable lengths, no significant changes of blood flow velocity were noticed based on the flow analysis. Our preliminary study indicates the safety of fenestrated stent grafts, however, further studies are required to verify the long-term outcome of this procedure.**

Keywords — **Aortic aneurysm, blood flow, fenestration, stent graft.**

I. Introduction

Abdominal aortic aneurysm (AAA) is a degenerative disease with dilation and focal weakening of the aorta, and it most commonly involves the abdominal aorta. The prevalence of AAA is up to 9% in elderly people above 65 years. Once the AAA is formed, it grows gradually and has a potential risk of rupture once it reaches certain size. Traditionally, the AAA is treated with open surgery, however, it is not only an invasive procedure but also carries perioperative and post-operative complications and mortality. Thus, a less invasive technique which could be used as an alternative to open surgery would benefit the patients, especially for those with co-morbid medical conditions.

Currently, endovascular repair of AAA through insertion of a stent graft into the aortic aneurysm has been confirmed to be an effective alternative to open surgery and it is widely used in clinical practice in the treatment of patients AAA [1, 2]. Since its first introduction in 1991, endovascular stent graft repair has undergone a series of technical developments which ranged from traditional infrarenal (covered stent graft is placed below the renal arteries) to transrenal fixation (covered stent graft is placed below the renal arteries with uncovered suprarenal stents placed across the renal or other visceral arteries) [3-5], and to the currently evolving fenestrated stent grafts (with holes in the graft material) [6, 7].

Fenestrated stent grafts involve creation an opening in the graft material to accommodate the orifice of the vessel targeted for preservation. This indicates that the stent graft can be placed above the renal arteries without compromising the renal perfusion or blood flow to other vital organs. Fixation of the fenestration to the renal and other visceral arteries can be provided by implantation of bare or covered stents across the graft-artery ostia interfaces so that a portion of the stents protrudes into the aortic lumen. Therefore, there are concerns about the interference of fenestrated stents with renal blood flow or renal function.

Traditionally, studies on hemodynamic changes were performed with computational fluid dynamics (CFD) with regard to the investigation of flow analysis, mainly based on aorta models [8, 9]. However, as the endovascular stent graft wall and aortic aneurysm are flexible, a measurable pressure is present even if in the absence of endoleaks due to the fluid-structure interactions. Therefore, fluid-structure interaction simulations can provide more accurate and realistic measurements of the blood flow and wall pressure and wall stress in patients with AAA after endovascular repair. The purpose of this study is to investigate the hemodynamic changes in patients treated with fenestrated stent grafts, based on a two-way fluid-structure interaction (FSI).

II. Materials and Methods

A. Patient CT data

4 patients with abdominal aortic aneurysms were selected for inclusion in the study. All of the patients were referred by vascular surgeons to the Cook R&D in Western

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1676–1679, 2009
www.springerlink.com

Australia for planning of fenestrated stent grafting, which was performed by a group of graft planners on a separate workstation equipped with Terarecon software [10].

CT scans were performed with a High-Speed Advantage scanner 64 x 0.625 mm (GE Medical Systems, Milwaukee, WI, USA) with the following scanning protocol: slice thickness, 1.25 mm, pitch 1.0, reconstruction interval of 0.6mm, 120 kV and 300 mAs.

B. Geometric reconstruction from CT images

Original CT DICOM data (digital imaging and communication in medicine) pre-and post-fenestration were transferred to a workstation equipped with Analyze V 7.0 (AnalyzeDi-rect, Inc., Lexana, KS, USA) for generation of 3D recon-structed images. Segmentation of the aortic artery branches and endovascular stents were performed with a semi-automatic processing involving CT number thresholding, region growing and object creation and separation. For generation of 3D model with inclusion of only vessels, the lowest and highest CT thresholds were set at 200 and 400 HU (Hounsfield unit) respectively to remove all of the soft tissues, bones and stent wires while keeping the contrast-enhanced artery branches; for generation of 3D model with inclusion of endovascular stents, the lowest threshold was set at 500 HU to remove all of the soft tissues and contrast-enhanced vessels while only keeping the high-density stent wires. Figure 1 shows the 3D model from the CT data of patient 3 in the case of pre- fenestrated stent grafting.

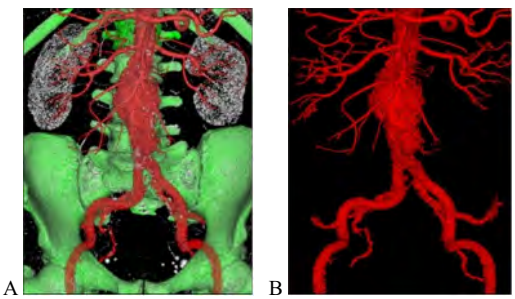

Fig. 1 The 3D model of structures (A), object separation to segment the aorta, branches and aneurysm from other structures (B).

C. Generation of aortic mesh model

Change After segmentation, the 3D object surface of the model was created using surface extractor available on the Analyze software, and the 3D surface object was saved in the STL (stereolithography)', a common format for computed aided design and rapid prototyping. The 'STL' file was converted into the CAD (computer aided design) model files using the CATIA V5 R18 (Dassault Systèmes, Inc., Suresnes Cedex, France). As each data involves both pre- and post-stent grafting, thus we have 8 CAD models in total. Then we generated the blood flow model for computing the CFD (compute fluid dynamics) analysis and the blood wall model for computing the structure analysis. The blood flow and blood wall models are generated at each case pre-and post-stenting, hence study consists of 16 models. Figure 2 shows the segmented aorta models based on patient 4 of pre-and post-stent grafting CT data.

The blood flow model mesh was defined by hexahedral volume meshes using ANSYS ICEM CFD 11 (ANSYS, Inc., Canonsburg, PA, USA). ANSYS ICEM CFD provides sophisticated geometric acquisition, mesh definition and mesh editing which is important for the accurately flow analysis. The blood wall model was defined by tetrahedral volume mesh using ANSYS Meshing 11 (ANSYS, Inc., Canonsburg, PA, USA). Figure 3 demonstrates examples of the CFD mesh model and structure mesh model of post-fenestrated stent grafting.

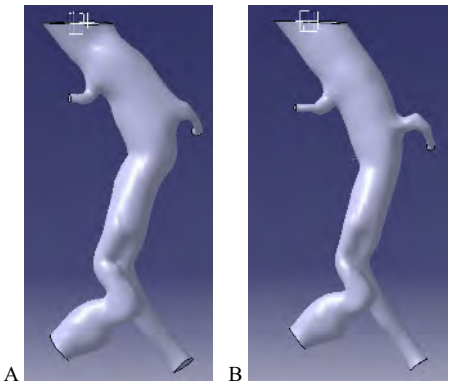

Fig. 2 3D segmented model in patient 4 with AAA pre- (A) and post-fenestrated stent grafting (B).

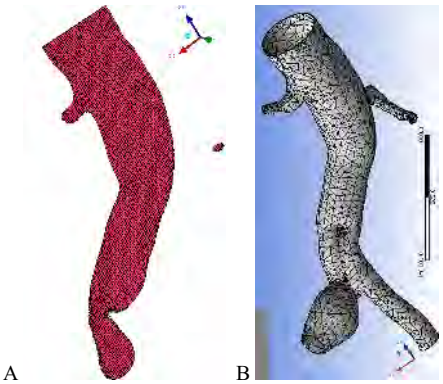

Fig. 3 the same patient as figure 2 of post-fenestrated stent grafting, showing the blood meshes model of cross section in middle of XZ-plane (A), and the blood wall meshes model (B).

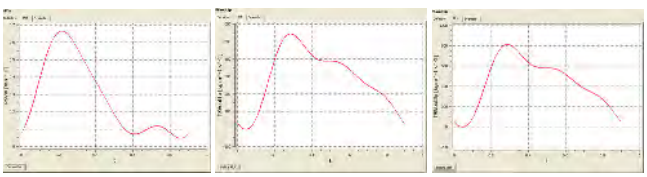
D. *Fluid structure interaction-hemodynamic analysis*



In order to ensure that our analysis reflects the realistic environment of human blood vessel, normal physiological hemodynamic conditions should be considered for the 3D numerical simulations. The fluid and materials properties for different entities were referenced from a previous study [11]. In the current study, we compared the flow rate at the aorta model containing the four arterial branches, namely bilateral renal arteries and common iliac arteries prior to and after stent graft implantation.

Based on the referenced parameters, the simulation of the complete cardiac cycle is performed by means of a fluid-structure interaction approach. This technique allows studying the aneurysmatic fluid mechanics by accounting for the instantaneous fluid forces acting on the wall and the effects of the wall motion on the fluid dynamic field. The blood flow was simulated at different cardiac phases (systolic and diastolic cycles) and measured in the aortic aneurysm, renal arteries and common iliac arteries using the ANSYS Multiphysic (ANSYS, Inc., Canonsburg, PA, USA). Blood flow pattern, wall pressure, and wall shear stress before and after stent-graft implantation were visualized and compared.

The boundary conditions are time-dependent [12]. The velocity inlet (abdominal aorta at the level of celiac axis) boundary conditions are taken from the referenced value showing measurement of the aortic blood velocity. A time-dependent pressure is also imposed at the outlets. Figures 4 show a time-dependent velocity and pressure.

The solid is (blood wall) 1 mm thickness in all models. The solid density was set to 1120 kg/ m^3, a Poisson ratio of 0.49, and a Young's modulus of 1.2 MPa, corresponding to the standard values cited in the literature [13].

The fluid (blood) is assumed to behave as a Newtonian fluid, as this was known for the larger vessels of the human body. The fluid density was set to 1060 kg/m^3 and a viscosity of 0.004 Pa s, corresponding to the standard values cited in the literature [12]. Given these assumptions, the fluid dynamics of the system are fully governed by the Navier-Stokes equations, which provide a differential expression of the mass and momentum conservation laws [11]. Time step was set to 0.025 s of end 0.9 s. The flow was assumed to be incompressible and laminar. The arterial wall was assumed to be deformable during flow analysis.

A B C

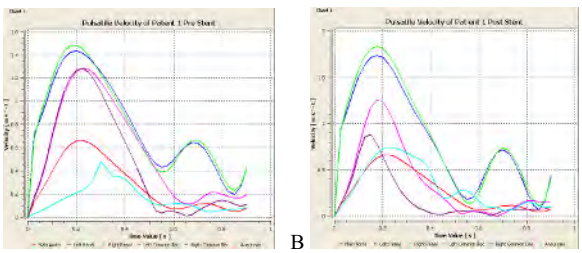


Fig. 4 Flow pulsatile in different cardiac cycles (A), Time-dependent pressure at renal arteries (B) and Time-dependent pressure at common iliac arteries (C).

III. Results

FSI analysis was successfully performed in all of these 4 cases. For the patient who developed type I endoleak, the endoleak was also clearly displayed in the aortic mesh model which allows hemodynamic analysis in the endoleak in regard to the flow and pressure changes in the abdominal aorta, especially under different cardiac cycles.

A. Hemodynamic analysis-flow velocity

Flow velocity was noticed to increase significantly inside the aneurysm following fenestrated stent grafting, indicating that the aneurysm was successfully excluded from the systemic blood circulation. The flow velocity did not show significant changes at the renal and common iliac arteries. Figure 5 shows the flow velocity measured at the main abdominal aorta, and other artery branches, pre-and post-fenestration observed in patient 1. As shown in the graphs, flow velocity to the renal arteries was increased following fenestrated repair due to intra-aortic protrusion of fenestrated renal stents, and it reaches the peak value at about 0.2 s.

A B

Fig. 5 Shows the flow velocity measured at pre- (A) and Post-stent grafting (B) at the main abdominal aorta, renal and common iliac arteries.

B. Hemodynamic analysis-wall pressure and shear stress

Wall pressure and wall shear stress were measured at different cardiac cycles as well, and our results showed that the wall pressure slightly decreased after stent grafting, indicating that less turbulent flow was noticed inside the aneurysm. The wall pressure reaches the peak value at the systolic phase at about 0.25-0.3 s, both pre-and post-stent grafting, Figure 6 shows an example of observation of the wall pressure in a patient pre-and post-stent grafting.

For the patient who developed type I endoleak, wall pressure within the endoleak was found to be as high as that

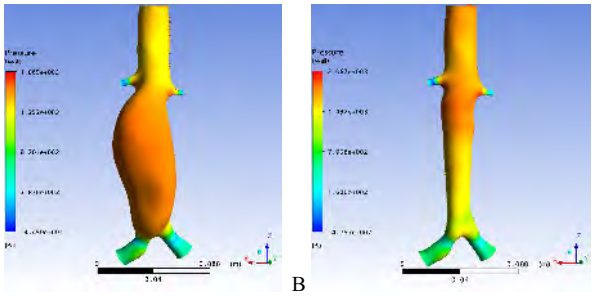

Fig. 6 Wall pressure measured at 0.250 s pre- (A) and post- (B) stent grafting, reaching the highest magnitude.

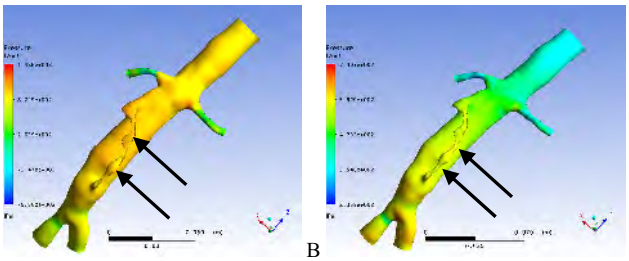

Fig. 7 Wall pressure measured in the endoleak (arrows) is consistent with that in the abdominal aorta, at 0.225 s (A) and 0.425 s (B), respectively.

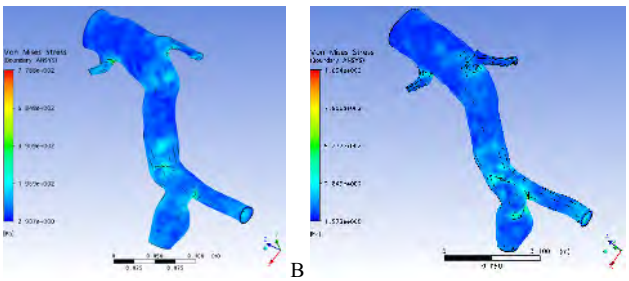

Fig. 8 Wall shear stress measured at both pre- (A) and post- (B) stent grafting, at 0.425 s.

inside the abdominal aorta. This indicates the communication between the aneurysm sac and systematic circulation due to presence of endoleak, as shown in Figure 7.

Maximum wall stress did not occur at the maximum diameter of aneurysm, but at the aneurysm necks (proximal and distal necks). Wall shear stress was not found to change significantly after fenestrated stent grafting. Figure 8 is an example showing the wall shear stress in patient 4 pre-and post-stent grafting.

IV. Conclusion

In conclusion, our preliminary study using FSI method to analyze the hemodynamic changes in patients with AAA treated with fenestrated stent grafts demonstrates the safety and promising outcomes of the endovascular repair of AAA. Change of flow velocity to the renal arteries was minimal with slightly increased after fenestration, although further studies are needed to confirm whether this is significant or leads to renal dysfunction. FSI method provides more accurate analysis of the hemodynamic changes at variable cardiac cycles. Future studies should be performed to investigate the aneurysm sac pressure in relation to the presence of thrombus and endoleak.

[4] Northwest Institute for Non-ferrous Metal Research, Xi'an, China

Abstract — **Objective: The goal of this study was to assess the osseointegration capability of Bone morphogenetic protein-2 and hyaluronic acid on hydroxyapatite-coated porous titanium. Method: Making porous titanium implants by sintering titanium powder at high temperature which were coated with hydroxyapatite by alkali and heat treatment and furthered using hyaluronic acid as delivery system to prolong the effect of Bone morphogenetic protein-2. The implants were inserted into the distal femora of rabbits. The animals were sacrificed in 6, 12 and 24 weeks to accomplish histological and biomechanical analysis. Result: According to the result of histological analysis, the osseointegration of Bone morphogenetic protein-2 group is better than hydroxyapatite -coated porous titanium group. In push-out experiment, all the samples have bigger shear stress as time is passing by. There is statistical difference between two groups in 6, 12 weeks but not in 24 weeks. Conclusion: Bone morphogenetic protein-2 and hyaluronic acid on hydroxyapatite-coated porous titanium has a good effect on repairing the defect of distal fumer in rabbit. It is a kind of fine biotechnology for future clinical application.**

Keywords — **Porous titanium, BMP-2, Hydroxyapatite, Osteointegration, Hyaluronic acid**

I. Introduction

Since Urist discovered bone morphogenetic protein[1], studies have kept focusing on many kinds of bone growth factors and the delivery systems. A multitude of studies have proved that TGF-β, IGF-I, BMP-3 and BMP-7 could facilitate bone formation[2-5]. But BMP-2 is the most powerful bone growth factors as we all know. It can induce undifferentiated mesenchymal cells to propagate and differentiate, so much more attention is paid to it[6,7]. Meanwhile some biomaterial, such as hydroxyapatite, coral, cancellated bone and collagen etc, can combine with bone growth factors to facilitate bone formation because of dual effects of bone conduction and bone induction[8-11]. At present titanium alloy implants with porous coat could be produced by many technologies. This makes it possible that new bone can grow into pore to improve the strength of synosteosis by mechanical lock between the interface of bone and implant[12] and to prolong the action time of bone growth factor. Some researchers have discovered that hyaluronic acid has good biocompatibility, can fill in porous structure, facilitate cell adhesion and won't disturb regional osteanagenesis. So it is a good retarder to guarantee long-time effective concentration of BMP-2[13]. This research made some composite implants which have three-dimensional structure, bone conduction and bone induction ability by using hydroxyapatite-coated porous titanium combined with BMP-2, Hyaluronic acid as retarder. The implants were fixed into distal femurs of rabbits to accomplish histological and biomechanical analysis.

II. Materials and methods

A. Implants and surface analysis

The size of porous titanium implants is ø4×10mm. Samples were immersed in 5.0mol/l NaOH aqueous solution at 60°C for 24h respectively. Washed with distilled water and dried in air for 24h, the samples were heated in an electrical furnace at heating rate of 5°C/min and kept at 600°C for 1h and cooled with the furnace. Subjected to alkali-heat, the samples were put in 0.5 mol/L Na2HPO4 for 24h, then saturated Ca(OH)2 for 5h. Washed with distilled water. Soaked in 30ml simulated body fluid (SBF) at 36.5°C to get hydroxyapatite coat. SBF was refreshed every 48h and prepared with ion concentrations nearly equal to those of the human blood plasma, and buffered at pH=7.40 with Tris-HCl at room temperature. The samples were taken out after 28 days respectively and washed with distilled water and dried in air. Titanium samples were cleaned ultrasonically in acetonee, ethanol and distilled water for 20 min respectively. Then put half of the implants in the tooting respectively. Blend BMP-2 and hyaluronic acid at the ratio of 8mg/g under aseptic conditions and dissolve in buffered sodium chloride solution. Soak the samples in and pump to vacuum under negative pressure. Take them out after fixiform. Finally hydroxyapatite-coated porous titanium carrying about 12μg BMP-2 were obtained. Observe it with SEM(JSM – 35C, HITACHI) under different enlargement.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1680–1683, 2009
www.springerlink.com

B. Animals and surgery

All experiments on animals were performed under the approval of the institutional review board. The implants were inserted into bilateral distal femora of 36 adult rabbits (New Zealand, body weight > 3.5 kg). The porous coated-hydroxyapatite implant was inserted press-fit into the femur. Each animal received one implant carrying about 12μg BMP-2 (group I). A hydroxyapatite-coated porous implant was placed as a control in the contralateral femur in the same manner (group II). Wounds were closed in layers. Bred in the same condition.

C. Implant retrieval and evaluation

Euthanasia was performed by using carbon dioxide after 6, 12, or 24 weeks. Following euthanasia, the implants with their surrounding tissue were retrieved and prepared for histological (n = 6 for each material and time period) and Mechanical analysis (n = 6 for each material and time period).

D. Histology

The histological samples were fixed in 4% phosphate buffered formaldehyde solution (pH = 7.4), dehydrated in a graded series of ethanol, and embedded in methylmethacrylate. Following polymerization, 10-μm thick sections were prepared per implant using a modified sawing microtome technique. Before sections were made, the specimens were etched with hydrochloric ethanol for 15s, stained with methylene blue for 1 min, and stained with basic fuchsin for 30s. The prepared sections were examined under a light microscope. Before sacrificed, three animals were injected subcutaneously with a fluorescent tetracyclin (25 mg/kg body weight, Merck, Darmstadt, Germany) five days in order to label the process of bone formation. In addition to the thin sections described above, two additional 30-μm thick sections were prepared from the samples of the three animals that received fluorochromes. These sections were not stained but evaluated with a fluorescence microscope equipped with an excitation filter of 470-490 nm. The light and fluorescent microscopic assessment consisted of a complete morphological description of the tissue response to the different implants. In addition, quantitative information was obtained on the amount of bone formation into the various mesh implants.

E. Mechanical testing

Soft tissues covering the bones were removed by using a scalpel blade from freshly excised specimens. The specimens containing implants were scoured to a flat surface, perpendicular to the implant long axis.The specimens were stored in physiological saline solution until mechanical evaluation, which was performed within 2 h after retrieval. The pull-out tests were conducted on a material testing machine (Instron 1185) linked to a computer at the speed of 1mm/min to test the shear stress. The interface shear strength was calculated by the following formula:

$$\sigma = \frac{F}{\pi dt}$$

σ = shear strength; F = max load when collapse; d = diameter of the specimen; t =height of the specimen

III. Result

A. Scanning electron micrograph

The particle of hyaluronic acid with BMP-2 was uniformly mixed and distributed over hydroxyapatite-coated porous titanium arranged irregularly. Part of the particle uniformly distributed among the porous titanium as globular or needle could combine with newly formed mixture in multi-punciform or multi-extent. The surface of the particle is exposed except contacted area and there are many irregular fissure 100μrn—200μrn interconnected to each other among them

B. Histology

After 6 weeks' implantation, there were no signs of inflammation and slightly newly formed bone filled in the interface gap of purely hydroxyapatite-coated implants. The interface of soft tissue was obvious. But to BMP-2-coated implants, more newly formed bone could be observed in the interface gap than control group. Bone grew into the cylinder pore and contacted with titanium sphere in some extent. Bone had also been formed along the outer surface of the cylinder. After 12 weeks' implantation, more newly formed bone and obvious reconstruction could be observed in purely hydroxyapatite-coated implants. And more newly formed and completely calcified bone could be obtained in BMP-2-coat group. Bone filled in almost all the gap and even the junction of titanium sphere. After 24 weeks' implantation, newly formed bone filled all the gap in two groups and there was no difference between two groups.

The growth of new bone could be clearly differentiated and recognized by observation of fluorescence microscope. The newly formed bone was deposited initially at the surface and then grew into the pore. Organized bone formation with clear ossification fronts was not observed in any of the implants. In all of the specimens, diffusely stained deposits

of tetracycline (and sometimes calcein) were mainly localized in contact with the Ti fibers

C. Mechanical testing

The results of pull-out test of purely hydroxyapatite - coated implants and BMP-2 groups were listed below. There were 36 implants inserted being prepared for mechanical tests, but 5 implants were excluded because of unexpected death or technical error during preparation or pullout(n=5). There was a significant increase in shear strength over time for all coatings. Shear strength values for the BMP-2-coated implants were higher than the HY-coated implants at 6 and 12 weeks($p < 0.05$). But at 24 weeks there were no significant statistical differences between two groups.

IV. Discussion

At present, many new researches about bony tissue and engineering focus on precursor cell of bone formation, implants and bone growth factor. Studies show that marrow stroma cells have the ability of multi-directional differentiation and bone formation, but the results of implantation were not the only as expected. Some studies show that combined MSC with HA or BMP-2 could improve the ability of bone formation greatly. It proved that good implantation with growth factor and MSC could get the best effect of bone formation[2-11] because it could gain better interface of impaction and sooner healing. The pattern of binding between bone and implantation is the major criterion to judge the biocompatibility and bioactivity. There might be some fibrae encyst of different thickness formed around the implantation with negative biocompatibility and thickening by the time. Eventually fluidify, inflammation or necrosis occurred between implantation and encyst could cause loosening or displacement leading to abortive implantation. Lamellate fibrous tissue formed on the interface between implantation and bone soon after insertion of titanium. It becomes thinning by time-lapse and does not lead to some adverse effect such as inflammation. Ideal synosteosis is direct osseo-integrate on the interface of implantation and bone. After implantation, environmental newly formed osteoblast leads to obvious bone formation, so compact direct osseo-integrate is getting sooner and better immediate union[14,15]. All these require implantations to have better bone tissue biocompatibility and bioactivity including bone conductivity and osteoinductive[16].

6 weeks later the cylinders of porous titanium is treated by alkali-heat were inserted, newly formed bone being observed on the interface and direct osseo-integrate being obtained to speed up healing of porous titanium means that hydroxyapatite coating could lead to bone formation satisfactorily because of its good biocompatibility.

The growth of bone after implantation of porous titanium was due to its surface structure, porous framework, survival ability of bony bed of host, coating with bioactivity and reconstruction of environmental bone. The rough surface of porous titanium could provide good interface for bone growth[17,18]. Studies showed that the tiniest diameter of pore which required bone growth in environmental and good blood supply was 100μm. Experimental result of cell culture in vitro showed hydroxyapatite coating could help osteoplast to adhere on the surface of implantation, to proliferate and diffuse. Meanwhile, Liang Huifang et al proved that bone formation of implants with hydroxyapatite coating was faster than those without whether on the surface and in the pores in vivo. Copious athletic osteoblast around the coating form new woven bone, which made it easier to grow into the pores, maturate and reconstruct. Hydroxyapatite coating also can eliminate the shield of stress caused by porous structure which allow new bone to form along the surface of porous structure to inner part even the impaction of titanium globular, so more direct conjunctive interface is obtained. All above can speed up the healing of porous titanium and bone tissue, profit stabilization of early period. It does benefit a lot to the recovery of bone defect, the fusion of vertebra and arthro-replacement.

There are three essential pacing factors for mesenchymal cells to induce bone formation: inducing factor, target cells and eligible environment. BMP-2 as inducing factor could stimulate the genes with effect of bone formation to express which cause the differentiation of mesenchymal cells. The target cells of BMP-2 include undifferentiated mesenchymal cells existing in muscles and connective tissue around blood vessels, marrow stroma cells including determined osteogenic precursor cell(DOPC) and inducible osteogenic precursor cell (IOPC) and connective tissue cell in periosteum. Marrow stroma cells are more sensitive to BMP-2 than others[17]. Studies showed that imbed marrow stroma cells origin from autologous bone marrow in bone defect could enhance the inducing ability of BMP-2 greatly[19,20]. It is not the truth that induction happens everywhere BMP-2 imbedded, but the induction of BMP-2 requires favorable environment, the strongest in bone marrow, muscles and brain tissue, the weakest in spleen, liver and kidney et al. This research showed that hydroxyapatite coating could enhance the combination of bone and implants, but the effect was not so satisfactory.as that in 6 weeks BMP-2 imbedded. More bone formation and osseo-integrate were observed than purely hydroxyapatite-coated implants especially the inner part of porous titanium to urge speeding up of healing. All these means BMP-2 has a good effect of

induction and can further to enhance the effect of hydroxyapatite –coating.

There are four breaking patterns between bone and implants: implants and tissue, woven bone and mature bone, in the mature bone and in the coating fracture face through the coating not on the face of bone. The rough surface of porous titanium could provide more interface for apposition growth. Porous structure could complicate the interface of bone and titanium and diffuse the strength on the surface including shear strength, pressure and tensile force etc. The internal inlaying locking due to above could obtain more conjunctive strength than some coating on the smooth surface[21]. And if added hydroxyapatite–coating to porous titanium, bigger conjunctive strength could be obtained [22]. In this research, direct osseo-integrate was formed between bone and implants. The mechanical inlaying impaction was caused by newly formed bone in the pore and the gradient structure between coating and implants enhanced conjunctive strength. According to the results of pull-out test, porous structure and hydroxyapatite–coating could promote conjunctive strength in intermediate and long-term stage, but the induction of BMP-2 in the earlier period after implantation could not be ignored. Newly formed bone could early grow into pores and form mechanical inlaying impaction. The results might be influenced by the position of pedestal(the distance of inner edge and interface of bone and implatation) in this research. Besides this, the size of titanium powders, surface roughness, the way making coating and the thickness might influence the results too.

V. Conclusions

Bone morphogenetic protein-2 and hyaluronic acid on hydroxyapatite-coated porous titanium has a good effect on repairing the defect of distal fumer in rabbit. It is a kind of fine biotechnology for future clinical application.

Landing Impact Loads Predispose Osteocartilage To Degeneration

C.H. Yeow[1], S.T. Lau[1], Peter V.S. Lee[1,3,4], James C.H. Goh[1,2]

Abstract — **Knee osteoarthritis is a prevalent disease worldwide and is characterized by progressive degeneration in structure and functionality of the articular cartilage. While it is widely suggested that activities involving large landing impact loads may lead to post-traumatic osteoarthritis, there is little understanding on whether these loads can inflict cartilage lesions and trigger degeneration. This study sought to investigate whether landing impact loads applied to the osteocartilage will render it towards degeneration. Menisci-covered and exposed osteochondral explants were extracted from tibial cartilage of fresh porcine hind legs and placed in culture for up to 14 days. A single 10-Hz haversine impact compression was performed at Day 1. Control (non-impact) and impacted explants were randomly selected for cell viability, glycoaminoglycan and collagen content assessment, histology, immunohistochemistry and micro-computed-tomography. When 2-mm displacement compression was applied, exposed explants attained a considerably greater peak impact stress than menisci-covered explants. There was no observable difference in cell viability, glycoaminoglycan and collagen content, and Mankin scores between menisci-covered and exposed explant groups. Both groups were noted with diminished proteoglycan and type II collagen staining at Day 14; the exposed group indicated increased cartilage volume at Day 7-14. Large landing impact loads can introduce structural damage to the osteocartilage, which leads to osteoarthritis-like degenerative changes. The inferior resilience of menisci-covered regions, against impact-induced damage and degeneration, may be a key factor involved in the meniscectomy model of osteoarthritis.**

Keywords — **Osteoarthritis, compressive impact, degeneration, damage, menisci**

I. Introduction

Knee osteoarthritis (OA) is a prevalent joint disease worldwide, with almost 1 in 3 adults displaying OA symptoms in the United States.[1] Post-traumatic OA can occur following sports injuries incurred during high-impact activities such as gymnastics and basketball. Therefore, impact trauma is a potential risk factor for joint degeneration and early-onset OA.[2] Huser and Davies[3] and Mrosek et al.[4] found that impact trauma on cartilage led to release of glycoaminoglycans (GAG), chondrocytic death, and diminished type II collagen and aggrecan expressions, which are characteristic of OA. However, the loading conditions adopted in these studies were inadequate for simulating landing impact. Different cartilage regions have varying resistance to loading. Thambyah et al.[5] demonstrated that menisci-covered cartilage was thinner than exposed cartilage by 40%, and possessed substantially lower subchondral bone quantity and calcified layer thickness. Furthermore, Yeow et al.[6] noted that exposed regions did not incur more damage than neighboring menisci-covered regions during simulated landing impact of the knee joint. Altogether, these studies suggested that exposed cartilage regions are more capable of load-bearing than menisci-covered regions. However, it is not well understood whether these regions may be different in their susceptibility to degeneration. This study sought to investigate whether landing impact loads applied to the osteocartilage will render it towards degeneration. We hypothesized that impacted menisci-covered regions are more vulnerable to structural damage and more inclined towards degeneration relative to exposed regions.

II. Methods

A. Specimen preparation and impact procedures

Fresh porcine hind legs (pig age: ~2 months old; weight: ~40 kg) were obtained from a local abattoir (Primary Industries, Singapore). Osteochondral explants (4-mm diameter; 7-mm height) were extracted from menisci-covered and exposed tibial cartilage regions at Day 0, and incubated at 37°C and 5% CO_2 for up to 14 days in Dulbecco's Modified Eagle's Medium (DMEM) (Gibco, Switzerland) supplemented with 1 g/L L-glutamine, 10 mg/mL streptomycin sulfate, 10,000 units/mL penicillin G sodium and 10% (v/v) fetal bovine serum (Sigma-Aldrich, US). A 30-mm-diameter compression plate was attached to the material testing system (810-MTS, MTS Systems Corporation, USA) to apply impact compression, which was displacement-controlled at 2-mm based on a single 10-Hz haversine loading curve to simulate landing impact.[6] Dental cement (Base-liquid and powder, Dentsply, China) was used to secure the explant in the potting cup. Each explant was immersed in medium and a 10-N pre-loading was applied by adjusting

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1684–1687, 2009
www.springerlink.com

the MTS actuator to allow contact between compression plate and explant. Impact compression was conducted on Day 1; peak impact stress was obtained from the peak compressive load, measured by the attached load-cell (9347B, Kistler, Switzerland), divided by explant cross-sectional area. Control (non-impact) and impacted explants were randomly selected for cell viability, GAG and collagen content assessment, histology, immunohistochemistry and micro-computed-tomography (MicroCT).

B. Cell viability, GAG and collagen content assessments

To quantify cell viability, explants were incubated for 30min in 2ml of medium containing 0.1% fluorescein diacetate, 0.05% propidium iodide (Sigma-Aldrich, US). Confocal fluorescence imaging (LSM510 META, Carl Zeiss, Germany) was performed using excitation wavelength of 488nm (green) and 543nm (red) to visualize surface live and dead cells. Pixel area fractions of viable green and non-viable red cells were measured using ImageJ (Version 1.4, National Institute of Health, US). To assess GAG and collagen content, cartilage was detached from the explant using a microtome blade, and measured for wet weight before immersing in 1ml of 0.025% pepsin in acetic acid for 1 week to permit degradation. The resultant solution was extracted for content assessment using Blyscan sulfated glycosaminoglycan assay and Sircol soluble collagen assay (BioColor Ltd, UK) respectively. These colorimetric assays allowed quantification by analyzing absorbance values of GAG- or collagen-bound dyes using a spectrophotometer, where wavelengths of 656nm and 540nm were used respectively.

C. Histology and immunohistochemistry (IHC)

Explants were fixed in 10% buffered formalin for 1 week and decalcified in 30% formic acid for 2 weeks. They were then dehydrated and progressively cleared in ethanol and toluene before embedding in paraffin. 10-μm slices were then obtained using a microtome (RM2255, Leica Microsystems, Germany), and were deparaffinized and stained using Hemotoxylin & Eosin and Safranin-O/Fast Green staining protocols to visualize osteochondral structure, cell distribution and proteoglycan distribution. Three independent observers were trained to grade the photomicrographs using Mankin scoring system; they were blinded against control and impact groups to eliminate bias. Additional histological slices were obtained for IHC analysis (Ultravision Detection System, LabVision Corp, USA). The slices were labeled with primary monoclonal anticollagen type II antibodies (Chemicon International, US), prepared at a dilution of 1:200, overnight at 4°C. Biotinylated goat anti-mouse secondary antibodies were then applied at 1:200 for 30min, followed by addition of strepavidin peroxidase for 45min and chromagen-substrate solution for 3min at 37°C.

D. MicroCT

Explants were scanned using MicroCT scanner (SMX-100CT, Shimadzu, Japan) with the following settings: X-ray voltage (32kV), current (115μA), detector size (5”), scaling coefficient (100) and pixel spacing (14.3μm/pixel). The scans were reconstructed to obtain 3D explant geometry using VGStudioMax (Version 1.2, Volume Graphics, Germany). The cartilage was segmented based on a consistent set of threshold gray-values (20086-24334), which permitted a fair demarcation of cartilage region from underlying bone. Cartilage volume of each explant was then measured to examine volume change over time.

E. Statistical analysis

Student’s t-test (SigmaStat 3.1, SysTat Software Inc, USA) was used to compare between control and impacted explants for cell viability, GAG and collagen content, Mankin scores and cartilage volume. Normalization was based against control menisci-covered explants at Day 0/1. All significance levels were set at $p=0.05$.

III. Results

There was a notable difference ($p<0.001$) in peak compressive stresses between menisci-covered and exposed explants (Fig. 1). Substantial cell death ($p<0.05$) was noted post-impact in menisci-covered explants at Day 1 and 14, and exposed explants at Day 1 and 7. No significant difference was observed between impacted explants from both regions at all time-points. For GAG content, we noticed a gradual reduction for menisci-covered and exposed impacted explants over time (Fig. 2).

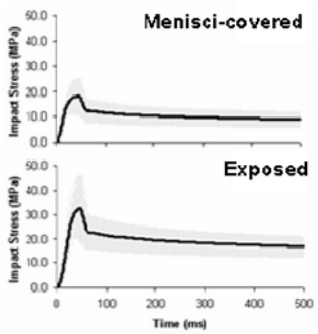

Fig. 1 Load responses of menisci-covered and exposed explants during 2-mm displacement compression

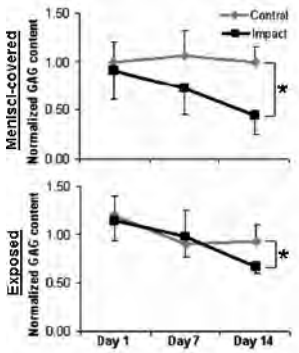

Fig. 2 Comparison of normalized GAG content between menisci-covered and exposed explants over time

Fig. 3 Structural damages observed in menisci-covered impacted explants at different time-points

The major difference ($p<0.05$) between control and impacted explants was detected at Day 14. A similar profile was seen for collagen content between control and impact groups with significant difference ($p<0.05$) at Day 14. No considerable difference was observed for GAG and collagen content between menisci-covered and exposed impacted explants across all time-points. For histology, we found that most menisci-covered and exposed explants sustained surface fraying and irregularities. Clefts in intermediate zones and tidemark disruption were also present (Fig. 3); hypocellularity was observed for impacted explants at Day 14. Marked reduction in proteoglycan staining was noted for menisci-covered and exposed impacted explants at Day 14, especially at the deep zone.

We also found a substantial reduction of type II collagen staining at Day 14 throughout the cartilage. We obtained considerably larger Mankin scores ($p<0.05$) for impacted explants than control explants. Substantial increase in Mankin score was observed for menisci-covered explants from Day 0-7 ($p<0.05$) and from Day 7-14 ($p<0.001$) but the score was only significantly increased from Day 7-14 ($p<0.05$) for exposed explants. Scores between menisci-covered and exposed impacted explants were not substantially different. The cartilage volume increased for exposed explants post-impact at Day 7 and 14 ($p<0.05$) compared to Day 0. For menisci-covered explants, the cartilage volume increased slightly at Day 1 and decreased at Day 7-14. However, the cartilage volume for exposed explants appeared to be elevated at Day 1 and increase further at Day 7-14. The reconstructed 3D geometry of the explants illustrated a change in surface cartilage morphology over time (Fig. 4).

Fig. 4 Comparison of explant surface geometry between menisci-covered and exposed explants pre- and post-impact

IV. Discussion

This study sought to investigate whether landing impact loads applied to the osteocartilage will render it towards degeneration. Previous studies demonstrated impact stresses of 20-30MPa could damage cartilage and underlying bone.[7,8] In our study, we noted a peak compressive stress of 20.2-34.9MPa for menisci-covered and exposed explants when subjected to 2-mm displacement compression. We also observed damage such as matrix disruption at superficial and intermediate zones, and tidemark lesions. For degenerative changes, there was a gradual increase in cartilage volume and diminished GAG content up to Day 14. A significant presence of surface cartilage cell death was noted post-impact up to 14 days. Our microCT scans revealed a visible change in surface cartilage morphology over time for pre- and post-impact explants, indicating impact damage, cartilage swelling and surface degradation. Our study revealed different load responses of menisci-covered and exposed explants when subjected to the same 2-mm compression. Thambyah et al.[5] showed that exposed regions possess a significantly larger cartilage thickness and subchondral bone density compared to menisci-covered regions. These factors may contribute in part to a higher overall stiffness in exposed explants, hence these explants will experience greater peak compressive impact stress, relative to menisci-covered explants. We did not obtain major differences between menisci-covered and exposed impacted explants for cell death, GAG and collagen content, and Mankin scores. This showed that though exposed explants generally sustained a higher impact load and the same mag-

nitude of compressive deformation, the damage and degenerative changes following impact was not substantially different relative to menisci-covered explants, which strongly reflects the superior capacity of exposed regions in resisting trauma-induced damage and degeneration. We also noticed elevated cartilage volume for exposed explants. Cartilage swelling may be due to the diminished capability of disrupted collagen network to counteract proteoglycan-induced swelling pressure.[9] Our data may suggest that the lower compressive load experienced by menisci-covered explants may lead to reduced collagen network damage, thus less swelling relative to exposed explants.

One limitation of this study was the use of a porcine model to investigate post-traumatic osteochondral damage profile. The porcine model minimized sample variability as they were derived from a common source. The daily activities performed by pigs are considerably more sedentary compared to humans, hence their knees do not normally sustain high impact or have a history of knee injury. Thus, we expect that the model to be suitable as control and impacted specimens. Another limitation was the use of culture medium to maintain explant viability. It would be ideal to use the synovial fluid to simulate physiological condition of the knee during landing impact, but due to the complex components present in synovial fluid which may complicate analysis, we thus used the standard culture medium as a simplified substitute, with appropriate osmolarity (280mOsm), pH (7.4) and supplement concentrations, to maintain tissue viability and understand the direct effect of landing impact on osteochondral damage and degeneration.

V. Conclusions

Our findings collectively illustrated that menisci-covered osteochondral regions have inferior load-bearing capacity and resilience to damage and degeneration, relative to their exposed counterparts. Meniscectomy will expose menisci-covered regions and increase risk of damage and degeneration in these regions. Our results revealed that these regions were prone to traumatic damage and also more susceptible to degeneration. The inferior resilience of menisci-covered regions, against impact-induced damage and degeneration, may be a key factor in the meniscectomy model of OA.

Drug Addiction as a Non-monotonic Process: a Multiscale Computational Model

Y.Z. Levy[1], D. Levy[2], J.S. Meyer[3] and H.T. Siegelmann[1]

Abstract — **Addiction is considered a "bio-psycho-social-spiritual disorder" [1] for which complete recovery cannot be assured. Although addiction was computationally characterized as a non-reversible process [2,3], behavioral evidences support the possibility of recovery [4, 5, 6,7].**

We thus propose to consider addiction as a non-monotonic dynamical disease. Previously, we presented a multiscale computational model that combines three scales of observations: behavior, cognition, and neuropsychology. This model evaluates the drug-seeking behavior in virtual subjects.

We use our model to analyze dynamical properties of two typical virtual subjects. One has become an addict at the age of 17 and has since expressed a severe multi relapse pattern. The other one was exposed to addictive behavior at age 36 but managed to cease drug seeking. The results are encouraging for further explorations into the individual dynamics in addicts.

Keywords — **Addiction, Multiscale Modeling, Behavioral Processes, Cognition, Neurophysiological Processes.**

I. Introduction

Drug use estimates presented in the United Nations World Drug Report 2008 claim that in 2006/07 about 24.7 million people used amphetamines, 16 million used cocaine, and 12 million used heroin at least once. In an effort to investigate the dynamics of addiction, we propose a computational model that considers addiction as a non-monotonic reversible process [8].

This mathematical framework combines three different scales of observations - *social, cognitive and neuropsychological* – and is hypothesized to predict the outcome of a virtual subject's behavior with respect to drug-seeking behaviors. We analyze two case studies in terms of their tendency to relapse and ability to rehabilitate.

II. Materials and Methods

The multiscale computational model combining neuropsychological (NepS), cognitive (CogS), and behavioral (BehS) scales is shown in Figure 1.

The output G(t) is the severity of the behavioral condition which that we propose to equate with the likelihood of drug-seeking behavior, generated at the BehS. The value G(t) lies in the interval [-1, 1], and we consider the range [-1,0] to correspond to a subject with maladaptive behavior and the range [0,1] to a subject with healthy behavior, both in the probabilistic sense.

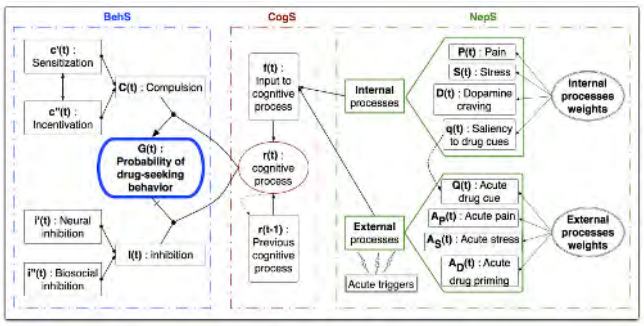

Fig. 1: Addiction model combining neuropsychological (NepS), cognitive (CogS), and behavioral (BehS) scales. The output G(t) is the likelihood of drug-seeking behavior.

The BehS is simply suggested to include the inhibition I(t) and compulsion C(t) functions. This is along the line of the I-RISA model that describes addiction as impaired inhibition (to stop sensory-driven behavior) and salience attribution (with larger interest in drugs than in other possible rewards) [9]. On the one hand, the function G(t) is positively influenced by the inhibition I(t), which by itself combines the inhibition stemming at the subject's neural development of the frontal lobes of the cortex [10, 11, 12] together with the inhibition coming from social rules of this individual. On the other hand, the function G(t) is negatively influenced by the compulsion C(t), which is calculated according to the incentive-sensitization theory of addiction [13,14]. In computing G(t), the balance between I(t) and C(t) is weighted by r(t), the cognitive process, as described in equation (1).

$$G(t) = \left[1 - r(t)\right] \cdot \left(-C(t)\right) + r(t) \cdot I(t) \qquad (1)$$

The cognitive process r(t) is a combination of its previous value r(t-1) and the input to the cognitive process f(t), as described in equation (2). Both functions r(t) and f(t) are computed at the CogS.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1688–1691, 2009
www.springerlink.com

$$r(t) = \frac{1}{2} \cdot \tanh\left[\alpha \cdot r(t-1) + \beta \cdot f(t) + \gamma\right] + \frac{1}{2} \qquad (2)$$

The input to the cognitive process f(t) is a weighted sum of the internal and external processes. While the exact realistic structure of f is hard to guess, we propose a reasonable model:

$$f(t) = \left[-\omega_S S(t) + \omega_P P(t) - \omega_D D(t)\right] + \left\{\omega_A\left[-A_S(t) + A_P(t) - A_D(t)\right] - \omega_Q Q(t)\right\} \qquad (3)$$

The internal processes are P(t), representing the level of pain or negative consequences in areas such as health or social relations; S(t), representing the level of stress or negative emotional state of the virtual patient; D(t), representing the craving level, based on the dopamine transmission in the Nucleus Accumbens (NAac); and q(t), representing the saliency of drug-associated cues. Intakes of drugs can increase P(t) [15]. The level of S(t) increases during withdrawal periods [16, 17, 18] and may trigger craving [19]. These intakes were shown to affect the level of dopamine in the NAac and the addicted behavior in rats [20, 21] and in humans [22, 23]. The value q(t) increases with repeated drug consumption [24, 25] and weights the affects of drug related cues Q(t) when encountered.

External processes in this model are $A_P(t)$, representing a painful trauma that may cause a virtual patient to stop taking drugs [26, 27]; $A_S(t)$, representing a stressful episode that may lead into instantaneous drug-use [28, 29]; $A_D(t)$, representing drug priming that may cause drug-use [30, 31]; and Q(t), representing a drug-associated cue [32].

Relevant mathematical details are presented in [8].

III. Results

In this section two different case studies of drug-seeking behavior are considered: The profile of GD outlines a continuous relapse pattern of a person who started using drugs at age 17 and has later been unsuccessfully trying to get away from drug-seeking behavior, whereas the profile of VD exhibits a person that has first used drugs close to age 36 and for which the drug-seeking behavior changes from healthy to maladaptive and back to healthy.

The G value of both cases, depicted in Figure 2, is averaged over 10 simulations, having a noise injected in the process. The constants used for both simulations are presented in Table 1. For the presented simulations, the inhibition I(t) of VR was set 33% higher than the one of GD, and the compulsion C(t) of VR was set 60% higher than the one of GD. The initial values of all the signals were chosen randomly in their defined intervals.

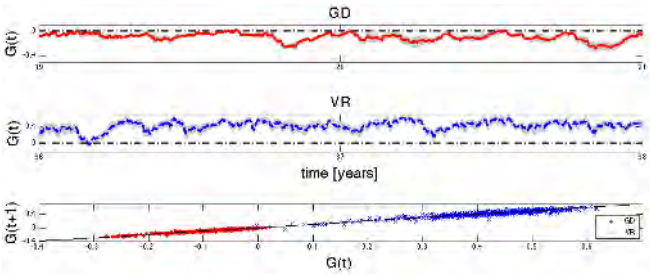

Fig. 2: G(t) means, SEMs and G(t+1) versus G(t) for 10 simulations. At the top, GD's evolution between ages 19 to 21, and at the middle, VD's evolution between ages 36 to 38. At the bottom, G(t+1) against G(t). The diagonal line corresponds to G(t+1) = G(t).

The age intervals considered in Figure 2 are 19 to 21 years old for GD, and 36 to 38 years old for VD. The bottom part of Figure 2 plots the ratio of G(t+1)/G(t). This ratio describes convergence to attractors when the trajectory falls on points with values < 1, and it describes divergence when the points are >1 [33]. We asked whether the dynamic of G is more converging (to addictive or healthy states) or diverging, and found that the trajectories neither converge nor diverge. For GD's profile 229 points of the trajectory had the value < 1 whereas 271 points were > 1. Similarly for VD's profile, 275 points had values < 1 and 225 points were > 1, out of 500 iteration points. The translational meaning is that addiction is a process of intervening parameters in a complex manner: addiction can be affected by external parameters given that they are provided during times of divergence.

Table 1 The values of the constants used in GD and VR simulations.

	Value		Value
alpha	0.15	beta	0.25
gamma	0.2449	S decay for G > 0	0.02
S decay for G < 0	0.02	P decay for G > 0	0.0002
P decay for G < 0	0.1	D decay for G > 0	0.00002
D increase steps	20	D decay for G < 0	0.02
A_S constant steps	20	A_S decay	0.9
A_S probability	0.02	A_S decrease steps	60
A_P decrease steps	20	A_P decay	0.4
A_P probability	0.04	A_P constant steps	10
A_D decrease steps	5	A_D decay	0.2
A_D probability	0.03	A_D constant steps	3
q saliency constant steps	10	q decay for G > 0	0.002
Q constant steps	20	q decay for G < 0	0.005
Q probability	0.01	Q decay	0.9
weight P	1.1	Q decrease steps	40
weight A	0.4	weight S	0.3
weight Q	1	weight D	0.4

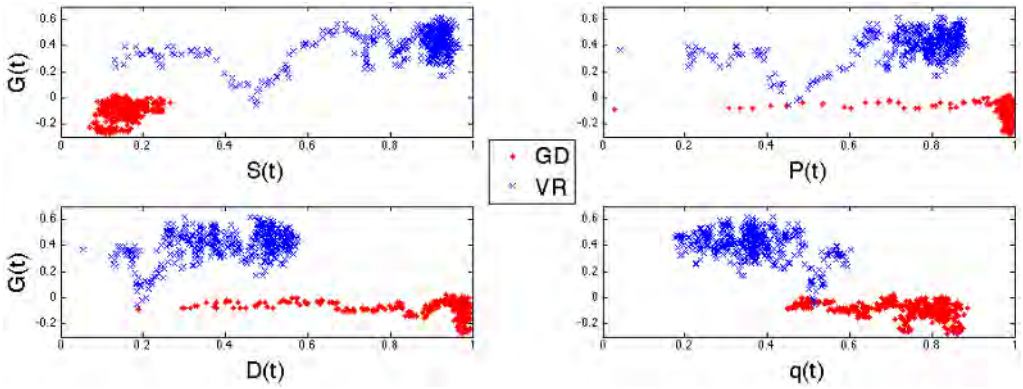

Fig. 3: The internal processes S(t), P(t), D(t), and q(t) plotted against G(t) for GD (red dots) and VR (blue cross).

Next, we asked whether the dynamic behaviors of the individuals differ in fluctuations based on the severity of their addiction. For both simulations, we measured average and standard deviation, and then calculated the integral of the function from its average to measure the consistency of the fluctuations. The values of averages, standards deviation and integrals were (-0.0975, 0.0623, 24.5661) for the more severe case, GD, and were (0.4117, 0.1083, 41.4371) for the lighter case, VR. The addictive person has less fluctuations and flexibility in his drug-seeking behavior that the healthier one, seemingly due to the strong saliency to cues [9].

In Figures 3 and 4 the values of G(t) for GD and VR are plotted against the internal processes and the external processes, respectively. The internal processes affect G, and G affects these processes. The values of S(t) are higher during withdrawal than during use. The values of P(t), D(t) and q(t), on the other hand are higher during drug use. The effect on G by both internal and external events correlates with equations (1), (2), (3).

IV. Conclusions

The dynamical analysis in this paper provides analytical measures to behavioral facts pertaining to addiction. The underlying hypothesis that addiction is a non-monotonic dynamical disease differs from the current state-of-the-art. The effort here is to understand the individual fluctuations in drug seeking behaviors with the future goal of predicting stages of possible treatments and stages of need for extra cautiousness.

The typical case of the more compulsive, less inhibited individual will have an early onset to addiction. His behavior does not fully converge to addictive behavior due to internal and external events that cause him to try a way out; we stress in our model that none of the cases are monotonic. This virtual individual demonstrates numerous efforts to rehabilitate mainly due to pain, and may have short periods of withdrawal, but relapses are fast and overwhelming. The overall flexibility of this subject's behavior is far smaller than the flexibility in the behavioral variables of the less severe case, probably due to the growing saliency to drug cues.

The healthier person, with the stronger inhibition falls into addiction later in life. With similar internal and external events to the other virtual case, this individual rehabilitates. The total flexibility and change in the behavioral parameters is overall much greater than the severely addicted individual, and the actual behavior do not present a relapse pattern.

Both cases demonstrated a behavior that is affected by internal and external events, providing a hope for rehabilitation for people in either situation. A translational application of the model could be the identification of a treatment that given with the right timing will change the effect that the internal and external processes have on the drug-seeking behavior of the individual, and hence ease the process of recovery.

The analyses presented in this work are promising, and we will continue with deeper investigations into the individual dynamics of addiction.

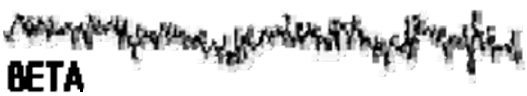
Adroit Limbs

Pradeep Manohar[1] and S. Keerthi Vasan[2]

[1] Sri sairam engineering college/EEE, Anna university, Chennai, India
[2] Sri sairam engineering college/ECE, Anna university, Chennai, India

Abstract — **Necessity is the mother of all inventions. Brain- The Master of our body generates signals in accord with our thoughts and decrees every part to perform the desired actions. This paper is a boon to the amputees since it can decrease their encumber. This paper targets in trapping the signals by the use of Brain wave sensor (Sensors that are attached to the scalp in order to monitor the Brain Wave activity in different parts of the brain) and feed the signals to the so designed artificial hand. Adroit limb is different from the already existing ones. It can encompass activities like peeling; feel things as our normal human hand. The existing models can provide only support but the proposed prototype for this paper can respond to External Stimulus. Brain waves are obtained from a special analysis of EEG (Electro Encephalo Gram). These brain waves show us the brain's response to an external stimulus or event. Brain activity before, during, and after a stimulus presentation is recorded. This allows us to observe where, when, and how the brain responds to a given stimulus.**



The need for an artificial hand plays a very important role in the life of Amputees and physically challenged. Such people are given an external attachment of an artificial hand which gives a look similar to that of a normal hand which cannot perform all the desired acts. The existing models cannot stimulate actions as per our thought. The signals are directly obtained from the brain without any pre existing sensor for this purpose. The problems faced by the amputees are also increasing day by day. The proposed prototype is a panacea for all such problems faced by them to a greater extent.

Keywords — **Artificial limb, Brain wave controlled, EEG technic, Amputees, Stepper motor**

I. WORKING PROCEDURE

A. WORKING STATE OF BRAIN

BETA STATE: Our brain usually operates at Beta wave state. Around 13 to 40 Hz A person in this state hasacuteconcentration.

ALPHA STATE: Our brain is said to be in alphastateat7to12Hz.

Fig. 1 Alpha

At this state our body and mind relaxes. Our mind reaches the gate way to creativity .

THETA STATE: The frequency in this state is around4to7Hz

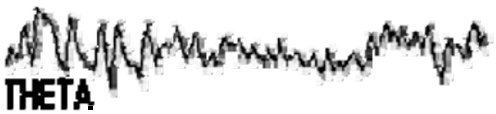


Fig.2 Theta

Our creativity and intuition shoots through the roof and we are approaching the gateway to enhanced learning and memory.

DELTA STATE: In this state a person has magnetic memory and increased learning capability. The frequency of the signal generated by the brain is less than 4 Hz. A person can remember things. .

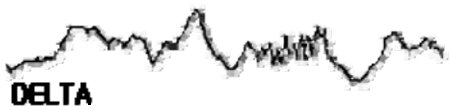

Fig.3 Alpha

B. BLOCK DIAGRAM:

The block diagram of our proposed project can be divided into sections:

Transmitter Section: The signal generated by the brain is captured, processed and finally converted to digital signal for transmission. The transmitter serves this purpose.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1692–1695, 2009
www.springerlink.com

Receiver Section: The processed signals are obtained by the receiving end and the signals are matched with actions that are programmed in the microcontroller and the action as per thought is performed by the proposed prototype.

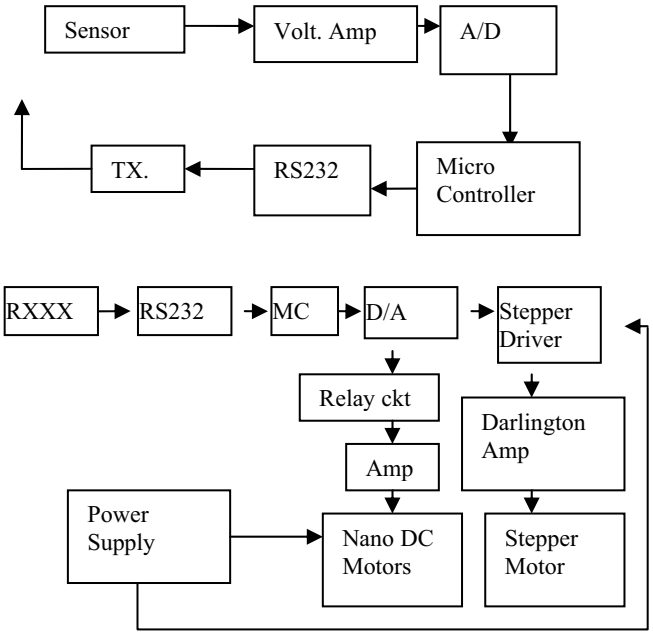

Fig.4 Transmitter and receiver section

C. CIRCUIT DESCRIPTION:

The components mentioned in the block diagram can be explained briefly as follows:

Sensor**:** In order to capture the thought of a person the mind reader/Brain wave sensor is used. **Electroencephalography** (EEG) is the measurement of electrical activity produced by the brain as recorded from electrodes placed on the scalp. In this paper we report the results from first human experiments using a new electrophysiology sensor called **ENOBIO**, using carbon nanotube arrays for penetration of the outer layers of the skin and improved electrical contact. These tests, which have included traditional protocols for the analysis of the electrical activity of the brain--spontaneous EEG and ERP--, indicate performance on a par with state of the art research-oriented wet electrodes, suggesting that the envisioned mechanism--skin penetration--is responsible.

Microcontroller: The micro controller is programmed using mat lab which would be the front end. The microcontroller is programmed for specific actions. So that when the signal generated by the brain is encountered by, it action is performed as per thought. The micro controller works in the range of 4.85 to 5V.It comprises of five ports and eight slots, different programs can be stored in these slots. It is programmed at its ports numbered 18 and 19 where the read and write operation can be performed. The purpose of using MAX232 is for level shifting. The program from the system is encoded in the microcontroller. Voltage amplifier: Because the signal strength of the biological signal is so low, the signal will also have to be amplified via a power amplifier with good SNR. This module modifies the signal in order to drive therestofthedevice.

Converters**:** In order to drive the microcontroller, the signal that is generated by the brain which is in analog formisconvertedtodigitalusingA/Dconverter.

RS232: In telecommunications, *RS-232* (Recommended Standard 232) is a standard for serial binary data signals connecting between a *DTE* (Data terminal equipment) and a *DCE* (Data Circuit-terminating Equipment). It is commonly used in computer serial ports. RS-232 devices may be classified as Data Terminal Equipment (DTE) or Data Communications Equipment (DCE); this defines at each device which wires will be sending and receiving each signal. The RS-232 standard defines the voltage levels that correspond to logical one and logical zero levels. Valid signals are plus or minus 3 to 15 volts. The range near zero volts is not a valid RS-232 level; logic one is defined as a negative voltage, the signal condition is called marking, and has the functional significance of OFF.

Darlington amplifier**:** the Darlington transistor (often called a Darlington pair) is a semiconductor device which combines two bipolar transistors in a single device so that the current amplified by the first is amplified further by the second. This gives a high current gain (written β or h_{FE}), and takes less space than two discrete transistors in the same configuration. Integrated packaged devices are available, but it is still common also to use two separate transistors. A Darlington pair behaves like a single transistor with a high current gain (the product of the gains of the two transistors):

$$\beta_{\mathrm{Darlington}} = \beta_1 \times \beta_2$$

Relays**:** One simple method of providing electrical isolation between two circuits is to place a relay between them.

Stepper motor**:** Since fingers need to perform precise actions. The use of stepper motor is incorporated at the joints. Unlike conventional motor, Stepper motor can perform accurate motions by rotating at specific degrees Stepper motors operate much differently from normal DC motors, which rotate when voltage is applied to their

terminals. Stepper motors, on the other hand, effectively have multiple "toothed" electromagnets arranged around a central gear-shaped piece of iron. The electromagnets are energized by an external control circuit, such as a microcontroller.

D. WORKING:

Brain, the source of all thoughts produces impulses according to the thoughts we make. These impulses are always analog in nature. These analog signals are sent through nerves to all parts of the body. These signals are of constant amplitude and of frequency modulated type. The impulse is of constant amplitude for one thought with varying frequency. For another thought there will be a sharp difference in the amplitude.The energized copper coil produces current. This current activates the printed circuit boards (PCB) at the other end. A transmitter/receiver device placed externally to the body, is connected to the PCB's. The connecting wires are through the tiny hair pores. The transmitter/receiver device, placed externally to the human body now takes the entire command. This acts as a secondary brain outside the body. This device relays the message, according to the information obtained from the brain to the computer or any robot that can act according to the instructions from the device. Also the robot may be connected through a computer. To operate a computer the instructions must be in the form of digital signals. But the brain, as already stated always produces analog signals only. Hence this analog signal has to be converted to machine understandable digital signals. So we incorporate an analog to digital signal converter. The transmission medium from the transmitter/receiver device may be designed according to the convenience. It may be a wire. But wire can be used only up to a limited range. So for the convenience of human radio waves are used for transmission.

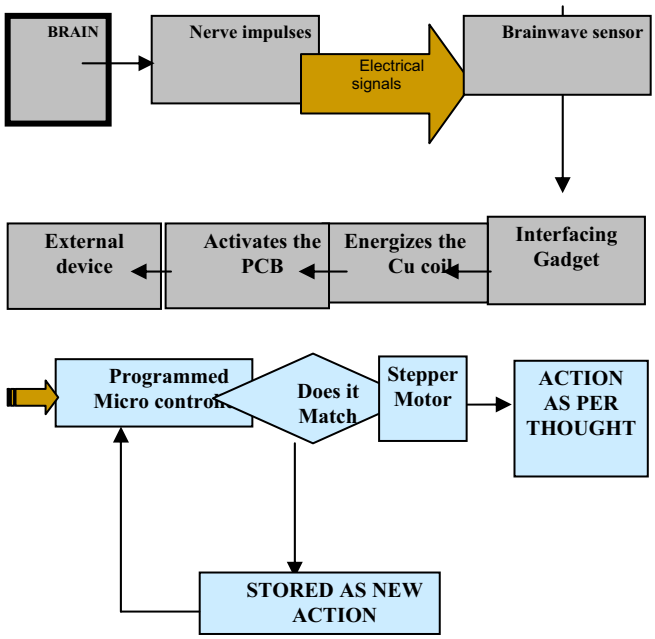

Fig.5 Working

The micro controller is programmed for certain actions to be performed. Any action to be performed is received from the brain. These actions are matched in with the already programmed actions in the micro controller. If the action given in by the brain does not match with the programmed one then it is stored in as a new action. This is in turn fed in to the stepper motor.

E. STAGES OF OUR PROTOTYPE:

First module: The first module in our prototype would be designing the model that will be attached (wrapped) to our hands and movements are made as per our thoughts, the actions produced by the model are viewed in the monitor.

Second module**:** The second module would be developing an artificial hand and making it perform actions as per the thought by fixing it either in the hands of physically challenged or normal people.

Final module: The final outcome would be our objective that is to make the hand perform normal actions such as making it to peel oranges and so on and this will be attached to physically challenged people. Thus it functions similar to normal hands.

F. ADVANTAGES:

Performs action similar to normal hand.Any actions can be performed as per thought. Simple construction and light weight. Capable of performing activities like peeling. Low cost. Respond to external stimulus.

G. DISADVANTAGES:

Subjected to battery weakness. Cannot lift heavy objects. Restricted not to do few actions.

II. Conclusion:

This paper is for the physically challenged people who love to live like the ordinary men and women they can perform all works in a much effective manner than a normal human. This technology definitely is a boon to special community.

A Mathematical Model to Study the Regulation of Active Stress Production in GI Smooth Muscle

Viveka Gajendiran[1] and Martin L. Buist[1]

[1] Division of Bioengineering, National University of Singapore, Singapore

Abstract — **In the gastrointestinal (GI) system, motility is governed by the contraction and relaxation of smooth muscle (SM) in response to many regulatory factors. SM in a hollow organ like stomach exhibits two types of contraction: tonic, to maintain the shape of the organ, and phasic, in response to neurotransmitters, hormones or other signaling molecules. Motility disorders such as dysphagia, gastroesophageal reflux disease, irritable bowel syndrome and hypotensive or hypertensive disorders all involve abnormal SM function. Hence, it is important to gain a deeper understanding of contraction and its regulation in GI SM cells. Skeletal muscle cells have force-velocity curves in which shortening velocities are determined only by load and the myosin isoform. In contrast, when smooth muscle activation is altered, e.g. by changing a hormone or agonist concentration, a different set of velocity-stress curves can be obtained. This difference is due to the regulation of both the number of active cross bridges (determining force) and their average cycling rates (determining the velocity). The regulatory system depends on the phosphorylation of cross-bridges, which in turn depends on cytosolic Ca^{2+} levels. Thus, a model has been proposed to study the effects of (a) Ca^{2+} concentration on the kinetics of myosin phosphorylation, (b) cross-bridge cycling rates, and (c) the latch state on tonic and phasic contractions. The objective of the model is to describe the regulation of myosin phosphorylation and active stress production in terms of the intracellular Ca^{2+} concentration. A mathematical formulation of cross bridge cycling has been adapted from the literature and the parameters have been fitted to experimental data from GI SM. Here it was assumed that the Ca^{2+}-calmodulin mediated phosphorylation of myosin is the primary determinant of the kinetics of cross bridge cycling. This model is the first step towards developing a dynamic model of GI SM contraction.**

Keywords — **Gastrointestinal (GI), Smooth muscle (SM) contraction, Myosin Phosphorylation, Active Stress, Cross-bridge model, Latch state**

I. Introduction

Smooth muscle cells line the walls of most of the hollow organs within the body. The ability of these cells to generate force and motion is essential to the normal functioning of the cardiovascular, respiratory, digestive systems. Since altered smooth muscle contraction may contribute to disease states, it is important to understand the mechanisms underlying smooth muscle contraction.

The functional role of the gastrointestinal tract is to digest and absorb nutrients. These processes are facilitated by the orchestrated movement of the luminal contents from the mouth to the anus [1]. Smooth muscle cells are the force producing elements of the GI tract. The force producing mechanisms of these cells are controlled by the intrinsic electrical slow wave activity and the enteric nervous system through electro-mechanical excitation-contraction coupling and also through pharmaco-mechanical coupling [2,4]. Pacemaker activity and the subsequent slow waves generated by the interstitial cells of Cajal (ICC) provide the background tone of the smooth muscle syncytium [1,2,4]. The tonic contractions contribute to maintaining the shape of the organ against an imposed load. Neurotransmitters from the enteric nervous system, along with hormones and paracrine factors released in response to physiological stimuli, modify SM cell behavior such that phasic contractions are elicited. A tonic contraction also enhances the open probability of voltage dependent Ca^{2+} channels in SM cells and increases the amplitude of phasic contractile activity in response to various stimuli.

The contractile unit of smooth muscle cells consists of thin actin containing filaments and the thick myosin containing filaments [5]. Tiny projections from the myosin filament called cross bridges extend towards the actin filament. These projections are the molecular motors which convert the chemical energy into mechanical work during their cyclic interaction with actin [5].

In smooth muscle, Ca^{2+} is the trigger for contraction [2]. Increase in intracellular Ca^{2+} can be due to several distinct mechanisms [3]. When the concentration of intracellular Ca^{2+} increases, a series of events take place. The ubiquitous cytoplasmic protein calmodulin binds to Ca^{2+} ions in a ratio of 4:1 [5]. In the absence of Ca^{2+}, caldesmon protein strongly binds to the tropomysin –actin complex on the thin filament preventing actin-myosin interaction. This inhibition is removed when the Ca^{2+}-calmodulin complex binds to caldesmon. In the thick filament, the Ca^{2+}-calmodulin complex binds to a specific site on the myosin light chain kinase (MLCK) converting it from the inactive form to the active form. This allows the MLCK to phosphorylate the regulatory light chain of myosin (MRLC)

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1696–1699, 2009
www.springerlink.com

resulting in actin-myosin interaction and this greatly potentiates the splitting of ATP and cross-bridge cycling [6]. The presented model is designed based on this mechanistic approach.

Apart from the regular cross-bridges, a population known as latch bridges is also produced [6, 7]. A latch is a state where there are reduced cross bridge cycling rates, dependent on low but significant levels of Ca^{2+}-dependent cross bridge phosphorylation. Latch–bridges contribute to sustained force maintenance during low levels of intracellular Ca^{2+}, especially during tonic contraction.

II. Methods

The Hai and Murphy model [8] is a kinetic model for the interaction of cross-bridge forming myosin heads with thin-filament actin which brings about contraction in SM. The model is based on the hypothesis of two types of cross-bridge populations – (a) cycling phosphorylated cross-bridges (AMp) and (b) noncycling dephosphorylated cross-bridges (latch bridges, AM). According to the model both of these populations contribute to the development of stress in SM. The schematic representation of the four state model is shown in fig 1 and the resulting equations are given below.

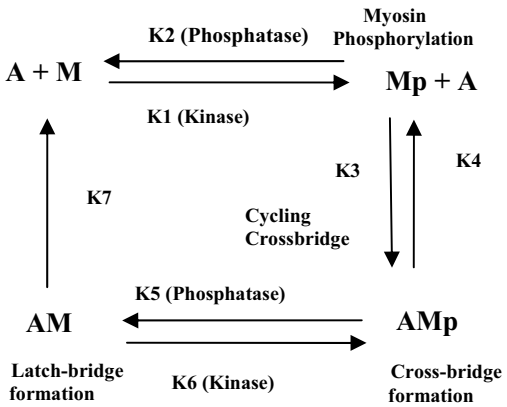

Fig.1 Four state cycling cross bridge model proposed by Hai and Murphy [8].

$$\frac{d[M]}{dt} = -K_1 [M] + K_2 [Mp] + K_7 [AM] \quad (1)$$

$$\frac{d[Mp]}{dt} = K_4 [AMp] + K_1 [M] - (K_2 + K_3) [Mp] \quad (2)$$

$$\frac{d[AMp]}{dt} = K_3 [Mp] + K_6 [AM] - (K_4 + K_6) [AMp] \quad (3)$$

$$\frac{d[AM]}{dt} = K_5 [AMp] - (K7 + K_6) [AM] \quad (4)$$

In addition to the assumptions used in the Hai and Murphy model [8], the following assumptions were made. Only one regulatory mechanism was considered; the phosphorylation of MRLC. In the absence of direct/conclusive evidence for the regulation of MLCP (phosphatase), K_2 and K_5 were set to be constants. The Hai and Murphy model (Eqns (1)-(4)) was implemented and solved in Matlab using an in-built explicit Runge-Kutta formula, the Dormand-Prince pair.Calcium dependence (Eqn (5)) was added through the regulation of rate of phosphorylation (K_1) by MLCK as proposed in the uterine contraction model of Bursztyn et al. [9]. Then simulations were run for time dependent intracellular Ca^{2+} data produced by the electrophysiology model developed by Corrias and Buist [11]. The rate of phosphorylation was made dependent on the intracellular Ca level, $[Ca^{2+}]_i$ through the relation

$$K_1(t) = \frac{[Ca_i(t)]^n}{[Ca_{(1/2MLCK)}]^n + [Ca_i(t)]^n} \quad (5)$$

where, Ca_i (t) is the time dependent intracellular $[Ca^{2+}]$, $Ca_{(1/2MLCK)}$ is the $[Ca^{2+}]_i$ required for half activation of MLCK and n is the Hill coefficient of activation.

Table 1 : Parameters used for the simulation (from [9])

NAME	VALUE	UNIT
K_2	1.2387	1/s
K_3	0.1419	1/s
K_7	0.0378	1/s
$Ca_{(1/2MLCK)}$	256.98	nM
n	8.7613	-
By assumption $K_6=K_1$; $K_5=K_2$; $K_4=k_3/4$ [8]		

Total myosin phosphorylation and stress were calculated using the following relations.

$$\text{Stress} = AMp + AM \quad (6)$$

$$\text{Phosphorylation} = Mp + AMp \quad (7)$$

III. Results

The model of gastric smooth muscle electrophysiology model from [11] was used to produce $[Ca^{2+}]_i$ as a function

of time for six slow waves with a plateau phase membrane potential of -43 mV. This is above the threshold membrane potential needed for the activation of contraction in SM [10, 12]. This $[Ca^{2+}]_i$ data, shown in fig 2, served as the input, $Ca_i(t)$, that was used to calculate $K_1(t)$ from Eqn 5.

The values $K_1(t)$ computed for the $Ca_i(t)$ data were substituted in Eqns 1-4, and solved for time dependent values of [M], [Mp], [AMp] and [AM] shown in fig 3.

The stress and phosphorylation produced in the SM cell was calculated from Eqns 6 & 7 and is shown in fig 4. The stress values were normalized by 0.8 (maximum stress) as the maximum number of attached cross-bridges (AMp + AM) was assumed to be 80% of the total myosin [8]. The phosphorylation was expressed as a fraction of total myosin.

Fig .3 Variation of the fractions of the Species (M, Mp, AMp and AM) along the slow wave corresponding to the $Ca_i(t)$ in fig 2.

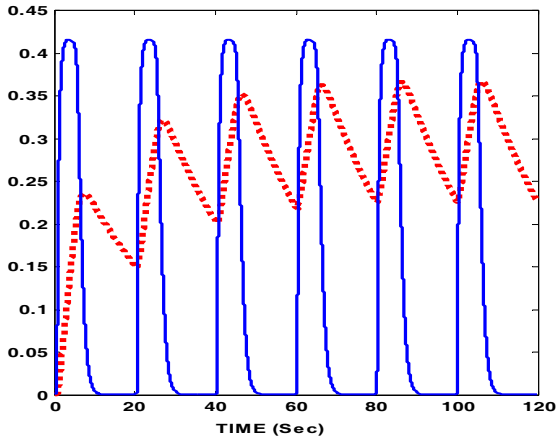

Fig.4 Normalized Phosphorylation (solid line) and Stress (dotted line) curves produced by the model for the Ca^{2+} data in Fig.2.

IV. Discussion

The Hai and Murphy model, modified to include a dependence on the intracellular calcium concentration, has been tested for the Ca^{2+} data produced by the electrophysiology model for gastric SM [11]. To date most of the modeling work in this field has been done for a single calcium ion transient event i.e. one cycle of $[Ca^{2+}]_i$ accumulation and decay over a time range [8,9]. This, however, may not accurately represent the physical situation. Physiologically a train of slow waves will determine the short and long term intracellular Ca^{2+}. Hence it is more useful to study the contraction pattern of smooth muscle in response to multiple slow waves. Here a train of six slow waves was chosen as the test data set.

The Ca^{2+} data corresponds to slow waves with a plateau phase membrane potential of -43 mV. Slow waves must exceed a 'mechanical threshold' for excitation-contraction coupling to occur. It has been found experimentally that the threshold value for different SM cells lies between -40 mV and -60mV, and above this threshold, there is a sharp rise in the Ca^{2+} concentration in many GI SM types causing active contraction to take place [10, 12].

The preliminary results presented here show that the slow waves with plateau phase above the mechanical threshold are able to produce phasic contractions. The latch bridge formation and its contribution in the stress can be seen evidently in figure 4. Though the phosphorylation levels begin to fall following the peak of the Ca^{2+} transient, the stress still increases to reach a maximum before decreasing at a later time. Also though the level of phosphorylation falls so as to be almost negligible, a considerable amount of stress is still maintained. This can also be seen in fig 3 in the AM (latch-bridge) curve.

The tonic contraction mechanism of GI SM will be studied in near future. Once it is established, it is intended to use the behavior to derive realistic initial conditions for the phasic contractions. It is believed that phasic contractions are superimposed on the inherent basal tone of the GI SM and occur in response to stimuli from various agonists [1,3,4,].

It has been noted that the contraction response to the Ca^{2+} current caused by the slow wave is biphasic [12]. That is, the first peak value in the slow wave causes contraction in the SM cells and if the plateau depolarization of the slow wave is above the threshold, a second phase of contraction is initiated with the amplitude of the contraction depending upon the membrane potential and the duration of the plateau phase. The current model is able to produce only a monophasic stress response as it can be seen in fig 4 (stress curve). This disagreement between the experimental observation and the model behavior needs to be addressed.

The model presented here is the first step towards developing a dynamic model of GI SM contraction. Though this model is based on the assumption that only the MAPK is regulated by the intracellular $[Ca^{2+}]_i$ concentration [9], other Ca^{2+} dependent and independent regulatory systems can not be excluded. Experiments are being done to examine if there is a thin filament regulatory pathway involved in the SM contraction [14,15]. Using the experimental results and evidence for such regulatory pathways, the present model will be further extended by the inclusion of more control systems. Recently studies have also been performed relating to Ca^{2+} sensitivity [13]. It is proposed that the sensitivity of the contractile apparatus to Ca^{2+} is not constant and varies under different conditions. This behaviour of the SM cell contractile elements can be accounted for by including a Ca^{2+} sensitivity factor in the model. The future developments do, however, depend upon the availability of concrete experimental evidence and data.

V. Conclusions

In summary, a simple model, adapted from the Hai and Murphy model [8], has been used to explain the calcium dependence of the SM contraction and its regulation. A mathematical formulation for the four states and cross bridge cycling has been used with parameters fitted from the experimental data to study the effects of (a) Ca^{2+} concentration on the kinetics of myosin phosphorylation, and (b) the latch state during tonic and phasic contractions.

As the model is being developed, we expect it to serve as a bridge between electrophysiological and mechanical behaviour of the SM cell. This model is at the cellular level of the hierarchy of cell – tissue – organ as seen in the Physiome project. In the future such models can serve as a tool to make predictions under prescribed conditions and also can be used to study diseases of the GI system.

Design of Customized Full Contact Shoulder Prosthesis using CT-data & FEA

D. Sengupta[1,2], U.B. Ghosh[1] and S. Pal[1]

[1] School of Bioscience & Engineering, Jadavpur University, Kolkata-700 032 India.
[2] Tata Consultancy Services, Technopark Campus, Kariyavattom, P. O. Thiruvananthapuram 695581, Kerala.

Abstract — **Shoulder joints were replaced due to trauma or chronic arthritis and other disease processes, osteoarthritis and or other disease processes. Usually the available prostheses generally use some standard ball diameters and stem length of the humeral component. Many varieties are available including modular type with replaceable ball diameter Therefore there is a mismatch in the ball size and actual bony cavity and the prosthesis that will be inserted leading to excess bone loss during insertion in the bone which sometimes calls for an early revision surgery.**

So patient specific hemi-shoulder prosthesis was designed from the CT- scan data obtained from a specific patient. The materials used were medical grade stainless steel (316L), Ti6Al4V, Co-Cr-Mo alloy respectively. This type of prosthesis will be manufactured using computer aided manufacturing technique.

Keywords — **Full contact, shoulder prosthesis, arthritis, customization, CT-data, FE-analysis**

I. Introduction

The first shoulder replacement was performed in 1893 by a French surgeon, Pean, for a tuberculosis infection. However, it was not until the 1970's that shoulder replacements were routinely performed. Initially, implant designs were highly con-strained devices that did not accurately restore shoulder biomechanics and ultimately failed. Modern total shoulder implants allow for more motion and less constraint. A shoulder replacement involves replacing the humerus) and the glenoid with metal and plastic parts that then act as a new shoulder joint [1, 2, 3]

Shoulder joints are replaced due to traumatic injury, osteoarthritis or other disease processes. Usually the available prostheses generally use some standard ball diameters and stem length of the humeral component. Many varieties are available including modular type with replaceable ball diameter, therefore there is a mismatch in the ball size and actual bony cavity and the prosthesis that will be inserted leading to excess bone loss during insertion in the bone which sometimes calls for an early revision surgery.

Therefore a patient specific hemi-shoulder prosthesis was designed using the CT-scan data obtained from a particular patient. The materials used for design of the prosthesis were medical grade stainless steel (316L), Ti6Al4V, Co-Cr-Mo alloy respectively.

II. Material & methods

The shoulder is a multifunctional joint with a large number of functions consists of a chain of bones connecting the humerus to the trunk. The shoulder consists of scapula and clavicle and functions as a movable but stable base for the motions of the humerus. The Sterno-Clavicular joint connects the clavicle and sternum, and the scapula in its turn is connected to the clavicle by the Acromio-Clavicular joint. Another connection between the scapula and the thorax is the Scapulo-Thoraeic Gliding Plane, which constraints possible movements with two Degrees-of-Freedom (DOF) and makes the system a closed chain mechanism. There are large numbers of muscles also which control the movement of the joint. The steps involved for processing the CT-data from a specific patient of a particular bone are as shown in figure 1.

Image processing of the CT slices (in the DICOM format), obtained from local hospital with informed consent for the exact contour generation of the inner medullary cavity of the humerus were performed using the software MIMICS® and the subsequent 3D model was formed which was meshed using the Magics® software to refine the finite

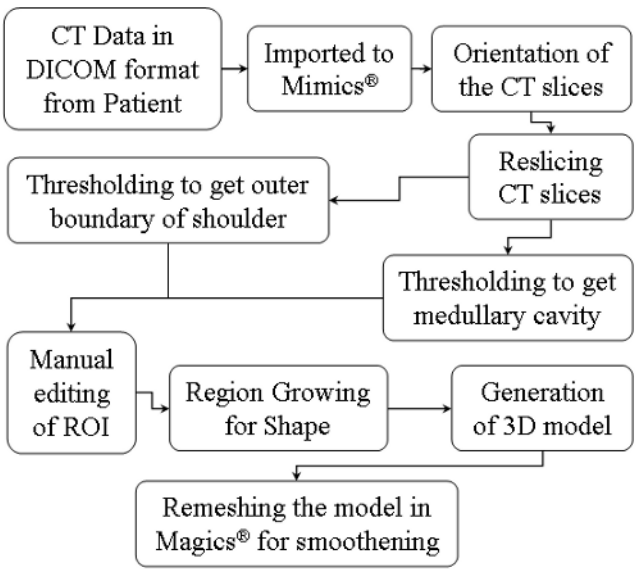

Fig. 1 Steps involved for the image processing of the CT slices

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1700–1703, 2009
www.springerlink.com

element mesh. Then it was exported to FEA-software Ansys® and then volumes were generated from these areas and meshed with 10-nodded tetrahedral element. Then this file was send to MIMICS for material property assignment based on gray values The Gray values were then converted to the Hounsfield units. The gray value is determined by the intensity of the colour. For air (colourless entity) the gray value is 0 which increases for the denser objects. The corresponding value of HU of air is –1024. Before assigning materials to the elements of the volumetric mesh, Mimics will first calculate a gray value for each element. This gray value will then be used in further calculations. MIMICS® uses an accurate method to assign gray values to elements by calculating exact intersections between voxels. The voxels are referred to those volumetric regions in a 3D region analogous to a pixel in a 2D region. While being accurate, care has been taken that the calculations can be performed efficiently.

For assigning the material property of bone a fixed value of 0.3 was given for Poisson's ratio. For assignment of material property element by element MIMICS® calculates the average gray value of all the voxel inside an element in HU and then the whole range of densities are linearly divided into the given number of groups. For each group it assigns a particular gray value of Young's modulus according the above formula. The loading conditions were adopted from the various angles of arm abduction from Van der Helm's data [4, 5] as shown in Table 1.

Table 1 Gleno Humeral Joint Reaction Force for Different Angles of Arm Abduction for Unloading Conditions (Van Der Helm 1994)

Load Case	Abduction Angle (°)	F_X(N)	F_Y(N)	F_Z(N)	Resultant Force(N)
2	30	164.46	-16.14	14.03	165.84
3	60	323.74	-3.68	-36.88	352.85
4	90	383.71	34.62	-77.28	392.95
5	120	314.03	45.56	-137.96	346.01
6	150	137.74	11.86	-134.43	192.83
7	180	39.78	-3.73	-72.51	82.79

In this study we have considered three cases for comparison and improved design 1) normal joint, 2) joint with standard prosthesis and 3) with a CT-data based customized shoulder prosthesis for a better understanding of our design.

The customized shoulder implant is designed by taking the measurement from the CT scan slices. The CT scan data collected from a local hospital were exported in image processing software MIMICS®. The slice distance was1mm and there were a total of 171 slices. The bone scale was chosen for proper visibility. The primary masking was applied with the threshold ranging from 226 to 1905 where –1024 corresponds to the gray value of air. Region growing is performed on the cortical region of the masked portion and a 3D volume is generated from this region. The polylines which were created thereafter were ex-ported as area.lis files in the finite element software Ansys for the designing of the customized implant.

The polylines which were generated by the software corresponding to the inner medullary cavity as shown in fig 2(A) were chosen and the outer polylines were deleted as in fig 2(B). Two planes mutually perpendicular to each other were drawn in order to add the innumerable small line which has been created corresponding to each of the CT slices while exporting from MIMICS®. These lines in each of the layers were then added by Boolean operation and areas were created. The coordinates of the center of the areas were retrieved and joined by spline in order to create the central axis. Four coordinates on each of the areas were chosen so that they can be joined to form segmented spline. The coordinates in the chosen layer lying in the same direction were joined by spline. Areas were created, from which volumes were generated which formed the humerus stem of the customized implant as shown in Fig. 3 A & B. The range of the Hounsfield unit in the Humerus is –1024 to 1650 (ref. MIMICS®). The computed density (ρ) from this range is

$$\rho = 689.3044 + 0.673148 \times HU \quad (1)$$

and Young's modulus(E) is given by

$$E = 689.3044 + 0.0000013 \times \rho^{3.15} \quad (2)$$

The models were solved using a PC with Intel® Pentium IV Processor (3.2 GHz, HT, 1536MB RAM) and in ANSYS®. Each of the models was solved in approximately 15 minutes. Altogether it took 11 hours for processing. The post-processing was done in ANSYS® postprocessor.

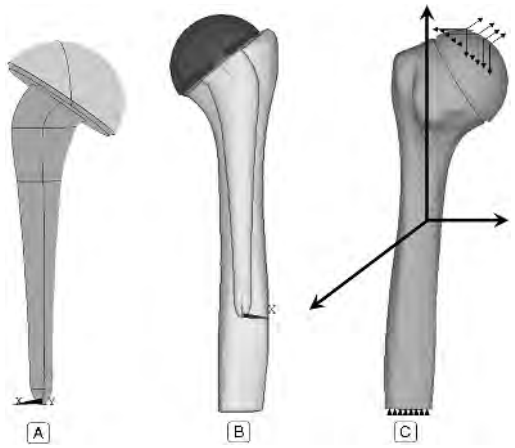

Fig. 3 (A) Designed customized prosthesis, (B) Prosthesis inserted inside bone, (C) constrained Prosthesis.

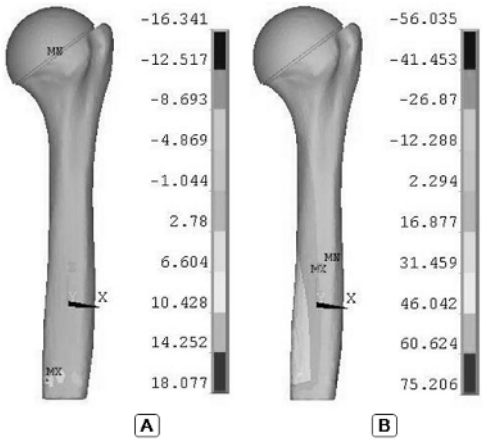

Fig. 5 Axial stress (MPa) in X (A) & Z direction (B) at 90º arm abduction in bone inserted with the customized prosthesis when the muscle forces are maximum.

III. Results & Discussion

The results of the study are quite involved and as we tried three Materials, SS316l, Ti6 Al4V and Co-Cr-Mo alloy. It was found that the materials didn't change the stress pattern significantly. We are showing the variation of the shear stress in Fig.4 and Fig.5 at 30º and 60º arm abduction using different materials as indicated. Similarly Normal, stress and Von Mises stress criteria for failure were also calculated for the normal humerus and humerus with standard prosthesis inserted and newly designed customized implant with the three different materials.

Now the corresponding Von-Mises stress on fig.6 (A) the customized prosthesis was depicted in the below and (B) VM-strain of Co-Cr-Mo. Alloy.

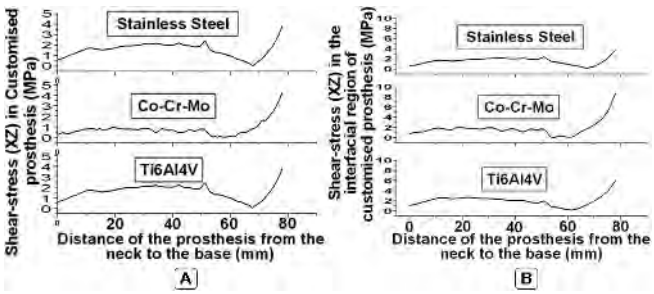

Fig. 4 (A) Variation of Shear stress (XZ) in standard prosthesis and 4(B) the customized prosthesis of the materials.

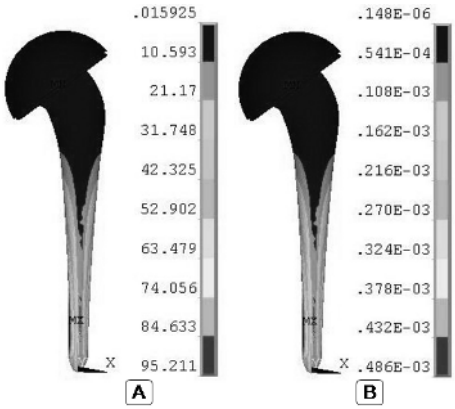

Fig. 6 (A) Von-Mises stress & (B) Von-Mises strain.

Table 2 Maximum Von-Mises stress in customized prosthesis During 90º arm abduction

Abduction Angle (º)	Von-Mises Stress (MPa)		
	Co-Cr-Mo	Stainless Steel	Ti6Al4V
30	64.706	95.34	55.565
60	131.47	118.07	58.164
90	169.6	95.34	10.104
120	245.04	132.65	58.164
150	61.802	--	--

From all these results we may infer that the effect of load transfer along the humerus, using a detailed 3-D Finite Element Analysis (FEA) showed a variation of stress along the length of the normal humerus from 2.0MPa to 20 MPa. For the stress-strain analysis of the surgical construct the prosthesis was inserted in the humerus. The failure criterion

von-mises stress in the interfacial nodes between the inserted Co-Cr-Mo prosthesis and the normal bone were in the range 18.0MPa to 245.0MPa, for S.S prosthesis was between 90.0 MPa to 130.0 MPa while for the Ti6Al4V was between 10.0MPa to 95.0MPa. Thus for all the above cases it is lesser than the corresponding yield stress of the metals and bone used, which ensures the safety of the construct under the subjected loading conditions. Only this prosthesis needs to be made using CAD technique. Now we are working on parametric model generation directly from the CT-data, getting the whole dimensions of the medullary cavity and ball diameter & length.

Acknowledgment

We gratefully acknowledge the Department of Science & Technology, New Delhi, Government of India for funding the project & CNCRI, Kolkata for providing CT-data.

An Interface System to Aid the Design of Rapid Prototyping Prosthetic Socket Coated with a Resin Layer for Transtibial Amputee

C.W. Lai[1], L.H. Hsu[1], G.F. Huang[2] and S.H. Liu[1]

[1]Department of Mechanical Engineering, National Cheng Kung University, Taiwan
[2]Department of Physical Therapy, Fooyin University, Taiwan

Abstract — **For employing the technology of rapid prototyping (RP) to fabricate prosthetic socket for transtibial amputee, a CAD stump model must be constructed. Currently, the commercial CAD systems need experienced skills to define objects. To simplify the construction procedure of stump model and easily used by a prosthetist, an interface system for the specific purpose of defining stump model should be developed. The main objective of this study is to improve the tedious process and quality uncertainty of conventional method to produce prosthetic sockets. This study developed an interface system that allows a prosthetist to modify the shapes of stump model so that the acceptable pressure distribution on pressure tolerant (PT) and pressure relief (PR) areas can be achieved.**

This study used C++ programming language and Open Graphic Library to develop an interface system. The point data of stump surface obtained by a T-scan system, which includes a hand-held 3D laser scanner and tracking system, is utilized to build the original shape of the stump. The primary shape of stump model is modified based on the requirements at the PT and PR areas of the specified amputee. As soon as the contact pressures between stump and socket are verified by finite element analysis, the modified stump model can be used to design a specific CAD socket model for the production using a RP machine.

This interface system directly used a file of scanned points to build a stump shape and also provided the functions to identify the shapes of PT/PR areas. The modification requirements, including designations of the regions to be modified and the distances to be indented or raised, can be easily manipulated through appropriate interface dialogs. After a RP socket model has been designed, the socket is manufactured using an FDM machine. To reinforce the strength, the RP socket is coated with a resin layer. The measurement of contact pressures has been implemented and its trial use is under way.

Keywords — **CAD, transtibial prosthetic socket, rapid prototyping, C++ programming.**

I. Introduction

In the traditional process of fabricating prostheses, there are many factors will effect the quality of fit. A shape of the residual limb is acquired by using plaster bandages. And a plaster positive model of the residual limb is made from plaster bandages. Plaster may then be added to the pressure relief areas which are sensitive and removed from the pressure tolerant areas which are loaded for weight bearing of the model. The modification of the plaster depends on the skill and expertness of the prosthetist.

CAD/CAM techniques had been viewed as a solution to reduce errors in the fabrication process [1]. This study employed reverse engineering to replace the plaster method to design and fabricate a prosthetic socket [2]. The prosthetic socket can be produced from a CAD model accurately and quickly by using rapid prototyping (RP) technology [3]. However, current CAD systems are not friendly for a prosthetist to operate. If a custom-made interface system is available and easily operated by any user such as a prosthetist, the prosthetic socket may then be fabricated conveniently.

II. Methods

A. Scanning

Employing the reverse engineering technology, the fist step is to acquire the point data of the shape by scanning the subject. The point data is the basis for subject construction. Therefore, how to measure the subject is the key to subsequent work.

In previous study, the point data of stump was acquired by using the CCD (Charge Coupled Device) laser scanner to scan the shape of gypsum positive model. As a result that the CCD laser scanner can't revolve around the subject, it was necessary to revolve the subject to complete the scanning mission. After all the gypsum positive model is just a rough copy of the stump. The credibility of the point data needed to improve.

With technology developing, the T-scan which is a hand-held laser scanner can scan the shape of subject easily and quickly (Fig. 1). Using the T-scan to scan the shape of stump directly improves the credibility of the point data of stump. The amputee just sits on a seat and doesn't need to change his/her posture. Taking the T-scan along the shape of stump, at the same time, the point data had be obtained will display on the monitor. It is easy to perceive the contrast between the point data acquired by using a CCD laser scanner to measure the gypsum positive model and using the T-scan to measure the stump directly.

www.springerlink.com

Fig. 1 Scanning the stump using T-scan

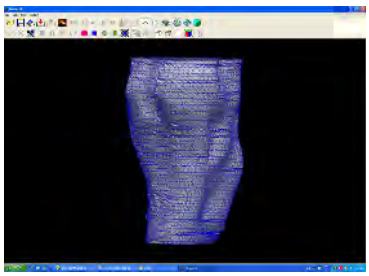

Fig. 2 Constructing the residual limb

B. Filtering the point data

Since there would be millions of point in the point data acquired by the T-scan, it is necessary to preprocess the point data. Filtering the trivial and unnecessary points in the point data benefits the stump model reconstruction. In order to simplify the operation when importing the point data to interface system and modifying surface of stump, the point data had been divided to multi-layer and every layer must have the same number of points.

C. Constructing the stump surface model

After a preprocessing process, the point data is imported to the interface system and the stump surface model will be constructed (Fig. 2). The stump surface model is constructed by many small triangle meshes. Changing the position of points will make the shape of stump to change. Using this method the socket surface will be designed from changing the stump surface.

D. The interface system

This study applied C++ program language and OpenGL to develop an interface system that can design the surface model of the socket. In order to achieve construction and modification of stump surface model, this interface system has following functions:

1. The function of point data reading. Point data is indicated by space parameters X, Y, Z. By reading the point data, the model can be constructed on the window.
2. The function of surface modification. The interface is capable of controlling the modification value and the smooth of surface after modification.
3. The model after construction and modification can be read and modified by other CAD software.

Program operation is reading point data to construct the surface model of the stump. And then users can define the shape and location of modification areas. After giving the maximum modification displacement, the program will let modification displacement of each point smaller than max modification displacement to keep the modification surface smooth. The modified model can be saved for fabricating (Fig. 3).

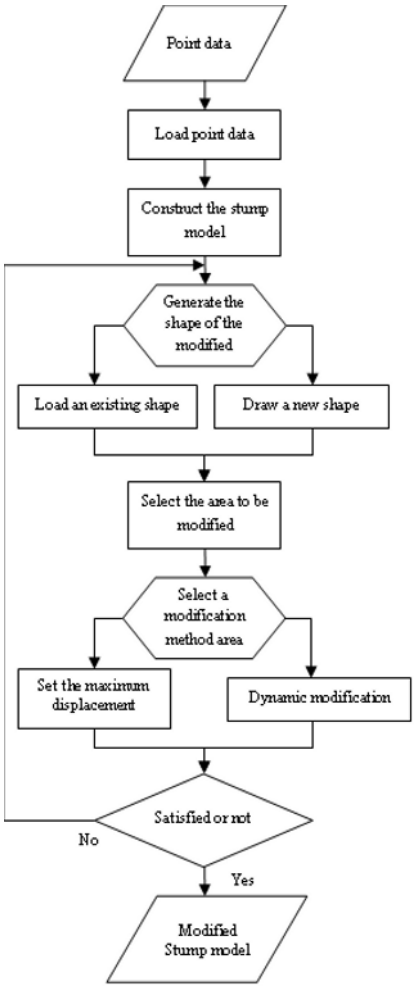

Fig. 3 Operating procedure of the interface system

III. Case Study

A. Acquiring the point data of a stump

After scanning the shape of the patient's amputation, the point data of a stump would be acquired. The point data preprocessing includes planar sectioning (Fig. 4) and filtering which is provided by CATIA; planar sectioning divides the point data divided into multi-layers, and filtering lets the point data have the same number of points per layer. Then, the data saved by CATIA is changed into TXT format (Fig. 5), the number of layers is inputted in the first row and the number of points per layer in the second row.

B. Modification of the stump shape by using the point data

The point data is imported into the interface system after preprocessing and reconstructed model of the patient's stump (Fig. 2). According to PR and PT areas of the stump, the appropriate shape and location are chosen to modify the surface of the stump. The PR areas should be offset outward of the stump surface, while the PT areas should be offset inward of the stump surface. For example, at Patellar tendon, PT area, choose a rectangle to fit the area and offset inward with an appropriate displacement (Fig. 6). The modified areas in this study include the Tibia, Fibula, Patella Tendon and Calf muscle (Fig. 7).

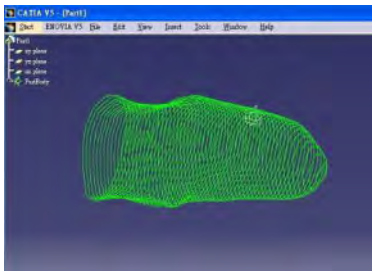

Fig. 4 Planar sections of the point data

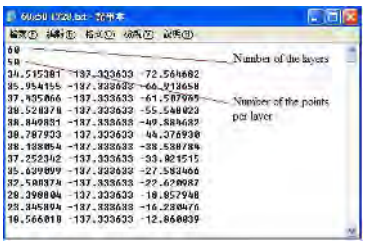

Fig. 5 File format of the data utilized in this study

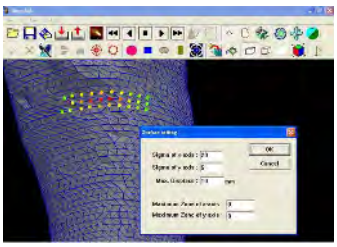

Fig.6 Modification of patellar tendon

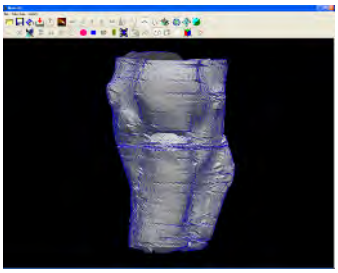

Fig.7 The modified stump model

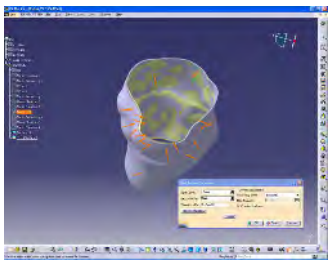

Fig. 8 Building the solid model of a prosthetic socket

C. Design of a socket model

The modified stump surface is imported to CATIA to design a socket. Because a patient would wear socks on their stump before putting on the prosthetic socket, there should be a gap between the stump and the prosthetic socket. This study designated 4.5 mm for the gap. The modified stump surface is offset 6 mm to form the outer surface of a prosthetic socket. The solid model of the prosthetic socket is obtained by shelling the outer surface with 1.5 mm. (Fig. 8). For connecting an adapter and a shank, the bottom of the socket should be made with a specific shape. As soon as a socket model is determined, a STL file is transferred to a rapid prototyping machine for fabricating prosthetic socket (Fig. 9). This preliminary RP socket is then coated with a resin layer for reinforcing its flexural strength.

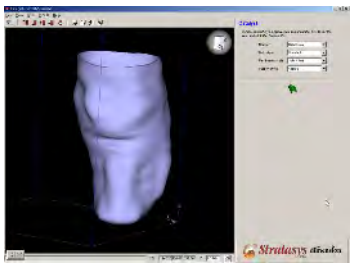

Fig. 9 Importing socket model into the slicing software for an RP machine

IV. Conclusions

This study developed a method together with a prototype interface system for surface modification during the design of a prosthetic socket. The interface system provided the following features:

1. The interface system demonstrated that a prosthetic socket can be designed using the scanned points of a stump. A preliminary socket is then fabricated by a RP machine using the socket model (Fig. 10). This preliminary RP socket is wrapped with a layer of resin to reinforce it strength (Fig. 11). The resin-reinforced socket has been worn by the specific amputee for trial use and the interface pressures between socket and stump has been measured.
2. The interface system allows a prosthetist to designate the required modification displacement and the corresponding modified shape can be acquired. The shape to be modified can be adjusted by five parameters that represented the weighting values of the space. This method is quicker than using control points to modify surfaces.
3. This interface also helps to shorten the training time of a prosthetist and to modify pressure-tolerant and pressure-relief areas more easily.
4. This interface can store the digitized socket model, which can be used to fabricate a new socket at the patient's request.

Since the interface system only provides shape modification, other functions needed in the socket design process, such as shelling the surface model of a stump to form a solid model, and the detailed shape at the end of a socket, should be developed.

Abstract — **Pathological changes in soft-tissues are primarily correlated with changes in their mechanical and electrical properties and are used to differentiate diseases from normals. Although there are evidences that establish the association of electrical and mechanical properties in biological aspects, their interrelationships are not well established. In this work, an attempt has been made to correlate electrical impedance of soft tissue-mimicking phantoms with those of its mechanical properties. The electrical property of the polyacrylamide gel phantoms prepared as per the standard protocol was studied using a precision impedance analyzer. Tensile tests were conducted using an universal testing machine and the derived mechanical properties such as breaking stress, breaking strain, initial modulus and Young's modulus were correlated with impedance values. It was observed that for a given concentration of a gel phantom the percentage variation in impedance correlate well with the percentage variation in the Young's modulus. The magnitude of variation in Young's modulus found to be more than that of the impedance. Similar correlations were observed for other mechanical properties. It appears that this study seems to be useful as the research on tissue mimicking phantom gels play important role in mechanical studies and in ultrasonic bioeffects. In this paper the objectives of the study, methodology and the significance of results are discussed in detail.**

Keywords — **palpation, mechanical properties, electrical impedance, soft tissue, polyacrylamide gel.**

I. Introduction

Physicians and surgeons evaluate the tissue behavior to diagnose medical conditions; any changes in tissue condition are seen as indicators of disease or illness. One of the primary interests of the physician is to examine the tissue stiffness or elastic modulus, a property pertaining to the material's resistance to deformation. This assessment of tissue stiffness is known as palpation and relies on the qualitative determination of tissue elasticity by the physician [1]. Several diseases are known to alter the mechanical properties of soft tissues.

During many abdominal operations palpation is used to assess organs, such as the liver, and it is not uncommon for surgeons to palpate tumors that were undetected previously by classic imaging methods such as CT, MRI, or B-scan ultrasound because none of these methods currently provide the type of information elicited by palpation. These findings imply that measurement of mechanical properties of tissues has a potential to offer a new method of classification of tissues [2].

Many tissue-mimicking phantoms have been developed and researchers have emphasized that these tissue-mimicking phantom gels play important roles in research on biomedical applications. Characterizing the mechanical behavior of small tissue samples and tissue-like phantoms can significantly contribute to better elasticity imaging algorithms [3]. Polyacrylamide gels are similar to tissues in many respects [4].

There are evidences that establish the association of electrical and mechanical parameters in biological aspects. The electrical activity of the heart generates an active tension that causes the heart to deform. It is therefore clearly evident that the mechanical activity of the heart is heavily dependent on the electrical activity. In turn, the mechanical activity affects the propagation of electrical activity [5].

The purpose of this study is to correlate the electrical impedance of polyacrylamide based soft tissue mimicking phantoms with their mechanical properties.

II. Materials and Methods

A. Description of the phantom

Polyacrylamide based tissue mimicking phantoms are chemical gels which are obtained through chemical reactions [4]. The gels are formed by co-polymerization of acrylamide and bis-acrylamide. A free radical generating system initiates the reaction. Polymerization is initiated by tetramethylethylenediamine and ammonium persulphate. Tetramethylethylenediamine acts as an electron carrier and activates the acrylamide monomer thus providing an unpaired electron to convert the acrylamide monomer to a free radical. The activated monomer reacts with the unactivated monomer to begin the polymer chain reaction. The polymer chains are crosslinked by bis-acrylamide, forming a complex web polymer which depends on the polymerization conditions and monomer concentration. To attain good repeatability in gel formation, the concentration of the ini-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1708–1711, 2009
www.springerlink.com

tiator, temperature, and pH must be controlled. Certain factors like impurities in the chemicals and water lead to incomplete gel formation. Polyacrylamide gels can be prepared to match the mechanical properties of different real tissues by changing the acrylamide concentration.

B. Preparation of 20% acrylamide gel

A 20% polyacrylamide gel requires a mixture of 19g acrylamide (extra pure) and 1g bis-acrylamide (extra pure) in 100ml deionised water. Ammonium persulphate and TEMED (N,N,N',N'-tetramethylethylenediamine) was added to initiate and catalyze the polymerization reaction.

C. Mechanical testing

The mechanical properties of the phantoms were measured using an Instron model 3367 dual column testing system equipped with a 10kg load cell and interfaced to a desktop PC. The phantom samples were cut using a fly type pillar press into flat dumbbell shaped specimens of gauge length 60mm, width 6.43mm and thickness 5.04mm. Tensile test was performed on the phantoms with the crosshead speed set to 0.25mm/min. Based on the destructive mechanical tests performed on the phantoms of various concentrations ,the mechanical properties such as breaking stress, breaking strain, initial modulus and Young's modulus were determined at a temperature of 25°C.

D. Electrical testing

The electrical and dielectric parameters such as resistance, capacitance, impedance and phase angle of the tissue mimicking phantoms were measured at a frequency range of 100 KHz to 110 MHz using a 4294A Precision Impedance Analyzer equipped with a two electrode system comprising of copper electrodes. The phantoms were cut into structures of dimensions 60mm x 6.43mm x 5.04mm. The electrical and dielectric properties of the polyacrylamide phantoms were measured for different concentrations ranging from 20 to 40 percent. The dimensions of the samples were kept the same for all the concentrations and investigations were conducted at a temperature of 25°C. In this study, the entire analysis was made using the electrical impedance specifically measured at a frequency of 100 KHz.

III. Results

In FIG 1, the percentage variation in electrical impedance and breaking stress is shown as a function of gel concentration ranging from 20 to 50 percent. It can be seen that the

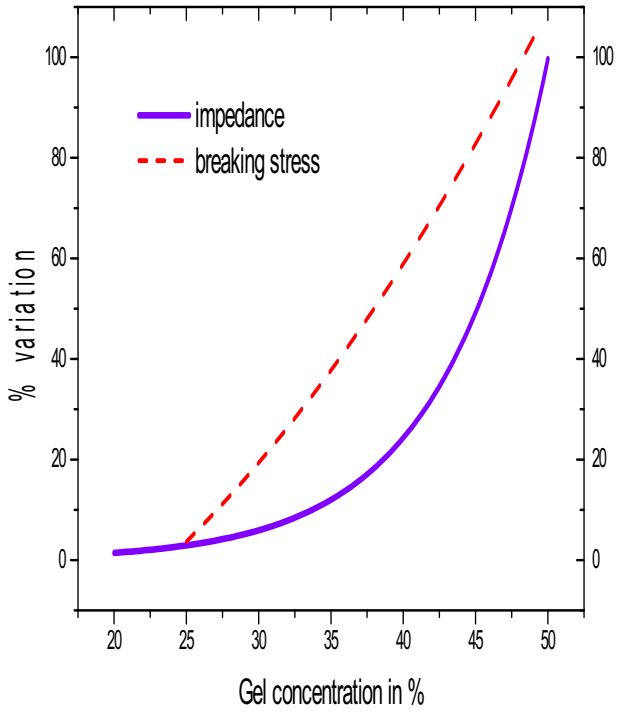

Fig. 1 Impedance and breaking stress Vs gel concentration

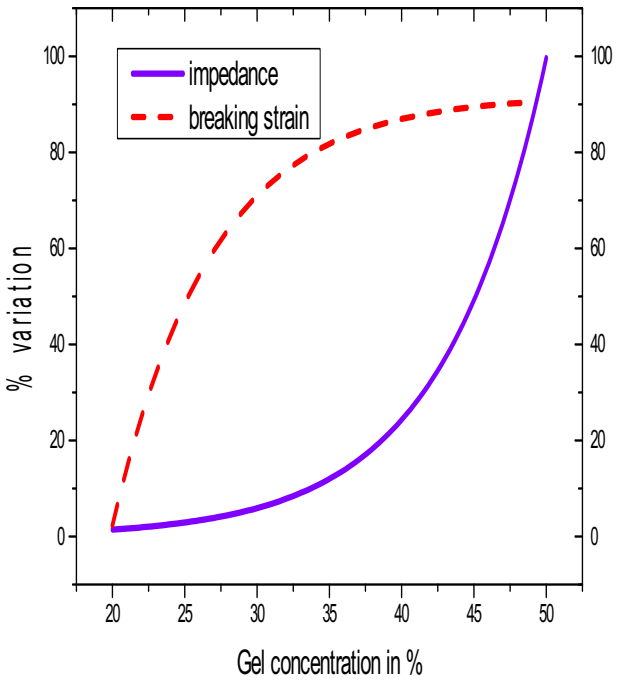

Fig. 2 Impedance and breaking strain Vs gel concentration

percentage variation in breaking stress increases linearly for a linear increase in gel concentration ranging. The percent-

age variation in impedance increases exponentially for the same concentration range. The correlation coefficients were calculated using the Pearson correlation method. The breaking stress correlates with the electrical impedance with an R value of 0.88.

The percentage variation in electrical impedance and breaking strain is shown in FIG 2 as a function of gel concentration ranging from 20 to 50 percent. It was observed that the percentage variation in breaking strain increases nonlinearly with respect to the gel concentration. The breaking strain correlates with the electrical impedance with a correlation value of 0.64.

In FIG 3, the percentage variation in electrical impedance and initial modulus is shown as a function of varied gel concentrations. The percentage variation in initial modulus increases linearly with increase in gel concentration. The initial modulus correlates with the electrical impedance with an R value of 0.89.

The percentage variation in electrical impedance and Young's modulus is shown in FIG 4 as a function of gel concentration ranging from 20 to 50 percent. The percentage variation in Young's modulus increases linearly with increase in gel concentration. In all the above cases, the percentage variation in impedance increases exponentially. A correlation value of 0.88 was found between the Young's modulus and electrical impedance.

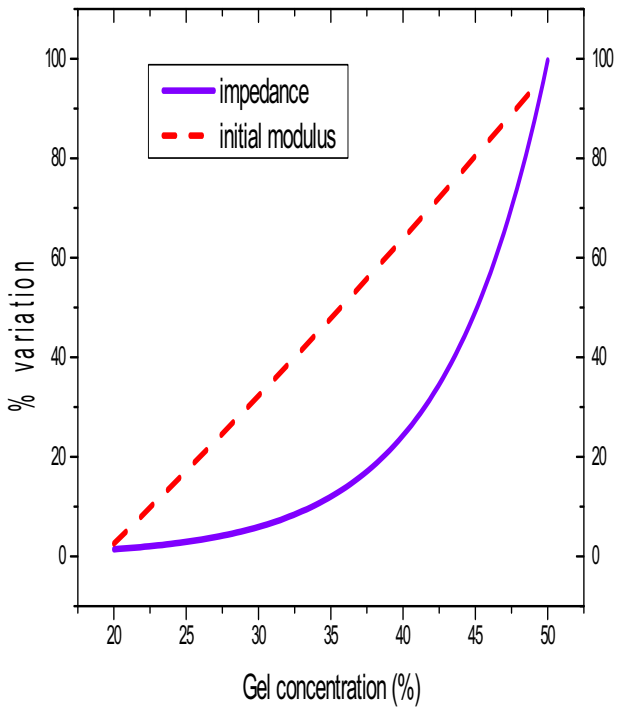

Fig. 3 Impedance and initial modulus Vs gel concentration

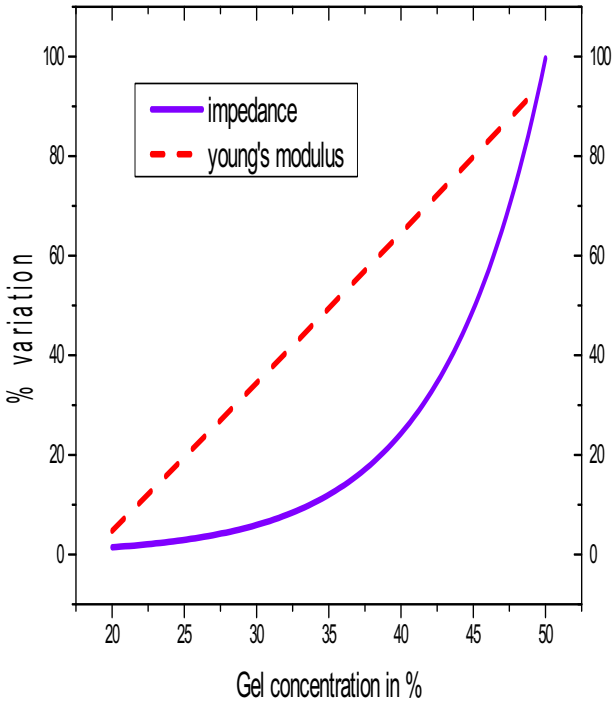

Fig. 4 Impedance and young's modulus Vs gel concentration

IV. Conclusions

Intact electrical and mechanical behavior of tissues is essential for proper physiological function. High degrees of correlations between electrical and mechanical properties have been shown in several cases such as in cardiac tissues. However, very few results are available on the correlation of electrical and mechanical behavior of soft tissues. In this work, an attempt has been made to correlate the electrical properties of tissue mimicking phantoms with mechanical properties. Tissue mimicking phantoms were prepared such that its mechanical properties fall in the physiological range to match the properties of tissues such as that of liver. The impedance measured on phantoms are correlated with breaking stress, breaking strain, initial modulus and Young's modulus in polyacrylamide gels. Results demonstrate that the changes in electrical impedance correlate well with Young's modulus, initial modulus and breaking stress. Hence, it appears that these studies are clinically useful as these gels are found to be similar to real tissues in many aspects.

Biomechanical Analysis of Influence of Spinal Fixation on Intervertebral Joint Force by Using Musculoskeletal Model

H. Fukui[1], J. Sakamoto[1], H. Murakami[2], N. Kawahara[2], J. Oda[1], K. Tomita[2] and H. Higaki[3]

[1] Graduate School of Natural Science and Technology, Kanazawa University, Kanazawa, Japan
[2] Kanazawa University Hospital, Kanazawa, Japan
[3] Faculty of Engineering, Kyusyu Sangyo University, Fukuoka, Japan

Abstract — **Evaluation of the intervertebral joint force in vivo is very important for clinical spine problems, for example, spinal instability, disorder of intervertebral disc, compressive fracture of osteoporotic vertebra, etc. Direct measurement of the joint force is difficult to get permission, so computational method to calculate the force is expected. Spine structure is mainly constructed of many vertebrae and flexible intervertebral disks, and it is unstable by itself under standing condition. Supporting by erector muscles and ligaments keep the spine standing condition, so that loading condition of each vertebra depend on the muscle and ligament forces. Biomechanical analysis of musculoskeletal system taking into account of large number of muscle and ligament forces is necessary to determine the intervertebral joint force. Commercial software to deal with the musculoskeletal system is available nowadays, and it has been applied to clinical, ergonomic or sport biomechanics problem.**

Surgery of spinal fixation is frequently operated for instability or disorder of intervertebral joints. Although stability of the joints is recovered and nervous symptom related with the disorder joints is relieved, additional trouble at adjoining joints with the fixation is concerned because excessive rigidity and posture change by the fixation makes load of the adjoining joints increase. It is required to evaluate the change of adjoining joint force by the fixation, to prevent additional trouble in advance. In this study, analysis of intervertebral joint force and muscle force was performed in the case with or without spinal fixation using full body musculoskeletal model developed by the AnyBody Modeling System (AnyBody Technology). The joint and muscle forces were evaluated under various posture of flexion and extension. Then influence of the spinal fixation on the intervertebral joint force at adjoining joints with the fixation was discussed.

Keywords — **Biomechanics, Musculoskeletal Model, Spine, Spinal Fixation, Adjoining Vertebra**

I. Introduction

Compression of spinal cord due to spinal instability, disorder of intervertebral disk causes pain and palsy. To eliminate pressure on nerve and reduce symptoms, surgery on vertebral bone and disk is carried out. In such case, surgery fixing unstable vertebrae or intervertebral joint with rod and screw is frequently operated. This is the spinal fixation. Although stability of the joints is recovered and nervous symptom related with the disorder joints is relieved, additional trouble is caused at unfixed joints after surgery. Especially at adjoining joints with the fixation, deformations of vertebral bone and intervertebral disk are frequently caused. Additional surgery of spinal fixation is required in such case. The trouble is concerned because excessive rigidity and posture change by the fixation makes load of the adjoining joints increase. It is required to evaluate the change of adjoining joint force by the fixation, to prevent additional trouble in advance.

However, direct measurement of the joint force is difficult to get permission, and computational method to calculate the joint force is difficult because loading condition of each vertebra change by large number of muscle and ligament forces depended on posture at the time. With the recent development of computational mechanics technique, a more realistic biomechanical analysis become possible, and commercial software to deal with the musculoskeletal system is available. Evaluation of the intervertebral joint force using full body musculoskeletal model is available, too.

In this study, to evaluate spinal fixation influence on vertebral loading condition, we analyzed intervertebral joint force and muscle force performed in the case with spinal fixation using full body musculoskeletal model. The joint and trunk muscle forces were calculated under various posture of flexion and extension. And then, we discussed the influence of the spinal fixation on the intervertebral joint force.

II. Analysis Method

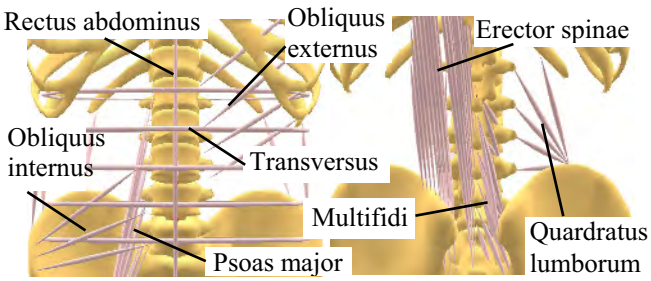
A. The AnyBody Modeling System

Musculoskeletal model was developed using the simulation software the AnyBody Modeling System (AnyBody Technology Inc.). This software handles model of human body mechanism, and the application area is medical, rehabilitation, ergonomic, sports or astronautical engineering, etc. By using the AnyBody Modeling System, we can de-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1712–1715, 2009
www.springerlink.com

velop 3-D musculoskeletal model by a script language called AnyScript. Model consists of segments regarded as bones or rigid elements, joints connecting segments, and muscle-tendon units having physiological characteristics. Driver modules of the AnyScript create posture and movement of joints. The AnyBody Modeling System calculates the joint and muscle forces from giving posture and external load by inverse dynamic analysis.

B. Analysis model



Analysis model was developed based on the Standing Model (the AnyBody Research Project, Aalborg University, Aalborg, Denmark, http://www.anybody.aau.dk/repository) which was human full body musculoskeletal model (Fig. 1).

(a) (b) (c)

Fig. 1 Analysis model : (a) 30 degrees extension posture, (b) upright posture, and (c) 45 degrees flexion posture.

Total number of muscle fascicles defined in this musculoskeletal model is 476. In trunk of model 158 fascicles were defined and divided into eight muscles (Fig. 2). Four abdominal muscles were included : rectus abdominus, transversus, obliquus internus and obliquus externus. Quadratus lumborum, psoas major, erector spinae and multifidi were defined as muscles of the lower-back [1].

(a) (b)

Fig. 2 Trunk of model in (a) front view and (b) back view. Eight muscles are defined as trunk muscles.

Spine model is composed of nine segments : sacrum, five lumbar vertebrae, T12, T11 and a lumped thoracic part over T10. Spherical joint with three degrees of freedom was set between every vertebra from T10 to sacrum(Fig. 3). These intervertebral joint angles were varied in according to spinal alignment or posture. Height of the model is set as 1.72m and weight is 63kg assuming a standard Japanese male.

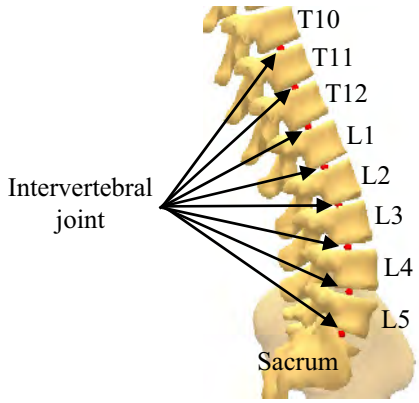


Fig. 3 The dots show the location of the rotational center of the intervertebral joints between the vertebrae.

C. Spinal fixation model

Spinal compression fracture is commonly caused on thoracolumbar vertebrae. Disk hernia or spondylolisthesis is frequently caused on lumbar. So, two cases are assumed as model with spinal fixation. One is case that thoracolumbar vertebrae is fixed, another is case that lumbar vertebrae is fixed. T12, L1 and L2 are fixed in the thoracolumbar vertebrae fixed model. L3, L4 and L5 are fixed in the lumbar vertebrae fixed model. Intervertebral joints between fixed vertebrae have no degrees of freedom in the model. Fixed vertebrae moved together as a rigid element when posture of the model was changed.

D. Analysis condition

Upper body angle of the model was changed from 45 degrees flexion to 30 degrees extention with 15 degrees interval. Posture of the model was set by changing intervertebral joints and hip joint angles. Joint angles of each posture in no fixation model were defined by using radiograph images of lumbar spine taken from a young male[2]. In case of the spinal fixation model, we gave larger joint angle to unfixed joints to compensate for lack of movement of fixed joints. Compensate joint angle were distributed equally among unfixed joints. We calculated intervertebral joint force and trunk muscle force in the case

with or without spinal fixation under each posture of flexion and extension. Influence of the spinal fixation on the intervertebral joint force at adjoining joints with the fixation was discussed.

The solution of the muscle recruited problem is minimization of the maximal muscle activity under constraints of the static equilibrium equations. Muscle activity means muscle force divided by the maximal isometric muscle force at each muscle's current working condition. The solution is equivalent to minimum muscle fatigue and it is computationally-efficient[3].

III. Analysis Result

A. Influence on trunk muscle

Influence of spinal fixation on back muscles is larger than one on abdominal muscles. Muscle forces of the back are shown in Fig. 4. These graphs show muscle forces comparing the cases of thoracolumbar vertebrae fixed, lumbar vertebrae fixed and no fixed. Analysis results of no fixation model show quadratus lumborum and psoas major work a lot in extension posture. Erector spinae works mainly in flexion posture and multifidi brings force in deep flexion posture. In flextion of 30-degree and 45-degree, multifidi muscle force of thoracolumbar vertebrae fixed model is larger than no fixation. Forces of the every back muscle of lumbar vertebrae fixed model are not larger than no fixation. So influence on muscle maintaining flexion posture is larger in case of thoracolumbar vertebrae fixed than case of lumbar vertebrae fixed.

In extension posture of 30-degree, quadratus lumborum and multifidi muscle force became significantly larger by lumbar vertebrae fixed. Lumbar vertebrae fixation increase quadratus lumborum muscle force by about threefold, and multifidi muscle force by more than fourfold when upper body is extended. Every muscle of thoracolumbar vertebrae fixed model show little change. Therefore, influence on muscle maintaining extension posture is larger in case of lumbar vertebrae fixed than thoracolumbar vertebrae fixed. In extension posture of 15-degree, psoas major muscle force is larger than other postures, because this posture is unstable in which hip joint angle is large in extension direction and spine is bended in flexion direction. Especially, multifidi is most affected by spinal fixation, because it is located deep muscle layer and attached between lumbar vertebrae. It is thought that excessive muscle force affect on muscle near vertebrae due to spinal fixation.

B. Influence on intervertebral joints

Intervertebral joint forces in flexion 45-degree are shown in Fig. 5. This graph shows joint forces in vertebral axial direction about the cases thoracolumbar vertebrae fixed, lumbar vertebrae fixed and no fixed. L5-sacrum (L5-S) and L4-L5 joint force of thoracolumbar vertebrae fixed model are larger than no fixation model. Therefore loading of sacrum and lower lumbar vertebrae is increased. This is caused by changing a moment arm from lower vertebrae to

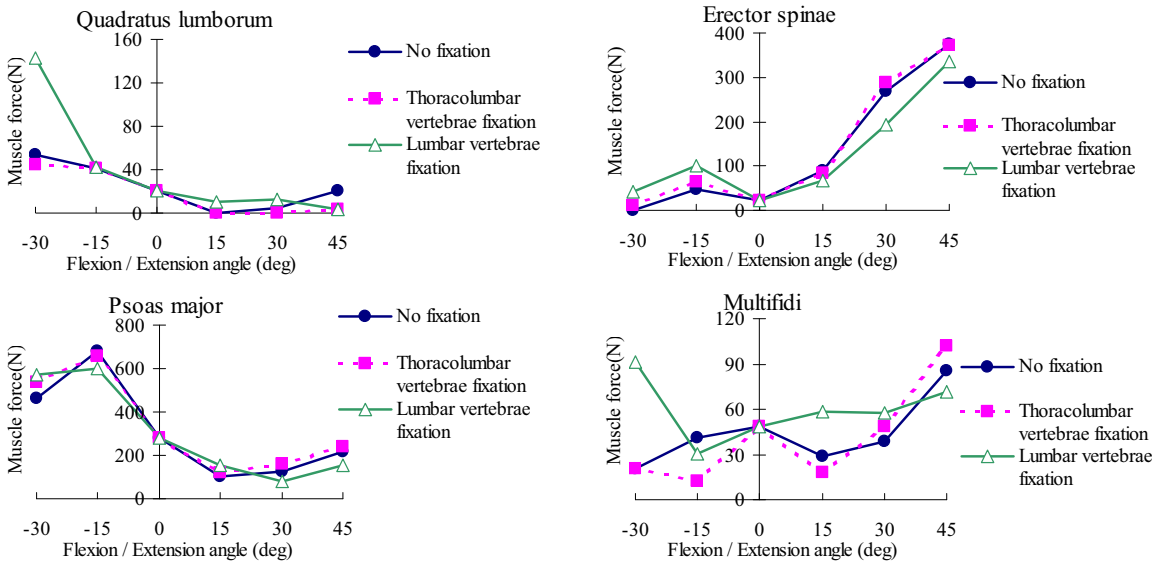

Fig. 4 Muscle forces of the back compared of the cases no fixation, thoracolumbar vertebrae fixation and lumbar fixation. Flexion angle is written positive value and extension angle is negative value.

center-of-gravity of the upper body. In flextion of deep angle, joint force of thoracolumbar vertebrae fixed model is increased. Consequently, influence of spinal fixation on intervertebral joint seems larger in lower vertebral joint when the upper body is flexed deeply.

Intervertebral joint forces in extension 30-degree are shown in Fig. 6. Joint forces on L5-S and L2-L3 of lumbar vertebrae fixed model are considerably larger than no fixation, and the force in L2-L3 joint of thoracolumbar vertebrae fixed model is greatly increased. These joints are adjoining to fixed vertebrae. Influence on adjoining intervertebral joints in flexion of 45-degree and extension of 30-degree are shown in Table 1. In thoracolumbar vertebrae fixed model, upper side of fixation is T11-T12 joint and its bottom side is L2-L3 joint. In lumbar vertebrae fixed model, upper and bottom of fixation is L2-L3 and L5-S joint. Although forces of adjoining joints in flexion posture are increased little, those in extension posture are increased at about 20% and 30%. Loading of adjoining vertebrae and disk might be greatly increased and develop disorders when a patient with spinal fixation takes extension posture.

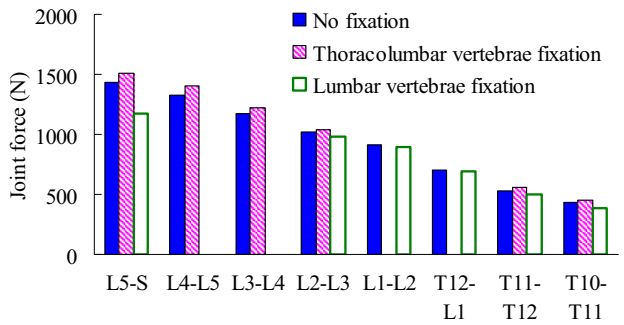

Fig. 5 Joint forces in vertebral axial direction in flexion 45-degree. Comparison of with and without fixation.

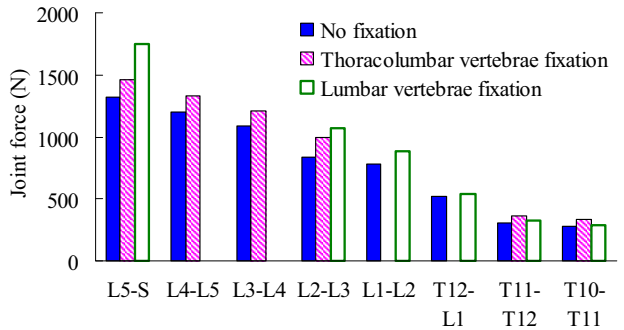

Fig. 6 Joint forces in vertebral axial direction in extension 30-degree. Comparison of with and without fixation.

Table 1 Influence on intervertebral joint adjacent to fixed vertebrae

Fixed part	Changes of joint force			
	Flexion of 45-degree		Extension of 30-degree	
	Upper side	Bottom side	Upper side	Bottom side
Thoracolumbar	+30N (+5.66%)	+20N (+1.96%)	+58N (+19.0%)	+167N (+20.0%)
Lumbar	-44N (-4.31%)	-260N (-18.2%)	+237N (+28.5%)	+430N (+32.6%)

IV. Conclusions

In this study, we analyzed influence of the spinal fixation on the intervertebral joint force using full body musculoskeletal model developed by the AnyBody Modeling System. Following conclusions were obtained.

(1) Excessive forces were produced in muscles near and attached lumbar vertebrae by spinal fixation.

(2) Which vertebra and muscle act big force depends on spinal fixation level and patient's posture.

(3) In flextion of deep angle, loading of lower lumbar vertebrae was increased when thoracolumbar vertebrae were fixed. It is recommended to avoid taking deep flexion posture for patients with thoracolumbar vertebrae fixation.

(4) Under extension posture, loading of adjoining vertebrae and disk with the fixation were greatly increased and subject to additional disorders. It is recommended to avoid taking excessive extension posture for patients with spinal fixation.

Although we described only spinal fixation in this paper, biomechanical analysis of musculoskeletal system will be applied many orthopedic problems. Significantly contribute will be expected for orthopedic therapies.

Abstract — **Anterior cruciate ligament injury is highly prevalent in activities that involve large and rapid landing impact loads. We hypothesize that restraining anterior tibial translation or axial tibial rotation can prevent the anterior cruciate ligament from failing at the range of peak compressive load that can induce ligament failure when both factors are unrestrained. Sixteen porcine knee specimens were mounted onto a material-testing system at 70-deg flexion. Single 10-Hz haversine impact compression was successively repeated with incremental actuator displacement until ligament failure/visible bone fracture was noted. During impact compression, rotational and translational data of the knee joint was obtained using motion-capture system via markers attached to the setup. Specimens were randomly classified into four test groups: Q (unrestrained setup), A (anterior tibial translation restraint), R (axial tibial rotation restraint) and C (combination of both restraints). The same impact protocol was applied to all specimens. Q specimens incurred anterior cruciate ligament failure in the form of femoral avulsion; the peak compressive forces during failure ranged from 1.4-4.0 kN. A, R and C specimens underwent visible bone fracture with ligament intact; the peak compressive force during fracture ranged from 2.2-6.9 kN. The posterior femoral displacement and axial tibial rotation for A and R specimens respectively were substantially lower relative to Q specimens. Both factors were significantly diminished in C specimens but the peak compressive force was larger compared to Q specimens. Significant restraining of these factors was able to prevent anterior cruciate ligament failure in an impact setup that can induce ligament failure with the factors unrestrained.**

Keywords — **Injury prevention, anterior cruciate ligament failure, compressive impact, tibial translation, axial rotation**

I. Introduction

Anterior cruciate ligament (ACL) ruptures has been estimated at 95,000 cases annually in the United States with associated treatment costs of almost one billion dollars [1]. ACL injury is highly prevalent in sports involving large and rapid landing impact loads, such as basketball and skiing. The ACL serves as primary and secondary restraints to anterior tibial translation and axial tibial rotation respectively [2]. Hence, excessive anterior tibial translation and axial tibial rotation are potential risk factors in ACL injury mechanism. ACL knee bracing prevents aggravated anterior tibial translation and axial tibial rotation in order to relieve ACL strain or stabilize an ACL-deficient knee. Several studies have performed functional tests to assess the effectiveness of ACL bracing in response to external loading. Beynnon et al. [3] observed that bracing protected the ligament by substantially mitigating the ACL strain in response to anterior-directed loading and internal-external torque of the tibia. However, Ramsey et al. [4] noted that there were no consistent attenuations in anterior tibial translation and bracing the ACL-deficient knee resulted in insignificant kinematics differences for tibiofemoral joint motion. It seemed controversial whether these braces were effective in serving their intended functions. There is no clear evidence that these braces can reduce anterior tibial translation and axial tibial rotation, and relieve ACL loading during injurious landing. Currently, there is no direct evidence to prove that restraining anterior tibial translation or axial tibial rotation prevents ACL failure. The study aimed to show in a previous experimental setup, in which ACL failure can be induced via impact compression, that the introduction of restraint fixtures for anterior tibial translation or axial tibial rotation will avert ACL failure. We hypothesize that restraining anterior tibial translation or axial tibial rotation can prevent the ACL from failing at the range of peak compressive load that can induce ligament failure when both factors are unrestrained.

II. Methods

A. Specimen Preparation

Sixteen porcine hind legs (pig age: ~2 months; weight: ~40 kg) were obtained at a local abattoir (Primary Industries, Singapore). Both tibia/fibula and femur were sectioned 15 cm from knee joint centre along the anatomical axes with surrounding soft tissues kept intact. The sectioned ends were then centrally-potted in dental cement (Base-liquid & powder, Dentsply, China), secured to steel potting

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1716–1719, 2009
www.springerlink.com

cups using screws and then mounted onto the Material Testing System (810-MTS, MTS Systems Corporation, USA).

B. Experimental setup

The setup, adapted from a previous study [5], constrained the mounted specimen to 70-deg flexion to simulate landing posture. The tibia/fibula was limited to axial z-displacement and rotation while the femur was restricted to transverse x- and y-displacements (Fig. 1). We attached passive markers on the tibial potting cup and femoral stage, and used a motion-capture system (ProReflex-MCU1000, Qualisys Motion-Capture Systems, Sweden) to obtain the marker trajectories necessary for determining rotational and translational motion of the tibia and femur respectively. A slight posterior preload was applied using a 5-kg weight through a pulley system.

C. Compression testing

The specimens were randomly classified into four test groups: Q (unrestrained setup), A (anterior tibial translation restraint), R (axial tibial rotation restraint) and C (both restraints, Fig. 1). All specimens were subjected to the same impact protocol. The mounted specimens were adjusted via MTS to eliminate tensile/compressive preloading. Impact compression was performed by displacement control at a single haversine of 10-Hz frequency [5] to simulate a landing impact. The compression trial was successively repeated with incremental actuator displacement of 1 mm; after each trial, the specimens were returned to the initial position before the subsequent trial. The compressive force response was measured by the triaxial load-cell (9347B, Kistler, Switzerland). A significant drop ($\geq$70%) in compressive force (F_{drop}) response was taken as a major ACL failure; F_{drop} was estimated from the difference between the peak compressive force (F_{peak}) during impact compression and the mean compressive force during post-compression time period 300-500 ms. The impact tests were ended when either a significant F_{drop} was observed (presence of major ACL failure) or a visible bone fracture was present (absence of major ACL failure). Presence/absence of ACL failure was confirmed via dissection. Posterior femoral displacement and axial tibial rotation angle at F_{peak} were obtained based on the tibial and femoral marker trajectories.

D. Statistical analysis

One-way ANOVA was performed between test groups to compare F_{peak}, F_{drop}, posterior femoral displacement and axial tibial rotation. All significance levels were set at p=0.05.

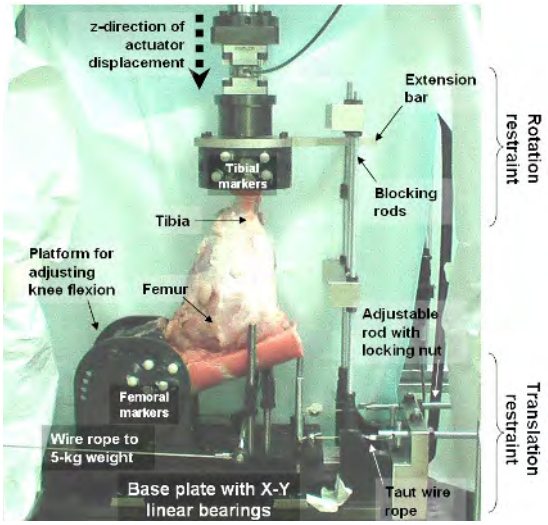

Fig 1 Experimental setup with both restraints

III. Results

All Q specimens underwent ACL failure via femoral avulsion, with mean F_{peak} of 3.0[1.1]kN. Corresponding posterior femoral displacements and axial tibial rotation angles at F_{peak} were 18.7[7.3]mm and 9.2[5.9]deg respectively. All A, R and C specimens developed visible bone fracture with the ACL intact. The mean F_{peak} obtained during fracture were 4.9[1.9], 3.9[0.7] and 5.5[1.2]kN for A, R and C respectively. Corresponding posterior femoral displacements were 1.5[0.9], 15.8[2.6] and 0.8[0.4]mm respectively while the axial tibial rotation angles were 16.1[8.7], 0.9[0.8] and 0.7[0.3]deg (Table 1). C specimens had a significantly higher F_{peak} ($p<0.05$) compared to Q (Fig. 2A). A, R and C specimens had substantially lower F_{drop} ($p<0.001$) compared to Q (Fig. 2B). The posterior femoral displacements for A and C were significantly lower ($p<0.001$) relative to Q and R (Fig. 2C). For axial tibial rotation angles, R and C had substantially lower rotation angles ($p<0.05$) compared to Q and A (Fig. 2D).

Table 1 Summary of mean peak compressive forces, posterior femoral displacements and axial tibial rotation angles for all test groups

Group	Peak Compressive Force (kN)	Posterior Femoral Displacement (mm)	Axial Tibial Rotation Angle (deg)
Q	3.0[1.1]	18.7[7.3]	9.2[5.9]
A	4.9[1.9]	1.5[0.9]	16.1[8.7]
R	3.9[0.7]	15.8[2.7]	0.9[0.8]
C	5.5[1.2]	0.8[0.4]	0.7[0.3]

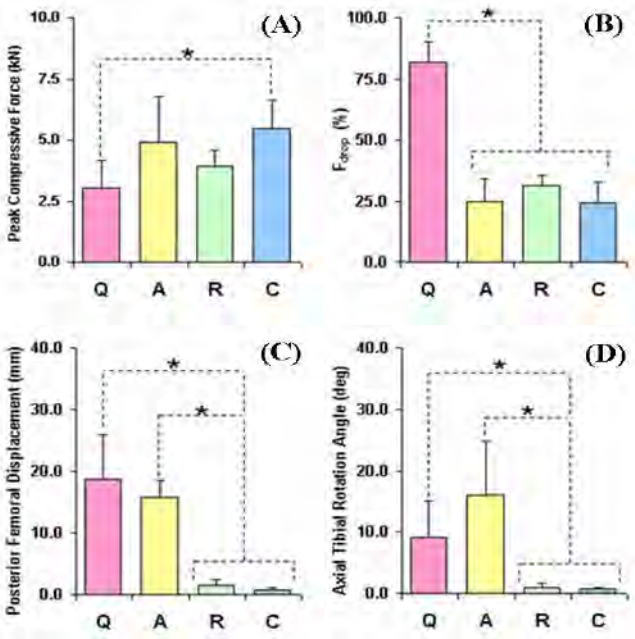

Fig. 2 Comparison of F_{peak} , F_{drop}, posterior femoral displacement and axial tibial rotation between test groups. (* significant difference, $p<0.05$)

IV. Discussion

The range of F_{peak} during ACL failure trials for Q was observed to be close to values obtained previously [5]. When posterior femoral translation (or relative anterior tibial translation) was restrained in A, we noted a significant reduction in posterior femoral displacement while axial tibial rotation was still present (Fig. 2D). This finding demonstrated that impact compression can lead to axial tibial rotation independent of anterior tibial translation. When axial tibial rotation was restrained in R, we observed a considerable decline in axial tibial rotation angle while posterior femoral displacement was still present (Fig. 2C). This finding illustrated that impact compression can give rise to anterior tibial translation independent of axial tibial rotation These results further revealed that sole inhibition of either factor can prevent ACL failure during impact compression. When both factors were restrained in C, we found that the values for these two factors were substantially diminished compared to Q while F_{peak} was also significantly larger relative to Q. These findings suggest that upon restraining both factors, ACL failure was not achieved even at high F_{peak} observed in C. This strongly showed that the concomitant restraints of both factors may work synergistically to mitigate the risk of ACL failure.

A main limitation of this study was the use of a porcine model to investigate the effects of anterior tibial translation and axial tibial rotation restraints on ACL failure. Meyer and Haut [6] and Yeow et al. [5] found that excessive impact compression of the human and porcine knee joints led to ACL failure, which implied similar failure mechanisms between both models. Furthermore, Xerogeanes et al. [7] suggested that the porcine model is preferred for assessing human ACL function as they found similar in-situ ACL forces and load distribution between ligament bundles for both models. Altogether, this validated our choice of the porcine model for investigating the restraining effects on ACL failure mechanism. One other limitation was the absence of muscle contraction during impact compression. Dominant quadriceps activity has been observed in landing [8], which is known to increase ACL loading. Moreover, the hamstrings serves to provide a posterior tibial pull [9]; However, quadriceps and hamstrings forces during injurious landing are largely unknown; hence, it would be difficult to simulate physiological muscle forces. The addition of quadriceps/hamstrings forces may affect the propensity of the knee joint for ACL failure. Since our study sought to investigate the effects of restraining anterior tibial translation and axial tibial rotation, we thus omitted the muscle forces in our setup in order to allow a direct analysis of the restraining effects. Another limitation was that full inhibition of anterior tibial translation and axial tibial rotation was not attained. The restraint fixtures were not able to entirely abolish anterior tibial translation and axial tibial rotation in the presence of high and rapid impact compression. However, our results illustrated a substantial decrease in both factors with the restraint fixtures in place. ACL bracing will not totally eradicate anterior tibial translation/axial tibial rotation as the bracing is only cupped to the upper and lower legs, and not fixed to the femur/tibia bones; the bones will still experience some anterior tibial translation/axial tibial rotation despite wearing the brace. Based on our results, if the brace can considerably reduce anterior tibial translation and axial tibial rotation during impact landing, the ACL injury risk would be greatly lessened.

Collectively, our results demonstrated that anterior tibial translation and axial tibial rotation are key factors in the ACL failure mechanism during impact compression. The presence of a compressive impact force through the knee joint is a dominant contributor to both anterior tibial translation and axial tibial rotation; it can give rise to each factor independently, though either factor may contribute in a minor manner to the other factor. Restraining anterior tibial translation and/or axial tibial rotation can prevent ACL failure at the range of peak compressive loads that were able to induce ACL failure in an unrestrained condition. Our findings suggested that the anterior tibial translation and

axial tibial rotation are intrinsic mechanisms of the knee joint to transfer, in part, the compressive impact load to the ACL and relieve other soft tissue structures, such as articular cartilage, of excessive loading. Extreme anterior tibial translation and axial tibial rotation may transmit a major portion of the compressive impact load to the ACL, resulting in failure. However, when both these factors are inhibited, the ACL will receive negligible impact loading while the soft tissues in the knee joint will have to sustain most of the compressive impact load.

V. Conclusions

There is a need to be aware that the use of braces that restraint the above factors may heighten the injury risk in other soft tissue structures. This is highly relevant for the articular cartilage, which is prone to traumatic lesions that may accelerate the onset of osteoarthritis [5]. In addition, though several studies have proven that braces which restrain these factors can mitigate ACL loading, no studies has yet to show that these braces can substantially diminish ACL injury risk during injurious landing. Our study established that significant restraining of these factors was able to prevent ACL failure in an impact setup that can induce ligament failure with the factors unrestrained. Our results would support a follow-on cadaveric study, which would be pertinent for understanding ACL injury prevention in humans.

The Analysis and Measurement of Interface Pressures between Stump and Rapid Prototyping Prosthetic Socket Coated With a Resin Layer for Transtibial Amputee

H.K. Peng[1], L.H. Hsu[1], G.F. Huang[2] and D.Y. Hong[1]

[1]Department of Mechanical Engineering, National Cheng Kung University, Tainan, Taiwan

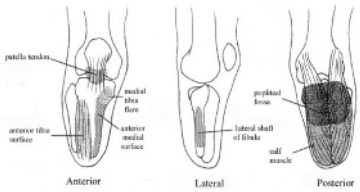
Abstract — **This study is to verify the applicability of the newly-developed prosthetic socket fabricated by rapid prototyping (RP) machine and then coated with a layer of resin to reinforce the flexural strength. This article aims to simulate and to measure the distribution of interface pressures on pressure tolerant (PT) and pressure relief (PR) areas of stump while amputee wearing a prosthesis and walking on a force platform. The results of comparison of the interface pressures between new type socket and conventional socket show that the RP socket could be made without using any plaster and the related information could be stored for further uses.**

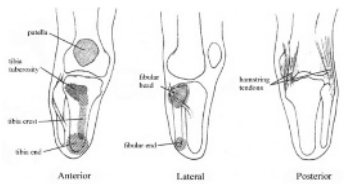
The quasi-static method is introduced in finite element (FE) modeling to simulate amputee walking. From the results of simulation, it can evaluate whether the socket shape is acceptable or not. The verified socket model is then transferred to rapid prototyping machine to produce a required prosthetic socket. Moreover, coating a resin layer on the RP socket to reinforce its strength was proposed. To validate this new type of socket, the interface pressures were measured by attaching socket sensors on PT and PR areas of the specific stump before wearing the RP socket.

The results of measurement and simulation of the pressure distributions of the resin-reinforced RP socket and the used socket are similar in the whole stance phase. Comparing to the used socket, the new type socket can bear more pressures at patella tendon. The FE analysis method is effectively to assist the shape modification of stump and socket can then be designed for the production using rapid prototyping machine.



Keywords — **prosthesis socket, rapid prototyping, finite element**

I. Introduction



Prosthesis is a custom-made limb that substitutes the defective body segment of an amputee. When wearing prosthesis, socket is the major part that directly contacts stump of amputee, fit of contact areas significantly affects amputee's comfort when wearing prosthesis. [1] However, the quality of a socket of prosthesis depends on whether the distribution of interface pressures between socket and pressure-tolerant (PT) and pressure-relief areas (PR) (Fig. 1) of the stump is appropriate.

In this study fabricating a socket method introduces prototyping (RP) and computer-aid design (CAD) systems. The amputee specific stump geometry will be captured by T-Scan which is a handheld scanner, and then using CATIA to modify the stump geometric model, a new socket model was then created. Since the prosthetic socket is used to bear the weight of an amputee, the interface pressures between socket and stump should be evaluated. As soon as a socket has been designed, the pressures can be simulated using FE model. In addition, the analysis results could be compared with the regional local load-bearing ability [2]. After a designed socket has been verified, a RP machine FDM is utilized to manufacture the socket. To overcome the disadvantage of the socket made by a FDM machine that is liable to breakage, coating a layer resin to reinforce the RP socket is proposed in this study. The new method for fabricating socket procedure will be developed.

Although FE analysis could be evaluated the interface pressures, but any computerized model must be verified by experimental measurements, this study employs Pliance Mobile System to measure local pressure distribution on PT and PR areas, there were two sockets selected to measure pressures, resin-reinforced and original used sockets, the results will be compared. Once the FE analysis model is verified, the FE analysis an effectively tool is to assist the shape modification of stump and socket can then be designed for the production using rapid prototyping machine.

II. Finite Element Analysis Method

Stump and socket interface pressures is a major factor which influences socket's suitability and comfort when wearing prosthesis. To obtain accurate results, the investigation of the FE analysis model and experimental measurement are based on the same socket model. The geometry of the bone structure was reconstructed from CT scanned data, and stump model was from T-Scan data. The FE analysis model is composed of residual limb model, liner with 5 mm thickness and socket (Fig. 2).

These FE models were meshed by Marc, each part contact condition and material properties are listed in table1.2. At first pre-pressure was considered that stump and socket are synthesized before gait, pre-pressure will be sustained during initial gait simulation. As gait simulation, to adopt Quasi-Static boundary conditions, loads ware transformed form force platform date and applied on top surface of bone, and fixed bottom of socket.

After FE analysis finished, the results will be compared with measures experiment results, to validate the FE analysis model.

III. Interface Pressures Measurement Method

A male volunteer weighing 60kg with a left below-knee amputation was selected in this experiment. Pliance Mobile System was employed to measure the local pressure distribution at the residual limb and socket interface. Prosthesis Sockets are resin-reinforced and original used sockets, remember resin-reinforced socket model was same as FE analysis model.

To begin with using porous sticky tape, attach the sensors on the positions of the stump which must be measured as Fig. 3. The positions measured in the experiment are as Table 3. The data will be synthesized with the gait cycle for stress analysis by the Pliance-X Expert. The resin-reinforced and original used sockets were introduced in this case, each socket was worn to measure the interface pressure five times, and after accomplishing the each sort of measurement, the volunteer can rest for 10 to 15 minutes. Connecting Pliance Mobile box to a computer by Bluetooth, the pressures data could be detected and recorded on the computer during measure experiment.

Fig. 3 Sensors attached to the stump

Table 3 PT and PR areas measured in this study

Pressure-tolerant(PT) areas	Pressure-relief (PR) areas
Patella tendon	Tibia end
Medial tibia flare	Tibia crest
	Fibular head
	Fibular end

IV. Results

The FE analysis results show that the area of patella tendon, which is the main pressure tolerant area, can bear more pressures (Fig. 4). The area of medial tibia flare, one of PT areas, can also share the bearing load. The areas of pressure relief including fibular head, tibia crest, tibia end and fibular end should bear as less pressures as possible. Based on the reference data provided by Zhang [2], the results of FE modeling are acceptable. The socket shape of the FE simulation model can be used to fabricate a physical prosthetic socket using rapid prototyping machine.

The resin-reinforced socket pressures experiment results are shown on Fig. 5, patella tendon, fibular head and tibia crest areas pressures are higher than other areas. Since the fibular end is the worst tolerant area [2], this study also made fibular end has the much lower pressure.

The local interface area pressures of FE analysis results and resin-reinforced socket measurement results were compared, original used socket measurement results was added to compare (Fig. 6), it was shown FE analysis could predict the trend of pressures. FE analysis model is verified with measure experiment results, FE is quite a practical tool for assisting prosthesis socket design. Based on basic criterion PT areas pressures are higher than PR areas, resin-reinforced socket performed a superior represent.

(e) Fibular Head

Fig. 6 Comparison of PT and PR areas

V. Conclusions

Using FE analysis to evaluate the interface pressures between resin-reinforced RP socket and stump can assist the design of prosthetic socket geometry. As soon as the estimated pressures are acceptable, the verified socket will then be fabricated using RP machine. The results of measurement also show that the FE simulation model is valid to support the design of socket.

Within the case study of FE modelling, the material properties provided by published references were employed. [3]. However, the resin-reinforced socket is a new type socket, its material properties should be given by experiments. Although rapid prototyping is an applicable technology to fabricate socket and RP socket coated with a layer resin is to reinforce it strength, its endurance testing should be conducted.

Analysis of Influence Location of Intervertebral Implant on the Lower Cervical Spine Loading and Stability

L. Jirkova[1], Z. Horak[1]

[1] Czech Technical University in Prague/Dept. of Mechanics, Biomechanics and Mechatronics, Prague, Czech Republic

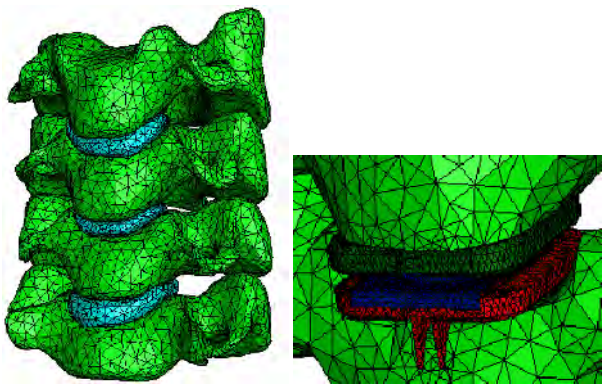
Abstract — **Because nerve/spinal cord impingement (decompression surgery) and spinal instability (fusion surgery) of the cervical spine are worldwide problems, biomechanics research is very important for developing new treatment methods. Spinal instrumentation (such as a small plate, artificial intervertebral replacement or fusion) can also be used to help increase stability to the spine column. A disadvantage of the fusion is a decrease of mobility in dependence on the increasing of adjacent vertebrae and discs loads. The aim of presented study was an analysis of influence location of intervertebral implant on the lower cervical spine loading and stability. A three-dimensional finite element (FE) model of the multi-level cervical spine C3-C6 has been developed using computed tomography (CT) data, and applied to determination of movement of the implanted mobile artificial discs prosthesis on the biomechanical behavior of the lower cervical spine in this directions (flexion-extension, axial rotation, and lateral bending moments). Models accuracy was validated by comparing with previously published experimental and numerical results for flexion-extension, axial rotation, and lateral bending moments. The influence of the various surgical techniques on the cervical spine stiffness was compared at the same time. The intact spinal segment and the implanted spine was compared using artificial disc replacement Prodisc-C made by Synthes. The different types of artificial disc are going to be compare between each other. The technology of discs share similar goals of replacing the original disc, but differ in their designs and materials. By the definition of the optimal position range of replacements investigated (neutral zone of spine) would be minimized overloading of the soft tissue components (ligaments, adjacent discs) and instability of the spine as well. The output data was used for effective treatment of the patients. The results achieved have a large medical gain in neurology and spine surgery.**

Keywords — **cervical spine, biomechanics, implant, finite elements, artificial disc prosthesis**

I. Introduction

The human spine is a complex structure whose principal function are to protect the spine cord, transfer loads, moments and damp dynamic effects due to loading from the head and truck to the pelvis. The cervical spine instability is a common disease in clinical practice. Surgical treatments for degenerative disc disease can be grouped into two categories: fusion (arthrodesis) and total disc replacement (arthroplasty). Because fusion limits motion of the fused segments, it is believed that fusion may induce or accelerate degenerative change at adjacent levels. Disadvantage of fusion is the decrease of mobility in dependence on increase of adjacent vertebrae stability and disc load. None of the currently available artificial intervertebral discs respects all properties of natural disc as well (no shock absorption, no bending and torsion stiffness).

In recent years, computation modeling, especially Finite Element Method (FEM) has made an important contribution to the study and understanding of the behaviour of the spine. This method seems to be the most suitable approach to study spinal biomechanics due to 3D irregular geometry, non-homogenous material arrangement, large complex loading and movement, and non-linear response including contact at the facet joints [1]. As computing power and software capabilities have increased over the years, more complex model and spinal problems can be analyzed and investigated. According to [2], FEM has been used in spine research for a number of reasons: a) to examine biomechanical behaviour of the healthy spine, b) to assess the spinal performance when affected by disease, degenerative changes, trauma, ageing or surgery, c) to investigate the influence of various spinal intrumentation on spine behaviour, and d) to assist in the design and development of new spinal implants.



The objective of this study is to develop an experimentally validated three dimensional nonlinear finite element (FE) model of lower cervical spine using previously published data to provide useful information for artificial disc designers and examine the effects of surgical treatment on the structure for clinicians. The validated FE model was used to evaluate the mobil-type disc prosthesis on the range of motion in the multi-level C3-C6.

II. Materials and methods

A three-dimensional nonlinear model of a three-level ligamentous cervical segment (4 vertebrae and 3 discs) was built and implemented with the FEM software ABAQUS 6.6.3. Fig. 1. Two different configuration of the model were considered: a) a ‘healthy model’ was built and validated by

www.springerlink.com

comparing with previously published data b) a 'mobile model' had the middle level implanted with a artificial intervertebral disc replacement Prodisc-C made by Synthes. The elements used in the model are available in Table 1. The mechanical characteristics of each spinal component used in the present study are based on published average values [3-10].

A. Reconstruction of the vertebrae and discs

The 3D geometrical details for FE model were obtained from computed tomography (CT) images of a 34-year-old man. The sequential DICOM files of lower cervical spine (C3-C6) were loaded into Mimics 11.1 (Materialise software), a software for visualization and segmentation of thee-dimensional (3D) scanned data, through which three-dimensional surface images were obtained from the sequential cross-section outline of the vertebrae at the 1-2 mm interval, depending on the regional geometrical complexity of the vertebra. The images were then converted and saved as a Binary STL files (Stereolithography format- CAD software), each vertebra having approximately 3000 surfaces, which were created as a triangles. These three-dimensional geometrical boundary data files were converted into a standard graphics exchange data format (inp), and were imported into a finite element package; ABAQUS 6.6.3. where all surface elements were converted to the volume elements.

B. Healthy model

A typical vertebra, appropriate to a C3, C4, C5 or C6 vertebra, was built in the two level model. The cortical and cancellous bones of the vertebral bodies were separately modeled. The thickness of the lateral cortical wall was 1 mm [3]. To develop the spinal motion segment (a functional unit), the intervertebral disc was modeled as three layers of solid alements: a) two layers (one superior and one inferior) to devone the endplates of the vertebral body. Each end plate has a thickness of about 0.5 mm, b) middle layer corresponding to the intervertebral disc comprised of the annulus and nucleus.

The thickness of the annulus in the anterior region was taken to be 1.2 times that of the posterior region, which was close to the publisher data [11]. The anterior disc height of 5.5 mm and posterior disc height of 3.5 mm were assumed which correspond to the published values [12]. Ligaments have an important role in spinal biomechanice and stability. The five intervertebral ligaments were incorporated and modeled as discrete axial connectors Tab.1. A natural ligament exhibits strong nonlinear load/deformation behaviour [13].

C. Mobile model

The mobile model of artificial dics replacement made by Synthes is called Prodisc. The disc consists of two cobalt-chromium-molybdenum alloy. The inlay is made of ultra-high molecular weight polyethylen (UHMWPE). The kinematics correspond to the point guidance in vertebral joints: The center of rotation is located just below the superior end plate of the affected caudal vertebral body. The location of the center of rotation and the flexion radius correspond to the natural point guidance in the vertebral joints. The physiological range of motion in begard to flexion/extension and lateral bending is restored. The axial rotation is limited only by the anatomical structures and not by the prosthesis. Pure translatory movements are not possible due to the ball and societ principle. The disc

prosthesis was implanted in C4-C5 level, and its effects on the entire levels from C3 to C6 were analyzed. To simulate the anterior surgical approach used for implantation of the artificial disc, the anterior longitudinal ligaments at C4-C5 level were removed in the FE analysis. Material properties used for Prodisc-C→CoCrMo (E=220GPa,ν=0.32), polyethylen inlay (E=1GPa,ν=0.49).

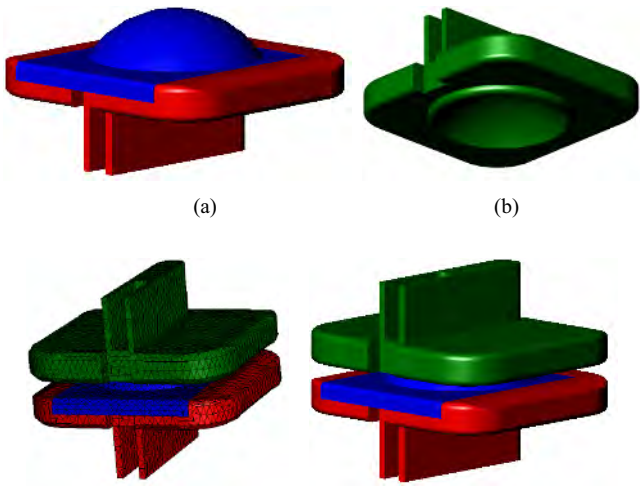

Fig. 2 Prodisc-C. Modular intervertebral disc prosthesis for restoring disc height and segmental motion in the cervical spine a) lower plate consists of CoCr Mo alloy and UHMWPE, b) upper plate-CoCrMo alloy, c) 3D set of the disc in the design software Rhinoceros, d) 3D meshed set with tetrahedral elements in ABAQUS

D. Simulation parameters

Loading conditions: Both models were loaded by a) 1.0 Nm flexion/extension moment, b) 1.0 Nm axial rotation moment, c) 1.0 Nm lateral bending moment. The loads were applied to the top surface of C3, while the bottom surface C6 was constrained the same way as in the in vitro experiments [4,15].

Boundary conditions: The translational degree of freedom of the nodes from the underlying endplate of the lowermost vertebra have been restricted completely.

III. Results

The two FE nonlinear models for physiological posture of the lower cervical spine (flexion, extension, lateral bending and rotation) was compared. The ROM and Stress response at the level (C3-C6) for two cases (intact and implanted spine) are shown at the Tab. 2 and 3. The segment movement-ROM of intact spine was higher than the implanted spine at C4-C5 by all of movemets with the exception rotation. These values ROM for the intact spinal segment are in very good accordance other measurements [16]. The ROM of the prosthesis implanted C4-C5 was reduced by about 50-70 % by (flexion, extension and right lateral bending). Under axial rotation moment, the ROM of the prosthesis implanted C4-C5 level is increases by about 18%. This is expected to result from the fact that the rotational moment in the intact disc is supported additionally by alternating annulus fibers with enhanced rotational stiffness. The maximal stress of the implanted segment at the bottom posterior region Fig. 3 was taken to be 2-3 times that of the intact one. The stress are concetrated on the bottom of the both plate and on the top of ball shape of middle plate (polyethylen) as well. The reason for this behaviour is given by the number of DOF of Prodisc-C, whose 3 DOF (3 rotation) decreases ROM and on the other hand the stress increases. The peaks of stresses are depicted in (Fig. 3, 2).

Table 2 Comparison of the ROM [°] between intact and implanted spine

Type of motion	Intact (no surgery)	Prodisc-C
Flexion	3.86	2.62
Extension	2.62	1.38
Right lateral moment	2.87	1.69
Rotation	1.65	1.95

Table 3 Comparison of the maximal Stress [MPa] between intact and implanted spine

Type of motion	Intact (no surgery)	Prodisc-C
Flexion	7.26	21.3
Extension	6.45	16.1
Right lateral moment	9.47	33.6
Rotation	5.32	12.2

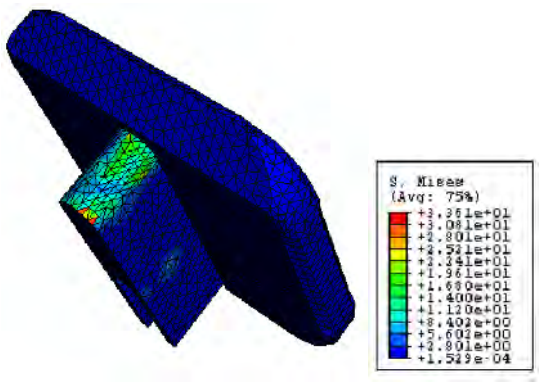

Fig. 3 Mises stress distribution at the bottom plate in direction (RLB)

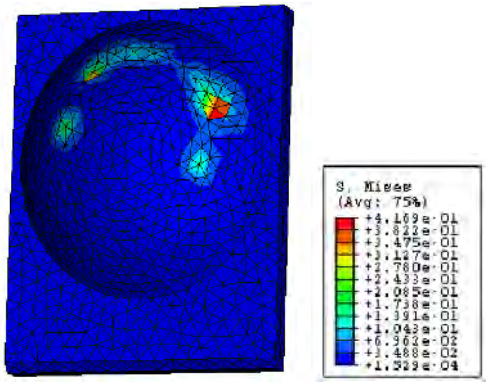

Fig. 4 Mises stress distribution at the polyethylen plate in direction (RLB)

IV. Conclusions

The FE analysis and experimental testing of cadaveric spine are the best method of investigating mechanical function and failure of the spine. Especially FE models can be used to explain experimental results of spine tissues.

The goal of this study was developing the anatomical nonlinear model of lower cervical spine. The movement of intact spine was validated with previously numerical and published results. In this project was carried out verification of modeling technique that is highly reproducible and objective. Nevertheless project is still in progress and the next step of this work is going to test next three mobile prosthesis, which has different mechanical properties and shapes as well. All is being researched in cooperation together with doctors from Motol-Hospital in Prague. The outputs are very useful for a clinical practices and surgeons. This biomechanics research is very important for developing new treatment methods as well.

Computational Fluid Analysis of Blood Flow Characteristics in Abdominal Aortic Aneurysms Treated with Suprarenal Endovascular Grafts

Zhonghua Sun[1], Thanapong Chaichana[2], Manas Sangworasil[2] and Supan Tungjitkusolmun[2]

[1] Curtin University of Technology/Department of Imaging and Applied Physics, Perth, Western Australia, Australia
[2] King Mongkut's Institute of Technology Ladkrabang/Department of Electronic Engineering, Bangkok, Thailand

Abstract — **The purpose of this study is to investigate the hemodynamic effects of suprarenal stent grafts on the renal arteries in the treatment of patients with abdominal aortic aneurysm. Suprarenal stent grafts have been increasingly used for treatment of aortic aneurysms with suboptimal aneurysm necks. However, the long-term safety of this procedure is yet to be determined. 2 sample patients undergoing suprarenal stent grafting were included in the study. Four variable configurations of stent wires crossing the renal artery ostium were simulated in aorta models based on CT generated data, at different cardiac cycles. The stent wires thickness was set 0.5 mm which is similar to the actual diameter of a stent wire. Computational fluid dynamic analysis showed slightly decrease of flow velocity to the renal arteries with multiple wires crossing, and no changes of flow velocity to the renal arteries with single wire crossing. Our preliminary results demonstrated the safety of suprarenal stent grafting. Further studies are required to investigate the effect of different wire thickness on subsequent hemodynamic changes to the renal arteries.**

Keywords — **Aortic aneurysm, blood flow, suprarenal stent, stent graft.**

I. Introduction

Endovascular repair of abdominal aortic aneurysm (AAA) through insertion of a stent graft has been widely used as an effective alternative to conventional open surgery, especially in patients with co-morbid medical conditions [1-3]. Suprarenal fixation of stent grafts has been developed to be an alternative to conventional endovascular repair in patients with unfavourable aneurysm necks (short, severe angulation, thrombus, or calcification) [4,5]. Clinical studies have shown that suprarenal fixation of stent grafts did not lead to the deterioration of renal function, based on short to mid-term follow-up [4-7]. However, the long-term outcomes of suprarenal stent grafting are still not fully un-derstood. This is mainly due to the fact that the long-term safety of placing the suprarenal stents cross the renal arteries is not known with regard to its effect on the renal arteries or renal function.

Our previous in vitro and vivo studies using CT data did not show any significant interference of suprarenal stent wires with the cross-sectional area reduction or renal function [8, 9]. Researchers using computer-generated aorta models also reported no significant changes of flow velocity to the renal arteries with variable stent wires crossing the renal artery ostia [10]. Although these results demonstrated the safety of suprarenal stent grafts, a more realistic, accurate method based on real patient's data is necessary to validate the effect of stent wires on renal arteries with regard to subsequent blood flow changes.

Thus, the purpose of this study is to investigate the hemodynamic changes in patients treated with suprarenal stent grafts in two selected patients with AAA using computational fluid dynamics (CFD) analysis.

II. Materials and methods

A. Patient CT data

2 patients with abdominal aortic aneurysms undergoing suprarenal stent grafting were selected for inclusion in the study. The stent grafts used in the study were Zenith AAA endovascular graft with a suprarenal uncovered component of 2.5 cm placed above the renal artery for acquisition of proximal fixation. Pre-and post-stent grafting CT scans were performed with a multislice CT scanner 16x0.5 mm beam collimation (Medical Imaging Systems, Kingsbury, UK), and scanning protocol was section thickness 1 mm, pitch 2.0, reconstruction interval of 1mm and gantry rotation time was 0.5 second. The renal artery diameters of these two cases were measured between 4.0 to 5.2 mm.

B. Configuration of stent wires crossing the renal ostia

Original CT DICOM data (digital imaging and communication in medicine) pre-and post-stent grafting were transferred to a workstation equipped with Analyze V 7.0 (AnalyzeDirect, Inc., Lexana, KS, USA) for generation of 3D reconstructed images. Generation of intraluminal images of the stent wires in relation to the aortic ostia was performed using a CT number thresholding technique, which was de-scribed in detail before [11]. According to our previous experience of 3D imaging in endovascular repair, the supra-renal stent wires were found to cross the renal artery ostium in four different configurations [8, 11], namely: single wire centrally crossing, single wire peripherally

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1728–1732, 2009
www.springerlink.com

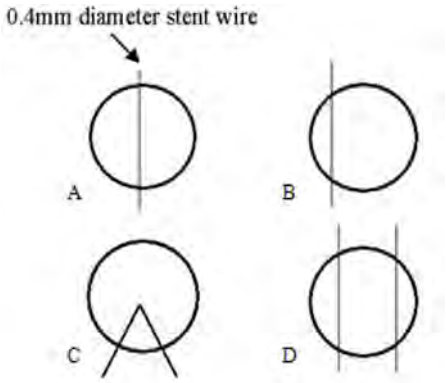

Fig. 1 Diagrams of different types of stent wires crossing the renal artery ostia.

crossing, V-shaped wire centrally crossing and multiple wires periphe-rally crossing. Figure 1 presents the diagrams of these types of configurations.

C. Generation of aortic mesh model

Generation of aorta model was performed with a semi-automatic segmentation technique using Analyze V 7.0. After segmentation, the 3D object surface of the model was created using surface extractor available on the Analyze software, and the 3D surface object was saved in the STL (stereolithography)', a common format for computed-aided design and rapid prototyping. The 'STL' file was converted into the CAD (computer aided design) model files using the CATIA V5 R17 (Dassault Systèmes, Inc., Suresnes Cedex, France). Figure 2 shows the segmented aorta models based on pre-and post-stent grafting CT data.

The blood flow model mesh was defined by tetrahedral volume mesh and three prism layers using ANSYS ICEM CFD 11 (ANSYS, Inc., Canonsburg, PA, USA). ANSYS ICEM CFD provides sophisticated geometric acquisition, mesh definition and mesh editing which is important for the accurately flow analysis. The blood wall model was defined by tetrahedral volume mesh using ANSYS Meshing 11 (ANSYS, Inc., Canonsburg, PA, USA).

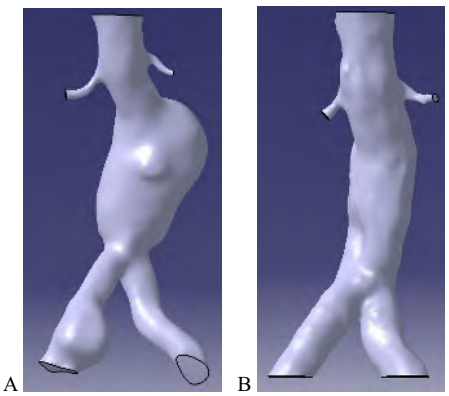

Fig. 2 pre- (A) and post- (B) stent grafting aorta models.

D. Simulation of intraluminal suprarenal stent wires

In order to simulate the intraluminal appearances of stent wires crossing the renal artery ostia, we generated a few models with a simulated wire thickness of 0.5 mm and placed in front of the renal artery ostia, as shown in Figure 3.

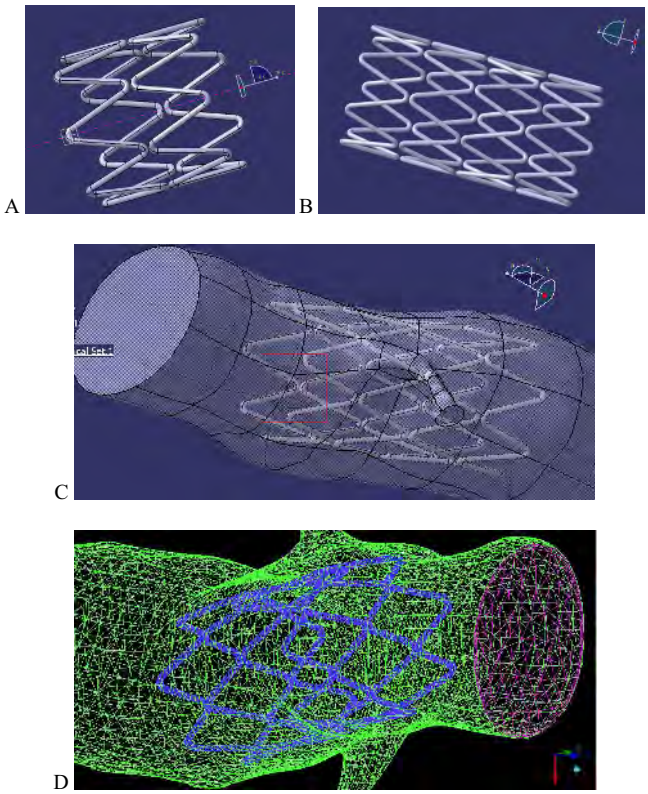

Fig. 3 A and B are simulated suprarenal stent wires, while 3C shows the appearance of stent wires placed inside the aorta model, and figure 3D demonstrates the simulated stent wires inside the mesh model.

E. Computational fluid dynamics (CFD)

In order to ensure that our analysis reflects the realistic environment of human blood vessel, normal physiological hemodynamic conditions should be considered for the 3D numerical simulations. The fluid and materials properties for different entities were referenced from a previous study [12]. In the current study, we compared the flow velocity at the aorta model containing the four arterial branches, name-

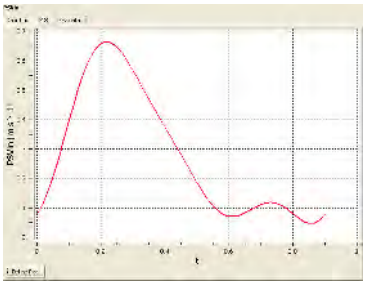

Fig. 4 Flow pulsatile in different cardiac cycles.

ly bilateral renal arteries and common iliac arteries prior to and after stent graft implantation. The blood flow was simulated at different cardiac phases (systolic and diastolic cycles) and measured in the aortic aneurysm, renal arteries and common iliac arteries using the ANSYS Multiphysic (ANSYS, Inc., Canonsburg, PA, USA) (Fig 4). Blood flow pattern, wall pressure, and wall shear stress before and after stent-graft implantation were visualized and compared.

The boundary conditions are time-dependent. The velocity inlet (abdominal aorta at the level of celiac axis) boundary conditions are taken from the referenced value showing measurement of the aortic blood velocity. A time-dependent pressure is also imposed at the outlets.

The solid is (blood wall) 1 mm thickness in all models. The solid density was set to 1120 kg/ m3, a Poisson ratio of 0.49, and a Young's modulus of 1.2 MPa, corresponding to the standard values cited in the literature [12].

The fluid is (blood) assumed to behave as a Newtonian fluid, as this was known for the larger vessels of the human body. The density was set to 1060 kg/m3 and a viscosity of 0.0027 Pa s, corresponding to the standard values cited in the literature [13]. Given these assumptions, the fluid dynamics of the system are fully governed by the Navier-Strokes equations, which provide a differential expression of the mass and momentum conservation laws [13]. The flow was assumed to be incompressible and laminar. The time step was set to start from 0 to 0.9 s with an interval of 0.025 s. The arterial wall was assumed to be deformable during flow analysis

III. Results

CFD analysis was successfully performed in all of these 2 cases with 4 aorta models (including both pre-and post-stent grafting). The artery wall was set at 1 mm thickness which reflects the actual diameter of the human artery vessel. All of the 4 renal arteries in these two patients were crossed by the suprarenal stent wires to variable extents with different configurations (single and multiple wires crossing). Details of suprarenal stents in relation to the renal arteries are as follows: the right renal artery ostium was crossed centrally by a single wire in patient 1 and multiple wires in patient 2; the left renal artery ostium was crossed by a single wire centrally and peripherally in both cases, respectively.

A. Hemodynamic analysis-flow velocity

Flow velocity was found to increase significantly inside the abdominal aorta following suprarenal stent grafting, indicating that the aneurysm was successfully excluded from the systemic blood circulation. The flow velocity slightly decreased at the right renal artery in patient 2 with multiple stent wires crossing (less than 5% reduction), while no apparent changes were noticed at the right renal artery in patient 1. Flow velocity was found to increase slightly at the left renal arteries on both cases. Similarly, no significant changes were observed at the common iliac arteries in both patients. Figure 5 shows the flow velocity observed in patient 1 pre-and post-stent grafting.

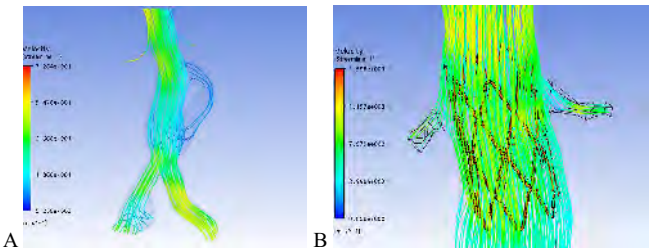

Fig. 5 shows the flow velocity in patient 1 pre- (A) and post- (B) suprarenal stent grafting.

B. Hemodynamic analysis-wall pressure and wall shear

Wall pressure and wall shear stress were measured at different cardiac cycles, and our results showed that the wall pressure slightly decreased after stent grafting. The wall pressure reaches the peak value at the systolic phase at about 0.3 s, both pre-and post-stent grafting. Figure 6 is an example of the wall pressure displayed in patient 2 pre- and post-stent grafting.

It is also observed that wall pressure is higher in the posterior aortic wall than that in the anterior wall, both pre-and post-stent grafting. This may be valuable to predict the location of rupture of aortic aneurysm. Figure 7 shows the wall pressure changes in patient 1 prior to and after suprarenal stent grafting.

Our results showed that wall shear was observed to change at the level of aortic aneurysms after stent grafting, as shown in Figure 8. While in other sections of the aorta, the change was not apparent.

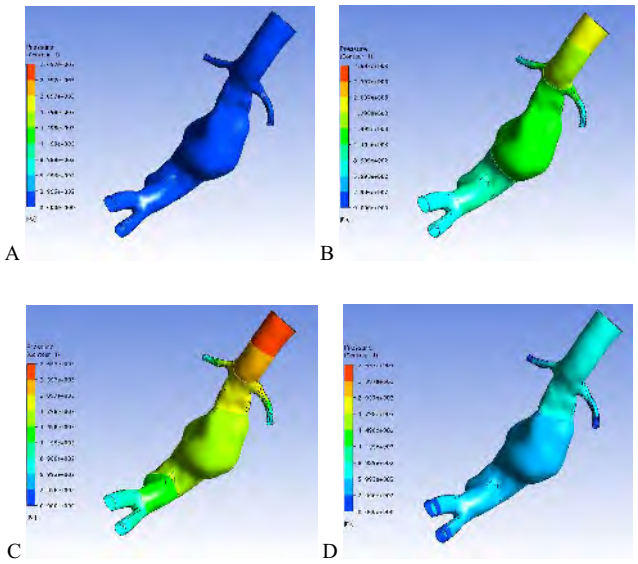

Fig. 6 Wall pressure was measured at 0.1 s, 0.2 s, 0.3 s and 0.8 s (A-D) pre-stent grafting, respectively, reaching the highest magnitude at 0.3s.

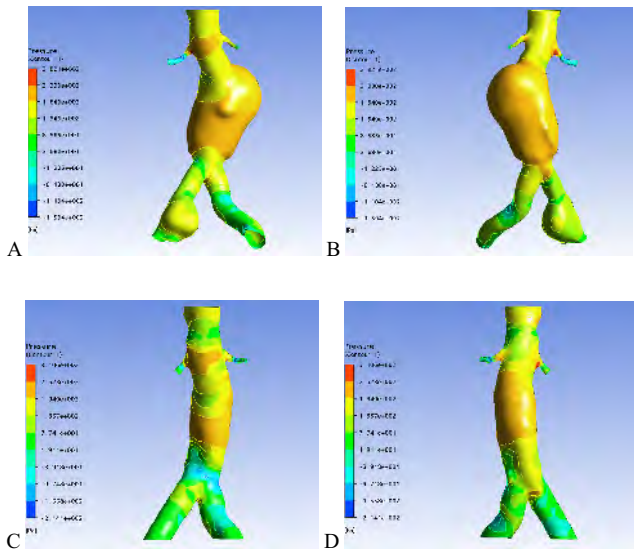

Fig. 7 demonstrates the difference of wall pressure measured at anterior (A, C) and posterior aortic wall (B, D), pre-and post-stent grafting.

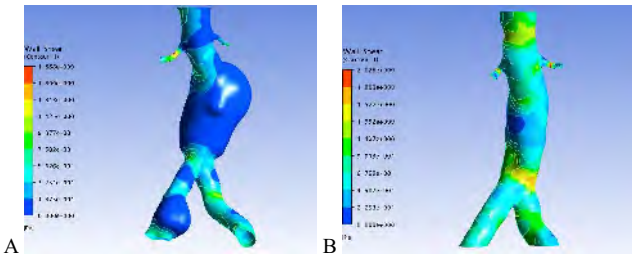

Fig. 8 Wall shear observed in patient 1 pre- (A) and post- (B) stent grafting.

IV. Conclusion

In conclusion, our preliminary study using CFD analysis to analyze the hemodynamic changes in patients with AAA treated with suprarenal stent grafts demonstrates minimal effect of stent wires on the renal arteries. Future studies are required to study the effect of different wire thicknesses on subsequent renal blood flow.

Abstract — **Quantitative measurement of the location of cementless hip implants postoperatively not only explains subsequent common complications, such as impingement and loosening, but can also predict postoperative subject-specific primary stability, if combined with the finite element method. However, the metal artifacts on the postoperative computed tomography (CT) image make it difficult to estimate the three-dimensional (3D) alignment, implant shape, bone geometry, and mineral density precisely. Therefore, we developed a novel, accurate measuring technique for the 3D implant position using pre- and postoperative CT images, which is based on a 3D surface registration algorithm. We can obtain a computer model of the femur from preoperative CT data combined with a stem model from computer-assisted design (CAD) data. This study assessed the accuracy of our novel technique for the 3D estimation of implant position. Five sawbones femurs and five cementless stems were used. Ceramic sphere markers were bonded to the bone and stem surface to define local coordinate systems for the femur and stem, respectively. Each femur underwent CT at slice pitches of 1, 2, and 3 mm before and after stem implantation. The relative positions of the stem and femur obtained using our method were compared with those measured using a 3D laser digitizer, used as the true value. The relative estimated position errors were within 0.3 mm in translation and 0.4º in rotation, regardless of slice pitch. From the viewpoint of pixel size of the CT image in a clinical situation, the estimation is sufficiently accurate. Therefore, our measurement technique is useful for quantifying the relative 3D position of implants to the bone geometry and for performing comparative studies among subjects.**

Keywords — **Total hip arthroplasty, CT image, Postoperative diagnosis, Loosening, Dislocation**

I. Introduction

The goals of total hip arthroplasty (THA) are to restore mobility by relieving pain and to improve the function of the hip joint. The common early complications that occur after cementless THA are dislocation of the femoral neck on the cup caused by impingement and loosening of the implant owing to a lack of primary stability at the bone-implant interface [1-4]. These mechanisms are associated with malposition or misalignment of the implant relative to the bone. Postoperative measurement of implant location not only explains these complications but can also predict the postoperative subject-specific range of hip motion and primary stability, when combined with the finite element method (FEM). However, the metal artifacts in the postoperative computed tomography (CT) image make it difficult to precisely estimate the three-dimensional (3D) alignment, implant shape, bone geometry, and bone mineral density.

Therefore, we developed a novel and accurate technique for measuring the 3D implant position, including the precise bone geometry and density data, using pre- and postoperative CT images and a 3D surface registration algorithm. This study reports the accuracy of our technique for the 3D estimation of implant position. We evaluated the patient-specific 3D position of cementless stem and bone mineral density using the proposed technique.

II. Methods

The technical procedure is applied to THA of the femur as follows (Fig. 1). First, we construct preoperative femur surface models from preoperative CT data. Then, the postoperative femur and a rough surface model of the stem are obtained from the postoperative CT data. These 3D surface models are generated using semi-automatic segmentation, including Wiener noise filtering and Canny edge detection. Next, the coordinates of the postoperative femur are transformed to fit the preoperative femur model using the iterative closest point (ICP) algorithm with least-square method [5]. This is a very common method of registration in which each point on the femur model from preoperative CT image that is nearest to the point on the postoperative femur model is assumed to be the corresponding point; the calculation is repeated to reduce the average distance between the each surface points. The rough stem model is also transformed by applying this coordinate transform matrix (Fig. 1A). Then, a precise stem model constructed from computer-assisted

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1733–1736, 2009
www.springerlink.com

design (CAD) data is matched to the transformed rough stem model using the ICP algorithm (Fig. 1B). Finally, we obtain a computer model of the femur from the preoperative CT data combined with the precise stem model from CAD data and can then evaluate the 3D-location of the stem relative to the femur (Fig. 1C). This computer model provides precise proximal bone geometry, and the mineral density can be derived from the CT number of the preoperative CT data.

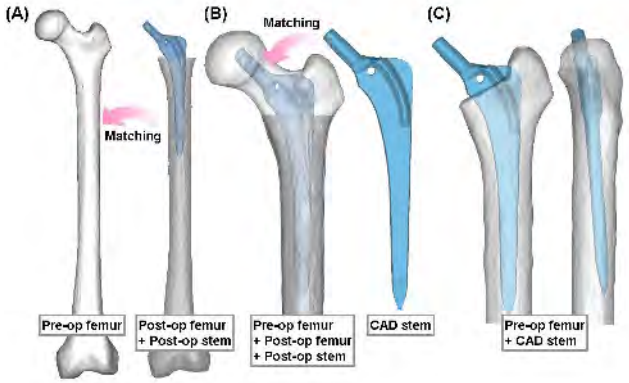

Fig. 1 The procedure used in the novel registration technique.

A. Accuracy of the estimated stem location

Five sawbones femurs and five cementless stems from the BiCONTACT total hip system (B. Braun Aesculap, Tuttlingen, Germany) were used. Spherical ceramic markers were bonded to the bone and stem surfaces to define local coordinate systems for the femur and stem (Fig. 2). In the femur, eight large ceramic markers (10 mm in diameter) were used. In the stem, two small markers (5 mm in diameter) and a large marker were bonded. Each femur was subjected to CT at slice pitches of 1, 2, and 3 mm, before and after stem implantation. The image matrix was set at 512 × 512, and the pixel size was set at a constant 0.68 mm (field of view = 350 mm), considering the general clinical situation. Femur models with the implanted stem were constructed using the proposed technique, and the central coordinates of each marker on the femur and stem were obtained (Fig. 2A). For a real sawbones femur with a stem, the central coordinates of each marker were measured using a 3D laser scanner (Roland, LPX-600, Japan) with a measurement accuracy of ±0.05 mm (Fig. 2B). The 3D location of the stem was represented as translations and rotations about each axis on the local femoral coordinate system. Stem locations obtained using our method were compared with those measured using the 3D laser scanner, which were used as true values.

B. Evaluation of patient-specific 3D position of stem

Five femurs of five female patients who underwent cementless THA with the BiCONTACT total hip system were evaluated. The preoperative diagnosis in all of the patients was the femoral neck fracture. The mean age of subjects was 74 years (range, 40-93 years). The average height was 152 cm (range, 148-158 cm) and the average body weight was 47 kg (range, 39-55 kg). Informed consent was obtained from all patients before the study. The patients were subjected to CT at a slice thickness of 3 mm before and after THA, with a calibration phantom (B-MAS200, Kyoto Kagaku, Kyoto, Japan). The stem position (anteversion and anterior inclination) were evaluated individually. The stem anteversion was defined as an angle between the stem neck axis and femoral posterior condyle axis (Fig. 3A). The anatomical axis of the proximal femur was defined as a line that is derived from the collinear approximation of centroid points for each section of femur in the region beneath the lesser trochanter. The anterior inclination was defined as an angle between the long axis of stem and the proximal axis (Fig. 3B). The bone mineral density of the femur was calculated using the calibration phantom from preoperative CT images.

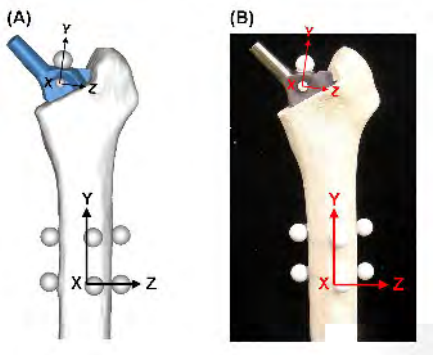

Fig. 2 The stem-implanted femur with spherical markers. (A) The computer model. (B) A sawbones femur with astem.

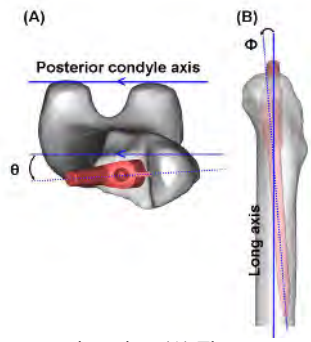

Fig. 3 The stem orientation. (A) The stem anteversion angle. (B)The anterior inclination.

III. Results

A. Accuracy of the estimated stem location

The average errors and root-mean-square errors (RMSE) of the estimated stem position relative to the femur are listed in Tables 1 and 2, respectively. The X, Y and Z axis of the femoral coordinate system corresponded approximately to the anteroposterior direction, the proximal femoral axis and mediolateral direction, respectively. The average error represents the bias of the estimated 3D location in each direction. The translation error along the z-axis was biased negatively. For rotations, the average errors had positive bias. The RMSE represents the measurement accuracy for the 3D estimation of the implant position. The total average accuracy of our novel technique was within 0.3 mm of translation and 0.4º of rotation, regardless of the slice pitch.

Table 1 Average error and standard deviation (SD) of the estimated stem position relative to the femur.

Slice pitch	Translation (mm)			Rotation (º)		
	X	Y	Z	X	Y	Z
1 mm	0.20 (0.24)	-0.11 (0.27)	-0.17 (0.18)	0.04 (0.31)	0.64 (0.17)	0.08 (0.39)
2 mm	0.20 (0.26)	-0.20 (0.34)	-0.22 (0.11)	-0.08 (0.34)	0.64 (0.24)	0.06 (0.36)
3 mm	0.20 (0.26)	-0.36 (0.41)	-0.28 (0.13)	-0.09 (0.33)	0.53 (0.23)	0.05 (0.34)

Table 2 The RMSE of the estimated stem position relative to the femur.

Slice pitch	Translation (mm)			Rotation (º)		
	X	Y	Z	X	Y	Z
1 mm	0.30	0.27	0.24	0.28	0.66	0.36
2 mm	0.30	0.36	0.24	0.32	0.68	0.33
3 mm	0.31	0.51	0.30	0.31	0.57	0.31

B. Evaluation of patient-specific 3D position of stem

The inter-subject (age, body height, weight, and bone mineral density) parameters and stem anteversion and anterior inclination were listed for each individual in Table 3. These parameters varied among subjects. The stem anteversion ranged from 7.6 to 33.6º. The anterior inclination ranged from -4.6 to 0.5º. The bone mineral density ranged from 0.46 to 0.56 g/cm^3.

Table 3 Inter-subject and surgical parameters.

Subjects	Inter-subject parameters				Surgical parameters		
	Age	BH (cm)	BW (kg)	Density (g/cm^3)	Stem size	Antever-sion	Anterior inclination
#1	80	155	55	0.46	15	7.6º	-4.6 º
#2	74	150	39	0.50	12	33.6 º	0.5 º
#3	93	148	32	0.51	11	33.0 º	0.1 º
#4	40	158	70	0.56	12	18.6 º	-2.6 º
#5	82	150	42	0.51	12	8.2 º	-3.2 º

IV. Discussion

It is important to evaluate the implant position relative to the bone postoperatively since malposition or misalignment of the implant leads to subsequent complications, such as loosening and dislocation after THA. We proposed a novel technique for measuring the 3D implant position, including the precise bone geometry and density data, using pre- and postoperative CT images and a 3D surface registration algorithm. This study assessed the accuracy of our novel technique for the 3D estimation of implant position. The results confirmed that the estimation is sufficiently accurate from the perspective of the pixel size of clinical CT images and is comparable to traditional roentgen stereophotogrammetric analysis (RSA). The reported accuracy of the RSA ranges between 0.05 and 0.5 mm for translations and between 0.15º and 1.15º for rotations (95% confidence interval) [6,7].

We found differences in the stem orientation (anteversion and anterior inclination) among subjects. These surgical parameters and the inter-subject parameters, such as body weight, height, and bone geometry and quality would affect the initial stability of the implant. This technique can be applied easily to other implant components such as the acetabular cup. The advantage of using this technique is that the resulting femur model incorporates precise bone geometry and density based on the preoperative CT data, which makes it possible to simulate impingement while considering the effect of bone geometry and to predict the initial stability of the implant postoperatively using the FEM. In conclusion, our proposed technique is useful for quantifying the 3D location of implants relative to the bone postoperatively and for performing comparative studies among subjects.

Abstract — **One of the potential therapeutic strategies in tissue engineering is to regenerate tissues from in vitro cell cultivations with porous scaffolds, and then implant the cellular-scaffold into patients suffering tissue defects. Tissues engineering is a multi-discipline composed of many subjects, for which quantification by means of mathematical modeling can interpret experimental results and identify dominating factors. In this paper we develop a hybrid mathematic model to simulate the in vitro cell cultures in tissue engineering. A discrete cellular automation model is used to treat the cell population dynamics affected by the biological phenomena of cell proliferation, aggregation, contact inhibition, nutrient-limited viability, and cell random walks. Cell growth rates are randomly taken using a gamma distribution with its mean value determined by the local oxygen concentration. The oxygen evolution in the scaffold is modeled by a differential diffusion-reaction equation, which is solved with a finite difference method. Simulations show for a uniform seeding case, increasing cell migration speed enhances the cell population to a maximum; however further increasing the migration speed turns to reduce the cell number. This is because cells with faster speeds move to the scaffold periphery and block the oxygen transfer toward the interior region, resulting in a nutrient limitation on the overall cell growth. We also test an artificial seeding condition where the same number of cells is initially seeded around the scaffold center. It is found cells in such a case proliferate slowly for a longer time compared with the case of uniform seeding, and ultimately reach a higher cell population as the nutrient limitation is avoided to some extent. The model offers an effective method to assess the cell population dynamics, and the simulation results can provide a design reference for tissue engineering applications.**

Keywords — **tissue engineering, hybrid model, migration, cellular automata, gamma distribution**

I. Introduction

Tissue engineering is an inter-discipline that combines biomedicine and engineering. Its aim is to develop biological substitutes to replace or repair damaged tissues [1]. The proposed approaches involve the development of in vitro cell-scaffold constructs inside which an enough number of cells are uniformly distributed. Many experiments discussed the relationship between the cell growth and nutrient transport in the cell-seeded scaffolds. Results show that the scaffold permeability decrease with cell growth, ultimately obstructing nutrients transport to the interior of the scaffold. Therefore nutrient transport is an important factor in engineering tissue grafts [2].

Mathematical modeling provides useful insights into the nutrient limitation in tissue engineering cell cultures. Previous research used the volume average method to treat the cell and nutrient phases of the cell culture system, describing the nutrient transport and consumption with a macroscopic view [3]. The effects of the nutrient concentration on cell proliferation in a scaffold can be assessed in an efficient way [4]. However, such an approach cannot exactly express cell individual behavior and its corresponding effects on the in vitro cell cultures.

Cellular automaton method takes a microscopic view of cell individuals. By dividing the entire scaffold domain into a cellular grid with each grid site called a cellular automaton. Cells are simulated to move from one automaton to another obeying characteristic rules proceeding with activities and expressing cell population dynamics as a whole. Zygourakis et al. used cellular automata to simulate the cell contact inhibition and showed cell growth rates slow down as a result of the shortage of available space in the later period of cell culture [5]. Kino-Oka et al. developed an asynchronous cell proliferation model in static culture [6]. The model predicted the cell proliferation is affected by nutrient concentration. More recently, Cheng et al. combined cell proliferation, random walks, contact inhibition and aggregation into the cellular automaton but the nutrient regulation on the cell growth was neglected [7].

In this study we develop a hybrid mathematic model to simulate the in vitro cell cultures in tissue engineering. A discrete two-dimensional cellular automation model is used to treat the cell population dynamics affected by the biological phenomena of cell proliferation, aggregation, contact inhibition, and cell random walks. The average cell cycle time is determined by the local oxygen concentration.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1737–1740, 2009
www.springerlink.com

II. Mathematical model

As illustrated in Figure 1 we consider cells are seeds onto a porous scaffold with interconnected pores [2]. The cellular construct is placed in a cell culture chamber in which the scaffold is submerged in the culture media. We focus on the cell culture in a scaffold, considering (i) the scaffold is a high permeable porous media (ii) the physical model is a biphasic system that involved cell phase and oxygen, the assumed cell-growth-regulating nutrient (iii) oxygen transported by diffusion only (iv) cells migrate in the construct interior only, cannot move outside construct (v) the scaffold periphery is kept with saturated oxygen concentration (vi) degeneration of the scaffold is neglected.

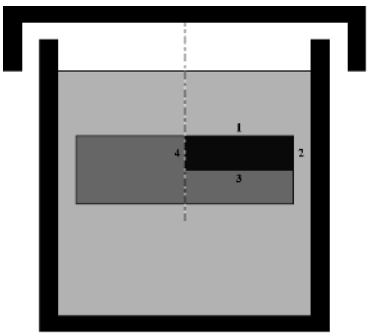

Fig. 1 A sketch of the culture system. For the sake of saving computational effort, only a quarter of the scaffold is taken based on symmetry.

A. Oxygen diffusion-reaction equation

The oxygen diffusion-reaction equation describes the nutrient diffusion by concentration gradient and consumption by cells is

$$\frac{\partial}{\partial t} C_{O_2} = -\nabla \cdot \mathbf{J} + R \tag{1}$$

where **J** is the nutrient concentration flux, and it can be written by Fick's law as

$$\mathbf{J} = -D_{eff} \nabla C_{O_2} \tag{2}$$

C_{O2} is the oxygen concentration, D_{eff} is the effective diffusion coefficient of oxygen. Its value corresponds to the value calculated using oxygen diffusion coefficients in the culture medium and cells,

$$D_{eff} = \begin{cases} D_o^w & \text{between vacant sites} \\ 2\left(\frac{1}{D_o^c} + \frac{1}{D_o^w}\right)^{-1} & \text{between vacant and cell-occupied sites} \\ D_o^c & \text{between cell-occupied sites} \end{cases} \tag{3}$$

where D_o^w is the diffusion coefficient of nutrient in culture media, D_c^c is the diffusion coefficient of nutrient in cells. Besides, R is the nutrient consumption rate, it can be written by the Michaelis-Menten type equation as

$$R = -\xi Q_{\max} \frac{C_{O_2}}{C_{O_2} + K} \tag{4}$$

where ξ = 1 or 0 depending on whether the automaton is occupied by a cell or not, Q_{max} is the maximum consumption rate for oxygen, and K is the saturation coefficient for oxygen consumption. For computational simplicity, we take a quarter of the scaffold as the computational region. The oxygen concentration at Boundary 1 and 2 is set equal to C_0. At boundary 3 and 4 which are the symmetric lines, the symmetry condition is applied with the nutrient flux being zero.

B. Cellular automaton model

The computational domain is divided into many cellular automata (Figure 2). Each cellular automaton is assumed to contain once a cell, so the length of each automaton is set as 8.5μm. The model uses the Moore neighborhood for the cells; hence the cell activity of a automaton is affected by its eight neighboring sites. An individual cell is considered to perform at discrete time step the characteristic behavior including cell proliferation, migration, contact inhibition, persistent random walks and cell collision. The time step used for the simulations is one hour.

The characteristic cell behavior is summarized as follows:

Cell proliferation: In different oxygen concentration condition, cell proliferation rates can be expressed by Moser equation as the following form [8],

$$\frac{1}{t_g} = R_g \frac{C_{O_2}}{C_{O_2} + K_0} \tag{5}$$

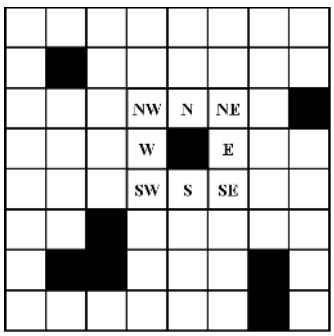

Fig. 2 A sketch of the cellular automata. Black sites denote the cell-occupied automata, white sites denote void space.

where t_g is the average cell proliferation time, R_g is the maximum cell growth rate, and K_0 is the saturation coefficient for cell proliferation. Cell proliferation rates decrease with decreasing oxygen concentration. The length of the cell cycle is randomly taken using a gamma distribution with its mean value equal to t_g [9].

Cell random walks: Cell can migrate to any direction during the cell culture. Each cell moves in one direction for a certain length of time. At the end of the interval, the cell turns into another direction randomly.

Contact inhibition: Cell proliferation is affected by space inhibition. If there is no enough void space around a cell, the cell division stops. In our model where the Moore neighborhood is used, a cell ceases division if the eight neighboring sites around the cell are occupied by other cells.

Cell aggregation: When the cell is migrating, it may collide with another cell in its moving path. Then the two collided cells stop moving for some time before resuming their migration. Furthermore if collided cells proliferate or are collided with other cells, they may form a cell aggregation.

C. Numerical method

A simplified two-dimensional simulation is performed with the combined differential nutrient equation and cellular automata. The x-y coordinates are adopted and the scaffold size is 1cm × 0.116cm (length × height). The calculation domain is divided into cellular automata with size being 8.5μm × 8.5μm. The oxygen evolution in the scaffold is modeled by a differential diffusion-reaction equation, which is solved with a finite difference method. The calculation is conducted by using the parameters and constants listed in Table 1. The calculated values of oxygen concentration are applied for determination of the cell cycle time in the cellular automaton model.

Table 1 List of parameters

Parameters	Values
Nutrient concentration in the surrounding medium, C_0	0.21 mol/m^3
Diffusion coefficient of nutrient in culture media, D_o^w	1.0×10^{-5} m^2/h
Diffusion coefficient of nutrient in cells, D_o^c	1.4×10^{-6} m^2/h
Saturation coefficient for oxygen consumption, K	5.0×10^{-3} mol/m^3
Saturation coefficient for cell proliferation, K_0	6.3×10^{-2} mol/m^3
Length of the automaton, l	8.5×10^{-6} m
Maximum consumption rate of oxygen, Q_{max}	12.2 mol/m^{3}h
Maximum cell growth rate, R_g	7.6×10^{-6} 1/sec
Cell migration speed, S	8.5×10^{-6} m/h

III. Results and Discussion

A. The effect of the migration speed

The spatial-temporal evolution of the cell population is shown in Figure 3 for a uniform seeding case, where initially the seeded cells are assumed to be uniformly distributed inside the scaffold in a random fashion. The associated oxygen evolution is also displayed. After some culture time, the cell divides more quickly around the scaffold periphery because oxygen supply is more sufficient there; in contrast cell divides slowly in the scaffold interior because of the low oxygen concentration due to diffusion limit. We discuss the effect of cell migration speeds on the overall cell growth in Figure 4. Increasing cell migration speed enhances the cell population to a maximum for a uniform seeding case, however further increasing the migration speed turns to reduce the cell number. This is because cells with faster speeds move to the scaffold periphery and block the oxygen transfer towards the interior region, resulting in a nutrient limitation on the overall cell growth.

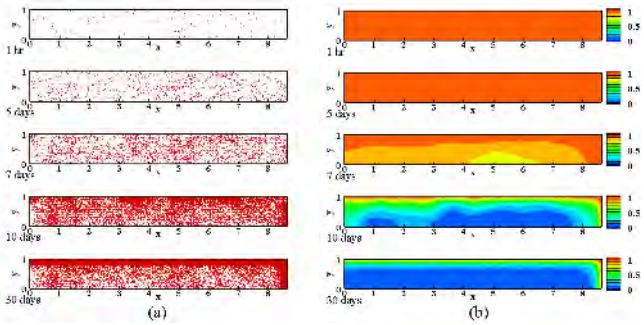

Fig. 3 A uniform seeding case. (a) cell, and (b) oxygen concentration distribution. The cell migration speed is 8.5μm/h.

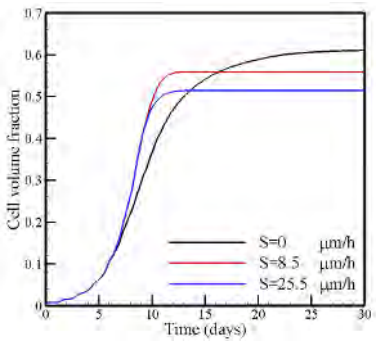

Fig.4 The effect of cell migration speeds on the average cell volume fraction over the scaffold in the uniform seeding case.

B. The effect of the seeding distributional style

We also discuss the effect of the seeding distributional styles by artificially assuming the same number of cells as in the uniform case is initially seeded at the scaffold center. The results of the cell population and oxygen concentration distribution are show in figure 5. It is found cells in concentrated seeding case proliferate slowly for a longer time compared to the case of uniform seeding, and ultimately reach a higher cell population as the nutrient limitation is avoided to some extent (Figure 6). In such a case, the cell can proliferate at the cell colony boundary, while the interior cells stop division due to the cell contact inhibition. However, since more enough oxygen can be supplied to the cell colony from the outside region, so that the cells can slowly spread toward the scaffold boundary.

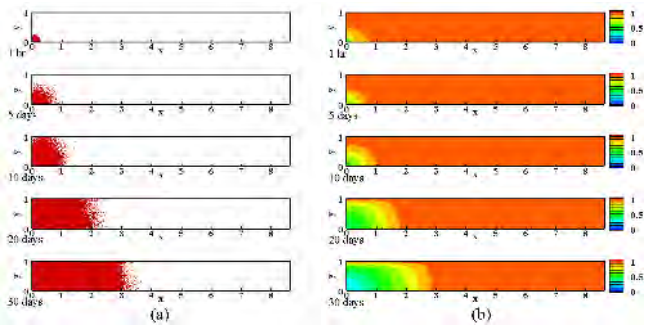

Fig. 5 A concentrated seeding case. (a) cell, and (b) oxygen concentration distribution. The cell migration speed is 8.5μm/h.

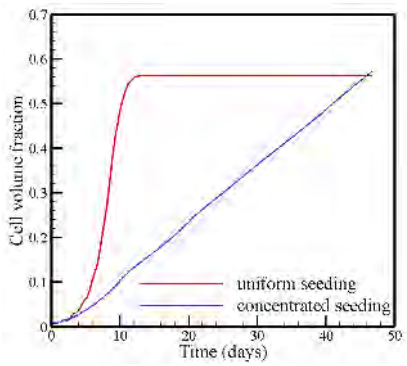

Fig. 6 The evolution of the average cell volume fraction over the scaffold in the uniform seeding case and the concentrated seeding case respectively. The cell migration speed is 8.5μm/h.

IV. Conclusions

In this article, we develop a hybrid model combining a differential nutrient equation and cellular automata to simulate tissue-engineering cell cultures. Simulations show for a uniform seeding case, increasing cell migration speed enhances cell population only to some limit; further increasing the migration speed turns to reduce the cell number. We also test an artificial seeding condition where the same number of cells is initially seeded at the scaffold center. Cells in such a case tend to proliferate slowly for a longer time compared with the case of uniform seeding, and ultimately can reach a higher cell population as the nutrient limitation is avoided to some extent. The model offers an effective method to assess the cell population dynamics, and the simulation results can provide a design reference for tissue engineering applications.

Upconversion Nanoparticles for Imaging Cells

N. Sounderya[1], Y. Zhang[1,2]

[1] Division of Bioengineering, National University of Singapore,Singapore 117574
[2] Nanoscience and Nanotechnology Initiative,National University of Singapore,Singapore 117576

Abstract — **Lanthanide doped upconversion nanoparticles (UCN's) were synthesized for imaging applications. The particles obtained are hydrophobic in nature. It is of great interest to make them hydrophilic for biological applications. Core/shell particles with UCN's as core and silica as shell were synthesized by Stober method in a basic medium. The silica shell was functionalized with amine group to enable antibody conjugation. TNBS(tri-nitrobenzene sulfonic acid) assay was performed to ensure amine functionalization.These particles were conjugated to an antibody targeted against Connexin 43, a well known gap junction protein. TEM was done on particles prior to conjugation of antibody. Characterization of the particles before and after conjugation was done by DLS, Zeta potential measurement. Confocal imaging experiment was done on the cardiomyocytes (H9c2 cells) with the UCN-silica-NH_2 particles conjugated with anti-Cx43. Experiments show the feasibility of using UCN's for targeting and imaging gap junctions.**

Keywords — **Upconversion, Nanoparticles, Core/Shell, Silica, Cardiomyocytes**

I. Introduction

Upconversion Nanoparticles(UCN's) are nanoparticles that absorb in the Near Infra Red (NIR) region and emit in the visible region. We have synthesized $NaYF_4$ nanocrystals doped with ions such as Er3+/Tm3+ and ytterbium in our lab.$NaYF_4$ have been known to be best for lanthanide doped upconversion nanoparticles. Hence, an organic route was employed to obtain the doped crystals. These crystals are hydrophobic in nature and are dispersed in solvents like cyclohexane or chloroform.The UCN's have some advantages over the commercial organic dyes and quantum dots.They do not undergo photobleaching on long term exposure to excitation source, they are chemically stable and less toxic. Use of these particles in cell imaging shows a high signal to noise ratio.This is due to reduced autofluorescence from cells in NIR region of excitation [1]. For application to cellular imaging it is necessary to make them hydrophilic. There are different methods to do this, such as attaching ligands to the surface, coating them with an oxide layer and coating materials that are hydrophilic for example polymeric materials like PEI, PAAc etc or silica [2, 3]. Silica coating of the particles was considered as an option because silica chemistry is well established. It is also known that silica surface is easy to functionalize and hence conjugation of biomolecules to the surface is also simple. It is possible to control the polymerization and obtain core/shell structures with silica coating. The UCN/silica and amine functionalization are achieved by Stober synthesis [4]. The particles obtained are monodisperse but have a tendency to form aggregates over time. Hence, the the particles are required to be stored in ethanol and transferred to water just before use. The surfactant concentration could also be a factor in aggregate formation, and modification to existing process is still being worked on to reduce aggregation.

These particles after suitable modification were to be used on biological system for imaging application. The cell type of interest was cardiomyocyte and the aim was to image the gap junctions formed between the cardiomyocytes . Gap junctions are channels that are formed between cells for electromechanical coupling. Cardiomyocytes are known to form gap junctions between them as well as with cells such as bone marrow cells and skeletal myoblast when co-cultured. The gap junction formation might suggest about the compatibility of skeletal myoblast or bone marrow cells upon transplantation to heart [6].So it's of particular interest to image the gap junctions formed. Current technique uses fluorescence recovery after photo bleaching to image and quantify the gap junctions [7, 8]. But these methods are restricted to in vitro studies and cannot be done in vivo. Since, the UCN's do not undergo photo bleaching and can be targeted to specific location; they can be used for in vitro and in vivo applications. Dev et al. have discussed the imaging of these particles after their injection in the rat thigh and abdomen. This suggest in vivo imaging application of these particles are possible [9]

This paper discusses the synthesis and silica coating of UCN's ,amine fucntionalization of the silica surface and conjugation of the antibody of interest, anti-connexin43 which is specific to the gap junctions, by Glutaraldehyde spacer method on the UCN/silica-NH2 [5]. The characterization and confocal imaging results have also been presented and discussed.

II. Materials and methods

Synthesis of UCN's and silica coating: The UCN's were synthesized by a one pot variable temperature method. The

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1741–1744, 2009
www.springerlink.com

method utilizes reagents in stoichiometric proportions to obtain almost complete reaction. The shape of the nanocrystals was found to vary with the volumes of surfactants (oleic acid and octadecene**)** used. [4].The surfactant concentrations were maintained such that hexagonal nanocrystals are obtained. The particles were dispersed in 50ml of cyclohexane with a concentration of 1 mmol.

Silica coating of the particles was done by Stober synthesis in a basic medium. 5ml of UCN's were reacted with 100 ul of TEOS (0.1ml TEOS in 0.9ml cyclohexane) in the presence of the surfactant (0.2ml Igepal Co-520 and 0.04ml ammonium hydroxide) for 48hrs with mild agitation. The silica coated UCN's were precipitated with acetone ethanol mixture and centrifuged. The precipitate was then resuspended in 15ml of ethanol. The particles were characterized by TEM and DLS measurements.

Membrane Integrity Assay: A membrane integrity test was performed on cells with the silica coated particles. The cell type used for cytotoxicity were skeletal myoblasts and the cell number was $5x10^{\wedge 4}$ cells in each well before incubation. The incubation time for the cytotoxicty test was 14hrs.

Amine functionalization and Antibody Conjugation: The silica coated nanoparticles have to be functionalized with amine or carboxyl groups to conjugate antibody to their surface. This was done by agitating 0.15ml of APTS/TEOS mixture(10 mol% APTS mixture) in the presence of 0.2 ml ammonium hydroxide and 10ml of silica coated UCN's.

Amine functionalization was checked by using TNBS assay. Ethanolamine was used as the standard. A range of volumes of ethanolamine were reacted for 2 hrs at 37^{o}C with 200ul of TNBS diluted with 600ul of double distilled water in the presence of 200ul of bicarbonate buffer. After 2 hrs, 600ul of 1N HCl was added and the solution was vortexed to ensure mixing. The absorbance of the samples was obtained on a UV-VIS spectrometer at 355nm. 50ul of the sample was treated with TNBS by the same procedure as stated above and the absorbance was measured. The absorbance was compared to absorbance plot obtained from the standard, ethanolamine. DLS and zeta potential data were obtained and compared to silica coated UCN's.

Gluteraldehyde spacer method was used to conjugate antibodies to the amine functionalized silica coated UCN's [5]. The antibodies were purified by using membrane centrifuge tube to remove sodium azide in the solution. 3ml of the functionalized nanoparticle beads are washed 2 times in PBS buffer of pH 7.2. PBS was used as wash and coupling buffer.After second wash the pellets were resuspended in 10ml of gluteraldehyde solution.(10% by volume of gluteraldehyde dissolved in PBS). The solution was vortexed and the solution was left under continous mixing for 1-2 hrs at room temperature. After 1.5 hrs the solution was centrifuged in PBS and resuspended in 5ml of PBS. Resuspension was ensured by vortexing and sonication. The antibody was dissolved in 5ml of PBS and the solution was added to the particle solution. The solution was left to react with continous mixing for 2-4hrs. 10ml of quenching solution, 30mM ethanol amine with 0.05% triton-X was added and solution left to stand for 30min . The particles were centrifuged twice with PBS and stored in 5ml of PBS with 0.01% triton-X the blocker. [6]

Antibody anti-connexin43 was used for the conjugation with particles and they were later used for imaging on H9c2 cells. UV-VIS absorbance was used to check for antibody conjugation. Fluorescence measurement was a done at an excitation of 350nm on the antibody conjugated particles using a microplate reader.DLS data was also obtained for the antibody conjugated particles.

Confocal Cell imaging: The antibody conjugated to the particles being anti-CX43, preliminary imaging experiments were carried out on cardiomyocytes. The cardiomyocytes(H9c2 cells) were plated on 8 well chamber and allowed to attach to the chamber. The cells were incubated with particles for 8hrs. And imaging was carried out on a confocal system with a 980nm wavelength continuous wave laser.

III. Results and Discussion

The DLS measurement and the TEM images for the UCN's with and without silica are shown in fig 1.

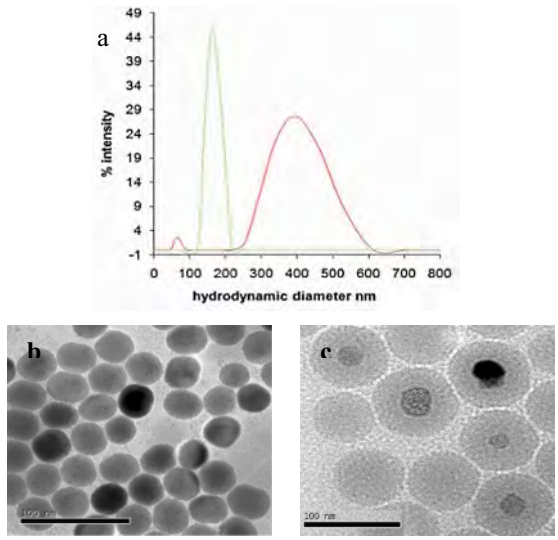

Fig 1. a) DLS data for UCN- silica(green), UCN- silica- NH_2 (black), UCN –silica- NH_2.antibody(red) b) TEM of UCN in cyclohexane c) TEM of UCN-silica in water

The comparision of the size of antibody tagged UCN-silica-NH_2 and UCN silica show an increase as expected.(Fig 1) The zeta potential of the UCN-silica and UCN-silica-NH_2 were measured and the zeta potential was found to decrease from high negative value for the UCN-silica as silica is negatively charged to a lower negative value for UCN-silica NH_2 as they have an addition positive charge on them apart from negatively charged silica.(table 1) . The negative charge on UCN-silica-NH_2 suggest that the coating on the silica is not complete. This could cause aggregation on storage ,hence coating should be further improved.

Table 1. Zeta potential of surface modified UCN

Particle Type	Zeta Potential (mV)
UCN -silica	-136
UCN-silica-NH_2	-60
UCN-silica-NH_2-antibody	-2.76

Further,TNBS assay ensured amine functionalisation. The absorbance for sample reaction with TNBS was compared to the standard curve obtained with ethanol amine reaction with TNBS. Through a trendline fit to the standard,the volume of standard having same absorbance as the sample was estimated (Fig 2). The estimated volume was 1.1ul of ethanol amine.TNBS reaction was performed for volumes ranging from 1.1ul to 1.2ul of ethanol amine with a 0.1 ul variation. The absorbance of the UCN-silica-NH_2 sample matched the absorbance value of 1.16ul of ethanol amine. This shows that the sample of 50ul had amine group equivalent to 1.16ul of ethanol amine. Thus this confirms the presence of amine group on the particles.

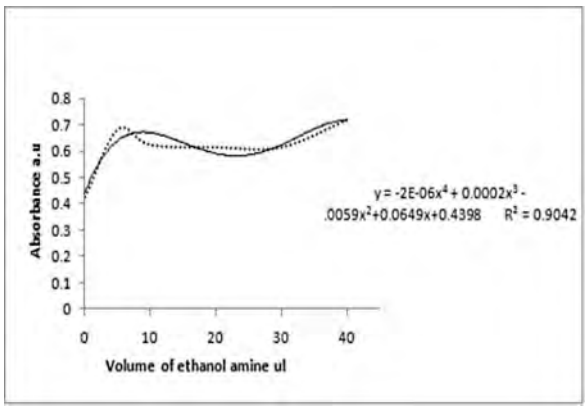

Fig 2. TNBS assay: absorbance of standard (Dashed Line) and trendline fit for the standard (Dark Line)

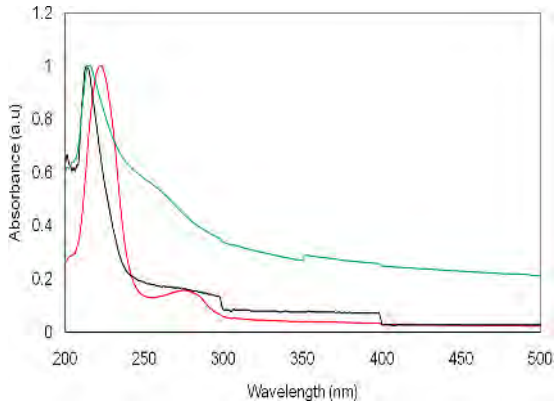

Fig 3. Absorbance data for UCN-silica-NH_2 (Green) , UCN-silica-NH_2-antibody (Black) and antibody (Red)

UV-VIS spectrometry was done after the conjugation of antibody to the UCN-silica-NH_2 and its peak of absorbance was compared to the peak of absorbance of the antibody (Fig 3). The peak at 260nm is known to be a characteristic of tryptophan group present in any protein ,in this case the antibody.

To further confirm the presence of antibody Fluorescence emission was checked for the UCN-silica-NH_2 ,UCN-silica-NH_2-antibody and antibody at an excitation of 350nm. The data obtained are shown in table 2. The fluorescence was measured by varying the emission filters to observe change in the intensity of emission for UCN-silica-NH_2 and UCN-silica-antibody. It is known that tryptophan in the antibody has a broad fluorescence emission and the amine groups show emission around 420-450nm. With no emission filter, the intensity for the antibody and UCN-silica-NH_2-antibody increased. The UCN-silica-NH_2-antibody emission was higher than that of UCN-silica-NH_2. And it was observed that the emission for UCN-silica-NH_2 was more than 3 times higher than UCN-silica-NH_2-antibody when an emission filter of 460nm was used. This decrease in the antibody conjugated UCN could be attributed to the emission peak cut off at a shorter wavelength.

Table 2. Fluorescence Emission data (normalized w.r.t UCN-silica-NH2-antibody) from Microplate Reader with excitation filter of 355nm

Emission Filter	UCN-silica-NH_2	UCN-silica-NH_2-Antibody	Antibody
No filter	0.52	1	0.35
460nm	3.77	1	0.56

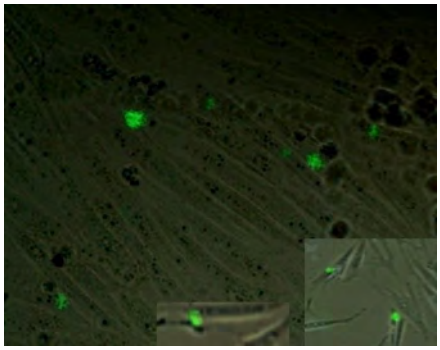

Fig 4. Confocal image of cardiomyocyte incubated with UCN-silica-NH_2-antibody.Inset: zoomed image of UCN at junction of two cells

Membrane integrity test was carried out on skeletal myoblats cells with the silica coated UCN's. The cell death percentage 10-20% after 14 hr incubation and for a concentration of upto 20ug/ml. 20ul of the particle solution was added to the cells. The working range for fluorescence imaging with these particles on cells is 1ug/ml – 3ug/ml and the volume range used is 10-20ul.The cell death data was consistent with that reported by Rufaihah *et al* [10].

The data for UCN-silica-NH_2 antibody are with antibody starting concentration of 0.025mg/ml for the conjugation.The absorbance peaks were weak for concentrations lower than the 0.025mg/ml. Also when the particles were incubated with cardiomyocyte cells for confocal imaging, the ones with lower concentration of antibody showed almost no fluorescence. At the concentration of 0.025mg/ml of antibody, the particles were easy to spot and hence, qualitatively, the uptake was good. Experiments are being carried out to quantify the cellular uptake.

Confocal imaging of cardiomyocytes was also done. The images obtained showed fluorescence from particles in between cells (Fig 4). UCN-silica-NH_2 and UCN-silica were used as negative controls for gap junction imaging. But the fluorescence images after 8 hr incubation for the UCN-silica-NH_2 with anti-Cx43 had more particles tagged between cells. The controls didn't show significant fluoresc ence. The presence of fluorescence in between cells suggest that the UCN's are targeting gap junctions. Thus it is feasible to image gap junctions with the silica coated antibody conjugated UCN's. The quantification of the cellular uptake is being done.

Conclusion

Upconversion nanoparticles with Erbium doping were synthesized and silica coating of the particles was done to make them hydrophilic. The surface was modified to make the particles suitable for application in a biological system of interest, the cardiomyocytes. The silica coating was functionalized with amine groups and experiments were carried out to confirm the functionalisation. Later, Anti-Cx43, an antibody that conjugates to connexin 43 in gap junctions of the cardiomyocytes was attached to the amine moiety by gluteraldehyde spacer technique. Particle size measurement was done to check the conjugation and an increase in the size was noted and also zeta potential measurements were done. The decreasing zeta potential was as expected upon antibody conjugation. Absorbance measurement also indicated a peak at 260nm (which is characterisitic of the tryptophan group in the antibody) for the antibody conjugated particles. The particles were also tested for cytotoxicity and also an imaging experiment was carried out on cardiomyocyte for a qualitative study of the particle targeting. The results show the UCN's could target the gap junctions .It is of interest to co-culture skeletal myoblast/bone marrow cells with cardiomyocytes and target the UCN particles with antibody to the gap junctions formed between these cells. Quantification of the cellular uptake shall also be done.

Simulation of Cell Growth and Diffusion in Tissue Engineering Scaffolds

Szu-Ying Ho[1], Ming-Han Yu[1] and C.A. Chung[1,2]

[1] Department of Mechanical Engineering, National Central University, Taiwan
[2] Graduate Institute of Biomedical Engineering, National Central University, Taiwan

Abstract — **With the development in recent years, tissue engineering is becoming one of the therapeutic strategies that have the potential for repairing the damaged or malfunctioned human tissues. The proposed scheme of tissue engineering generally contains seeding cells onto a porous scaffold. The cell-scaffold construct is then cultured in vitro for a period of time and transplanted into the patient afterward. Because the biochemical materials are expensive and the experimental procedures are time-consuming, it is valuable to have a simulation model that can assess the cultivation conditions beforehand. We develop a continuum mathematical model for the simulation of cell growth and migration in porous scaffolds based on the basic principle of mass conservation for both cells and nutrients. In addition to cell growth kinetics, we incorporate cell diffusion term to treat the macroscopic effect of cell random walks on cell distributions. The model is validated by comparison with experimental data available in literature. The simulation model is applied to investigate cell growth and distribution under uniform and various concentrated seeding circumstances. Results show that the overall cell growth rate in a scaffold is affected both by the extent of the cell diffusion surface and the amount of the nutrient supply. Uniform seeding finishes the first growth rate out of the seeding cases considered, because uniformly seeded cells can diffuse evenly in all directions, preventing nutrients uptake only from some over crowded, local areas. For the concentrated seeding cases, the larger the cell diffusion surface the faster the cells can grow. Moreover, cells grow faster when seeded close to the scaffold periphery because cells can obtain more nutrient supplies in such cases. The model provides an efficient way of assessing cell-scaffold developments in vitro for tissue engineering applications.**

Keywords — **Tissue Engineering, Mathematical Model, Cell Seeding Positions**

I. Introduction

Tissue Engineering is considered a replacing technology for the traditional organ transplants. Since the traditional method of transplant operations face problems such as donor shortages, the blood type and size match problems, and immune system rejections, it is not a satisfying way to repair human body. By contrast, tissue engineering creates autologous grafts using cells isolated from a small biopsy, expanding the cells in vitro and seeding them onto a scaffold matrix. No immune problem will be encountered with the cell-seeded implants. However, as cell-scaffold developments consist of complex multi-disciplines, both experimental and theoretical efforts need to be made before reaching the final goal of tissue replacement.

Experiments investigated the in-vitro cultivation of cell seeded scaffolds. The outcome shows that the thicker the scaffold is, the lower the resulting cell density becomes, which suggests that the cell growth in a scaffold tends to be inhibited by nutrient diffusion limitation because new grown cells take up the spaces inside the scaffold and leading to the obstruction of nutrient transportation [1]. Theoretical models using species continuity equations to describe the spatial-temporal evolution of cells and nutrients also reveal the diffusion limit on cell growth [2, 3].

Cell seeding as the first step of cell-scaffold construction determines the initial cell number and distribution inside a scaffold. The subsequent cell growth, migration and phenotype expression are affected by the seeding methods. Static and spinner flask seeding have been utilized, for which low cell seeding efficiency is shown, and cells tend to concentrate around the scaffold surface [4, 5]. The most efficient way that has been demonstrated so far for cell seeding is the oscillatory perfusion, through which high cell numbers and uniformity have been reported.

For a theoretical assessment on seeding effects, we develop a mathematical model. The model is validated by matching simulation results with the experimental data from literature [1] by adjusting the cell growth coefficient. Simplified two-dimensional simulations are then performed for investigation of cell growth and migration in scaffolds concerned with different cell seeding positions and different cell seeding areas.

II. Mathmatical model

For the sake of simplicity, the mathematical modeling is set by assuming no diffusion of nutrients through the scaffold matrix, and we also neglect the scaffolds degradation during cell cultivation. In addition, we set the cultivation environment as the combination of cell colony space (cell phase) and interstitial medium space (fluid phase), and in both spaces the nutrient transports by diffusion. Only one kind of nutrient (glucose) is considered in the simulation.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1745–1748, 2009
www.springerlink.com

The cell growth and distribution are conducted by proliferation, apoptosis, and migration.

A. Mass conservation of nutrient

The continuity equation of glucose describes the nutrient concentration change with time affected by the nutrient diffusion in both cell phase and fluid phase, and consumption in the cell phase. By volume averaging, the conservation equation governing the nutrient concentration can be written as

$$\frac{\partial}{\partial t}\left(C_f\phi_f + C_c\phi_c\right) + \nabla\cdot\left(\boldsymbol{J}_f\phi_f + \boldsymbol{J}_c\phi_c\right) + R_n\phi_f = 0 \tag{1}$$

where ϕ_f and ϕ_c are defined as the fluid and cell volume fraction respectively. The average nutrient concentrations in fluid and cell phases are defined as C_f and C_c. In the diffusion term, coefficients $\boldsymbol{J}_f$ and $\boldsymbol{J}_c$ represent the nutrient flux in the fluid and cell phases. In the equation, R_n is expressed as

$$R_n = R_m C_f \tag{2}$$

where R_m is the maximum nutrient consumption for cells in a single time unit. From the Fick's Law, we obtain

$$\frac{\partial}{\partial t}(C_f\phi_f + C_c\phi_c) = \nabla\cdot(D_f\phi_f\nabla C_f) + \nabla\cdot(D_c\phi_c\nabla C_c) - R_n\phi_f \tag{3}$$

where D_f and D_c are diffusion coefficient for nutrient transportation in fluid phase and cell phase respectively [2]. We further assume that the nutrient diffusion has reach balance between the fluid and cell phases, which yields

$$C_c \cong K_{eq}C_f \tag{4}$$

where K_{eq} is the equilibrium coefficient. By using Equation (4), we can obtain a single unknown, the nutrient concentration variable in the fluid phase, governing by the following equation

$$\frac{\partial}{\partial t}\left[\left(\phi_f + K_{eq}\phi_c\right)C_f\right] = \nabla\cdot\left[\left(D_f\phi_f + D_c\phi_c K_{eq}\right)\nabla C_f\right] - R_n\phi_c \tag{5}$$

B. Mass conservation of cells

Cell equation is dominated by two factors. The first is the cell diffusion due to random walks and the second is the cell growth regulated by nutrient concentration. The volume average equation of cell mass can be written as

$$\frac{\partial}{\partial t}(\rho_c\phi_c) + \nabla\cdot\boldsymbol{J} = \tilde{R}_c \tag{6}$$

In the equation, the cell motion caused by cell random walks is described by

$$\boldsymbol{J} = -D\nabla(\rho_c\phi_c) \tag{7}$$

where D is the diffusion coefficient for cellular random motion, and ρ_c is the cell average density in cell phase in scaffolds. Combine the previous equations (6) and (7), we rewrite the cell equation as

$$\frac{\partial}{\partial t}\phi_c = D\nabla^2\phi_c + \tilde{R}_c/\rho_c \tag{8}$$

Then, we apply Modified Contois Equation [6] to describe the effects on cell proliferation due to the inhibition of cell density, nutrient saturation and cell growth products. The cell growth kinetic function, $\tilde{R}_c$, is written as

$$\tilde{R}_c = \left[\frac{R_g C_c}{K_c(\rho_c\phi_c) + C_c} - R_d\right]\rho_c\phi_c \tag{9}$$

Here, the coefficient K_c is the Contois saturation coefficient, ρ_c is the cell mass density of which the value is taken as 1.020 g/cm^3 for cartilage cells [7], R_d is the apoptosis rate, and R_g is the maximum growth rate. We set K_c to be 0.154, and we assume R_d =3.3×10^{-4} sec^{-1} concerning the average life cycle of 35 days for cartilage cells, and R_g varies with different scaffold thickness obtained by matching the experimental data [1]. Inserting equation (4) into equation (9) yields

$$\frac{\partial}{\partial t}\phi_c = D\nabla^2\phi_c + R_c\phi_c \tag{11}$$

and R_c is defined as

$$R_c = \left[\frac{R_g C_f}{K_c(\rho_c\phi_c)/K_{eq} + C_f} - R_d\right] \tag{12}$$

C. Initial and boundary conditions

For the initial cell seeding condition, we consider six kinds of cell seeding cases, which are shown in Fig. 1. The basic one is *Uniform Seeding*, which is also the one used to compare with the experimental result in literature. In the six seeding cases, the same amount of cells is seeded into the scaffolds. Except for the uniform seeding, the seeding areas of the five concentrated seeding cases are equal size. The six cell seeding cases are designed to be influence by two geometric factors: The initial cell diffusion surface, and the cell seeding surface contact with the scaffold boundary. For the concentrated seeding, instead of using a step function

for the initial cell distribution, a more realistic distribution is expressed as [8]

$$\phi_c = \frac{N_0 V_{cell}}{A_d x_d}(1+\frac{2x_i}{x_d})(1-\frac{x_i}{x_d})^2 \quad (18)$$

where N_0 is initial cell seeding numbers, V_{cell} is the volume of a single cartilage cell, A_d is the size of seeding area, x_i accounts for the seeding location and x_d is the width of seeding area.

For the boundary conditions, we considered that the scaffolds are submerged in culture medium. The nutrient concentration at the four boundaries of the scaffolds is assumed a constant equal to that of the submerging culture medium. As for the boundary condition for cells, we assume that the cells cannot cross over the boundaries of the scaffold.

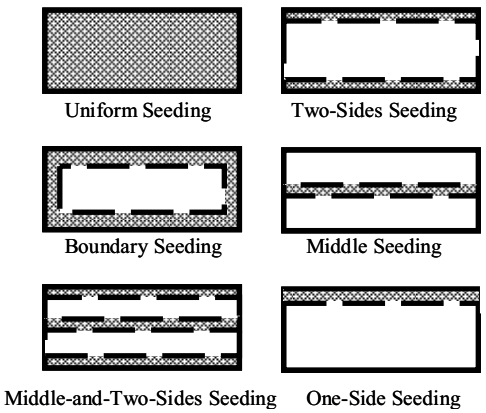

Fig. 1 Six seeding cases

Table 1 The characteristic for 6 cell seeding cases (in dimensionless scale)

Seeding Case	Initial cell diffusion surface	Surface for cell seeding area contact with boundary
Uniform Seeding	Whole scaffold	8.4
Middle-and-Two-Sides seeding	12.8	6.55
Boundary Seeding	7.9	8.4
Two-Sides Seeding	6.4	6.55
Middle Seeding	6.4	0.15
One-Side Seeding	3.2	3.35

D. Solution Procedure

We use COMSOL Multiphysics v3.2a as our mathematic solver, which utilize a finite element method, and a triangular mesh is used for computation. Mesh refinement test is performed to ensure the relative errors smaller than 10^{-4}, or the absolute errors smaller than 10^{-5}.

III. Results and Discussion

To validate our model, we compare our simulation result with the experimental data of Freed et. al [1]. By matching the cell growth coefficient R_g, we find that this simplified formulation can give quite fair agreements with the experiments. The comparison is shown in Fig. 2. It is the cell growth result over a 30-day cultivation. The symbols ☆, △, □, ○ represent the experimental data, ☆ for scaffold thickness 0.088cm, △ 0.116cm, □ 0.168cm, and ○ 0.307cm. The four lines are the simulation results.

The cell growth in the six cell seeding cases are compared by setting the thickness of the scaffold as 0.307 cm, the length as 1 cm, and the cultivation time is 50 days. The ranking of cell growth is shown in Fig. 3. Worthy of mentioning is that when the cultivation time is prolonged, the resulting cell volume fractions in all cases gradually become similar. In other words, seeding position seemingly affects only the overall rates of cell growth determining by the time span that is needed for cells to reach the maximal population in a scaffold, but not affect the ultimate cell number. The reason for the difference in growth rates between the six seeding cases is interpreted as follows. From the difference between the *Uniform Seeding* and *Boundary Seeding*, we infer that the growth rate of *Uniform Seeding* is higher because there is less restriction on the cell diffusion direction in the case, therefore it prevents cells to compete nutrients in crowded areas.

We further compare the cases with different cell diffusion surfaces. In the case of *Middle-and-Two-Sides Seeding*, the cell diffusion surface is twice than the *Two-Sides Seeding*, the cell growth rate in the previous case is therefore relatively higher. We also observe the same comparative situation between the *Middle Seeding* and *Side Seeding*.

Besides the effects of cell diffusion surface, another point worth noticing is the surface contact between cell seeding area and the surrounding medium. We pick out the comparison between the *Two-Sides Seeding* and *Middle Seeding* for discussion. In these two cases, they both have the same size of cell diffusion surface, but they are different in the surface contact with the culture medium. As table 1 shows, *Two-Sides Seeding* has the surface contact area of 6.55, while *Middle Seeding* has only 0.15. And this contact area difference leads to the better cell growth rate for the *Two-Sides Seeding* case.

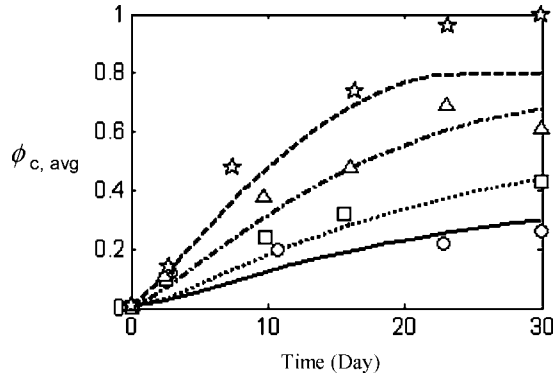

Fig. 2 Result comparison between simulation and experiment.

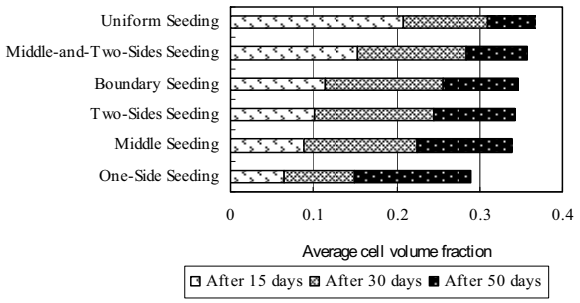

Fig. 3 Cell growth for six cell seeding cases

IV. Conclusion

The research of cell cultivation simulation in the past did not discuss how cell seeding areas and cell seeding positions influence the cell growth rate. In this article, we investigate the relationship between the geometry of cell seeding and cell proliferation, and we obtain the following seeding conditions that affect cell cultivation. First, the most significant factor that affects cell proliferation is the size of diffusion surface for the cells to migrate from the initial seeding area to other region of a scaffold. With the larger cell diffusion surface, cells are able to expand freely in the scaffold, leading to a more even cell distribution in the scaffold, and therefore lessen the conditions of cell competing nutrient in a over crowded area.

Another factor that affects cell growth is the contact surface of the seeding area with nutrient supply. Under same cell diffusion surface, the cases with larger surface contact between cell seeding area and scaffold boundaries tend to have a better cell growth rate. Cells can obtain nutrient more abundantly and easily when they are contacted with the scaffold boundaries, through which nutrients are transfer into the scaffold. Inversely, the lesser the boundary contact, the worse the cell growth rate can be.

The conclusion of this article can be used as a reference for cell cultivation environment setting. Yet, there are still some limitations in our mathematical model. For instance we have not included the dual role of growth promotion and space inhibition by the extracellular matrix that we are planning to incorporate in the future studies.

Simulation of the Haptotactic Effect on Chondrocytes in the Boyden Chamber Assay

Chih-Yuan Chen[1] and C.A. Chung[1,2]

[1]Department of Mechanical Engineering, National Central University, Jhongli City, Taiwan, R.O.C.
[2] Graduate Institute of Biomedical Engineering, National Central University, Jhongli City, Taiwan, R.O.C.

Abstract — **Tissue growth, wound healing, inflammation response and cancer spread are closely related to cell movement phenomena. Cell movement often exhibits random walks as well as tactic responses to certain chemicals. Boyden chamber assays have been widely used to measure the cell diffusive and tactic coefficients for cell motion assessments. We develop a mathematical model based on the mass conservation principle, and apply it to carefully elucidate the Boyden chamber experiment conducted by Shimizu et al. (1997), in which chondrocytes were tested for their haptotactic behavior responding to type II collagen. The whole process including cells sediment through the cell suspension in the upper well and the consequential migration within the collagen-coated membrane is well simulated using the developed model. To our knowledge, cell sediment phenomena have so far been neglected in previous literature. The haptotactic effect is treated by the receptor-kinetic model, and the cell random walk is characterized macroscopically as cell diffusion. Finally, the values of cell diffusive, haptotactic coefficients and saturation constant of haptotaxis are determined by regression. Results show the chondrocytes perform the maximal haptotactic response when the Boyden chamber membrane is coated with a linearly distributed type II collagen with the maximal concentration, 35 μg/ml. As the collagen concentration increases, the effect of haptotaxis turns to gradually decrease. It's also found that the haptotactic velocity has the same order of the cell migration velocity (10^{-7} cm/s). The saturation constant of haptotaxis to type II collagen is found to be quite small (10^{-6} g/cm^3), therefore we speculate the haptotaxis is possible to impose an influential impact on the migration of chondrocytes in the early stage of cartilage formation.**

Keywords — **Haptotaxis, migration, simulation, chondrocyte, Boyden chamber.**

I. Introduction

Cells are the basic element of life and their behaviors significantly affect the performance of tissues and organs. Tissue growth, wound healing, inflammation and cancer spread are all closely related to cell motion. Cell motion can be divided into several steps. First of all, cells onward extend their cytoplasma and cell membrane to make their leading edge attach on the matrix. Cells then generate contraction force, and at the same time their rear end detaches from the matrix and result in migration forward. These motions are not only related with properties of cells but also influenced by extra-surroundings.

Cell motions can be classified into three categories: *kinesis*, *taxis* and *guidance* [1]. *Kinesis* means stimulated cells will alter their magnitude of motility without moving in a specified direction. For example, cells in chemical solutions of different concentrations will exhibit variant magnitude of random walks, which is called chemokinesis. That cells move with variant speeds responding to variant substrate concentrations is referred to as haptokinesis. *Taxis* is that cells migrate specifically toward a higher (or lower) concentration gradient. For instance, bacteria moving toward higher oxygen concentration is termed chemotaxis and cells migrating along the matrix concentration gradient is termed haptotacxis. Finially, *contact guidance* refers to the cell motion which is being guided by surface grooves, curvature and stress of the substrates.

Many kinds of cells are residing on the extracellular matrix (ECM) and these matrices aren't homogenous. For example, collagen concentration on the cartilage surface is more than that inside. Chondrocytes have been discovered to exhibit haptotaxis to their ECM [2]. The mechanism behind the haptotactic effect was at first not clear. Some researchers considered that haptotaxis was due to the chemical stimulation in the solid matrix therefore substantially equal to chemotaxis. However, according to the experiments and mathematical modelings, cell motions in liquid and solid substrates reveal different behaviors. Chemotaxis happens when cells are stimulated by soluble chemicals and migrate to the higher concentration of the attractant. Haptotaxis in contrast is due to the non-uniformly attached sites between the receptors and matrix, which leads cells to passively move toward the stronger attachment site.

Many studies have been using Boyden chambers to measure the chemotacitc and haptotactic magnitudes. Mathematical models that simulated these experimental results have also been developed to look for the chemotactic coefficients. To the best of our knowledge, there have been however few mathematical models regarding haptotaxis. Besides, the cell suspension in the upper well of the Boyden chamber has usually been ignored for the sake of simplicity. In order to gain more insights into how the haptotactic mi-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1749–1752, 2009
www.springerlink.com

gration of chondrocytes can be affected by type II collagen, we develop a simulation model for depicting the experiment of Shimizu et al. [2]. In this model, the effect of cellular sediment through the upper well of the Boyden chamber is investigated by considering both the cell conservation equations in the suspension as well as in the membrane. The simulation results are then used to fit the experiment result with a regression method, so as to determine the cell motility coefficients.

II. Mathematical model

The Boyden chamber comprises an upper and lower well, which are separated by a membrane in the middle (Fig. 1). The membrane in the haptotactic experiment is coated with type II collagen. Cell suspension is initially positioned in the upper well. Assuming that cells do not move into the lower well, we divide the computational domain into two parts, describing the cell motion in the upper well and migration in the membrane respectively.

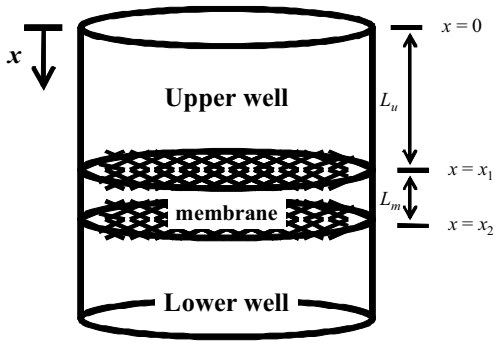

Fig. 1 Schematic diagram of the Boyden chamber. L_u is the height of upper well and L_m is the thickness of membrane.

A. Cell conservation equation in the upper well

Some considerations are made to simplify the mathematical complexity. First, chondrocytes have no cilia or flagella so they only diffuse and sediment in the upper well. Second, chondrocytes, being an anchor-dependent cell, cannot proliferate during the sedimentary process. Finally, we assume that chondrocytes are spherical and have constant density and volume. Based on the mass conservation principle, the cell conservation equation is

$$\frac{\partial}{\partial t}\varepsilon_{c,u} + \nabla \bullet \boldsymbol{J}_{c,u} = 0\,,\ 0 < x < x_1 \tag{1}$$

where $\varepsilon_{c,u}$ is the volume fraction of cell in the upper well, subscript "u" denotes the upper well, and the cell volume flux is derived from the Maxwell-Stefan equation [3] and of the following form

$$\boldsymbol{J}_{c,u} = -D_p \nabla \varepsilon_{c,u} + \varepsilon_{c,u} \boldsymbol{V}_s\,, \tag{2}$$

$$D_p = D_{p0}\left(1 - \varepsilon_{c,u}\right)^{3.65}\,,\ \boldsymbol{V}_s = \boldsymbol{V}_{s0}\left(1 - \varepsilon_{c,u}\right)^{4.65}\,, \tag{3a, b}$$

$$D_{p0} = RT/\left(N_A 3\pi\eta d_c\right)\,,\ \boldsymbol{V}_{s0} = \forall_c \boldsymbol{g}\left(\rho_c - \rho_f\right)/\left(3\pi\eta d_c\right)\,, \tag{4a, b}$$

where N_A is Avogadro's number, $\boldsymbol{g}$ the gravity, R the universal constant (8.314×10^7 g×cm^2/(s^2×mol×K)), T the experimental temperature (310 K), η the viscosity of the medium, d_c the diameter of chondrocyte, $\forall_c$ the volume of chondrocyte (411×10^{-12} cm^3), and ρ_c and ρ_f the density of cell and fluid respectively. Here we have assumed the activity coefficient of the chemical potential to be one to derive Eqs. 2 and 3a. The exponential values 3.65 and 4.65 are obtained from the experimental data under the circumstance that the sedimentary Reynolds number, $Re = V_{s0} d_c \rho_c / \eta = 7.8\times10^{-5}$ is very small [4].

B. Cell conservation equation in the membrane:

Proliferation and death are both neglected as chondrocyte proliferate time is about 3.5 to 17 hours [5; 6], death time is about 30 days [6], which are all much larger than the experimental time of only 5 hrs. Besides, we ignore that type II collagen may degrade in the medium resulting in the chemotactic effect. The cell motion considered here thus consists of cell random walks and the haptotaxis by type II collagen. The cell conservation equation is expressed as

$$\frac{\partial}{\partial t}\varepsilon_{c,m} + \nabla \bullet \boldsymbol{J}_{c,m} = 0\,,\ x_1 < x < x_2 \tag{5}$$

where $\varepsilon_{c,m}$ is the volume fraction of cell in the membrane, subscript "m" denotes the membrane, "$\boldsymbol{J}_{c,m}$" can be written as

$$\boldsymbol{J}_{c,m} = -D_r \nabla \varepsilon_{c,m} + \varepsilon_{c,m} H \nabla\left(\frac{\varepsilon_{col}}{\varepsilon_{col} + \lambda}\right). \tag{6}$$

The first term of equation (6) accounts for the diffusion of cells induced by the cell random walks, and the second term is a haptotactic flux with "H" being the coefficient of haptotaxis and "λ" the half saturation constant. The form based on a receptor kinetic model implies that cells have a maximal haptotactic velocity where the collagen concentration is equal to half saturation constant, i.e. $\varepsilon_{col} = \lambda$. We further assumed the coated collagen is linearly distributed over the membrane thickness,

$$\varepsilon_{col} = \frac{\left(x - L_u\right)}{L_m}\frac{C_{col}^{max}\varepsilon_{void}}{\rho_{col}}\,,\ x_1 \le x \le x_2 \tag{7}$$

where ε_{void} = 0.65 is the porosity of membrane, and ρ_{col} =1.438 g/cm^3 the collagen density. The maximal collagen concentration is at the bottom of the membrane, and the minimal equal to zero is at the membrane top. Furthermore, the maximal concentration of collagen is lower than that in the pure collagen solution, C_{col}^{max}, because of the reduced void space in the membrane.

C. Initial and boundary conditions

We assume the cell flux is zero at the top of the suspension, and neglect that cells fall from the bottom of membrane. At the interface between the suspension and membrane, we consider the cell flux is continuous and the membrane has only 5% of area can be through by cells. These boundary conditions can be expressed as

$$-D_p \frac{\partial \varepsilon_{c,u}}{\partial x} + V_s \varepsilon_{c,u} = 0 \ , \ x = 0 \tag{8}$$

$$-D_p \frac{\partial \varepsilon_{c,u}}{\partial x} + V_s \varepsilon_{c,u} = -D_r \frac{\partial \varepsilon_{c,m}}{\partial x} + H \varepsilon_{c,m} \frac{\partial}{\partial x}\left(\frac{\varepsilon_{col}}{\varepsilon_{col} + \lambda} \right), \ x = x_1 \tag{9a}$$

$$\varepsilon_{c,m} = 0.05 \varepsilon_{c,u} \ , \ x = x_1 \tag{9b}$$

$$-D_r \frac{\partial \varepsilon_{c,m}}{\partial x} + H \varepsilon_{c,m} \frac{\partial}{\partial x}\left(\frac{\varepsilon_{col}}{\varepsilon_{col} + \lambda} \right) = 0 \ , \ x = x_2 \ . \tag{10}$$

As for the initial conditions, we assume cells initially are uniformly distributed in the cell suspension, and there is no cell in the membrane. So

$$\varepsilon_{c,u}(0,x) = C_{c0} V_c, \ 0 \le x \le x_1 \ , \tag{11}$$

$$\varepsilon_{c,m}(0,x) = 0, \ x_1 < x \le x_2 \ , \tag{12}$$

where C_{c0}=2×10^6 cells/cm^3 is the initial cell number density.

III. Results and Discussion

The mathematical model was solved by a commercial finite element code, Multiphysics 3.2 (COMSOL). We used quadratic shape function and fine meshes at the boundaries. The validation of the simulation model was tested by comparison with the experiments in literature. The cell number in a microscopic field of view is calculated by integrating the cell volume fraction of cell over a cell diameter at the bottom of membrane:

$$\left(A \times \int_{x_2 - d_c}^{x_2} \varepsilon_{c,m} dx \right) \Big/ V_c \ , \tag{13}$$

where A is the area of the field of view. The comparison between the current model and the experimental data of Shimuzi et al. [2] is displayed in Fig. 2, which shows good agreement. As shown there are more and more cells that have migrated to the bottom of the membrane as the collagen concentration increases from zero. Chondrocytes perform the maximal haptotactic response when the Boyden chamber membrane is coated with a collagen solution of 35 μg/ml. Once the collagen in the solution exceeds 35 μg/ml, cells gradually slow down their motion toward the bottom of membrane. Although the experimental data in Fig. 2 have not shown a decrease in migrated cell number at higher collagen concentrations, the theory predicts such a trend. The trend conforms to some other previous experimental results and theory: attachment strength between cells' receptor and matrix is weak at lower and higher collagen concentration, and the associated haptotactic velocity will accordingly become low. The diffusion, haptotaxis and saturation coefficients obtained via fitting the experiment by minimizing the least squares of errors between the experimental and theoretical data are listed in Table 1. The value of the diffusion coefficient is of the same order as that of Chung et al. [6] and Chang et al. [8]. From equation (6), the haptotactic velocity responded to the distribution of collagen is also close to the value of the observation (1.38×10^{-7} cm/s) [8].

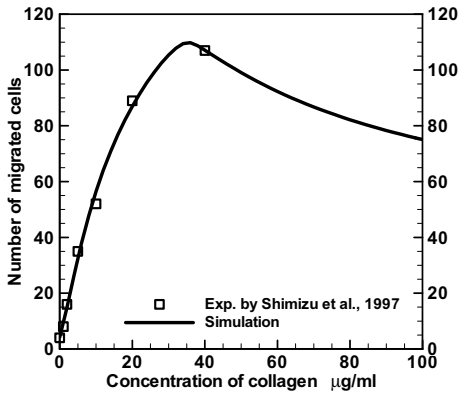

Fig. 2 Comparison between the current model and the experimental data of Shimuzi et al. [2]

Table 1 List of parameters

Name	Value	Reference
Density of chondrocyte, ρ_c	1.02 g/cm^3	[9]
Density of media, ρ_f	1.009 g/cm^3	[9]
Diffusion coefficient, D_r	1.169×10^{-10} cm^2/s	This work
Haptotactic coefficient, H	8.897×10^{-10} cm^2/s	This work
Saturation const. of haptotactic, λ	1.623×10^{-6}	This work
Viscosity of media, η	8.4×10^{-3} g/(cm×s)	[9]

Fig. 3 and 4 respectively display the simulated cell distributions in the upper well and membrane during the process. At beginning, cells are uniformly distributed in the upper well. Then, they move down through the suspension medium by the gravity action. Because the porosity size of membrane is only 8 μm and the surface porosity is only 5%, cells cannot pass through it right away. They accumulate onto the membrane surface, and then form a cell boundary layer (Fig. 3). Cells thereupon migrate into the membrane through the pores via diffusion and haptotactic motions. A local cell aggregate is formed and moving down in the membrane, and cells gradually deposit onto the bottom of membrane (Fig. 4). The local cell aggregate forms because the haptotactic velocity becomes smaller as cells get closer to the membrane bottom where the collagen concentration is much larger than the saturation value λ.

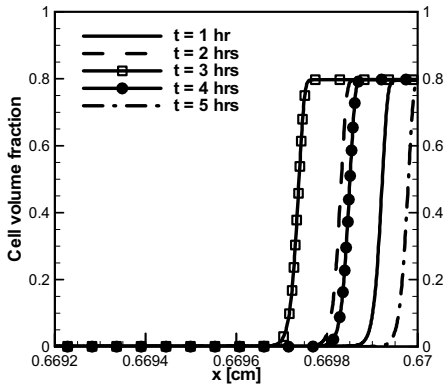

Fig. 3 Cell distribution in the upper well

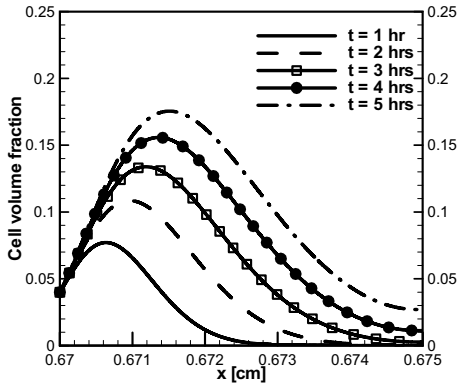

Fig. 4 Cell distribution in the membrane

IV. Conclusion

In this article, we consider theoretically the effect of the suspension layer on the haptotactic migration of chondrocytes in the Boyden chamber assay. Simulations match the experimental data from literature. The corresponding coefficients obtained for chondrocytes are 8.897×10^{-10} cm^2/s for haptotactic coefficient and 1.623×10^{-6} for the saturation constant. In a mature native cartilage, ECM occupies as much as one forth of the *in vivo* volume, and the native collagen with 90-95% (v/v) being type II collagen constitutes 65% of the ECM. Consequently, the volume fraction of type II collagen may be as high as 15.4% *in vivo*, which is much larger than the saturation value of 1.623×10^{-6}. According to equation (6), the haptotactic velocity is of maximum when type II collagen concentration is close to the saturation coefficient. Therefore, haptotaxis may be insignificant to mature cartilage; however, it is possible to impose an influential impact on the migrating chondrocytes in the early stage of cartilage formation.

Abstract — **The ability of method we've previously used for the quantification of rigidity in Parkinson's disease was improved. Using Data previously obtained from torque-displacement behaviour during passive movement of elbow joint, the range of motion was divided in three parts: the first, the middle and the last. The ability of m-file previously had been used in MATLAB was improved so that the viscous and elastic indices were calculated in each part, separately. To find the most remarkable index for distinguishing patients and controls, also prediction of level of PD, statistic tests were done. The number of PD's was 41 and controls were 11 people. Results showed that the viscous index of the last part of ROM normalized to Rom, which we call it Normalized Extension Hysteresis, NEH, had the highest correlation with rigidity levels (r=0.899) and can be used to distinguish patients and control (p=0.000).**

Keywords — **Computational biomechanics, Visco-elastic, Parkinson's disease, Statistic method, Rigidity, Hysteresis.**

I. Introduction

One of the major exams currently is used by neurologists to detect Parkinson's Disease and to find it's level of severity, is examination if rigidity during passive movement of the limbs [1,2]. The method is called Unified Parkinson's Disease Rating System, UPDRS which rates rigidity from 0 to 4. Zero level indicates no abnormal rigidity and four indicates maximum rigidity or even freeze. Subjective nature of such an exam makes it open for the influence of the examiner. Many researchers tried to find an objective method so that the rigidity could be measured objectively [3-8].

In the research previously done [9,10], using a device fabricated, elastic and viscous indices of rigidity during passive movement of elbow was measured. Correlation of indices and UPDRS rigidity levels in group of parkinsonians were examined and finally concluded that viscous index of rigidity was dominant to the elastic one for evaluation of rigidity in PDs. However in the mentioned study, it was proposed to check for the rigidity indices in different parts in the range of motion.

The aim of this research was to improve the ability of method we've previously used for the quantification of rigidity in Parkinson's disease [9]. To do so, we've improved the m-file previously used in Matlab, so that the sub indices of hysteresis loops of torque-displacement were calculated during passive movement of elbow.

II. Material and Methos

In this study, we used rigidity data previously recorded for groups of parkinsonians and controls. For every individual case, data had been measured both with the device and by neurologist using the conventional UPDRS method [9].

Based on the recorded data, we've provided a more sophisticated m-file in Matlab-R14 which was able to calculate the following 9 indices in addition to those previously were calculated (Fig. 1, 2):

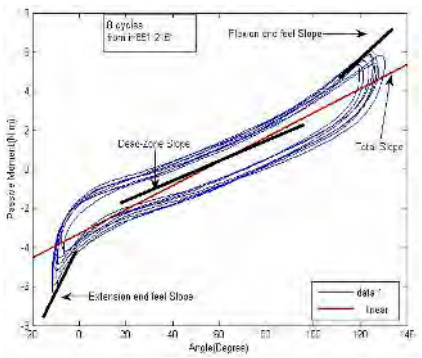

Fig. 1 Passive moment- angular displacement curves for an individual case and elastic indices indicated on it.

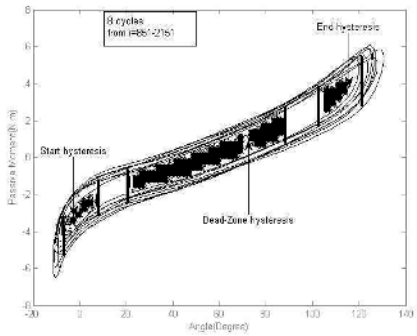

Fig. 2 Passive moment- angular displacement curves for an individual case and viscous indices indicated on it.

1. Slope of the last 10 percent of loading phase as Flexion End Feel, FEF.
2. Slop of the last 10 percent of un-loading phase as Extension End Feel, EEF.
3. Slop of the 56 median percent of loading and un-loading phases as Dead Zone slop, DZS.
4. Area between loading and un-loading curves for the first 10 percent of range of motion as Flexion Hysteresis, FH.
5. Area between loading and un-loading curves for the last 10 percent of range of motion as Extension Hysteresis, EH.
6. Area between loading and un-loading curves for the median 56 percent of range of motion as Dead Zone Hysteresis, DZH.
7. Each of the following 6 indices normalized to range of motion of each individual case, ie. Normalized Flexion Hysteresis, NFH, Normalized extension Hysteresis, NEH and Normalized Dead-Zone Hysteresis, NDH.

The first 3 indices were considered as elastic indices of rigidity and the rest were attributed as viscous ones.

To find the best characteristic index, we chose the statistic exams of independent t-test for paired groups of Control/Patients, Men/Women, Right/Left sides and With/Without reinforcement. One way ANOVA was performed to check for the best index for differentiation among UPDRS groups. Pearson's correlation test was done to find the highest linear ratio of indices and UPDRS levels.

III. Results

Except for the FEF index, other indices had the ability of distinguishing between controls and patients. This was considered by p-values less than 0.05 (Table1). Almost all indices showed no significance in sex and side paired groups. Significance among UPDRS levels in all indices was seen. NEH had p-value of 0.000 in distinguishing between with and without reinforcement groups.

In an overall word, viscous indices had bigger correlation ratios to UPDRS scores than those of elastic ones (Fig. 3-8). Correlations were still higher when viscous indices were normalized to ROM (Fig. 9-11). The highest correlation ratio of 0.899 was found for NEH index.

Table 1 P-values of statistic tests indicating the significances of pre-described indices in groups of Controls/Patients, Men/Women, With/Without reinforcement, Right/Left sides, and UPDRS levels of 0 to 4.

	Controls/ Patients	Sex	Rein-force	Side	UPDRS levels
FEF	0.011	0.373	0.630	0.770	0.000

IV. Discussion

In this research, we continued to find the cardinal index for quantification of UPDRS rigidity score which was partly studied previously. To do so, we considered more indices including elastic and viscous sub items of hysteresis loops extracted from passive movement of elbow joints of controls and patients.

Results confirmed with results of the previous study [9]: viscous indices are more likely related to UPDRS rigidity score. Further more, viscous index of late flexion range of motion is seem to have priority to other indices. This can imply that parkinsonian rigidity has the most effect in the final extreme of range of motion. NEH index had the highest correlation ratio to UPDRS levels also, had the highest significance to distinguish between with and without reinforced rigidity which is one of the most known characteristics of PD.

NEH index examined here was similar to that previously studied by Kirolos and co-workers [4]. The mean values of their index were 0.07 and 0.25 for control and patients respectively, while values in our study were 0.017 and 0.033. It should be noticed that Kirolos and co-workers had examined just two patients while we did for 41 patients with different range of UPDRS rigidity. Further more, they had normalized the hysteresis index to the final part of range of motion(i.e. 115-155 degrees flexion), while the normalization in our study was done to total range of motion of each case to consider for differences in physiological range of motion in different people.

In this research and similar researches, ordinary statistic methods were used to find the best relating index to rigidity caused by Parkinson's disease. However new analysing methods such as neuro-phasy and genetic algorithm are proposed to find more reliable results.

V. Conclusion

It can be concluded that viscous element described as normalized extension hysteresis can be the best quantitative index for evaluation of parkinsonian rigidity.

Relative Roles of Cortical and Trabecular Thinning in Reducing Osteoporotic Vertebral Body Stiffness: A Modeling Study

K. McDonald[1], P. Little[1], M. Pearcy[1], C. Adam[1]

[1] Queensland University of Technology / Institute of Health and Biomedical Innovation, Brisbane, Australia

Abstract — **While the effects of reduced bone density on osteoporotic vertebral strength are well known, the relative roles of cortical shell and trabecular architecture thinning in determining vertebral stiffness and strength are less clear. These are important parameters in investigating the changing biomechanics of the ageing spine, and in assessing the effect of stiffening procedures such as vertebroplasty on neighbouring spinal segments. This work presents the development of a microstructural computer model of the osteoporotic lumbar vertebral body, allowing detailed prediction of the effects of bone micro-architecture on vertebral stiffness and strength.**

Microstructural finite element models of an L3 human vertebral body were created. The cortex geometry was represented with shell elements and the trabecular network with a lattice of beam elements. Trabecular architecture was varied according to age. Each beam network model was validated against experimental data. Models were generated to represent vertebral bodies of age <50 years, age 50-75y and age >75y respectively. For all models, an initial cortical shell thickness of 0.5mm was used, followed by reductions in the age >75y models to 0.35mm and 0.2mm to represent cortical thinning in late stage osteoporosis. Loads were applied to simulate in vitro biomechanical testing, compressing the vertebra by 20% of its height.

Predicted vertebral stiffness and strength reduced with progressive age changes in microarchitecture, demonstrating a 44% reduction in stiffness and a 43% reduction in strength, between the age <50 and age >75 models. Reducing cortical thickness in the age >75 models demonstrated a substantial reduction in stiffness and strength, resulting in a 48% reduction in stiffness and a 62% reduction in strength between the 0.5mm and 0.2mm cortical thickness models. Cortical thinning in late stage osteoporosis may therefore play an even greater role in reducing vertebral stiffness and strength than earlier reductions due to trabecular thinning.

Keywords — **Vertebra mechanics, FE modeling, trabecular architecture, osteoporosis, cortical shell**

I. Introduction

Osteoporosis is a disease which affects more than 75 million people in Europe, Japan and the USA, and is the cause of more than 2.3 million fractures annually in Europe and America alone [1]. Osteoporosis is characterized by low bone density and micro-architectural deterioration of bone tissue, resulting in increased susceptibility to fracture [2]. The micro-architectural deterioration includes thinning of the trabeculae, increased spacing between trabeculae, and in the later stages, thinning of the cortical shell. These changes transform the structure from dense and plate-like to a sparse, rod-like structure. It is believed there is an associated change in the failure mechanisms from plastic collapse of the trabeculae to inelastic, or possibly even elastic, buckling of the trabeculae. Due to the experimental difficulty in investigating this complex structure, the effect of bone loss on trabecular failure mechanisms and whole vertebra mechanics is still poorly understood.

To overcome experimental difficulties, previous studies have employed computational modeling methodologies. These studies utilize two distinct approaches. Firstly, the *macro scale approach*, whereby a solid, whole vertebra is simulated and the structure of the trabecular bone approximated as a continuum. The material properties of the vertebral core are varied to represent the changes in trabecular structure and the effect of this change on whole vertebra mechanics is observed. Secondly, *micro scale approaches*, whereby an isolated section of the trabecular structure is simulated using either continuum or beam elements. Continuum elements are computationally expensive and therefore only small regions of bone can be modeled. Conversely, computationally efficient beam elements have been used to simulate larger regions of trabecular structures. The results for these micro scale models are then extrapolated for a whole vertebra.

This study aimed to create a multi-scale finite element model of an L3 human vertebral body. The architectural changes observed in osteoporosis (trabecular thinning, increased trabecular spacing and cortical shell thinning) were modeled and the effect of these changes on whole vertebra mechanics and trabecular mechanics explored.

II. Methods

A finite element model of an L3 human vertebra was analysed under compression to assess the relative affect of cortical and trabecular microstructure on vertebral mechanics. The trabecular structure was modeled using three-dimensional beam elements and the vertebral cortex simulated with shell elements. Model development involved

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1757–1760, 2009
www.springerlink.com

ascertaining the efficacy of the beam elements in simulating trabecular biomechanics, validation of the beam element trabecular lattice and simulation of an intact vertebra.

A. Modeling the trabecular core

Three dimensional beam elements were used to represent individual struts within the trabecular lattice. As buckling is an important failure mode of longitudinally oriented trabeculae [3], it was important that the model accurately predicted buckling behavior. Therefore, analyses were performed on various beam element configurations to determine an appropriate trabeculum model. The effect of element type, initial beam curvature, mesh density and solution time increment were investigated.

Due to the paucity of data on trabeculum failure mechanisms at the microstructural level (specifically buckling), it was necessary to use a buckling mechanics study based on another material to verify the trabeculum model. Investigations performed by Rahman [4] gave critical buckling loads determined experimentally for solid columns of stainless steel (SUS304). This work covered a comprehensive range of slenderness ratios (14-184) and hence failure modes, from purely elastic to purely plastic. The material properties and slenderness ratios of the trabeculum model were altered to represent the steel columns, and Rahman´s experimental results used to verify the prediction of the model. From these analyses it was concluded that two quadratic beam elements, with a slight initial curvature, were able to predict failure (be it elastic buckling, inelastic buckling, or plastic collapse) with a mean error of 20% for the whole range of slenderness ratios. For the trabeculum model, an initial offset of 0.001mm in the centre of the column was necessary to induce buckling. Once confidence was obtained in the ability of the FE techniques to predict buckling, they were applied to represent a trabecular core model.

A three dimensional trabecular core was created using a lattice of individual trabeculum beams. Three-node, quadratic beam elements were used to represent the longitudinal trabeculae, and two-node, linear beam elements represented the transverse trabeculae. Since the transverse trabeculae are primarily loaded in tension, the additional complexity of the quadratic beam representation was considered unnecessary. To provide a degree of irregularity to the lattice, as is seen in real trabecular bone, a perturbation factor of 0.3 was applied [5]. The perturbation factor defines the maximum distance each node may be perturbed by as a proportion of the trabecular spacing. For example, with a perturbation value of 0.3, each node point was perturbed ±0-30% of the spacing value.

The trabecular spacing and thickness values for the transverse and longitudinal trabeculae were derived from Mosekilde [6]. The values are shown in Table 1. Three trabecular structures were created; age < 50, age 50-75 and age > 75. A tissue modulus of 8GPa and a Poisson´s ratio of 0.3 were applied [7, 8]. An elastic-perfectly plastic yield definition was included which had a yield strain of 0.85% and a yield stress of 68 MPa. The yield strain was determined as an average of the reported compressive and tensile yield strains for trabecular bone [9].

Table 1 Trabecular spacing and thickness values for female vertebral trabecular bone for age < 50, age 50-75 and age > 75 [6]

Model	Transverse Spacing (mm)	Longitudinal Spacing (mm)	Transverse Thickness (mm)	Longitudinal Thickness (mm)
Age <50	0.674	0.633	0.150	0.208
Age50-75	0.861	1.100	0.116	0.187
Age >75	1.145	1.668	0.107	0.201

The trabecular core model was verified against experimental results. As well as providing structural parameters for three age groups, the Mosekilde study also provided the compressive strength of the trabecular cores for these age groups. To provide a comparison, trabecular core models were created to replicate the *in vitro* cylindrical bone samples tested by Mosekilde (radius 3.5mm, length 5mm). To replicate the axial compression test performed in the study, the upper nodes of the cores were were free to move only in the axial direction and held in all other degrees of freedom. All bottom surface nodes were held in all degrees of freedom. The upper nodes were displaced in the axial direction until failure of the core occurred. The models were solved using ABAQUS/Standard (version 6.7, Abaqus Inc, RI, USA) using a large displacement (non-linear geometry) quasi-static solution procedure. The maximum compressive strength and stiffness of the cores were determined and compared to the experimental results. Once confidence was gained in the trabecular core model, an intact vertebra was simulated.

B. Modeling the Vertebra

Using a similar methodology to that employed for the trabecular core, an intact vertebra was simulated whereby the inner trabecular lattice of the vertebra was enclosed by a thin vertebral cortex. Age < 50, age 50-75 and age >75 vertebra models were produced. The cortex was meshed using three dimensional, linear shell elements and the geometry was based on equations given by Mizrahi [10]. The mesh density gave shell elements 2mm in size. The material properties of the cortex were assumed to be the same as the trabecular bone [7, 8]. The thickness of the shell ele-

ments was 0.5mm, which represents a normal cortical shell [11]. In the age > 75 model, the shell thickness was reduced to 0.35mm, and then again to 0.2mm to represent shell thinning, as is observed in the later stages of osteoporosis [11]. This resulted in five vertebra models, all at different stages of osteoporosis.

Loads were applied to simulate in vitro biomechanical testing, compressing the vertebra by 20% of its height. The upper endplate was displaced by -6mm axially and held in the transverse plane. The lower endplate was held in all directions. A quasi static solution step (total length 1 sec) was used with a minimum time increment of 0.01 sec and a maximum time increment of 0.1 sec. As previously stated, the ABAQUS non linear geometry capability was used to include the effect of large deformations in the solution.

III. Results

The apparent modulus of the trabecular cores and vertebral models were determined using the linear region of the stress strain graph, between 0-0.4% apparent strain. The maximum compressive strength was considered to be the maximum total vertical reaction force that was reached in the simulation.

A. Trabecular core

Table 2 shows the compressive strength of the various trabecular core models determined experimentally by Mosekilde [2] and the corresponding computed compressive strengths from the trabecular core model. The table also shows the apparent stiffness of the cores determined computationally, however Mosekilde did not report the stiffness of the cores tested experimentally and hence no direct comparison can be made. Other studies have reported vertebral trabecular bone samples from the lumbar spine have an apparent modulus of 165 ± 110 MPa [12].

Table 2 Compressive strength of the trabecular core samples determined experimentally by Mosekilde and by FE trabecular core model and the stiffness of the cores predicted by the FE models

	Age < 50	Age50-75	Age >75
Mosekilde maximum compressive strength (MPa)	3.91 ± 1.61	1.35 ± 0.64	0.93 ± 0.4
FE trabecular core maximum compressive strength (MPa)	2.84	1.21	0.54
FE trabecular core apparent modulus (N/mm)	253	138	74

B. Vertebra Model

Figure 1 shows the stress strain curve for each of the vertebra models. The corresponding stiffness and compressive strengths are shown in Table 3.

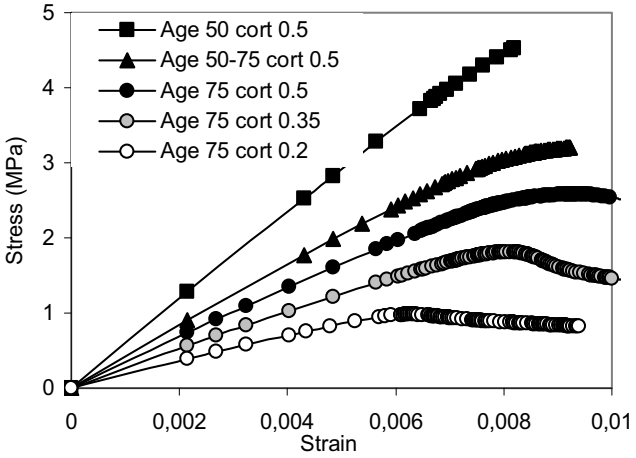

Fig. 1 Stress versus strain for the vertebra models.

Table 3 FE predicted compressive strength and stiffness of the vertebra models

Model	Cortical thickness (mm)	Stiffness (N/mm)	Max. Compressive strength (kN)
Age <50	0.5	595	5.74
Age50-75	0.5	412	4.06
Age >75	0.5	336	3.28
Age >75	0.35	256	2.30
Age >75	0.2	176	1.25

IV. Discussion

The trabecular core model was able to reproduce compressive strengths and apparent moduli determined experimentally. The predicted compressive strengths for the cores of various structures were within one standard deviation of Mosekilde´s experimental results for the corresponding ages. The apparent moduli determined computationally were within the range of values (165±110 MPa) in the literature [12]. With these results, confidence was achieved in the trabecular beam model.

The vertebra model confirms that changes in architecture have a large effect on overall vertebra stiffness and strength. A change in architecture from the age < 50 to the age > 75 cases resulted in a 44% decrease in stiffness and a 43% decrease in vertebral strength. With the age > 75 model, a change in shell thickness from 0.5mm to 0.2 mm, without

any change in trabecular structure, resulted in a 48% decrease in stiffness and a 62% decrease in compressive strength. These results not only highlight the importance of the trabecular architecture changes that occur with the osteoporosis process, but also the biomechanical importance of the cortical thinning that occurs in the later stages of the disease.

A current limitation of this model is that it has yet to be validated against experimental data for a full vertebral body (including the cortical shell). However validation of the trabecular core model and initial comparisons with the literature indicate the predictions of the vertebra model are reasonable. Reported vertebral body compressive strengths range from approximately 60MPa for a 20 year old vertebra to 2.6MPa for an 80 year old vertebra [13]. The predicted compressive strengths for the vertebral models of different ages are comparable with these values, although slightly lower.

The premise for this modeling approach was that buckling mechanisms dominate the response of rod-like osteoporotic bone. Hence, replicating the trabecular network using beam elements provides a sophisticated microstructural model capable of simulating plastic collapse, inelastic buckling, or elastic buckling in bone of various ages. Taking a closer look at the trabecular struts in the age > 75 vertebra model shows the trabecular beams are undergoing large buckling deformation, but no plastic deformation is seen, indicating that the overall failure of the vertebra is due to elastic buckling of the trabeculae. In the age 50-75 model, the beams also experience large amounts of buckling; however there is also plastic deformation throughout the structure. This suggests inelastic failure of the trabeculae is playing a key role in the vertebra failure. Finally, the beams of the age < 50 model show almost no buckling, yet a high amount of plastic deformation, signifying plastic collapse of the structure. While further model investigation and validation needs to be done before any quantitative data on the trabeculae can be reported, these results highlight the distinctive insight into both the trabecular and vertebral mechanics this model allows.

In future work, this model will be validated against human vertebra specimens. Once validated, it will be used to investigate current drug therapies and their effects on the bone architecture and vertebral strength, as well the effect on trabecular and vertebral strength of surgical treatments such as vertebroplasty.

V. Conclusion

This paper has presented the development of a novel multi-scale, vertebra model produced with beam and shell elements. The model predictions have been validated against experimental data in existing literature and show good agreement. The investigation into the effects of changes in architecture indicate that while the changes in trabecular architecture have a large effect on vertebral strength and stiffness in the early stages of osteoporosis, cortical thinning may have as great an effect (if not greater) in the later stages.

Musculo-tendon Parameters Estimation by Ultrasonography for Modeling of Human Motor System

L. Lan[1], L.H. Jin[2], K.Y. Zhu[1] and C.Y. Wen[1]

[1]Nanyang Technological University, Singapore
[2]Tianjin Zhonghuan Semiconductor Joint-stock Co. Ltd, China

Abstract — **To provide quantitative insights in analyzing human movement, the musculoskeletal model is widely used to predict the muscle force output. It is important to accurately estimate the model's parameters on subject specific basis. This paper presents an approach to obtain the parameters in vivo by the ultrasound imaging technology. The origin and insertion points, pennation angle, fascicle length and cross-sectional area of brachialis are measured by off-line analyzing of ultrasound image. The data is used to calculate values of musculotendon length, moment arms, optimal muscle fascicle length, tendon slack length and maximum isometric force. These musculotendon parameters can be used in a musculoskeletal model to predict the muscle force and torque.**

Keywords — **Ultrasound, musculotendon model**

I. Introduction

Model of musculoskeletal system is widely used to simulate the muscle force in analyzing human movement [1]. One of the main challenges in modeling is to accurately estimate the musculotendon parameters on subject-specific basis. The underlying muscle contraction and dynamics information can be provided by appreciate modeling. Furthermore, the fact that the modeling and simulation results are significantly affected by the accuracy of estimated values of musculotendon parameters is also revealed by the sensitivity and validation study.

In biomechanics studies, most researchers simply adopted formerly reported values from cadaver specimen to predict muscle force and torque [2]. However, parameter values vary widely for even the same muscle in real human limb, and properties of musculotendon systems can also change over age in the same person [3]. To provide quantitative insights in analyzing human movement, it is necessary to estimate the parameters in vivo. Some researchers had used medical imaging techniques to do this task, such as ultrasound [4], computerized tomography (CT) [5] and magnetic resonance imaging (MRI) [6]. Considering the disadvantage of MRI or CT, such as high cost and radiation exposure, the medical ultrasound imaging might be the better choice than others. Furthermore, ultrasonography is convenient on repeated measurement, because medical ultrasound image can reveal the border between the fat, muscle and bone. The previous musculotendon parameters measurements using ultrasound were mainly used to evaluate the muscle function [7]. Few reports were available on ultrasound measurements to estimate musculotendon parameters for building a customizing specific musculotendon model.

In this study, human brachialis muscle is measured, which is the elbow flexor muscle with the larger physiological muscle cross-sectional area (PCSA) in the muscle group of elbow flexors [8]. The physiological parameters of the musculotendon structure are estimated by the geometric model of brachialis muscle and medical ultrasound image. These parameters are employed in an extended Hill-type model to predict muscle force production.

II. Model description

In this study, the elbow joint is modeled as a uniaxial hinge joint and the axis is determined by the centers of the capitulum and trochlear sulcus. The range of elbow angle is defined from 0° (full extension) to 90° (full flexion). Muscles are modeled as line segments attaching at bones and joints. In anatomy, brachialis muscle started in the middle of humerus and ended in the head of ulna. We assume that origin and insertion points of the muscle are concentrated at center of muscle attachment areas. Fig. 1 shows the anatomical relationship of brachialis muscle at the elbow joint.

The musculotendon model is based on the musculotendon actuator described in [1]. To well and truly describe the physiological structure, we use a modified Hill-type formulation by Brown et al. [9] for the force development of the muscle. That is, the muscle force F^M is described as the sum of force produced by the contractile element F_{CE} and the force produced by the passive elastic element F_{PE}. That is,

$$F^M = F_{PE} + F_{CE} \tag{1}$$

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1761–1765, 2009
www.springerlink.com

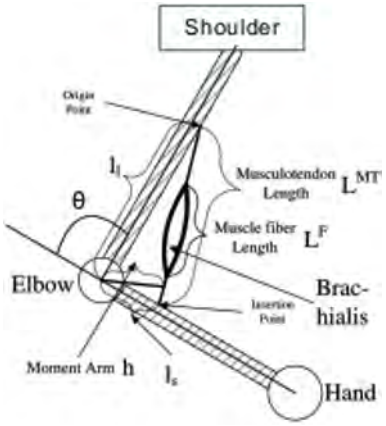

Figure 1. The anatomical sketch of elbow and brachialis muscle. The relative position of original and insertion points determine the value of moment arm and musculotendon length.

where F_{CE} is determined by,

$$F_{CE} = F_{max} FV(V) FL(L) E(t) \tag{2}$$

where L is the normalized muscle fascicle length L^M to the optimal muscle fascicle length L_o^M. V represents the normalized muscle contraction velocity to the maximum shortening velocity of the muscle, which is simplified as the derivative of L. $E(t)$ is the muscle activation, and F_{max} represents the maximal isometric active force. FL is the force length factor, which is modeled as a polynomial curve.

$$FL = dL^2 - 2dL + d + 1 \tag{3}$$

where $d = -3.188$ is a scaling factor. FV is the force velocity factor, which is approximated by an exponential function [2],

$$FV = \frac{a}{1 + e^{b(V-c)}} \tag{4}$$

where $a = 1.5$, $b = 8.0$, $c = 0.0866$.

The parallel elastic element is modeled as a two parallel spring system. The total force produced by PE can be presented into two components: F^{PE1}, represents the force produced by the non-linear spring to resist stretch in the passive muscle; F^{PE2}, represents the force produced by the non-linear spring to resist compression during active contraction at short lengths, i.e.,

$$F^{PE} = F^{PE1} + A(t) F^{PE2} \tag{5}$$

The values of F^{PE1} and F^{PE2} are given as,

$$F^{PE1} = \{c^{PE1} k^{PE1} \ln\{\exp[(\frac{\tilde{L}^M / \tilde{L}^M_{max} - L^{PE1}}{k^{PE1}}] + 1\} + \eta V\} F_{max}, F^{PE1} \geq 0 \tag{6}$$

and

$$F^{PE2} = \{c^{PE2}(\exp(k^{PE2}(\tilde{L}^M - L^{PE2})) - 1)\} F_{max}, \quad F^{PE2} \leq 0 \tag{7}$$

where c^{PE1}, c^{PE2}, k^{PE1}, k^{PE2}, L^{PE1}, L^{PE2} and η are the constants.

F^M is transferred by the tendon (SE) to generate the movements. (Fig. 2). In this study, the tendon is modeled as a linear spring with a stiffness of K_t. Thus, the tendon length can be determined as:

$$L^T = \frac{F^T}{K_t} + L_s^T \tag{8}$$

where F^T is the tendon force with $F^T = F^M * \cos\alpha_p$, L_s^T is the tendon slack length, that is, the length on elongation where tendon just begins to develop force. Tendon slack length is determined as,

$$L_s^T = L_o^{MT} - 1.2 L_o^M \tag{9}$$

where L_o^{MT} represents the maximally elongated musculotendon length, and L_o^M is muscle optimal physiological length.

Then, based on a geometrical model of the musculotendon structure (Fig. 3), the muscle fascicle length L^M is calculated by subtracting tendon length L^T from the

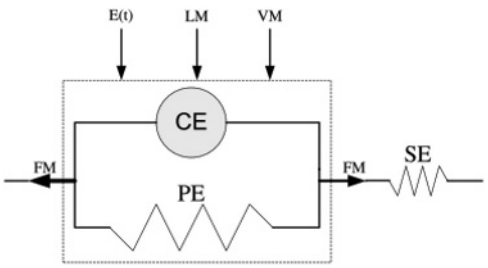

Figure 2. A schematic of Hill-type model for contraction dynamics of muscle tissue. The fascicles are represented as the parallel contractile element (CE) and passive elastic element (PE). The series-elastic element (SE) represents the combined tendon and aponeurosis [1].

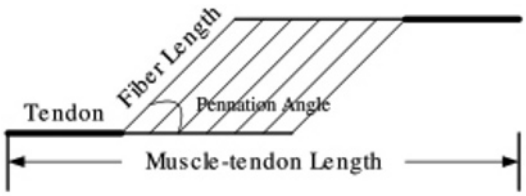

Figure 3. The musculoskeletal structure for ultrasound. All muscle fibers are assumed to be arranged in parallel with the same length, and to insert on tendon with pennation angle. when the muscle fibers shorten, pennation angle increases, but the width of the muscle remains constant.

whole musculotendon length L^{MT}, and the pennation angle (α_p) is taken into account:

$$L^M = \frac{(L^{MT} - L^T)}{\cos\alpha_p} \tag{10}$$

At rest, the relationship of the pennation angle verse joint angle θ can be fitted with a linear function [7], i.e.,

$$\alpha_p = a_p\theta + b_p \tag{11}$$

Finally, the musculotendon variables (moment arms h, length of musculotendon L^{MT}) can be calculated by the distance between the origin point to elbow l_l and the insertion point to elbow l_s based on the trigonometric function (Fig. 1).

III. Ultrasonography Measurement

For the model described in the last section, to customize musculotendon model for specific muscles, the following parameters should be specified: the peak isometric muscle force F_{max}; the optimal muscle fascicle length L_o^M; musculotendon length L^{MT}, the moment of arm h; the tendon slack length L_s^T; the maximally elongated musculotendon length L_{max}^{MT} and muscle's intrinsic maximum shortening velocity V_{max}. In these parameters, the parameters L^{MT}, h, L_s^T and L_{max}^{MT} are determined by the attachment points (insertion and origin), the optimal muscle fascicle length and the pennation angle. The maximum muscle contraction velocity V_{max} can be expressed in optimal fiber length L_o^M per second, i.e., 10 L_o^M per second for young adults and 8 for older adults [10]. The peak isometric muscle force (F^{MAX}) is assumed to be proportional to PCSA. To sum up, the positions of attachment points, the pennation angle, the optimal muscle fascicle length and the PCSA are required to be measured on subject-specific basis.

Firstly, the position of the muscle attachment points can be directly identified with respect to the corresponding skin surface under the middle point of the ultrasound probe.

Secondly, based on the equation 11, the pennation angles with full extension and half flexion are measured from ultrasound image to calculate the values of a_p and b_p (Fig. 4). Thus any pennation angles can be determined by the corresponding elbow angles, which can be measured by the goniometer.

Thirdly, the muscle fascicle length (L^M) can be calculated using a trigonometry method from the longitudinal view of the ultrasonography of brachialis (Fig. 4). i.e., L^M is given as [7]:

$$L^M = L_F + \frac{L_{MT1}}{\sin\alpha_p} + \frac{L_{MT2}}{\sin\alpha_p} \tag{12}$$

where L_F is the visible part of the muscle fascicle, L_{MT1} is the distance from fiber proximal end to the bone, L_{MT2} is the distance from fiber distal end to the superficial aponeurosis. Due to the force-length property presented by Zajac [1], for muscle with a maximum isometric contraction, we can expect the muscle fascicle length L^M equal to optimal muscle fascicle length L_o^M.

Finally, the PCSA is measured by enclosing the outline of the muscle. That is, the muscle linear dimensions (lateral dimension (LD) and the anteroposterior dimension (APD))

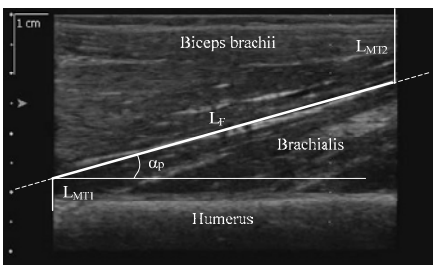

Figure 4. The longitudinal view of the ultrasonography of brachialis and biceps brachii, the data is collected from subject 1. The white fringe of the humerus bone and the dark muscle fascicle can be easily observed in the image.

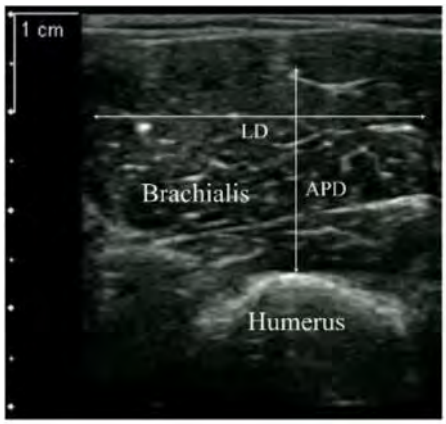

Figure 5. The transverse view of the ultrasonography of brachialis, the data is collected from subject 3. The LD and APD can be measured from the image.

are measured to evaluate PCSA. The values of LD and APD are measure from the The transverse view of the ultrasonography (Fig. 5).

IV. Results

In this research, a B-mode ultrasonography scanner with 12 MHz, 38 mm line probe (Ultrasonix Sonix RP) is used for data acquisition. Healthy subjects (4 males, age: 21-28 years) sit on a height adjustable chair with a solid back. Their forearms are placed on a horizontal plane at the same height of the shoulder and supported by a bracket. The shoulder is in 90° abduction and 0° flexion. During the test, the ultrasound probe is moved along the anterior part of upper arm to find the best image. To enhance ultrasound conduction, coupling gel is applied between the probe and skin surface. To find the muscle architecture parameters, ultrasound image and video are recorded and analyzed off-line. The estimated parameter values are shown in table 1.

Table 1. Estimated parameter values

Parameters	Subjects			
	1	2	3	4
F_{max} (N)	250.8	211.2	257.4	231
L_o^M (m)	0.095	0.086	0.092	0.086
a_p	0.16	0.17	0.16	0.15
b_p (rad)	0.22	0.18	0.2	0.18

These results agree with the values reported in literatures (F_{max} : 184.8[11], 178.2[12], 217.8[13], 254.4[14]; L_o^M : 0.099[12], 0.09[13], 0.0942 [14]).

I. Conclusion

Ultrasonography is a low-cost and comfortable method to get the musculotendon parameters in vivo. Our study provides an approach to estimate the parameters of the musculotendon model by the medical ultrasound image and the geometrical model of the anatomical structure. Since the use of cadaver data in modeling of muscle functions will cause accumulating errors in the results, our approach is helpful to build a more accurate model than the models reported in previous studies.

Abstract — **Mechanical loading is critical for maintaining bone mass, while weightlessness, such as that associated with reduced physical activity in old age, long-term bed rest, or space flight, invariably leads to bone loss. Fragile bone tissue is more susceptible to fractures. By contrast, extremely low-level oscillatory accelerations, applied without constraint, can increase bone formation. To examine the role of vibration in preventing and improving the fragility of bone, we tested the effect of vibration on bone structure in a tail-suspended hindlimb-unloaded (HS) mouse model. Male 22-week-old Jcl-ICR mice were allocated randomly to the following groups: daily-standing control, HS without vibration, HS with vibration at 45 Hz (HS+45Hz), and HS with standing (as an alternative to vibration) (HS+stand). Vibration was given for 5 min/day for 4 weeks. During vibration, a group of mice was placed in a box on top of the vibrating device. The amplitude of vibration was 1.0 mm. After 4 weeks of treatment, the mice were anesthetized and killed by cervical dislocation. Trabecular bone of proximal tibial metaphyseal region of tibial diaphyseal region parameters were analyzed morphologically using in vivo micro-computed tomography. In trabecular bone, the microstructural parameters were improved in HS+45Hz group compared with HS and HS+stand group, including bone volume (BV/TV), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp) and trabecular bone pattern factor (TBPf). In conclusion, the results suggest a beneficial effect of vibration in preserving the complexity of trabecular bone.**

I. Introduction

The sensitivity of the skeleton to changes in the mechanical environment is characterized by a rapid and site-specific loss of bone tissue after the removal of function. Conditions such as bed rest, spinal cord injury, and spaceflight can be severely detrimental to the mass, architecture, and mechanical strength of bone tissue, potentially transforming specific skeletal regions into sites of osteoporosis [1- 4]. Whole-body vibration (WBV) can have an anabolic effect in bone tissue and may contribute to more fracture-resistant skeletal structures [5]. Therefore, WBV may provide a practical, non-pharmacological alternative for preventing and/or reversing osteoporosis without adverse invasive or pharmacological effects. Despite these potential benefits, few studies have investigated whether WBV can prevent or reverse deleterious changes in bone formation, resorption, or morphology induced by catabolic stimuli. In this study, we analyzed the effects of WBV on osteopenia and unloading-induced bone loss using a mouse model.

II. Materials and methods

We performed the effect of vibrations on bone structure in a tail-suspended, hindlimb-unloaded (HS's) mouse model (Fig.1). Twenty male Jcl-ICR mice (Kyudo co., Ltd., Fukuoka, Japan), 22-week-old at the start of the experiment, were allocated randomly to the following groups: normal condition control (Cont), HS without vibration (HS), HS with vibration at 45 Hz (HS+45Hz), and HS with short-term standing as an alternative to vibration (HS+stand). Vibration was given for 5 min/day for 4 wk. During the while-body vibrational treatment, a group of mice was placed in a box on top of a vibrating device (Fig.2). The amplitude of vibration was 1.0 mm. After a 4-wk treatment period, the rats were sacrificed by cervical dislocation under anesthesia with diethyl ether. The tibia of each mouse was removed

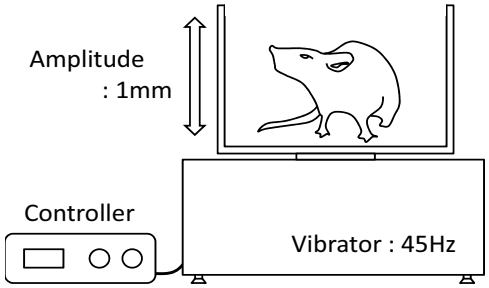

Fig.2 System for whole-body vibration of mice.

and placed in 70% ethanol. Trabecular bone of proximal tibial metaphyseal region of tibial diaphyseal region morphology was analyzed using in vivo micro-computed tomography (micro-CT). The trabecular region was selected using contours inside the cortical shell on each two-dimensional image. The measured parameters included the trabecular bone volume/total volume fraction (BV/TV), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp), trabecular number (Tb.N), node number (N.Nd/TV), and trabecular bone pattern factor (TBPf).

Differences between the groups were analyzed using the Kruskal-Wallis test. In case of difference, the Mann-Whitney U test was applied to test the difference between the different groups. The significance level was 0.05 and all data are presented as mean ± SD.

III. Results

Table 1 displays the bone morphological parameters analyzed from the micro-CT images. The grading criterion for regulation and/or modeling was the presence of a significant difference in the bone parameters between groups. The BV/TV was reduced in the HS group (HS, HS+45Hz, HS+stand) compared with the Cont group. There were significant positive effects on BV/TV in response to standing and especially in response to vibration. Although similar positive trends were observed for Tb.N and Tb.Sp in the HS+stand with HS+45Hz groups, the effects were not statistically significant. There was no significant difference in N.Nd/TV between the Cont and HS+45Hz groups.

IV. Discussion

Preventing the loss of bone attributable to a change in the mechanical environment is an important aspect of effective rehabilitation. The sensitive of bone to physical stimuli is evident from exercise studies [6, 7], long term bed rest [8] and local load as seen in the humerus of tennis player [9, 10]. The exact mechanical control of bone adaptation is not fully understood. As the important stimuli for bone adaptation, strain magnitude, strain rate, fluid shear flow, strain energy density had been proposed. However, very little is known about the actual bone adaption under absence of mechanical stimuli environment. In this present study, we estimated the effects of whole-body vibration on the bone structure in mechanically unloaded mice. Unloaded mice exhibited significant decreases in the values of trabecular bone parameters relative to the control group, and these decreases were significantly prevented by the short-term reloading of mice in the HS+stand and especially the HS+45Hz groups. Additionally, the values of Tb.N and Tb.Sp in the short-term reloaded mice tended to return to the control values. The values of other parameters were also improved in response to 45 Hz-vibrations (HS+45Hz group). These results emphasize the importance of mechanical loading on the morphological complexity of trabecular bone. Furthermore, these results suggest that losses in bone quality owing to various unloaded conditions may recover with vibrational treatment. Recent studies have indicated that trabecular bone loss and impairment of mechanical properties reduce bone strength and increase fracture risk [11, 12], emphasizing the importance of bone tissue properties for bone mechanical behavior. Our findings suggest that short-term, whole-body vibration may be a practical, non-invasive, and effective means of providing early recovery in cases of bone loss due to mechanical factors.

V. Conclusions

Tail-suspended hindlimb-unloaded mice subjected to 5 minutes of daily while-body vibration for 4 weeks had increases in bone volume (BV/TV), trabecular thickness (Tb.Th), trabecular number (Tb.N) and trabecular bone pattern factor (TBPf) compared with HS and HS+stand group. These results suggest that a while-body vibration effective prevented unloaded bone loss in a site of active metabolism, such as trabecular bone.

A Biomechanical Investigation of Anterior Vertebral Stapling

M.P. Shillington[1,2], C.J. Adam[2], R.D. Labrom[1] and G.N. Askin[1]

[1] Mater Health Services, Brisbane, Australia
[2] Queensland University of Technology, Brisbane, Australia

Abstract — **An immature calf spine model was used to undertake anatomical and biomechanical investigations of an anterior vertebral staple used in the thoracic spine to treat scoliosis. The study involved three stages: (1) displacement controlled testing to determine changes in bending stiffness of the spine following staple insertion, (2) measurement of forces in the staple using strain gauges, and (3) micro-CT scanning of vertebrae following staple insertion to describe the associated anatomical changes. The results suggest that the mechanism of action of stapling may be a consequence of hemiepiphysiodesis causing convex growth arrest, rather than the production of sustained compressive forces across the motion segment.**

Keywords — **biomechanics, thoracic spine, staples, shape memory alloy.**

I. Introduction

Adolescent idiopathic scoliosis (AIS) is a complex three dimensional spinal deformity diagnosed between 10 and 19 years of age. The natural history of curve progression in AIS is dependent on the patient's skeletal maturity, the curve pattern, and the curve severity. Currently treatment options for progressive scoliosis are limited to observation, bracing, or surgery.

While brace treatment is noninvasive and preserves growth, motion, and function of the spine, it does not correct deformity and is only modestly successful in preventing curve progression. In contrast, surgical treatment with an instrumented spinal arthrodesis usually results in better deformity correction but is associated with substantially greater risk. The risks of surgery are related to the invasiveness of spinal arthrodesis, the instantaneous correction of spinal deformity, and the profoundly altered biomechanics of the fused spine.

Fusionless scoliosis surgery may provide substantial advantages over both bracing and definitive spinal fusion. The goal of this new technique is to harness the patient's inherent spinal growth and redirect it to achieve correction, rather than progression, of the curve. This effect is thought to occur as a consequence of the Hueter-Volkmann law which states that increased compressive loads across a physis will reduce growth, while conversely, increased distractive forces will result in accelerated growth [1]. Currently there are several surgical treatments incorporating the fusionless ideology, one of which is anterior vertebral stapling (see Figure. 1). By applying implants directly to the spine, anterior vertebral stapling is theoretically more advantageous than external bracing because it addresses the deformity directly at the spine and not via the chest wall and ribs, and, because it eliminates problems with patient noncompliance during brace treatment. Furthermore, minimally invasive tethering of the anterior thoracic spine by means of endoscopic approach is also a less extensive procedure than arthrodesis, with no requirement for discectomies, preparation of the fusion bed, or harvest of bone graft.

Results for stapling in humans were presented as early as 1954, but the results were disappointing [2]. Correction of the scoliosis was limited because the children had little growth remaining at the time of treatment, and the curves were severe. Some staples broke or became loose, possibly because of motion through the intervertebral disc.

Recently, clinical interest in stapling has increased following the release of a new staple designed specifically for insertion into the spine by Medtronic Sofamor Danek (Memphis., TN). These staples are manufactured using nitinol, a shape memory alloy (SMA) composed of nickel and titanium. SMA staples are unique in that the prongs are straight when cooled but clamp down into the bone in a "C" shape when the staple returns to body temperature, providing secure fixation.

Despite the increased clinical interest in the use of SMA staples, little is known about the mechanism of their effect or the consequences of their insertion on the adolescent spine.

Fig 1. Radiograph demonstrating anterior vertebral staples inserted into the thoracic spine

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1769–1772, 2009
www.springerlink.com

The aim of this study was threefold. Firstly, to measure changes in the bending stiffness of a single spinal motion segment following staple insertion. Secondly, to describe and quantify the loading experienced by the staple during spinal movement. Thirdly, to describe the structural changes to the vertebra following staple insertion.

II. Materials and methods

A. Specimen Preparation

Six to eight week old bovine spines have previously been validated as a model for the adolescent spine [3]. Specimens were obtained from the local abattoir and stored frozen at the testing facility. All specimens underwent pre-test CT scanning to exclude vertebral anomalies. Each vertebral column was cut into monosegmental functional spinal units (FSU) consisting of two adjacent vertebrae with intervening disc, facets, and ligaments. The FSU was then carefully denuded of all paraspinal muscle with care to preserve ligaments and bony structures. In addition, both sets of ribs and part of the spinous processes were removed to induce significant instability. Once prepared the specimens were potted in polymethylmethacrylate to facilitate coupling of the specimen to the testing apparatus.

B. Surgical Procedure

Four pronged nitinol staples were cooled in an ice bath as per recommended surgical procedure to facilitate their deformation. Using standard instruments the staple was opened to a position of 90°. The surgeon then placed a 5mm nitinol staple (Shape Memory Alloy Staple; Medtronic Sofamor Danek; Memphis, TN) just anterior to the insertion of the rib head so that it spanned the disc and adjacent vertebral endplates. Accurate positioning of the staple was confirmed on post-test radiographs.

C. Biomechanical Evaluation

A displacement controlled six degree-of-freedom robotic facility was used to test each specimen through a predetermined range of motion in flexion, extension, lateral bending, and axial rotation (see Table 1). Each specimen was tested first in an un-stapled (control) state. A staple was then inserted using the technique described previously and the testing protocol repeated. A total of fourteen segments were tested composing six T3-4, four T5-6, and four T7-8.

Force and moment data for each test was recorded via the robot's force transducer. A fixed axis of rotation for the segment was calculated to be five millimeters anterior to the posterior edge of the annulus in the mid-sagittal plane. Using a custom designed MATLAB (version 6.0, MathWorks Inc., Natick, MA) program the force transducer data was synchronized with the robot position data and filtered using moving average methods. The rotational stiffness of the functional spinal unit (FSU) for each applied motion was calculated in Nm/degree of rotation.

Each rotational stiffness was calculated as an average of five cycles per test, which were performed following one 'settling' cycle. Paired t-tests were used to compare average stiffness mesurements in the stapled and control conditions for each direction of movement. A significance level $p<0.05$ was considered statistically significant.

D. Measurement of Staple Loading

A single axis strain gauge (Vishay Micro-measurements, Singapore) was attached to base of three of the staples after insertion into the testing specimen in order to measure the force experienced by the staple during prescribed motions. Each specimen underwent the testing protocol described above and strain data was recorded on a data logger. Following this, individual calibrations for each strain-gauged staple were performed to convert the staple strain measurement into an equivalent staple 'tip' force in Newtons (defined as a force acting normal to, and positioned at the staple tips, with positive values tending to separate two opposing staple tips, and vice versa).

E. Changes in Vertebral Structure Following Staple Insertion

The final phase of testing was a descriptive study of the damage caused to the structural elements of the vertebra following insertion of an SMA staple. For this phase of testing, specimens that had completed phase one of the study were used.

Following completion of the phase one testing protocol a diamond saw was used to cut the staple in half and the two staple halves were removed with care to prevent further damage. The specimen subsequently underwent micro-CT scanning using a uCT 40 scanner (Scanco Ltd., Switzerland) at an isotropic voxel resolution of 36 microns, with image reconstructions to create a descriptive picture of the structural damage to the vertebra following staple insertion.

III. Results

A. Biomechanical Investigation

Stiffness measures in the non-stapled control group correlated with the previously published results of Wilke et al [4]. The results of the comparison in motion segment stiff-

ness between the stapled and non-stapled specimens are presented in Table 1.

A significant decrease in stiffness ($p<0.05$) following staple insertion was found in flexion, extension, lateral bending away from the staple, and axial rotation away from the staple. Stiffness for axial rotation towards the stapled side was significantly greater than for away. A near significant increase in lateral bend stiffness away from the staple compared with towards was also seen.

Table 1 Results for biomechanical testing

Movement	ROM	Change in stiffness following staple insertion	P-value
Flexion	2.5°	↓	0.003
Extension	1.5°	↓	0.04
Lateral bend towards staple	3°	-	0.09
Lateral bend away from staple	3°	↓	0.02
Axial rotation towards staple	4°	-	0.25
Axial rotation away from staple	4°	↓	0.01
Lateral bend toward staple vs. away	3°	-	0.06
Rotation toward staple vs. away	4°	↑ towards	0.04

B. Measurement of Staple Loading.

The greatest staple forces were seen in flexion and the least in extension. Time-based plots of staple tip loading in each plane of motion are shown in Figures 2-4. Of interest, each staple shows a baseline compressive loading on the tips following insertion which gradually, but consistently, decreases across the five cycles of testing

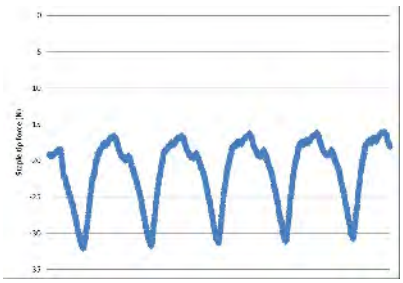

Fig. 2 Equivalent staple tip force versus time in flexion-extension

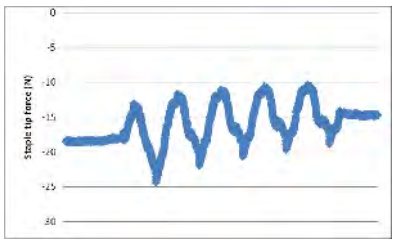

Fig. 3 Equivalent staple tip force versus time in lateral bending

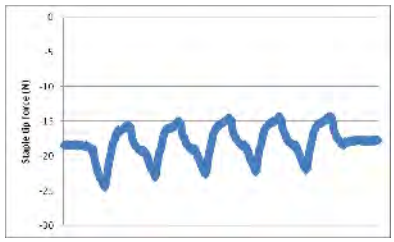

Fig. 4 Equivalent staple tip force versus time in axial rotation

C. Changes in Vertebral Structure Following Staple Insertion

A coronal reconstruction of a micro-CT scan showing extensive trabecular bone and physeal damage following staple insertion is shown in Figure 5.

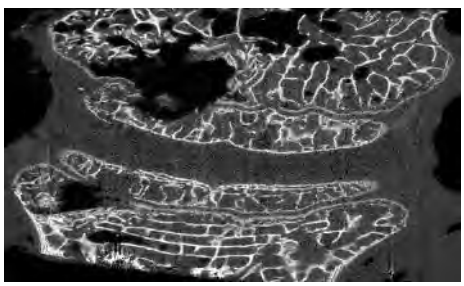

Fig 5. Micro-CT showing vertebral damage following staple insertion

IV. Discussion

The goal of this study was to describe the anatomical and biomechanical consequences of the insertion of an SMA staple in the thoracic spine. The findings from the biomechanical investigation indicate that staple insertion consistently decreased the stiffness of the motion segment. These results could not be attributed to changes in anatomy or tissue properties between tests as each specimen acted as its own control.

Intuitively staple insertion would be expected to increase motion segment stiffness. Indeed, a recent paper by Puttlitz

et al [5] found a small but significant decrease in the range of motion in lateral bending and axial rotation using moment controlled testing. In this paper T4-T9 motion segments were stapled with a variety of staple constructs and compared to a non-stapled control condition. The significance of these results were questionable however as the changes in range of motion were only a few degrees over several vertebral levels and statistical outcomes were of low power. Furthermore methodological flaws, in particular the fact the vertebrae were re-used for testing after removal of a staple, which in our experience is associated with significant structural damage, make these small differences in range of motion difficult to interpret.

In our study we have attempted to create a superior testing methodology. By using only single motion segments and not re-using testing specimens we hope to have eliminated confounding factors. In addition, the use of only one staple construct, the double-pronged laterally placed staple, which is the most commonly used clinically, increases the relevance of the findings.

An explanation for the finding of decreased motion segment stiffness may be found in the outcomes of the strain gauge testing and micro-CT scan. The strain gauge testing showed that once inserted the staple tips applied a 'resting' force to the surrounding trabecular bone and vertebral end-plate. This finding would be consistent with the belief that the mechanism of effect of the SMA staple is via the Hueter-Volkmann law. Interestingly however, as the motion segment progressed through five cycles of each test the baseline load on the staple tips gradually decreased, implying that the force at the staple tip – bone interface was decreasing. We believe that this was likely occurring as a result of structural damage to the trabecular bone and end-plate by the staple which effectively caused 'loosening' of the staple.

This hypothesis is further supported by the findings of the micro-CT scan. The pictures depict significant trabecular bone and physeal injury following staple insertion. Furthermore the staple tines are shown to 'clamp down' once inserted into a position that would be unlikely to allow a sustained and uniform force on the growth plate for growth modulation.

Early results to date with SMA staples have been promising in both animal [6] and human [7] trials. We propose that the effectiveness that is suggested by this early work is not as a consequence of the Hueter-Volkmann effect, but rather because the insertion of an SMA staple causes vertebral hemiepiphysiodesis and subsequent convex growth arrest.

The published outcomes of convex growth arrest in congenital scoliosis have generally been successful [8]. However, to date no study has evaluated the use of hemiepiphysiodesis in adolescent idiopathic scoliosis. Based on our findings it is likely that the insertion of the SMA staple causes a similar, albeit somewhat less invasive and extensive epiphysiodesis effect as has been described for use in congenital scoliosis. If an epiphysiodesis effect is not desirable in the treatment of AIS then alternative staple designs may need to be considered.

V. Conclusions

The results of this study show that growth modulation achieved using SMA staples is likely due to disruption of the growth plate rather than sustained biomechanical compression across the motion segment as occurs with the Heuter-Volkmann effect.

Measurement of Cell Detaching force on Substrates with Different Rigidity by Atomic Force Microscopy

D.K. Chang[1], Y.W. Chiou[1], M.J. Tang[2] and M.L. Yeh[1]

[1] Institute of Biomedical Engineering, National Cheng Kung University, Tainan, Taiwan
[2] Institute of Physiology, National Cheng Kung University, Tainan, Taiwan

Abstract — **Cell adhesion plays an important role in cell morphology, motility, and differentiation, and cancer metastasis. The rigidity of the substrates is one of the factors that can affect cell behaviors. How the rigidity of substrates influence the initial attaching strength of cell is not well investigated yet. Cell probe attaching cell on the AFM cantilever tip is a new approach to study cell mechanics.**

The purpose of this study is to investigate the relation between the rigidity of substrate and cell detaching force by cell probe. Fibroblast cell was used to quantify cell detaching force. All the surfaces of substrates were coated with type I collagen. The contact times were set at 30, 60, 90, and 300 seconds with contact compression at 500 pN. The substrates used were 1037 Pa, and 10930 Pa poly acrylamide (PAA) and glass.

Under the same contact time, the detaching force rose gradually with increasing substrate rigidity. They were 482.11±194.34, 1820.11±949.29, and 3373.45 ±1867.02 pN respectively for 1037 Pa, and 10930 Pa PAA and glass for 300 seconds.

Our results showed cell adhesion could be influenced by substrate rigidity. This cell probe technique can be further used for parameter studies on cell substrate interaction in the future.

Keywords — **AFM, cell probe, cell detaching force, substrate rigidity**

I. Introduction

Cells interact with neighboring cells and extracellular matrix through adhesion molecules. The adhesion behavior is modulated by the intracellular physiology and affected by extracellular environment. It has decisive effect on cell physiology such as, morphology, migration, motility and differentiation and cancer cell metastasis [1-2].The ability for cell to attach represents the normal physiology behavior for cells.

Currently, several approaches have been developed to study the cell adhesion force, like micropipette [3], optical tweezers [4], cell detacher [5] and atomic force microscopy (AFM) [6]. Cell probe is a new approach by AFM [7]. It attached the cell on the end of usually tipless cantilever. Once the cell probe established, it can be used to evaluate the interaction between the attached cell and single cell or cell layer on the surface. It is known the stiffness of substrate can affect cell behavior [8]. The reaction and sense of cell to the stiffness also vary with cell types. The purpose of this study is to use the cell probe approach to measure how stiffness of substrate affecting the initial adhesion forces.

II. Materials and methods

A. Cell culture

Rat fibroblast (NIH-3T3) cell line was used in this study. Culture medium was 10% Fetal Bovine Serum (FBS)(Sigma-Aldrich, St. Louis) with 1% Penicillin(Sigma-Aldrich, St. Louis) and Dulbecco's Modified Eagle's Medium (DMEM). (Sigma-Aldrich, St. Louis)

B. Substrate preparation

PAA (Polyacrylamide) (Sigma-Aldrich, St. Louis) gel was used to make soft substrates. By adjusting the ratio between Acrylamide (Sigma-Aldrich, St. Louis) and Bis-acrylamide (Sigma-Aldrich, St. Louis), two stiffness of substrates (modulus 1037 and 10930 Pa) were made. Stiff glass surface (70GPa) was used as control. All the substrates were then coating with type I collagen solution (Sigma-Aldrich, St. Louis). Briefly, dishes were added with Sulfo-SANPAH (Sigma-Aldrich, St. Louis) as cross-linking agent then irradiated by UV light(120,000 microjoules, 302 nm wavelength, UVP, CL-1000) for 10 minutes. PBS was then used to remove unbonding cross-linking agents. Afterward, 200 μg/ml type I collagen solution was spread on dish surface and then placed on the shaker inside 4 degree C refrigerator for 24 hours for well-mixing the type I collagen solution.

C. AFM system

The AFM system used in this study is JPK NanoWizard® II on top of inverse light microscope (Zeiss Axio Observer). In order to fully separate the tether of pulling cell during separation, the AFM system includes CellHesion® which has vertical movement up to 100μm.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1773–1776, 2009
www.springerlink.com

D. Functionalized cantilever tip

Tip-less cantilever (CSC12, MikroMasch) with spring constant 0.03 N/m was used in this study. The dimension of the cantilever is 350 X 35 X 1 μm with resonant frequency of 10 kHz. First the cantilever was cleaned with acetone for 5 minutes followed by exposed to 120,000 microjoules, UV radiation for 15 minutes. Then the tip was put into biotin-BSA solution (Sigma-Aldrich, St. Louis) in 37 degree C incubator overnight. After rinsed with PBS to wash out the extra biotin, the tip was further functionalized by streptavidin solution (Sigma-Aldrich, St. Louis) for 30 minutes at room temperature. The tip was then rinsed with PBS again to remove unbonding streptavidin. The tip was then immersed into conA (Sigma-Aldrich, St. Louis) for 30 minutes. After washed with PBS, the tip was put in D.I. water and ready for cell catching.

E. Calibration for cantilever tip

The mechanical property of testing material depends on the accuracy of spring constant and deflection of cantilever tip. Due to the nominal thickness of the cantilever is usually not accurate, it is necessary to use other approach to measure its spring constant. Thermal noise method, the resonant frequency correlated to its spring constant, was used to measure the spring constant of individual cantilever before each test.

F. Cell probe preparation

After 4 days of culture of 3T3, the cells were removed from flask by trypsin (Sigma-Aldrich, St. Louis) then dropped on culture dish. Use the optical microscopy to observe the cell morphology and locate a cell with proper shape. After moving the tip above the cell, the functionalized tip was approached at the rate of 5 μm/s on the cell and pressed at 500 pN for 5 seconds then retracted. In most case, the cell was attached on the bottom of the cantilever. The cell probe was retracted to 100 μm above the surface and ready for adhesion test.

G. Measuring cell adhesion force

One of the three substrates which are two PAA gels with modulus 1037 and 10930 respectively and hard glass was selected for surface. Four contact times, 30, 60, 90 and 300 seconds were studied. The cell probe approach on the substrate at 5 μm/s and the contact force was set at 500 pN. At the same cell, four contact times were conducted at randomly order till the cell lost its activity. After each test, the cell rested for 2 minutes to recover. The approach and retract force curves were collected and analyzed.

H. Data analysis

The extract force curves can be used to quantify the adhesion strength between cell and the surface. The relationship between the adhesion force and different stiffness of substrates at 4 different contact times were recorded. One-way ANOVA was used to test the difference among groups and Tukey's HSD was used as post-hoc test.

III. Results and Disscusion

A. Cell probe

The successful cell probe image was caught by optical microscopy (Fig. 1). When the tip approached the surface and made contact with the surface, the cell instead of the tip directly touched the surface. The breaking strength on force curve was the adhesion between the cell and the surface.

The adhesion force increased with contact time in all three substrates (Fig. 2). However the increasing rates were different among them. For hard glass substrate, the adhesion force increased quickly at early time and had the trend to

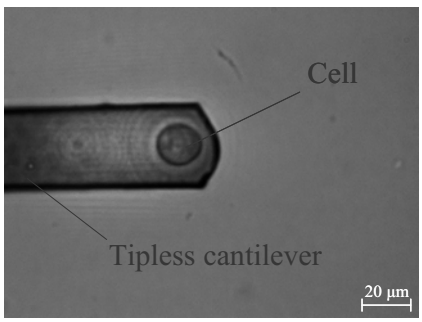

Fig. 1 The image of cell adhered on the bottom of AFM tip

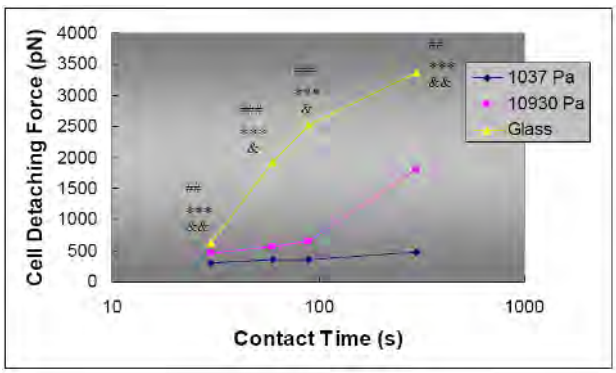

Fig. 2 Temporal change of adhesion force for 3 substrates
&significant different between 1037 Pa and 10930 Pa
*significant difference between 1037 Pa and glass
#significant difference between 10930 Pa and glass

reach stable. For 10930 Pa substrate, the adhesion force increased slowly between 30 to 90 seconds, but increased rapidly after 90 seconds. For softest 1037 Pa substrate, the adhesion force increased slowly through 300 seconds. They were significant different among 4 contact times for glass surface. For 10930 Pa PAA surface, only 300 seconds contact time was significant different from other 3 shorter contact times; however, there were no difference among 30, 60 and 90 seconds contact time. For soft 1037 Pa substrate, there were no difference among 4 contact time.

Cells interact with extracellular matrix through integrin. The bonding was believed through covalent bond [9]. Single covalent bond strength was about 1400 pN [10]. We use this strength to define the starting time for stable bonding between the cell and surface. Glass can start to have stable bonding in 48 seconds. The time to have stable bonding for 10930 Pa substrate is about 225 seconds. However, it never reached stable bonding for 1037 Pa substrate before 300 seconds.

B. Adhesion force vs. stiffness

The substrates at three different rigidities were used in this study. The adhesion force for stiff glass was significant larger than the other two softer substrates at all contact times (Fig. 3). The adhesion forces between 1037 Pa and 10930 Pa were also significant different at all four contact times. The stiffness of substrate could have dramatically effect on cell's initial bonding strength. When cell was on different substrate, the stiffness of substrate can be sensed by the cell. Our results clearly show the early adhesion force increases at different rate for different substrates. This early adhesion force is comparable to late stable force, but the differences among different substrates are more significant.

*significant different from glass
#significant different between 1037 Pa and 10930 Pa

IV. Conclusions

This study has successfully built the cell probe technology to measure the cell's early adhesion force. This method can be used to study the physiological phenomenon between the substrate and the cell and measure their adhesion forces. The results find the initial adhesion force was influenced by contact time and substrate stiffness. The adhesion force increases with the stiffness of the substrate during the first 300 seconds. The adhesion force increases with time at different rate for different substrates. Nevertheless, the time to reach stable adhesion (1400 pN) also depends on the substrates. This information can be important guide for understanding the mechanism how substrate affecting the cell adhesion and following biochemical signal pathway. Combining the confocal microscopy, fluoresce technology and biochemical assay, this cell probe technology can be used to further study the detail of cell surface interaction.

Abstract — **Body segment parameters (BSP) are essential inputs in the kinetic analysis of human motion. These data include mass, center of mass and moments of inertia, and are usually obtained from population-specific predictive equations. Several limitations remained with the use of cadaveric measurement. These include limited sample size, as well as discrepancies in age and morphology. The limitations motivated the development of direct BSP measurements on living subjects. However, other limitations such as exposure to radiation, high cost and sheer lack of facilities that are readily available evolved. In addition, some methods provide only two-dimensional (2-D) measurements while others require intensive tomographic images for three-dimensional (3-D) reconstruction. This article proposes a novel technique for reconstructing subject-specific 3-D body mass distribution using from Dual Energy Absorptiometry X-ray imaging and 3-D exterior geometry. The accuracy of our method was assessed by calculating percent error between the criterion based on total body mass and our proposed total body mass measurements (TBM). We found less than one percent error between the criterion and our TBM measurements for subjects of four different body types: endormorph, mesomorph, ectomorph and central. We found significant differences between our proposed method as compared to cadaver-based and living-based models for segment mass (SM) at the hand; center of mass (CM) at the thigh, shank, foot, head and neck, trunk, upper arm, forearm and hand; and moments of inertia at the hand, shank, foot and trunk. Extensions of the research could further examined the influence of other BSP measurements derived from our proposed method and the four selected estimation models, as well as their impact on the inverse dynamics solutions in human motion.**

Keywords — **Body segment parameters, Dual Energy Absorptiometry X-ray, 3-D geometry, biomechanics**

I. Introduction

The accurate determination of the body segment parameters (BSP) specific to individual has been a long-standing problem in biomechanical analysis of the body during motion. These analyses often require knowledge of the inertial properties of body segments which include the mass, length, mass centroid and moments of inertia of each segment. The accuracy of the biomechanical model is largely dependent on the extent to which the estimated mechanical values of the body replicating the actual anatomical structure [1]-[7].

Generally, BSP estimation methods are based on predictive equations obtained from elderly male cadavers or small samples adult Caucasian able-bodied males [8]-[11]. Neither of these groups is representative of the majority of the current population under study. Other predictive equations are based on living subjects using stereo-photogrammetry [12]-[13]; gamma-ray [14]; magnetic resonance imaging (MRI) [15]-[18]; computerized-tomography (CT) [19]-[22]; ultrasound [23]. However, the use of such direct BSP measurements are limited in daily biomechanical research due to the complexity of the procedures as they require a lot of tomographic images for a three-dimensional (3-D) reconstruction; danger of exposure to radiation; high cost; and the sheer lack of facilities that are readily available. In addition, accurate estimates of direct BSP measures have been limited to technical and ethical constraints, small sample sizes, variation in segment boundaries, as well as the constraint of adopting a representative literature of BSP sources for the population under study.

Recently, two-dimensional (2-D) in vivo imaging technique, known as dual-energy X-ray absorptiometry (DXA), has been used to capture full body 2-D projection of mass densities through X-ray technique. In comparison with other imaging techniques, it is relatively inexpensive and the radiation exposure is substantially less than normal background sources [28]. DXA measurements can be used to determine total mass, bone and soft tissue mass for each body segments. This scanner has been determined to be useful for obtaining accurate 2-D BSP values of human subjects [4], [5], [29]. It is also capable of giving accurate direct measurement of the entire body or of a defined region of interest [30], [31] where mass properties can be computed. However, BSP values computed from DXA images are accurate in the frontal plane only.

The purpose of this paper is to: (1) describe an in vivo method by incorporating DXA with 3-D geometry to estimate total body mass; (2) evaluate the accuracy of the proposed method by comparing it to criterion values of meas-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1777–1780, 2009
www.springerlink.com

ured body mass; and (3) examine the difference in distribution of segment mass between the proposed method and selected BSP models.

II. Materials and Methods

A. Subjects

Four healthy males (age: 27.5 ± 4.6 years; mass: 79.7 ± 32 kg; height: 1.75 ± 0.06 m) of different body types participated in this study. Somatotypes were evaluated using the Heath-Carter (1967) method and subject characteristics are shown in Table 1. Institutional Review Board approval was obtained from the research and graduate review committee of the Physical Education and Sports Science (PESS), Nanyang Technological University. Informed consent was obtained from each subject. Standing height was recorded to the nearest 0.1 centimeters (cm). The body mass was recorded to the nearest 100 grams (g) using Seca (Model 767) balance scale.

Table 1 Somatotype, age, height, body mass and percent body fat of the subjects (n = 4)

	Ectomorph	Endomorph	Central	Mesomorph
Somatotype	2-3.5-5.5	7-5-0.5	4-3.5-3	3-6-1.5
Age (year)	33	31	23	24
Height (cm)	179.1	181.1	171.1	170.1
Body mass (kg)	58.8	127.39	63.0	70.6
Body fat (%)	13.8	34.2	21.4	18.6

B. Instrumentations

Full body DXA scans were performed using a Hologic QDR-1000/W densitometer (Hologic, Bedford, MA, USA) with the subjects lying supine on the scan bed. 3-D exterior geometry was obtained with subjects standing upright using 3-D digitizer system (3-D Capturor II, InSpeck Inc., Montreal, Quebec, Canada).

The full-body DXA image was segmented into 14 segments as shown in Fig. 1 and defined as the head-and-neck, trunk, right and left upper arms, right and left forearms, right and left hands, right and left thighs, right and left shanks, right and left feet.

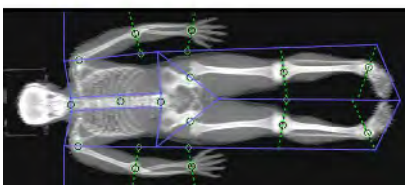

Fig 1. Full body segmentation

C. Dual Energy X-ray Absorptiometry Imaging

We adopted the classification algorithm proposed by Pietrobelli et al. [33] to identify each pixel by material groups, fat, lean or bone tissues. The source releases a beam of photons which is related to the attenuated intensities via the classic attenuation formula

$$I = I_0 e^{-\mu_m \times \rho \times L} \tag{1}$$

where e is base of natural logarithms, I is the transmitted photon intensity, I_0 is the initial photon intensity, L is path length (cm), ρ and μ_m are the object's density (g.cm^{-3}) and mass attenuation coefficient (cm^2.g^{-1}) respectively.

The object domain was discretized from the imaging resolution $X \bullet Y$ across a proportional depth (z), and assumed constant material in each volume element. The log-attenuation ratio is a sum of elemental attenuation over the pixel at (x, y)

$$\ln\left(\frac{I(x,y)}{I_0}\right) = \sum_z -\mu_m \times \rho(x,y,z) \times dz \tag{2}$$

where ρ and μ_m is the object's density (g.cm^{-3}) and material properties are now specific to the volumetric element.

We casted volumetric reconstruction as a non-linear constrained minimization problem. We aligned the 3-D bounding manifold of the object G to the plane of the acquired images, $I \in R^{2\times N}$. With N = 2 for DXA scans, we discretized the space such that G is enclosed within a volumetric domain D comprising $m \times n \times d$ cells. Each cell, also known as voxel, $v = (x,y,z)^T \in D$, was assumed to have uniform material property.

We set the scalar function $f : D \to R$ to denote the unknown volumetric density field. We also set constraints to the values of f such that the implicit surface f = 0 delineates G

$$f(v) = \begin{cases} +ve, & v \text{ is interior to } G \\ 0, & v \text{ lies on } G \\ -ve, & v \text{ is exterior to } G \end{cases} \tag{3}$$

where G represents the 3-D exterior geometry of the object and v is the voxel of each cell.

Geometric closure and orientability were required of G. Otherwise, the signed distance function would be ill-defined

Suppose $\alpha = \ln\left(\frac{I(x,y)}{I_0}\right)$, the integral of each column would be

$$\alpha = \sum_z \{f(x,y,z) \mid f(x,y,z) > 0\} \quad (4)$$

where $f(x,y,z) = -\mu_m \times \rho$ is the differential attenuation of the photon beam through a path of unit length, which confined the summation to voxels interior to the object.

One-way analyses of variance (ANOVA) were performed to test for significant differences between our method and four BSP estimate models on segment mass, center of mass and moments of inertia about the full body segments. All statistical tests were performed using SPSS software.

III. Results

The proposed method was able to accurately estimate total body mass of 4 male subjects, thus validating mass constant. The percent error between the estimated and measured body mass were less than 1% (Table 2).

Table 2 Criterion measured total body mass (MBM), and total body mass (TBM) from our proposed method (n = 4)

Body types	MBM (kg)	TBM (kg)	% error
Ectomorph	58.8	59.13	0.56
Endomorph	127.39	126.93	0.36
Central	63.0	63.09	0.14
Mesomorph	70.6	70.09	0.73

Comparisons between the inertial parameters derived from selected BSP models and our proposed method were made. The inertial parameters were the segment mass (*SM*), center of mass (*CM*), and the moments of inertia (I_{xx}, I_{yy} and I_{zz}). The results showed that BSP values differ substantially as a function of the BSP model employed. ANOVA revealed significant differences between our proposed method as compared to cadaver-based and living-based models for *SM* at the hand.

ANOVA indicated significant differences between our proposed method as compared to cadaver-based and living-based models for *CM* at the thigh, shank, foot, head and neck, trunk, upper arm, forearm and hand. Post hoc comparisons revealed that the *CM* derived from our proposed method are significantly less than Dempster [11] and Cheng et al. [15] at the hand, forearm, trunk, thigh, shank and foot.

ANOVA showed significant differences between our proposed method as compared to cadaver-based and living-based models for moments of inertia at the hand, shank, foot and trunk. Post hoc comparisons revealed that the moments of inertia derived from our proposed method are significantly more than Cheng et al. [15] at the hand, shank, foot and trunk.

IV. Discussion

Previous studies have examined the effect of variations in BSP during gait and advocated the need for accurate BSP values in high acceleration movements [3], [6], [30]. Significant differences were found in segment mass estimated using our proposed method when compared to cadaver-based [8], [11] and living-based models [14], [15].

Total body mass and were estimated using our proposed method and compared with measured body mass. Percent errors between estimated and measured body mass were less than 1% for all subjects. The variations between subjects may be attributed to the difference in ability of distinct beam energies to identify each pixel of material groups such as fat-and-lean or soft tissue-and-bone which can be vastly different for different body types. In general, the percent errors between estimated and measured body weight ranged between 0.14 to 0.73%. This is comparable to Jensen's [14] elliptical zone modeling approach who reported maximum 1.82% error between estimated and measured body mass. Our proposed method permits direct computation of all segmental parameter values specific to individuals, and takes into account the shape of the actual body segments. We also accounted for varying tissue densities for fat, lean and bone tissues. One limitation of this method is the assumption of uniform material property for each cell, and hence volume column. Another limitation would be inherent errors due to redistribution of tissues when subjects lie supine in the DXA scan position. This may change the inertial properties of the segments to a certain extent. Nevertheless, the ability of this method to distinguish unique density for bone, lean and fat tissue is still more rigorous than assuming uniform segment densities.

V. Conclusions

Extensions of the research could further examined the influence of other BSP measurements derived from our proposed method and the four selected estimation models, as well as their impact on the inverse dynamics solutions in human motion. The information can be used to gain insights in sport skills or gait; identification of aetiology of conditions such as osteoarthritis; and for the development of medical instruments.

Abstract — **Low back pain due to spinal segmental instability is common in lumbar degenerative diseases. Instability of the spinal segment is difficult to define and occur in any motion direction. In particular, rotational instability has been implicated in the pathogenesis of low back pain. Biomechanical measurements assess motion properties that are essential for estimating segmental instability. To detect spinal segmental instability, we developed a new system for measuring spinal mobility during lumbar spine surgery. The system consists of a motor driven mechanical apparatus with a computerized controller, load cell, optical displacement transducer and spinous process holders that allow handling of the spinal process without damaging the supraspinal and interspinal ligaments. In this study, the repeatability test was performed to demonstrate the potential of the measurement system. Displacement generated by the actuator at a speed of 1.0 mm/sec was applied to the tip of the holders with a maximum displacement of 4.0 mm from the neutral position for five cycles of axial rotation. After 5 min, the same specimen was retested for five more cycles of axial rotation, and this process was repeated ten times. In total, this test generated 50 load–displacement curves for each specimen. From the load–displacement curve, we determined three motion parameters: stiffness, neutral zone and absorption energy, and calculated the coefficients of variation (CVs) by dividing the standard deviation by the mean of each parameter and converting it to a percentage. The small CVs for each parameter measured reflected the high repeatability of the load–displacement curves. The measurement had sufficiently high repeatability for clinical use, as indicated by the low CV for each motion parameter.**

Keywords — **Spine, instability, rotation, mobility, neutral zone, measurement.**

I. Introduction

Intraoperative biomechanical measurements assess motion properties that are essential for estimating segmental instability. Ebara et al. developed a method of measuring spinal stiffness that used a spinal spreader and measured the tensile stiffness of a mobile segment; they concluded that tensile stiffness depends on disc degeneration, decompression, and interbody fusion[1)]. Brown et al. developed a motor-driven vertebrae distractor to measure motion segment stiffness. They concluded that the vertebral distractor allows objective and quantitative intraoperative measurement of the stiffness of a mobile lumbar spine segment[2),3)].

In the above studies, spinal segmental mobility was evaluated using the stiffness in flexion. However, from a biomechanical perspective, estimates of additional parameters, such as the neutral zone (NZ), are needed to assess spinal mobility[4)]. Clinical instability cannot be estimated by measuring mobility in flexion only, and measuring the rotational mobility of the spinal segments is also important[5)].

Instability of the spinal segment can occur in any motion direction[6)-13)]. In particular, torsional instability has been implicated in the pathogenesis of low back pain[13)]. Therefore, multidirectional measurement of the target segment is desirable. In the study described here, we developed and tested another system for measuring spinal mobility. This system, which measures rotational mobility in the axial plane, was evaluated for its ability to detect segmental mobility in porcine lumbar segments.

II. Materials and methods,

To detect spinal segmental instability, we developed a new system for measuring spinal mobility during lumbar spine surgery (Figure 1). The system consisted of spinous process holders (Gi-5; Mizuhoikakikai, Niigata, Japan), a motion generator, and a personal computer. The spinous process holders were designed to handle the spinal processes without damaging the supra- and interspinous ligaments. The motion generator consisted of a computerized linear actuator, an optical displacement transducer (LB-080; Keyence, Tokyo, Japan), a load cell (LUR-A-200NSAI; Kyowa Dengyo, Tokyo, Japan), and a multidirectional ball joint that connected the motion generator to the spinous process holders. The motion generator was attached through the ball joint to two spinous process holders, which gripped the adjacent spinous processes firmly. The linear actuator (RC-RSW-L-50-S; IAI, Shizuoka, Japan) generated continuous displacement applied to the spinous process holders at speeds of 1.00 to 100 mm/sec. The mobile segment was displaced from the neutral position and rotated right and left

www.springerlink.com

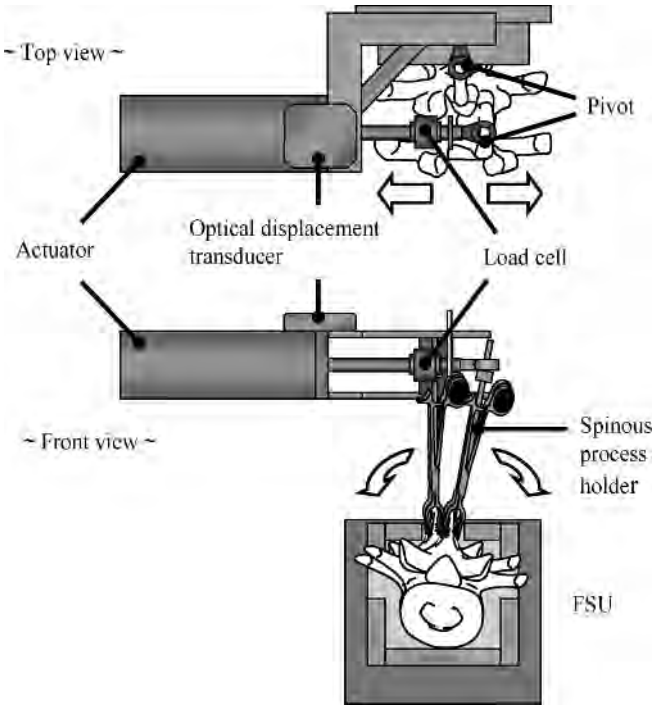

Fig. 1 Schematic diagram of a new system developed to measure spinal rotational mobility. An actuator is used to move the caudal spinous process holders. Load is measured with a load cell, and displacement is measured using an optical displacement transducer.

cyclically. The neutral position was defined as the segment position when no load was applied. In the experiments, the load and displacement at the tip of the caudal spinous process holder were measured using a load cell and an optical displacement transducer, respectively, and the load-displacement curves were plotted on a computer screen.

In vitro experiments were performed using fresh-frozen porcine lumbar spines to demonstrate the potential of the measurement system, and the specimens consisting of functional spinal units (FSUs) were harvested from mature porcine lumbar spines. The FSUs were dissected to remove all muscles and fatty tissues, while the ligamentous tissues (supraspinal, interspinous, anterior longitudinal, anterior longitudinal, posterior longitudinal, transverse ligament, and flavum), discs, facet joints, and osseous structures were left in place. During the experiments, six FSUs (two each of T12/L1, L2/L3, and L4/L5) were used to demonstrate the potential of the system, and eight FSUs (two each of T12/L1 and L2/L3, and one each of L1/L2, L3/L4, L4/L5, and L5/L6) were used to assess destabilized segments, as shown Table 1. During the tests, the specimens were maintained at a constant temperature and humidity to prevent deterioration.

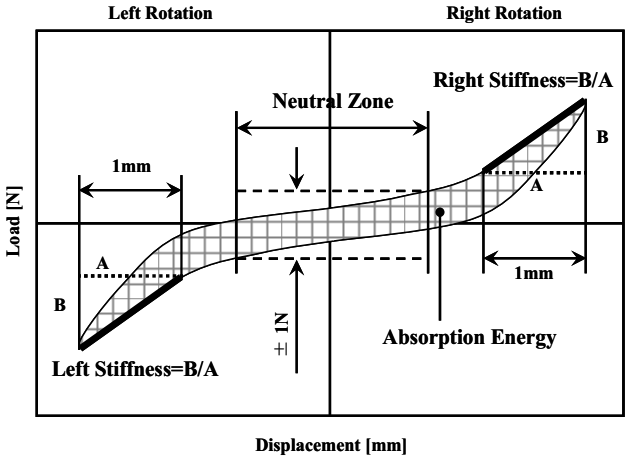

Fig. 2 Determination of each parameter from the third load–displacement curve. The left and right stiffness (N/mm) values were defined as the slopes of the lines fitting the load-displacement curve from –1 to –2 mm and from 1 to 2 mm, respectively. The neutral zone (mm) was defined as the displacement that occurred while the load was reduced from 1 N to –1 N along the load-displacement curve. Absorption energy (J) was defined as the area of the resulting hysteresis loop.

From the load-displacement curves, we determined three motion parameters to evaluate the spinal motion: the stiffness, NZ, and absorption energy (AE) (Figure 2). Stiffness describes the relationship between the load and displacement of the spinal segment while rotation is applied. In this study, the stiffness was defined as the slope of the line fitting the load-displacement curve from 1 to 2 mm on right rotation and from ?1 to ?2 mm on left rotation. The NZ is the flat region of the load-displacement curve around the neutral position. This indicates that the passive spinal column offers little resistance. The NZ was defined as the displacement that occurs while the load is reduced from 1 N to -1 N. The load-displacement curve showed hysteresis, as the load lagged behind the change in displacement. The area inside the load-displacement curve has units of energy. This energy is absorbed by the discs, ligaments, and other soft tissues around the spinal segment while the segment is moving. The AE was defined as the area surrounded by the load-displacement curve during one cycle of spinal motion.

The repeatability test was performed to demonstrate the potential of the measurement system. In this test, each FSU was assessed while intact. Displacement generated by the actuator at a speed of 1.0 mm/sec was applied to the tip of the holders with a maximum displacement of 4.0 mm from the neutral position for five cycles of axial rotation. After 5 min, the same specimen was retested for five more cycles of axial rotation, and this process was repeated ten times. In total, this test generated 50 load-displacement curves for each specimen. We determined three motion parameters

from each cycle for every load-displacement curve and calculated the coefficients of variation (CVs) by dividing the standard deviation by the mean of each parameter and converting it to a percentage.

III. Results

To determine the repeatability of the spinal mobility measurement, we calculated the CV of each mechanical parameter determined from the load-displacement curve. The CV is a statistical measure of the dispersion of a probability distribution and is defined as the ratio of the standard deviation to the mean. The CVs were as follows: right rotational stiffness 2.28-5.75% (mean 4.57%), left rotational stiffness 2.10-5.50% (4.30%), NZ 4.44-7.75% (6.20%), and AE 6.28-12.78% (8.57%). The small CVs for each parameter measured reflected the high repeatability of the load-displacement curves (Table 1).

Table 1 Coefficient of variation (CV) for each mechanical parameter.

	R stiffness (%)	L stiffness (%)	Neutral zone (%)	Absorption energy (%)
T12/L1	2.96	3.58	4.62	6.48
L2/3	5.44	4.42	7.75	6.68
L4/5	5.37	5.50	6.85	12.78
T12/L1	5.62	4.98	5.92	6.88
L2/3	2.28	2.10	4.44	6.26
L4/5	5.74	5.22	7.61	12.35
mean	4.57	4.30	6.20	8.57

IV. Discussion and conclusions

After a half-century of controversy, a clear definition of clinical instability of the spine has yet to be established, partly because facts elicited from ex-vivo or animal studies[7)-17)] appear inconsistent with those from patients with mechanical low back pain or motion-induced radiculopathy. Although conventional radiographic measurements are still popular for the clinical diagnosis of instability, radiographic examinations[18)-25)] are limited to still measurements with a large range of values, so that normal angulatory motion cannot be precisely defined[26)]. In addition, these radiographic measures demonstrate some kinematics, but they do not yield biomechanical data concerning the load-deformation relationship, which is necessary to determine the segmental instability. Thus, no clinically convenient and biomechanically accurate tools that yield results correlating with those of extensive basic studies have been available.

Our approach constitutes an attempt to bridge the gap between the basic biomechanical data and the clinical symptoms observed to arise from instability. The final goals of our intraoperative measurement for segmental instability are to determine distinct criteria based on the biomechanical data and to certify a rationale for lumbar fusion, the gold-standard therapy for segmental instability, from a biomechanical point of view. We have already launched the clinical application of the measurement system for sagittal plane (flexion-extension) motion properties[27)] following several ex-vivo studies[28),29)]. However, since instability of the spinal segment can occur in any motion direction[7)-13),23)] , multidirectional measurement of the target segment is desirable. This study provides a basic confirmation of the potential of our new measurement system for quantitating clinical motion properties in the axial plane.

The measurement had sufficiently high repeatability for clinical use, as indicated by the low CV for each motion parameter. The computerized motor-driven measurement system, which was able to accurately rotate the segment at a constant speed, and the specially designed spinous process holder, contributed to the excellent repeatability. This study demonstrated the potential utility of our system for obtaining useful data on spinal mobility.

Abstract — **Nanoparticles which selectively bind to the atherosclerotic lesion can be used in diagnostic imaging and efficient drug delivery. We have developed peptides conjugated polymer nanoparticles which selectively bind to atherosclerosis plaque. Hydrophobically modified glycol chitosan (HGC) nanoparticles were used as carriers, and the peptides which showed selective binding to the atherosclerotic plaque was screened using phage display. We synthesized peptides conjugated HGC-Cy5.5 nanoparticles and examined their binding characteristics on the activated endothelial cells in vitro under static and flow conditions. Under static condition, the peptide tagged nanoparticles did not show significant selective binding for the activated endothelial cells at low particle concentrations (25 and 50 μg/ml), but they more avidly bound to the activated endothelial cells at high particle concentration (100 μg/ml) comparing to the unactivated endothelial cells. Under fluid flow condition, selective binding of peptide tagged nanoparticles was more prominent.**

Keywords — **Atherosclerosis, Molecular Imaging, Nanoparticle, Shear Stress.**

I. Introduction

Various nanoparticles have recently been developed for diagnostic and therapeutic use owing to the advance of nanotechnology [1-3]. Target specificity of nanoparticles can enhance the efficiency of drug delivery and diagnosis while reducing the side effects such as toxicity and immunogenicity. Targeting has been generally achieved by conjugating nanoparticle surfaces to antibodies or peptides which show binding specificities to the target. Multivalent attachment of antibodies or peptides to nanoparticles enhances target specific binding efficiency. Also surface modification of nanoparicles can modulate pharmacokinetic properties such as blood half-life, elimination and biodegradation. Conjugation of nanoparticles to antibodies for diagnosing and treating cancer and atherosclerosis has been attempted [4,5], but using antibodies as targeting moieties involves difficulties such as limited shelf life, regulations, and potential immunogenicity.

We would like to develop polymer nanoparticles functionalized by peptides which selectively bind to atherosclerosis. Hydrophobically modified glycol chitosan nanoparticles (HGC) are used as carriers because of their blood compatibility, adequate circulation retention time, and high endothelial cellular uptake [6,7]. Peptide which shows specific binding to the atherosclerotic plaque is screened using phage display, and conjugated to the surface of nanoparticles. In this study, binding characteristics of the peptides tagged chitosan nanoparticles on the activated endothelial cells have been examined in vitro in order to develop atherosclerosis specific targeting agents. Effects of particle concentration, incubation time and fluid flow were explored.

II. Materials and Methods

A. Endothelial cell culture and activation

Bovine aortic endothelial cells (BAECs; a kind gift from Dr. B.H. Lee, Kyungbuk National University) were cultured in tissue culture flasks in Dulbecco's Modified Eagle Medium (DMEM-low glucose, Sigma-Aldrich, St.Louis, MO). For static flow experiment, cells were resuspended in the medium, and seeded in 8-well and 24-well cell culture clusters at a density of $1x10^4$ and $5x10^4$ cells per a well, respectively. Cells were allowed to grow for 1 day and monitored for uniformity. Recombinant human tumor necrosis factor-α (TNF-α) was obtained from Chemicon International (Millipore Corp., Billerica, MA). Cells were treated with 10 ng/mL of TNF-α for 6 hours for activation.

For convective flow experiment, $1x10^4$ cells were seeded in the commercially available flow channel (μslide I®, Ibidi, Integrated Diagnostics, Germany). This plastic flow channel had a rectangular channel (0.4 mm height, 5 mm width, 50 mm length). Cells were cultured until reaching confluence, and activated by TNF-α as previously described.

B. Preparation of AP-1 peptide-tagged HGC-Cy5.5 conjugate

The HGC (degree of substitution=12%) was synthesized in the presence of 1-ethyl-3(3-dimethylaminpropyl) acrbo-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1785–1787, 2009
www.springerlink.com

diamide hydrochloride (EDC) and N-hydroxysuccinimide (NHS), as described previously [8]. Peptide sequences with seven motifs, named AP-1, were screened by phage display. A phage library containing random peptides was screened for binding to atherosclerotic plaques. After three rounds of screening, the DNA insert of selected phage clones were sequenced, and then translated into corresponding peptide sequences electronically. Of these, the most frequently occurred peptide was named as AP-1 peptide and chosen for further study.

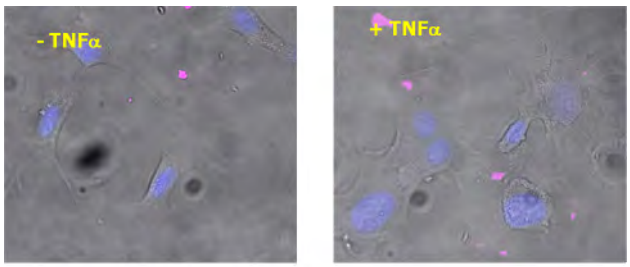
Hydrophobically modified glycolchitosan (HGC, 180 mg, 3.6 μmol) was dissolved in 6 ml of anhydrous DMSO (dimethyl sulfoxide), and then SMCC [N-succinimidyl-4-(maleimidomethyl) cyclo-hexanecarboxylate, 18.05 mg, 54 μmol] was added. The reaction was allowed at room temperature for 12 hours. The solution was dialyzed against distilled water using dialysis membrane (MWCO 12,000~14,000, Spectrum®) for 1 day, and lyophilized to obtain product 1 (HGC-MCC) (144 mg, yield=79.6%). MCC-HGC (50 mg, 0.99 μmol) and Cy 5.5 (2.25 mg, 1.99 μmol) were dissolved in 4 ml DMSO and reacted for 12 hours. The mixture solution was then dialyzed (MWCO 12,000~14,000, Spectrum®) for 1 day, and freeze-dried. The yield of productt was nearly 100%. MCC-HGC-Cy5.5 conjugate (40 mg, 0.78 μmol) was dispersed in the mixture of 10 mM PBS (pH 6.7)/DMSO (10 ml, 9:1) and AP-1 peptide (25 mg, 21.5 μmol) was added. The mixture solution was stirred at room temperature for 1 day, and then dialyzed against distilled water and further freeze-dried.

C. Particle binding on BAECs: Fluorescence microscopy study

1 mg of nanoparticles was dissolved in 1 ml of distilled water and sonicated three times using a probe type sonifier (Sigma Ultrasonic Processor, GEX-600). Different concentrations of nanoparticles (25, 50, 100 μg/ml) were prepared.

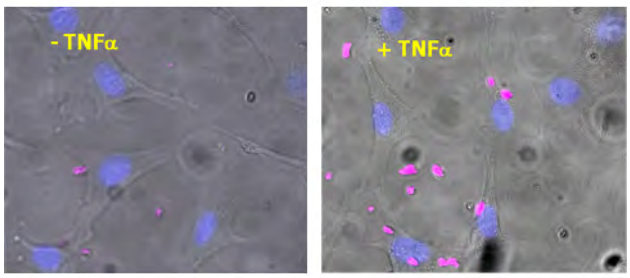
For static flow experiment, the medium in the 8-wells was replaced with suspensions of nanoparticles and incubated for a given time (30 min, 1hr and 2hrs). At the end of the incubation period, the nanoparticle suspension was removed from wells and cells were rinsed three times with DPBS. 2 mL of FA/GA solution (4 and 0.05 %, v/v, in DPBS) was added and incubated for 10 min at room temperature. After twice washing with DPBS, 2 mL 4',6-diamidino-2-phenylindole, dilactate (DAPI) solution in PBS (pH 7.4, 3 μM) was applied to each well and cells were incubated for 5 minutes. After washing with DPBS, gel mount aqueous mounting medium (G0918) was added. The wells were covered with coverglasses and fixed with manicure for fluorescent microscopic observation.

For convective flow experiment, in a μslide I® channel was inserted into a flow circulation loop which consisted of a collecting reservoir, an infusion pump and a silicone tubing system. The flow loop was perfused with growth medium containing nanoparticles. To maintain the temperature of the perfusate passing through the channel at 37 ^{o}C, the reservoir was warmed up by water bath. The wall shear stress was adjusted to 5 dyne/cm^2 so as to simulate the blood flow in the arterial flow by controlling the flow rate. After two hours of flow circulation, the μslide I® channel was detached from the flow loop. Cells were washed with DPBS and fixed with FA/GA solution as previously described.



Fluorescence microscopic observation was carried out by Axioskop 2 FS plus microscope (Carl Zeiss, Thornwood, NY). All images were obtained by using 40 × water immersion objective lens (Achroplan, IR 40×/0.8W lens). Bright field (BF) images were captured by using phase-contrast filter with 100 ms exposure time. Exposure times for DAPI and Cy5.5 were 1 s and 100 ms, respectively. Acquired images were colored and exported as a Tiff format by aid of AxioVision software (Carl Zeiss). Without further modification, image montages were prepared by NIH Image J software (ver. 1.36).

III. Results



Nanoparticles (HGC and HGC-AP) were reacted with the activated and unactivated endothelial cells for different concentrations in static condition. The binding of HGC-AP to the BAECs was dependent on cytokine activation and the concentration of nanoparticles in the medium. Fig. 1 showed the fluorescence intensities of the activated BAECs and inactivated BAECs for different the particle concentration (50, 100 μg/ml). For lower concentration (25 and 50 μg/ml) of HGC-AP, particles bound to both activated and unactivated cells. As the particle concentration increased, HGC-APs bound more avidly to the activated BAECs. The result implied that AP-1 peptide might slightly bind to the endothelium whether it was activated or not, but HGC-APs bound more avidly to the activated endothelium at high concentration. Static incubation time (1 hr and 2 hr) did not affect nanopaticle binding, which implied that nanoparticle binding and uptake might occur within an hour.

In order to study the effects of convective fluid flow on particle bindings on the cells, a μslide I® channel was placed in a flow circulation loop for two hours. Binding of nanoparticles to the endothelial cells occurred in the similar fluid flow environment as in the arterial blood circulation. Activated and unactivated BAECs experienced fluid flow in the medium which contained HGCs and HGC-APs (100

μg/ml). Fluorescence microscopy observation showed negligible binding of HGCs to both the activated and unactivated cells as in the case of static flow. HGC-APs bound to the activated endothelial cells while no significant bindings were observed in the unactivated cells (Fig. 2). Selective binding of HGC-APs to the activated endothelial cells was more prominent.

(a) 50 μg/ml

(b) 100 μg/ml

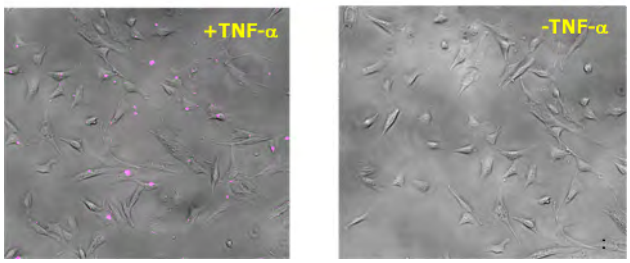

Fig.2 Fluorescent image of binding particles (red dots) in flow condition

IV. Concluions

We conjugated chitosan nanoparticles with atherosclerotic plaque binding peptides and studied their binding characteristics on the endothelial cells in vitro. The peptide-tagged nanoparticles were more avidly bound to the activated endothelial cells comparing to the unactivated endothelial cells at high particle concentration. Selective binding of peptide tagged nanoparticles was more prominent in fluid flow environment. Since peptide tagged nanoparticles showed selective binding characteristics at high concentration, they could be further developed for the target specific imaging probes and drug delivery carriers.

Abstract — **Malaria is a deadly human disease that infects more than 500 million people each year. When the human red blood cell (RBC) is infected by a malaria parasite called Plasmodium *falciparum*, it loses its deformability and is unable to squeeze through small capillaries to transport oxygen to the various parts of the human body. Among the various techniques that have been used to quantitatively study the mechanical properties of malaria infected RBCs, micropipette aspiration has its advantage in exerting a wide range of suction pressure on specific locations of the cell membrane. Hemispherical cap model and homogenous half-space model were also developed to calculate the elastic modulus of the aspirated cell. Here, a detailed multi-component model is developed to model the complex infected cell and to study the membrane shear elastic modulus of the infected RBCs, especially during their mid to late stages of infection and when the parasite occupies a non-negligible volume of the host cell. The results show that the membrane shear modulus of a late stage infected cell calculated by the commonly used hemispherical cap model may not be accurate due to its ignorance of the internal structural changes of the host cell.**

Keywords — **Cell mechanics, malaria infected red blood cells, micropipette aspiration, finite element method, hyperelasticity.**

I. Introduction

Malaria is a severe human disease that infects 300-500 million people and results in 1.5-2.7 million deaths each year[1]. Among the four different species of the malaria parasite that infect humans, Plasmodium *falciparum* is the most deadly[2]. The highly deformable healthy red blood cell (RBCs) are able to squeeze through extremely small capillaries to transport oxygen from the lung to various organs and to remove the carbon dioxide back to the lung. However, when the Plasmodium f*alciparum* parasite invades into the RBC, it multiplies and modifies the host cell. Parasitic proteins are also known to be exported to and induce the stiffening of the host cell membrane. As a result, the RBC loses its deformability and results in capillary blockage, which is detrimental to health.

Various techniques have been used to measure the mechanical properties of malaria infected RBCs, such as micropipette aspiration[3-5], optical tweezers[6], laminar shear flow system[2,7] and microfluidic systems[8]. Among them, micropipette aspiration has its advantage of exerting a wide range of suction pressure to induce specific localized deformation on a cell membrane instead of the whole cell. Hemispherical cap model[9] and homogenous half-space model[10] have also been developed to evaluate the elastic modulus of a whole cell undergoing micropipette aspiration by assuming the cell as a homogenous entity despite the fact that a cell is heterogeneous and can comprise various components inside the cell.

Here, we seek to develop a multi-component model for the micropipette aspiration of malaria infected RBCs by accounting for the parasite within the infected RBC. Finite element method is used to model and evaluate the change in the mechanical properties of the infected cell. Results obtained will be compared with that obtained using the hemispherical cap model and homogenous half-space model. Since the severe structural changes only occur during the mid to late stages of parasite invasion, we will focus on these two stages here.

II. Methodology and Results

A. Finite Element Model

After parasite invasion, structural changes occur in the host cell[11]. The changes are not obvious in the early

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1788–1791, 2009
www.springerlink.com

stage, which is called ring stage. But 10-20 hours after invasion, which is called the trophozoite stage, the parasite grows and occupies almost 40% of the host cell. In the last stage, which is called the schizont stage, the parasite multiplies into 16-32 merozoites. Due to these severe structural changes during the mid to late stages of infection, the compound Newtonian liquid drop model was adopted[12,13]. Based on the fact that the parasite is stiffer than the cytoplasm, this model has three layers. The outer layer is the host cell membrane. The middle layer is the fluid-like cytosol. The core layer is the enclosed parasite.

The cell membrane was modeled using a hyperelastic material[14], expressed in the form of strain energy potential,

$$U = \frac{G_0}{2}(\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) + C_3(\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3)^3 \quad (1)$$

where G_0 is initial shear modulus, and λ_i (i = 1,2,3) are the principal stretches. It is assumed that the membrane material is incompressible, which means $\lambda_1\lambda_2\lambda_3 = 1$.

The initial shear modulus of the membrane μ_0 is given by[15]

$$\mu_0 = 0.75 G_0 h_0 \quad (2)$$

where h_0 is the initial membrane thickness.

B. Hemispherical Cap Model & Homogeneous Half-space Model

The hemispherical model assumes the cell membrane to be 2-dimensional and incompressible. The Newtonian fluid in the cell does not affect the shear deformation of the membrane. The contact between the cell and pipette is frictionless. The deformation can be approximated by[9],

$$\Delta P = \frac{2.45\mu}{R_p^2} L_p + C, \quad \left(\frac{L_p}{R_p} \geq 1\right) \quad (3)$$

where ΔP is the increase in suction pressure, R_p is the radius of the micropipette, L_p is the protrusion length, and μ is the shear elastic modulus.

The homogeneous half-space model was based on a homogenous viscoelastic plate[10]. It provides a linear solution, which is suitable for small deformation,

$$L_p^{\Delta} = \frac{L_p}{R_p} = \frac{3\Phi_p}{2\pi}\frac{\Delta P}{E} = \frac{\Phi_p}{2\pi}\frac{\Delta P}{G} = 0.3342\frac{\Delta P}{G} \quad (4)$$

where Φp is a pipette geometric factor and E = 3G is the Young's modulus. Φp can be taken as 2.1 approximately for the punch model.

C. Results & Discussion

Each cell was modeled individually according to their different radius of host cell, parasite and inner/outer pipette. Finite element method was used to simulate the progress of the infected cells in micropipette aspiration.

Fig. 1 shows the experimental results as well as computational modeling of a trophozoite stage malaria infected RBC being aspirated into the pipette at different suction pressure using a finite element program ABAQUS. The rigidity of the parasite was assumed to be far larger than the host cell membrane.

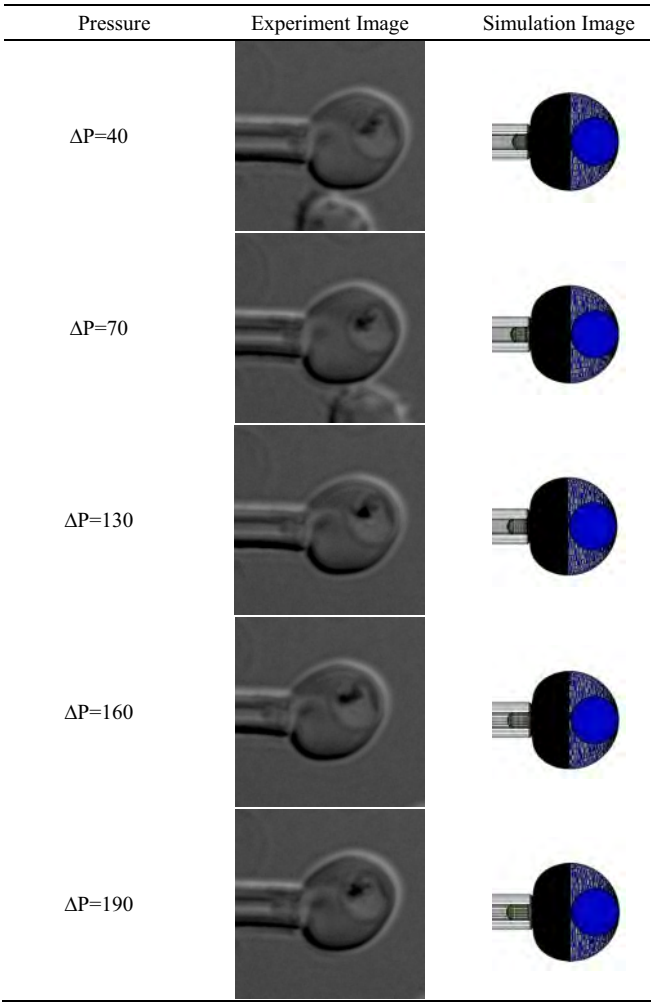

Fig. 1 Comparison between experimental and simulation results of the micropipette aspiration of a specific trophozoite stage malaria infected RBC

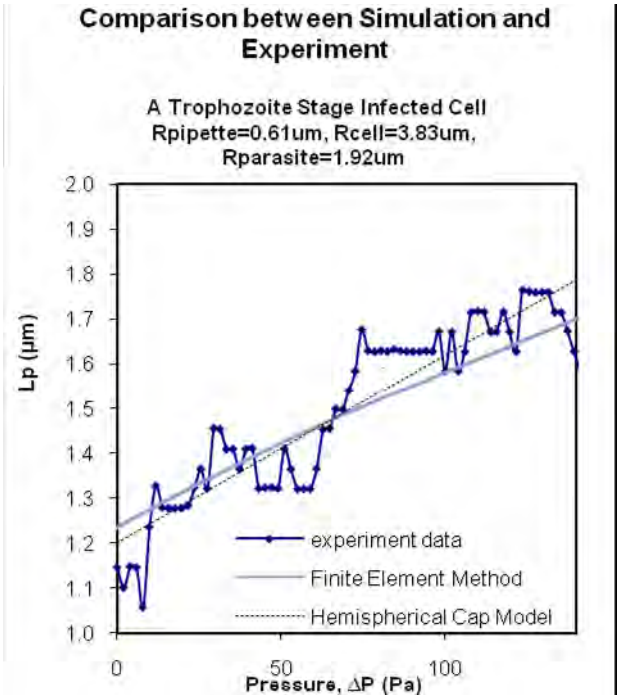

Fig. 2 Comparison between experiment and simulation data of a specific trophozoite stage malaria infected RBC

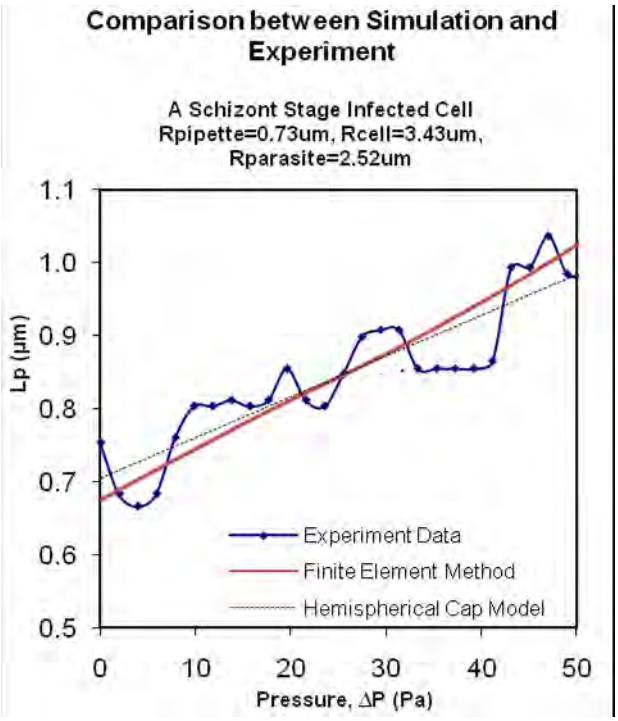

Fig. 3 Comparison between experiment and simulation data of a specific schizont stage malaria infected RBC

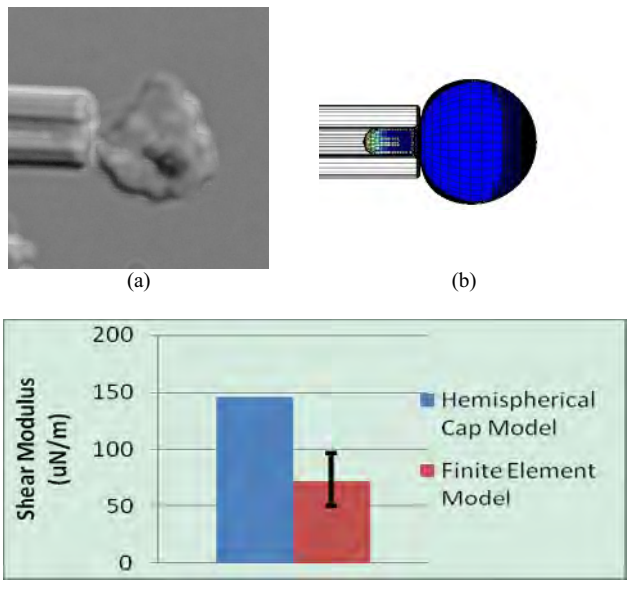

Figures 2 & 3 showed comparisons between simulation and experimental data for two specific cells, in their trophozoite and schizont stage, respectively. The dashed line was the linear trend line of the experimental data. The gradient of the trend line was used for the calculation using the hemispherical cap model. The solid line represents the deformation curve obtained from the finite element method, with the same initial shear modulus calculated using hemispherical cap model. The simulation curves overlap the experimental data.

For all the trophozoite stage cells and most of the schizont stage cells tested, the membrane shear modulus calculated by using the hemispherical model falls in the range of those obtained from finite element simulation, as shown in Table 1.

However, for those schizont stage cells that enclose large parasites, the hemispherical model gives much higher values of shear modulus than that of simulation. An example is shown in Fig. 4. The large parasite itself might

Table 1 Shear modulus of the cell membrane

Cell Stage	Hemispherical Cap Model	Finite Element Method
Trophozoite	28.26 ± 4.74 μN/m	33.96 ± 11.74 μN/m
Schizont	89.19 ± 47.16 μN/m	46.09 ± 12.97 μN/m

(a) (b)

(c)

Fig. 4 A schizont stage malaria infected RBC with enclosed large parasite being sucked into a pipette, (a) in experiment, (b) in finite element simulation, (c) shear modulus calculated from hemispherical cap model and finite element model for this particular cell.

inhibit the host cell from being sucked into the pipette, while the hemispherical cap model attributes the deformation to only the cell membrane. This might lead to a larger shear modulus as obtained using the hemispherical cap model. In this case, homogeneous half-space model was used, and the elastic shear modulus of this schizont stage cell is found to be 162.16 Pa.

III. Conclusions

To summarize, a computational model of the micropipette aspiration of malaria infected RBCs was developed using the finite element program ABAQUS. The proposed multi-component model was able to interpret the deformation-pressure relationship obtained from experiments to the shear modulus of the host cell membrane. This model replicates well with the commonly used hemispherical cap model for mid stage malaria infected RBCs, but predicts different shear modulus for some of the late stage infected RBC, due to the inclusion of the severe internal structural changes occurring during this stage.

Abstract — **Micro- and Nanoindentation technique has become a standard method for material testing of mechanical properties recently. Especially, indentation method with Oliver and Pharr theory for an analysis of isotropic elastic materials is very strait forward and become a part of every indenter's software. Some multidirectional indentation analyses have been successfully applied on bone tissues such as cortical osteons and trabecular lamellae to identify their local elastic orthotropic or transverse isotropic properties. Present nanoindenters make possible an acquisition of creep and relaxation data, for that a model of creep or relaxation function can be found in the literature and the viscoelastic material parameters are derived.**

Our previous structural and mechanical studies of porcine intervertebral disc (IVD) and its parts showed clear viscoelastic behavior of tissue. Annulus fibrosus (AF) responses on cyclic, relaxation and ultimate tensile tests proved its viscoelastic manner. Annulus fibrosus is hierarchical structure made up with bundles of collagen fibers within the lamellae. We developed the mathematic geometrical model of IVD, where we respect such a lamellar structure with one lamella as a representative volume element (RVE). Our RVE is supposed to be locally orthotropic with main material directions along the collagen fiber orientation. We try to feed this model on material constants of RVE obtained by nanoindentation and show the nanoindentation technique's state of art in a material description of hierarchical tissues.

Keywords — **Nanoindentation, Intervertebral Disc, Curvilinear coordinates, Viscoelastic tissue**

I. Introduction

Hierarchical organized connective tissue needs to be study in micro- or nanolevels of material to understand their responses to mechanical loading. Scientists look for representative volume element (RVE) of very small sizes and determine the macroscopic material properties of a tissue from it. The single lamella made up by oriented collagen fibrils is mostly considered to be the fundamental structure. Anatomically, IVD consists of end plates (EP), nucleus pulposus (NP) and annulus fibrosus (AF). Structural studies of AF show the alternate light and dark lamellae in the transversal and sagittal cuts. That is caused by the differences of reflected light from the surface of angle-ply lamellar structure with angle of collagen fibers ~120° [1, 2]. Next to the certain type of collagen, which varies in different parts of AF [2, 3], the important structural compound is elastin. Elastin fibers create the elastic sheaths between the collagen lamellae; moreover elastin forms the crossbridges through the lamella [3]. Two compounds composite or laminate is one of the modeling approaches in the literature. Collagen fiber and the matrix possess different elastic properties [4]. Even the analytical model of AF is presented [5] with properties of crossed collagen fibers allowing to move or firmly bounded to each other. Finite element modeling uses the approach of poroelastic continuum to get closer to the reality. The interstitial fluid flows through the AF. The avascular AF tissue needs to be supplied by solutes. It's being realized by two-dimensional flow in EP-AF and NP-AF direction [6, 7]. Decline in EP permeability has a strong influence on IVD dysfunction and its degeneration.

Experiments done on the IVD usually show the viscoelastic behavior. Voigt's model has been used even for frequency dynamic loading for IVD material interpretation [8]. There is evidence of viscoelastic properties of AF e.g. in Young's modulus or absorbed deformation energy dependence on load rate [9, 10, 11]. AF showed the ability to relax during cyclic loading as well in our previous studies [10]. We have created the geometric mathematical model of IVD, which respects the lamellar hierarchical structure of annulus fibrosus. Material parameters were supplied using nanoindentation technique.

II. Methods

A. Samples

We used porcine lumbar AF strips for luminescent microscopy studies (Fig. 1, Fig. 2) and nanoindentation. Transversal wedge-shaped cuts according to [12] and sagittal cuts of lumbar motion segments were done. Thus the specimens contain all the structures employed in intervertebral articulation: vertebral body with apophysis part, cartilaginous end plate, annulus fibrosus and nucleus pulposus. The cuts were 2 up to 4 mm thick and glued on laboratory glass with UHU glue. Surface of samples were polished under the wet condi-

tions. It was necessary because of rough surface of cartilaginous EP improper for nanoindentation. Annulus fibrosus lamellae were not visually affected by this procedure. AF lamellae were distinguishable under optical set up of Hysitron TriboLab™ and sufficient wide to place the indent from the optic view to the single lamella.

B. Geometrical and Mathematical Model of IVD

Elastic lamella can be described by classical Hook's law. We supposed the elastic membrane to be isotropic (Fig. 5); however according to Yu et. al [3] elastin fibers in the membrane are oriented in parallel with collagen fibers within viscoelastic collagen lamella. Therefore the models of both elastic and viscoelastic lamellae turn to locally orthotropic case and according to curvilinear coordinates (Fig. 6) the Hook's law is written:

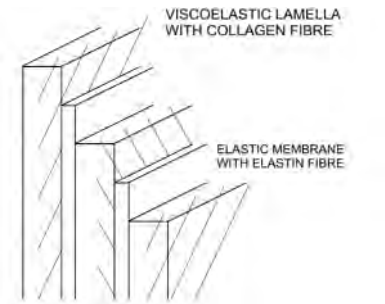

Fig. 5 Sketch of our modeling approach to alternating elastin and collagen lamellae of annulus fibrosus with respect to the literature [1, 3]. One lamella is our geometric representative volume element (RVE) with certain material properties.

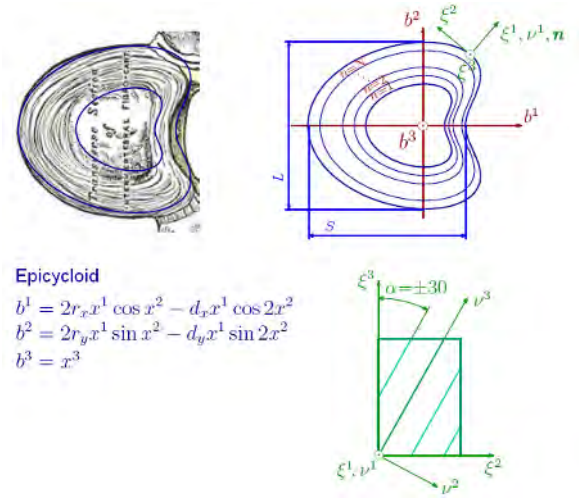

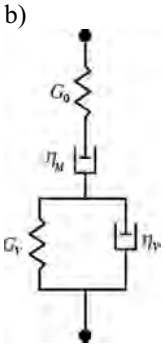

Fig. 6 Annulus fibrosus structure can be mathematically described from the coordinates of local orthotropy ν, local Cartesian coordinate system ξ and global Cartesian coordinate system b, which is transformed to the curvilinear description of IVD shape using parametrical description of epicycloid.

$$\overset{\nu}{\sigma}^{ij} = \overset{\nu}{E}^{ijkl}\,\overset{\nu}{\varepsilon}_{kl} \tag{1}$$

Viscoelastic lamella's material properties are interpreted by common linear dashpot – spring models (Fig. 7). Due to oriented collage fibers there are the plane symmetries in the material. The anisotropic behavior of AF lamella with a value of in-plane Poisson's ratio has been already published [13]. Therefore the 1D (4) viscoelastic properties are expressed by 3D (5) constitutive equations in the tensorial forms:

b)

$$G_0\eta_V\dddot{\gamma} + G_V G_0\ddot{\gamma} = \eta_V\ddot{\tau} + \left(G_V + G_0 + \frac{\eta_V G_0}{\eta_M}\right)\dot{\tau} + \frac{G_0 G_V}{\eta_M}\tau \tag{2}$$

$$C^{ijkl}\ddot{\varepsilon}_{kl} + D^{ijkl}\dot{\varepsilon}_{kl} = \ddot{\sigma}^{ij} + A^{ij}{}_{kl}\dot{\sigma}^{kl} + B^{ij}{}_{kl}\sigma^{kl} \tag{3}$$

Fig. 7 a) Four parameter b) five parameters linear viscoelastic models when ν_0 is taken into account. *A,B,C,D* tensors of constants.

C. Nanoindentation of Viscoelastic Material

It is supposed in this study that the material behavior is dominated by the viscoelastic effects. Several formulations can be employed for this case. We adopted two assumptions: (i) material is linearly viscoelastic and (ii) viscous deformation (creep) is associated only with deviatoric deformations. For such assumptions, analytical solutions of the problem can be derived as was elaborated e.g. by Vandamme & Ulm [14]. Viscoelastic parameters can be obtained directly from the history of indenter displacement measured during the dwell period at which the load is kept constant. The best results are obtained with a 5-parameter combined Kelvin-Voigt-Maxwell creep model (Fig. 7a). The model utilizes the functional formulation:

$$e_{ij} = \int_0^t C^d(t-\tau)\dot{s}_{ij}(\tau)d\tau \tag{4}$$

where t = time; e_{ij} = deviatoric strain tensor; s_{ij} = deviatoric stress tensor; the overdot denotes differentiation with respect to time; and

$$C^d(t) = \frac{1}{G_0} + \frac{1}{G_V}\left(1 - e^{\frac{-G_V}{\eta_V}t}\right) + \frac{t}{\eta_M} \tag{5}$$

is the shear creep function with material parameters G_0, G_V, η_V, η_M. The volumetric behavior was considered as purely elastic. Young's modulus E_0 and associated shear modulus G_0 were estimated from the unloading branch of the load-displacement plot by the standard Oliver & Pharr method [15]. Poisson's ratio ν_0 was supposed to be time independent for the given material.

III. Results

A. Nanoindentation

Trapezoidal loading-dwell-unloading nanoindentation curve was set for load control mode of testing. Maximal load P_{max}= 4000μN was applied in 10s and hold for 30s during the dwell period. Unloading segment for evaluation of elastic modulus and shear modulus G_0 respectively took 10s and Poisson's ratio was ν_0=0.4 in case of endplate. The same time segments were used for nanoindentation of AF lamella; however the force value was P_{max}= 10μN only. Indentation of viscoelastic lamella was comprehended as 1D problem with in-plane anisotropic Poisson's ratio ν_0=2. The value of ν_0 was chosen from parametric study of the best fit of creep data (Fig. 9). In-plane Poisson's ratio has no bounded value in anisotropic case of material. Material parameters calculated from the data fit (Fig. 1) are presented in the table (Tab. 1).

2	-0.0176	$4.24.10^6$	0.3761	0.0277

B. Model

Our computational model uses the theory of small deformation and nucleus pulposus as highly pliant elastic isotropic material.

$$E^{abcd}_{pulposus} = \lambda g^{ab} g^{cd} + \mu g^{ac} g^{bd} + \mu g^{ad} g^{bc} \tag{6}$$

where λ, μ are Lame's constants and g^{ab} is the contravariant metric tensor in computational curvilinear coordinate system, x. The principle of total potential energy minimum was used in calculation [16]. The tiny geometry of endplates had no significant contribution to total potential energy; therefore they have been removed. In our model of intervertebral disc consists of lamellar annulus fibrosus and nucleus pulposus, the deformation is prescribed as a rigid movement of the rigid plates, which represents the vertebral bodies. The deformations of IVD were calculated in GNU Octave using the above principles (Fig. 10, Fig. 11, Fig. 12).

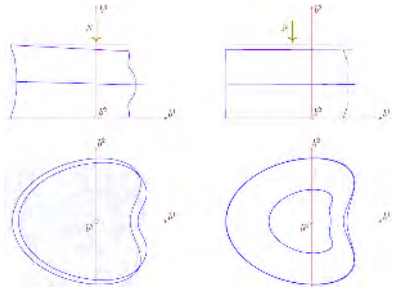

Fig. 10 Model deformation from axial and nonaxial pressure load. Buckling is always present in posterior region, which indicates the weak part of IVD.

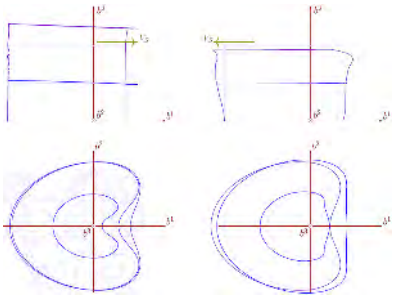

Fig. 11 Sagittal shear load applied over the top plate of IVD shows again the major deformation in posterior part of IVD.

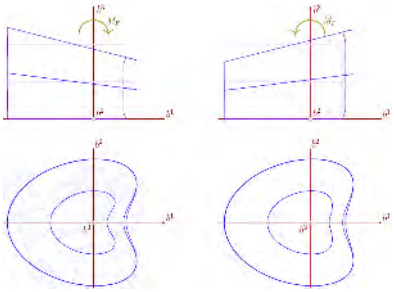

Fig. 12 Bending in frontal plane caused deformation only in posterior part. Anterior profile of IVD remained strait; only mass shift occurred.

IV. Discussion and Conclusions

Annulus fibrosus is very soft and sticky material; therefore it's tricky to find an initial contact and loading curve is affected by adhesion forces. Swelling of AF lamellae immediately after cutting caused the rough surface. Swelling also occurs even when the samples are placed in the water or during the testing in the physiological condition. In the contrary the surface of cartilaginous endplate can be prepared nicely and perform the nanoindentation testing without any problem. Viscoelastic model derived by Vandamme and Ulm [14] fits well measured data. However; there's still missing a solution for analyzing the viscoelastic anisotropic material, which AF lamella is the case. Multidirectional indentation test for one lamella seems to be feasible. Moreover the orientation of collagen fibers within the sample can be estimated, which gives us the main material directions.

Mathematical models can work with spatial material properties easily. They need to be fed with material constants in tensorial interpretation. Of course the resulting deformations (Fig. 10-12) are not physiological due to missing ligaments (posterior and anterior longitudinal ligament), muscles and the effect of spine column. However our geometrical and mathematical model demonstrates the usage of chosen RVE. This approach brings us fast to the first results and show the posterior part of IVD as the weakest region of IVD, which corresponds to the literature. IVD model was considered to be uncompressible, which explains the mass shift over the IVD with bulging only in posterior part.

Effects of Floor Material Change on Gait Stability

B.-S. Yang[1,2] and H.-Y. Hu[1]

[1] Department of Mechanical Engineering, National Chiao Tung University, Hsinchu, Taiwan
[2] Brain Research Center, National Chiao Tung University, Hsinchu, Taiwan

Abstract — **Falls are the leading cause of unintentional injuries in the elderly in Taiwan and many industrial countries, and commonly occur at home. To reduced fall-related socio-economic cost, the goal of this study is to identify suitable floor materials on which the elderly could have stable gait. We tried to quantify the gait stability under different floor conditions in this paper. Six healthy subjects (aged 20-23 yrs) have been tested. A six-camera motion capture system and two force platforms were used to obtain kinematics and kinetics of whole body during gait on different floor conditions. In consistent conditions (same floor materials on the whole walkway), the lower the coefficient of friction (COF) of the floor material, the smaller values of cadence and required COF (RCOF) under subjects' feet, and the larger values of gait stability-related variables, such as stance time, stride time, and step width, during walking at self-selected comfortable speed ($p<0.05$). As compared with the consistent conditions, walking from a material with higher COF to another with lower COF would induce larger ankle dorsi/plantar-flexion angle at heel contact. In addition, the peak RCOF during the stance phase was higher after the floor material change. The results of this study suggest that double support time, stride velocity, and mean gait velocity might be good indicators of gait stability. Walking from one floor material to another with lower COF may induce higher risk of falls than walking on a floor with consistent materials. Therefore, avoiding or using caution, especially for the elderly, when walking from one floor material to another with lower-COF is suggested.**

I. Introduction

Falls are the leading cause of unintentional injuries in the elderly in Taiwan and many industrial countries and commonly occur at home [1]. To reduced fall-related socioeconomic cost, the goal of this study is to identify suitable floor materials on which the elderly could have stable gait, i.e. less likely to fall. We will quantify biomechanical gait variables of young subjects and compare their movement and balance during walking on different floor materials. We especially focus on the condition of the gait transition from one floor material to another.

II. Materials and Methods

A. Subjects

Six healthy young adults were recruited (mean 21.3 years, 1.71m, 63.54Kg) from the general student population at National Chiao Tung University. All subjects have no history of neurological or orthopedic diseases and any difficulties that could obstruct normal locomotion. A written informed consent was obtained from every subject.

B. Experimental design

Four commonly-used floor materials in Taiwan – plane-wood (PW), rough-wood (RW), rough-ceramic tile (RC), and polyvinyl chloride (PVC) – were employed for examining gait stability. English XL (William English, Inc., Alva, Florida, USA) was used with rubber test fragment to measure the coefficient of friction (COF) of the floor materials. To study the change of gait stability while walking from one floor material to another, we used different combinations of the above-described floor materials to created *consistent* conditions (same floor materials on the whole walkway) and *transition* conditions (from one material to another) of walkway. In the consistent condition subjects walked on dry plane-wood, dry rough-ceramic tile, or wet rough-ceramic tile. In the transition condition, subjects walked from dry plane-wood to PVC, from dry rough-wood to PVC, or from dry rough-ceramic to PVC. The consistent condition was treated as a baseline condition for comparing the change of gait stability after transition.

Two force platforms (Bertect corporation, Columbus, Ohio, USA) were placed underneath the middle of the walkway (right after the interface of two floor materials in the transition conditions). A six-camera motion capture system (BTS Bioengineering, Garbagnate Milaness, Italy) and the force platforms were used to obtain kinematics and kinetics of whole body during gait on different floor conditions (Fig. 1). Twenty-two 15mm-diameter markers were placed on the bony landmarks of subjects. The positions of markers were based on the Helen-Hayes marker set [2] with seven additional markers. The seven additional marker positions were both sides of shoulders, femoral great trochanter, external condyle of tibia and the 7th cervical verte-

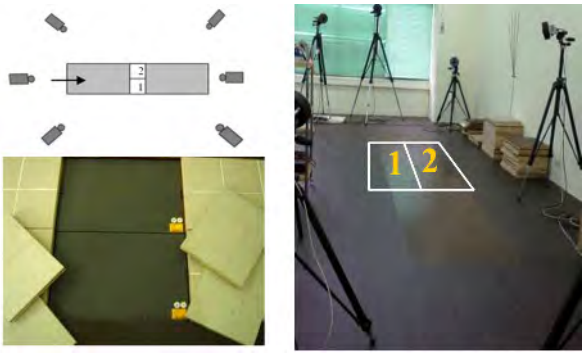

Fig. 1 Experimental set-up for examining gait stability experiment. Left top: sketch of camera positions and walkway. Left bottom: force plates and changeable floor materials. Subjects start walking from the window-side (right).

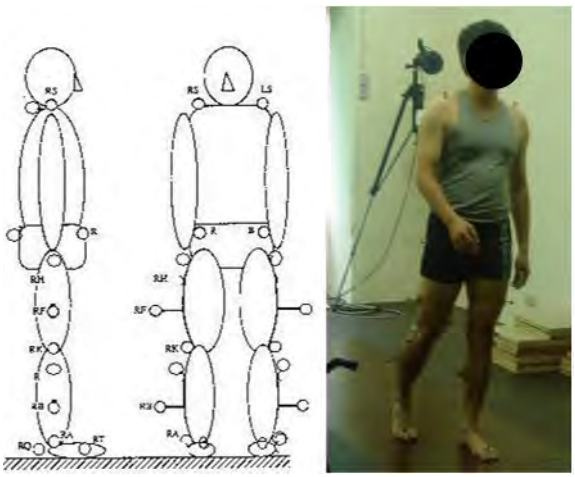

Fig. 2 Diagram of marker set (left) and the actual condition (right)

bral bone (Fig. 2). The motion capture system and force platforms were synchronized and sampled at 250Hz and 1000Hz, respectively.

During the experiment, subjects were asked to walk on a 6-m long and 0.8-m wide walkway with barefoot; the floor materials over the walkway was changeable (Fig. 1). Prior to the experiment, subjects practiced on the walkway to identify their preferred walking speed. The preferred cadence (step/min) was then determined for each subject, and audio cues were used to keep the subject walking at the same preferred cadence throughout the experiment and subjects were asked to also keep the step length the same as at the preferred walking speed. To ensure that subjects achieved steady state of walking when stepping on the force platforms, the starting line was set at least 3.0m away from the force platforms on the walkway.

The test order of the floor conditions were randomized. Twenty trials were tested under each condition. Trials with missing or incomplete data were excluded from data analyses. The primary variables investigated here include foot angle at heel strike, peak required coefficient of friction (RCOF), and mean (gait) velocity. T-tests were used to compare the means in different test conditions. $P<0.05$ was considered statistically significant unless otherwise stated.

III. Results

A. Coefficient of friction

The coefficients of friction (COF) of the tested floor materials are shown in Fig. 3. All COFs were above 0.7 when the surface was dry and clean. However, in water-spilled (wet) condition, only COFs of rough-wood and plane-ceramic tile were larger than 0.6. The COF of wet rough-ceramic tile was only 0.29.

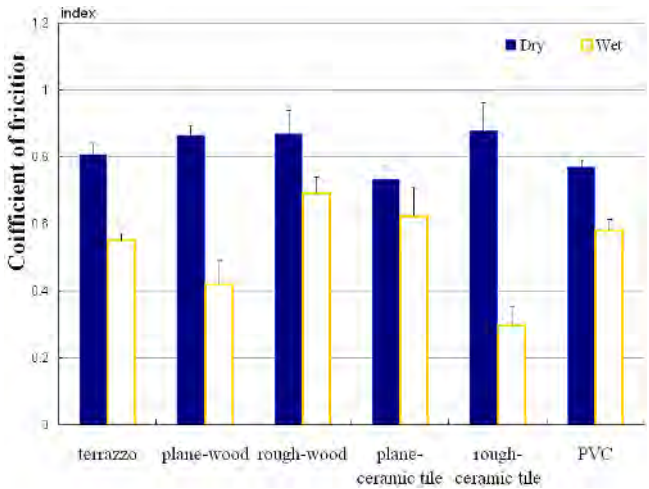

Fig. 3 Coefficient of friction of the tested floor materials

B. Gait stability

Table 1 shows the changes of some investigated variables in the consistent conditions. The results showed that floor materials had significant effects on most investigated gait variables: stance phase, double support time, and stride time were longer, but the values of cadence, step length, stride velocity, and mean velocity were smaller on a lower-COF (wet) floor than on a higher-COF (dry) floor ($p<0.05$).

Compared with walking under the consistent condition of plane-wood floor, the foot angle at heel strike decreased when walking from a higher-COF floor material to a lower-COF floor: 31.5% decrease in foot angle while walking

Table 1 Time-distance variables of consistent condition (paired t tests comparing RC with water-spilled RC condition: *: p < 0.05; **: p < 0. 01)

Materials (COF)	RC (0.87)	Water-spilled RC (0.29)
Stance Phase* (%)	61.5	62.1
Swing Phase* (%)	38.2	37.5
Double Support** (%)	11.6	12.2
Stance Phase** (s)	0.75	0.77
Swing Phase (s)	0.47	0.46
Stride Time** (s)	1.22	1.23
Cadence* (step/min)	98.3	97.3
Step Length* (m)	0.56	0.54
Stride Length (m)	1.21	1.18
Step Width (m)	0.172	0.172
StrideVelocity*** (m/s)	0.991	0.954
Swing Velocity (m/s)	2.279	2.227
Mean Velocity** (m/s)	0.965	0.931

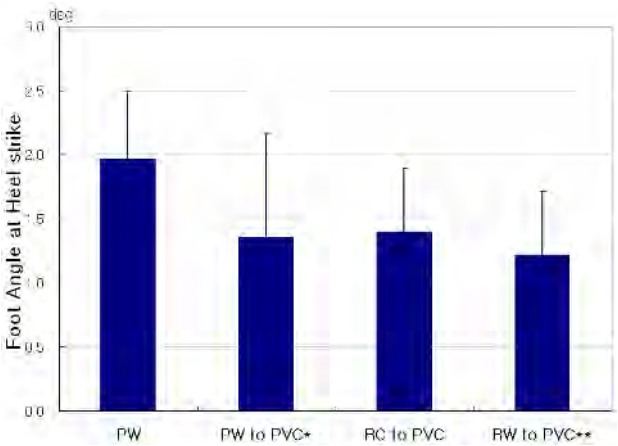

Fig. 4 Foot angle at heel strike in the transition conditions (paired t tests comparing PW with transition condition: *: p < 0.05, **: p < 001)

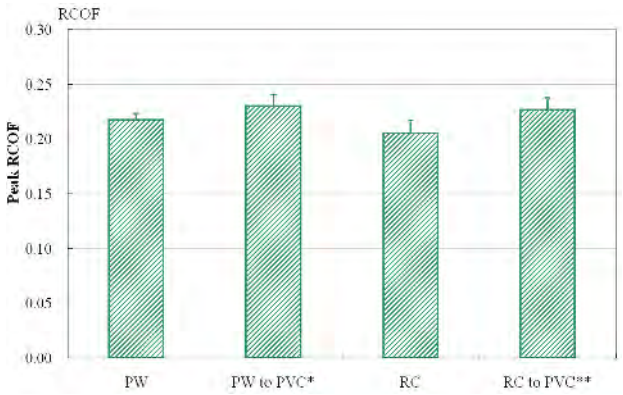

Fig. 5 Peak RCOF in different floor conditions (paired t tests comparing PW with transition condition: *: p<0.05; **: p<0. 01)

from plane-wood to PVC (p<0.05); 28.9% decrease from rough-ceramic to PVC; 38.1% decrease from rough-wood to PVC (p<0.01) (Fig. 4). Peak required COF (RCOF) values were greater in the transition condition than in the consistent condition: 5.8% increase in the peak RCOF when walking from plane-wood to PVC (p<0.05); 10.4% increase from rough-ceramic tile to PVC (p<0.01). (Fig.5).

IV. Discussion

In the consistent conditions, the double support phase was longer, and the stride velocity and mean velocity were smaller while walking on a wet floor as compared to those on a dry floor. These results are consistent with the findings from previous studies [3, 4]. The three investigated variables which show the most significant effects of floor conditions – double support time, stride velocity, and mean velocity – might be good indicators for gait stability.

Several studies have reported that individuals would adjust gait to reduce RCOF in order to lower the risk of falls on slippery (low-COF) floor [5, 6]. In this study we further show that walking from one material to another with lower COF could cause larger peak RCOF than walking on a floor without material change, which might lead to higher risk of falls. Furthermore, older adults usually have longer reaction time and less accurate sensory feedback, which increase the likelihood of slips and falls [7]. Therefore, avoiding or using caution when walking from one floor material to another, especially one with lower-COF, is suggested. The change of floor materials should be avoided for the living environment of the elderly.

V. Conclusions

The results of this study indicate that double support time, stride velocity, and mean gait velocity might be good indicators of gait stability. Walking from one floor material to another with lower COF may induce higher risk of falls than walking on a floor with consistent materials.

Onto-biology: Inevitability of Five Bases and Twenty Amino-acids

K. Naitoh[1]

[1]Waseda University, Faculty of Science and Engineering, Tokyo, Japan

Abstract — **The inevitability of only five nitrogenous bases, twenty amino acids, and various proteins in living beings is systematically revealed on the basis of physics as the weft and molecular biology as the warp. First, we focus on fact that symmetry and asymmetry coexist in biomolecules. The nitrogenous bases that form nucleic acids have two large purines (A and G) and three small pyrimidines (C, T, and U), for an asymmetric ratio of molecular types of around 2:3, while those forming DNA have a symmetric ratio of 1:1, with two purines of A and G and two pyrimidines of C and T. Size ratios of around 2:3 are seen in base pairs such as A:T and G:C in DNA and also 1:1 in RNA. Chargaff's rule shows that the frequencies of purines and pyrimidines in double-strand DNA are deterministic with a symmetric ratio of 1:1, while the asymmetric frequency ratios of purines and pyrimidines in RNA are between 1:1 and approximately 2:3, which is fairly stochastic. Thermo-fluid dynamics clarifies the reason why a 1:1 deterministic symmetric ratio and a slightly stochastic asymmetric ratio of around 2:3 exist together. This analysis also reveals the further reason why molecules such as the five bases and twenty amino acids are naturally selected in living beings. Finally, it is shown that microorganisms such as yeast also undergo symmetric and asymmetric cell divisions, with size ratios between 1:1 and 2:3, and that human beings also have left-right asymmetric organs such as the liver and the heart and symmetric ones such as the lungs and kidneys. The physical principle is clarified for determining whether organs become asymmetric or not.**

I. Introduction

Anfinsen has shown that thermodynamics can explain the stable structures of proteins. [1] However, the inevitability of the sizes and frequencies of biological monomers and polymers has not been revealed so clearly, although the number of fundamental blocks is limited to only five bases and twenty types of amino acids.

Computer simulations of molecular dynamics and quantum chemistry can not analyze quantitatively the inevitability of biomolecules swimming in lots of water molecules, because computer power is still insufficient.

In this paper, thought experiments based on thermo-fluid dynamics and molecular biology clarify the inevitability of the sizes, the number of types, and the frequencies for the fundamental building blocks such as nitrogenous bases and amino acids, larger molecules such as RNA and proteins, biomolecules which are not coded by DNA, and cells. They are described in the following sections, in ascending order.

II. Elements

We classify the five bases of adenine (A), guanine (G), cytosine (C), thymine (T), and uracil (U) into two groups--purines and pyrimidines. Purines (A and G) have a relatively large size, while pyrimidines (C, T, and U) are small. The asymmetric size ratio of the main rings in purines and pyrimidines of around 3:2 naturally leads to an asymmetric number of types, i.e., "two" types of purines and "three" types of pyrimidines. This is understood from the mass conservation law with respect to molecular weight, that is, from the fact that the main rings of purines have "nine" molecules of carbon and nitrogen, while "six" molecules form the main rings of pyrimidines (Fig. 1).

Some people may feel that there is a trick in this logic. However, phenomena, including living beings, can not escape from the constraint of mass conservation. (There is also a 2:3 ratio in immune globulin (IgX). Two types of large immune globulines (IgM and IgE) and three small ones (IgG, IgD, and IgA) are naturally selected. See Fig.1.)

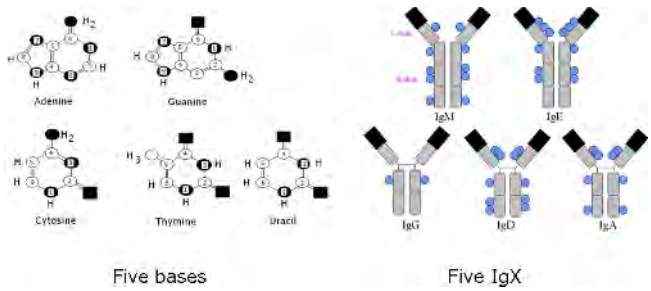

Fig. 1. Similarity between five bases and five immune globulins.

III. Base pairs and nucleic acids

This grouping specifically refers to the asymmetric size ratio of purines and pyrimidines of around 3:2 in their hydrogen bonds within base pairs (in Watson-Crick base pairs), although base pairs with a symmetric size ratio of 1:1 are often observed in RNA.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1801–1804, 2009
www.springerlink.com

In our previous reports based on the cyto-fluid dynamics theory [2], we revealed the reason why base pairs are in a fusion of asymmetry of around 2:3 and symmetry of 1:1. [2, 3] We consider two nitrogenous bases such as a pair consisting of a purine and a pyrimidine, connected by hydrogen bonds in a large quantity of water. We assume that each nitrogenous base and the water molecules around the base act as a flexible continuum spheroid particle (parcel), in which the flow is irrotational. Further, we assume that the spheroid particle size is proportional to the size of each base. Based on these assumptions, we derive a deterministic momentum equation describing particle deformation. When a small disturbance is given for two connected flexible particles, the dimensionless deformation x of each particle dependent on dimensionless time t can be described as

$$d^2x/dt^2=(e-1)(dx/dt)^2+(e^3-3)x+q(t), \quad (1)$$

where parameter e and term $q(t)$ denote the size ratio of the two particles connected at the equilibrium condition and the time-dependent force generated by the other connected particle, respectively. When the particles are spheres at the equilibrium condition, x is zero. A symmetric ratio of 1.0 makes the first term on the right-hand side of the equation zero, while an asymmetric ratio of $\sqrt[3]{3}$ (around 1.5) makes the second term zero. (These two ratios appear as the n-th root of n with n = 1 and n = 3). The deformation speed is smaller for e = 1.0 and $\sqrt[3]{3}$ than for the other values of e. Life is relatively stable (quasi-stable), when the size ratio of hydrogen-bonded nitrogenous bases takes the values of 1.0 and $\sqrt[3]{3}$ for n=1 and 3, respectively. [2, 3, 4]

The present quasi-stability maintains the hydrogen-bonded pairs of two identical bases and of purine-pyrimidine pairs just after the small disturbance affects the pairs. (It is stressed that the flow inside the flexible continuum particle is potential flow, i.e., irrotational flow, because impulsive disturbances generate potential flow at the start of deformation motions. Equation 1 also describes only base pairs without water molecules, because even a base will deform slightly when disturbances enter and because the governing equation for the elasticity theory of solid materials is also identical to that in potential flow.)

Next, let us look at nucleic acids. We examined the databases on RNA. [3, 4] The average frequency ratio of purines and pyrimidines in over five-thousand types of transfer RNA (tRNA) sequences is actually about 1:1.10. The databases on ribosomal RNA (rRNA) show a value of around 1:1.30, which is relatively larger than that for tRNA.

This value of less than 1.50 for the frequency ratio of purines and pyrimidines in RNA stems from the following reason. Because the frequency ratio of purines and pyrimidines in the stem of tRNA is approximately 1.0, RNAs having longer stems bring the mean value closer to 1.0. Ribosomal RNAs show a value of around 1.30, which is larger than that of tRNAs, because rRNA has a shorter stem than tRNA. The variation in the frequency ratio of purines and pyrimidines in RNA is related to the variety of stem lengths and leaf sizes in RNA, i.e., various functions of RNA. [3, 4]

IV. Inevitavility of only five bases

As was shown in the previous section, tRNA has a relatively longer stem than rRNA, because the frequency ratio of purines and pyrimidines is closer to 1.0. Richer G + C conditions for stable hydrogen bond connections in base pairs also stabilize the longer stems of base pairs in tRNA. [5] (This tendency of rich G-C pairs in tRNA is related to the fact that the A-U base pair has only two hydrogen bond connections, whereas the G-C base pair has three.) In fact, databases show that the frequency ratio of G and C in tRNAs is larger than that in rRNAs. [5]

Two types of base pairs (A-U and G-C) are necessary in order to change the stem length. In other words, four types of bases, A, U, G, and C, are necessary for generating two types of RNAs. DNA, with more stable information storage than RNA, needs a fifth base, T.

Next, we consider the possibility of having more than five base types. *Let us recall that modified bases such as inosine and ribosylthymine are often in RNAs. Inosine is slightly modified from adenine, while ribosylthymine is close to uracil. If a giant base, extremely heavier than the five bases, enters into DNA, the giant base will break the spiral shape and also bring severe variations in the loop size of anti-codons in tRNA, leading to unstable connections with codons. Thus, the five bases are building blocks, although slight modifications are possible.*

V. Energy carriers

As RNAs in living beings have richer GTPs and CTPs due to their relatively stronger hydrogen bond connections, the redundant free ATPs ad UTPs are thrown outside the RNAs. [5] This consideration based on mass and energy conservation laws provides an outline of the inevitability of ATP as an energy carrier. *ATP runoff from RNA resembles the joker (or remaining unmatched queen) in the card game of Old Maid.*

Redundant UTP can be used for generating polysaccharide for producing cell walls, because UTP is also an energy carrier for generating cell walls. [5] (In the pre-biotic proc-

esses such as an RNA world with high temperatures, cell surfaces will also be produced with this mechanism.)

VI. Inevitability of twenty amino acids

The anti-codon inside the leaf of tRNA permits a maximum of sixty-four patterns, because A, U, G, and C are possible for each of the three loci (4 x 4 x 4 = 64). Because the third locus inside the anti-codon has a relatively weak connection with the codon, the minimum number of patterns is sixteen. This implies that the number of amino acids is between sixteen and sixty-four. The weak connection at the third locus permits twenty types of amino acids, a little more than sixteen. *It is emphasized that clarification of the leaf size with an anti-codon of three loci leads to the general inevitability of twenty amino acids*. [6]

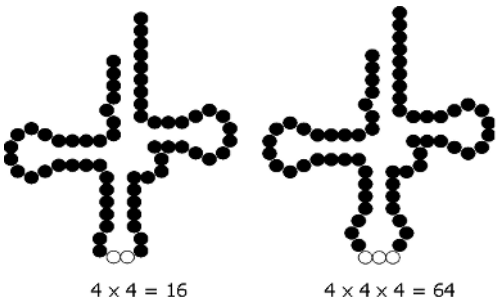

Fig. 2. Relation between leaf sizes and amino acids.

The reason why the size of the leaf having an anti-codon of three bases is inevitable is related to the fact that the frequency ratio of purines and pyrimidines in tRNA is between 1.0 and 1.5, as was explained in Section III. (Purine and pyrimidine pairs do not easily form in the presence of only one type of base. An extremely large frequency ratio, say, far larger than 1.5, can not produce the stem in tRNA It is also well-known that, in DNA without leaves, purines and pyrimidines have the same frequency. This is the well-known Chargaff's rule. The fact that tRNA has loops (leaves) in the clover structure makes it possible for asymmetric frequency ratios of purines and pyrimidines to exist, because the loci inside the leaves (loops) are free from hydrogen-bonded connections. [3, 4])

Both hydrophilic and hydrophobic amino acids exist in proteins. If we employ the classification of R-side chain grouping, the frequency ratios of hydrophilic and hydrophobic amino acids in proteins are also asymmetric in many cases, between 1:1 and approximately 2:3. [7] Asymmetric symbiosis of hydrophilic and hydrophobic molecules also produces the complex convexoconcave shapes of proteins, as hydrophobic parts are often folded inside proteins. (Amino acids have various molecular weights. The frequency ratios of hydrophilic and hydrophobic amino acids in proteins are more stochastic than those of purines and pyrimidines in nucleic acids. Information carriers such as nucleic acids bring determinism, while molecules related to functions such as proteins are more stochastic.)

VII. Cells and organs

Symmetric and asymmetric size ratios are also observed at the cell level of microorganisms. Homma et al. reported the details of the cell size distribution. [8] It is stressed that the size ratio of larger and smaller cells after division is also mostly between 1.0 and 1.5. We also note the fusion of symmetric and asymmetric divisions of cells such as yeast.

This cell size ratio between 1.0 and 1.5 is inevitable, because cells are mathematically similar to flexible particles, including the base, dominated by convection and surface tension. [2, 3] Equation 1 also describes the small deformation and motions of connected cells, assuming that the parameter e denotes the size ratio of two cells connected under equilibrium conditions. Then, the second term on the right-hand side of Eq. (1) shows that *a small surface deformation entering a cell leads to an asymmetric division at an asymmetric size ratio of* $\sqrt[3]{3}$ *(around 1.5)*. [2, 6] (Losick et al. reported that small fluctuations of cells are important for determining the morphogenetic processes. [9] Living microorganisms such as bacteria move round, although dead ones are stationary. Small deformations and fluctuations are important for living beings. Small fluctuations of molecules are also important for fitting drug molecules into the target molecule.)

Let us consider an aggregation of connected cells. Inner cells inside the aggregation receive forces from many directions due to the presence of other cells in a homogeneous field. Inner cells move relatively with the deformation of the cell surface. However, outer cells close to the surface are relatively difficult to deform, because one part of the cell is free without any connection to other cells. *As a result, the inner cells divide asymmetrically.*

The present analysis also clarifies the reason why the left-right symmetric distribution of arms and legs is observed in outward appearance, although the inner body, including the heart and the liver, is asymmetric.

It is posited that the lungs are symmetric because of contact with the outer air during breathing. The kidneys are symmetric because of continuous contact with outer water in the form of urine owing to the fact that the amniotic fluid of the fetus is fetal urine.

The reason why vertebrae in the center of mammals are symmetric is related to the fact that water containing Ca ions enters the inner region when gastrulation occurs, because the primordial gut is also in the outer part of water.

Blood vessels are closed and must not be open to the outer world in order to prevent virus infections. The heart and liver filled with blood are asymmetric due to this process similar to buckling behavior. (Details are in Ref. 12.)

Fig. 3 Asymmetric liver and symmetric kidneys.

It is also stressed that the center and outer parts of DNA have symmetric arrays of bases such as the centromere and telomeres, while the middle part of DNA is asymmetric.

Cell deformation also brings deformations of molecules such as DNA and proteins, which lead to gene changes. Asymmetric cells promoted by fluid-dynamical stability are fixed through evolution by the asymmetry at the molecular level.

VIII. Conclusion and Outlook

Fusion of ratios of 1:1 and approximately 2:3, described by the unified number of the n-th root of n, can be observed in nitrogenous bases. The inevitability of only five bases comes from the main constraints of mass and momentum conservation laws. The fact that the G+C rate in RNA determines the leaf size is related to the energy conservation law. The dominant constraint for each molecule and each part varies in living beings. The sizes and frequencies of amino acids and proteins are a little more stochastic. Literally, the molecules for information storage may be relatively deterministic, while ones having functions are relatively stochastic. Immune globulins are strongly related to information, because they can distinguish various types of antigens. Cell divisions are fairly deterministic with asymmetric size ratios of around 2:3 and 1:1, because the cell size produces information for determining the spatial displacement of organs. *It is stressed that the asymmetry reported in this paper is not directly related to chirality.*

Further thought experiments based on physics brings the outlook. Thus, we will show two more points. First, we will see that DNA employs deoxyribose as sugar, while RNA uses ribose. Giant sugars larger than ribose and deoxyribose will break a constant pitch between the bases in each single strand, making it difficult to generate RNAs. The molecular weights of ribose and deoxyribose are 150 and 134, respectively, and the molecular weights of T and U are 126.11 and 112.0, respectively. The two summations of U+ribose and T+deoxyribose are nearly the same. Thus, DNA can produce RNAs.

The second point concerns repeat DNA. We will classify the repeats into the "odd group" with an odd number of bases such as tri- and penta-nucleotide repeat motifs and the "even group" with an even number of bases such as di-and tetra-nucleotide repeat motifs. When the single strand of sequences having repeats in the "odd group" such as GCGGCG is bent at the center of the sequences in two-dimensional space, the sequences take a straight shape in many cases, because it is difficult to make base pairs. On the other hand, the repeat DNA in the "even group" such as GCGC makes base pairs, which leads to concavity, convexity and functions.

An Improved Methodology for Measuring Facet Contact Forces in the Lumbar Spine

A.K. Ramruttun[1], H.K. Wong[1], J.C.H. Goh[1], J.N. Ruiz[2]

[1] National University of Singapore, Department of Orthopaedic Surgery, Singapore
[2] National University Hospital, Department of Orthopaedic Surgery, Division of Spinal Surgery, Singapore

Abstract — **Accuracy methods using resistance-based sensors for measuring contact facet loads were previously published. However, the force measurement errors reported were relatively significant (≥18%) for the range of loads studied. Hence, a methodology to improve the accuracy and hence reliability for measuring facet contact forces using Tekscan 6900 sensor (1100 PSI rating) was implemented.**

The sensor was equilibrated and calibrated (linear & 2-pt) at 150N in between an Aluminium-Silicone rubber interface. For the accuracy test, 5 pairs of facet joints were trimmed and separately potted in PMMA and the calibrated sensor was then inserted in between the joints. The setup was mounted on an Instron machine where perpendicular known forces of 25, 50, 100 and 150N were applied. For the reliability test, the sensor was inserted into the L3L4 and L4L5 facet joints of an L2S1 human cadaveric test model and the latter mounted on an MTS machine to simulate ±10Nm flexion/extension, lateral bending and axial rotation with a follower preload of 300N.

The sensor overestimated the applied force for the linear calibration by 29.12±13% and 5.72±9% for 25 and 50N respectively while underestimated the applied force by 18.36±10% and 29.52±3% for 100 and 150N respectively. For the 2-pt calibration, the sensor overestimated the applied force for the linear calibration by 19.36±10% and 14.00±9% for 25 and 50N respectively while underestimated the applied force by 3.70±10% and 11.27±13% for 100 and 150N respectively. The average facet loads recorded for the range of motion studied were within published range for both types of calibration with a more significant difference during axial rotation.

The Tekscan sensor force measurement produces more accurate results for the 2-pt as compared to the linear calibration using the improved methodology and can be reliable in validating FEM facet joints studies.

Keywords — **Facet joint, joint kinetics, Lumbar spine, Tekscan sensor, Follower Preload**

I. Introduction

The loading of facet joints play an integral part in the understanding of the normal stability and kinematics of lumbar spine. Radiographs and MRI scans are possible in-vivo methods of investigating facet biomechanics but are limited since only planar kinematics are extractable while facet kinetics are inexistent using these methods. Hence, a proper in-vitro experimental analysis of the facet joints is necessary in order to yield better outcomes and a better understanding of the joint mechanics. In fact, the altered joint kinematics and kinetics of the posterior segmental spinal elements upon the advent of instrumentations such as intervertebral artificial discs and cages, as potential replacements for dysfunctional elements can be biomechanically and clinically important. Mathematical FEM models of the human lumbar spine can also be validated from experimental measurement of spine parameters such as facet contact loads. Hence, accurate and reliable facet load measurements are essential in order to enable the proper reproduction of in-vivo simulated conditions.

Facet contact forces in lumbar spines have been previously using various experimental sensors [1-6]. Tekscan pressure sensors (Tekscan Inc, South Boston, MA, USA) have been used earlier for knee kinetics investigations [7, 8] but their applications in investigating spinal facet joint kinetics has just been recently reported [1, 2, 9]. The use of Tekscan sensor in measuring joint kinetics is thus becoming popular but non-representative interface materials used to calibrate the sensor do not closely mimic the mechanical properties of articular cartilage and maximum loading forces of only 100N as reported previously do not comply with the actual physiological conditions of the spinal facet joints.

Since sensor performance is directly related to the compliance of the interface materials and the sensor preparation protocol (conditioning, equilibration and calibration), hence, our study will propose a new methodology to improve the accuracy and reliability of the Tekscan 6900 sensor performance for measuring facet contact forces by choosing the best suitable interface materials and increase the expected loading force on the sensor.

II. Materials and Methods

Mechanical testing protocol for interface materials

1. 5 cycles for preconditioning (up to 50% compression at a loading rate of 11mm/min) are subjected to each material using a material testing machine (Instron 5543, Canton, MA, USA)

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1805–1808, 2009
www.springerlink.com

2. Using an optical method (Digital Camera with a 10x zoom), the transverse and longitudinal strain are recorded 0, 25, 30 & 50 % compression to determine the Poisson Ratio, v ($- \varepsilon_{\text{transverse (x)}} / \varepsilon_{\text{longitudinal (y)}}$)
3. An additional 3 loading/unloading cycles (with similar preconditioning conditions as above) are applied to the materials to determine the stress/strain characteristic curves and hence derive the elastic/tangential Young Modulus, E

The comparison of the mechanical properties for the interface materials are tabulated as shown below (Table 1 and Table 2).The closest match was the Shinetsu KE1300T silicone and was used to test the performance of the sensor.

Table 1: Comparison of the Poisson Ratio of the various potential interface materials including the facet joint articular cartilage and capsule from FEM and In-vitro studies respectively

Sensor Preparation

The interface material was moulded in two individual 35mm (Length) x 35mm (Width) x 1.5mm (Thickness) mould. The Tekscan 6900 I-Scan sensor (1100 PSI rating) was inserted in between the silicone and aluminium plates and prepared according to manufacturer's recommendation. The sensor was first conditioned 5 times at 120% of the expected load (180N) followed by an equilibration of 180N in between Aluminium-Shinetsu KE1300 T Silicone rubber interface mounted on an Instron 5543 testing machine. The Linear calibration profile is obtained by loading the sensor at 80% (120N) while that of the 2-point calibration is derived by applying 20% (30N) and 80% (120N) of the maximum expected load of 150 N.

Accuracy Test

5 pairs of facet joints were separately harvested, disarticulated and trimmed with the capsular ligaments and capsule removed. Each of the superior and inferior facet joints was separately potted in PMMA while ensuring a parallel and horizontal alignment with respect to each other and a perpendicular positioning of both individual facets with the loading direction. The previously calibrated sensor was then inserted in between the joints. The setup was mounted on an Instron testing machine where perpendicular known forces of 25, 50, 100 and 150N were applied. The force from the machine (True force) was then compared with the calibrated sensor force readings for both the linear and 2-point calibration and the force measurement error calculated as previously discussed [1].

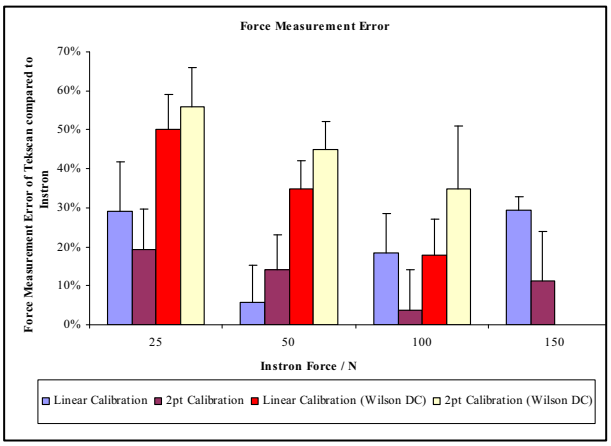
Reliability Test

The calibrated sensor was inserted into the L3L4 and L4L5 facet joints of an L2S1 human cadaveric test model and the latter mounted on an MTS machine to simulate ±10Nm flexion/extension, right/left lateral bending and clockwise/anticlockwise axial rotation [11] with a follower preload of 300N [10]. The sensor was recalibrated after each test following the procedures described in the sensor preparation above. The raw values from each sensor were recorded and the equilibration, linear and 2-point calibration

files were loaded into the recorded Tekscan movie files. The average force for each of the 4 branches of the sensor was individually computed and analyzed for the range of motion studied.

III. Results

The sensor overestimated the applied force for the linear calibration by 29.12±13% and 5.72±9% for 25 and 50N respectively while underestimated the applied force by 18.36±10% and 29.52±3% for 100 and 150N respectively. For the 2-pt calibration, the sensor overestimated the applied force for the linear calibration by 19.36±10% and 14.00±9% for 25 and 50N respectively while underestimated the applied force by 3.70±10% and 11.27±13% for 100 and 150N respectively (Fig 1). The measurement errors from a recent publication [1] were also included in the chart and were significantly higher than those from our experiment.



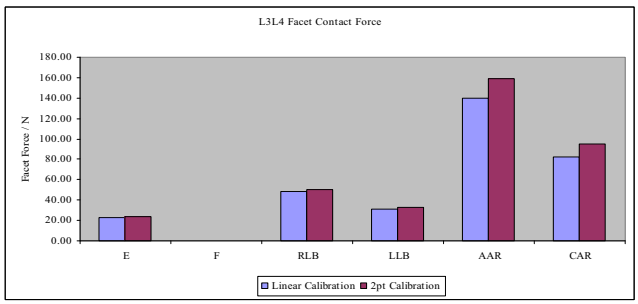


Fig 1: The force measurement errors of the sensor as compared to the Instron Force and recent publication [1]

The range of facet forces measured using the Tekscan Sensor for the range of motions investigated at both L3L4 and L4L5 are illustrated in Fig 2 & 3 respectively. The average facet force ranged from 0N during flexion to 159N and 161.9N during anticlockwise axial rotation for both linear and 2-point calibration at L3L4 and L4L5 levels respectively.

The minimum average difference in the facet force was 1N and 0.10N for extension while the maximum of 19N and 32N was registered for anticlockwise axial rotation at L3L4 and L4L5 respectively.

RLB & LLB – Right & Left Lateral Bending
CAR & AAR – Clockwise & Anticlockwise Axial Rotation

Fig 2: The range of facet forces measured using the Tekscan Sensor for the range of motions investigated at L3L4

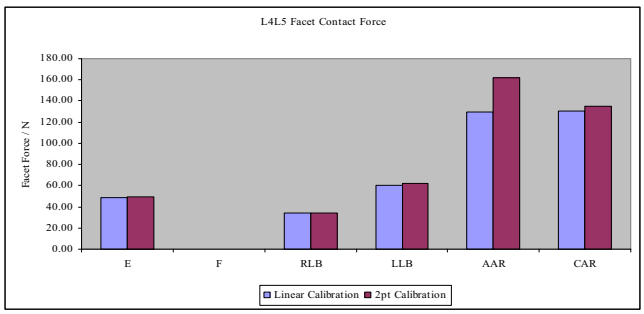

Fig 3: The range of facet forces measured using the Tekscan Sensor for the range of motions investigated at L4L5

IV. Discussion

Our results for the accuracy test, using the separated facet joints after the sensor has been conditioned, equilibrated and calibrated using Shinetsu KE 1300T silicone as the interface material, showed that the 2-point calibration is significantly better than the linear calibration. Hence, the method described in this experiment showed that the accuracy of the sensor is improved as compared to the force measurement error of at least 18% reported for the range of loads investigated of 25-100N) [1]. For the reliability test, the maximum forces obtained from the sensor of 161.9N during the investigation of physiological motions were close to the expected force of 150N used to calibrate the sensor. The values are much higher as those reported from previous publications especially during axial rotation and could be due to the effect of the follower preload system and the maximum moment of 10Nm used during our assessment.

The yardstick of an optimum sensor performance is to find a compliant interface material as close as possible to

the facet joint cartilage mechanical properties. Different materials have been reportedly been used to calibrate the Tekscan sensor. Some calibrated the sensor in between two 3.2 mm lubricated rubber whose mechanical properties have not been reported [7, 9] while others used a 3mm thick foam with a nominal compressive strength of 50 kPa at 25% and 90 kPa at 50% deflection [1]. Detailed mechanical properties of the various commercially-available interface materials with an average thickness of 3mm have been evaluated with particular reference to the Elastic Young Modulus and Poisson Ratio. The choice of Shinetsu KE 1300T was due to the closeness of its mechanical properties to that of the articular cartilage of the facet joint.

Tekscan Flexiforce (A101-500) was used to investigate the effect of instant axis of rotation on the facet forces [2] but the accuracy of the sensor was not looked into. Another publication [9] investigated the effect of a dynamic posterior stabilization system (Dynesys) on Facet Joint Contact Forces using Tekscan 6900 sensor. The loading range was estimated to be 100N and the sensor was calibrated while following manufacturer's recommendations. The accuracy and repeatability of the Tekscan 6900 sensor as a potential experimental force transducer for measuring spinal facet loads was also investigated [1]. Published force measurement errors reported are 18% at best and a loading range of only 25-100N. However, recent FEM studies [12, 13] have reported much higher facet loads. The biomechanics of the lumbar spine and its behaviour with varying position and height of a mobile core type artificial disc in which the facet load at the implanted and adjacent levels was estimated at a maximum of 200 N during extension while the effect of large compressive loads on the spine during flexion and torsion which reported a total maximum facet force of 100 to 150 N at a moment of 10 Nm were reported respectively. Hence, the calibration range of 100 N seems inadequate and higher facet loads can be expected especially with the advent of the follower preload system. Furthermore, the behavior of the Tekscan 6900 sensor is still unknown in terms of the accuracy of the calibration beyond 100N, hence, the motivation behind this study. The forces measured from the sensor can also be used to validate FEA of facet joint forces. So far, the only validation of current model is by comparing with published data as well as in-vitro biomechanical testing of intact spine. Hence, the facet forces from the Tekscan sensor can provide useful information to help validate and improve the predictive ability of the models.

V. Conclusion

The main aim of this paper was to assess the accuracy and reliability of the Tekscan 6900 I-Scan sensor using an improved methodology in order to reduce the force measurement errors when measuring spinal facet joint forces. By using a more compliant interface material and facet joints, the Tekscan sensor force measurement produces more accurate results for the 2-pt as compared to the linear calibration using the improved methodology and can be reliable in validating FEM facet joints studies.

Multi-scale Models of Gastrointestinal Electrophysiology

M.L. Buist, A. Corrias and Y.C. Poh

Division of Bioengineering, National University of Singapore, Singapore

Abstract — **We have developed quantitative mathematical descriptions of a gastric smooth muscle cell (SMC) and a gastric interstitial cell of Cajal (ICC). Together these two cell types, with input from the enteric nervous system, govern the electrical and mechanical actions of the stomach that combine to generate motility. Each of these models has been developed from the underlying physiology and has been validated against whole cell experimental recordings. Such models form the building blocks necessary to construct multi-cellular and multi-scale simulations that link sub-cellular behavior to whole organ function.**

With these building blocks, tissue and organ level models have been developed. The geometry of the stomach has been digitized from photographic images from the visible human project and a derivative continuous serosal surface has been fitted using an iterative linear minimization technique. The volume of the *muscularis externa*, representing the layers in the stomach wall responsible for gastric motility, was created through an inward projection from the serosal surface. Within this volume a high resolution hexahedral finite element mesh was created over which a non-linear reaction diffusion equation was solved to describe the macroscopic propagation of electrical activity in the stomach.

At the other end of the spectrum, a mutation in the gene encoding the gastrointestinal sodium channel has been described and linked to clinical symptoms. To elucidate the effects of subcellular maladies such as this, a true multi-scale framework has been developed to investigate gastrointestinal electrophysiology; from ion channel to cell to tissue to organ. This framework will allow us to better understand the emergent behavior of the system in a way that would be difficult, if not impossible, to decode experimentally. The development of the framework and the first results from its implementation are presented.

Keywords — **Electrophysiology, Finite element, Gastrointestinal, Smooth muscle, ICC**

I. Introduction

The muscular layers in the walls of the stomach produce omnipresent rhythmical membrane potential fluctuations that are known as slow waves [1]. These are initiated in the mid-corpus of the stomach, quickly forming a ring of activity before propagating distally towards the pylorus at the entrance to the small intestine. This activity is the result of interplay between gastric smooth muscle cells and the interstitial cells of Cajal (ICC), while the enteric nervous system (ENS) provides an additional extrinsic level of control. Together these cells act as a syncytium in which the electrical activity is conducted from cell to cell [2]. Recent evidence suggests that it is the ICC that are primarily responsible for the initiation and propagation of slow waves while the smooth muscle cells receive input from the ICC and the ENS and contract in accordance with their level of stimulation [1].

While between 60 and 70 million people in the US alone are affected by digestive diseases [3], relatively little is known about the fundamental mechanisms involved with the initiation and propagation of the electrical activity in the gastrointestinal (GI) tract. Current diagnostic techniques can, for example, quantify the degree of gastroparesis (nuclear medicine, gastric emptying studies) or identify the dominant frequency associated with gastric electrical activity. However, none of the current methods can detect the underlying electrophysiological disturbances that cause gastroparesis. In addition, should an electrical disturbance be detected there are large gaps in our knowledge as to how this should be interpreted.

Our approach to these problems is the development of an anatomically and biophysically based multi-scale model of the human digestive system, initially focused on the stomach. The resulting modeling framework covers a wide range of spatial scales, from the level of an ion channel to that of a cell, to tissue, organ and whole torso models. This represents a significant advance over previous modeling studies in this area as the majority represents the previous state of knowledge in which the smooth muscle cells were thought to be self-exciting [4]. In addition, more recent attempts to describe the system have been largely phenomenological [5-6]. The modeling framework can be summarized as shown in Figure 1.

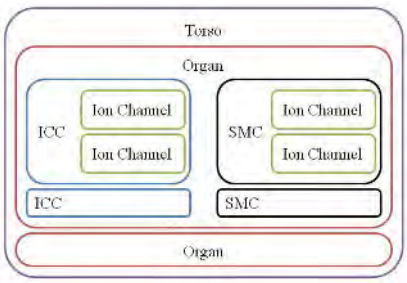

Fig. 1 Model hierarchy; ion channels are encapsulated by cells which combine to form organs that are encapsulated within the torso.

II. Materials and methods

Cell models: Two models of cellular electrophysiology were developed, one ICC model and one smooth muscle cell model. These were developed following the classical Hodgkin-Huxley approach where the cell membrane was described by an equivalent electrical circuit consisting of a membrane capacitance connected in parallel with a number of variable conductances, each representing a different pathway for the movement of charged ions [7].

$$\frac{dV_m}{dt} = \frac{-1}{C_m}(I_{ion} + I_{stim}) \quad (1)$$

Here V_m (in mV) is the membrane potential, C_m (in pF) is the cell capacitance, I_{stim} (in pA) is an externally applied stimulus current (if present), and I_{ion} (in pA) represents the sum of the ionic currents crossing the cell membrane. An extensive literature search was undertaken to identify the major ion channels present in each cell type.

The ion channels identified in gastric smooth muscle cells were selected as described in [8]

$$I_{ion} = I_{CaL} + I_{LVA} + I_{Kr} + I_{KA} + I_{BK} + I_{Kb} + I_{Na} + I_{NSCC} \quad (2)$$

where I_{CaL} represents the influx of Ca^{2+} ions through voltage gated, dihydropyridine (DHP)-sensitive L-type Ca^{2+} channels that are commonly expressed in most muscle cells of mammalian organisms [9-10]. I_{LVA} represents the second, low voltage-activated, fast inactivating, DHP-insensitive component of the inward current that was described in several types of smooth muscle cells and is often termed a 'T-type' Ca^{2+} current [11]. I_{Kr} refers to the typically TEA and 4-AP –sensitive ionic conductance through delayed rectifier potassium channels commonly expressed in a wide variety of excitable cells [12]. I_{KA} refers to the fast inactivating, Ca^{2+}-independent, TEA-insensitive, outward A-type K+ current that was first described in mollusc neurons [13]. Ca^{2+}-activated K+ channels have been traditionally divided in three categories according to their large (BK), intermediate (IK) or small (SK) conductance. To date only BK channels have been described in gastrointestinal tract and are included here through I_{BK} [14]. A background potassium conductance was also included in the model through I_{Kb}. Sodium currents have been reported in guinea-pig gastric fundus and the human jejunum. We have therefore chosen to include a relatively Tetrodotoxin (TTX)-resistant sodium channel, with current I_{Na}, in the model [15]. I_{NSCC} is a non-selective cationic channel (NSCC) that has been described in both guinea-pig and canine gastric smooth muscle [16]. In addition, a phenomenological model of calcium extrusion was included to represent the activity of the sarcoplasmic reticulum and sodium/calcium exchangers on the plasma membrane in order to maintain long term intracellular calcium homeostasis.

The electrophysiology of an ICC cell was described using the following ionic currents [17].

$$I_{ion} = I_{CaL} + I_{VDDR} + I_{Kv11} + I_{ERG} + I_{BK} + I_{Kb} + I_{Na} + I_{NSCC} + I_{Cl} \quad (3)$$

Two types of Ca^{2+} channel have been identified in ICC. One is a DHP-resistant conductance, I_{VDDR}, whereas the other one has been molecularly classified as an L-type Ca^{2+} channel, I_{CaL} [18-19]. I_{Kv11} is the current flowing through the voltage dependent K^+ channels encoded by the Kv1.1 gene. Ether-a-go-go (ERG) channels have been proposed as important regulators of pacemaker activity in ICC. The characteristics of the I_{ERG} current in ICC have been studied in detail in ICC by [20]. The presence of Ca^{2+}-activated K^+ channels (BK) has been confirmed in ICC via immunocytochemical techniques. The I_{BK} channels in ICC were assumed to be not substantially different from those in gastric smooth muscle cells. A background K^+ conductance, I_{Kb}, was also included in the model. An SCN5A-encoded Na^+ conductance has been found in human intestinal ICC by RT-PCR experiments. This current, I_{Na}, believed to influence the rise phase of the slow waves, is TTX-resistant [21]. I_{NSCC} is theorised to be the primary pacemaking conductance and allow ionic fluxes into the restricted subspace enclosed by the plasma membrane, mitochondria and sarcoplasmic reticulum [1]. An inwardly rectifying whole cell current has been identified that the authors believed was carried primarily by Cl^- ions. This is represented in the model through I_{Cl}. Both a plasmalemmal Ca^{2+} pump (PMCA) and the Na^+/Ca^{2+} exchanger (NCX1) have been identified in ICC. However, quantitative data pertaining to the kinetics of these proteins was not available so a phenomenological description of the Ca^{2+} extrusion mechanisms was included.

Geometric models: The anatomical data source used for the construction of the stomach and torso models was the visible human project [22]. Computational meshes were created by digitizing surfaces from the axial visible human images and then fitting an initial bilinear surface mesh to the resulting data. This initial mesh was then used with a second round of fitting to produce derivative continuous surface meshes of the relevant geometries. Wall thickness was added to the hollow organs of the digestive system by an inward projection of the outer surface towards the centerline of the mesh based on available anatomical thickness data. This 3-D geometry was then divided into layers representing the circular and longitudinally aligned smooth muscle cells and the intervening myenteric plexus with its dense network of ICC [23]. Within the gastric musculature, the monodomain simplification of the bidomain equations was used to model the syncytium of the muscularis externa.

$$\nabla\cdot(\sigma\nabla V_m)=A_m\left(C_m\frac{dV_m}{dt}+I_{ion}\right) \quad (4)$$

Here σ represents the tissue conductivity and A_m is the ratio of the membrane surface area to the tissue volume. The other terms are as stated for Equation 1. A high resolution structured finite element mesh was generated over the stomach over which Equation 4 was solved. In the passive regions outside the electrically active stomach, the torso volume conductor was described using a generalized Laplace equation that was solved using a boundary element approach [24].

III. Results

Each of the cell models was tested individually to ensure they produced slow wave profiles that were both qualitatively and quantitatively similar to those recorded experimentally. The resulting slow wave profile from the smooth muscle cell model is shown in Figure 2 while the slow wave profile from an ICC is shown in Figure 3.

Each of these models was then validated through testing against experimental data from a wide range of pharmacological interventions, the details of which can be found in [8,17]. This was performed to ensure that the model results could be trusted in pathological as well as physiological conditions.

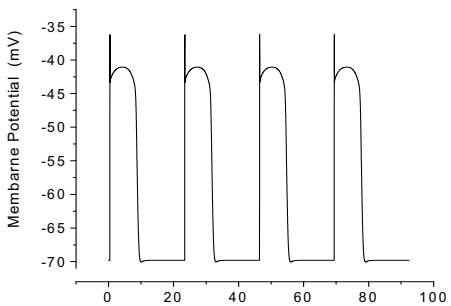

Fig. 2 Membrane potential as a function of time for the model of gastric smooth muscle electrophysiology.

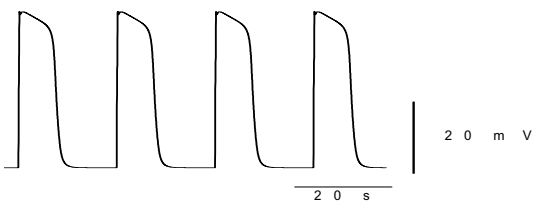

Fig. 3 Membrane potential as a function of time for the model of gastric ICC electrophysiology.

After completing the validation of the single cell models, these were placed into the 3-D stomach model through the I_{ion} term. Essentially one of these cell models was placed at each node in the high resolution finite element mesh (over 300,000 in total). Smooth muscle cells were placed in the longitudinal and circular muscle layers whereas the ICC model was placed in the myenteric plexus and also intramuscularly. The monodomain equation (Equation 4) was then solved with a time step of 0.01 ms and the membrane potential, V_m, was calculated over the stomach as a function of time. The resulting potential field at one time instant is shown on the left of Figure 4.

After each 1 ms of simulation time, equivalent current dipole sources were calculated from the membrane potential distribution as described in [25]. These were then placed within the boundary element torso model and used to calculate the body surface potential field from which an electrogastrogram could be constructed, and also the components of the biomagnetic field that could be recorded on a plane just in front of the torso surface.

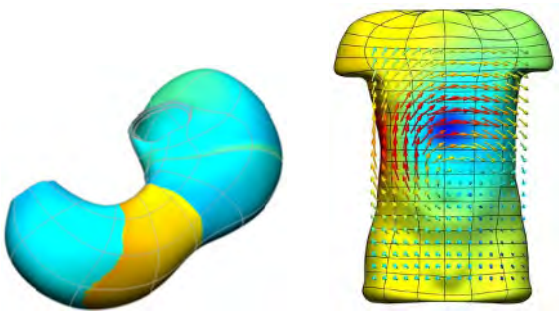

Fig. 4 On the left one snapshot of the membrane potential on the outer surface of the stomach shows a slow wave (yellow) progressing from right to left down the stomach; blue tissue is excitable. The right figure shows the body surface potential and also the biomagnetic field strength that is the result of the stomach cellular activity; blue potentials are negative and red are positive.

IV. Discussion

This modeling framework represents the entire scale of physiological events required to accurately model gastrointestinal electrophysiology. The building blocks of each cell model are mathematical descriptions of individual ion channel function. The cell models in turn represent the building blocks for describing organ function; an organ is constructed from its cell models as the cell models are constructed from their ion channels. Mutations of the genes encoding each ion channel alter channel function, cell function, and ultimately organ function if the mutation is sufficiently severe. This modeling framework is thus uniquely

positioned to describe the downstream effects of such ion channelopathies.

When constructing multi-scale models such as that presented here, computational tractability must always be a consideration. The majority of the computational time here was spent integrating the systems of differential equations needed to describe cell function. To minimize the computational cost the cell models do not include an exhaustive list of every ion channel ever found in the two cell types. Instead, only those ion channels capable of making a significant contribution to the whole cell current were included. The result was a 3-D model that can be run on a desktop computer. With this assumption in mind, the cell models were written in a modular fashion such that additional channel types can be easily added as they are experimentally characterized and their influence becomes better understood.

One common criticism of detailed mathematical models in biology is that there are so many free parameters that essentially any behavior can be represented. Here no global parameter fitting algorithms were employed. Each ion channel model was fitted to experimental data and then validated against the data from which it was created. The ion channel models were then combined using the Hodgkin-Huxley formalism and the resulting slow wave profiles were tested against whole cell experimental recordings. Data was also available from experiments where pharmaceutical agents were added to whole cells or tissues. The validity of our models was further verified by simulating the presence of these agents and ensuring the model response was consistent with the experimental observations. By linking to real data at each stage in the model construction we avoid the aforementioned criticism and can be confident in the robustness of the model.

V. Conclusion

A modeling framework has been developed to describe the electrophysiology of the gastrointestinal tract, integrating the available physiological information from the subcellular level through to whole organ function. This represents an invaluable platform to further our knowledge of gastrointestinal electrophysiology in health and disease.

Postural Sway of the Elderly Males and Females during Quiet Standing and Squat-and-Stand Movement

Gwnagmoon Eom[1], Jiwon Kim[1], Byungkyu Park[2], Jeonghwa Hong[2], Soonchul Chung[1], Bongsoo Lee[1], Gyerae Tack[1], Yohan Kim[1]

[1] Konkuk University, Choongju, Korea
[2] Korea University, Seoul, Korea

Abstract — **In this paper, COP (center of pressure) during quiet standing and squat-and-stand movement was analyzed to compare the postural control of young and elderly subjects with special interest in the elderly females who were reported to have higher fall rate than the elderly males. Subjects include the young subjects (10 males: 21.8±2.6yrs, 10 females: 20.4±0.3yrs) and the elderly subjects (8 males: 75.5±4yrs, 8 females: 72.3±3.5yrs).**

Analysis parameters were the mean of the distance between the instantaneous COP and the average COP (COP distance) and the mean of the COP movement velocity (COP velocity) in both AP (anterio-posterior) and ML (medio-lateral) directions.

During quiet standing, the COP distance in ML direction of elderly females was significantly greater than that of elderly males and the COP velocity of elderly females in both ML and AP direction were significantly greater than those of all the other groups.

During squat-and-stand movement, the COP distance of elderly females was not significantly different with that of the elderly males. However, the COP velocity of elderly females was significantly greater than that of all the other groups.

The large lateral weight shift (COP distance) of elderly females during quiet standing may explain their greater fall rate. However, this does not apply to squat-and-stand movement.

In contrast, COP velocity results show that the elderly females' COP is rapidly trembling compared to that of elderly males during both quiet standing and squat-and-stand movement. This result suggests that rapid trembling or postural sway may reflect the reduced postural control ability and higher risk of fall in elderly females.

Keywords — **fall-risk, gender, COP, quiet standing, squat-and-stand**

I. Introduction

One thirds of the elderly older than 65 years experience fall more than once per year which reduces the quality of life by limiting the activities of daily living [1-3]. It was reported that the fall rate of elderly females is 49 % higher than that of elderly males [7]. Fall was attributed to the deficit in postural control which was evaluated by the postural sway in center of pressure (COP) [8-11]. However, it is still unclear that what difference in postural control is related to the difference between the fall rates of elderly males and females. Therefore, this study aims to compare the postural sway characteristics in elderly males and females, during quiet-standing and squat-and-stand movement.

II. Method

A. Subject

Sixteen elderly subjects and ten young subjects participated in this study whose physical characteristics are shown in Table 1. Subjects were divided in four groups as young male, young female, elderly male and elderly female.

Table 1 Physical characteristics of the subjects.

	Elderly		Young	
	Males (n=8)	Females (n=8)	Males (n=10)	Females (n=10)
Age	75.5±4.2	72.3±3.5	21.8±2.6	20.4±0.3
Weight[kg]	56.3±9.2	54.3±6.1	70.3±9.3	58.5±6.7
Lean body mass[kg]	43.6±6.9	35.3±3.8	58.2±2.8	41.6±3.1

B. Measurement and analysis

COP trajectory during static condition (quiet-standing, 30s) and also dynamic condition (squat-and-stand movement, 5 times) was measured in all subjects by using a force-platform.

The mean distance (MD) of COP from the center of the trajectory (mean value) was derived from the COP data. MD was determined in anterio-posterior (AP), medio-lateral (ML) and in total (TOT) direction. Similarly, the mean velocity (MV) of COP was derived in each direction. Difference of the above COP parameters among groups are analyzed by ANOVA and post-poc test (Tukey).

III. Result and discussion

A. Quiet-standing

MD of elderly females in ML direction was significantly greater than those of elderly males and this was reflected in

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1814–1816, 2009
www.springerlink.com

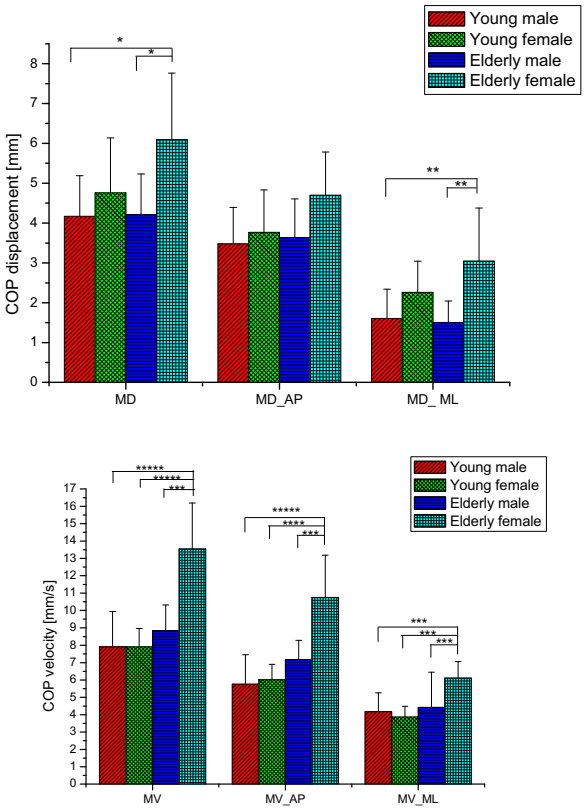

Fig. 1 Comparison of COP parameters among groups during quiet standing (* p<0.05, ** p<0.01, *** p<0.001, **** p<0.0001, ***** p<0.00001)

MD of total direction (Fig. 1a). This indicates that the large lateral weight shift is occurring during quiet standing in elderly females and it might be related to the higher fall rate, because three times of elderly females experience fall-related fracture in hip joints due to the fall in frontal plane [24].

MV of all directions in elderly females was significantly greater than those of all the other groups (Fig. 1b). This indicates that the rapid trembling of body weight even during quiet-standing might be related to the deteriorated postural control ability and the higher fall rate.

B. Squat-and-stand

MD in ML direction in elderly females was not different from those of elderly males and this was reflected in MD of total direction (Fig. 2a). This indicates that the postural control strategies in all groups during squat-and-stand movement are similar, at least in terms of the COP displacement.

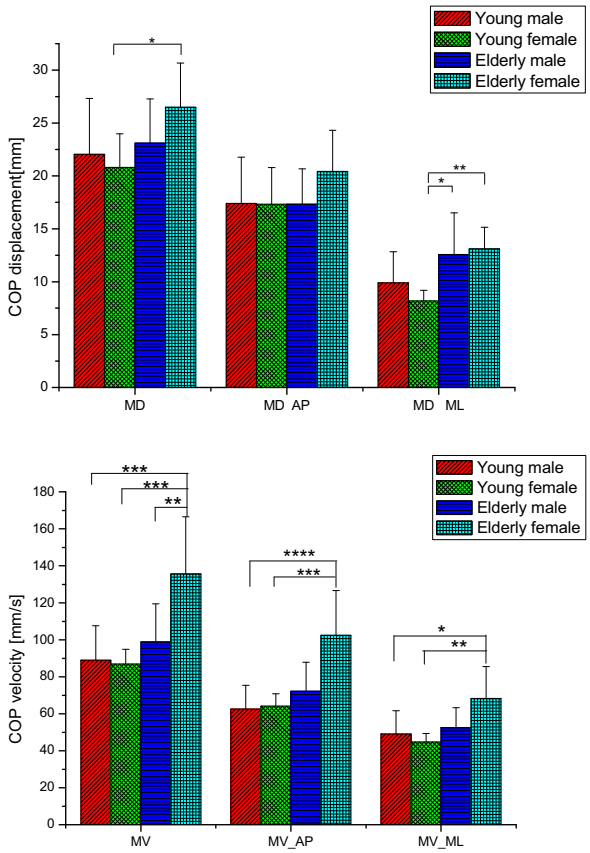

Fig. 2 Comparison of COP parameters during squat-and-stand movement (* p<0.05, ** p<0.01, *** p<0.001, **** p<0.0001, ***** p<0.00001)

MV of total directions in elderly females was significantly greater than those of all the other groups (Fig. 2b). This indicates that the rapid trembling of body weight during squat-and-stand movement might be related to the deteriorated postural control ability and the higher fall rate during dynamic motion, as walking.

IV. Conclusion

Elderly females' MD in ML direction during quiet standing was significantly greater than those of elderly males. Elderly females' MV in total direction during both quiet standing and squat-and-stand movement was significantly greater than those of all the other groups. Rapid trembling of body weight during both static and dynamic condition might be related to the deteriorated postural control ability and the higher fall rate.

Abstract — **Mechanical loading acting on the foot plantar soft-tissue in the form of focal stress plays a central pathogenic role in the onset of diabetic neuropathic ulcers. Current instruments which merely allow superficial estimate of plantar loading acting on the foot, severely limit the scope of many biomechanical/clinical studies on this issue. Recent studies have suggested that peak plantar pressure may be only 65% specific for the development of ulceration. These limitations are at least partially due to surface pressures not being representative of the complex mechanical stress developed inside the subcutaneous plantar soft-tissue, which are potentially more relevant for tissue breakdown. This study established a three-dimensional and nonlinear finite element model of a human foot complex with comprehensive skeletal and soft-tissue components capable of predicting both the external and internal stresses and deformations of the foot. The model was validated by experimental data of subject-specific plantar foot pressure measures. The stress analysis indicated the internal stresses doses were site-dependent and the observation found a change between 1.5 to 4.5 times the external stresses on the foot plantar surface. In the forefoot, peak external stress was found in the medial region (the first metatarsal heads). Peak internal stress, however, was shifted to the lateral forefoot region (the fourth and fifth metatarsal heads). It suggested that the normal protective plantar soft-tissue has the potential to redistribute the plantar load such that the internal peak stress can have a significantly different location than the external. The results yielded insights into the internal loading conditions of the plantar soft-tissue, which is important in enhancing our knowledge on the causes of foot ulceration and related stress-induced tissue breakdown in diabetic foot.**

Keywords — **foot ulcers, biomechanics, foot plantar pressure, internal tissue stresses, finite element model.**

I. Introduction

Foot ulcers are among the most devastating complications of diabetes. The lifetime risk for a patient with diabetes developing a foot ulcer could be as high as 25%, and limb amputation, the most costly and feared consequence of a foot ulcer, occurs 10 to 30 times more often in diabetic patients than in general population [1]. Although the development of foot ulceration is a matter of considerable uncertainty, epidemiological and biomechanical studies have indicated that mechanical loads acting on the foot in the form of peak plantar pressures (focal stress) are highly associated with tissue breakdown in diabetic foot [2].

To address foot risks, in the past, many in vivo and in vitro studies have been focused on delineating the potential overloading of the foot by plantar pressure measurements [3]. However, given a combination of complex geometry and nonlinear material behavior of the subcutaneous plantar soft-tissue, force acting on the plantar surface may lead to highly inhomogeneous internal mechanical loading conditions. This is especially true for the sites underneath the prominence of the metatarsal heads, in which soft-tissue contacts with irregular-shaped bony structure causing stress concentration [4]. Therefore, the relationship between the plantar pressure and internal stress is unlikely to be simple. Recent high resolution magnetic resonance imaging (HR-MRI) has revealed that disruption of the subcutaneous deeper plantar tissue in diabetic feet with micro-haemorrhage [5]. If it is true that ulceration of the plantar soft-tissue results from excessive mechanical stress, then it appears reasonable that foot ulceration may be internally initiated and work up toward the outermost skin level.

Therefore, the aim of this study is to develop a detail three dimensional finite element model of the foot capable of predicting the internal stress and strain states. The model is validated by subject specific plantar foot pressure measurements.

II. Method

A. Plantar Barefoot Pressure measurement

In order to obtain plantar barefoot pressure during standing, a foot pressure test was conducted using the F-Scan In-shoe Pressure System (Software v. 5.03, Tekscan. Boston, MA) on a 26 year-older male subject who was free of any foot abnormalities and pathologies. These pressure sensors have a high spatial resolution (4 sensing elements per cm^2) and are ultra-thin (0.15mm), thus can effectively capture the interface pressure between the foot plantar and ground with minimally intrusion. The subject was instructed to stand barefoot on a metal plate (Aluminum-Alloy Standard 2014-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1817–1820, 2009
www.springerlink.com

T6) which represents the ground. Then material property of the plate i.e. ground was thus known which can be defined in the FE model (Density= 2800 kg/m^3, Young's modulus = 72 GPa, Poisons ratio = 0.33). The pressure sensor was inserted between the foot plantar and the ground. To produce reliable measures, five static plantar pressure trials were collected from the subject's right foot. For each test, plantar pressure distribution (force pattern), peak plantar pressure and foot-plate contact area were recorded.

B. Finite Element Modeling

The 3-D geometry of the soft tissue-skeletal foot and ankle joint complex was created based on the coronal computer tomography (CT) scan of the right foot of a male adult who was free of any foot abnormalities and pathologies. Foot structures such as articular cartilages, ligaments and plantar fascia that could not be reconstructed from CT were determined through magnetic resonance (MR) imaging and histological observations. 30 bony parts with articular cartilages, including sesamoids, were created individually and then were enveloped into a mass of foot soft tissue in which the muscular constitutions were not separately identified. A total of 5 sub-bands of plantar fascia and 134 major ligaments (Ligs) were also incorporated into the model to passively stabilize the cartilage-mediated bony joints: 14 ankle Ligs, 11 talocalcaneal Ligs, 14 talonavicular Ligs, 9 calcaneocuboidal Ligs, 13 navicocuneiform Ligs, 27 tarsometatarsal Ligs, and other 46 short Ligs.

In order to simulate the joint interactions among the tibia, fibula, calcaneous, talus, navicular, cuboid, cuneiforms, and metatarsals, ABAQUS "contact" conditions were defined accordingly, which allow bones to slide frictionless over one another. Since the joint surfaces were all wrapped with articular cartilages, the governing stiffness during contact was set to be 1.01MPa which is consistent with the compressive material properties of the foot joint cartilage [6]. Both the bony structures and soft-tissue were meshed with 4-noded tetrahedral elements, while the ligaments and plantar fascia were represented by 2-noded tension-only truss elements. A second-order polynomial hyperelastic material model was applied to incorporate the nonlinear properties into the pad soft tissue. Other structures were assumed to behavior in linear isotropic manners.

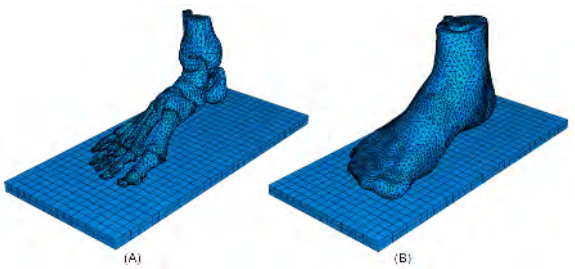

Fig. 1 . FE model of the skeletal structures of the human foot including their ligaments (A) enveloped by a mass of soft-tissue under the skin. (B)

During static standing, an estimated ground reaction force of 325 N (half of the BW) was applied to the foot model through uniformly distributed pressure. An estimated gastrocnemius-soleus muscle force of 162 N acting through Achilles tendon to the calcaneus was also applied by using force vectors, and the superior part of tibia, fibula and soft tissue were all fixed by all degree of freedom. In addition, a frictional contact interaction was established between the foot plantar surface and the ground.

C. Validation

The FE computed axial compressive stress on the ground (σ_{yy}, along Y-direction, perpendicular to the contacting surface of foot plantar) were compared to the plantar pressure distribution measured using F-scan. Quantitative results on nine clinically significant regions as defined by rectangular regions of interest (ROI) on plantar soft-tissue were chosen for comparison: the subhallucal (H), the 1st submetatarsal [medial M1(M) and lateral M1(L) sesamoids], the 2nd to 5th submetatarsal (M2 to M5), the lateral submidfoot (L) and the subcalcaneal (C) region. Moreover, the FE computed center of contact pressure (COP), peak contact stress (PCS), and total contact area (TCA) were also compared with the experimental measures.

D. Regional external/internal stress analysis

The same nine ROI were subsequently used for regional external/internal stress analysis. The stress level calculated from the integration points within each ROI of the plantar surface (outermost plantar soft-tissue) represents the external stress; while the stress level calculated from the innermost plantar soft-tissue which interfaces with the foot bones represents the internal stress. The tissue stress was presented in terms of von Mises stress (σ_V), and principal normal stress (σ_{xx}, σ_{yy} and σ_{zz}) which were linked by the von Mises yield criterion in the form of:

$$\sigma_v = \sqrt{2}/2\left[\left(\sigma_{xx}-\sigma_{yy}\right)^2+\left(\sigma_{yy}-\sigma_{zz}\right)^2+\left(\sigma_{zz}-\sigma_{xx}\right)^2\right]^{1/2}$$

These stresses were averaged over all integration points of tetrahedral element within the boundary of each ROI (4 integration points for each tetrahedral element).

III. Results

As revealed in Figure 2, the FE model predicted similar patterns of plantar pressure distribution with the F-scan

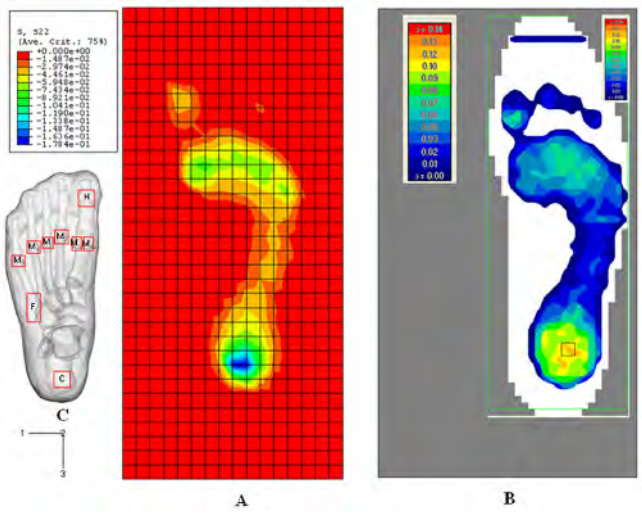

Fig. 2 The FE-computed ground compressive stress distribution (A), and F-scan measured plantar pressure distribution (B) of the same subject during standing. Regions interfacing with the nine rectangular regions of interest (ROI) of foot plantar (C) were compared for FE model validation.

Table 1 Comparison of FE predictions and F-scan measurements

	COP	PCS (MPa)	TCA (mm^2)
F-scan data	Heel center located	0.130	10,700
FE predictions	Heel center located	0.178	7,522

measures. Both the computed peak compressive stress and the measured peak plantar pressure were located beneath the center of the heel region. Forefoot at the level of metatarsal heads predicted the second highest focal stress during plantar support, followed by the big (great) toe and the midfoot which were only minimally involved in weight-bearing process. Site-to-site comparison revealed deviations of FE predictions from F-scan measures ranged from 11.7% to 32.5%. The maximum deviation was located at M5, while M2 displayed the best match between FE prediction and F-scan data. Good agreements were also found between the FE computed foot-ground contact characteristics and F-scan data in terms of COP, PCS and TCA, especially true for the COP and PCS predictions.

The internal stress beneath the adjacent foot bones was significantly higher than the external stress across all nine ROI of the foot plantar. The internal ROI generally showed over 2 folds more stress than the external. The external and internal stress at ROI M2 depicted the largest difference. The internal stress at this site was over 4.5 times greater than the external. The magnifications in other ROI in the descending order are: M4 with 4.4, M5 with 4.0, C with 3.5, M3 with 3.3, M1 (M&L) with 2.0, H with 2.0 and L with 1.5. It demonstrated that stress distribution inside the plantar soft-tissue was inconsistent with the external stress distribution. For forefoot region, externally, sites M1 (M) and M1 (L) experienced the highest stress; while internally most stress was concentrated at M2, M4, and M5. The relationship between external and internal stress of plantar soft-tissue seems to be site-dependent.

IV. Discussion & Conclusions

Abnormally high foot pressures have been shown in the past to be associated with an increased risk for developing foot ulceration [7]. Clinically, an empirical plantar foot pressure of 600KPa has been considered to be indicative of patients at high risk for foot ulceration [8] [9]. In the present study, the internal stress was found to be site-dependent and the observation showed a change between 1.5 to 4.5 times the external stress on the foot plantar surface. Therefore, based on the computed magnification factors, the internal stress inside the plantar soft-tissue can vary from 900KPa up to 2,700KPa. Considering the local pathological stiffening [10] or migration (displacement of fat-pad from beneath bony prominences) [11] of the plantar soft-tissue across the foot plantar, an even higher internal stress or possibly overdosed stress can be expected inside the diabetic foot. Although the exact stress thresholds or the tolerance of the different tissue for normal and diabetic foot are still missing, the external/internal stress associations obtained from the current foot model can serve as a useful baseline case for future work.

The Influence of Load Placement on Postural Sway Parameters

D. Rugelj and F. Sevšek

University of Ljubljana, College of Health Studies, Ljubljana, Slovenia

Abstract — **School children, recreational backpackers, soldiers, fire-fighters carry a range of loads from 8 to 40 kg. Little is known about the extent to which carrying an external load on the body affects postural sway. The purpose of the present study was to investigate the effects of increasing load on postural sway in two different carrying positions: backpack and waist jacket.**

31 subjects (age 21.7 ± 1.9; 8 male and 22 female) in backpack group and 20 subjects (age 22.5 ± 1.9; 4 male and 16 female) in the waist jacket group participated in the study. The increment of additional load in both groups was 12, 21 and 30 kg. Stabilometry was used to assess the amount of postural sway. Data were collected by a force platform Kistler 9286 AA. The outlines of the measured data were determined by Fourier coefficients. The sway area, total path length, medio-lateral and antero-posterior path length of the centre of pressure were calculated.

In the backpack group the ratio between no load and additional load of 12 kg, 21 kg and 30 kg for total path length was 1.3, 1.6 and 1.7 respectively, for medio-lateral sway it was 1.3, 1.5 and 1.7 and for the antero-posterior sway 1.3, 1.6 and 1.8. The ratio for sway area was 1.8 at 12 kg, 2.5 at 21 kg, and 2.9 at the load 30kg. However, no significant change of the analyzed parameters was found while subjects carried additional load in the waist jacket.

Our results indicate that the participants' ability to maintain steady position while standing was altered by the external load carried in the backpack. The sway linearly increased for all of the measured parameters. Carrying weight in a backpack increases postural sway with increasing weight whereas carrying weight in the waist jacket does not influence the postural sway. The position of load is thus of significant importance for the postural sway.

Keywords — **Stabilometry, postural sway, load placement**

I. Introduction

Postural stability during load carriage is an important issue for different professions and/or activities. For instance, recreational backpackers carry a range of loads on their backs ranging from 8 to 35 kg [1], soldiers up to 50 kg [2], depending on mission requirements, and fire-fighters with their protective clothes and breathing apparatus with the weight of 26 kg [3]. School children of various age daily transport loads on their back ranging from 8.2 % of their body weight and this value increases with age to 12 % or even 20 % of their body weight [4,5].

Intensive studies were performed to discover the impact of load carriage on energy cost, the influence on gait parameters, effect of load distribution and sex differences – review of [6,7], for the soldiers. On the other hand the problem of stability while carrying heavy load has not been much investigated.

Postural steadiness is related to balance function. Intact and effective balance is important when a person is working on higher surfaces, in altered sensory conditions such as on the soft surfaces or in poorly lit or dark environments.

Postural stability is often assessed with stabilometry which defines the amount of postural sway and indicates the displacement of the centre of mass relative to the base of support. Centre of pressure (CoP) calculated from the ground reaction forces of standing subjects represents the outcome of the postural control. Measurement of the CoP movement with a force platform (stabilometry) is a standard procedure for assessment of postural stability. Subjects are asked to stand still on a special platform that is mounted on pressure sensors transmitting data to a computer where the time dependence of the trajectory of CoP (sway) can be monitored.

Little is known about the extent to which carrying an external load on the body affects postural sway parameters. The linear effect of load weight on the postural sway parameters has been observed in the population of young military service subjects [2]. Increased load challenged subjects' stability, reduced the randomness of postural sway and required greater muscle control in order to maintain balance. Altered sensory conditions (eyes closed) and additional load of 26 kg (full fire-fighters equipment) resulted in increased velocity of postural sway [3]. The position of the relatively small load - 12 kg [8] also influenced the amount of postural sway and subjects swayed more while holding the load above their heads as compared to shoulder or knuckle height.

The above studies did not record more than one load [8] and did not compare the load results to the no load conditions [2] or tested only one additional weight [3]. Majority of the research reports study young male population who are trained to carry weights on daily basis. However, recreational backpackers carry load on their backs as well and they differ in age, gender and physical fitness. Thus the purpose of present study was to investigate the effects of increasing load in a backpack upon postural sway as com-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1821–1824, 2009

pared to increasing load in a waist jacket in a population of young college students.

II. Methods and materials

A. Methods

Stabilometry was used to assess the amount of postural sway. Data were collected by a force platform (Kistler 9286 AA) with 50 Hz sampling rate using BioWare program. Raw data were uploaded to a Linux server and analysed by specially developed software. A typical analysis of the stabilometric data started by data smoothing using moving averages over a chosen number of points (usually 10). It then proceeded by plotting the time and frequency distributions, determining the outline of the measured data, calculating its Fourier coefficients and the total path length of the CoP, medio-lateral and antero-posterior path lengths and finished by determining the total sway area [9].

The Statistical Package for Social Sciences (SPSS 15, SPSS Inc., Chicago, IL USA) was used for statistical analysis. Two sample t-test was applied to test the differences between the two groups for each of the load conditions whereas one way ANOVA was calculated to obtain the differences between the load conditions within a group and the significance level was set at 0.05.

B. Participants

Fifty-one healthy college students with no history of musculoskeletal injuries participated in this study. Minimal required body weight was 50 kg - lighter volunteers were not included. 31 subjects were assigned to the backpack group and 20 subjects to the waist jacket group (Table 1). The study was approved by the National Medical Ethic Committee and the participants gave their informed consent prior to the participation in this study.

Table 1 Demographic data of the participants in the study.

	Backpack group	Waist jacket group
	mean (SD)	mean (SD)
No. of participants	31	20
Age (years)	22.54 ± 4.9	22.45 ± 3.5
Height (cm)	171.96 ± 8.5	173.4 ± 7
Weight (kg)	67.16 ± 10.1	65.6 ± 12.6
Gender (m, f)	8 m, 23 f	4 m, 16 f

C. Procedure

Each participant was tested with three additional loads in a backpack or waist jacket: 12 kg, 21 kg and 30 kg. Participants were instructed to stand as still as possible on the force platform with their feet close together, arms at their sides and looking to a point on the wall 2 m away. All of the participants were tested in five consecutive trials, each lasting for 60 seconds.

The backpack group were carrying a Karrimor backpack with the capacity of 45 litres and were instructed to fix it on the pelvis and to adjust the shoulder straps to fit the backpack as comfortable as possible. Parameters of the body sway were measured first without additional load, then 12 kg sand bags were placed into the backpack. Afterwards the sand bags were added to the backpack to reach the weights of 21 and 30 kg. The last test was a repeated measurement without any additional load.

The subjects in the waist jacket group wore a jacket which consisted of pockets where diving weights (8x5x3 cm, 2 kg) could be placed at the hip, waist and chest height. For the purpose of our study the weights were placed around the waist, half anteriorly and the other half posteriorly. The measurements were performed in the five different load conditions with the same protocol as used for the backpack group.

III. Results

A. Backpack group

The parameters of the postural sway: total path length of the CoP, medio-lateral and antero-posterior path lengths and the sway area significantly increased with the added load in

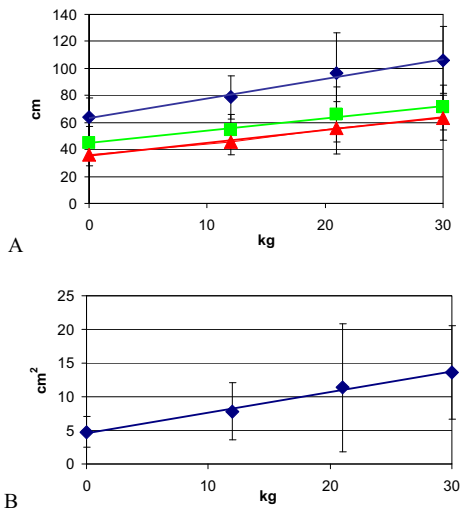

Fig. 1 Linear relationship between four different load conditions for CoP excursions at different loads in the backpack group: (A) total path length (diamond), mediolateral path (square) and anteroposterior path (triangle); (B) total sway area.

a backpack as compared to the no load conditions ($p < 0.01$). Compared to no load, 12, 21 and 30 kg loads resulted in the increase of the total path length by 27.1 %, 55.9 % and 70.9 %, respectively, whereas the medio-lateral sway increased by 26.4 %, 54.2 %, 66.3 % and the antero-posterior sway by 30 %, 60.8 % and 80.4 %. Sway area increased even more with the load: 84.5 % at 12 kg, 154.6% at 21 kg, and 289 % when the load was 30 kg (Fig 1).

Linear regression showed that the total path length increased by 1.6 cm per kg ($R^2 = 0.99$), medio-lateral sway by 0.9 cm/kg ($R^2 = 0.98$), antero-posterior sway by 0.94 cm/kg ($R^2 = 0.99$) and the sway area by 0.3 cm^2/kg ($R^2 = 0.99$). These relations were well reproduced by the linear function as seen from Fig. 1.

B. Waist jacket group

The statistical analysis of the waist jacket results showed that the parameters of the postural sway did not significantly differ between the four load conditions with the p values ranging between 0.306 and 0.938 (Fig. 2).

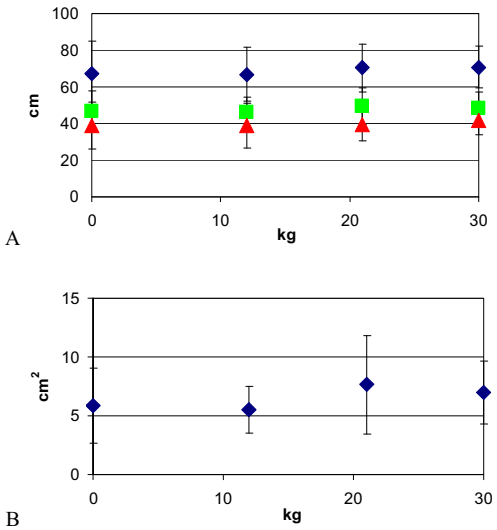

Fig. 2 Mean and standard deviation values for CoP excursions at different loads in the waist jacket group: (A) total path length (diamond), mediolateral path (square) and anteroposterior path (triangle); (B) total sway area.

C. Between group analysis

The t-test revealed that the difference between the backpack and waist jacket groups was not significant at the no load conditions (the first and the last measurements) while the differences between the two groups were statistically significant for the loads of 12 kg ($p = 0.011$) and even more so for 21 kg and 30 kg ($p < 0.001$) as shown in Fig. 3.

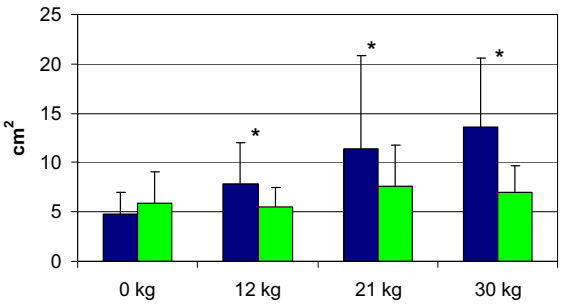

Fig. 3 The influence of two different placements of loads on the sway area for the backpack (left) and the waist jacket groups (right).

IV. Discusion

In the present study we investigated the influence of increased load carriage on the postural sway parameters. Additionally we investigated the influence of two different load placements. Our study design differed from the previous ones in the volunteers sample. Namely, majority of the reported studies investigating parameters of postural sway and other related studies were performed on young, fit soldiers who were trained to carry different loads, whereas our participants were young college students who reported to participate in recreational activities on the average only three times a week.

Our results indicate that the participants' postural steadiness, while standing with different loads in a backpack, was altered. The sway measures showed significant linear increase in the length of CoP excursions in the antero-posterior and medio-lateral directions as well as the sway area. Similar linear dependency on the increasing load was described for young soldiers for all of the postural sway parameters [2]. However, that study did not compare the results to the no additional weight situation. Besides, in our study we repeated the no load condition as the last one in the series of five measurements. Namely, the random nature of the CoP movements, which results in the variability of the postural sway [10], led us to design the additional control measurement. It has shown that there was no statistically significant difference between the both no weight measurements which allows us a higher level of confidence in the linear relationship between the additional load and the amount of postural sway. Similar conclusions were obtained by Punakallio et al [3] for professional fire-fighters carrying 15.5 kg steel air bottles on their backs - their weight was found to significantly impair both postural and functional balance.

Besides, the position of the load has been shown to influence subjects' energy expenditure: evenly distributed load in a double pack [7] required less energy as compared to a

backpack. Our results of stabilometry showed similar relationship for the postural sway parameters - increased weight placed evenly around the waist did not influence the size of CoP movements contrary to the case when the weight was carried in a backpack. The comparison of the results at the same additional weight in different positions showed no differences of the postural sway parameters in both no load conditions whereas with all other weights (12 kg, 21 kg and 30 kg) the differences between the two weight positions were statistically significant (except for the antero-posterior sway at 12 kg).

The control of the centre of mass position is expected to differ with the position of load on the body. For instance, load in the backpack requires more forward body lean and more forward rotation about the hips and ankle [11] and the moment at the joints is greater when the load is placed higher on the body [12]. The difference between the sizes of CoP displacements could be attributed to larger rotational inertia of the load that is higher an not evenly distributed around the torso.

The variability of CoP fluctuations and increased postural sway has been traditionally considered as a sign of loss of control, usually related to the deterioration due to age or disease. More recently this variability has become considered an essential element of the movement parameters that are under direct control of the central nervous system [13,14]. In the waist jacket group the variability between the subjects, expressed as standard deviation, decreased with the increasing load (Fig.2). These results indicate that with increasing weight most of the subjects adopted similar strategy. Decreased variability could also be attributed to increased stiffness of the postural muscles. On the other hand, in the backpack group the sway parameters and the variability between the subjects increased with increasing load which may indicate different control strategy in the situation when the load is placed in the backpack, which shifts the centre of mass posteriorelly, as compared to the load placed in the waist jacket where its position is not changed.

V. Conclusions

Maintaining of balance in a situation of additional weight carried on the persons back is important for different occupations as well as for the recreational purposes. Carrying weight in a backpack linearly increases postural sway parameters with increasing weight whereas evenly distributed weight does not affect the sway parameters. Weight distribution is thus an important parameter that influences postural sway and balance maintenance. For the prevention of balance related injuries it is advisable to consider not only the size of the carried weight but also its distribution.

Shape Analysis of Postural Sway Area

F. Sevšek

University of Ljubljana, College of Health Studies, Ljubljana, Slovenia

Abstract — **Measurement of the human body centre of pressure (COP) movement (postural sway) with a force platform is a standard procedure for the assessment of postural stability. Recently we proposed a method where the outline of the sway region is expressed in terms of Fourier coefficients determined by asymmetric fitting and minimal outline bending. The index of sudden excursions (ISE) is defined as the ratio of this sway area to the one obtained by the standard principal component analysis. The meaning and the discriminative power of this index is still an open question, which is addressed in present work.**

Stabilometric data were simulated by considering movements of COP in a potential that consisted of a flat central ellipsoidal region and increased quadratically outside it. Using random walk procedure, combined with the Metropolis algorithm, positions of COP were simulated. The parameter called temperature was defined so that it was related to the probability of COP movements against the potential.

A large number of data were calculated for a set of different values of the temperature and the ISE values were determined. For the series of 3000 points the average values of ISE were found at first to increase with temperature from 1.3 to 1.85 as the temperature increased from 0 to 0.195 and then started to decrease towards 1.2 with temperature.

It was shown that ISE is sensitive to the actual shape of the measured postural sway area. It increases if there is a small number of large excursions of the COP outside the central region, which are mostly missed by the conventional analysis.

Keywords — **stabilometry, postural sway, force platform, sway area**

I. Introduction

Measurement of the movement of the human body centre of pressure (COP) with a force platform (stabilometry) is a standard procedure for assessment of postural stability. Here a subject stands still on a special platform that is mounted on pressure sensors that transmit data via analogue to digital converter to a computer. In such a way, with suitable software, the time dependence of the trajectory of the COP (postural sway) can be determined. Thus obtained stabilogram can be used to assess the balance properties of the investigated subjects. Although this method is well established, the interpretation of the results and the physiological meaning of the calculated parameters is still an open issue. Besides the standard parameters such as COP trajectory length, velocity, displacements and frequency distribution, the interpretations in terms of non-linear dynamics are also very promising [1]. Yet a simple measure to discriminate stabilograms of different populations, of mostly elderly subjects, is needed. For this purpose the shape and size of the area covered by the COP is determined.

The usual method to determine the area of a stabilogram is by the principal component analysis (PCA) of the covariant matrix [2]. The eigenvalues (σ_0^2) of the covariant matrix (σ_{xy}^2)

$$\sigma_{xy}^{\ 2} = \frac{1}{N}\sum_{i=1}^{N}(x_i - \bar{x})(y_i - \bar{y}) \tag{1}$$

are calculated as

$$\sigma_0^{\ 2} = \frac{1}{2}(\sigma_{xx}^{\ 2} + \sigma_{xy}^{\ 2} \pm \sqrt{(\sigma_{xx}^{\ 2} - \sigma_{xx}^{\ 2})^2 + 4(\sigma_{xx}^{\ 2})^2}) \tag{2}$$

where $\bar{x}$ and $\bar{y}$ are the average values and the summation is done over all N measured points.

The sway area is usually reproduced by the ellipse with the two principal axes of the size 1.96 σ_0^2. It thus includes 95 % of points along each axes if the distribution is bivariate Gaussian and as a result only 85.35 % of the data points are within the perimeter of the so defined ellipse [2]. This method reflects the general properties of the sway area but is not sensitive enough to differentiate between clinical conditions where the important changes are expected to be seen mostly near in the sway area perimeter.

This led us to develop a new method based on the Fourier analysis of the sway area outline (FAO) [3, 4]. It was shown that such an analysis realistically approximates the postural sway area and also gives the indications about its shape. This method is based on the observation that a suitable approximation to the sway area is a region determined by a rather simple, mostly convex outline which is predominantly at the outer border of the sway area. From the measured stabilogram the outline is determined by a boundary following algorithm [5]. Such an outline can be reproduced by a Fourier series:

$$\mathrm{R}(\varphi) = \mathrm{R}_0 + \sum_{m=1}^{m_{\max}}(A_m \cos m\varphi + B_m \sin m\varphi) \tag{3}$$

where φ is the polar angle to a point at the outline in a chosen coordinate system, A_m and B_m are the appropriate Fou-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1825–1828, 2009
www.springerlink.com

rier coefficients and m_{max} the maximal number of coefficients used to describe the outline - the more coefficients are used, the smaller details of the shape are reproduced. So defined Fourier coefficients are similar to the Fourier descriptors usually employed in shape recognition procedures [6, 7, 8], the difference is that our outline points are function of the angle rather than the distance along the outline path.

The fitting of the sway area outline is done by minimizing the characteristic function (F):

$$F = \sum_{i=1}^{N} \omega_i (R(\varphi) - R_i)^2 + \gamma \sum_{m=0}^{m_{max}} m^2 (m-1)^2 (A_m^{\,2} + B_m^{\,2}) \quad (4)$$

where the first term is the asymmetric sum of the squares between the calculated (R(φ)) and the measured (R_i) outline points. The asymmetry parameter ω determines the distance the fitted curve can penetrate inside the measured sway area. It equals to one when the distance of the calculated point from the chosen centre is larger than the measured one otherwise it has a preselected value. The second term in eq.(4) is related to the outline bending energy and penalizes the short distance undulations of the outline, depending on the value of the parameter γ.

From our previous work [3] the ratio between the areas as determined by the FAO and PCA methods seemed to be the most promising discriminating parameter between the stabilograms that differed mainly by the small number of COP excursions from the central region. We thus named it the index of sudden excursions (ISE). To better understand the meaning and properties of this index we, in as follows, analyze the simulated data using the same procedure as for the experimental data.

II. Methods

The meaning of the index of sudden excursions (ISE) which is defined as the ratio between the FAO and PCA areas was thoroughly studied by analyzing simple simulated data.

The fluctuation of the COP position was described by a model that was equivalent to the movement of a particle in a potential that is flat in the central ellipsoidal region and quadratic outside it. In such a way COP could move outside the chosen central region, but the probability of finding it there decreased with the distance from the boundary whereas the temperature parameter (T) defined this probability.

Thus the calculations were done by considering completely free random movement of the COP within a chosen ellipsoidal region and with Boltzmann distribution of the probability to find it outside. For this purpose random walk procedure was used combined with Metropolis algorithm

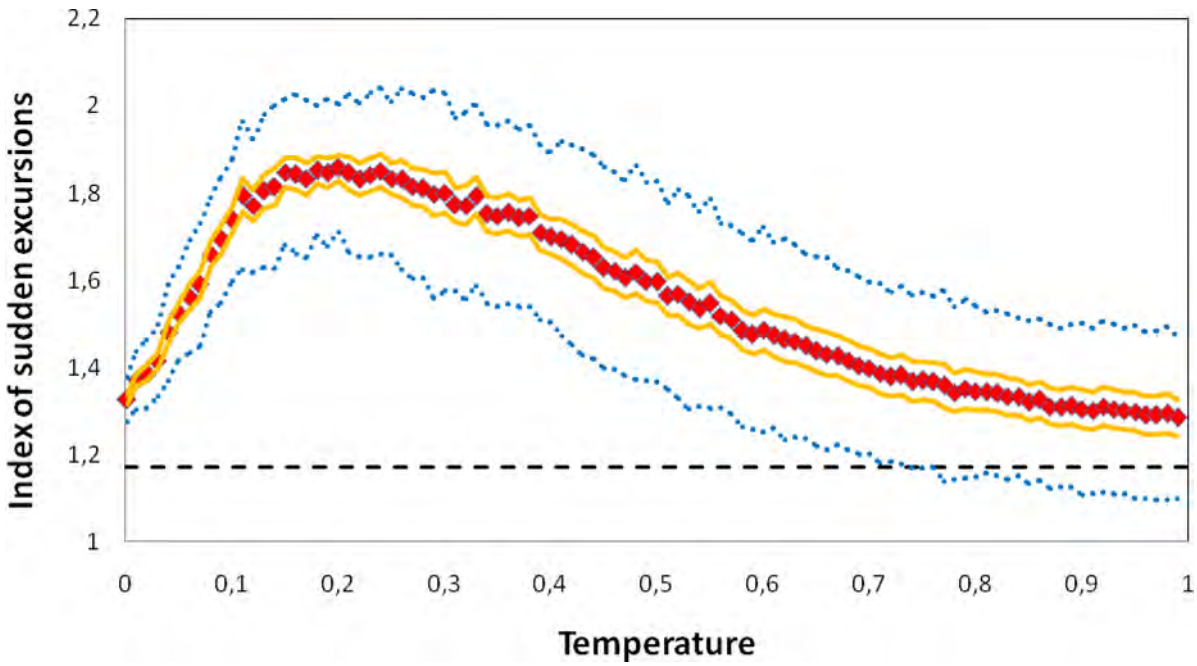

Fig. 1 Index of sudden excursion (ISE) as a function of temperature parameter in units of 1/2π, as defined in text, for the simulated data of 3000 points. Besides the calculated average values of 20 simulation runs (red squares), the lines represent the region of the standard error (yellow) and standard deviation (dotted blue) whereas the dashed line at 1.2 represents the low temperature limit.

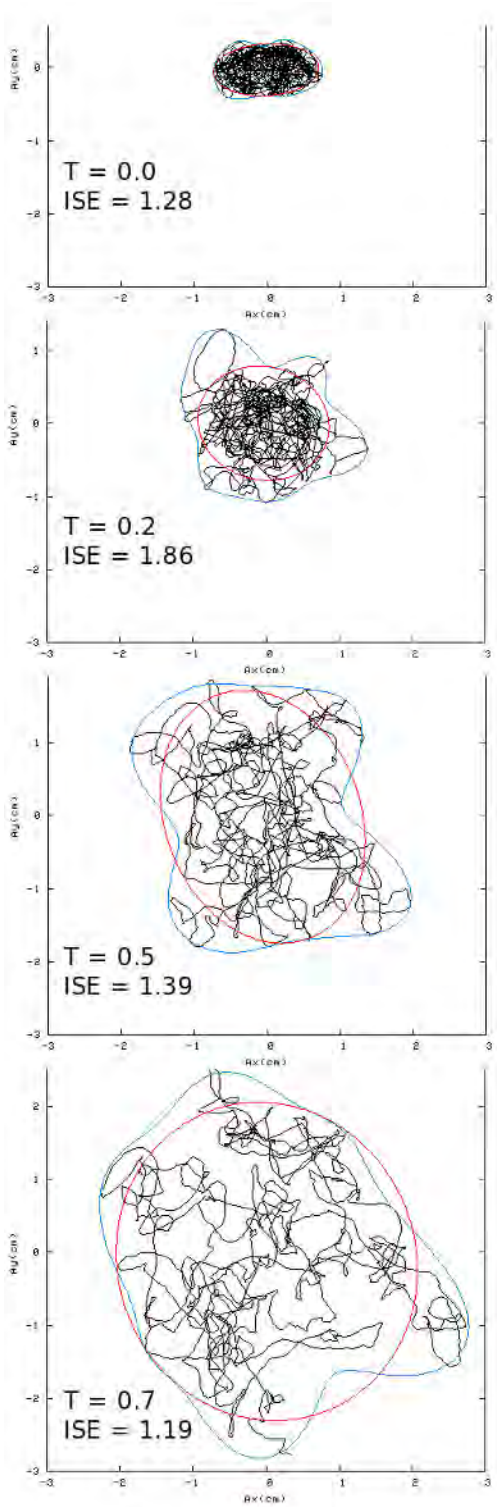

Fig. 2 Simulated data (black lines) for four different temperatures with the PCA ellipsis (red) and the FAO outlines (blue).

[9]. In each step the COP position was randomly moved. If the resulting position was within the central ellipsoidal region it was accepted and the procedure was repeated. But, when the resulting position was outside this region and the previous one was inside it, the distance (ΔR) from the border was calculated. Such a move was accepted only with the probability $\exp(-\Delta R^2/T)$, where ΔR^2 played the role of energy that was proportional to the square of the distance, whereas T corresponded to the temperature. The procedure was similar also in the case when the previous point was outside, but in this case the calculated value ΔR was the difference between the distances of the two points from the centre. If ΔR was negative, the move was accepted, otherwise it was accepted only with the probability $\exp(-\Delta R^2/T)$. After a large number of steps thus generated trajectory samples the configurations in accord with the canonical Boltzmann distribution. [9]

The actual calculation always started with a point somewhere inside the ellipsoidal region and the first few ten thousand points were rejected to allow the system to thermalize. After collecting the required number of data points they were analyzed with the same procedures as the experimental measurements.

The computations were mostly performed on a PC-type computer based on Pentium 2 GHz processor, running under Linux operating system. The data simulation program was written in Fortran and used the portable pseudo-random number generator ran3 [10], based on a subtractive method that has very long period and no evident defects.

III. Results and Discussion

Data were simulated as described above with the Boltzmann distribution at different temperatures. Choosing arbitrary the ratio of the ellipsis axis to be a/b = 2 and the maximal step length in each simulation to be equal to the semiminor axis of the central ellipse (b) the only free parameter of the model remained the temperature (T). As it was measured in the units of b^2 the properties of the model were independent of the actual dimension of the simulated region. After eliminating the first 20000 steps the next 60000 moves were considered. This corresponded to the 20 consecutive series of 3000 points that were each comparable to 60 s of the experimental data with 50 Hz sampling rate.

As an example the simulated data for four different temperatures are shown in Fig. 2. The size of b was chosen to be $(1/2\pi)^{1/2}$ so that the area of the central ellipse was equal to one.

It may be noticed that for low temperatures most of the COP fluctuations are within the central region and the principal component method reproduces well the general prop-

erties of the area. As it encompasses 85.35 % of all points, the area ratio between the real outlines, as determined by the FAO method, and the one of the PCA, is expected to be close to 1.2 for long enough simulations. Thus at low temperature increasing it results in more excursions of the COP outside the central region during the observational time. The FAO to PCA area ratio thus at first increases with the temperature and is expected to depend upon the observational time - longer times result in more regular shapes. But at a certain temperature this trend is inverted - still further increasing the temperature results in lowering the FAO to PCA area ratio. This is not surprising since at higher temperatures the positions of the COP get more and more evenly distributed over the entire region.

This behavior is evident from the Fig. 1 where the average values of ISE for 20 simulation runs are shown together with the regions of the standard error and standard deviation. It is interesting to note that for our simulations the area ratio is maximal at the temperature 0.195 ± 0.03 b^2 where it reaches the value of 1.850 ± 0.004. Due to the random nature of this calculation the exact position and value of this maximum cannot be determined from the calculated data as shown in Fig. 1.

IV. Conclusions

By analyzing a large series of simulated data it was shown that ISE is sensitive to the actual shape of the measured postural sway area. It increases if there are small number of large excursions of the COP outside the central region, which are mostly missed by the conventional analysis. Anyhow, the applicability and usefulness of the proposed index to clinical data still remains to be investigated.

Concurrent Simulation of Morphogenetic Movements in Drosophila Embryo

R. Allena[1], A.-S. Mouronval[1], E. Farge[2] and D. Aubry[1]

[1] MSSMat Laboratoire, CNRS UMR8579, Ecole Centrale Paris, Chatenay-Malabry, France

Abstract — **The present work describes a 3D Finite Elements model of the *Drosophila* embryo designed to investigate large strains of epithelial tissues during embryogenesis. Three movements standing out for specific mechanical constraints are simulated: ventral furrow invagination, cephalic furrow formation and germ band extension. A deformation gradient decomposition is used to couple an imposed active deformation, according to the morphogenetic movement considered, and a passive elastic deformation consequence of the latter. The model also imposes boundary conditions such as the rigid contact with the vitelline membrane and the yolk pressure. The concurrent simulation of the three events is allowed; here we present the mechanical and the numerical formulation of the highly non-linear problem with special emphasis on the incorporation of cell deformations into a sound mechanical framework.**

Keywords — **Drosophila, Morphogenetic movements, Cell deformation**

I. Introduction

During embryogenesis nonlinear anisotropic tissues undergo large deformations including growth and contraction so that their final configuration and the physical form of the organs are optimally designed to carry out their specialized functions. Therefore the understanding of the mechanics of the four-dimensional process of morphogenesis is required [13].

Drosophila embryo starts as a single cell surrounded by a semi-hard *vitelline membrane* and only after fertilization and mitosis, nuclear division begins with the formation of the cellular blastoderm at the fifth stage. It is at stage sixth that *gastrulation* starts with the mesoderm invagination that takes about twenty minutes to complete. The invagination of the blastula creates the mesodermal and ectodermal germ layers. The sequence of morphogenetic movements starting at the onset of *gastrulation* is tightly controlled by the cascade of developmental gene expression. But latest experimental observations have demonstrated that the expression of such genes is often influenced by mechanical stresses [4], [8], [9]. While genetics and molecular processes of *Drosophila* embryogenesis have been well investigated during the last decades, only recently mechanical modeling have become important to a complete understanding of the biological system as a whole. Several 2D models have been developed [1], [2], [10], [12] and in different ways they solve the biomechanical challenge of *Drosophila gastrulation* but one common drawback is that they allow to simulate only one mechanism at the time. Furthermore only Brodland [5] and Conte [6] have developed so far 3D models so that they have been able to take into account all the aspects of the problem.

The present work provides a unique 3D Finite Elements model able to concurrently simulate three morphogenetic movements: ventral furrow invagination, cephalic furrow formation and germ band extension. Therefore it is possible to consider the eventual influence that one event may have on the other two and vice versa. Also we analyze the elementary and mesh independent deformations occurring to the material pseudo-cells along the simulations.

II. Theoretical approach of the problem

Large strains of the mesoderm are considered using a deformation gradient decomposition method where the total deformation of a cell is decomposed into a non-stress-generating deformation relative to the reference configuration (what we have defined as individual deformation for each cell) and a stress-generating elastic deformation due to the deformation incompatibility between adjacent cells. The model presented here does not take so far into account potential causes for the active deformations; no forces external to the cell layer are implemented, except for the required *yolk* pressure and the contact between the mesoderm and the rigid *vitelline membrane*.

If x represents the current position of a point in a cell of the mesodermal tissue and p its reference position, the total deformation is described by its deformation gradient

$$F = D_p x \tag{1}$$

During morphogenesis, each cell tends to change its shape because of endogenous mechanical or chemical stresses. These individual changes must be considered with the fact that the cells are part of a system and thus in contact with one each other. Therefore single shape modifications lead to a new configuration of the embryonic tissues. If we

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1829–1832, 2009
www.springerlink.com

impose the initial individual deformation occurring to each cell, we can define the relative deformation gradient as

$$F_0 = F_0\left[p, \alpha(t)\right] \tag{2}$$

function of the initial position of a material point p and of some parameters $\alpha(t)$ depending on the time.

Thus the elastic deformation gradient, which triggers the mechanical stresses, is

$$F_e = FF_0^{-1} \tag{3}$$

Mesoderm is considered here as a Saint-Venant material because it seemed to us the most suitable choice even if hyper-elastic characteristics could have been used [2], [5], [6]. Let be w the virtual displacements field, we can finally introduce the virtual work, which results to be function of π, the first Piola-Kirchhoff stress, therefore of F_0

$$W = Tr\left(\pi\, D_p w^T\right) = f\left(F_0\right) \tag{4}$$

An important aspect to be taken into account is the contact between the mesoderm and the stiff *vitelline membrane*. We did not model the shell surrounding the embryo but we use an adaptive penalty method to sort out this issue. The main idea is to introduce a surface force, which pushes back the mesoderm when it penetrates the *vitelline membrane*, while no force is applied when penetration is not detected. Two situations can be contemplated so that the applied force f_{se} is

$$\begin{aligned} s < 0 \quad & f_{se} = t_n n_e \\ s > 0 \quad & f_{se} = -p_e\left(s\right) n_e = -\left(t_n + k_n s^2\right) n_e \end{aligned} \tag{5}$$

where s represents the overlapping, along the outward normal n_e, between a generic point and the vitelline membrane while t_n is a small constant force and k_n a parameter depending on the pre-defined maximal admissible penetration $s_{\max}$.

The *yolk*, a viscous material, which fills the embryo, is not meshed here because its mechanical characteristics are still not well known. Anyway it plays an important role exerting a pressure on the mesoderm, which can influence the response of the system. To take into account this aspect, we decided to compute a uniform pressure p_y coupled with the global volume change of the *yolk* [6].

The surface force f_{sy} is assumed to be

$$f_{sy} = -p_y n_y = \left(p_{y_0} - k_y\left(V_y - V_{y_0}\right)\right) n_y \tag{6}$$

where p_{y_0} and V_{y_0} are the initial pressure and volume of the *yolk*, k_y the *yolk* compressibility and V_y the actual volume defined as follows

$$V_y = \int_{\Omega_y} \frac{div\, x}{3} dV = \frac{1}{3}\int_{\partial\Omega_y} \left(x, n_y\right) dS_x \tag{7}$$

where n_y is the inward positive normal on the internal surface of the mesoderm.

It has to be noticed that, while for the contact with the *vitelline membrane*, the surface force depends on the local displacement, in the case of the *yolk* pressure, p_y is function, by V_y, of the displacements of the whole interior boundary of the mesoderm.

III. Mechanical Modelling of the Embryo

As mentioned before, only mesoderm was modeled; it is represented as an ellipsoid whose dimensions have been deduced from experimental manipulations. It is 500 μm in length and it has a diameter in the cross-sections equal to 150 μm, while thickness is 15 μm (Fig.1a, b). We choose from literature [14] a Young's modulus of 100Pa and a Poisson's coefficient $\nu = 0.45$.

Each one of the three movements we simulate, stand out for specific biological forces occurring to the cells that induce lengthening, intercalation, rearrangement, flexion, apical constriction and apico-basal elongation.

We analyze each relative context from the mechanical point of view, trying to describe the different events.

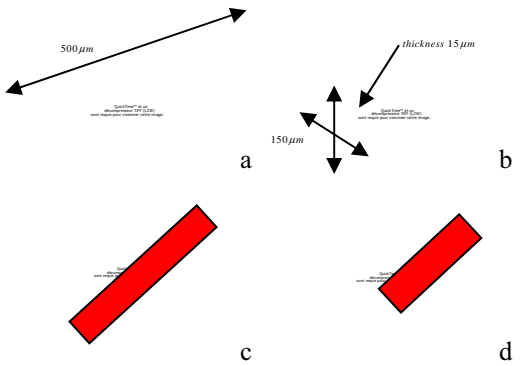

Fig.1 (a,b) Geometry of the embryo. In red the regions where the apical constriction and the apico-basal elongation (c) and the convergent-extension movement (d) have been applied respectively.

A. Ventral furrow invagination and cephalic furrow formation

Ventral furrow invagination is the first movement of the *Drosophila* embryo and one of the most well studied in biology [7]. At this stage of morphogenesis, the embryo is composed of a single layer of columnar epithelial cells having their apical surfaces outward facing and the apico-basal axis aligned along the axis of radial symmetry and each cell is in lateral contact with its neighboring. Several movements can be observed during the invagination, but we focus only on apical constriction and apico-basal elongation of the cells. Practically cells change their shape from cylindrical to trapezoidal form inducing the curvature necessary for the invagination of the mesoderm into the *yolk*.

Same mechanical forces drive the formation of the cephalic furrow at about 65% egg length, simulteously with the ventral furrow invagination, but this time the reference axis is inclined at about 30° with respect to the vertical axis. Using cylindrical coordinates (r,θ,z), the initial position (before any deformation) $p_0(\theta,z)$ of a point along the middle surface of the mesoderm, defined parametrically by $\rho(z)$, is

$$p_0(\theta,z) = \rho(z) i_r(\theta) + z\, i_z \tag{8}$$

Moving trough the thickness of the mesoderm, the position of a generic point becomes

$$p(\theta,z,\zeta) = p_0(\theta,z) + \zeta n_0(\theta,z) \tag{9}$$

where $n_0(\theta,z)$ is the normal vector to the middle surface. The apical constriction and the apico-basal elongation are applied on a restricted area of the ventral region of the embryo (Fig.1c) and the final position after deformation can be shown to be

$$x(\theta,z,\zeta) = p_0(\tilde{\theta}(\theta,\zeta),z) + \left(1+\alpha^{abe}\right)\zeta n_0(\tilde{\theta}(\theta,\zeta),z) \tag{10}$$

where

$$\tilde{\theta}(\theta,\zeta) = \theta + \alpha^{ac}\zeta m(\theta) \tag{11}$$

is the deformation angle depending on α^{ac}, the amplitude of the apical constriction, and on $m(\theta)$, which is a periodic function allowing to have the same deformation for each cell, and α^{abe} is the amplitude for the apico-basal elongation. For the cephalic furrow, we started by modeling it perpendicular to the vertical axis so that the final position x of a generic point can be written as

$$x(\theta,z,\zeta) = p_0\left(\theta,\tilde{z}\left(\alpha^{ceph},m(z)\right)\right) + \zeta n_0\left(\theta,\tilde{z}\left(\alpha^{ceph},m(z)\right)\right) \tag{12}$$

with z here again depending on a periodic function $m(z)$ and on the amplitude of the deformation α^{ceph}.
Finally F_0 can be computed for both simulations from

$$F_0 = \frac{\partial x}{\partial\theta}\otimes\nabla_p\theta + \frac{\partial x}{\partial z}\otimes\nabla_p z + \frac{\partial x}{\partial\zeta}\otimes\nabla_p\zeta \tag{13}$$

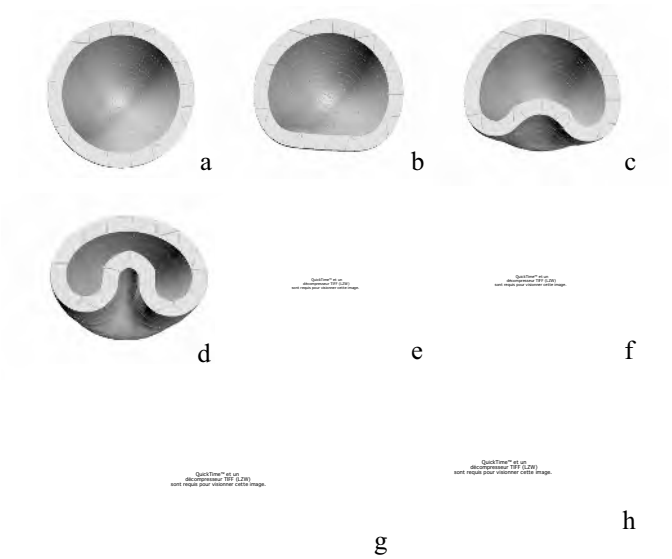

Fig.2 (a:e) Successive phases of ventral furrow invagination; (e) Global view of the shape changes occurring to the material pseudo-cells. The more the mesoderm invaginates, the higher the apical constriction. Also the constriction switches from apical to basal according to the tissue bending; (f) Influence of the apico-basal elongation on the invagination; (g) Preliminary results for a cephalic furrow perpendicular to the vertical axis with a pseudo-cell in the cross-sectional view (h) undergoing apical constriction.

B. Germ band extension (GBE)

After invagination of the ventral furrow and the formation of the cephalic furrow, germ-band starts to extend at ventral region of the embryo.

Germ band extension is a convergent-extension movement of the cells, which may be a passive response to some forces generated elsewhere in the embryo or active, force-producing process. Cells lengthen along the dorsal-ventral axis and shorten from the dorsal to the ventral region. Actually during GBE tissues change their morphology due to interactions occurring between cells rather than interactions with external boundaries. At this stage no cell growth and appropriate changes in cell shapes have been observed,

probably rearrangement and intercalation of cells have to be considered [3], [11].

Let p_0 be the initial position of a point on the middle surface of the mesoderm (Eq. [8]) and p the position of a point trough the thickness of the mesoderm (Eq. [9]).

We propose a uniform membrane convergent-extension deformation movement applied in the region of the germ band (Fig.1d), so that the final position x after deformation comes to be

$$x(\theta, z, \zeta) = p_0(\tilde{\theta}, \tilde{z}) + \zeta n_0(\tilde{\theta}, \tilde{z}) \qquad (14)$$

where $\tilde{\theta} = (1 + \alpha_\theta^{gbe})\theta$ and $\tilde{z} = (1 + \alpha_z^{gbe})z$, with α_θ^{gbe} and α_z^{gbe} are the amplitudes respectively of the extension along the anterior-posterior axis and of the shortening from the dorsal to the ventral region. Finally F_0 can be again computed as in Eq. [12].

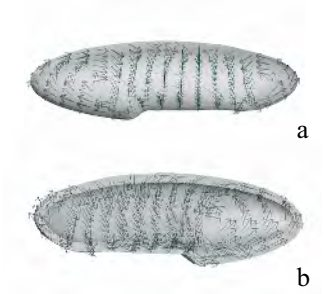

Fig.3 Frontal (a) and cross-sectional (b) views of germ band extension simulation. Tissues elongate towards the anterior and posterior pole, while they converge from the dorsal to the ventral region of the embryo.

IV. Conclusions and perspectives

Our model presents a concurrent simulation of three morphogenetic movements; the original contribution of this work is that we take into account elementary and mesh independent deformations of the material pseudo-cells. This represents a useful tool to analyze the eventual long-range feedback between mechanics and gene expression.

Still many aspects have to be investigated in order to have a more global and relevant view of the problem.

First of all, we think the geometry of the embryo can influence the response of the entire system; for this reason we have designed a more suitable embryo in which the curvature is more similar to the one of the Drosophila: it varies from positive in the ventral region to negative in the dorsal.

Interesting would be also to analyze the self-contact, which may occur during ventral furrow invagination and thus engenders new repulsive forces.

Finally, for what concerns the mechanical characteristics of the mesoderm, a non-linear constitutive behavior will be implemented for further simulations.

Abstract — **A nerve conduit with suitable biomechanical and biochemical environment may improve the regeneration of axons of the injured peripheral nerve. The PC-12 cells were cultured in PRMI medium 1640 and then axonal growth was induced by using nerve growth factor. Time-course morphological changes of the cells were analyzed by using an optical microscope. Regional viscoelasticity and adhesion force of axons were measured by an atomic force microscope by using ramp-and-hold indentation and scratching. The data were fitted with a quasi-viscoelastic model by a method developed previously. Morphological results revealed that cell body length and branch number were highly correlated with axonal growth process and average axon length can be used to define the stage of growth process. Electrical field with intensity of 100mV/mm could enhance the growth rate of axons by 2.88 folds. AFM results showed that the mean elastic modulus of axon increased with stage and the growth cone region has higher Young's modulus than the middle region. Furthermore, the adhesion force on middle region of axon was smaller than that of proximal region and growth cone.**

Keywords — **PC-12 cell, Quasi-linear-viscoelasticity, Axon growth, Atomic force microscopy, Electrical stimulation.**

I. Introduction

The nerve conduit plays an important role on auxiliary nerve tissue and cell regeneration during the therapy of injured peripheral nerve [1]. The efficiency of axon regeneration in the nerve conduit depends on many factors such as the neurotrophic factors, the nerve growth factors, the formation of fibrin bridge and the migration of fibroblasts, regenerating axons and Schwann cells [2]. In the past, the silicone rubber has been adopted for conduit material. However, it is prone to body rejection or compressing surrounding nerve tissue and might have to be removed by second operation after full regeneration of nerve. To avoid this, biodegradable materials such as PLA, PGA, PLGA and PCL coated with extracellular matrix to improve the adhesion of Schwann cell are utilized [3]. Many researches suggest that electrical stimulation may accelerate the regeneration of axons and yet the regenerated axons have smaller diameter than the intact axons. It is believed that contractile myofibroblasts in the nerve tissue may hamper the outgrowth of axon along the fibrin bridge. Exploring the biomechanical properties of the axon during the growing process and the effects of static electrical field on axonal growth may help the design of new nerve conduit.

Atomic force microscopy (AFM) has become a useful tool for studying morphology and biomechanics of cells. Using the Hertz contact model or modified Hertz model, the elasticity of many cells such as erythrocytes, platelet, fibroblasts, and endothelium have been investigated [4]. Recently, the viscoelastic properties of 3T3 fibroblasts are analyzed [5]. To explain the motility of 3T3 cell, the viscoelasticity of lamellipodium is studied [6]. The morphological and mechanical properties of different regions of growth cone of Aplysia bag cell are reported in [7].

The goals of this study were three-folds: First, growth of axonal of the PC-12 cell was quantified from morphological analyses and the effect of electrical stimulation on axonal growth was evaluated. Second, AFM ramp-and-hold indentations on three regions of the growing axons were performed and quasi-linear viscoelasticity of the growing axons was studied. Third, the regional variations of axonal adhesion on different substratum were compared by AFM detachment tests.

II. Materials and Experiments

Rat adrenal pheochromocytoma cells (PC-12) was the experimental subject [8]. Before the experiment, the cells were cultivated at 37 deg C, 5% CO_2 in RPMI 1640 medium supplemented with 10% horse serum and 5% fetal bovine serum, penicillin, streptomycin and sodium pyruvate. The medium was replaced every 48 hours. In the experiment, the cells were plated on collagen-coated 35 mm cell culture dishes. Nerve growth factor (100ng/ml) was added to induce axon growth. The dish was put inside an environment control system (Tokai Hit, Inu-Onics-F1) under 37 deg C and 5% CO_2. The system was attached on a phase-contrast inverted microscope (Nikon, TE2000-U) equipped with a CCD camera and image acquisition system (Fig.1a). The micrographs of the cells were then taken every 20 minute for 48 hours by the image system automatically. In the electrical stimulation experiment, a pair of parallel Pt-Ir wires was used to apply electrical field intensities of 75mV/mm and 100mV/mm (Fig.1b).

www.springerlink.com

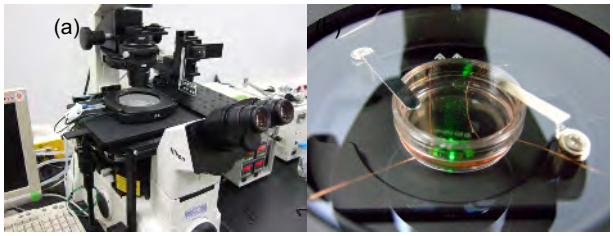

Fig. 1 (a) The environmental control system and the inverted microscope system (b) the parallel Pt-Ir wires for applying electrical filed

From each frame of the micrograph film, cell length (long axis), number of axon branches and branch lengths of selected cells were measured and recorded by using the image process software. Fig. 2 showed definitions of cell length, L_0, axon branch number, N, and branch length, L_i. Since variations of above parameters among cells were quite large so averaging and normalization were used. The average axonal length, L_{ave} (t), at time t is calculated by:

$$L_{ave}(t) = \sum_{i=1}^{N} L_i(t) \ / N(t) \cdot \tag{1}$$

where $L_i(t)$ was the length of i^{th} neurite and N(t) the number of neurites at time t. The normalized total length of axons, $L_{nor}(t)$, was computed as:

$$L_{nor}(t) = \sum_{i=1}^{N} L_i(t) \ / \ L_0(t) \tag{2}$$

where $L_0(t)$ was the cell length at time t. The relative change of axon length, $L_{rel}(t)$, was given by:

$$L_{rel}(t) = \sum_{i=1}^{N(t)} L_i(t) - \sum_{i=1}^{N(0)} L_i(0) \tag{3}$$

These morphological parameters were first analyzed to define the stage of growth process in biomechanical analyses.

An atomic force microscope AFM (Agilent 5500) was employed to scan the surface of the axon by touching mode. The top of the cross section could be allocated and indented.

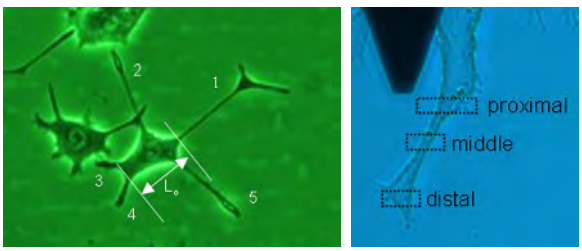

Fig. 2 Definitions of branch number, cell length and branch length (Left), regions of the axon (Right)

Since the biomechanical properties of axon might be region and growth stage dependent, the ramp-and-hold indentation was performed on proximal, middle and distal regions (Fig. 2). The probe was raised from the contact point by 2.5 μm and then rest for 10 seconds. Then it was descending with a velocity of 100 nm/sec and when the indentation depth reached 40% of the initial height the probe was kept still for 120 seconds. Based on the geometry of the probe, the deflection signal and the PZT command, a quasi-linear-viscosity model combined with the Bilodeau mode of the cell could be fitted. A method was also developed to compensate for the creeping of PZT. The QLV model of the cell could be written as:

$$F(t) = \int_{-\infty}^{t} G(t-\tau) \frac{\partial F^{(e)}(\delta)}{\partial \delta} \frac{\partial \delta(\tau)}{\partial \tau} d\tau$$

where G(.) was the reduced relaxation function, F was the measured indentation force and δ the indentation depth and $F^{(e)}$ the elastic indentation force.

$$F^{(e)}(\delta) = 0.753 \frac{\tan \alpha E_y}{(1-\nu^2)} \delta^2 \tag{4}$$

$$G(t) = \left[1 + \int_0^{\infty} S(\tau) e^{-\frac{t}{\tau}} d\tau\right] \left[1 + \int_0^{\infty} S(\tau) d\tau\right]^{-1}$$

$$S(\tau) = \frac{c}{\tau} \quad for \quad \tau_1 < \tau < \tau_2 \tag{5}$$
$$= 0 \quad for \quad \tau < \tau_1, \tau > \tau_2$$

The apparent Young's modulus and parameters c, τ_1 and τ_2 could be obtained by minimizing the squared errors between the model simulation and the experimental data [9]. A cell detachment method was used to evaluate the adhesion force at the three regions of growing axons. Detailed of the methods could be found in [10, 11].

The two-way ANOVA method and Bonferroni t-test were used to analyze the significance of region and stage of growth or substrate material on biomechanical property and morphological parameters.

III. Results

Fig. 3 showed the histories of average axon branch number and average axon length for a population of six PC-12 cells. The mean branch number showed two types of growth: transient for 0-24hr and steady from 24-42hr. After that the cells had fully grown with just one axon. The group mean of average axon length showed similar trend but it increased rapidly starting at 36 hr and reach a plateau at 42hr. In Fig. 4 the history of mean cell length were com-

pared with that of the group mean average axon length. The cell length (or length of the long axis) had a trend of increasing and decreasing with significant variance during 0-23 hr. After 23hr the cell length jumped to 15um and between 25hr and 36 hr the length was varied between 13.5 um and 16 um. Then it increased again and reached a mean of 18um. From the results, instead of using elapsed time or the cell length, one may divide the axon growth process into three stages based on the average axon length as: stage I ($20<L_{ave}<30$), stage II ($35<L_{ave}<45$), stage III ($50<L_{ave}$).

The axon growth rate was proportional to the electrical field intensity. However, a field with intensity higher than 120mV/mm could damage the cells. At 6hr, the statistical analysis showed that the relative axon lengths due to different intensities were statistically different.

In Fig. 5, group variations of the apparent Young's modulus at different regions of the growing axon during different stages were compared. The proximal region had the highest Young's modulus while the middle region had the lowest Young's modulus. The average Young's modulus of three regions increased with the growth stage. Statistical analysis showed that, at the middle region, the stage difference of Young's modulus was statistically significant.

Fig. 6 compared the variations of adhesion at different regions of the axon and different substrates. The mean width of the axon at the corresponding region was also shown. On either the collagen coated substrate or the bare dishes, the proximal region had the highest adhesion force while the middle region had the lowest adhesion force. The distal region had higher adhesion than the middle region. The collagen coated substrate yielded better adhesion. The width of axon cross section at the distal region was larger than that of the middle region.

IV. Discussion

In this study, the growth of axon of PC-12 cells was observed for 48 hours. From the group mean branch number of axons and the average axon length histories, one confirmed that in the first day, the cells were in a transient state in which PC-12 cell would divide and migrate and the neurites extended and retracted frequently. In the second day, the NGF starting to affect the cell and although frequent changes of axon branch number occurred in 24hr-36hr but it was followed by a rapid increasing of average axon length and reached a steady-state from 42 hr on. The number of axon branch reduced to one indicated that fully growth of axon might be achieved.

The growth rate of the cells was enhanced by 2.88 folds when subject to electrical field of intensity of 100 mV/mm. Although in the literature, intensity as high as 200 mV/mm has been suggested, we found that an intensity of 120 mV/mm might damage the cells. It was suggested that polarization of guiding factor Netrin-1 by the applied electrical field can activate the focal adhesion kinase and make the growing axon to migrate along the electrical filed gradient [12, 13, 14].

In most commercial AFM systems, the vertical movement of probe is achieved by open-loop control of PZT. For ramp-and-hold indentation of soft specimens like cells, the creeping of the PZT was often neglected. In our results, we found that an error as high as 17.31% may exist if the indentation depth trajectory was not calibrated.

The apparent Young's modulus of the three regions of axon increased with the stage of growth. This might due to the cytoskeleton inside the axon was forming and the cross sectional area was increased. The difference between regions might due to the structure of the axon. At the distal region, the growth cone is formed mainly by actin and in the middle region microtubule dominates. The Young's modulus of actin is higher than that of microtubule has been suggested by thermal fluctuation method [15]. Our finding was consistent with it.

The axon had better adhesion on collagen-coated substrate which is similar to the PC-12 cell. The adhesion properties of substrate play a very important role on the indentation testing of cell. The high adhesion force at the proximal region of axon may be contributed by the nearby soma. The relative small adhesion at middle region might due to its small width of cross section.

From morphological and biomechanical analyses of the growing axons, a nerve conduit may be suggested that it should include a pair of electrode to apply static electrical field, the passage for axon may be coated with collagen and the strength of the scaffold may be designed based on the biomechanical properties of the axon at stage III.

V. Conclusions

The division of growing process based on average axon length might be feasible although more samples are needed. AFM ramp-and-hold indentation on PC-12 cells revealed that the viscoealsticity of growing axons is region and stage dependent. The information might be applied to design scaffold of nerve conduit.

Effect of Irregularities of Graft Inner Wall at the Anastomosis of a Coronary Artery Bypass Graft

F. Kabinejadian[1], L.P. Chua[2], D.N. Ghista[3] and Y.S. Tan[4]

[1] PhD Student, Nanyang Technological University, School of Mechanical and Aerospace Engineering, Singapore
[2] Associate Professor, Nanyang Technological University, School of Mechanical and Aerospace Engineering, Singapore

[4] Cardiothoracic and Vascular Surgeon, Mount Elizabeth Hospital, Singapore

Abstract — **It is well-established in medical literature that venous valves play a role in late segmental stenosis of vein grafts in the coronary artery bypass grafts (CABG). However, from the engineering point of view, vein grafts are always assumed as smooth tubes in the existing simulations, and no efforts have been put on the effects of vein valves and jaggedness of the graft inner wall due to the competent valves (in case of reversed saphenous vein (SV) grafts) or the valve cusps remnants and valve sinus (in case of valve-stripped SV grfats) on the blood flow.**

In this preliminary study, the effects of the inner surface unevenness of a vein graft on the blood flow is investigated at the distal anastomosis with a more realistic geometry of valve-stripped SV, by means of numerical simulation of pulsatile, Newtonian blood flow. For this purpose, three CFD models of the distal anastomosis are designed, including one model with a smooth inner wall vein graft, one model with a vein graft containing one valve remnants and sinus, and one model containing two valve remnants and sinus in the graft. The proximal segment of the coronary artery is fully occluded in all models.

The simulation results show that the valve remnants and sinus only cause some minor disturbances in the flow field and hemodynamic parameters (HP) just distal to the valve remnants, and not at the anastomosis.

Therefore, assuming valve-stripped SV graft as a tube with a smooth inner surface will not affect the simulation results considerably at the anastomosis. This validates the assumption of smooth inner wall in case of bypass with valve-stripped vein grafts for simulation.

Keywords — **Coronary artery bypass grafting (CABG), Saphenous vein, Venous valve remnants, Hemodynamics, Stenosis**

I. Introduction

It is usual that surgeons remove the valves before grafting a commonly used SV, since abnormal venous valves may cause obstruction to flow unrelated to technical error or poor run-off [1]. Moreover, the pressure trap, caused by competent valves in the distal segment of a vein graft, results in segmental hypertension which can play an important role in the graft stenosis [2]. Therefore, the alternative method for reversed vein grafting is the valve-stripped vein grafting.

Nevertheless, this method is not devoid of complications. Apart from the probable internal vein trauma caused by valvulotomes, the valve sinus and remnants of the valve cusps cause irregularities on the vein inner wall and deviating its geometry from an ideal, smooth, regular tube, which may affect the hemodynamics in the graft.

In this investigation, the effects of the valve sinus and remnants of the valve cusps on the distal anastomosis of a CABG with a valve-stripped vein graft are studied by means of numerical simulation of pulsatile, Newtonian blood flow.

II. Materials and Methods

A. Geometric models

Three distal anastomosis models of the right coronary artery (RCA) bypass graft are designed for the CFD simulation as follows: One distal anastomosis model with a smooth inner wall vein graft having neither valve nor its remnants; another model with a vein graft containing one valve sinus and the valve remnants; and finally, one distal anastomosis model with a vein graft containing two valve sinus and the valve remnants.

The models are designed planar, according to Galjee et al. [3] who demonstrated that the typical location and course of saphenous vein in RCA bypass graft could be assumed approximately planar. The proximal segment of the coronary artery is fully occluded in all models.

The dimensions of the models are listed in Table 1, where D_G, D_A, L_P, L_B, L_D, L_1, L_2, and L_V stand for the graft diameter, coronary artery diameter, length of occluded proximal section of the host artery, length of anastomosis bed, length of distal section of the host artery, distance between the anastomosis and the nearest valve, distance between two valves, and length of the valve region respectively, as shown in Fig. 1.

B. Numerical model and flow conditions

For pulsatile blood flow, it is recommended to use the Womersley number (α) as an indicator of whether non-Newtonian effects are important (α<1) or not (α>1) [4]. In the present study, the minimum Womersley number in the coronary artery is 1.34. Hence, the assumption of Newtonian fluid is reasonable.

Blood flow through the coronary artery bypass has the characteristics of three-dimensional, time-dependent, incompressible, isothermal, and laminar, whose governing equations (continuity and Navier-Stokes equations) are as follows:

$$\nabla \cdot \mathbf{u} = 0 \tag{1}$$

$$\rho \frac{\partial \mathbf{u}}{\partial t} + \rho(\mathbf{u} \cdot \nabla)\mathbf{u} = -\nabla p + \mu \nabla^2 \mathbf{u} \tag{2}$$

Where **u** is the velocity vector, ρ the density, t the time, μ the dynamic viscosity, and p is the pressure. The density and dynamic viscosity of the blood are assumed to be 1050 kg/m^3 and 0.00408 Pa.s respectively [5].

The commercial CFD software, FLUENT (version 6.3.26), is used in this study to solve the governing equations for the models numerically by finite volume method. In this method, the solution domain is divided into discrete control volumes (CV) and the governing equations are integrated over individual CVs to construct discretized algebraic equations for dependent variables at the centroid of the CVs. Finally, the discretized equations are linearized and the resultant linear equation system is solved to yield updated values of the dependent variables.

In the present study, segregated solver is used to solve the governing equations sequentially. The semi-implicit SIMPLEC algorithm is used as the pressure-velocity coupling scheme. Time stepping employed a fully implicit scheme, and each pulse cycle is divided into 90 time steps of size 0.01s. The convergence criterion is set at 5×10^{-5}. Beside, in order to eliminate the start up effects of transient flow, the computation is carried out for 5 periods.

A fully developed pulsatile flow is applied at the inlet whose flow waveform and the velocity profile are based on the measurements by magnetic resonance phase velocity mapping within a coronary artery bypass graft [6]; however, some modifications are exerted and the waveform is smoothened. The resulted waveform with the period of 0.9s and average velocity values adapted for this study is demonstrated in Fig. 2.

The Womersley solution is assumed for the inlet axial velocity profile which is derived as a fully developed pulsatile flow [7], whose velocity profile in a circular tube in the cylindrical coordinate can be expressed as [8]:

$$v_z(r,t) = 2B_0\left[1-\left(\frac{r}{R}\right)^2\right] + 2\mathrm{Real}\left\{\sum_{n=1}^{n=N} B_n \frac{\left(1-\dfrac{J_0\left(i^{\frac{3}{2}}\alpha_n \dfrac{r}{R}\right)}{J_0\left(i^{\frac{3}{2}}\alpha_n\right)}\right)}{\left(1-\dfrac{2J_1\left(i^{\frac{3}{2}}\alpha_n\right)}{i^{\frac{3}{2}}\alpha_n J_0\left(i^{\frac{3}{2}}\alpha_n\right)}\right)} e^{in\omega t}\right\} \tag{3}$$

Where i is the imaginary unit, R the tube radius, J_0 and J_1 the first kind Bessel functions of order zero and one respectively, α the Womersley number, B_n the Fourier coefficients, and Real{} represents the real part of the complex expression.

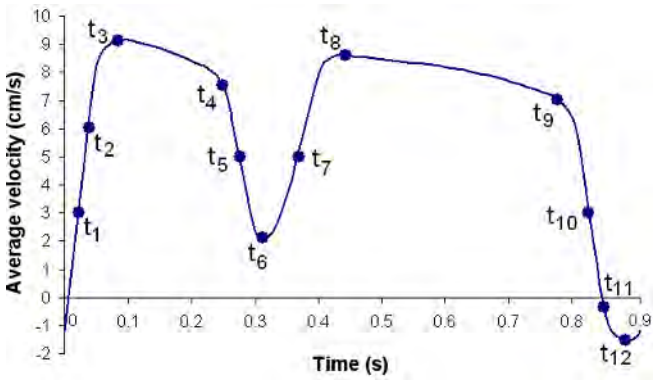

Fig. 2 Average velocity waveform adapted for the present study (labels indicate times at which flow and HP are studied)

A user defined function (UDF) is provided to implement the above equation and calculate the velocity for the pulsatile flow as the inlet boundary condition within FLUENT.

The exit flow is assumed to be in a fully developed condition; thereby the FLUENT's outflow boundary condition is set to assume a zero normal gradient for all flow variables except pressure. In this study, vein and arteries are considered as rigid tubes, and no-slip boundary condition is applied to all walls, owing to the fact that blood is a viscous fluid.

III. Results

A. Flow behavior

Flow field and HP in all models are studied in 12 instant of time as shown on the waveform in Fig. 2, some of which are presented in this paper.

During the systolic phase (t_1 to t_6), a vortex appears at the heel region of the anastomosis in all models, and in models containing valve remnants, a vortex appears in each valve sinus whose size increases with time till the first valley in the velocity cycle (t_6) when it occupies the whole valve sinus as demonstrated in Fig. 3 (b, c).

Yet, the size of the vortices does not further increase due to diastolic acceleration phase starting from time t_6. The flow field during the diastolic acceleration and early diastolic deceleration phase (t_7 to t_{10}) is the same as that of corresponding systolic phase (t_1 to t_6).

As the graft net flow rate becomes negative (t_{11}), in the model with smooth graft, the size of the vortex at the heel increases and one more vortex appears at the graft outer wall near the toe as shown in Fig. 4 (a). While in the models with grafts containing valve remnant, these two vortices (located at the heel and over the toe) have merged with the vortex in the valve sinus (whose size has further increased at this phase) due to the short distance between the valve remnant and the distal anastomosis in the present models. Another vortex is also formed proximal to the valve remnant at the inner wall of the valve remnant containing grafts, which merges with the vortex in the valve sinus as well.

At the peak reversed flow (t_{12}), the blood is flowing back towards the aorta in all models, and those two vortices in the anastomosis region are vanished. In the valve remnant containing models, the vortex in the valve sinus reduces in size and shifts toward the graft axis while the flow streamlines are smooth near the graft wall as demonstrated in Fig. 5.

Nevertheless, general flow characteristics are the same within all models at the anastomosis region.

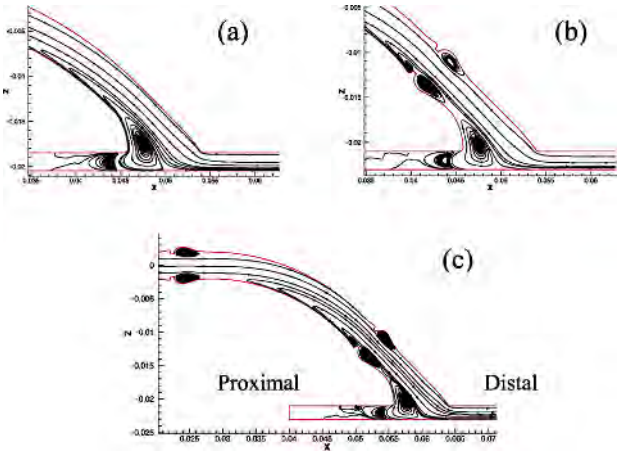

Fig. 3 Streamlines at the symmetry plane at time t_6=0.31s

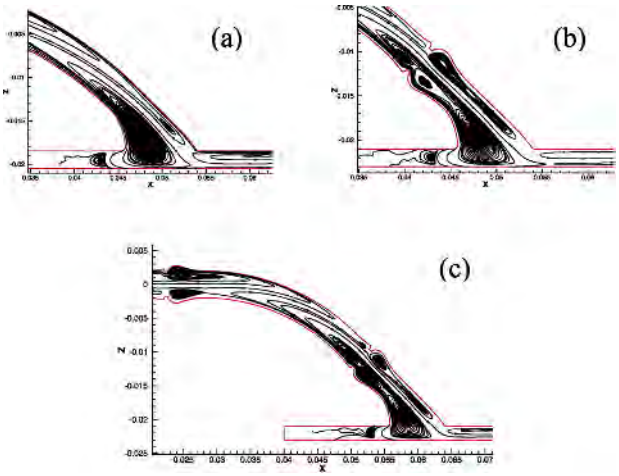

Fig. 4 Streamlines at the symmetry plane at time t_{11}=0.84s

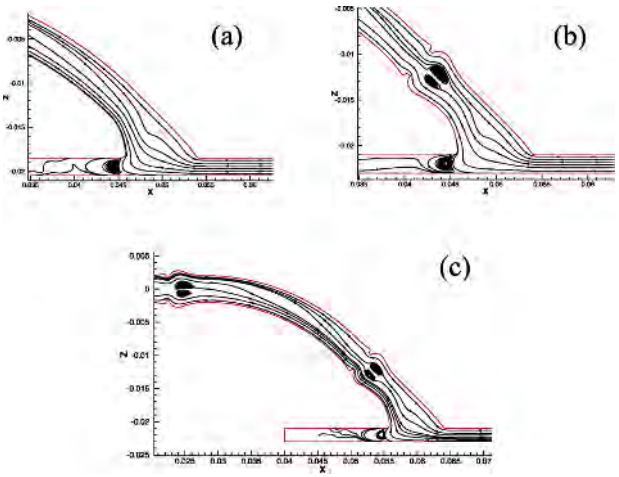

Fig. 5 Streamlines at the symmetry plane at time t_{12}=0.88s

B. Hemodynamic parameters distributions

Since localized distribution of low-WSS and high-OSI strongly correlates with the focal locations of atheroma [9], and also spatial WSSG contributes to the elevated wall permeability and atherosclerotic lesions [10], in order to compare the distribution of HPs quantitatively at the critical sites of the anastomosis, such as suture line, toe, heel, and bed (as shown in Fig. 6), the segmental average of the HPs including WSS, WSSG, and OSI are calculated (by TECPLOT software) for different models and presented in Table 2.

As demonstrated in Table 2, the segmental averages of all HPs are more or less the same at the anastomosis regions in all models.

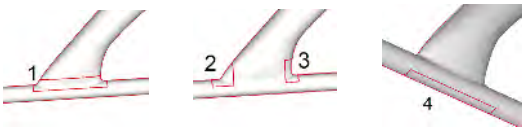

Fig. 6 Critical anastomotic regions: 1-Suture line, 2-toe, 3-heel, 4-bed

Table 2 Comparison of segmental average of <HP>s in different models

Model	Location	<TAWSS> (Pa)	<TAWSSG> (Pa/m)	<OSI>
No valve remnant	1- Suture line	2.54	4854	0.07
	2- Toe	5.81	10079	0.01
	3- Heel	0.13	180	0.24
	4- Bed	2.44	991	0.09
1 valve remnant	1- Suture line	2.54	4912	0.07
	2- Toe	5.81	10151	0.01
	3- Heel	0.13	189	0.24
	4- Bed	2.46	962	0.09
2 valve remnants	1- Suture line	2.55	4825	0.07
	2- Toe	5.82	10084	0.01
	3- Heel	0.13	186	0.23
	4- Bed	2.46	924	0.09

IV. Conclusion

In this paper, the effects of the inner surface unevenness of a graft due to valve remnants and valve sinus in case of valve-stripped SV graft on the blood flow is studied at the distal anastomosis of a CABG by means of numerical simulation.

There are only some minor disturbances due to the valve remnants and valve sinus observed in the flow field just distal to the valve remnants and not at the anastomosis, and hemodynamic parameter distributions do not experience any change in the anastomotic region of the three models studied.

Therefore, assuming valve-stripped SV graft as a tube with a smooth inner surface will not affect the simulation results. Thus, it is verified that the assumption of smooth inner wall in case of bypass with valve-stripped vein grafts is valid for simulation, and deviation of the results from the reality would be negligible.

Abstract — **Living cells possess properties that enable them to withstand the physiological environment as well as mechanical stimuli occurring within and outside the body. Any deviation from these properties will undermine the physical integrity of the cells as well as their biological functions. Thus, a quantitative study in single cell mechanics needs to be conducted. In this paper we will examine fluid flow and Neo-Hookean hyperelastic deformation. The study of these problems requires quantitative information regarding the interaction between blood flow and human cell deformation under realistic physiological conditions. For our aims, a Finite Element Method (FEM) analysis package has been exploited: the cellular level model consists of a continuum representation of the field equations and a moving boundary tracking capability to allow the cell to change its shape continuously.**

Keywords — **Cell adhesion, Contact mechanics, Detachment, Fluid-structure interaction, Endothelial cells models.**

I. Introduction

In order to present a physical model and determine the effect of the blood flow in presence of a human cell, a FEM-based approach has been exploited. It requires the geometrical and physical definition of the blood vessel, the cell and flow parameters. For our purpose, we verify cell deformation under actual conditions. Thus, a brief description of the theoretical framework for the mechanical is given. Then, we describe the exploited approach through FEM analysis simulating the human cell and the blood flow, and so modeling an endothelial wall cross of a blood flow.

Our aim was to focus the contact part among cell and endothelial wall about the deformation field. Our opinion is that the simulation notice the deformation inhomogeneity namely different concentration areas with different deformation values. This important observation should be connected with a specific form of the stored energy deformation that, in this case, loses the standard convexity to show the multy-well form. Consequently, we have more minimum and the variational problem seems more difficulty.

Solutions through minimizing sequence are applied and this relieve microstructure formation.

II. Theoretical framework and FEA approach

A. Mechanical aspects

From mechanical point of view this is a detachment problem and, according to [1] & [2], it can be formulated as the peeling of an adhesive membrane initially glued to a flat surface. Regarding the cell as membrane solid pulled with a forces system, we say that, when the blood flow is regular the cell will remain perfectly glued to the endothelial wall, while when the flow intensity augments part of cell may be pulled away. Let **u** the displacement field, then the equation of motion hold

$$\rho\,\mathbf{u}_{tt} + T\nabla^2\mathbf{u} = f(x,y,t) \quad \text{on } \Omega \tag{1}$$

where ρ is the supposed constant density and T the stress tensor. Clearly a the boundary of the detached part we have

$$\mathbf{u} = 0 \qquad \text{on } \Omega_D \tag{2}$$

Here the problem is the determination of Ω_D. By [1] we recall the breaking condition in the form

$$(T\text{-}\rho v^2)\,\partial u/\partial n = -F \qquad \text{on } \Omega_D \tag{3}$$

where ν denotes the normal velocities of Ω_D, $\partial\mathbf{u}/\partial n$ is the normal outer of **u** on Ω_D and F is the cohesive forces. The closed form of (1) exists only for some particular cases. For instance let f^* the static resultant of the flow actions and supposing it just applied at the origin of the system. So, in this case $f(x,y,t) = f^*\delta(x)\delta(y)$ with $\delta(\cdot)$ the delta function. For instance supposing the u filed symmetrical about to the origin, we consider a circular region and so $u = u(r)$ and the region Ω_D becomes a circular region which radius is λ. Under this consideration the solution of (1) has the form

$$u(r) = (f^*/2\pi T)\,\ln r + \cos(t) \tag{4}$$

namely

$$u(r) = (f^*/2\pi T)\,\ln(r/\lambda) \tag{5}$$

and in $\nu = 0$

$$\lambda = (f^*/2\pi F) \tag{6}$$

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1842–1845, 2009
www.springerlink.com

The complete solution in closed form becomes

$$u(r)= (f^*/2\pi F) \ln(2\pi fr/ f^*) \text{ on } r \le \lambda \quad (7)$$

B. Model generation

In this section of the paper we show how to simulate the effect of a blood flow in presence of a cell in a blood vessel. Using our FEM package [3-5], the blood flow and pressure drop across human cell have been studied and a mathematical model of the process has been constructed and analyzed. The constructed mathematical model consists of the equations of continuity (representing conservation of mass), motion (representing conservation of momentum) for the flow of blood through human cell [6] (see Fig. 1).

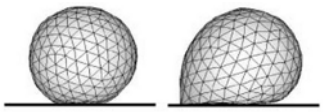

Fig. 1 2D-view of cell deformation effect: at t_0=0 (s) on the left and at t_1=0.125 (s) on the right.

These equations are supplemented by appropriate models which represent the stress/strain behaviour of human cell [7]. Simulation of fluid-structure interaction is a challenging problem for computer modellers. Fluid flow and Neo-Hookean hyperelastic deformation modelling has been the subject of numerous research during the past few decades.

Our approach provides reliable simulations for both these steps. The study of these problems requires quantitative information regarding the interaction between blood flow and human cell deformation under realistic physiological conditions. The complexity of such a task is such that only computer based numerical simulations can be used. In this work we exploited FEM to solve the developed mathematical 2D model representing the operations of human cell. For our aims, the Comsol Multiphysics® package has been exploited. Computer modeling can help in this context if it is based on an appropriate mathematical model and an accurate reliable solution. So it is needed to fit a model to the problem and get a satisfactory solution.

C. Governing equation of elastic-solid deformation

For a purely elastic solid [5]:

$$\frac{\partial}{\partial x_j}\sigma_{ij} + f = 0 \quad (8)$$

$$\sigma_{ij} = -p\delta_{ij} + p_{ij} \quad (9)$$

σ is the strain tensor. Let **u** is the displacement field, then under the material incompressible hypothesis

$$\nabla \cdot \mathbf{u} = 0 \quad (10)$$

$$\tau_{ij} = 2Ge_{ij} \quad (11)$$

$$p = -k(\nabla \cdot \mathbf{u}) \quad (12)$$

where G and k are, respectively, the shear modulus and the bulk modulus. Specific finite element techniques such as the penalty method are well suited to combine the described set of Neo-Hookean hyperelastic and fluid equations.

D. Governing equation fluid motion, conservation of mass and momentum

If an inelastic generalized Newtonian flow behaviour is assumed [6, 7], the Cauchy stress tensor σ can be written as

$$\sigma = -p\mathbf{I} + 2\eta(\gamma)D_v \quad (13)$$

where $\eta(\gamma)$ is the shear-rate-dependent dynamic viscosity and D_v denotes the rate of deformation tensor

$$D_v = \frac{1}{2}[\nabla v + (\nabla v)^T] \quad (14)$$

The shear rate parameter γ must be defined in terms of the second invariant of the rate of deformation tensor. For incompressible fluid this is

$$\gamma = \sqrt{2D_v : D_v} \quad (15)$$

The Non-Newtonian behaviour of blood can be described very well with the Carreau-Yasuda model

$$\frac{\eta(\gamma) - \eta_\infty}{\eta_0 - \eta_\infty} = [1 + (\lambda\gamma)^a]^{\frac{n-1}{a}} \quad (16)$$

with η_0, η_∞, λ, a and n being parameters of the model. For a time constant λ=0 this model reduces to a simple Newtonian model with $\eta(\gamma)=\eta_0$.

E. FEM Analysis

The following section shows proposed model for fluid-structure interactions. It illustrates how fluid flow can deform surrounding "structures" and how to solve for the flow in a continuously deforming geometry using the arbitrary Lagrangian-Eulerian technique [10-12]. The model geometry consists of a horizontal flow channel in the middle of which is a human cell, with a circular structure. The cell forces the fluid into a narrower path in the upper part of the channel, thus imposing a force on the structure's walls resulting from the viscous drag and fluid pressure. The cell structure, being made of a Neo-Hookean hyperelastic material, bends under the applied load. Consequently, the fluid

flow also follows a new path, so solving the flow in the original geometry would generate incorrect results. The Navier-Stokes equations that solve the flow are formulated for these moving coordinates. The simulations exploit the FEM and require geometrical and physical definition of the blood flow and the human cell [13]; the latter has been modeled as a circumference with a portion of perimeter adherent to the venous paries. In this example the flow channel is 100 (μm) high and 300 (μm) long. The cell structure has a radius of 1.25 (μm), and is adherent 1 (μm) long at the channel's bottom boundary. Assume that the structure is along the direction perpendicular to the image. The fluid is a water-like substance with a density ρ=1000 (kg/m^3) and dynamic viscosity η=0.001 (Pa·s). To demonstrate the desired techniques, assume the cell structure consists of a Neo-Hookean hyperelastic material with a density ρ=7850 (kg/m^3) initial tangent E=80 (kPa). The model consists of a fluid part, solved with the Navier-Stokes equations in the flow channel, and a structural mechanics part, which you solve in the human cell. Transient effects are taken into account in both the fluid and the cell structure. The structural deformations are modeled using large deformations in the Plane Strain application mode. The displacements and displacement velocities are denoted u, v, u_t, and v_t, respectively. Fluid flow is described by the Navier-Stokes equations for the velocity field, $\mathbf{u}=(u,v)$, and the pressure, p, in the spatial (deformed) moving coordinate system:

$$\rho\frac{\partial \mathbf{u}}{\partial t}-\nabla[-\rho\mathbf{I}+\eta(\nabla\mathbf{u}+(\nabla\mathbf{u})^T)]+\rho((\mathbf{u}-\mathbf{u}_m)\cdot\nabla)\mathbf{u}=\mathbf{F} \quad (17)$$

$$-\nabla\cdot\mathbf{u}=0 \quad (18)$$

In these equations, **I** denotes the unit diagonal matrix and **F** is the volume force affecting the fluid. Assume that no gravitation or other volume forces affect the fluid, so that **F**=0. The Navier-Stokes equations are solved in the spatial (deformed) coordinate system. At the inlet, the model uses a fully developed laminar flow. Zero pressure is applied at the outlet. No-slip boundary conditions, that is **u** = 0, are used at all other boundaries. Note that this is a valid condition only as long as you are solving the stationary problem. In this transient version of the same model, with the cell starting out from an undeformed state, it is necessary to state that the fluid flow velocity be the same as the velocity of the deforming obstacle. The coordinate system velocity is $\mathbf{u}=(u_m,v_m)$. At the channel entrance on the left, the flow has fully developed laminar characteristics with a parabolic velocity profile (see Fig. 2) but its amplitude changes with time.

At first, flow increases rapidly, reaching its peak value at 0.215 (s); thereafter it gradually decreases to a steady-state value of 3.33 (cm/s).

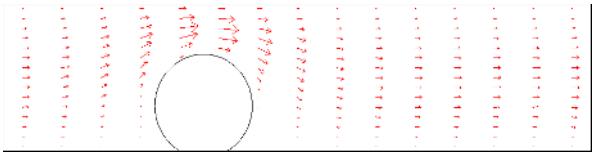

Fig. 2 Schematic of the problem statement. Simulated flow with cell presence at t=0.005 (s).

The centerline velocity in the x direction, u_{in}, with the steady-state amplitude U comes from the equation

$$u_{in}=\frac{U\cdot t^2}{\sqrt{(0.04-t^2)^2+(0.1t)^2}} \quad (19)$$

where t must be expressed in seconds. At the outflow (right-hand boundary), the condition is p=0. On the solid (non deforming) walls, no-slip conditions are imposed, u=0, v=0, while on the deforming interface the velocities equal the deformation rate, $u_0=u_t$ and $v_0=v_t$. The structural deformations are solved for using an hyperelastic formulation and a nonlinear geometry formulation to allow large deformations. For boundary conditions, the cell is fixed to the bottom of the fluid channel, so that it cannot move in any direction. All other object boundaries experience a load from the fluid, given by

$$\mathbf{F}_T=-\mathbf{n}\cdot(-\rho\mathbf{I}+\eta(\nabla\mathbf{u}+(\nabla\mathbf{u})^T)) \quad (20)$$

where **n** is the normal vector to the boundary. This load represents a sum of pressure and viscous forces. With deformations of this magnitude, the changes in the fluid flow domain have a visible effect on the flow and on the cell, too. Fig. 3 shows the geometry deformation and flow at t=4 (s) when the system is close to its steady state.

Due to the channel's small dimensions, the Reynolds number (R) of the flow is small (R << 100), and the flow stays laminar in most of the area. The swirls are restricted to a small area behind the structure. The amount of deformation as well as the size and location of the swirls depend on the magnitude of the inflow velocity. Most of time, the

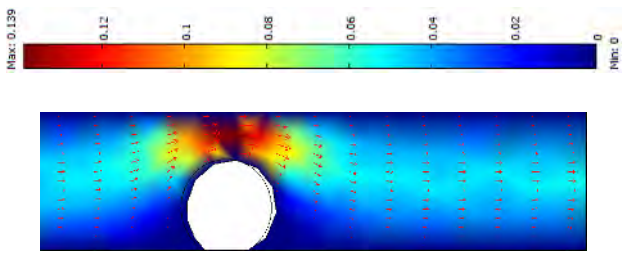

Fig. 3 Simulated flow velocity and geometry deformation at t=4 (s). The vectors indicate the flow direction and the color scale indicates flow-velocity magnitude (m/s).

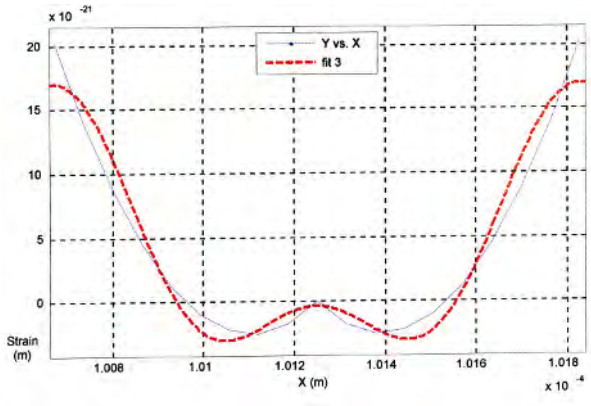

Fig.4 The non-monotone deformation law.

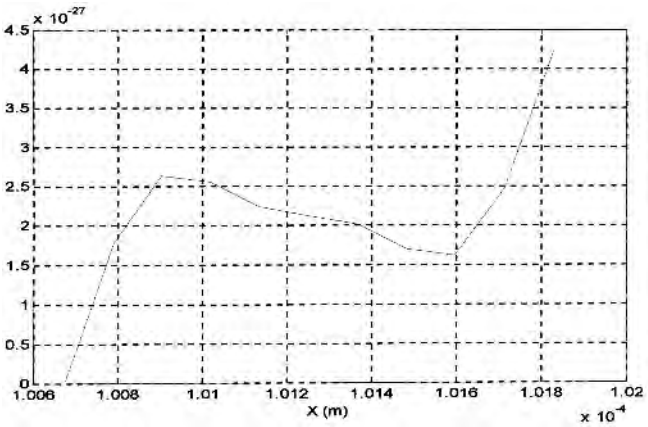

Fig. 5 The complementary deformation density as integral of the deformation function.

deformation follows the inflow velocity quite closely. Whenever the inflow velocity starts to decrease. Toward the end of the simulation, when inflow and structure deformation approach their steady-state values, the mesh velocity also decreases to zero. For the fluid domain are applied the following settings. For the boundary settings, we imposed a inlet condition with a mean velocity equal to u_{in} (set to 3.33 (cm/s)). For the sides we apply condition of wall with sliding absent; for the boundary ($\delta\Omega$) on the right we imposed type of outlet with a condition of pressure and no viscous stress with p_0=0. The edges of the cell are characterized by conditions wall mobile dispersant (structural displacement) with the exception of the base cell which is fixed and not involved in the dynamic physical process, according to

$$\mathbf{n}(\eta_1(\nabla\mathbf{u}_1+(\nabla\mathbf{u}_1)^T)-\rho_1\mathbf{I}-\eta_2(\nabla\mathbf{u}_2+(\nabla\mathbf{u}_2)^T)-\rho_2\mathbf{I})=0 \quad (21)$$

Our studies have been based on a discrete domain with 231 elements. The number of degree of freedom is 1984. Mesh has been generated with triangular elements, having a geometric side of 0.00005 (mm) for vessel and cell. We exploited a FEM implementation utilizing a time-dependent direct linear solver with parallel calculation 12]. Subsequently, we present final simulations in order to stress and strain results.

III. Conclusions

Simulated results were highly reliable, so our FEA package was very successfully simulating fluid–structure interaction in the human blood vessel. Our interest was to point out the concentration or inhomogeneity of the deformation on the contact area cell-wall. This particular result open the way to simulate the adhesion-detachment problem through more sophisticated model (i.e. functional analysis tools) such that microstructural characterization can be emphasized.

Abstract — **Identification of gene regulatory networks and prediction of gene behavior through their expression data have become major problems in computational molecular biology in the last few years. In this study, a novel approach for time series gene expression prediction based on Mamdani neuro-fuzzy networks is proposed.**

In this work, a set of gene expression data is studied and neuro-fuzzy networks are designed to obtain models for gene expression prediction over time. In each neuro-fuzzy network, one of the genes is considered as the output and the other genes as the inputs. The time series expression values of the output are predicted by analyzing the time series expression values of the inputs.

We study a popular gene expression data set of SOS DNA repair network of *Escherichia coli* bacterium. By comparing the results of proposed algorithm with previous works, it is obvious that our networks are predicting more precisely.

Keywords — **Time Series Gene Expression, Mamdani Neuro-Fuzzy Network, Mathematical Modeling, *Escherichia coli***

I. Introduction

In recent years, gene expression data is widely used to discover genes behavior under different conditions. Many experimental techniques are performed to increase the available time series gene expression data sets such as microarray technology which can simultaneously monitor the expression levels of thousands of genes during important biological processes and across collections of related samples. Therefore, massive amounts of biological data await interpretation. By using computational methods, these data sets can be employed for analyzing and modeling techniques.

The availability of expression data made the possibility of predicting unknown genes functional information. However, as the ultimate goal of molecular biologists is to uncover the complex regulatory mechanisms controlling cells and organisms, the reconstruction, prediction and modeling of gene networks remain as the central problems in functional genomics. Due to the fact that gene expression data sets are usually noisy, the methods for modeling and function prediction should be robust to noise.

In this paper, a new approach is employed to predict the time series behavior of genes in a cell by studying the behavior of other genes in the cell. For achieving to this target, Mamdani Neuro-Fuzzy Network is applied to the SOS DNA Repair network of *Escherichia coli* (*E. coli*) bacterium time series gene expression data.

It is known that both fuzzy logic systems and neural networks are capable to process knowledge like human. Artificial neural networks are well-known as universal function approximators, in terms that they can approximate any continuous function represented by data subject to have an appropriate neural network model. On the other hand, fuzzy logic is a natural language for linguistic modeling of data; as a consequence, it is consistent with the qualitative linguistic–graphical methods used to describe biological systems. In neuro-fuzzy systems, the advantages of both neural networks and fuzzy logic are employed; therefore, the system is capable to not only approximate but also model the data subjected to the system [2]. Besides to these advantages, the neuro-fuzzy system presented by Mamdani has enough simplicity to work on gene expression data sets and the ability to deal with noisy data.

II. Proposed methods

A. Neuro-Fuzzy Network

The computational approach described in this paper is Mamdani neuro-fuzzy network (MNFN) that is able to overcome the drawbacks specific to pure neural networks, which act as black boxes. By incorporating elements specific to fuzzy reasoning processes, we are able to give to each node and weight their meaning and function as part of a fuzzy rule, instead of just being abstract numbers [1].

A Mamdani neuro-fuzzy system uses a supervised learning technique, usually back-propagation learning, to learn the parameters of the membership functions [6]. The architecture of this system is illustrated in Fig. 1. The details of each layer are as follows:

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1846–1849, 2009
www.springerlink.com

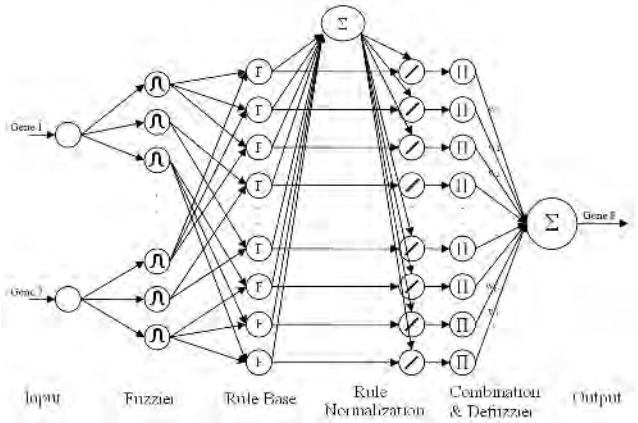

Fig. 1 Mamdani Neuro-Fuzzy Network [6]

- Input Layer (Layer 1): As shown in Eq. (1), no calculation is done in this layer. Each node, which corresponds to one of input variables, only transmits input value to the next layer directly. The link weight in layer 1 is unity.

$$O_i^{(1)} = G_i \tag{1}$$

where G_i is the expression value of the i^{th} gene, and $O_i^{(1)}$ is the i^{th} output of layer1.

- Fuzzifier Layer (Layer 2): Each node in layer 2 corresponds to one linguistic label which is low-expressed, average-expressed or high-expressed. The output link of this layer, represented as the membership value, specifies the degree to which the input value belongs to the respective label. A clustering algorithm decides the initial number and type of membership functions (MFs) to be allocated to each of the input variables. The final shapes of the MFs are fine tuned during network learning.

As shown in Eq. (2), membership functions are represented as Gaussian form.

$$O_{ij}^{(2)} = \exp\left(-\frac{\left(O_i^{(1)} - m_{ij}\right)^2}{\sigma_{ij}^{\ 2}} \right) \tag{2}$$

where *i, j* indicate the input variable and the related number of fuzzy sets respectively, m_{ij} and σ_{ij} are the mean and variance of the membership functions, while $O_i^{(1)}$ is the value of the i^{th} input variable.

- Rule Base Layer (Layer 3): A node in this layer combines the antecedent part of a fuzzy rule using a T-norm operator. In this study, T-norm operator is considered as minimum operation. The output of each node represents the firing strength of the corresponding fuzzy rule which is calculated by Eq. (3). The number of nodes in this layer equals to the number of rules.

$$O_k^{(3)} = \min_r \left(\exp\left(-\left\{ D_r\left(O_r^{(1)} - m_r\right) \right\}^T \left\{ D_r\left(O_r^{(1)} - m_r\right) \right\} \right) \right) \tag{3}$$

$$D_r = diag\left(1/\sigma_{r1}, 1/\sigma_{r2}, ..., 1/\sigma_{rn}\right) \tag{4}$$

$$m_r = \left(m_{r1}, m_{r2}, ..., m_{rn}\right)^T \tag{5}$$

where *r* runs through all the selected nodes of layer 2 corresponding to the k^{th} rule.

- Rule Normalization Layer (Layer 4): The number of nodes in this layer is the same as layer 3; the rules are normalized by Eq. (6).

$$O_i^{(4)} = \frac{O_i^{(3)}}{\sum_{i=1}^{m} O_i^{(3)}} \tag{6}$$

where *m* is the number of all rule sets.

- Combination and Defuzzier Layer (Layer 5): All the rules are combined and defuzzificated using Eq. (7):

$$O_i^{(5)} = \sum_{i=1}^{m} w_i O_i^{(4)} \tag{7}$$

where w_i is the weight multiplied to the i^{th} rule.

B. Learning procedure

The parameters of proposed MNFN must be trained to obtain a predicting system for our data. Therefore, in learning procedure, some parameters of the network including means and variances of fuzzy sets and weights corresponding to the rules are trained by back-propagation (BP) learning algorithm which is widely used for training neural or fuzzy networks and based on gradient descent [7].

Owing to the simplicity of the BP learning algorithm, we adopt this method to tune parameters of the MNFN model by means of error propagation via variation calculus.

For each network, an error criterion is defined in order to test the accuracy on a given data set, by using an overall error measure based on the difference between the predictions and target values of the output variable i.e. gene. One of the most common criteria is Mean Square Error (MSE) described by Eq. (8):

$$E_i = \frac{1}{N} \sum_{i=1}^{N} \left(y_i^{predicted} - y_i^{measured} \right)^2 \tag{8}$$

where N is the number of samples in the data set.

The number of rules governs the expressive power of the network. Intuitively, an increase in the number of rules

describing the gene interactions in a certain network results in a decrease in the error measure of Eq. (8). However, pursuing a low error measure may result in the network becoming overfitted and tuned to the particular training data set and exhibiting low performance on the test sets [1].

Therefore the problem becomes one of combinational optimization: minimize the number of rules while preserving the error measure at an adequate level by choosing an optimal set of values for the parameters (overlap degree between learning rates and rule creation criteria) [1].

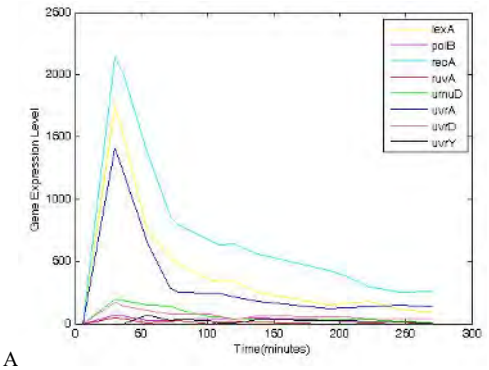
C. Data

The proposed method in this study is validated using gene expression measurements for the SOS DNA Repair network of *E. coli* bacterium. Gene expression patterns give an indication of the levels of activity of genes in the tissues under study. The SOS system has a 'single input module' architecture [4], where a single transcription factor controls multiple-output operons, all with the same regulation sign (repression or activation), and with no additional inputs from other transcriptional factors. This is a basic recurring architecture in transcriptional networks [3] and characterizes more than 20 different gene systems in *E. coli* [4].

In this paper, we have used time series gene expression measurements presented by Ronen et al. [5] for SOS DNA Repair network of *E. coli* bacterium which is downloadable at [8]. The measurements include four different data sets: experiment 1, 2, 3 and 4 which are done under various light intensities. Experiments 1 and 2 are under 5 J/m^2, and experiments 3 and 4 are under 20 J/m^2 light intensity.

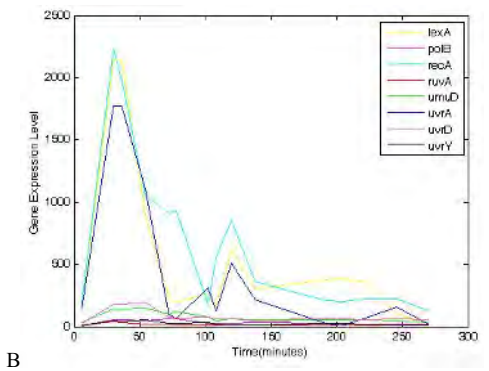
In these experiments eight major genes are monitored which are: uvrD, lexA, umuD, recA, uvrA, uvrY, ruvA and polB; each experiment consists of 50 time points with a time period of 6 min.

III. Results



This study attempts to emphasize MNFN in the subject of gene expression prediction based on time series data set. The data is stored in a matrix with rows containing gene expression measurements over time samples in columns.

A number of MNFNs that match the number of genes are constructed; the output of each network is one selected gene and the inputs are the remaining genes from the data set. Networks attempt to describe the behavior of the output gene based on possible interactions from the input genes; and the knowledge derived from gene–gene interactions is stored in a set of fuzzy rules.



Following, we create eight multi-input single-output (MISO) MNFNs that describe each one of the genes involved in the SOS system. Each network is trained using 35 time points of data set and evaluated using the remaining 15 time points. The mean of experiment 1 and 2 are employed for training and testing the networks.

In the work of Maraziotis et al. [1] and Ronen et al. [5], all time points of data from experiment 1 were used to train their networks. In Ronen et al. work, all time points of data from experiment 2 were used to evaluate their system, and Maraziotis et al. tested their system using all time points of data from experiments 2, 3 and 4. It should be noted that, in both works, training and testing procedure include the same time points from data set in different experiments. As the experiment 1 and 2 are performed in parallel with the same conditions, their systems are tested with the similar data to the training. In our work, the networks are tested by the data with different time point comparing to the ones used as training. This can lead us to more accurate and realistic evaluation from our networks.

In Fig. 2, the results obtained from proposed MNFNs for all 8 genes are illustrated. In Fig. 2 (A), gene expression values in test time points and in Fig. 2 (B) the predicted values for these points are shown. The results of training and testing of the method are presented in Table 1 in terms

A

B

Fig. 2 (A) Gene expression target values of test time points, (B) predicted gene expression values by proposed method in the same time points.

Table 1 MSE of the 8 MISO gene prediction networks in train and test data subsets

Gene Name	Train Error (MSE)	Test Error (MSE)	Function
uvrD	0.0112	0.0129	Nucleotide excision repair, recombinational repair
lexA	0.0008	0.0192	Transcriptional repressor
umuD	0.0029	0.019	Mutagenesis repair
recA	0.0051	0.0088	Mediates LexA autocleavage, blocks replication forks
uvrA	0.0048	0.0273	Nucleotide excision repair
uvrY	0.0336	0.0634	SOS operon of unknown function, additional roles in two-component signaling
ruvA	0.0152	0.0386	Double-strand break repair
polB	0.017	0.0432	Trans-lesion DNA synthesis, replication fork recovery

of the MSE criterion. It is obvious from this table that the proposed method has accurate prediction ability for time series gene expression values.

IV. Conclusions

The paper presents a method to predict a selected gene behavior based on possible interactions from other related genes. Towards this goal, we have presented a Mamdani neural fuzzy network that is able to achieve the task in an accurate and fast manner. This leads us to find possible relations in the form of fuzzy rules, among 8 SOS DNA Repair genes of *E. coli* bacterium. Also, these fuzzy IF-THEN rules can help us in building a model describing the functional relationship and the interactions among genes.

Acknowledgment

We would like to highly thank Ms. Tahmineh Lohrasebi and Mr. Amir Feizi for useful discussions and supports relating to this study.

Abstract — **Tight blood glucose (BG) control is known to reduce mortality and improve outcomes in critical care patients by 29-45% [1]. Several first principles models have been put forward to predict BG levels in patients so that tighter BG control may be achieved. These models have been employed in both simulation and clinical studies. However, to the best of our knowledge, they have not been tried for intensive care unit (ICU) patients in Singapore. Hence, the primary objective of this study is to evaluate the applicability and effectiveness of selected models for BG prediction in ICU patients, with the eventual goal of achieving tighter BG control. Two models are selected and tested for predicting clinical BG data in 8 surgical ICU patients. Results of this exploratory study are presented and discussed.**

Keywords — **Blood Glucose, Surgical ICU, Bergman Model, Chase Model**

I. Introduction

Under severe stress, the human body loses some of its homeostatic capacity, in particular its ability to regulate the blood glucose (BG) level. Abnormal BG levels can lead to two conditions: hyperglycemia (i.e., high BG) and hypoglycemia (i.e. low BG). Prolonged and frequent hyperglycemia causes multiple organ failure [1]. Hypoglycemia, on the other hand, causes seizures and death, and hence is serious [1].

A patient suffering critical illness is typically under extreme stress and there is a good chance that he/she will experience poor BG regulation. Hence, maintaining BG at acceptable levels in critically ill patients is vital and a very important component of care in Intensive Care Units (ICUs). Studies have shown that tight control of BG can reduce mortality in critically ill patients by 45% [1].

Mathematical models based on first principles have been developed to predict the time evolution of BG. These models and predictions can allow medical staff to make better decisions for tighter control of BG in critically ill patients. We focus on two leading models: the Bergman Minimal model [3] and the Chase model [2]. Some factors that we have paid particular attention to in our study are that the patients we have access to are Singaporeans and the availability of data from the surgical ICU at the National University Hospital.

A. Singaporean Patients

The applicability of BG models to Singaporean Asian populations has not been investigated. In the past, this group has proved problematic with respect to standardized measures derived from predominantly Caucasian populations, for example, the 2005 redefinition of the BMI range for Singapore based on WHO recommendations [9]. This is attributed to the fact that the body composition and percentage of body fat of the typical Singaporean Asian is different from the typical Caucasian. Since some of these factors (namely percentage of body fat) are relevant in other BG conditions, e.g. diabetes [1], we feel that it is worthwhile to investigate the applicability of BG models to this population.

B. Availability of Data in the Surgical ICU of the National University Hospital (NUH).

We use the selected models on retrospective surgical ICU data on BG, external insulin and dextrose infusions only. This is because we have aimed to keep the data collection as unobtrusive as possible for the patients and the medical staff. Basal insulin levels in the blood are therefore unavailable to us. Also, our data readings are spaced by about four hours, while the Bergman model was developed using data with a 2-minute sampling interval [3] and the Chase model uses data with a sampling interval of 1 hour [2].

The data collection for this study was approved by local institutional ethics committees (IRB and DSRB).

II. Modelling glucose-insulin dynamics

In this study, we have chosen to focus on two BG models: the diabetic extension of the Bergman minimal model [4] and the Chase model [2]. These two models are chosen for their simplicity [3, 4] and the fact that they are based on physiological principles [2, 3, 4]. Bergman model has been used in a number of studies, and the Chase model is a recent extension of the Bergman model, which was successfully used. These two models are briefly described below.

A. Diabetic Bergman Minimal model

This is a first principles model with two physiological compartments for glucose and one physiological compart-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1850–1853, 2009
www.springerlink.com

ment for insulin. The endogenous insulin of the original Bergman model is replaced with an exogenous insulin flow to deal with the insulin deficiency caused by pancreatic β-cell destruction in diabetics. A glucose meal disturbance is added to represent the external glucose feed. The diabetic Bergman model is as follows [4]:

$$\frac{dG(t)}{dt} = -\left(p1 + X(t)\right)\cdot G(t) + p1\cdot G_b + \frac{F_G}{V_G}$$

$$\frac{dX(t)}{dt} = -p2\cdot X(t) + p3\cdot\left(I(t) - I_b\right)$$

$$\frac{dI(t)}{dt} = -n\cdot I(t) + \frac{F_I}{V_I}$$

This model is fairly simple but is well suited to our study because it preserves compatibility with known physiological facts and was validated in clinical studies [3].

In the above model, *G(t)* (mmol/L) and *I(t)* (mU/L) represent the time courses of glucose and insulin in plasma following a rapid glucose injection (usually 0.3 g of glucose per kg of body weight). *X(t)* (1/min) describes the effect of insulin on net glucose disappearance, and G_b (mmol/L) is the glucose basal level in the blood. F_G is the meal glucose disturbance variable. I_b (mU/L) represents basal insulin. V_I (L) is the insulin distribution volume, V_G (L) is the glucose distribution volume, F_I (mU/min) is exogenous insulin flow and F_G (mmol/min) is glucose flow that enters the glucose compartment.

The model has four patient-specific parameters: pl (1/min), p2 (1/min), p3 (L/mU.min^2) and n (1/min). Parameter. p1 describes 'glucose effectiveness'. The ratio of p3 to p2 defines S_I (L/mU.min), the insulin sensitivity index, which represents the insulin-dependent increase in the net glucose disappearance rate. Parameter n represents fractional insulin clearance. Nominal parameter values of p1 = 0.0131, p2 = 0.0135, p3 = 2.9x10^{-6}, n = 0.13, V_I =3.15, V_G= 12, are used as first estimates since they are most commonly used in literature [4, 5, 6].

B. Chase model

The Chase model is based on the Bergman model but takes into account transient dynamics due to the long-term effect of exogenous insulin [2]. It accounts for exogenous insulin disappearance from plasma as following a non-linear saturation and its saturable utilization to reduce BG levels. This matches the model to known physiological knowledge [8]. The Chase model is as follows:

$$\frac{dG}{dt} = -p_G G(t) - S_l\left(G(t) + G_E\right)\frac{Q(t)}{1 + a_G Q(t)} + \frac{P(t)}{V_G}$$

$$\frac{dQ(t)}{dt} = -kQ(t) + kI(t)$$

$$\frac{dI(t)}{dt} = -\frac{nI(t)}{1 + a_l I(t)} + \frac{u_{ex}(t)}{V_l}$$

In the above equations, $G(t)$ (mmol/L) is the concentration of the plasma glucose above the equilibrium level, G_E (mmol/L) is the equilibrium level of plasma glucose concentration, $I(t)$ (mU/L) is the concentration of the plasma insulin above the basal level, $Q(t)$ (mU/L) is the effect of previously infused insulin being utilized resulting from exogenous insulin input, $P(t)$ (mmol/min) is the exogenous glucose infusion rate, $u_{ex}(t)$ (mU/min) is the insulin infusion rate, V_I (L) is the insulin distribution volume, V_G (L) is the glucose distribution volume, n (1/min) is the first order decay rate for insulin from plasma, p_G (1/min) is the time-varying fractional clearance of plasma glucose at basal insulin, S_I (L/mU.min) is the time-varying insulin sensitivity, k (1/min) is the parameter controlling the effective half life of insulin, α_I (L/mU) is the Michaelis-Menten parameter for insulin transport saturation, and α_G (L/mU) is the Michaelis-Menten parameter for glucose clearance saturation [2, 5].

Nominal parameter values of p_G = 0.01, S_I = 0.0002, α_I = 0.0017, α_G = 0.04, n = 0.16, k = 0.0099, V_I =3.15 and V_G= 12, are used as first estimates [5, 6].

III. Methodology Employed

The methodology employed for BG prediction consists of two phases: parameter estimation to find values of some parameters in the model, and one-step-ahead prediction to predict the BG at the next sampling/measurement time. The MATLAB® Optimization Toolkit was used in this methodology.

For every patient data set, we estimated model parameters that are patient-specific and time variant using the fminsearch function in MATLAB. This function computes the optimal model parameter values by minimising the sum of prediction errors between measured and model predicted values, and requires an initial parameter estimate which can be given based on literature data [3, 6].

For each patient, we use the first *n* data points to estimate optimal parameter values. The BG value at each subsequent sampling time is predicted using the parameter estimates

calculated using all the previous data points. The procedure is repeated at the next sampling time using n+1 data point. This approach is termed 'one-step-ahead prediction'. Such a one-step-ahead prediction which includes time-variant and patient-specific parameter values is likely to yield better prediction accuracy than fixed parameter estimates. We believe this to be closer to how an eventual tool would be used in the ICU.

The minimum number of data points required for the first prediction is based on the number of model parameters to be estimated, and it is 3 in our case for both the models. These 3 data points translate into an average of 12 hours. This is a reasonable period as a prediction could be made just after the first 12 hours of a patient's stay at the ICU.

At each instant of parameter estimation and prediction, average of BG measurement over the previous 3 data points (8-12 hours) was used as G_b (basal glucose) in the Bergman model and G_E (equilibrium glucose) in the Chase model. This approach is based on the technique used in [6] on the Chase model and that we extended to the Bergman model. For parameter estimation for the first 3 points, the BG measurement for that point is used for G_b and G_E.

Both the models have two physiologically important parameters: glucose effectiveness and insulin sensitivity. *Glucose Effectiveness* represented as p1 in the Bergman model and p_G in the Chase model, is the effect of glucose to enhance glucose disappearance, at basal insulin in the absence of dynamic insulin response [7]. *Insulin Sensitivity* represented as a ratio of p2 and p3 in the Bergman model and S_I in Chase model: Insulin Sensitivity reflects the ability of insulin to enhance the effect of glucose to normalize its own concentration after injection [7].

IV. Results and Discussion

We present the complete results for one patient that can be described as typical of the group of patients we have studied. Patient 35 is a 70 year old female with a history of diabetes (type II). For this patient, Figure 1 shows the insulin and dextrose inputs, Figures 2 and 3 compares the BG predictions by the Bergman and the Chase model respectively, with measured data. Table 1 presents the mean percentage error (MPE). Figure 4 and 5 are parity plots of measured versus predicted BG value for all patients and at all prediction instants for the Bergman model and the Chase model respectively.

Our MPE lies between 2% and 13% (Table 1), which is very near to the acceptable range of 2-11% [6]. Taking into consideration our unobtrusive data collection methods (in contrast with the collection methods in [2], [3] and [4]), our study has yielded very promising results. We also note, based on table 1 and figures 4 and 5, how the more complex Chase model consistently outperforms the Bergman model. This is because the Chase model accounts for the delayed insulin utilization [2], whose effect is substantial due to the long sampling interval of four hours used. This average sampling interval of four hours limits our understanding of how the BG level fluctuates between two samples and we cannot account for any possible spikes or dives in BG level that may occur in this interval.

Table 1 Mean Percentage Error for Several Patients

Patient Number	Mean Percentage Error for Predictions by	
	Bergman model	Chase model
1	5.1	2.3
2	12.6	12.1
22	5.1	2.4
24	5.2	2.7
25	3.3	4.2
30	7.0	2.1
34	6.4	4.3
35	10.1	3.8

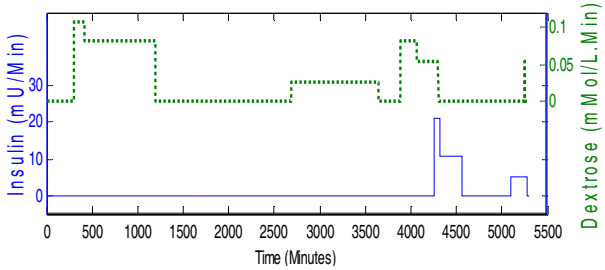

Fig. 1 Insulin and dextrose inputs for patient 35

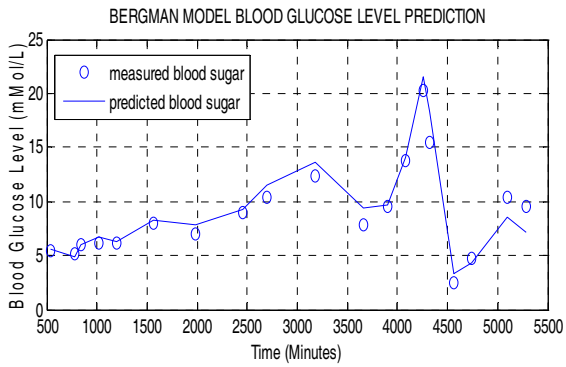

Fig. 2 Comparison of the BG prediction by the Bergman model with the measured data for patient

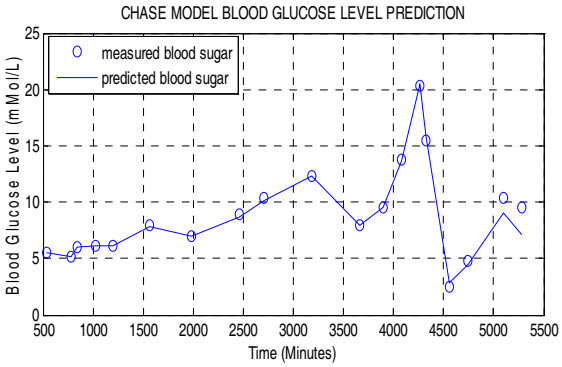

Fig. 3 Comparison of the BG prediction by the Chase model with the measured data for patient 35

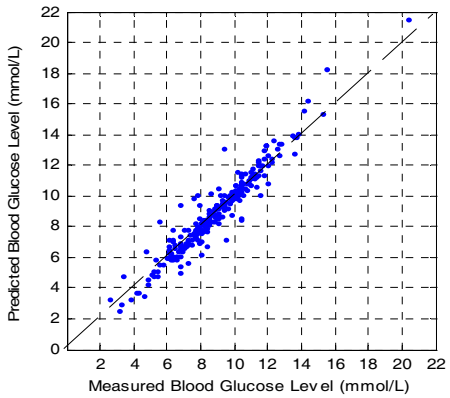

Fig. 4 Comparison of the predicted BG by the Bergman model with the measured BG for all patients

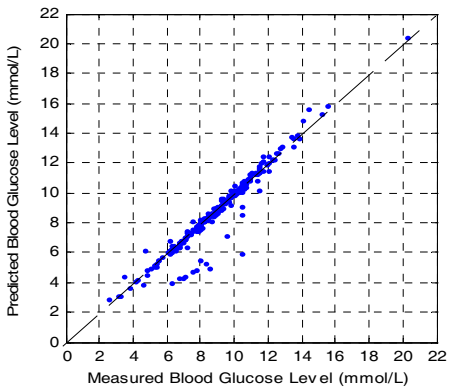

Fig. 5 Comparison of the predicted BG by the Chase model with the measured BG for all patients

V. Conclusion

This study has shown that the Chase model and, to a lesser extent, the diabetic Bergman model, can predict BG value reliably for Singaporean patients in surgical ICU, using the 'one-step-ahead prediction' procedure. MPE values obtained for these two models are consistent with the previous work [6]. Both the Chase and Bergman models should be further evaluated for eventual use to achieve tight control of BG levels in critically ill patients. We recommend that the two models be investigated using data with a sampling interval of no more than one hour, to assess the improvement in the accuracy of model predictions.

Method of Numerical Analysis of Similarity and Differences of Face Shape of Twins

M. Rychlik[1], W. Stankiewicz[1] and M. Morzynski[1]

[1] Poznan University of Technology, Department of Combustion Engines and Transportations, Division of Methods of Machine Design, Poznan, Poland

Abstract — **This article presents application of the PCA (Principal Component Analysis) method for analysis and computation of three dimensional biometric description of 3D objects. As the data input the geometrical data sets (three-dimensional points coordinates) of faces are used.**

Authors apply 3D version of PCA method for numerical estimation of similarity and extraction of difference of analyzed faces. PCA decompose set of 3D objects into mean face and individual features (empirical modes), which describing deviations from mean value. Obtained mean shape describe the similarity of faces, eigenmodes present geometrical differences between faces. Eigenvalues can be used to numerical (mathematical) comparison of study faces.

In this paper three sets of data of different type of twins (identical – monozygotic, fraternal-dizygotic) and thirteen typical faces are used and compared. The mean face and the features (eigenfaces) are presented and discussed.

Authors propose using the set of eigenfaces and corresponding coefficient values (computed from PCA) for security verification. As an example of authorization key the set of coefficient values for the faces are presented. Each key describes individual shape of face and can be decoded and compared with the original data of user to obtain access to restricted area or data.

I. Introduction

With the expansion of international traffic and globalization of the world, increase the necessary of research in security systems area. The security and access systems are very important and rapidly advancing not only in computer vision. Such systems are used obviously during passenger control on the airport or boundary crossing [9]. Also every day activities, like data protection, on-line banking or shopping may utilize the results of new technology developed. To increasing level of security the many identification and verification techniques are used.

The process of identifying an individual which is common used in every day activity is usually based on two things: username and a password. There are three types of methods of authentification [4]:

- something the user knows – user name, password, pin;
- something the user has – tokens, ID cards, smartcard;
- something the user is – voiceprint identification, retinal scan, face recognition.

The most advanced methods of identification belong to third group. These methods are common name biometrics systems. One of the important and rapidly advancing areas of security identification and verification is face recognition.

II. Biometric technology

Biometrics identify people by measuring some aspects of individual anatomy or physiology – such as hand geometry or fingerprint, some deeply ingrained skill, or other behavioral characteristic – handwritten signature, or something that is a combination of the two – voice [1]. In generally the biometrics can be sorted into two types [3]:

- physical – face, fingerprint, hand/finger, iris, ear, retinal, DNA, vein, blood pulse, dental, lips, nail;
- behavioral – voice, gait, tapping, signature, keystroke dynamics, mouse dynamics.

The disadvantages of the most commonly used recognition techniques are not enough reliability of them [5]. A 2D dimensional photo cannot be measured like a landscape and simply doesn't contain the same amount of information as the 3D photo. This problem is especially essential for twins, when the similarity of face shape is very high.

Facial identification reads the peaks and valleys of facial features. These peaks and valleys are known as nodal points (exist 80 nodal points in a human face, but usually only 15-20 are used for identification – known as „golden triangle" region between the temples and the lips [6].

The face recognition method is the oldest and the most "natural" method of identification persons. Recognizing people by their facial features is going back at least to our early primate ancestors [10]. Biologists believe that a significant part of our cognitive function evolved to provide efficient ways of recognizing other people's facial features and expressions [7].

In further sections, authors presents 3D face identification method with applied of cheap non contact system for data acquisition (structural light scanning technology) and 3D PCA analysis for feature extraction and coding of the shapes of faces. Data base used in presented experiment contains regular and twin's faces (different type of twins).

III. Principal componenet analysis – empirical modes

Modal analysis methods are used for statistical analysis and minimize the number of parameters which describe 3D objects. One of the method which based on modal decomposition is PCA (Principal Component Analysis, known also as POD – Proper Orthogonal Decomposition). If empirical modes (PCA) are optimal from viewpoint information included inside of the each modes [8], often decomposition based on mathematical (e.g. spherical harmonics) or physical modes (vibration modes) are used.

PCA transformation gives orthogonal directions of principal variation of input data. Principal component which are connected with the largest eigenvalue, represent direction of the largest variation of data in data space. Variation is described by eigenvalue connected with the first principal component. The second principal component, describe the next in order, orthogonal direction in the space with the most large variation of data. Usually only few first principal components are responsible for a majority variations of the data. Data projected onto other principal components often have small amplitude and don't cross a amplitude of measurement noise. Therefore they can be deleted, without dangerous of decreasing of the accuracy. PCA method has in practice been used to reduce the dimensionality of problems. And uses second order statistics information to reduce the data dimension in the minimal mean square error sense.

Independent from name and type of application, the method is generally the same and she based onto statistical representation of the random variables.

The shape of the every object is represented in the data base as the set of 3D points cloud. Each pints cloud is described by vector (1)

$$S_i = [s_{i1}, s_{i2}, \ldots, s_{iN}]^T, \; i = 1,2,\ldots,M, \qquad (1)$$

where $s_{ij} = (x, y, z)$ describes coordinates of the points in Cartesian coordinates system, M is the number of the faces which are in database, N is the number of the points in single points cloud. In the next step the mean shape $\overline{S}$ and covariance matrix C are computed (2):

$$\overline{S} = \frac{1}{M}\sum_{i=1}^{M} S_i \,, \; C = \frac{1}{M}\sum_{i=1}^{M} \widetilde{S}_i \widetilde{S}_i^{\,T} \qquad (2)$$

The difference between mean and object that is in data base are describe by the deformation vector $\widetilde{S}_i = S_i - \overline{S}$. The statistical analysis of the deformation vectors gives us the information about the empirical modes. Modes represent the geometrical features (shape) but also can carry other information like texture, map of temperature and others. Only few first modes carry most information, therefore each original object S_i is reconstructed by using some K principal components (3):

$$S_i = \overline{S} + \sum_{k=1}^{K} a_{ki} \Psi_k \,, \; i = 1,2,\ldots,M, \qquad (3)$$

where Ψ_k is an eigenvector representing the orthogonal mode (the feature computed from data base), a_{ki} is coefficient of eigenvector.

IV. Numerical analysis of shape of human faces

Numerical experiment is prepared onto the database which consist multiple faces. There are 19 faces (fig. 1) with neutral expression of different persons. In presented case three sets (6 faces) of the twin's faces (two sets of identical – monozygotic twins and one set of fraternal – dizygotic twins). For data acquisition the 3D scanning was used.

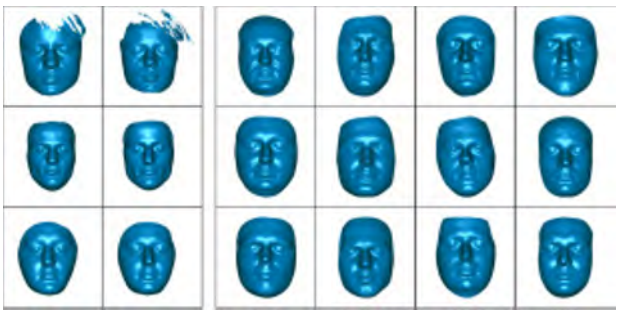

Fig. 1 Examples of faces in database: faces of the twins (left two columns)

A. Data acquisition – 3D scanning

For 3D scanning the structural light technique was used (fig. 2). On each face was projected set of 201 lines (raster matrix) after camera was capture image. Projected lines are calculated in triangulation process onto curve network. In next step from curves set of points (200 points per line) are extracted. Finally each face is described by individual point clouds (40200 points).

The Principal Component Analysis requires the same position, orientation and topology of the data input (the same number of nodes, matrix connection, etc.) for all objects. To achieve this, every new object added to database must be registered. Origin point of coordinate system is arranged in

Fig. 2 Data acquisition process (from upper left): hardware configuration, raster matrix, captured image, 3D curve network, extraction points from curves, input data (points cloud)

cross section of two lines: vertical middle line on the face, horizontal – eyes line

B. Face shape analysis – PCA analysis

For prepared database of 19 faces the Principal Component Analysis was done. The result of this operation is the mean face, nineteen modes and set of coefficients (fig. 3).

The eighteen modes include one hundred percent of information about decomposed geometry (table 1.). Mode nineteen contains only a numerical noise. For further reconstruction of face geometry only first eighteen modes are used.

Modes describe the features of the faces. Two first modes characterize global transformation: first mode changing of the face size in vertical direction and deep of eyes, second mode changing the size in horizontal direction. Further modes describe more complex, local deformations.

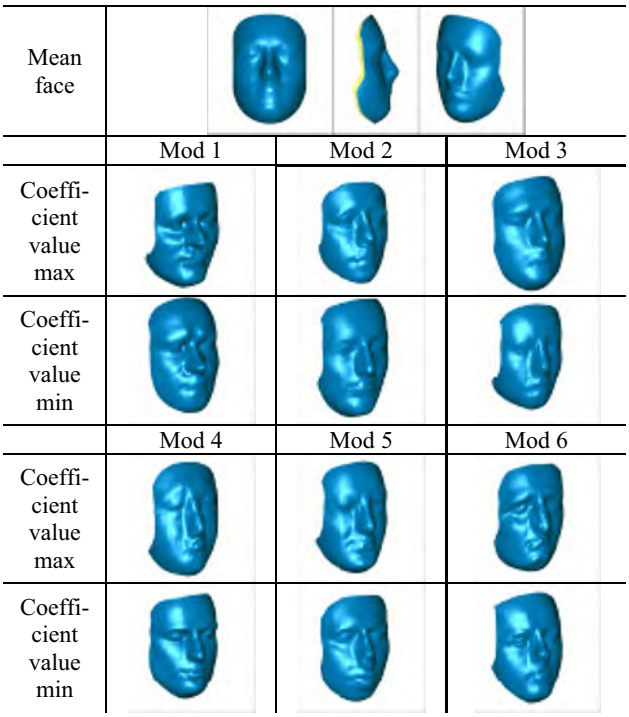

Fig. 3 Visualizations of the mean face and first five empirical modes of faces (for max and min coefficient value)

Table 1 Participation of the modes in face description

Number of the mode	Participation of the mode [%]	Total participation of the modes [%]
1	41,3730939	41,3730939
2	20,4650772	61,8381711
3	14,1903043	76,0284753
4	8,6513257	84,6798011
5	3,4490109	88,1288119
6	2,5576350	90,6864469
7	2,1880060	92,8744530
8	1,3711281	94,2455811
9	1,1804560	95,4260371
10	0,9962907	96,4223278
11	0,8217357	97,2440635
12	0,6042358	97,8482994
13	0,4746871	98,3229865
14	0,4590013	98,7819878
15	0,3851753	99,1671631
16	0,3188265	99,4859897
17	0,2656575	99,7516472
18	0,2483528	100,0000000
19	0,0000000	100,0000000

Results of the statistical analysis (empirical modes) can be used for reconstruction of geometry (in CAD systems) of individual features of the object.

C. Similarity and differences of twins faces – PCA

PCA analysis which are make for each set of twins faces give information about common shape and differences of face (also surface map of differences). For two sets of twins faces individual PCA analysis was done (fig. 4, fig. 5).

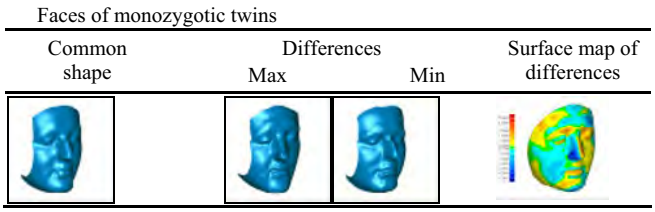

Fig. 4 Visualizations of the common shape (mean face) and differences (empirical mode and surface map of difference) for monozygotic twins

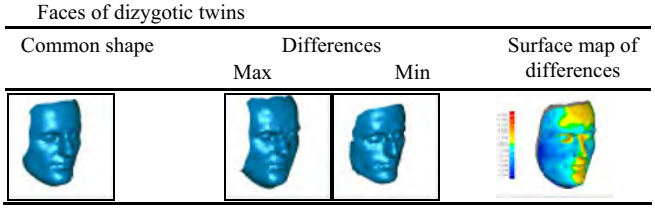

Fig. 5 Visualizations of the common shape (mean face) and differences (empirical mode and surface map of difference) for dizygotic twins

V. 3D BIOMETRIC DESCRIPTION – FACE CODING

Empirical modes give us information about 3D mean shape of population objects and set of the geometrical features which describes principal deformations in analyzed population of the objects. Each face in database has unique set of coefficient values – "ID code" (fig. 6).

As the authorization key the set of coefficient values for the faces can be used. Each key describes individual shape of face and can be decoded and compared with the original data of user to obtain access to restricted area or data files. Also for identical (for human eye view) monozygotic twins this "face code" is incomparable for each one face similar like for fingerprints [2].

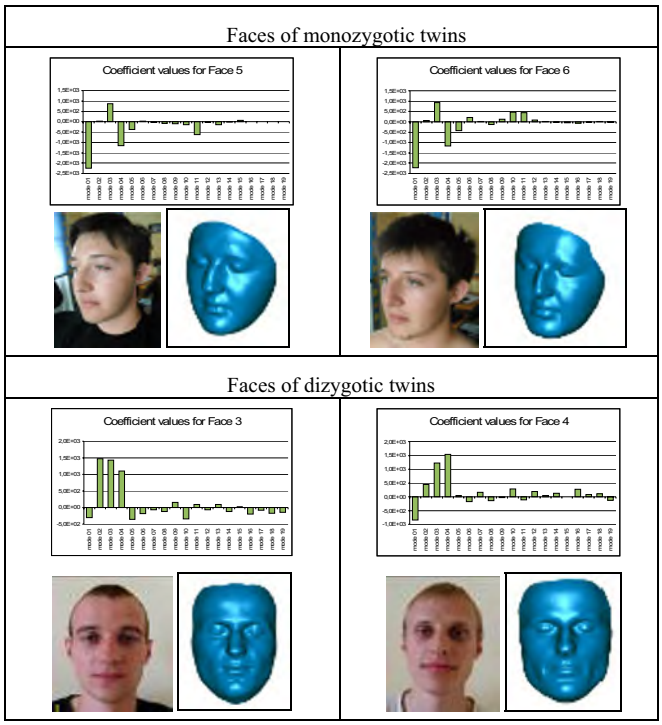

Fig. 6 Face ID code for faces of two types of twins (from upper left): face code – coefficient values, original photo, 3D face model

VI. CONCLUSIONS

Presented method as the source of data input apply cheap non-contact measurement method and full 3D face information instead set of control points (few nodal points in "golden triangle" area). 3D face code is more proof onto fake than 2D face recognition systems. Further is possible to add to data base additional information's (not only about geometry) like e.g. thermal photo (map of temperature).

Application of 3D PCA into biometric security systems make possible using 3D faces as the access code. Each face has individual set of coefficient values – unique face code. That information (code) can be easily recorded onto electronic ID card – similar to 2D biometric data's.

This method can be used for extraction and description of similarity and differences of twins faces. Advantages of this method is possibility of distinguish of identical monozygotic twins what is usually very difficult for standard security systems (2D pictures analysis).

Birds' Flap Frequency Measure Based on Automatic Detection and Tracking in Captured Videos

Xiao-yan Zhang, Xiao-juan Wu, Xin Zhou, Xiao-gang Wang, Yuan-yuan Zhang

School of Information Science and Engineering, Shandong University
Jinan 250100, P. R. China

Abstract — **Flap frequency of birds, as an important feature in identification and behavior assessment to attractants, has not found a good way to measure in videos. In the paper, we try to measure flap frequency of birds automatically based on detection and tracking. The size of bird's area in image fluctuates with wing flaps. In the 90° pitch angle case, when wings are flat, the area is the largest, and then the area decreases along with wings moving upwards or downwards. Based on the feature, we get flap frequency of birds by analyzing fluctuation periods of area size signals.**

Videos are captured by pointing the camera upwards to make the image against the sky, and moving with birds to get large range flapping motion. The detection part is based on two levels background update algorithm to achieve fast background update under abrupt scene changing. The tracking of maneuverable birds is achieved by using a Markov Chain Monte Carlo (MCMC) filter with a flexible motion model to adjust tracking boxes duly to cover areas of birds. Then local time flap frequencies are gotten by using Short-Time Fourier Transform (STFT) to analyze size signals after a smooth filter and a normalizing filter. The average frequency of every window is computed to reflect the quantitative local frequency.

The experiment results show that the frequency spectrum and average frequency of size signal can accurately reflect the actual flap frequency of birds. Based on the fluctuation of local frequencies we can estimate the flight pattern of birds, even in a bird cluster, we can analyze the flight character of the cluster by choosing several interested targets. The change of flap frequency in different flight patterns can give us inspiration for making artificial aircraft.

Keywords — **flap frequency, detection, track, STFT, bird**

I. Introduction

Wing flap frequency of birds play significant role in birds behavior. The abnormity of wing flap frequency can be used to assess the influence of attractants (for example chemicals and light). Determination of frequency of wing flaps during the bird flight is important for understanding mechanical power output of muscle and flight pattern [1]. Wing flap frequency of each species overlaps all other species. However, mean wing flap frequencies are significantly different for all species, so the difference of wing flap frequencies between species has been great information in identification [2, 3, 4].

Videos can capture all the information of free flight. The key of the research based on video is to extract the needing information. Though there has been a long study history of wing flap frequency, but methods based on the video are scarce. The most often used method for free flight is radar [2, 5], for the temporal pattern echo signature depends mainly on the variation in the shape of the target which for birds is caused by change in body shape due to flapping. But a significant proportion of the signals observed is provided by insects, bats, other flying objects and weather phenomena [2]. So it is a problem to separate bird signals from non-bird ones. Another method is using a beat-frequency oscillator as well as personal auditory analysis, but it contains many interferences produced by the birds movements that are not connected with flight (for example, respiratory movements of abdomen) [6, 7].

In flight, birds flap their wings upwards and downwards. When the relative angle between camera and birds is fixed, sizes of birds' areas in image fluctuate with wing flaps. In 90° pitch angle case, as the bird in red box shown in Fig.1, when wings are flat, area is the largest, and then the area decreases with the wing moving upwards and downwards. So in continuous flight, size signal of bird's area in image fluctuate in the same frequency with wing flaps. This gives us inspiration for measuring the wing flap frequency by analyzing the size signal of bird's area. Size signals are recorded based on accurate detection and tracking.

We use two levels (pixel level and frame level) background update algorithm [8, 9] to get excellent foreground in real time. In frame level, three thresholds are used to update the background to achieve fast background update under abrupt scene changing produced by moving clouds. Targets are detected from binary foreground after retrieving contours. In tracking, for getting accurate areas of tracked

50 flat #53 downwards #55 upwards

Fig. 1 A wing flap period in 90° pitch angle case

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1858–1861, 2009
www.springerlink.com

targets, tracking boxes should adjust in real time to cover areas of birds. This is achieved by using a Markov Chain Monte Carlo (MCMC) [10, 11, 12, 13] filter with a flexible motion model.

Recorded size signals are processed by a smooth filter and a normalizing filter which is to delete the influence of distance between camera and birds. Local time flap frequencies are gotten by using Short-Time Fourier Transform (STFT) to make time-frequency analysis and computing the average frequency of every local window.

II. Materials and Methods

A. Getting Videos

In capturing, the camera moves with free flight birds in open sky to get large range flapping motion. To avoid abrupt changing background in videos, which is a seriously problem for detection and tracking, the camera is pointed upwards and makes the image against the sky. The relative angle between camera and birds is fixed in range 30°-90°. All the videos are in avi format and the resolution is 320×240 with frame rate 25fps.

B. Birds detection and tracking

We adopt background subtraction algorithm to segment moving targets in videos. The background is updated in frame level and pixel level each time [8, 9]. In pixel level update, pixels that change in continuous λ frames will be updated into the background B(t) at time t with a weight α. α and λ are set according to the character of the background, but for making sky as background, α is 0.1-0.4 and λ is 4-8. In frame level, three thresholds $TL1$ (smaller than 0.001), $TL2$ (in 0.5-0.7), $TL3$ (in 0.7-0.8) are used to update the background separately to achieve fast background update under the situation of the abrupt scene change. Given the width and height of the image w, h, the change rate of the whole frame is

$$v = \frac{\sum_{j=1}^{w}\sum_{i=1}^{h} F_{i,j}(t)}{w \times h} \tag{1}$$

Once v is smaller than TL_1, we will make a decision that no moving targets in current image. If v is bigger than TL_3, it is seen that there is a new scene in current image. In the two cases, we will update all the pixels to the background. When v is between TL_2 and TL_3, background will be updated with bigger weight α (bigger than 0.5).

The foreground is gotten by subtracting the updated background from the image. Then birds are detected from the binary foreground after retrieving contours.

Detected birds will be tracked using MCMC algorithm with a flexible motion model. The state of every target is defined as $\boldsymbol{X}_{i,t} = (x_{i,t}, y_{i,t}, w_{i,t}, h_{i,t}, r_{i,t})$, where $(x_{i,t}, y_{i,t})$ is the center, $w_{i,t}$ and $h_{i,t}$ are the width and length of the target, and $r_{i,t}$ is the relative orientation. At each time step, N_M (the number to reach mixing time) samples are generated using Metropolis-Hastings (MH) algorithm [10].

The motion model is defined as

$$\boldsymbol{X}_{i,t} / \boldsymbol{X}_{i,t-1} = \boldsymbol{X}_{i,t-1} + [\Delta x, \Delta y, \Delta w, \Delta h, \Delta r] \tag{2}$$

Where Δx, Δy, Δw, Δh, Δr are Gaussian random walks. The deviation of each Gaussian random walk decides the diffuse range of the corresponding parameter. σ_w, σ_h as deviations of Δw and Δh are set about 0.5 to adjust the tracking box fast to cover shape changing birds in real time.

We use the binary observation model proposed by Kevin Smith in [12, 13]. Given the precision v and recall ρ measures of targets i and j as in [12], the observation model is

$$\phi(\boldsymbol{X}_i, \boldsymbol{X}_j) \propto \exp(-\lambda\sqrt{v(\boldsymbol{X}_i, \boldsymbol{X}_j)\rho(\boldsymbol{X}_i, \boldsymbol{X}_j)}) \tag{3}$$

C. Pre-processing of recorded data

Size signals of tracked birds are recorded by counting the number of pixels which have a value 1 in the binary foreground and are tracked by the corresponding tracking box.

When capturing videos, for the maneuverability of birds, the distance between camera and birds is not fixed, so area sizes of the same action at different times are not on the same level. To get accurate flap frequency, original size signals are processed by a normalizing filter.

The original size signal $F(n)=[f_1,\ldots, f_N]$, N is the length of the signal, is smoothed first by a smooth filter. Local minimum value points of the smoothed size signal $GF(n)$ are $P_1, P_2,\ldots,P_L$ and $P_0=1$, $P_{L+1}=N+1$. The part between two consecutive local minimum value points P_i and P_{i+1} is a flap period. The adjusted signal $AF(n)$ is given for l=0,…,L

$$AF(n) = GF(n) - \frac{\sum_{m=P_l}^{P_{l+1}-1} GF(m)}{P_{l+1} - P_l}, \qquad n = P_l, ..., P_{l+1} - 1. \tag{4}$$

Finally the normalized signal $NF(n)$ is

$$NF(n) = AF(n) / V_{max} \tag{5}$$

where V_{max} is the maximum value of $AF(n)$, n=1,…,N.

D. Flap frequency analysis

STFT is used to analyze the time-frequency distribution of the pre-processed size signal. It is defined as

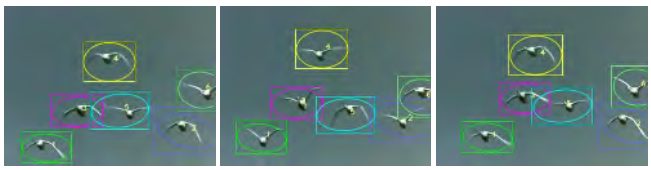
$$S(k,n)=\sum_{m=-\infty}^{\infty} x(m)w(m-n)e^{-j\frac{2\pi k}{\mathrm{M}}m},\quad k=0,...,\mathrm{M}-1 \quad (6)$$

where $x(m)$ is the signal and $w(m)$ is the analysis window. M is the length of $w(m)$ and it influences the resolution of time and frequency domains, so it should be decided according to the length and character of signal $x(m)$.

In equation (6), for every value of n, we can get a spectral array $S(k)$, $k=0,...,\mathrm{M}-1$. Every spectral array shows a spectrum. In order to get quantitative local frequencies, we compute average frequency $\overline{f}_n$ of every spectrum. The average frequency is defined as

$$\overline{f}_n=\frac{\sum_{k=0}^{\mathrm{M}-1}S(k)\cdot f(k)}{\sum_{k=0}^{\mathrm{M}-1}S(k)} \quad (7)$$

$$f(k)=k\cdot\frac{\mathrm{F_S}}{\mathrm{M}-1} \quad (8)$$



where $f(k)$ is the frequency value of the k-th point, and $\mathrm{F_S}$ is the sampling frequency [14]. When moving the window, we can get an average frequency array $\overline{f}_n$, n=0, 1, 2….

III. Results

In a bird cluster, all birds almost fly in the same flap frequency. We can see this clearly in Fig. 2 (the video is part of bird migration from "The Traveling Birds"), where poses of the six tracked birds in frame 78 are approximately the same as those in frame 69 for the time from frame 69 to 78 is a flap period. So the flap frequency of one bird in a cluster reflects the frequency character of the cluster.

The size signal of No.1 bird was recorded in Fig. 3 to measure the flap frequency of the cluster. The original recorded size signal (the fist signal in Fig. 3) is not smooth and has an increasing trend, but the period of every flap is clear. The smooth filter removed small saw teeth of it and the normalized signal kept the wave character of the original signal and adjusted every period to the same level (the third signal in Fig. 3).

Fig. 4 shows wing flap frequency analysis results. The length of the STFT window is 29, and the length of signal is 126. To avoid the influence of boundary, we only computed average frequencies of frames from 15 to 112. The time-frequency image (Fig. 4(a)) and the average frequency array (Fig. 4(b)) both reflect that the flap frequency of the cluster is about 3Hz, but at the time period, the flap frequency fluctuates at 2.8-4HZ.

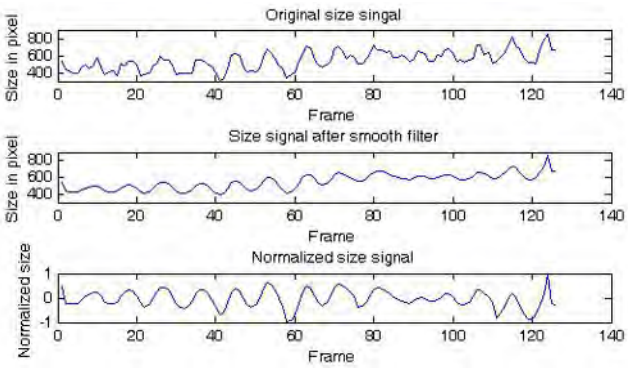
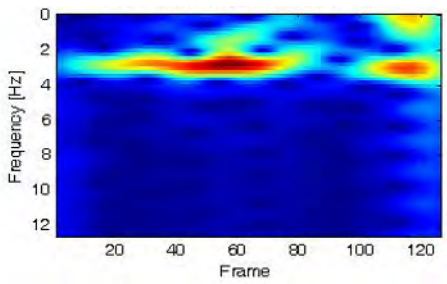
Fig. 2 A flap period of a tracked bird cluster





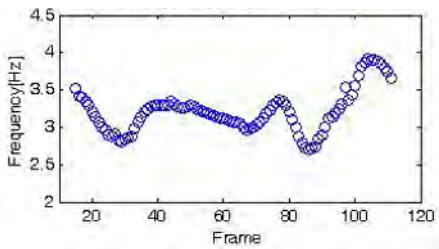


Fig. 3 The pre-processed result of the original size signal

(a) Time-frequency image

(b) Average frequency array

Fig. 4 STFT analysis results

IV. Discussion

In order to check the accuracy of analysis results based on the size signal, we computed the frequency of every period F_s /T in Fig. 5, where T is the length of every period gotten by visual observation. Comparing Fig. 4(b) and Fig.5, we can see that the average frequency of every local window after STFT analysis correctly reflects the fluctuation of flap frequency with time, but at frames 70 to 80, the average frequencies have some error, for the influence of the big change of the 9-th and 10-th periods. STFT is to use a window to select short time intervals for spectral analysis, so at the turn of two frequencies, the analysis result will have some error. This proves that the average frequency of every time does not represent the instantaneous frequency, but reflects the local frequency character.

Even the rhythm of every bird is not always the same in a cluster as in Fig. 1 and Fig. 2, the flap patterns of them are always the same with same fluctuation of flap frequency, so we can choose one or several interested birds as analysis targets to research the cluster's flap character.

Compared with free-flight methods using radar and sensor, the method based on video is more reliable, for we can check the result with visual image and have no interference from other species.

In capturing, the camera needs not have the same speed with birds, for the influence of relative distance can be deleted by using the normalizing filter as in Fig. 3, but the relative angle between camera and birds should be fixed in a small range. The range of consecutive flap motion that can be captured by camera is limited. In order to research wing flap frequency of migrating birds, we can capture videos in different stages, for example level cruising flight, tacking off and climb or fall.

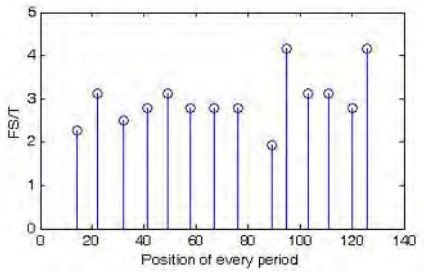

Fig. 5 F_s /T, T is the length of every period

V. Conclusions

In the paper, we measure wing flap frequency of birds in videos. The useful signal is the changing size of birds in flight. Size signals are gotten from accurate detected and tracked birds' areas. The fluctuation of flap frequency in flight is analyzed using STFT and average frequency array. Using the proposed method, we can get the local flap frequency of every time. The wing flap frequency measured in captured videos is important information for classifying birds using pattern identification methods. This can be used in surveillance systems at sensitive areas, for when knowing the species of birds, we can make measures to prevent the intrusion. The time-frequency distribution shows us clearly the change of flap frequency in different flight stages which gives us inspiration for making artificial aircraft.

Effects of Upper-Limb Posture on Endpoint Stiffness during Force Targeting Tasks

Pei-Rong Wang[1], Ju-Ying Chang[2] and Kao-Chi Chung[2]

Abstract — **Endpoint stiffness is characterized as the relationship between externally imposed displacements of the hand and the elastic forces generated in response and can be estimated during the application of short-term perturbations to endpoint based on measured force and position data. This research was aimed to investigate biomechanical properties via estimation of upper limb endpoint stiffness and joint torques during force targeting tasks. Sixteen able-bodied subjects were recruited in the study and the informed consent was signed by each subject. A 10-N force task was conducted at right and left directions for three upper limb postures. Hand endpoint trajectories and the response forces were recorded simultaneously for each trial. The 2x2 endpoint stiffness matrix and corresponding stiffness ellipse were determined by least squares error method. Resultant shoulder and elbow torques were also calculated by inverse kinetics. Kruskal-Wallis test was used to analyze the effect of postures and movement directions on endpoint stiffness and joint torques. The results of this research indicated that the postures have significant effects on endpoint stiffness ellipse of upper limb, the shoulder and elbow joint torques during force production tasks (p<0.05). These results demonstrate the importance of upper-limb posture when performing force targeting tasks. The clinical implementation suggests that endpoint stability can be more effectively affected by different upper-limb postures.**

Keywords — **Upper-limb, endpoint stiffness**

I. Introduction

Endpoint stiffness, defined as the relationship between externally imposed displacements of the hand and the respond force generated, stabilizes the hand position [1,2]. Previous researches have suggested the spring-like properties of muscles determine the individual joint stiffness [3]. To observe the multi-joint stability of the arm system, displacement of hand by externally applied displacements has been resisted instantly by elastic force resulted from various muscles of upper extremity. In addition, the resultant elastic resistance is not only due to joint stiffness, but depends on the posture-dependent joint angles and respective limb segment lengths [1,3]. The endpoint stiffness is related to the geometric factors of joint angles and limb segment lengths [3]. It is indicated that posture is more effective than joint stiffness in stabilizing hand position [3]. The endpoint stiffness ellipse, which is characterized from the eigenvalues of endpoint stiffness matrix, represents the stability of the hand[4]. The major axis of the ellipse is oriented along the direction of the maximal stiffness; the minor axis of the ellipse is oriented along the direction of the minimal stiffness [5]. The orientation of the ellipse is decided upon the eigenvector associated with the maximal eigenvalue of endpoint stiffness matrix, and indicated the direction of the maximal stiffness [5]. It is seemed to be most successful in stabilizing hand position when the direction of the force production is aligned with the direction of greatest endpoint stiffness [3]. However, the quantitative relationships between the force production task and the geometric factors are still less discussed. This research is to investigate the effect of postures and movement direction on endpoint stiffness and joint torques during force production task. More specifically, this research is aimed to:

1. design a 2-D platform system to provide upper limb's training and assessment ,
2. investigate the effect of posture and movement direction on endpoint stiffness of upper limb during force production tasks,
3. investigate the effect of posture and movement direction on shoulder and elbow joint torques during force production tasks.

II. Materials and methods

A. Instrumentation

The first stage of this research is to design and develop the 2-D platform system for upper limb's objective endpoint assessment and training, including conceptual and functional design, hardware selection and integration, calibration and performance testing. The hardware included two servomotor and encoders (SV4835, King Right Motor Corporation, Taiwan), two force transducers (RVQ16YN, Cosmos, Jin Hua Electronic CO.LTD., Taiwan), two slide mechanisms, one stainless steel manipulandum and the iron frame, as in Fig. 1. There are two mainly operation modes of the 2-D platform system: active and passive movement modes. The passive movement mode contains two evaluation and training functions: relaxation and force target functions. This research selects the force target function from the pas-

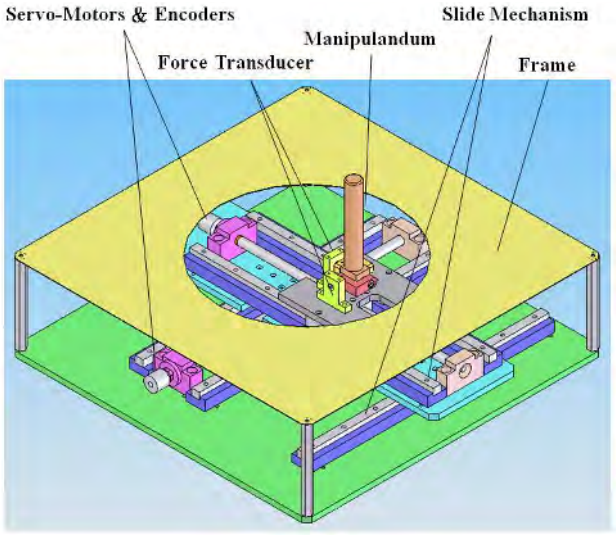

Fig. 1 Illustration of 2-D platform system

sive movement mode to investigate the biomechanical properties of upper limb endpoint stiffness and joint torques during force production tasks.

B. Biomechanical modeling

The two-link and open kinematic chains used to simulate the kinematic model of upper limb are the mainly biomechanical model of this research. The 2x2 endpoint stiffness matrix, which is the change in endpoint force with respect to change in endpoint position, is presented by the following equation Eq. 1 [5]. The 2x2 joint stiffness matrix related to shoulder and elbow joint torques is determined by inverse dynamics, as shown in Eq. 2, where the Jacobian, J, is a function of the limb segment lengths and joint angles [5]. The orientation of the endpoint stiffness ellipse is determined by the direction of the eigenvector associated with the maximum eigenvalue of the endpoint stiffness matrix. The ratio of endpoint stiffness ellipse is determined from the long axis divided by short axis and means to the shape of the endpoint stiffness ellipse.

$$K = \begin{bmatrix} \frac{\partial F_x}{\partial x} & \frac{\partial F_x}{\partial y} \\ \frac{\partial Fy}{\partial x} & \frac{\partial F_y}{\partial y} \end{bmatrix} = \begin{bmatrix} K_{xx} & K_{xy} \\ K_{yx} & K_{yy} \end{bmatrix} \quad (1)$$

$$\begin{bmatrix} TQ_s \\ TQ_e \end{bmatrix} = J^T \begin{bmatrix} F_x \\ F_y \end{bmatrix} = J^T K_s \begin{bmatrix} dx \\ dy \end{bmatrix} \quad (2)$$

C. Experimental procedures

Sixteen subjects ranging from 23 to 28 years-old (nine male and seven female) with no history of neurological impairments were participated in this study. The protocol was approved by human experiment and ethics committee of National Cheng Kung University Hospital, ROC. The informed consent was signed by every subject prior to the study. There were total three sitting positions for this study: the central position was defined subject's hand located 40 cm far in front of sternum, the left and right position were defined apart one-thirds shoulder girdle width from central position, respectively. All subjects accomplished tasks with their right arm. Before initiating every trial, the subject seated and always the same experienced researcher measured the limb length of upper arm and forearm, and the shoulder and elbow joint angles. Anthropometric data for every subject included upper arm length (Lu) measured from right acromion process of scapula to right lateral epicondyle of humerus, forearm length (Lf) measured from the right lateral epicondyle of humerus to right styloid process of radius, shoulder joint angle at the right position (RSangle), elbow joint angle at the right position (REangle), shoulder joint angle at the central position (CSangle), elbow joint angle at the central position (CEangle), shoulder joint angle at the left position (LSangle), and elbow joint angle at the left position (LEangle). Demographic and anthropometric data for all subjects were illustrated in Table 1.

There were totally 6 conditions (2 direction targets × 3 sitting position) in the experiment (Fig. 2). Initial position of the hand on the screen was centered on the start window. Two goal-oriented targets were located both sides on the window screen and randomly showed. Subjects were instructed to push the robotic manioulandum to right or left according to the targets appearing on the screen. While the subject was holding the manipulandum with 10-N force magnitude for six seconds, the displacement perturbation with 1cm was applied to interrupt the force task trial. Subjects were asked to stabilize the hand with visual feedback while counteracting a destabilizing force field generated by the robotic manipulandum. There were eight perturbation directions from 0° to 360°. The endpoint forces and displacements, shoulder and elbow joint angles were recorded. There were three trials in every set of the force production task, and every trial contained four times of the random perturbations. The subject took a rest about 30 to 60 seconds between trials for avoiding muscle fatigue. The subject was conducted the perturbation experiment for three upper-limb postures for right and left movement directions.

Table 1 Demographic data of all subjects

Item	N	Mean	Std.
Age (y/o)	16	25.3	1.3
Height (cm)	16	167.1	6.1
Weight (kg)	16	61.4	8.2
Lu (cm)	16	30.4	1.8
Lf (cm)	16	26.7	1.7
RSangle (deg)	16	97.1	11.6
REangle (deg)	16	31.9	10.3
CSangle (deg)	16	72.3	5.0
CEangle (deg)	16	51.5	8.6
LSangle (deg)	16	51.8	13.7
LEangle (deg)	16	52.5	7.2

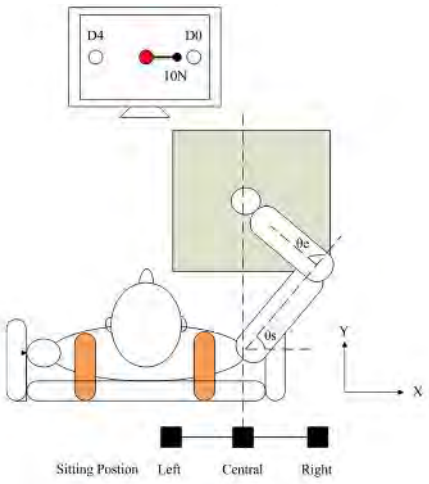

Fig. 2 Diagram of study protocol: including the coordinate system with the subject, two goal-oriented targets (D0 & D4), and three sitting position (left, central, right sitting position)

For each perturbation direction, the endpoint stiffness matrix was calculated from endpoint forces and displacements through Eq.1. For each subject, the parameters of endpoint stiffness matrix were estimated by least squares error method on 8 perturbation directions. The parameters of endpoint stiffness ellipse were characterized and calculated by the eigenvalues of the endpoint stiffness matrix. The shoulder and elbow joint torques (Ts, Te) were estimated by endpoint forces and joint angles through the Jacobian matrix by inverse dynamic equation (Eq.2). Kruskal-Wallis test was used to analyze the effect of postures and movement directions on endpoint stiffness and joint torques. The significance level was at a 0.05 level.

III. Results and Discussion

Table 2 shows the median of endpoint stiffness matrix estimated from 16 subjects for 3 different postures and for 2 movement directions. The median of long axis, orientation, and ratio of the endpoint stiffness ellipse are shown in Table 3. The median of shoulder and elbow joint torques are shown in Table 4. The results of statistical analysis (Table 5) have revealed that : (1) the postures have significant effects on endpoint stiffness ellipse of upper limb, the shoulder and elbow joint torques during force production tasks (p<0.05), (2) the movement directions have no significant effects on endpoint stiffness of upper limb, the shoulder and elbow joint torques during force production tasks.

IV. Conclusions

The contribution of this research emphasizes the importance of upper-limb postures during force targeting tasks. It suggests a simplified strategy which is posture-independent in the central nervous system using to regulate the whole arm mechanics during force targeting tasks. The clinical implementation suggests that endpoint stability can be more effectively affected by different upper-limb postures.

Complex Anatomies in Medical Rapid Prototyping

T. Mallepree[1], D. Bergers[1]

[1] University of Duisburg-Essen, IPE-PP, Duisburg, Germany

Abstract — **The complex anatomy of the nasal airways is an anatomy that is difficult to understand from conventional two-dimensional anatomy images. The objective of the present study was to establish the methods and parameters necessary to provide three-dimensional triangulated models for Rapid Prototyping. Anatomical data derive from scanned medical images made with computerized tomography. Different data sets of nasal airway structures were segmented and 3D reconstructed. With high-resolution scans, accurate segmentation of the structures was possible. The reconstructed and triangulated models were evaluated in order to determine triangulation parameters that are needed for Rapid Prototyping models. Gaining insight in the interplay of parameters necessary for modeling complex anatomies for Rapid Prototyping enables to provide accurate Rapid Prototyping models for biomedical engineering applications.**

Keywords — **Nasal airways, Rapid Prototyping, Triangulation**

I. Introduction

The planning of complex surgical procedures necessitates reliable models of the individual human anatomy. With a physical model at hand, it is possible to rehearse different surgical plans realistically. Medical modeling techniques known as biomodeling provide the possibility to reconstruct three-dimensional (3D) models of anatomical templates of parts of the human body [1]. Biomodeling methods can be employed to develop a 3D model for Rapid Prototyping (RP).

Recent studies introduced RP applications to specific research areas of surgical planning and manufacturing of personalized RP models [2,3]. For instance, Gibson et al. [3] used RP to demonstrate the possibility of manufacturing parts of the human anatomy and biological structures. De Zélicourt et al. [4] used the generative RP procedure of stereolithography to study a specific case of cardiovascular fluid dynamics. However, it remains unknown whether they studied the accuracy of the triangulation procedure in biomodeling. Due to Giannatsis [5] the virtual model construction phase is the main source of observed inaccuracies. The complete procedure and its related parameters of virtual model generation are of interest in order to provide accurate and reliable biomodels for medical RP procedures in a short period of time.

In contrast, our study used three different nasal anatomies to determine the decisive parameters for developing triangulated complex 3D models of the nasal airways in RP applications. We investigated the procedure from the tomographic computerized scan to the virtual biomodel that is converted to the stereolithography (.STL) format for RP. As marked in Figure 1, the study was focused on the decisive procedure of .STL data manipulation.

We performed evaluations on model quality and accuracy to determine a target area of parameter to use. The results could be supportive for a rapid but qualitative production of complex anatomies like the nasal airways in medical RP.

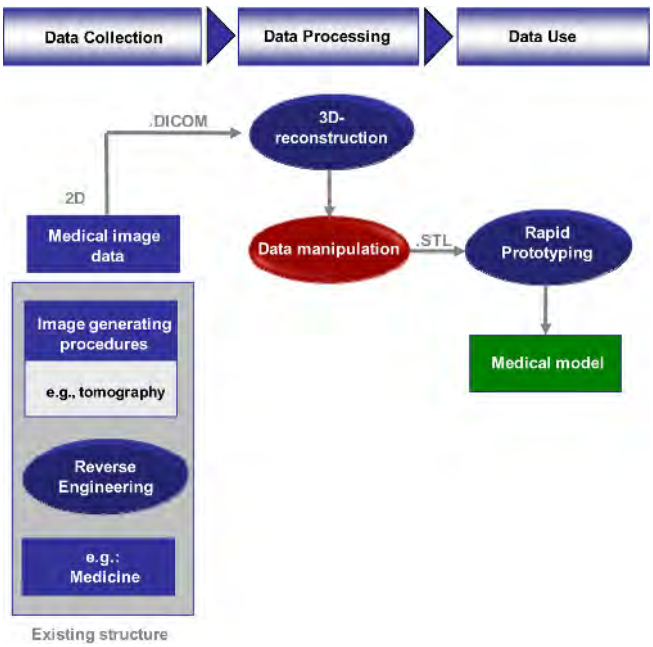

Fig. 1 Medical RP process

II. Methods

Three different high-resolution CT images were obtained as follows: the image matrix was set to 512x512 pixels, the slice thickness was set to 0,5 mm and the slice increment to 0,3 mm using a multi-slice CT scanner (Siemens Somatom

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1866–1869, 2009
www.springerlink.com

Sensation Open, Siemens Medical) in order to guarantee lowest possible deviations in scanning the geometry. In the data processing step, the scanned 2D images were imported as .DICOM files into the 3D reconstruction software Mimics (Materialise's Interactive Medical Image Control System, Materialise NV, Leuven) in order to reconstruct 3D volume models (Fig. 1). The nasal airways were segmented by selecting a mean density of about -1000 Hounsfield Units (HU) as threshold for extracting the air. That operation was followed by the connected component analysis of region growing. 3D triangulated models of each segmented structure were generated in Mimics using a marching cubes algorithm for iso-surface extraction. The produced triangular mesh models were .STL files that were manipulated for importing them into an RP application. The .STL data analyzing tool 3-Matic (Materialise NV, Leuven) was used for measuring the accuracy in terms of generating reference attributes (Table 1).

Table 1: Reconstructed reference models

Reference attributes	Model 1	Model 2	Model 3
File size	25.727 kB	20.250 kB	12.527 kB
Number of triangles	526.880	414.712	256.540
Measure x-direction	119,21 mm	105,67 mm	109,83 mm
Measure y-direction	344,65 mm	355,37 mm	288,54 mm
Measure z-direction	178,23 mm	199,52 mm	176,43 mm

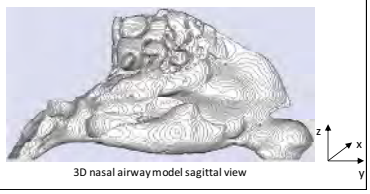
The depicted reference values (Table 1) of the three models were derived from 3D reconstructed data sets without using triangle reduction and smoothing functions in order to keep all geometry information. In Mimics the STL mesh quality and model accuracy can be influenced directly by triangle reduction and smoothing parameters. To find an optimum range of mesh quality and accuracy an evaluation study was carried out. First, the accuracy was tested (case A) and secondly the achievable STL mesh quality that defines the steadiness of the reconstructed surface (case B). The study investigated the influence of smoothing and triangle reduction in respect with the specific parameters depicted in Table 2.

The values to test were verified to find the best possible range to carry out triangle reduction and smoothing in terms of evaluating parameters for demonstrating the conflict of accuracy (case A) and STL mesh quality (case B). This was tested by the use of three data sets. The parameters were evaluated by varying the influencing factors of tolerance, edge angle and smoothing factor. The smoothing algorithm used was based on the Laplacian 1st order function.

Table 2 Triangulation parameter

Parameter	Function
Triangle Reduction:	
Tolerance	Maximum deviation of triangles that build a aggregation of triangles, which deviate about the set value for tolerance
Edge Angle	Defines the maximum angle that triangles enclose in one plane before they will be linked to a different plane. Triangles with an angle smaller as the set edge angle will be modified
Iterations	Defines the number of runs for reducing the data
Mode	Defines the methodology of triangle reduction.
Smoothing:	
Iterations	Defines the number of runs for smoothing the surface
Factor	The Laplace filter iteratively traverses all surface vertices and moves each vertex into the geometric center of its topological neighbors. The factor regulates the effect of the direct neighbors on the new position.

Measurements were performed for verification. The spatial measures in x-, y-, and z-direction were compared in each case to detect possible deviations. Part comparisons with the reference data sets (Table 1) and tested data sets (Fig. 2, Fig. 3) were carried out additionally in order to evaluate deviated triangles. The distance from one triangle to the next one was measured to state a maximum deviation.



III. Results

Analyzing the outcome of the tested three models as shown in Figure 2 and 3, it could be stated that there was a conflict between accuracy and STL mesh quality. The decisive parameter that influences different outcomes was the smoothing factor. Using the parameters as depicted in Figure 2, resulted in high accurate models that were of a lower STL mesh quality. Selecting a smoothing factor of 0,1 in combination with the triangle reduction parameters as depicted in Figure 1, there was a data reduction of more than 75 %, a measure deviation in x-direction of not more than -0,23 mm, a measure deviation in y-direction of not more than -0,20 mm, and a measure deviation in z-direction of not more than -0,07 mm. The results were high accurate models that are of a lower STL mesh quality.

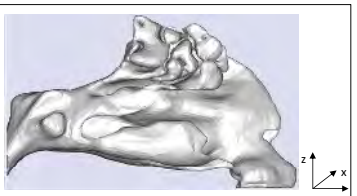

Fig. 3 Parameter best STL mesh quality (case B)

Part comparisons conducted with the specific reference models (Table 1) revealed that 90% of existing triangles were not higher deviated than 0,104 mm in case A.1, 0,09 mm in case A.2, and 0,127 mm in case A.3. As Figure 4 demonstrated exemplary by case A.1 (Fig. 2), deviations (red marked) were distributed all over the surface.

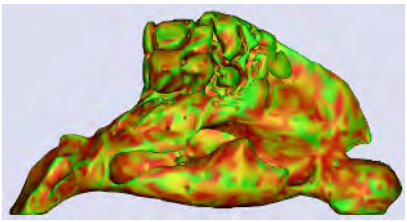

Fig. 4 Part comparison

Partial tests on triangle reduction revealed that a tolerance of 0,15mm, an edge angle of 15°, a number of iterations of 4, and the mode of advanced edge allowed optimal data reduction. The use of triangle reduction parameters and smoothing parameters in combination as shown in Figure 3 revealed that a data reduction of 89,99 % at minimum was possible along with a mesh of high quality. That result was affected negatively by measure deviations in x-, and y-direction of not more than -1,61 mm, and in z-direction of not more than -0,26 mm. Part comparisons conducted with the specific reference models (Table 1) revealed that 90% of existing triangles were not higher deviated than 0,508 mm in case B.1, 0,336 mm in case B.2, and 0,826 mm in case B.3.

In summary, the parameter evaluation for triangle reduction and smoothing detected values as depicted in Table 3.

Table 3: Determined parameter values

Parameter	Determined values
Triangle Reduction:	
Tolerance	0,15 mm
Edge Angle	15°
Iterations	4
Mode	Advanced Edge
Smoothing (Laplace 1st order):	
Iterations	3
Factor	0,1 - 1

The highest accuracy could be measured in case A.3. In that case, the highest deviation was -0,15 mm in x-direction.

IV. Conclusions

The main finding of this study is the good agreement observed between three different data sets from which RP models of the nasal airways could be derived by validated parameter. The determined parameters confirm the ability of RP for producing complex medical models like the nasal airways.

It is hard to pinpoint the exact reason for the relative disagreement observed at the different models in respect with the measurement values. Consequently, it could be explained by the different anatomies scanned. Larger geometries lead to more triangles in the resultant .STL file. Different meshing is the consequence and leads to a different number of triangles and measures. The high accuracy in case A.3 mainly seems related to the original number of triangles of 256.540. That could be explained by the lowest number of triangles that needs to be optimized during the smoothing operation.

Combining results of both triangle reduction and smoothing using the determined parameter as depicted in Table 3 leads to a conflict of accuracy or STL mesh quality. The result is influenced by the factor of smoothing. Though, smoothing should be conducted carefully in order to obtain accurate models for the final RP application. Avoiding inaccurate virtual 3D models for RP, the proposed parameters will lead to high-qualitative and process feasible RP models even of complex anatomical models like the nasal airways when effective triangulation parameters will be used. Due to Ma et al. [5], the generation of accurate .STL files is essential for manufacturing high-qualitative models for RP applications in medicine. Since RP allows manufacturing of anatomical objects, knowing the parameters to use for providing models for RP may finally support accuracy of medical models and decrease processing time in biomedical engineering applications.

Early Changes Induced by Low Intensity Ultrasound in Human Hepatocarcinoma Cells

Y. Feng, M.X. Wan

Laboratory of Biomedical Information Engineering of Ministry of Education, Department of Biomedical Engineering, School of Life Science and Technology, Xi'an Jiaotong University, Shaanxi Province, China

Abstract — **To determine whether low intensity ultrasound irradiation can induce early changes in human hepatocarcinoma cells and investigate the effects of ultrasound intensity, sonication time and incubation time post-sonication on US induced early changes, HepG2 cells were irradiated by low intensity US, at different intensity with different sonication time and incubation time post-sonication, respectively, in this study. Morphologic changes of cells were examined by light and fluorescent microscopy respectively. The percentage of viable, apoptosis and secondary necrosis cells were detected by flow cytometry with double staining of FITC-Annexin V/PI. Percentages of cells in different states were analyzed by L9 33 orthogonal test to find out most effective parameters for US induced early changes. The morphological characteristics of early apoptosis and secondary necrosis are found in US irradiated cells, however few in control. The fluorescent photos also prove early changes, such as phosphatidylserine externalization, increase significantly after US irradiation. The results from flow cytometry show the percentages of early apoptosis and secondary necrosis cells increase significantly after US irradiation ($P<0.05$). Orthogonal analysis reveals US induced early changes increase with the increase of ultrasound intensity; Moreover, US induced early changes may be an early time-dependent event with early apoptosis reaches its maximum at about 12 h. In this study, it is suggested that optimal early apoptosis with minimal necrosis is acquired when HepG2 cells were exposed to ultrasound at 5 W/cm^2 for 1 min and incubated for 12 h post-sonication. It reveals that ultrasound induced apoptosis is a preferred mode of killing cancer cells and suggests the optimal parameters setup for both *in vitro* experiments and its clinical application.**

Keywords — **low intensity ultrasound, early apoptosis, secondary necrosis, hepatocarcinoma, orthogonal analysis.**

I. Introduction

It is known that low-intensity ultrasound could induce early changes, such as early apoptosis and secondary necrosis, in several carcinoma cell lines [1]. During this process, many factors need to be considered to attain a controlled and predictable killing of cells in a desired mode of death. *In vivo*, because the apoptotic bodies are rapidly recognized and phagocytized by either macrophages or adjacent epithelial cells, no inflammatory response is elicited. Due to less immune reaction activated in the body during apoptosis, induction of apoptosis is a preferred mode of killing the cancer cells in the cancer therapy [2, 3].

During the irradiation process, several ultrasonic parameters, such as ultrasound intensity, sonication time and incubation time post-sonication, significantly work on ultrasound induced apoptosis. To get optimal apoptosis with minimal necrosis, these parameters could be optimized for both in vitro experiments and its clinical application.

Based on the knowledge above, the aim of this study is to prove low intensity ultrasound could induce early apoptosis and secondary necrosis in human hepatocarcinoma HepG2 cells, and then investigates the effects of several ultrasonic parameters on the ultrasound-induced early changes by orthogonal analysis. The results would be significant for the application of ultrasound in non-surgical cancer treatment.

II. Material and methods

A. Cell line culture

Human hepatocarcinoma HepG2 cell line was supplied by the Center of Laboratory Animals of the Forth Military Medical University, China. The cells were cultured in RPMI 1640 culture medium supplemented with 10% heat-inactivated fetal bovine serum (FBS) at 37 ^{o}C in water-saturated atmosphere with 5% CO2. The cells used in the experiment were in log-phase. The cell viability before irradiation was always over 95%.

B. Ultrasound exposure system

The ultrasound exposure system is shown in Fig.1. The central frequency is 1.2 MHz. The cell samples were carried in a specially designed inverted "T" tube described by Feril et al.[4]. Before the sample was filled in, the US pressure in the inverted "T" tube was detected by needle hydrophone probe (0.5-mm in diameter, HPM05/3 Precision Acoustic Ltd., Dorchest, UK). Temperature of water in the tank was controlled at 25 ^{o}C by circulating and monitored by thermocouple (0.5-mm diameter, Type K, Inor, Sweden), showing the maximum temperatures were less than 27^{o}C.

www.springerlink.com

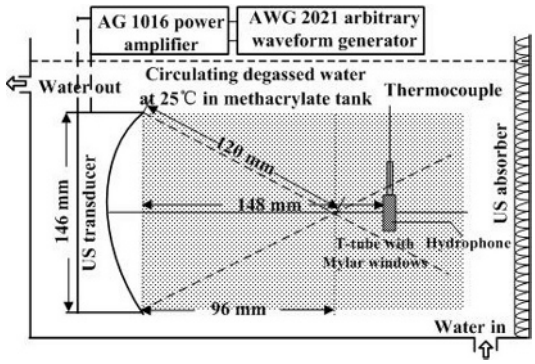

Fig.1 Ultrasound irradiation system

C. Study design

HepG2 cells were exposed to low intensity ultrasound at different intensity for different sonication time with different incubation time post-sonication. The experiment was constructed according to the principle of $L_9\ 3^3$ orthogonal method. The detail is shown Table 1 and Table 2. Fraction of early apoptotic and secondary necrotic cells in the ultrasound sonicated samples were counted and analyzed by orthogonal analysis, which would suggest the relationship between ultrasound induced early changes and the ultrasonic parameters.

Table 1 Factors and their levels used for orthogonal array

Symbol	Factor	Level 1	Level 2	Level 3
A	Ultrasound intensity	2 W/cm^2	3 W/cm^2	5 W/cm^2
B	Sonication time	1 min	2 min	5 min
C	Incubation time post-sonication	6 h	12 h	24 h

Table 2 The $L_9\ 3^3$ orthogonal array and flow cytometry results for early apoptosis and secondary necrosis

No.	A	B	C	Early apoptosis	Secondary necrosis
1	1	1	1	20.3 ± 1.53	9.87 ± 0.94
2	1	2	2	28.2 ± 4.86	11.53 ± 1.68
3	1	3	3	20.7 ± 2.59	15.43 ± 1.17
4	2	1	2	29.6 ± 2.59	12.9 ± 1.50
5	2	2	3	27.47 ± 3.57	15.23 ± 1.28
6	2	3	1	25.67 ± 2.79	15.03 ± 1.69
7	3	1	3	29.13 ± 4.20	15.8 ± 1.58
8	3	2	1	28.5 ± 2.51	13.67 ± 1.27
9	3	3	2	35.0 ± 3.37	15.13 ± 1.76

D. Measurement of cell viability

Trypan blue exclusion test was performed to examine the cell viability. Cell suspension was incubated with 0.4% Trypan blue solution for 5 minutes at room temperature. The number of cells excluding Trypan blue (unstained) was counted using hemocytometer to estimate the survival (cells that are intact and viable) immediately after irradiation.

E. Morphologic observation

Early changes of cells are characterized by unique morphological changes, such as cell swelling or shrinkage, breakage of plasma membrane and nuclear chromatin condensation. In this study, the morphologic changes representing early apoptotic and secondary necrotic cells were examined by light microscopy with Trypan blue staining. Fluorescence microscopy is also used to examine the early changes, such as phosphatidylserine externalization, in sonicated cells stained by Annexin V-FITC.

F. Detection of early apoptosis and secondary necrosis

FITC-Annexin V/PI fit was purchased from Jingmei Biotechnology Company, China. Double staining for phosphotidylserine (PS) and DNA, respectively, by fluorescein isothiocyanate (FITC)-labelled Annexin V and propidium iodide (PI) was performed according to the protocol of the manufacturer. After incubation with FITC/PI at 4 ^{o}C for 10 min in the dark, the cells were analyzed with flow cytometry (Coulter Elite ESP, Coulter, Hialeah, FL) to detect PS exposure on the cell membrane as typical marker of early apoptosis.

G. Statistical analysis

All the data are presented as the mean ± standard deviation (SD). Difference between any two groups were assessed with student's t-test at 95% confidence interval; $P<0.05$ was considered to be significant.

III. Results

A. Effects of low intensity ultrasound on cell viability

Cell viability was measured by the Trypan blue exclusion test immediately after ultrasound sonication and plotted as a line graph, shown in Fig. 2. HepG2 cells were exposed to different intensity of 1.2 MHz continuous ultrasound for different sonication time. It is shown that the cell viability decreased with the increasing ultrasound intensity and increasing sonication time. To acquire optimal early apoptosis

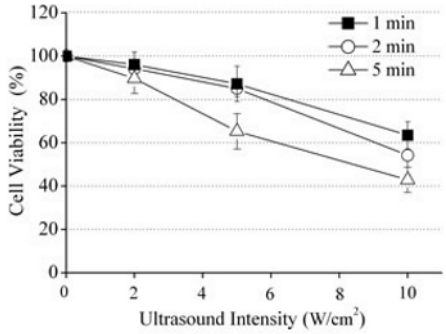

Fig. 2 Intensity-dependent and sonication time related ultrasound induced loss of cell viability. Error Bars in the figure represent means ± SD (n=3).

with minimal necrosis, the intensity used in orthogonal test is ranged from 2 to 5 W/cm^2.

B. Morphological changes of irradiated cells

The morphologic observations showed that the distinct morphologic characteristics of apoptotic cells, such as condensation of nucleus, chromatin margination (Fig.3 b and c) were found after the cells were exposed at 5 W/cm^2 for 1 min and incubated for 12 h post-sonication. Simultaneously, the characteristics of apoptotic cells were not observed in the control samples incubated at 37 ^{o}C in humidified air with 5% CO_2 (Fig.3 a). It is also proved in Fig.4 as the cells with green fluorescence increased significantly after cells were exposed to ultrasound.

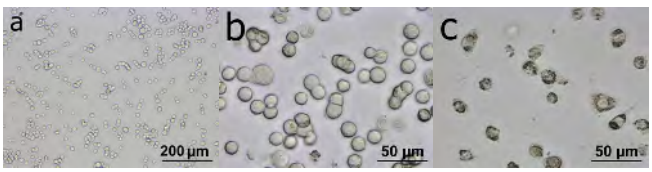

Fig. 3 Morphologic characteristics of HepG2 cells before and after ultrasound sonication.

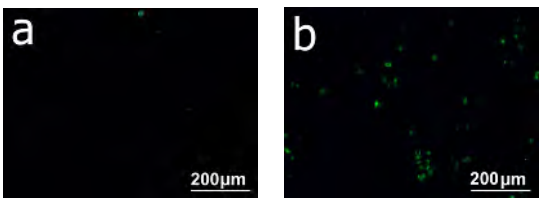

Fig. 4 Fluorescence images of phosphatidylseline externalization induced by ultrasound sonication. (a) untreated control cells; (b) cells 12 h after sonication, 5W/cm^2 (I_{SPTA}), 2 min.

C. Functional assay

It is shown in Fig.5 the fraction of early apoptotic and secondary necrotic cells from the surviving cells after 12-h incubation post-sonication at 5 W/cm2 for 1 min. The percentage of early apoptotic and secondary necrotic cells increased significantly compared with the cells before US sonication. It revealed ultrasound indeed induced early changes in HepG2 cells in this study.

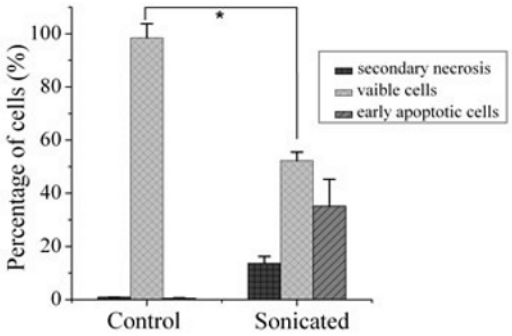

Fig. 5 The fraction of ultrasound induced early apoptosis and secondary necrosis, as measured by flow cytometry. The error bars represent SD from the mean of at least three independent trials (*$P < 0.05$).

D. Orthogonal analysis

The last two columns of Table 2 show the experimental results of early apoptosis (eA) and secondary necrosis (sN) measured by flow cytometry. The results represent mean ± SD (n=3). Based on orthogonal analysis, the response diagrams for the designed factors are shown in Fig. 6. The results show that ultrasound induced eA and sN increase with increasing ultrasound intensity. EA also increases with increasing incubation time post-sonication and reaches its maximum at about 12 h. however, sN keeps increasing even after incubated for 12 h and then become dominant over early apoptosis. Sonication time influence sN significantly, however, it shows few enhancement for eA when the cells are sonicated for 5 min comparing with 2 min. It is suggested that optimal early apoptosis with minimal necrosis

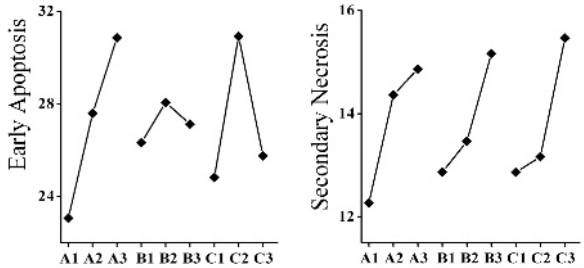

Fig. 6 Response graph of designed factors to ultrasound induced early apoptosis and secondary necrosis.

Table 3 Results of variance analysis for early apoptosis

Factor	Sum of square (S)	Degree of freedom (f)	Variance (V)	F-ratio (F)	Contribution (σ) (%)
A	276.76	2	138.38	9.32**	53.80
B	13.21	2	6.61	0.44	2.57
C	194.80	2	97.40	6.56*	37.86
e	296.90	20	14.85	1	5.77
Total	781.67	26	-	-	100%
$(e)^a$	11.14	2	5.57	-	-

* $F > F_{0.01}(2,20)$; * * $F > F_{0.005}(2, 20)$; $(e)^a$ is pooled error.

Table 4 Results of variance analysis for secondary necrosis

Factor	Sum of square (S)	Degree of freedom (f)	Variance (V)	F-ratio (F)	Contribution (σ) (%)
A	34.16	2	17.08	5.74*	32.95
B	26.55	2	13.27	4.46*	25.61
C	37.01	2	18.50	6.22*	35.69
e	59.53	20	2.98	1	5.75
Total	203.36	26	-	-	100%
$(e)^a$	2.60	2	1.30	-	-

* $F > F_{0.05}(2, 20)$; $(e)^a$ is pooled error.

could be acquired when the cells are sonicated at 5 W/cm^2 for 1 min and incubated for 12 h post-sonication.

The results of variance analysis for eA and sN are shown in Table 3 and Table 4. The contribution ratio has shown that ultrasound intensity is most significantly effective factor for early apoptosis, and incubation time post-sonication for secondary necrosis.

IV. Discussion

After sonicated by ultrasound, the degree of membrane damage caused by the mechanical effects of ultrasound and the degree of repair by the fate of cells will determine the type of cell death, as shown in Fig.7. Higher ultrasound intensity would induce more damage on cell membrane, in this way, early apoptosis and secondary necrosis are increased. Continuous sonication accumulates energy on the cell membrane. Compared with pulsed ultrasound, there is few time for the cells to repair themselves during sonication, so it increases irreversible damage induced by ultrasound. It may be the reason for more secondary necrosis induced however early apoptosis doesn't change significantly with increasing sonication time. Incubation time post-sonication gives damaged cells the time and more chance to repair themselves post-sonication successfully, and then develop to apoptosis. It reaches the peak after about 12 h. After it, more early apoptotic cells develop into secondary necrosis. It explains optimal early apoptosis is obtained at about 12 h post-sonication.

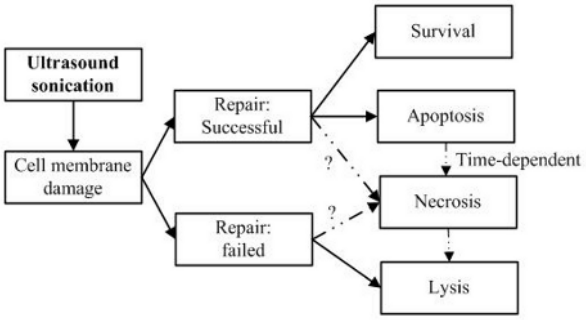

Fig. 7 Scheme showing that membrane damage and repair after ultrasound sonication.[4]

V. Conclusions

It is proven that low intensity ultrasound induces early apoptosis and secondary necrosis in HepG2 cells in this study. Based on the orthogonal analysis, optimal apoptosis with minimal necrosis is acquired when the cells were exposed to ultrasound at 5 W/cm^2 for 1 min and incubated for 12 h post-sonication. Our data clearly show that certain conditions to optimize apoptosis induction do exist. For the application in cancer therapy, every parameter, including proper timing, is therefore essential in establishing a protocol for effective induction of apoptosis by ultrasound.

Visual and Force Feedback-enabled Docking for Rational Drug Design

O. Sourina[1], J. Torres[2] and J. Wang[1]

[1] Nanyang Technological University/School of Electrical and Electronics Engineering, Singapore
[2] Nanyang Technological University/School of Biological Science, Singapore

Abstract — **Transmembrane helices play basic roles in biology: signal transduction, ion transport and protein folding. While antibodies can be directed towards hydrophilic regions of molecules, transmembrane regions have not been targeted so far. In this paper, we propose a novel approach to search for helix-helix complementary pairs in order to inhibit, or modulate, the function of membrane proteins where point mutations at the transmembrane domain have been found to lead to various forms of cancer such as the homodimeric epidermal, or fibroblast, growth factor receptors. This method employs visual and force feedback tools to search for the optimal interaction between helices. The search is manual, exploring helix tilt, helix rotation and side chain rotamer selection, with feedback from the models consisting of a repulsion or attraction force. We developed a prototype system that allows real-time interactive visualization and manipulation of molecules with force feedback in virtual environment. In our system, we implemented haptic interface to facilitate the exploration and analysis of molecular docking. Haptic device enables the user to manipulate the molecules and feel its interaction during the docking process in virtual experiment on computer. In future, these techniques could help the user to understand molecular interactions, and to evaluate the design of pharmaceutical drugs.**

Keywords — **Visual docking, force feedback, molecular docking, haptic interface**

I. Introduction

During the past decade, efforts have been made to predict complex structures from the structures of individual proteins. Membrane protein structure determination is till the Wild West of Structural Biology [1]. Structural determination using classical techniques such as X-ray diffraction or Nuclear Magnetic Resonance (NMR) is hindered because of the experimental problems associated with lipid-embedded domains. Given the experimental difficulties in membrane protein structure determination, there is a pressing need for prediction methods. Prediction of membrane protein structure consists of two parts: one is topology, the other is helix-helix interaction. Prediction of location of transmembrane (TM) helices and topology has been in general successful. It is often possible to develop a limited set of topological models from the sequence. The total success of membrane protein structure prediction, however, will depend largely on the second challenge, which is to correctly pack topologically arranged helices [2]. In this respect, the fact that the main contribution to transmembrane interhelical packing is Van der Waals interactions converts the problem into a docking one [3].

We propose and develop visual haptic-based molecular docking system to explore the conformational space of helix-helix interaction manually in the hope to find an optimal conformation with the minimum amount of time. Docking the transmembrane helices is a difficult task for automatic conformational search algorithms when polytopic membrane protein structure is explored because of the exponential increase in conformations as the number of α-helices is increased. Given the difficulties in exploring the whole conformational space available in polytopic membrane proteins, our strategy for docking TM helical domains is to use a manual approach in a virtual reality environment. This manual approach greatly simplifies the searching task, as changes in helix register, tilt and rotational orientation of the helices around their long axis are accomplished by hand. Feedback will be provided as attraction or repulsion forces felt by the user, which will be generated after calculating bonding and nonbonding interactions.

The paper is organized as follows. In Section II, the proposed method is elaborated. In Section III, the system prototype is described and helix-helix docking examples are given. Conclusion and future work is given in Section IV.

II. Approach

There are a number of methods that attempt to solve the docking problem, which entails finding the optimum interaction between two molecular systems by using a scoring function. These methods normally use a conformational search algorithm to explore the conformational space, which is exceptionally time-consuming. In these studies, drug-receptor or protein-protein interactions are the preferred subject of study. One reason for this is that the ultimate goal for the use of transmembrane helices is not as immediately obvious. The other is the lack of structural data for membrane proteins, which precludes 'direct' docking attempts between drug and, for example, a membrane receptor. In complex systems, however, the number of unknowns grows

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1874–1877, 2009
www.springerlink.com

exponentially as the symmetry that exists in homooligomers is lost. In this case, additional experimental approaches or demanding computational search methods are necessary. This converts the exhaustive search of conformational space for a 6 TM protein in a formidable task, as rotation, tilt and register can all change in each of the TM helices. One alternative that we propose in our project is to explore the conformational space manually using force feedback in the hope to find an optimal conformation with the minimum amount of time. This manual approach greatly simplifies the searching task, as changes in helix register, tilt and rotational orientation of the helices around their long axis are accomplished with visual and haptic feedback. This is especially convenient when exploring the conformational space in a polytopic membrane protein, in which all TM helices are different.

Thus, our strategy for docking TM helical domains is to use visual and haptic feedback in a virtual reality environment. Feedback will be provided as attraction or repulsion forces felt by the user. The rough binding region can be decided based on shape complimentary by visualization system. So far, the sphere models corresponding to Van der Waals surface are implemented in the system we are working on. The key requirement in simulating of the ligand binding process is to have a good model of the interaction between ligand and receptor. During binding, the ligand is moving in the potential field created by the receptor's atoms, and the system is searching for a stable low potential configuration. While moving one of the molecules around binding site based on shape complimentary, the potential energy at each position is calculated and compared, the minimum value of potential energy is recorded together with the position of the ligand molecule.

The possible docking orientations between molecular systems are sampled with input from force calculations that is fed back to the user through the haptic device. The molecular systems are visualized with their van der Waals surfaces. The force feedback requires a high refresh rate (at least 1 kHz), therefore interaction energy calculations should be simplified. This brings the challenge in the project. The problem of fast haptic rendering could be solved by computation of the interactive forces in advance and storing it in a volumetric grid. After preliminary study we also found out that when molecular system is manipulated, the Cartesian coordinates corresponding to interactions with local energy minima should be dynamically stored on the volumetric grid as well. When only forces in rigid docking are required, we could use only the Lennard-Jones (L-J) potential as the main scoring function, as it has been found to be the most important in transmemebrane α-helix interaction [3]. The essential features are approximated quite well by a Lennard-Jones potential [4] (also referred to as the L-J potential, 6-12 potential or, less commonly, 12-6 potential). There are many different force field models that can be used to simulate proteins and other organic molecules implemented in AMBER [4], CHARMM [5], MM3 [6], MM4 [7] and MMFF94 [8]. If each force field is normally developed for a particular type of molecule, they rather well adapt to different structures in atomic types. The one we use and which is described below is called OPLS-aa [9] [10] [11]. It was parameterized for use in protein simulations, and also for small organic molecules, and has functional groups for all 20 common amino acids. For the homo-atomic pairs, there are published LJ parameters available (i.e. [12] for OPLS-aa). For the homo-atomic pairs, the interaction of hetero-atomic pairs, the effective values of σ and ε are calculated from those for the homo-atomic pairs. The way of calculation is called mixing rule. OPLS-aa uses the same non-bonded functional forms as AMBER, and the Lennard-Jones terms between unlike atoms are computed using geometric mean mixing rule [13].

III. Results

We are developing a prototype of Transmembrane α-helices Docking System HMolDock (**H**aptic-based **Mol**ecular **Dock**ing), using the haptic device PHANTOM 1.5/6DOF (6 degrees of freedom) [14-15]. The molecular structure file format in the Protein Data Bank .pdb [16] is chosen as an input, although there are wide variety of file formats based on standard Cartesian (x, y, z) coordinates (e.g., .mpl, .car, .pdb) for which we will use conversion programs. For now, basic molecular visulization is accomplished. Atom coordinates are got from input PDB files; atom radius and correspondent color are determined based on atom type and its belonging residue which are extracted from PDB data. Two molecules or one molecule and the probe are visualized on the screen. The user can assign a haptic mouse to the probe or to one of the molecules and move the probe/molecule towards/around to another molecule. In Fig. 1, Van der Waals forces of molecular system are investigated with the atom probe. An interaction force is calculated at each position, and the resulting attraction/repulsion force is felt by the user through the haptic device. The force direction and magnitude are visualized as a vector. Thus, a probe/molecule can be selected by the haptic mouse and moved around to let the user 'feel' the force changing. In Figure 2, Van der Waals surfaces of two helices are visualized by current system prototype. To differentiate the helices, two color schemes are used. The attraction/repulsion force in this case is mostly due to van der Waals force interactions, as no charged residues are present.

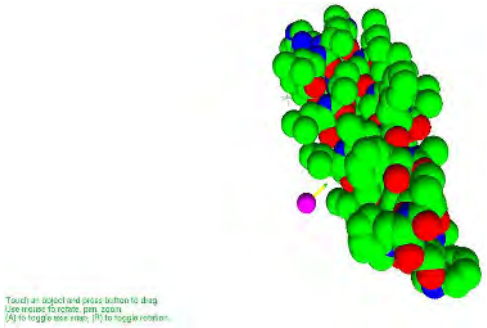

Fig. 1 Van der Waals forces is investigated with the atome probe

Fig. 2 Van der Waals surface model of a homodimer with two different color schemes

To demonstrate application of our method, let us give an example in molecular medicine. Currently, we are working on models and algorithms of rigid molecular docking. Although Van der Waals surface is represented in our system using simple atoms, we show here a more complex example.

To demonstrate application of our method, let us give an example in molecular medicine. Currently, we are working on models and algorithms of rigid molecular docking. Although Van der Waals surface is represented in our system using simple atoms, we show here a more complex example. The example in Figure 3 is especially pertinent to molecular medicine, where an important strategy is to achieve function regulation by modulation of protein-protein interactions. In membrane proteins, a recent approach targets the transmembrane region with certain peptides [17]. The rationale is that transmembrane mutations, for example in receptor tyrosine kinases, have been associated to many types of cancer and developmental deficiencies, which are explained by unregulated activation. Inactivation of the

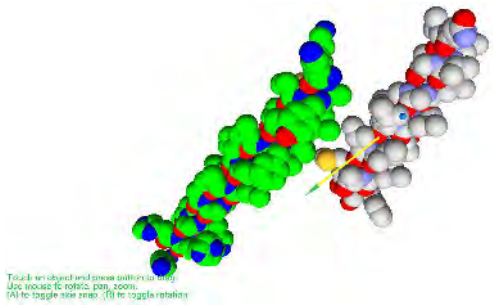

Fig. 3 Interaction of αIIb integrin transmembrane helix and a designed antibody-like complementary peptide anti-αIIb, separated

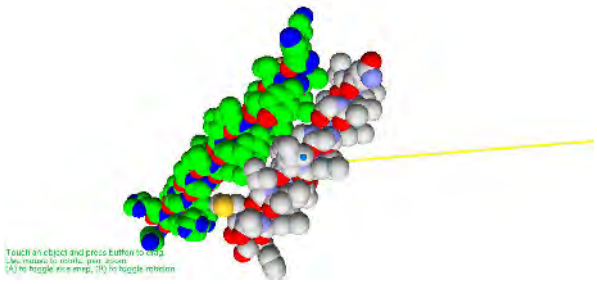

Fig. 4 Interaction of αIIb integrin transmembrane helix and a designed antibody-like complementary peptide anti-αIIb, in contact

receptor is thus crucial for targeted treatment, and this can be achieved with synthetic α-helices that target the native α-helices of the receptor. Figure 3 shows the two transmembrane domains, target and probe, corresponding to αIIb intregrin and a designed anti-αIIb integrin [17], respectively. In Figure 4, the helices move close and they become in contact.

IV. Conclusions

We propose a novel approach in helix-helix interaction research and rational design of peptides. We propose and implement novel approach to search for helix-helix complementary pairs that will facilitate the search for membrane helical inhibitor in future. Novel models and algorithms specific to helix-helix docking will be proposed and developed. For now, drug-receptor or protein-protein interactions are the preferred subject of study, and specific features of helix-helix docking are less studied by researchers. Drug design with our system will be tested. Based on the preliminary study with our system, we believe that understanding of the reason certain mutations alter transmembrane interactions and cause disease can be improved with the proposed methods. We are going to do in silico experiments on bio-

molecular docking to study helix-helix interactions in rational drug design.

A Coupled Soft Tissue Continuum-Transient Blood flow Model to Investigate the Circulation in Deep Veins of the Calf under Compression

K. Mithraratne[1], T. Lavrijsen[2] and P.J. Hunter[1]

[1] Auckland Bioengineering institute, University of Auckland, Private Bag 92019, Auckland, New Zealand
[2] Department of Biomedical Engineering, Technische Universiteit Eindhoven, PO Box 513, Eindhoven, The Netherlands

Abstract — **A coupled computational model of a 3D soft tissue continuum and a one-dimensional transient blood flow network is presented in this paper. The primary aim of the model is to investigate the reduction in vessel cross section area and resulting vessel wall shear stresses (WSS) in response to the compression applied on the calf. Application of external compression on the lower leg is a commonly used prophylaxis against thrombus formation in deep veins. The soft tissue continuum model is a tri-cubic Hermite finite element mesh representing all the muscles, skin and subcutaneous fat in the calf and treated as incompressible with homogeneous isotropic properties. The deformed state of the soft tissue due to the applied compression is obtained by solving large or nonlinear deformation mechanics equations using the Galerkin finite element method. The geometry of the main deep vein network is represented by a 1D Hermite cubic finite element mesh. The flow computational model consists of 1D Navier-Stokes equations and a non-linear constitutive equation to describe vessel radius - transmural pressure relationship. Once compression is applied, the transmural pressure is computed as the difference between the fluid and soft tissue hydrostatic pressure. The latter arises due to the incompressibility of the soft tissue material. Transient flow governing equations are solved using the McCormack finite difference method. The geometry of both the soft tissue continuum and vein network is anatomically-based and was developed using data derived from magnetic resonance images (MRI). Simulation results from the computational model show a reasonably good agreement with the results reported in the literature on the degree of deformation in vein cross-section area estimated using MRI.**

I. Introduction

Deep vein thrombosis (DVT) or formation of thrombi in deep veins of lower limbs is a commom problem in hospitalized patients. It often remains clinically unapparent and resolves without intervention. However, it may lead to other complications such as chronic venous insufficiency and pulmonary embolism. The latter has been estimated to cause about 10% of all hospital deaths [1]. DVT is also known as 'economy class syndrome' as it is linked to prolonged seated immobility in long-haul flights [2,3].

It is believed that there are three thrombogenic factors involved in DVT: stasis, hypercoagulability and injury to the vessel wall [4]. Two types of prophylaxis, medicinal anticoagulants (e.g. heparin) and mechanical methods (compression) are generally used for DVT. Most mechanical methods act on the calf and can be further divided into static and intermittent compression. Of the two compression methods, simplicity and low cost have made static method more attractive, especially for concerned air travelers. Compression stockings are commonly used for static compression and they usually apply uniform pressure over the entire calf. In intermittent compression, inflatable cuffs are wrapped around the patient's calf and periodically inflated using a pump.

Despite several clinical and biological studies [5-8] to show the efficacy of the compression method, the mechanism by which it acts is still not well understood. The external compression is generally thought to cause reduction in deep vessel cross-section area, which in turn results in increased flow velocities. Another hypothesis is based on the haemodynamic vessel WSS and its effect on the degree of stimulus for endothelial cell activation [8-9]. It is believed that shear stress and cyclic strain can influence the release of tissue plasminogen activator (t-PA) and its gene expressions. t-PA then converts plasminogen to active plasmin, which dissolves fibrin and prevents thrombus formation.

A number of studies [4,10] have looked at modeling external compression and resulting blood flow in deep veins. All these models, however, have either employed images (e.g. MRI) directly [4,10-12] or used the deformation of 2D continuum models (plane strain analysis) of surrounding soft tissue structures to reconstruct the deformed (collapsed) geometry of vessels. The computational model developed in this study is based on a 3D soft tissue continuum model undergoing large deformations (finite elasticity) due to applied external compression with 1D flow network of major deep vessels embedded in it. Coupling between fluid and soft tissue is archived via the vessel wall constitutive equation that describes the relationship between vessel radius and the transmural pressure. The latter is the difference between the fluid pressure and soft tissue *hydrostatic pressure* which arises due to the incompressibility of the soft tissue material.

II. Materials and Methods

A. Imaging and construction of model geometries

The right leg of a healthy 21 year old male volunteer was imaged using a 1.5T MRI scanner (Siemens Magnetom Avanto). The subject was placed in prone position to minimize compression of the calf which would otherwise cause deformed or collapsed veins. A multi-slice 2D time-of-flight sequence was used to enhance the contrast between veins and arteries. The images were acquired with a spacing of 5.36 mm and the slice thickness was set at 8mm.

The Bioengineering modeling software CMISS [13] was used to manually segment the MRI images and derive the necessary data for the construction of model geometries. A tri-linear Lagrange finite element (FE) mesh representing the 3D geometry of the soft tissue continuum consisting of skin, subcutaneous fat and muscles was first created and fitted to the digitized data to obtain tri-cubic Hermite FE mesh [14]. Fig. 1 depicts the fitted soft tissue mesh.

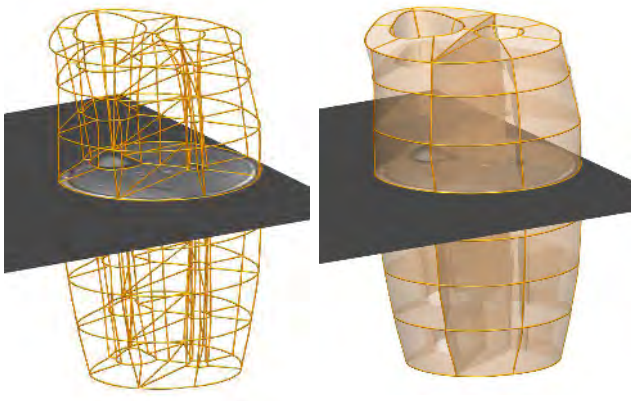

Fig. 1 Fitted tri-cubic Hermite FE mesh of soft tissue continuum in the calf

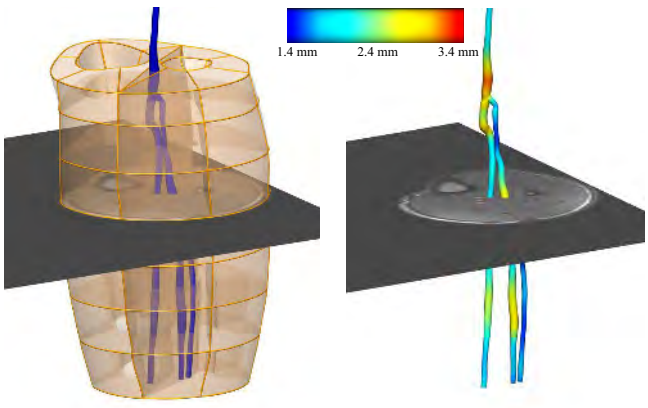

Fig. 2 (a) Fitted 1D cubic FE mesh of the flow network
(b) Radius field (cubic Hermite) in the flow network

Only the vessels with good contrast relative to the surrounding soft tissue were digitized. These included the popliteal vein (PV), the posterior tibial vein (PTV), the lateral posterior tibial vein (LPTV) and the medial and lateral peroneal veins (MPV, LPV). Furthermore, on each image, four data points were created to define the each vessel boundary. The position coordinates of the vessel on each image was then calculated by taking the average of these points. The mean radius of the un-collapsed vessel was also inferred using the same points. A 1D cubic Hermite FE mesh was then created by fitting to the data so obtained. The mean un-collapsed or reference radius of vessel was also fitted as a cubic field along the 1D geometry. The fitted FE mesh of flow network with radius field is shown in fig. 2.

B. Soft tissue model

The deformation of the soft tissue continuum in response to the applied compression (pressure) on the calf can be obtained by solving the static Cauchy equation,

$$\frac{\partial \sigma_{ij}}{\partial x_j} + \rho_s . b_j = 0 \quad : i, j = 1..3 \tag{1}$$

where σ_{ij} are Cauchy stress tensor components, x_j are spatial coordinates, b_j are the body force components and ρ_s is the soft tissue density.

The mechanical characteristics of the soft tissue were modeled as isotropic, incompressible Mooney-Rivlin material with homogeneous properties. Thus, the constitutive equation of the soft tissue material can be described by a strain energy density function (SEDF) as follows,

$$w = c_{10}(I_1 - 3) + c_{20}(I_1 - 3)^2 + p(I_3 - 1) \tag{2}$$

where w is SEDF, I_1 and I_3 are the invariants of the right Cauchy deformation tensor. The incompressibility constraint $(I_3 = 1)$ is appended to the SEDF via a Lagrange multiplier, p (hydrostatic pressure). As mentioned earlier, soft tissue hydrostatic pressure acts on the external surface of the vessel wall. Hydrostatic pressure was interpolated using tri-linear Lagrange basis functions.

The material parameters used in eq.(2) were 10.0 kPa for both c_{10} and c_{20} [15]. Boundary conditions for the problem were prescribed as follows. All nodal degrees of freedom (dofs) of the inner surface where the soft tissue is in contact with bones were fixed. A uniform traction (compression) of 2.67 kPa (20 mmHg) was applied on the outer surface to mimic the action of static compression. The compression pressure of 2.67 kPa was chosen to fall within the range of values used in the experiments reported in reference [11].

Eq. (1) was numerically solved using the Galerkin FE method for large or non-linear deformations of the soft tissue continuum within CMISS [13].

C. Flow model

The blood flow in veins was modeled as an incompressible, homogeneous, Newtonian fluid with axisymmetric laminar flow in a compliant tube. It was further assumed that radial and circumferential flows are negligible compared to the flow in the axial direction and the axial velocity has parabolic variation in the radial direction [16]. With these assumptions, the reduced form of the Navier-Stokes equations (continuity and momentum) can be written as,

$$\frac{\partial R}{\partial t}+V\frac{\partial R}{\partial x}+\frac{R}{2}.\frac{\partial V}{\partial x}=0 \tag{3}$$

$$\frac{\partial V}{\partial t}+(2\alpha-1)V\frac{\partial V}{\partial x}+2(\alpha-1)\frac{V^2}{R}.\frac{\partial R}{\partial x}+\frac{1}{\rho_f}\frac{\partial P}{\partial x}+\left(\frac{2\nu\alpha}{\alpha-1}\right)\frac{V}{R^2}=0 \tag{4}$$

where V is the mean velocity of the profile, R is the vessel radius, P is the fluid pressure and ρ_f and ν are fluid density and kinematic viscosity respectively. α is the velocity profile parameter.

The velocity profile is given by,

$$u=\left(\frac{\gamma+2}{\gamma}\right).V.\left[1-\left(\frac{r}{R}\right)^{\gamma}\right] \text{ and } \gamma=\frac{2-\alpha}{\alpha-1} \tag{5}$$

where u is the axial velocity at r.

The constitutive equation of the vein wall which describes the mechanical characteristics (vessel radius–transmural pressure relationship) was defined as a cubic polynomial of radius ratio $\left(\frac{R}{R_0}\right)$ by fitting the experimental data [17] obtained from canine femoral vein,

$$P_{tr}=(P-p)=a\left(\frac{R}{R_0}\right)^3+b\left(\frac{R}{R_0}\right)^2+c\left(\frac{R}{R_0}\right) \tag{6}$$

where P_{tr} is the transmural pressure (difference between fluid and hydrostatic pressures), R_0 is the un-collapsed (reference) radius and a, b & c are the polynomial fitting coefficients.

The above system of equations was solved numerically using the McCormack's finite difference method [18]. This finite difference scheme is a two-step (corrector-predictor), fully explicit scheme and possesses second-order spatial and temporal accuracy. The following values were used for fluid density and kinematic viscosity: $\rho_f = 1050$ kg/m^3 and $\nu = 3.2$ mm^2/s. The flow parameter, α was set at 1.1.

A range of flow rates reported in the literature was prescribed as inlet boundary conditions. A number of studies have reported the mean popliteal venous flow in the horizontal position: 1.7 ml/s [19], 2.2 ml/s [20] and 3.8 ml/s [21]. Since the anterior tibial vessels and medial posterior tibial vessels were not included in the flow net work, it was assumed that the inlet flow to be half of the reported values. The fluid pressure was prescribed as the boundary condition at the outlet. It was also assumed that the pressure at the outlet (popliteal vein) is equal to the femoral venous pressure. The average of the femoral venous pressure (1.3 kPa) reported in the literature [22-24] was used in simulations. All flow simulations were performed by linearly increasing the flow from zero to the rate required.

III. Results and Discussion

The network geometry was reconstructed with respect to the deformed soft tissue continuum to examine the degree of reduction in vessel cross-section area caused by gross deformation of the tissue continuum (without taking the hydrostatic pressure effects into account). The mean radius change of the venous network due to the gross deformation was found be insignificant (less than 2%).

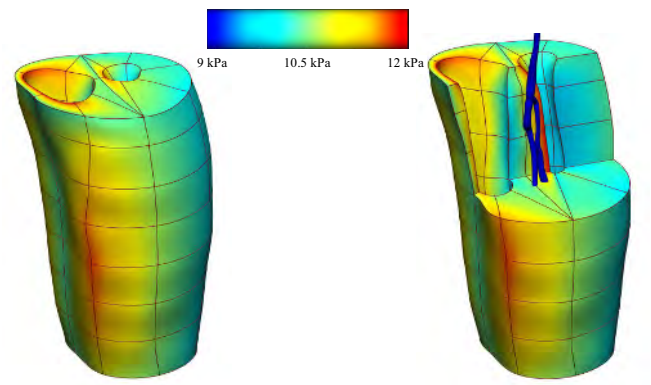

Fig. 3 Hydrostatic pressure distribution of the calf at deformed state

The hydrostatic pressure distribution in response to the application of external compression is depicted in fig 3. The distribution of hydrostatic pressure was obtained by fitting it as a tri-linear FE field. The field, thus fitted, was then interpolated to determine the external pressure acting on the vessel wall at each finite difference grid point of the venous

flow network. The mean cross-sectional area of the flow network at various flow rates due to externally applied compression is given in table 1.

Table 1 Change in vessel mean cross-section area

	Flow rate [ml/s]				
	0.25	0.50	1.00	1.50	2.50
Mean area [mm^2]	2.4	2.7	3.2	3.5	4.2
% Reduction	84	82	79	77	72

Percentage reduction is based on a mean area of 15 mm^2 at 1.0 ml/s

The WSS was computed using eq. 5 (flow profile equation). It is directly proportional to the axial velocity gradient in the radial direction at the wall $\left(\left. \frac{\partial u}{\partial r} \right|_{r=R} \right)$. Table 2 gives the WSS at various flow rates simulated.

Table 2 Change in vessel wall shear stress (WSS)

Mean WSS [Pa]	Flow rate [ml/s]				
	0.25	0.50	1.00	1.50	2.50
Uncompressed	0.15	0.30	0.60	0.90	1.42
Compressed	2.20	3.76	6.12	7.96	10.8

The reduction in cross-section area at 1.0 ml/s based on a MRI study [10] has been reported to be about 62%±10%. The predicted value from the present study compares reasonably well with the experimental data. The overestimation could be due to the soft tissue constitutive properties. The WSS estimated using the flow simulations based on reconstructed vessel geometry at 1.0 ml/s from the same MRI study is 1.2 Pa in deep veins. The discrepancy could be attributed to (a) soft tissue mechanical properties and (b) flow profile. It can be easily shown that the flow profile parameter, α, determines the gradient of the axial velocity at the wall which is directly proportional to the WSS.

IV. Conclusions

A coupled computational model of a 3D soft tissue mechanics and a 1D transient flow network were developed. The model was used to investigate the reduction in vessel cross-section area, the resulting flow and wall shear stress. The coupling of soft tissue and fluid was achieved via the vessel constitutive equation, which is a function of the soft tissue hydrostatic pressure and fluid pressure.

Finite Element Analysis of Articular Cartilage Model Considering the Configuration and Biphasic Property of the Tissue

N. Hosoda[1], N. Sakai[2], Y. Sawae[2] and T. Murakami[2]

[1] Graduate School of Systems Life Sciences, Kyushu University, Fukuoka, Japan
[2] Faculty of Engineering, Kyushu University, Fukuoka, Japan

Abstract — **Articular cartilage tissue has high water content from 70 to 80% and shows biphasic behavior in which both solid and fluid properties should be considered. Furthermore, the mechanical behavior of cartilage shows depth-dependence. Therefore it is necessary to consider not only the average tissue property but also the local one to explain mechanical and functional behavior.**

Previously, we created cartilage tissue model considering the depth-dependence of Young's modulus distribution and applied two-dimensional finite element method (FEM) based on biphasic theory[1]. As a result, the deformed profile of depth-dependent Young's modulus model immediately after unconfined compression corresponded to actual profile. Consequently, we confirmed that Young's modulus has a distribution in the depth direction. In contrast, the total load capacity in FEM analysis was about one order lower than the experimental one. Immediately after compression at high rate, it has not enough time for intrinsic fluid to flow in cartilage, and thus whole tissue including intrinsic fluid shows the behavior like elastic body. Furthermore, the polymeric materials increase their stiffness at higher strain rate. Therefore, apparent elastic modulus is assumed to be larger than the equilibrium Young's modulus. During total deflection is maintained after compression, the intrinsic fluid flow gradually occurs, and the stress relaxes with decrease of apparent elastic modulus. After enough stress relaxation, an apparent elastic modulus becomes an equilibrium Young's modulus. We think this is connected to configuration of the cartilage tissue.

The aim of this study is to consider configuration of the tissue in addition to the character of biphasic property on the mechanical behavior of cartilage tissue. In this study, we created cartilage tissue model considering spring elements that express function arisen from collagen fiber and Young's modulus distribution depending on the depth. Then, we analyzed the unconfined compression and compared experimental results to FEM analysis.

I. Introduction

The human synovial joint possesses superior load-bearing and jointing functions with very low friction and low wear. Articular cartilage tissue plays an important role to maintain this function through whole life. The arthrodial joint forms a connection between two or more bones, and functions by supporting and transmitting loads. Cartilage has high water content from 70 to 80 % and shows biphasic behaviors in which both solid and fluid properties should be considered.

One of the representative diseases on the synovial joints particularly for elder persons is osteoarthritis. Osteoarthritis causes degeneration and destruction of articular cartilage, which lead to the disturbance of motility. Articular cartilage degenerated by osteoarthritis decreases load-buffering capacity and leads to the bone deformation, the formation of osteophytes, and the subchondral bone induration and thickening. Especially in joints of lower extremities, there are many reports linking age and obesity to the osteoarthritis, or external injury and career to the occurrence of osteoarthritis. Consequently, mechanical factors are believed to play a crucial role in the pathogenesis of osteoarthritis.

As a new treatment method, tissue engineering has attracted attention in recent years. At the present stage, however, the mechanical function of tissue-engineered cartilage has not reached the level of native cartilage. It is noted that mechanical stimulation in culture process promotes extracellular matrix synthesis and leads to better function. Therefore, it is necessary to study the optimum conditions of mechanical stimulation.

Gaining better understanding of the mechanical and functional environment around chondrocytes is crucial to the clarification of the mechanism of osteoarthritis pathogenesis, the assessment of mechanical properties of the regenerated cartilage, and the clarification of the optimum condition of mechanical stimulation on the metabolism of chondrocytes.

A. Articular cartilage

Articular cartilage is composed of chondrocytes and an extracellular matrix. Extracellular matrix is mainly composed of proteoglycan and collagen, and produced by chondrocytes to provide scaffold to chondrocytes and support load to cartilage. Proteoglycan is highly hydrophilic and therefore can store a large amount of water and contribute to viscoelasticity. The hydrated proteoglycan is distended but confined by collagen network, and thus it supports the compressive load, while the collagen is given under

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1883–1887, 2009
www.springerlink.com

pulling coercively. Cartilage is categorized into the surface, middle and deep zones, and calcified zone by the gradient direction of collagen fibrosis, the morphology of the cells, and the presence or absence of calcareous deposits (Fig.1). Consequently, mechanical properties are different in the location.

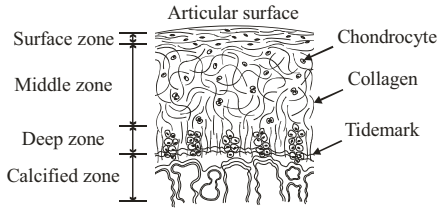

Fig.1 Cross-section diagram of cartilage tissue

B. The behavior of cartilage tissue to mechanical stimuli

The structure and property of articular cartilage have depth-dependence. If the load acts on the tissue rapidly, the tissue does not have enough time to exude the interstitial fluid and thus presents similar behavior to the elastic body. While the load acts on the tissue slowly, the interstitial fluid is gradually exuded through the tissue. In compression, the permeability of cartilage becomes lower with an increase in compression strain[2]. When cartilage is compressed at high rate and kept at the definite position, the occurrence of peak stress and following stress relaxation behavior are observed as shown in Fig.2. In our unconfined compression test of 10~15% strain at 1000μm/s, peak stress ranged from 0.71 MPa to 3.76 MPa. To understand the mechanotransduction in chondrocytes in cartilage, the actual time-dependent and depth-dependent stress and strain around chondrocytes should be clarified.

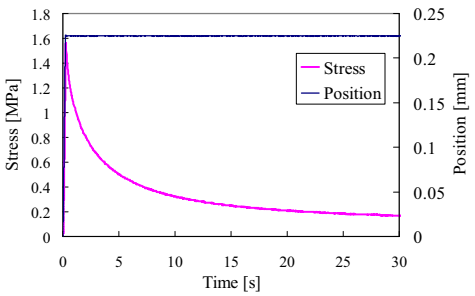

Fig. 2 Compressive behavior of articular cartilage to definite compressive deflection

C. Young's modulus distribution depending on the depth

Previously, we performed unconfined compression test of articular cartilage at definite total deformation in compression tester located on the stage of CLSM. Then, the local compression strain is calculated from the change in distance between the corresponding living cells stained with Calcein-AM 1 μL (Molecular Probes) in 1000 μL PBS in the fluorescence images before compression and at equilibrium. We derived Young's modulus distribution function using inverse relationship between strain and Young's modulus for nearly uni-axial compression.

In this study, we applied the compression velocity of 200 μm/s and the compression strain of 10 %. Mean value of the average Young's modulus E_0 of solid phase at equilibrium is 0.37 MPa. The Young's modulus depending on the depth are Eq. (1). We normalized Young's modulus depending on the depth and plotted those against relative position x in depth direction in Fig.3. The surface side is depicted as 0, and the deep zone end side is 1.

$$E(x) = \frac{3.66}{46.2e^{-6.53x} + 2.84} \tag{1}$$

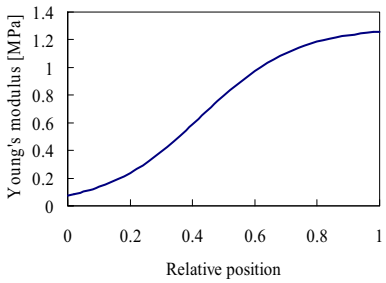

Fig.3 Young's modulus distribution

II. Finite Element Analysis of Articular Cartilage Model and Boundary Conditions

A. Finite element model

General-purpose finite element analysis software (ABAQUS v.6.5) was used to analyze the biphasic model [3].

The shape of articular cartilage model is rectangle that has 2 mm height and 3 mm width. We use two-dimensional model as the first step to future plan on multi-scale analyses to include chondrocyte. Characteristic behaviors in deformed profile, Mises stress and pore pressure obtained from two-dimensional model except small difference in stress and pressure values was verified by our related study using three-dimensional one. We modeled using biphasic fluid

element (CPE4P). The size of the each element corresponds to 40 μm x 40 μm and total number of element is 3750.

In this model, the upper 10 % of cartilage tissue is surface zone, the lower 20 % of the tissue is deep zone and middle zone is located between surface and deep zones.

Young's modulus of the model is described as equation(1). Articular cartilage model was divided as 50 layers to depth direction and the corresponding Young's modulus was provided for each layer.

The void ratio e is provided for ABAQUS by the following equation.

$$e = \frac{dV_V}{dV_g + dV_t} \tag{2}$$

Where dV_v is a volume of voids, dV_g is volume of grains of solid material, and dV_t is a volume of trapped wetting liquid.

In this study, we assumed that water content of 80 % included in cartilage tissue is a volume of voids and other 20 % is sum of the volume of grains of solid material and a volume of trapped wetting liquid. Thus, void ratio is 4.

Poisson's ratio and permeability of solid phase were assumed as constant and used literature data shown in Table.1 [4]. The analysis was conducted for test duration of 300 s.

Table.1 Material properties.

Young's modulus of solid phase, E0 [MPa]	Poisson's ratio of solid phase, ν	Permeability k [$m^4/N \cdot s$]
0.74	0.125	2.0×10^{-15}

B. Spring element performed function caused by collagen fiber

The structures of articular cartilage tissue are inhomogeneous and anisotropy. Then, it is believed that locally different property and configuration develop the function of cartilage.

We noticed function of collagen fiber network. When proteoglycan supports compression loading, collagen fiber supports tension loading coercively because collagen network confines proteoglycan. So we created cartilage model considering the function of collagen fiber using nonlinear spring element. In this study, as shown in Fig. 4, we conect node of biphasic element in a horizontal direction by nonlinear spring element(SPRINGA) and assumed these nonlinear spring element affect only tensile deformation[5].

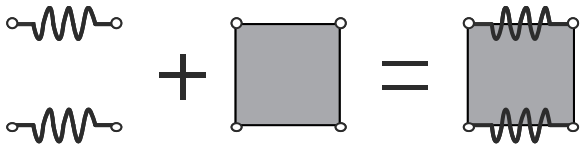

Fig. 4 The finite element and the arrangement of spring elements.

C. Boundary conditions

To compare experimental result with finite element analysis, the boundary condition for FEM was given to correspond to the compression test. FEM simulation of compress-ion test was performed under compression velocity of 200 μm/s and compression ratio of 10 %. Thus, amount of com-pression, compression velocity and compression time to definite deflection were 0.2 mm as 10 % of thickness, 200 μm/s and 1.0 s, respectively.

We assumed that there is rigid body plate on the cartilage tissue model and gave compressive displacement The node of top surface was compressed at displacement of 0.2 mm by the plate and the transform in y direction (parallel to surface) was unconfined. The node of lower surface was confined and the displacements of the node in both x and y directions were 0. To simulate impermeable compressing plates in compression tester, water was assumed to seep only through right and left side of rectangle model.

III. Result

In this study, we created three kinds of cartilage tissue models considering nonlinear spring element and biphasic property of the tissue, analyzed and compared experimental results to FEM analyses. First, we noticed the total load capacity of the model. The total load capacity of the model corresponds to reaction force to rigid body plate. The total load capacity of the experimental value is a measured value by a load cell in experiment.

To conform the total load capacity of FEM simulation based on biphasic theory to the experimental value during compression, we defined an nonlinear behavior for spring element (Spring 1 in Fig. 5). This model was named Model 1. In this model, the average stress during stress relaxation was too high as shown in Fig.6. Therefore, the spring property during stress relaxation was changed to decrease gradually from Spring 1 to softer one as shown in Fig. 5. The model was named Model 2. The total load capacity of Model 2 corresponded to experimental one.

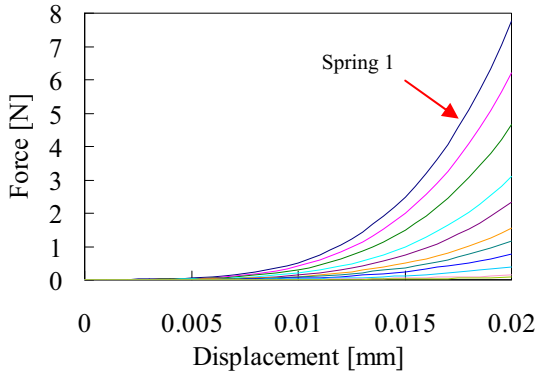

Fig. 5 The behavior of nonlinear spring element.

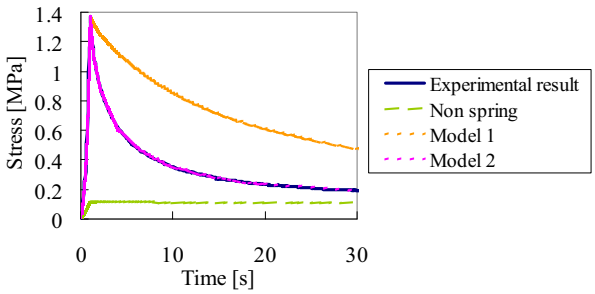

Fig. 6 Total load capacity.

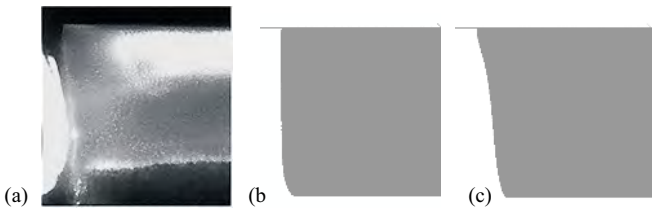

Fig. 7 Profile of compressed cartilage immediately after compression. (a)Cartilage specimen.(b)Model 1. (c)Model 3.

However, immediately after compression, the deformed profile of the Models 1 and 2 showed barreled profile and disaccorded with experimental one(Fig. 7). The polymeric materials increase their stiffness at higher strain rate. Therefore, apparent Young's modulus is assumed to be larger than the equilibrium Young's modulus. So, we adopted instantaneous elastic modulus as an instantaneous ratio of stress to strain, created the model, and named Model 3. The deformed profile immediately after compression of Model 3 corresponded to actual profile as shown in Fig. 7.

IV. Discussion

In the case we unused nonlinear spring element, peak stress in FEM model is about one order lower than the experimental one. The total load capacity of the model during compression coressponded to experimental one by using nonlinear spring element. So, it is thought that collagen network play a important part to stress development during compression. However, the stress relaxation behavior of the Model 1 disaccorded with experimental one. It is thought that stress relaxation curve indicated moderate change because nonlinear spring elements supported load and the flow of intrinsic fluid became slow. In actual cartilage tissue, it is thought that tensile deformation of collagen network comes loose with increase of fluid flow. Then, an apparent spring constant decreases. So, we created the model with sowly decreased spring constant. As a result, the total load capacity of FEM model corresponded to experimental one from the start of compression test to equilibrium. To reflect the depth-dependence of Young's modilus distribution for the defomed profile immediately after compression, we need change in nonlinear spring constant and instantaneous elastic modulus.

V. Conclusions

In this study, we created a cartilage tissue model considering the configuration and biphasic property of the tissue, and analyzed by biphasic theory. Then, we compared experimental results to FEM analyses and found the following facts.

(1) FEM value of the total load capacity during compression corresponded to experimental one using nonlinear spring element.

(2) In this biphasic model, to conform the total load capacity of FEM simulation to the experimental value during stress relaxation, it is necessary to control behavior of nonlinear spring element.

(3) The defomed profile immediately after compression corresponded to actual profile by controlling nonlinear spring constant and instantaneous elastic modulus.

Abstract — **Low back pain (LBP) is estimated to affect 50-90% of women during pregnancy with more than a third of women reporting it as a severe problem compromising their ability to work during pregnancy and affecting normal daily life and sleep patterns. The aim of this study was to investigate the differences in kinematics and kinetics of lifting in pregnant subjects.**

Methodology

Fifteen maternal subjects (age: 32.0±2.3 yrs; height: 165.3±5.5cm; weight: 71.7±6.4kg) were tested at the third trimester of pregnancy (32-38 weeks). Twenty-seven retro reflective markers were placed on the various bony landmarks of the subjects. An eight-camera motion analysis system (VICON 512, VICON, Oxford, UK) was used to record movements of the body segment and synchronised force plate (AMTI, Watertown, MA, USA) parameters in three dimensions. Eight non-pregnant subjects (age: 29.6±3.1yrs; height:167.3±5.6cm; weight:65.4±8.4kg) were used as controls.

Each subject lifted a 4 kg plastic box (dimension: 31.5x25x20 cm), which is representative of commonly lifted items. Motion of the ankle, knee and hip joints and pelvic segments were investigated. Principal component (PC) analysis was applied to 23 kinematic and kinetic variables from each group. The total PC score for each subject was calculated, and a one-tail student-t test was used to test for significant differences between the groups.

Results

Significant group differences ($p<0.05$) were found for three of the PC scores. Parameters found to be major contributors to these differences included minimum hip flexion extension moment; maximum knee flexion moment; maximum ankle plantar flexion and knee flexion angles and average hip flexion extension angles.

Discussion

PCA was able to identify different lifting kinematics and kinetics in pregnant subjects and important biomechanical differences when compared with the control group. This is the first study to identify such lifting differences during pregnancy.

Keywords — **lifting kinematics, pregnancy, feature extraction, Principal Component Analysis**

I. Introduction

Low back pain (LBP) is estimated to affect 50-90% of women during pregnancy with more than a third of women reporting it as a severe problem compromising their ability to work during pregnancy and affecting normal daily life and sleep patterns [1]. Analysing biomechanical motion data is challenging due to its high dimensionality, temporal-dependence and high variability and correlate nature [2]. It is possible to generate thousands of parameters to represent key features of an individual's or group's data [2].

Principal components analysis (PCA) is a quantitatively rigorous method for achieving data/parameter reduction and separating useful parameters from redundant ones.

The method generates a new set of variables, called principal components (PC). Each PC is a linear combination of the original variables. All the principal components are orthogonal to each other, so there is no redundant information. The principal components as a whole form an orthogonal basis for the space of the data [3].

The objective of PCA is to reduce the dimensionality of the data set (or number of parameters) while retaining the original variability in the data. The first PC accounts for as much variability in the data as possible with the remaining PCs accounting for the remaining variability. By examining plots of these few new variables, it can offer a deeper understanding of the driving forces that generated the original data.

Smaller number of new variables usually allows easier interpretation of the data's structure [3, 4]. Each of the resulting PCs consist of correlated parameters which have a common link which can be used to develop a single equation that gives a single score which represents that component. This score can then be used as a new, dimension-reduced feature parameter. For example, the PCA studies by Olney et al. [4], Yamamoto et al. [5] and Sadeghi et al.[6] reduce large original parameters to between two to four PCs. These PCs have clinical relevant names in gait studies which includes grouping based on symmetry [4-6], speed and postural flexion bias [4], knee function and overall gait ability [5]. The majority of reported studies using PCA focused on gait studies with only three studies reported on lifting kinematics [7-9] .

The aim of this study was to use PCA investigate the differences in kinematics and kinetics of lifting in pregnant subjects compared with a control group.

II. Methodology

Fifteen maternal subjects (age: 32.0±2.3 yrs; height: 165.3±5.5cm; weight: 71.7±6.4kg) were tested at the third trimester of pregnancy (32-38 weeks). Twenty-seven retro reflective markers were placed on the various bony landmarks of the subjects. An eight-camera motion analysis system (VICON 512, VICON, Oxford, UK) was used to record movements of the body segment and synchronised force plate (AMTI, Watertown, MA, USA) parameters in three dimensions. Eight non-pregnant subjects (age: 29.6±3.1yrs; height: 167.3±5.6cm; weight: 65.4±8.4kg) were used as controls.

Each subject lifted a 4 kg plastic box (dimension: 31.5x25x20 cm), which is representative of commonly lifted items. Motion of the ankle, knee and hip joints and pelvic segments were calculated and normalised to one hundred percent of the lifting cycle. From the data, we measured the maximum, minimum, mean, range and standard deviation for each of the joints. A student t-test was performed to establish statistical significant differences between the two subject groups (see table 1). Principal component analysis (PCA) was applied to 23 kinematic and kinetic variables from each group (see table 2) based on the method described by Daffershoer et.al [10] . The total PC score for each subject was calculated using the Statistical Toolbox in Matlab (The Mathsworks Inc., Natick, MA,USA), and a one-tail student-t test was used to test for significant differences between the groups (see table 3).

III. Results

Twenty-three input parameters were used in the PCA as shown in table 2.

Figure 1 shows the percent of the total variability explained (VE) by each principal component with the first five PCs explain roughly two thirds of the total variability in the standardized ratings.

Major contributing parameters can be presented by using the percent VE values, as shown in figure 2.

The total PC score for each subject was calculated, a one-tail student-t test was used to calculate the p-value for the two groups, as shown in table 3, a p-value of 0.011 indicated that there are significant differences between the two groups.

Based on figure 2, the following parameters were found to be major contributors to these differences: minimum Hip Extensor Moment; Maximum Knee Extensor Moment; Minimum Pelvic Tilt; Mean Hip Flexion; Maximum Knee Flexion; Minimum Ankle Dorsiflexion and Maximum Ankle Dorsiflexion.

IV. Discussion

Lifting Duration

Maternal subjects spend a slightly longer lifting time (3.61s compare with 3.28 seconds), however the difference was not statistically significant.

Maternal subjects lifted with an increased base of support and at a lower speed. This is possibly a strategy maternal subjects use to maintain stability and achieve a smooth lifting approach to minimise biomechanical stresses.

Lifting Kinematics

In the sagittal plane, the pelvis in maternal subjects has a slight anteriorly increased range compared with the control subjects throughout the lifting and lowering phase. Maternal subjects had a slight decrease in the hip range compared with the control subjects. The timing of the first peak is delayed with a significant lower hip extension in maternal subjects. However, in the control group, the maximum hip flexion is significantly higher in the lowering phase with a significant lower range of motion in the lowering phase.

The results at the knee showed that maternal subjects had an increased knee flexion. When holding the box in standing, maternal subjects locked their knees in a slight hyper-extension range. Similarly, control subjects employed the same strategy, but with the higher peak knee flexion occur in the lowering part.

At the ankle, maternal subjects had an increase in ankle dorsiflexion when compared with control subjects. Both the maximum ankle dorsiflexion and range of motion in maternal subjects were statistically higher in both the lifting and lowering phase.

On contrary to this Sinnerton et al. [11] reported that the performance of lifting tasks remained unchanged in pregnant women. The difference is probably due to their results taken from earlier stage of pregnancy (at 18-20 weeks of gestation compared with 32-38 weeks in the present study).

Lifting Kinetics

In the sagittal plane kinetics, the maternal subjects had a prolonged hip extensor moment throughout the lifting phase, which correlates to the lack of hip extension in the kinematics. They also lacked the hip flexor moment in the lifting to lowering transition phase. At the knee, the maternal subjects had an increase in knee extensor moment that correlates to the lack of knee extension during lifting. At the ankle, maternal subjects lack the plantar flexion moment range. The kinetic results from this study concurred with other qualitative studies [12, 13] such that pregnant women assume many awkward postures and with muscle weakness or overuse, some daily tasks such as lifting will be difficult. Nichols and Grieve [12] reported that pregnant women

identified picking up objects from the floor, desk work, ascending stairs, driving and getting in and out of cars as some of the most difficult activities to perform. Cherry [13] reported that in pregnancy workers, health complaints were systematically related to job postures and physical work demands, including prolonged standing postures, twisting of the trunk and lifting weights.

Principal Component Analysis

The first five Principal Component Coefficients (PCCs) accounted for 68.14% of the total variability (see table 3). From the first three PCCs, a major contribution to differences between maternal and control subjects related to the hip and knee moment; and the sagittal kinematics were found. Wrigley and colleagues [7] found five PCs capturing kinematics associated to the control and placement of a box on the shelf and the timing of the sagittal extension moment. Khalaf et.al [9] reported that higher PCCs are required to represent velocity and acceleration and joint moments . Our results showed that maternal subjects had a slower lifting time, but neither statistically significant differences nor significant contributions from the PCCs were found. A further analysis should compare the difference between the lifting and lowering phases.

V. Conclusion

Using principal component analysis, we were able to identify different lifting kinematics and kinetics parameters in pregnant subjects and important biomechanical differences when compared with the control group. Future investigations on lifting capacity during pregnancy should also include other aspects of lifting such as different lifting weight and speed, as well as coordination between the trunk and hip and between the hip and knee kinematics.

Abstract — **In a postoperative rehabilitation program following anterior cruciate ligament (ACL) reconstruction surgery, it is most important to avoid exerting excessive stress on the reconstructed graft. We have been using a quadriceps muscle exercise, "front bridge" which is carried out in the prone position.**

[Purpose] To analyze anterior tibial translation and quadriceps muscle activity during "front bridge" exercise.

[Materials and Methods] Anterior displacement of the tibia were measured in two patients with ACL insufficiency during two kinds of front bridge exercises which place a fulcrum on the proximal (P-FB) and distal (D-FB) lower leg

Muscular activity during P-FB and D-FB was also measured in nine healthy volunteers using electro-myography.

[Results] From 30 to 0-degree of knee angle, the P-FB did not exerted anterior translation of the tibia in involved knees compared to that in uninvolved ones. Muscle activity of P-FB exercise was less than that of D-FB exercise even though muscle activity on P-FB exercise was larger than 60%MVC.

[Discussion] The anterior tibial translation by quadriceps femoris muscular activity and the effects of gravity in the prone position was prevented by the reaction force produced from the proximal fulcrum on the lower leg. Because P-FB showed more than 60%MVC muscle activity, it was thought that the P-FB had the strengthening effect of the quadriceps femoris muscle. These results suggest that the front bridge exercise which places a fulcrum on the proximal lower leg is effective exercise for quadriceps femoris muscle training with safe following ACL reconstruction surgery.

[Conclusion] The P-FB displayed more posterior tibial position than D-FB in extension position. Muscle activity of P-FB exercise was less than D-FB exercise. And also P-FB exercises had the strengthening effect of the quadriceps femoris muscle.

Keywords — **anterior cruciate ligament (ACL), anterior tibial translation, fluoroscopy, exercise, quadriceps**

I. Introduction

Anterior cruciate ligament (ACL) injury is the most common sports injury of the knee. Because this ligament has little capacity for spontaneous healing, reconstruction surgery of ACL is frequently chosen as a treatment option. In postoperative rehabilitation following surgery, it is most important to avoid exerting excessive stress on the reconstructed graft. In addition, it is also important to restore the strength as well as stability of the knee. The strength of the quadriceps muscle is indispensable for sports activity and it is necessary to strengthen it in order to perform sports with safe.

Strain on the ACL increases with extension, and contraction of the quadriceps femoris exerts an anterior shear-force on the knee [1]-[3]. Since training of the quadriceps femoris muscle near the extension position produces great stress on the reconstructed graft, it should be avoided in the immediate postoperative phase[4], [5], resulting delayed recovery from muscle weakness after operation [6], [7].

In order to perform safe training of the quadriceps femoris muscle near the extension position at an earlier postoperative phase, we developed a "front bridge" exercise with proximal fulcrum to prevent anterior displacement of the tibia (Fig. 1). This front bridge is a knee extension exercise carried out in the prone position.

The purpose of this study was to assess the anterior tibial translation and quadriceps muscle activity during "front bridge" quadriceps muscle exercise.

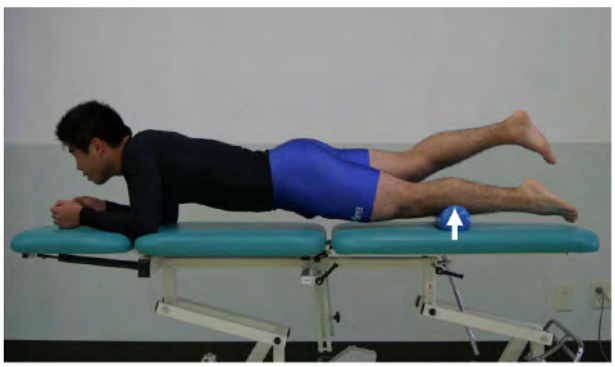

Fig. 1 "Front bridge" quadriceps muscle exercise with proximal fulcrum

II. Materials and Methods

A. Experiment 1; Measurement of tibial position on front bridge exercises

Subjects were two patients with ACL insufficiency: case A was male (41 years old, 167cm, 85kg), and case B was female (28 years old, 170cm, 58kg).

They performed two kinds of front bridge exercises. One of the exercises was front bridge placing a fulcrum on the distal lower leg (D-FB). Another of exercises was front bridge placing a fulcrum on the proximal lower leg (P-FB).Each exercises extended the knee from 30-degree of flexion to full extension. All exercises were carried out on the involved and uninvolved sides.

Lateral views of X-ray for the knee joint were taken during exercise (Allura Xper FD20, Philips Co.). The position of the tibia at 0, 10, 15 and 30 degree of knee flexion in relation to the femur was measured according to the method of Franklin et al [8].

B. Experiment 2: Measurement of the muscular activity during front bridge

Subjects were nine healthy persons (one female and eight males, 24.4±7.1 years old, 173.7±6.0 cm, 63.8±5.6 kg) without history of knee injury. They performed two kinds of front bridge (D-FB and P-FB) exercises, maintaining the knee in the extension position for 5 seconds in each task.

The muscle activities of the rectus femoris, vastus lateralis, and vastus medialis for 3 seconds were analyzed using an EMG system and software (Myosystem1200 and MyoResearch: Noraxon USA Inc., Scottsdale, AZ, USA) with a sampling rate of 1080 Hz and digitized to integrated EMG (IEMG) in each of the 2 tasks. The root mean square of IEMG was obtained for 3 second within the 5-second analysis period, omitting the first and the last seconds. EMG was normalized relative to the values obtained during maximum voluntary isometric contraction (% MVC) at 60-degree of knee flexion.

III. Results

A. Experiment 1: Measurement of anterior translation of the tibia on knee extensor training

The position of the tibia for each task is shown in Table1.

P-FB exercise did not exert anterior translation of the tibia in the involved knee compared to that in the uninvolved ones from 30 to 0-degree of knee flexion (Fig. 3). When the positions of the tibia in the uninvolved knees were compared among the two exercise tasks, P-FB exercise showed more posterior position of tibia (Fig. 4). D-FB exercise demonstrated anterior translation of the involved knee more than those of the uninvolved ones.

Table 1 Tibia translation

[mm]

			knee angle 30°	15°	10°	0°
Case A	D-FB	involved	2.1	7.0	6.6	1.8
		uninvolved	1.8	1.8	4.0	4.4
	P-FB	involved	-6.7	-1.6	-0.9	-1.3
		uninvolved	-5.0	0.8	3.4	2.1
Case B	D-FB	involved	5.5	6.0	6.6	5.8
		uninvolved	6.5	6.5	6.4	4.4
	P-FB	involved	-7.1	-5.0	-2.1	0.0
		uninvolved	-6.2	-3.8	-1.8	0.6

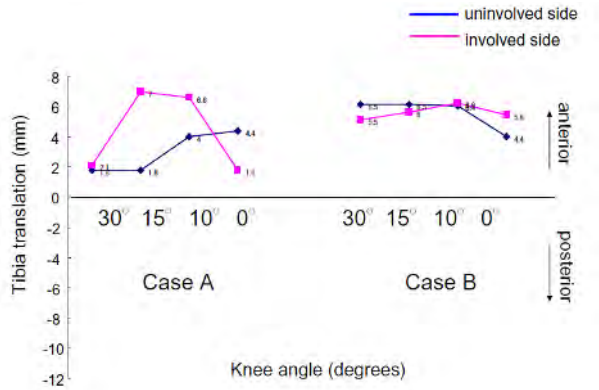

Fig. 2 Tibia translation during front bridge of distal fulcrum

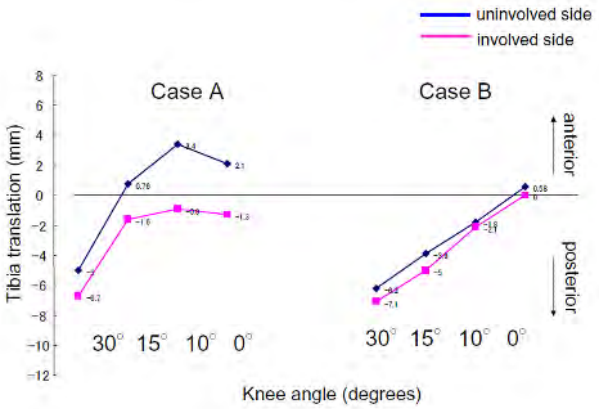

Fig.3 Tibia translation during front bridge of proximal fulcrum

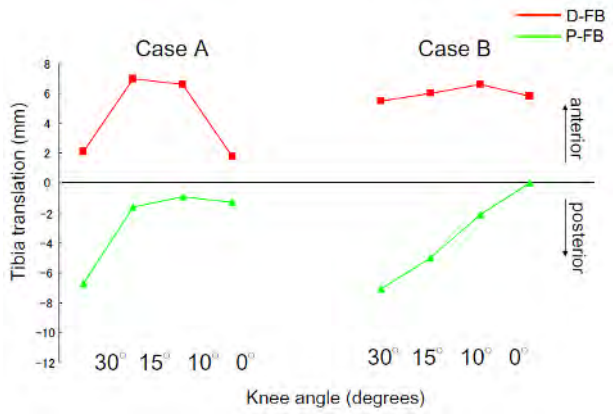

Fig. 4 Tibia translation of involved side during each exercise

B. Experiment 2: Measurement of the muscular activity during front bridge

Muscle activities in the D-FB and P-FB exercises are shown in Table 2 and Fig. 5.

Muscle activities of vastus medialis and vastus lateralis in P-FB exercise were larger than 70% of MVC, although those in D-FB exercise were larger than P-FB exercise.

Table 2 Muscle activities during exercises

	Vastus medials		Vastus laterals		Rectus femoris	
	Mean [%MVC]	SD	Mean [%MVC]	SD	Mean [%MVC]	SD
front bridge of distal fulcrum (D-FB)	91.82	21.67	96.70	13.33	78.50	32.90
front bridge of proximal fulcrum (P-FB)	78.59	25.22	70.00	16.80	53.05	20.65

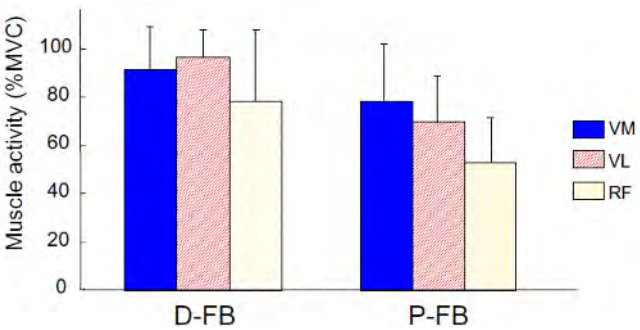

Fig. 5 Muscle activity during exercise

IV. Discussion

In the prone position, because gravity helps the tibia to move anteriorly and generates anterior shear-force of the knee joint, causing the risk for the knees after ACL reconstruction surgery. (Fig.6 left)

Although FB exercise was performed in the prone position, the position of the tibia in P-FB exercise was the more posterior than P-FB exercise and uninvolved knee, indicating that the anterior displacement of the tibia was braked by the reaction force (posterior shear-force) produced from the proximal fulcrum on the lower leg (Fig. 6).

These results showed that the front bridge with "proximal fulcrum" was a safe training method following the ACL reconstruction surgery.

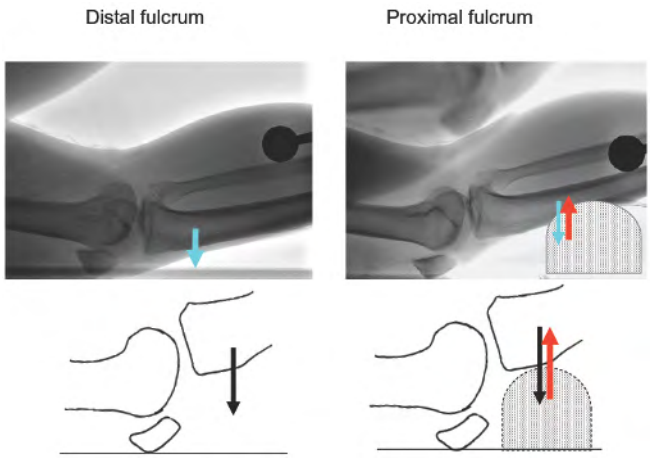

Fig. 6 The effect of proximal reaction force

Muscle activity of the knee extensors exceeded 70% of MVC except for the rectus femoris during P-FB exercise. Since strength training exceeded 60% of MVC muscle activity is effective, the front bridge exercise appears to be suitable as the strength training method for the vastus muscle group.

V. Conclusions

The “front bridge” quadriceps muscle exercise using a proximal fulcrum displayed more posterior tibial position than uninvolved in knee extension position. Muscle activity of front bridge exercise of proximal fulcrum was less than front bridge exercise of distal fulcrum exercise. And also front bridge exercise of proximal fulcrum had the strengthening effect of the quadriceps femoris muscle.

Coupled Autoregulation Models

T. David[1], S. Alzaidi[1], R. Chatelin[1] and H. Farr[1]

[1] Centre for Bioengineering, University of Canterbury, Christchurch, New Zealand

Abstract — **Cerebral tissue requires a constancy of both oxygen and nutrients (notably glucose). During periods of pressure variation, which occur normally as well as in cases of hypo- and hyper-tension, the body's cerebral autoregulation mechanism cause the arterioles to vasoconstrict/dilate, thus maintaining a relatively constant cerebral blood flow. A non-dimensional representation of autoregulation coupled with an asymmetric binary tree algorithm simulating the cerebro-vasculature has been developed. Results are presented for an autoregulation algorithm of the cerebro-vasculature downstream of the efferent arteries, in this case the middle cerebral artery. These results indicate that due to the low pressures found in the arteriolar structure the myogenic mechanism based on the increased open probability due to pressure of stretched activated ion channels does not provide enough variation in the vascular resistance to support constancy of blood flow to the cerebral tissue under variable perfusion pressure. Results show that under variations in pressure the metabolic mechanism provides sufficient variation peripheral resistance to accommodate constancy of cerebral blood perfusion.**

Keywords — **autoregulation, blood flow.**

I. Introduction

Cerebral tissue requires a constancy of both oxygen and nutrients (notably glucose). During periods of pressure variation, which occur throughout the normal day as well as in cases of pathological hypo- and hyper-tension, the body's cerebral autoregulation mechanism cause the arterioles to vasoconstrict/dilate in response to changes in cerebral perfusion pressure over a certain range, thus maintaining a relatively constant cerebral blood flow. These effects are of particular importance when investigating how blood is redistributed not only via the circle of Willis but throughout the cerebral tissue. It should be noted that there have been a number of cerebral autoregulation models proposed [1, 2], including models incorporated with a circle of Willis [3-5]. However, the combination of an autoregulation model with a fully populated arterial tree able to regulate dynamically remains a relatively unexplored field.

Considerable research effort has been expended in furthering the understanding of how an artery alters its radius and the associated chemical pathways. Particular interest has focused on the myogenic mechanism where the systemic blood pressure exerts an influence on vascular smooth muscle. Fundamental studies were carried out by Harder [6, 7]. Less research has been done for the metabolic condition where variations in pH and CO_2 are considered to be the prime movers for dilation/contraction of the small arterioles deep in the vascular tree. The most comprehensive study of blood flow control has been that of [8], however even in this case several important constants remain unknown making the model somewhat constrained.

The present model uses previous work by Gonzalez-Ferrandez and Ermentrout [9] to closely couple a myogenic model and a ne metabolic model of cerebral autoregulation with a representation of a vascular tree taken from the work of Steele et al [10]. In order to allow all parts of the tree to vary in its arterial radius (and hence resistance) the myogenic and metabolic models are non-dimensionalised enabling a single algorithm to be utilised. The work shows that in order to replicate the well-known variation of peripheral resistance with pressure the metabolic model is by far the dominant mechanism, so much so that the myogenic mechanism seems to hardly play a role.

II. Methods

The creation of vascular tree is based on the binary algorithm of Steele et al [10]. The parent vessel bifurcates in to two daughter arteries according to a phenomenological law described in [10]. The present model utilizes the early work of Kamiya and Togawa [11]which allows an evaluation of the angle between parent and daughter arteries. Such that

$$\cos\theta_1 = \frac{r_p^4 + r_{d1}^4 - r_{d2}^4}{2r_p^2 r_{d1}^2}; \quad \cos\theta_2 = \frac{r_p^4 + r_{d2}^4 - r_{d1}^4}{2r_p^2 r_{d2}^2}; \quad (1)$$

Figure 1 shows the basic construction.

In order to map the binary tree into a 3D space we randomise the normal vector of the plane defined by the two daughter artery vectors. This randomization allows for "forcing" the arteries to grow in particular directions as used by Schreiner et al [ref Schreiner]. The tree is terminated when the arterial size reaches a lower limit and we consider the end terminals to be connected to a network of capillaries, each of which is modeled by Krogh cylinder. For our present work the binary tree can be made from up to 1,000,000 segments with approximately 500,000 terminal arteries.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1896–1899, 2009
www.springerlink.com

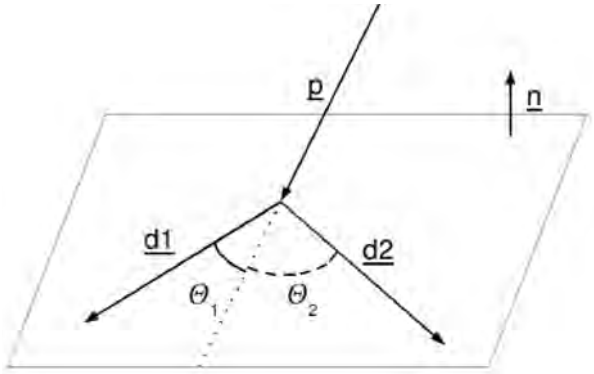

Figure 1

Passing "up" and "down" the tree structure determines the peripheral resistance of the vascular bed by assuming Poiseuille flow through the arterioles.

The myogenic model uses the work of Ferrandez-Gonzalez and Ermentrout [9] to associate systemic blood pressure with the opening of calcium activated ion channels. This produces variations in cytosolic Ca^{2+} allowing MLCK (myosin light chain kinase) activation and subsequent smooth muscle contraction. We have introduced extra equations to model the consequencial production of eNOS from both Ca^{2+} variations and wall strear stress values . We have non-dimensionalised the resulting equations so as to be able to implement this myogenic response over all arteries in the vascular tree. The membrane potential is given by

$$C\frac{dv}{dt} = -\sum_{i}^{N} g_i\left(v - v_i\right) \tag{2}$$

The g_i 's are ion channel conductances and v_i Nernst potentials.

Ca^{2+} is given by

$$\frac{dCa^{2+}}{dt} = -\rho\left(m_\infty\left(v-1\right) - kCa^{2+}\right) + \gamma F\left(\tau_w\right) \tag{3}$$

$F\left(\tau_w\right)$ is a strain energy function varying with wall shear stress τ_w, m_∞ the equilibrium open channel probability for Ca^{2+}, and k a reverse reaction rate. A similar equation is written for eNOS.

Although selective ion channels in the smooth muscle cell of the cerebro-vasculature respond to variations in both CO2 and pH our initial mode for the metabolic response uses the simple assumption that the set of arterioles feeding the capillary bed are in close proximity to the venous return. Excess carbon dioxide in the venules is diffused to the arterioles and induces a relaxation/contraction of the arteriolar radius thus allowing increased/decreased blood flow to convect away carbon dioxide and hence maintain the correct CO2 concentration. This model was also used in the 1D models of Alastruey et al. [12].

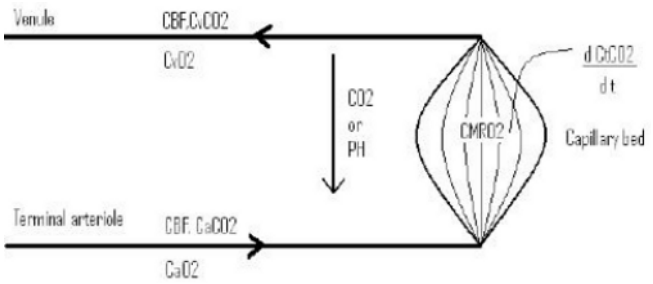

Figure 2

Figure 2 shows the proximity of arteriole and venule connected by the capillary bed.

Equation (4) represents a conservation equation where the rate of change of carbon dioxide is balanced by the production (due to metabolism) and that convected away by the blood flow.

$$\frac{dCO_{2,tissue}}{dt} = CMRO_2 + CBF\left(CO_{2,artery} - CO_{2,tissue}\right) \tag{4}$$

where $CO_{2,tissue}$ is the tissue concentration of carbon dioxide, CO2;artery is the arterial concentration of carbon dioxide (assumed to be 0.49ml/ml) CMRO2 is the cerebral metabolic rate of oxygen consumption (assumed to be a constant 0.035ml/g/min for all parts of the brain), which due to the stoichiometry of the aerobic metabolism in the brain tissue, is equal to the cerebral metabolic rate of carbon dioxide production. CBF is the flow rate in the terminal artery and thus entering the capillary bed. We use a reverting differential equation for the radius of the arteriole given by

$$\frac{dr}{dt} = G\left(CO_{2,sp} - CO_2\right) \tag{5}$$

here $CO_{2,sp}$ is the solution to the homogeneous equation for $CO_{2,tissue}$ (equation (4)).

CMRO2, the metabolic rate of oxygen consumption is determined by a space-time partial differential equation given by

$$\frac{\partial C}{\partial t} = D\left(\frac{\partial^2 C}{\partial r^2} + \frac{1}{r}\frac{\partial C}{\partial r}\right) - \Psi\left(C\right) \tag{6}$$

modelling convection of blood flow through the capillary and oxygen diffusion into the tissue of the Krogh cylinder. $\Psi(C)$ is the depletion rate of oxygen in the cerebral tissue. Boundary conditions at the capillary/tissue surface are formed by solving the equation of Blum [ref Blum]. This provides a value of $CMRO_2$ which is a function of the cerebral blood flow in the capillary.

Equations 2-5 are solved using a standard Runge-Kutta adaptive time-step algorithm whilst equation 6, due to it's non-linearity uses an implicit Crank-Nicholson scheme. The binary tree mapping is also non-linear in determining the daughter angles and is solved at each bifurcation by a Newton-Raphson algorithm with an analytical Jacobian.

III. Results

Figure 3 shows a representation of a binary tree mapped to 3D space. The number of terminal segments is small compared to those used for the Figures 4 and 5.

Figure 4 demonstrates the relationship between systemic pressure plotted and normalized cerebral blood flowrate for the myogenic model. This is a representation of the blood flow required to perfuse the brain tissue supported by the middle cerebral artery. The plot shows that although the myogenic autoregulation model does provide some change from the no autoregulation case, it does not successfully emulate the ideal observed autoregulatory response.

For comparison, the no-autoregulation case and the ideal autoregulation response are also shown. Our analysis of the pressure distribution in the binary vascular tree shows that the smaller arterioles of this arterial tree contribute the vast majority of the total resistance of the tree, as expected.

These smaller arterioles have very low pressures, and according to the myogenic autoregulation model only very small changes occur at these low pressures, indeed these changes could well be dilatory! The percentage change of the smaller arterioles (in the range of 10 and 100 microns) that is required to reach the ideal autoregulation profile is of the order of 30%. This change cannot be induced using the current myogenic autoregulation model.

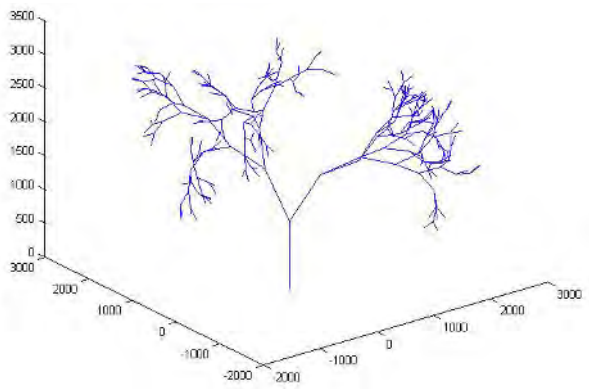

Figure 3

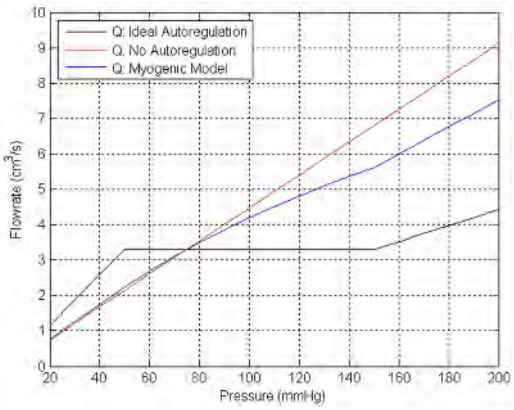

Figure 4

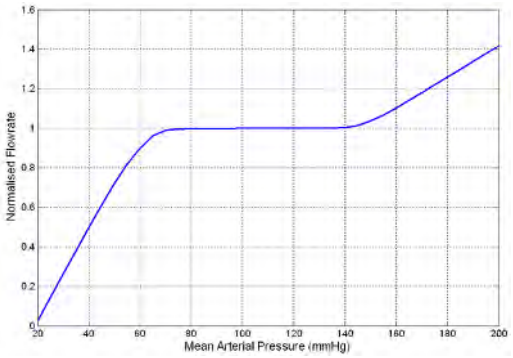

Figure 5

The metabolic algorithm described above is now substituted for the myogenic model where the look-up table contains values of radius and pressure evaluated as before for large times so as to reach asymptotically stable values. For each pressure value ranging from zero to 200 mmHg and for each pressure value in the tree the radii of segments, where these radii lie between 10 and 100 microns, are changed in an iterative manner (using the look-up table previously evaluated from equations 4 and 5 until a converged value of the total peripheral resistance is found. Segments of the tree with radii outside of the range given above are unchanged. This algorithm has been used to yield the following results. Figure 5 plots physiological perfusion pressure vs the total normalised flow rate in the tree. This flow rate is normalised to that known value ($2.85\,mLs^{-1}$) required to perfuse

the volume of the brain supported by the middle cerebral artery at "normal" physiological conditions (systemic pressure of 100 mmHg). As can be seen the metabolic autoregulation model provides the correct variation in peripheral resistance to ensure constancy of flow rate to the cerebral tissue without myogenic support.

IV. Conclusions

By developing a non-dimensional representation of the arterial wall model of Gonzalez-Ferrandez and Ermentrout and the asymmetric binary tree algorithm of (Oufsen3) results are presented for an autoregulation algorithm of the cerebro-vasculature downstream of the efferent arteries, in this case the middle cerebral artery. These results indicate that due to the low pressures found in the arteriolar structure the myogenic mechanism does not provide enough variation in the vascular resistance to support constancy of blood flow to the cerebral tissue under variable perfusion pressure. A metabolic model has been developed under the assumption of close proximity between venules and the vascular tree at the arteriolar level. Results show that the metabolic mechanism seems to be the dominant mechanism for cerebral autoregulation.

Measurement of Changes in Mechanical and Viscoelastic Properties of Cancer-induced Rat Tibia by using Nanoindentation

K.P. Wong[1], Y.J. Kim[1] and T. Lee[1]

[1] Division of Bioengineering, National University of Singapore, Singapore

Abstract — **The aim of this research is to evaluate the changes in mechanical and viscoelastic properties of cancer induced rat tibias and to establish a correlation between viscosity and elastic modulus. Nanoindentation was conducted up to a magnitude of force equivalent to 500 nm with a load rate of 20 nm/s. After a 30-seconds peak hold time, the indenter was unloaded. A total of 30 indentations were made, each at least 30 μm away from an adjacent indentation surrounding canaliculae in the bone structure. Creep displacement-time curve was fitted using the following equation: $h^2(t)=(\pi/2)P_0 cot\alpha[(1-exp(-tE/\eta))/E]$. Viscosity was computed based on the curve fitting of creep displacement by non-linear regression. Cancer-induced tibias showed significantly lower indentation viscosity and modulus than sham-operated ones ($p<0.05$). Positive linear relationships were found between indentation modulus and viscosity for both cancer-induced and sham-operated tibias. However, there is no significant difference in the correlation between cancer-induced and sham-operated rat tibias ($p>0.05$).**

Keywords — **Elastic modulus, Hardness, Viscosity, Rat tibia, Nanoindentation**

I. Introduction

Bone metastases are bone diseases that cause an increased morbidity, mortality and medical expenses worldwide. They occur in approximately 70% of patients with an advanced breast or prostate cancer and 15-30% of patients with a carcinoma of the lung, colon, stomach, bladder or kidney. Furthermore, once tumor had metastasized to bone, they correspond to an advanced stage of malignancies and are usually incurable. [1] However, cancer cells do not directly caused osteolysis. They enhance osteoclast activities, thus in turn increase bone resorption, leading to osteoporosis and reduction of bone structural properties.

As a biological material, human bone exhibits a complex microstructure and microcomponents, which results in complicated mechanical properties. Viscoelasticity is one of these properties. Because of the viscoelastic nature of collagen fibres in the bone matrix, bone itself has remarkable viscoelasticity. Thus, bone can also exhibit a viscoelastic response which is commonly termed "creep". [2] Creep is a slow, progressive deformation of a material under constant stress. Creep processes occur in the steady-state loading of materials. In a creep experiment, the stress is suddenly raised to a constant level beginning at time zero, and the strain or displacement is measured of a function of time.

Traditionally, biomechanics has focused on examining the material and structural properties of living tissues, both in their normal and diseased states. This approach is primarily one of mechanics and is relevant to understanding the load bearing capacity of tissues. However, a bone at risk of fracture cannot simply be determined by the amount of bone that exists. Bone quality or fracture susceptibility is very important to precisely determine the bone's mechanical behavior. [3] Improved preventive and therapeutic strategies for skeletal diseases such as bone metastases rely on a better understanding of the lamellar mechanical properties of bone.

Nanoindentation is an emerging technique that is capable of evaluating bone's quasi-static and dynamic mechanical properties on extremely small volumes of tissue. With nanoindentation, it is possible to measure properties of the bone at the micron and sub-micron levels, thus study the properties of bone microstructural components having dimensions of only a few microns or less. [4] In a nanoindentation test, a creep phenomenon is usually observed as an increase in depth during a hold period at maximum load in the load-displacement data. The output parameters, including hardness and elastic modulus, are derived from the elastic response of the indented material to the applied load.

The aim of this research study is to establish a correlation between viscosity and the mechanical properties of bones by nanoindentation creep. The objective of investigating this relationship is to find an improved tool for predicting the risk of fractures in diseased and degenerative bone. The hypothesis was tested that the cancer-induced bones has lower mechanical and viscoelastic properties than normal bones.

II. Materials and Methods

A. Animals

8-10 week-old Sprague-Dawley male rats (SD rats) were randomly divided into two groups which are the control group and the cancer group. The control group received

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1900–1903, 2009
www.springerlink.com

only the sham operation with saline injected into the right femur. The cancer group had Walker Carcinosarcoma 256 (W256) cancer cells injected into the right femur via a hole drilled through the intercondylar notch. The cancer group rats received no treatment after surgery. At 30 days after the surgery, 3 rats from each group were euthanized in the carbon dioxide chamber.

B. Sample Preparation

The euthanized rats' tibia bones were harvested. At room temperature, bone marrow and soft tissue of the rat tibia bone specimens were removed thoroughly while taking care that the bone sample was not damaged. By mixing the resin and hardener for 2 minutes to minimize the formation of air bubbles, the bone samples were positioned vertically in the centre of the embedding mold and the resin and hardener mixture was poured over the bone sample. The sample was then left for 24 hours at room temperature to allow bonding of the resin to bone surface. The disposable mold was removed once the resin had cured. By using Isomet 1000 precision saw (Buehler Ltd, Lake Bluff, IL) with counterbalanced sliding load weight system, under constant irrigation, a 5mm of the rat tibia bone sample was sliced from the diaphyseal region perpendicular to the long axis of the tibia. A total of six samples were prepared and labeled respectively – 3rtc, 3lts, 4rtc, 4lts, 6ltc and 6rts.

C. Polishing

The embedded sample was metallographically polished to produce the smooth surface needed for nanoindentation testing. After being ground using silicon carbide abrasive papers of decreasing grit size (600, 800 and 1200 grit) under de-ionized water, the samples were polished on microcloths with finer grades of alumina powder of grit size 3µm, 1µm, and 0.25-0.05µm. Final polishing was on a plain microcloth under de-ionized water, after which the samples were ultrasonically cleaned to remove the particles and debris resulted from polishing. [4]

D. Calibration and Placement of Indentations

All nanoindentation tests were performed using a pyramidal Berkovich tip for MTS Nano XP nanoindenter (Nano Instruments Inc., Oak Ridge, TN. A line of indents was performed on a calibration sample of fused quartz to calibrate of the tip area function. [4] The prepared samples mounted on the magnetized stage. Indent locations were selected using the optical microscope mounted on the moving stage in parallel with the load sensing transducer. Indenting was conducted up to a magnitude of force equivalent to 500nm with a load rate of 20nm/s. After a 30-seconds peak hold time, the indenter was unloaded. A total of 30 indentations were performed in each sample. Each indent is made at least 30µm away from an adjacent indent surrounding canaliculae in the bone structure.

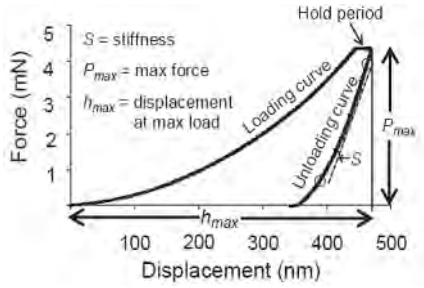

Figure 1: Load-Displacement Data

As seen in the plot in **Figure 1**, it presents a typical set of load-displacement data. After the initial loading, in which most of the plastic deformation occurs and hardness impression is formed, there is a hysteresis in the data, which indicates a non-negligible portion of the indentation displacement is viscoelastic. Creep was measured during a 30-seconds hold period at peak load for every indent in each sample. Creep displacement-time curve was fitted using the following equation (Equation 1),

$$h^2(t) = (\pi/2)\, P_0 \cot \alpha\, [\, (1-\exp(-tE/\eta))/E] \qquad (1)$$

where h(t) is indentation creep displacement as a function of time.

P_0 is the indentation peak force;

α is an equivalent cone semi-angle 70.3º to the face angle of the Berkovich indenter;

E is an elastic element of the Voigt model (GPa);

η is the indentation viscosity (GPaS).

This equation represented two elements of the Voigt model in which a spring and a dashpot are linked in parallel. The viscosity, η was computed based on each curve fitting by using the software SPSS for the non-linear regression analysis. A statistical student t-test was performed to compare the values of indentation modulus and viscosity between our own results values and data obtained from literature reviews.

III. Results

A summary of the elastic modulus(E) and viscosity(η) of the rat lamellar bone is represented in **Table 1**. Comparison was done between the nanoindentation modulus and viscosity between sham-operated group and cancer-induced group of rat tibia bones as shown in **Figure 2 and 3**, respectively. Linear regression of the elastic modulus and viscosity for

Table 1: Mean values of Elastic Modulus and Viscosity of rat tibia bones.

each group was considered separately and all together, in **Figure 4**.

Cancer-induced rat tibias showed significantly lower indentation modulus and viscosity than the sham-operated group of rat tibias (12.81±1.39 vs. 17.83±3.03 GPa for modulus and 80236.38±2606.73 vs. 109700.90±21410.25

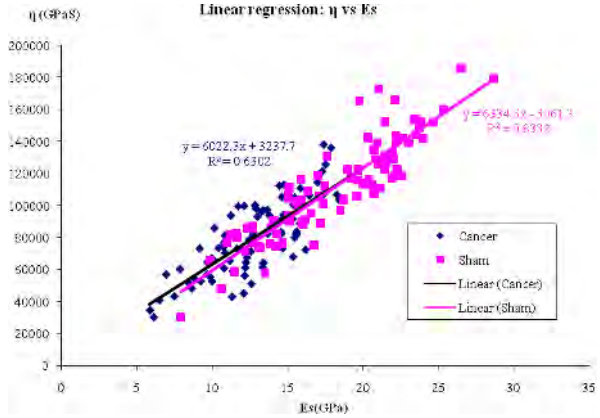

Figure 4: Linear regression relationship between indentation viscosity vs indentation modulus.

GPaS for viscosity, $p<0.05$ for both. Significant positive linear relationships were found between indentation modulus and indentation viscosity for sham-operated rat tibias ($R^2=0.83$, $p<0.05$) as well as for cancer-induced rat tibias ($R^2=0.63$, $p<0.05$). However, there is no significant difference in the correlation between the sham-operated and cancer-induced rat tibias ($p>0.05$) (Figure 4).

IV. Discussion

Nanoindentation technique has several advantages and is now widely used in material science for probing the mechanical properties of small microstructural features. The major benefit is from the accurate positioning capability and the high resolution load and depth-sensing capabilities which make it possible to study mechanical properties of finely structures where relatively small area need to be tested and measured. From analysis of nanoindentation load-displacement data, it is possible to derive values of elastic modulus and hardness.

In the present study, the elastic modulus, viscosity and hardness of the cancer-induced group tibia had shown significant difference with the sham-operated rat tibias. It is worth noting that the measurements may not be as accurate when only one data indentation point was made surrounding the canaliculi in each lamellar during the analysis, due to variations in properties within single lamellae. To take account of those variations, a total of thirty indentations in each specimen were made, with an average of 3-4 indention point surrounding different canaliculi, representing all portions of each lamellar.

In combination with the results of Bak et al. [5], the nanoindentation results obtained here suggest that the elastic modulus of sham-operated rat tibias are significantly greater

than the value of a normal non-fractured bones widely used, E=10.6GPa, obtained by mechanical testing. Some of this discrepancy may be due to the drying of the specimens prior to the nanoindentation testing. In previous study done by Hengsberger et al. , who found that drying increases bone's elastic modulus by as much as 55% [3,6,7]. Another question which arises is the extent to which embedding in epoxy affects the nanoindentation measurements. It is important to choose an embedding material appropriate for the specific bone under investigation. Measurements of bone hardness are sensitive to the modulus and viscosity of the embedding material [3,8]. Hence, to minimize this effect, indentations close to the bone-epoxy interface were not included in the data. In order to get further results with a higher accuracy, it should be possible that to make nanoindentation measurement on both wet and dry bone. But it seems unlikely that rat tibia can be studied without embedding.

To the best of our knowledge, the elastic modulus of cancer-induced rat tibia has not been measured previously. Our finding of a positive correlation between nanoindentation viscosity and modulus of rat tibia lamellar tissue agreed with previous observation from nanoindentation tests performed by Tang et al. [9]. Mulder et al. found that indenatation modulus is linearly related to the degree of mineralization. In general, bone properties will improve if calcium content is higher [10]. Therefore, the positive viscosity-modulus relationship found in the current study can be interpreted as an increase in viscosity is associated with an increase in the degree of mineralization of lamellar tissue of rat tibia.

We found that the nanoindentation viscosity of cancer-induced rat tibias is significantly lower than in the sham-operated group. This result indicates that cancer-induced bones are more responsible to time-dependent deformation of bone under a prolonged constant load. These findings also suggest that cancer-induced bones, simulation of the in-vivo bone metastases, have an increased inhomogeneity of creep deformation under constant load which may trigger damage at the interface and lead to degradation of mechanical stability of cancer bones [10].

V. Conclusion

Nanoindentation technique had been used to quantify hardness and elastic modulus of sham-operated and cancer-induced rat tibias. The viscosity of rat tibias was computed based on the curve fitting of creep displacement by non-linear regression of the nanoindentation results. Cancer-induced rat tibia bones showed significantly lower mechanical and viscoelastic properties than sham-operated bones, as hypothesized. Therefore, current results would be further used to evaluate the response of cancer-induced osteolysis to chemotherapeutic and anti-osteoporotic treatment for predicting risk of fractures in diseased bones.

Surface Conduction Analysis of EMG Signal from Forearm Muscles

Y. Nakajima[1], S. Yoshinari[1] and S. Tadano[2]

[1] Dept. of Product Technology, Hokkaido Industrial Research Institute, Sapporo, Japan
[2] Graduate School of Engineering, Hokkaido University, Sapporo, Japan

Abstract — **Determining muscle forces of the finger during heavy work is important for an understanding and prevention of tenosynovitis. Electromyography is one index of muscle activity. Measurements by surface electromyography (sEMG) are noninvasive and simple to apply to obtain signals of muscle action potentials. The sEMG potentials of muscles near the electrode are superimposed. To identify the muscle activities from sEMG measurements, it is necessary first to analyze the characteristics of sEMG conduction in the forearm. This paper develops a conduction model of the forearm that incorporates the muscles and the *radius* and *ulna* bones. sEMG distributions were analyzed using the finite element method. The Root mean square (RMS) values of sEMG values and the power exponent of the attenuation (PEA) in relation to the length between the electrode and the source of muscle action potential were estimated in this work. Further, the positions of muscle action potential were reverse-estimated using the RMS values and the PEA. As a result, the PEA was found to increase monotonically with increases in the inter-electrode distance (IED) of the surface electrode pair. The errors in the estimated positions of muscle action potential increased with decreases in the distance between the source of muscle action potential and the *radius* and *ulna* bones.**

Keywords — **Forearm, Muscle Force, Surface Electromyography (sEMG), Conductive Model, Reverse-estimation.**

I. Introduction

Fingers do work from fine operations to heavy–duty tasks. The long continuing work will often cause arthritis and tenosynovitis. To prevent this, the load of fingers has been estimated using electromyography and computer simulation. Recently, a method to estimate muscle forces of fingers with needle electromyography and musculo-skeletal model has been reported [1].

This method is effective to estimate muscle activities individually, but a limitation is that a needle electrode needs to be inserted into the muscle causing pain to subjects. Surface electromyography (sEMG) is an attractive method to measure muscle activity because of easy application and no pain.

sEMG technique has some problems when measuring the activity of individual muscles in the forearm. Myoelectric potentials from all muscles near the electrode are superimposed in sEMG signals. The muscle activity of individual muscles must be estimated from sEMG

This paper reported a conduction model of the forearms by the finite element method. The conduction model was composed of a cylinder consisting of muscle, *radius* and *ulna* bones, and a source of muscle action potential. Simultaneously, changes in sEMG distribution caused by changes in the position of the source are investigated. Further, the source positions are reverse-estimated using the volume conduction characteristics and the analyzed sEMG distribution.

II. Materials and Methods

A. Geometry of the models

A model of the left forearm in supinated position is developed with a 40mm arm radius and a 300mm long cylinder (Fig. 1). The model incorporates the muscle tissue, and the *radius* and *ulna* bones. The model is used to reverse-estimate the position of the source of muscle action potentials.

The origin of the global coordinates is on the center of the model, the *z*-axis is the center axis, the *y*-axis is the dorsal direction, and the *x*-axis the lateral direction. The *radius* and *ulna* bones are cylindrical of 10mm radius and are the same length as the model. The centers of *radius* and *ulna* bones are at 23mm of radius from the center of the model, parallel to the *z*-axis. The positions of the *radius* and the *ulna* bones are symmetric to the *yz*-plane, and the center axes of the bones are 120° apart in the *z*-axis direction.

www.springerlink.com

Another model incorporating only the muscle tissue is developed with the same arm radius and length. The muscle only model is used to calculate the characteristics of the attenuation of sEMG.

B. Governing equation

The electric scalar potential V [V] in the model obeys the following equation:

$$\nabla \bullet \left[\left(\boldsymbol{\varepsilon} \frac{\partial}{\partial t} + \boldsymbol{\sigma} \right) \nabla V \right] = 0 \qquad (1)$$

where $\boldsymbol{\sigma}$ [S/m] denotes the conductivity vector, $\boldsymbol{\varepsilon}$ [F/m] and t [s] denote permittivity and time, respectively; $\nabla\bullet$,∇, and $(\partial/\partial q)$ denote the divergence, gradient, and partial differential with respect to q, respectively. Eq. (1) follows directly from Maxwell's equation describing Ampere's law under the assumption of negligible magnetic effects.

The muscle and bone anisotropic conductivities are $\boldsymbol{\sigma}_M$ and $\boldsymbol{\sigma}_B$, respectively. The radial, circumferential and axial component of the conductivity is shown in table 1 [2][3]. The permittivity is disregarded as it is very small.

Table 1 Conductivity of muscle and bone components [2][3]

	Muscle[S/m]	Bone[S/m]
Radial	0.148	4.65×10^{-3}
Circumferential	0.148	6.33×10^{-3}
Axial	0.446	66.7×10^{-3}

C. Sources of muscle action potential

The transmembrane current caused by depolarization of the muscle-cell membrane generates a muscle action potential. Depolarization propagates in the muscle fibre at a constant speed and gives rise to the current inflow and outflow, the source of the muscle action potential.

To simplify, the source of the muscle action potential is replaced by a current dipole with pole separation of 2.1mm [4][5]. The dipole is placed on the xy-plane and at a circumferential angle θ_P around the z-axis based on the y-axis and depth d_P below the surface of the cylinder. The direction of the current dipole is parallel to the z-axis, and the current strength is normalized to be 1mA.

D. Finite element analysis

The commercial FEM software package ANSYS MultiPhysics Ver.10 was used to analyze the distribution of the sEMG measurements. The element size of the model at the source is 0.1 mm, at the surface nearby just above the dipole from 2 mm and up to 6 mm elsewhere.

A 20mm thick air layer, as the boundary condition of the analysis, surrounds the model. The air layer has an isotropic conductivity $\sigma_A = 1.0\times10^{-10}$ S/m, very much smaller than that of the muscle. The element size of the air layer is 8mm. The outside edge of the air layer was assumed to be grounded (0mV).

The model analyzed conditions of depth d_P changed from 5 to 40mm at intervals of 5mm, and the angle around the z-axis, θ_P from 0 to 90° changed at intervals of 10°.

III. Results

A. Reduction of the RMS value of sEMG

The potential distribution $V=V(\theta,z)$ on the surface of the model was obtained with θ as the circumferential angle around the z-axis at the position of the source.

Generally, actual sEMG measurements determine potential differences, changed dynamically, between electrode pairs. Then the RMS value of the recorded potential difference is calculated. The analyzed sEMG distribution is static because of the static source. However, RMS values can be approximated by a simulated static distribution with the following three conditions assumed: 1, the component in the forearm has no capacitance; 2, the field strength at a point sufficiently far left from the source is zero; and 3, the speed of conduction of the depolarization is constant.

The method can be represented as follows, with the centered difference in the z-direction ΔV:

$$\Delta V(\theta, z) = V(\theta, z + \Delta z/2) - V(\theta, z - \Delta z/2) \qquad (2)$$

where Δz is the difference interval and corresponds to the IED of the electrode pair; ΔV also corresponds to the potential difference of the electrode pair. Outside both ends of the distribution ($z < -L_A/2+\Delta z/2$ or $L_A/2-\Delta z/2 < z$), ΔV is assumed to be zero because of the small potential differences.

The RMS value distribution sV is calculated as follows.

$$sV(\theta) = \left(\frac{1}{L_A} \int_{-L_A/2}^{L_A/2} \Delta V^2 dz \right)^{1/2} \qquad (3)$$

The attenuation characteristics of the RMS values are obtained with the relation between distance l from the center of the electrode to the source and the sV of the muscle only model. The RMS values rapidly decrease with increases in the distance l. This decrease was fitted with the following power function (4).

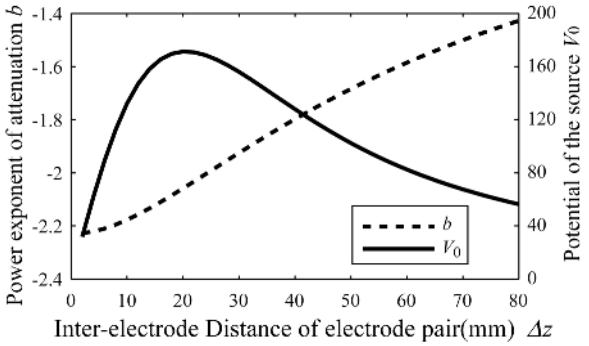

Fig. 2 The PEA and potential of the source by differences in IED

$$sV(\theta) = V_0 l(\theta, d_P)^b \tag{4}$$

Where V_0 denotes the potential of the source, and b denotes the power exponent of the attenuation (PEA).

The PEA b is -2.18 at Δz = 10mm and -1.68 at 50mm. Fig. 2 shows the relation between Δz, V_0, and b (PEA) in Eq. (4). The PEA increases with increases in Δz, suggesting the tendency also reported in Roeleveld [6], where narrow IEDs of electrode pairs measured the action potentials of muscle fibres near the electrode. It is possible to measure the contribution of also distant fibres with a wide IED. Using two different electrodes at intervals allows the measurement of muscle activities of individual superficial and deep muscles.

B. Estimation of the source position

The source position was reverse-estimated from the RMS value distribution sV of the model consisting of the *radius* and *ulna* bones and muscle, using the PEA regressed by Eq. (4).

The method is as follows. The RMS value $sV_i = sV_i(\theta_i)$ obtained from an virtual electrode pair i (i=1...n) at a circumferential angle θ_i is known, and the right side of Eq. (4) is replaced by the following f_i as a function of the unknown position of the source $\boldsymbol{x_p} = (x_P, y_P)$ and also the unknown source potential V_0.

$$f_i(x_p, y_p, V_0) = V_0 l_i^{\,b} \tag{5}$$

$$l_i = l(\theta_i, x_P, y_P) = \sqrt{(x_p - R_A\cos\theta_i)^2 + (y_p - R_A\sin\theta_i)^2} \tag{6}$$

The PEA b in Eq. (5) has been regressed to the value obtained by the muscle only model. The error in the RMS value estimate e_i is defined by Eq. (4) and (5).

$$e_i = sV_i - f_i \tag{7}$$

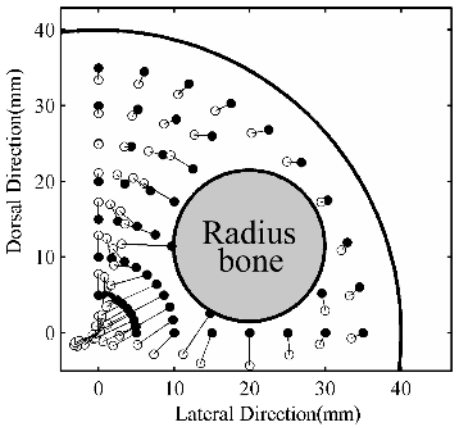

Fig. 3 Estimating the source position by RMS values of 10mm of IED. (white circles: estimated position of the source, black circles: true position)

With Taylor expansion of the first degree of Eq. (5) with respect to x_p, y_p and V_0, the following equation is obtained by assigning the result to Eq. (7).

$$\boldsymbol{e} = \begin{bmatrix} \frac{\partial f_1}{\partial x_P} & \frac{\partial f_1}{\partial y_P} & \frac{\partial f_1}{\partial V_0} \\ \vdots & \vdots & \vdots \end{bmatrix} \begin{bmatrix} \Delta x_P \\ \Delta y_P \\ \Delta V_0 \end{bmatrix} = \boldsymbol{D}\Delta\boldsymbol{x} \tag{8}$$

Where $\boldsymbol{e}$ is the vector of the error $[e_1 \,..\, e_n]^T$, $\Delta\boldsymbol{x}$ gives the direction minimizing the vectorial norm of $\boldsymbol{e}$, and $\Delta\boldsymbol{x}$ is calculated by the following equation using Moore-Penrose matrix inverse $\boldsymbol{D}^+$.

$$\Delta\boldsymbol{x} = \boldsymbol{D}^+\boldsymbol{e} = \left(\boldsymbol{D}^T\boldsymbol{D}\right)^{-1}\boldsymbol{D}^T\boldsymbol{e} \tag{9}$$

The $k\Delta\boldsymbol{x}$ that is obtained by multiplying a small constant k by the $\Delta\boldsymbol{x}$ obtained by Eq. (9) and this is added to $\boldsymbol{x}$. The calculation is repeated until the norm of $\boldsymbol{e}$ is the minimum. Then the estimated position (x_P, y_P) can be calculated.

shows the results of the estimates of the source position obtained by this method, 36 virtual electrode pairs at intervals of 10° are used. The error grows for sources close to the *radius* and *ulna* bones or under *radius* and *ulna* bones viewed from above the source. The maximum error calculated given by the results of 10mm of IED is 8.4mm, and that of 50mm is 8.2mm.

IV. Discussion

A. Separating sEMG of adjacent muscles

According to the results, the PEA of the RMS values of sEMG increases with increases in IED Δz. The RMS values

measured with a narrow IED, decrease quickly, with wide IEDs more slowly. Using two electrodes with different IEDs makes it possible to measure the superficial and deep muscle activities separately.

To achieve such measurements, appropriate circumferential electrode intervals around the forearm are important. In determining the interval, it is necessary to consider the spatial frequency of the sEMG distribution and the intervals between adjacent muscles, and intervals within about 15° are considered adequate.

B. Attenuation of muscle action potential

Roeleveld et al. have measured the attenuation of the muscle action potential with respect to the amplitudes of the potential difference of electrode pairs [6]. The values of the analytical results and those of Roeleveld were compared, and the attenuation tendencies agreed. However, the PEA of our analysis is about 0.5 smaller than that in Roeleveld. This may be suggested to be an influence of differences in the anisotropic conductivity used in the analysis. Anisotropic changes in the electric conductivity cause expansion or contraction of the sEMG distribution in the direction of the cylinder axis, and then cause a change of the PEA.

Further, it is known that fat has a lower conductivity and higher permittivity than muscle tissue, and has an effect similar to a low-pass filter when a muscle action potential is conducted [5]. Further, it is necessary to consider the influence of noise and drift, which would restrict the measurement limits in actual measurements to within a distance of 30mm.

C. Estimation error of the source position caused by radius and ulna bones

When the source is close to the *radius* and *ulna* bones, the sEMG distribution has been considerably distorted, here the error of estimating the source position becomes as much as 8.4mm. And this size of error may result in confusing the activity of one muscle for that of another. To prevent such miss-estimations caused by the *radius* and *ulna* bones, a method for correcting estimates by applying these analytical results can be devised, and the accuracy of estimates can be improved if correction by such analytical result is applied to the measured results, using previously input positions of electrode pairs, muscle, and *radius* and *ulna* bones. Further, a method to correct the estimates of the muscle activity can be devised by arranging the experimental set-up for the measurements. Measuring the conductivity of the forearm by a weak current from electrodes would improve the accuracy of the estimates.

The method suggested here estimates only one activated muscle position and activity; it is necessary to estimate the activities of multiple muscles in actual measurements. However, measurements using electrodes of narrow and wide IEDs as mentioned above can obtain sEMG of superficial and deep muscles. Using these measurements and an optimization method together would allow separate activity estimates of each of the deep muscles.

V. Conclusions

The attenuation characteristics of sEMG were calculated with the conduction models of the forearm, and the positions of the source of the muscle action potential were reverse-estimated with the RMS values of sEMG and the PEAs. The PEAs were found to increase monotonically with increases in the IEDs. The error in the estimated positions of the source increased with the decrease in the distance between the source of muscle action potential and the *radius* and *ulna* bones, up to a maximum of 8.4mm.

Multipoint sEMG measurements by narrowly and widely spaced electrode pairs around the forearm are planned for a verification of the model.

A Distributed Revision Control System for Collaborative Development of Quantitative Biological Models

T. Yu[1], J.R. Lawson[1] and R.D. Britten[1]

[1] Auckland Bioengineering Institute, The University of Auckland, New Zealand

Abstract — **With CellML 1.0, models are encapsulated completely by a single file. CellML 1.1 now allows a model to be decomposed into many smaller files that can represent a single component of a model that can be reused by other related models. Unfortunately, managing even just tens of models with hundreds of shared component files may be a daunting task. For instance, updating a shared component for one model may break another, or it may be difficult to locate the correct component to be included into a model that one may be building.**

A new version of the CellML Repository software is under development, and seeks to address those issues. This software, the Physiome Model Repository 2 (PMR2) has been prototyped. The PMR2 prototype uses a distributed version control system (DVCS) as the foundation, with a web-based front end that allows annotation of specific models. DVCS will allow a group of modelers to work together to construct models and using multiple versions of shared components with ease without reliance on a centralized server. The web-based front end of the prototype contains "exposure" pages that highlight a specific revision of a model; those pages contain curation information, various documentation and rendering of annotations (metadata). Simulation results can also be included on the exposure page, giving users a quick overview of what the models are capable of.

Keywords — **quantitative modeling, CellML, repository, e-science**

I. Introduction

Advancements in modeling techniques and computational power have resulted in the dramatic increase in the number of quantitative models describing biological systems. As more models are created, there exists a need for software systems used to track them. While traditional file-based storage systems can be sufficient, they have a number of drawbacks that can be eliminated by more powerful systems. Such systems should also provide powerful search capabilities.

For larger models, a group of modelers may choose to construct models collaboratively. If a powerful model storage system exists with models in it, it will be possible to query for preexisting model components. Modelers can import, or use, the preexisting components to speed up development of their models. Such software systems should also provide collaboration facilities to assist modelers in merging their separate but related pieces of work to form their final quantitative model.

Here we present the Physiome Model Repository (PMR), developed as part of the CellML [1] project. This system has been deployed and is currently accessible at: http://www.cellml.org/models. A second version of PMR, called PMR2 is under development, and some of the goals for the PMR2 system are discussed.

II. Current system

In the initial release of PMR, the immediate need was to provide a method to edit and render metadata. A content management system (CMS) called Plone was chosen. Plone is deployed on top of Zope, an application development platform with an object database called ZODB.

PMR has basic version control mechanisms, but it has certain shortcomings, for example, it is possible to replace an old version of a file with different contents while retaining the same version number. It is also too easy for a user to accidentally base updates to a model on an older version rather than the latest version, which results in a new version that undoes changes that were present in the previous version of the same model. This would also allow accidental overwriting of good models with malformed ones. There is no mechanism in PMR for a set of related models and information to be updated as a single atomic unit, such that all information related to the model can all be guaranteed to be synchronized.

PMR also assumes each model is composed of only a single file. This was true for CellML 1.0, where the model import mechanism did not exist. This results in a repository system that excludes other supporting file types, such as images; they should be included into the repository as supporting documentation. With the introduction of CellML 1.1, PMR has become inadequate in addressing the future needs of the CellML project.

PMR supports curation, providing the ability to grade models. The curation method within the repository involved a star system to signify the curation status of a CellML model [2]. This method was sufficient to a certain degree, as the models that were curated usually fell within the preset guidelines. However, a more detailed curation process re-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1908–1911, 2009
www.springerlink.com

quires more flexibility, such as the need to show that modifications may have been made to a model such that it no longer matches the math as written in the original publication (often necessary due to typographical errors or other reasons), or perhaps the alteration was authorized by the original author. These specific curation ratings do not fit into any of the categories of the star-based curation system.

Although Plone does provide a good workflow mechanism, this was not fully exploited by PMR to facilitate model development and curation. If this mechanism had been properly utilized by PMR, workflow states for the entire life cycle of models could have be defined. Workflow states can contain preset access control permissions to limit access to specific groups of users, such as restricting access from curators only until the model is submitted for curation. They can also provide notification mechanisms to inform interested parties when they may access the model, for instance, curators would be given a list of models that are ready for curation. The modeler could then specify the correct workflow state for the model and Plone could then manage the permissions of these models in a consistent manner.

To address these issues, a second version of the repository system is under development, called PMR2. PMR2 will address all the above issues by integrating Mercurial, a Distributed Revision Control System (DVCS) with Plone. PMR2 will also fully exploit the workflow features provided by the Plone CMS, such that the model life cycle outlined above can be implemented.

III. Distributed model development, with Mercurial and PMR2

Version Control Systems (VCS) have historically been centralized software systems running on a server, used extensively by software programmers to preserve history and manage concurrent access to their work. When changes need to be made, they are committed to the VCS, which will automatically assign a revision identifier such that this particular set of changes can be referred to later, meaning they don't overwrite existing data or get overwritten themselves. This system can allow different users to concurrently read and write to the system, as changes that do not conflict with each other can be merged together automatically. If conflicts do arise due to mutually incompatible changes, a merging mechanism exists and can be used to reconcile them manually.

Instead of using a standard, centralized VCS, PMR2 will use a Distributed VCS (DVCS) as this framework is more relevant to model development workflows. A DVCS enables direct collaboration between model developers without being tethered to a centralized system: researchers can cooperate directly until they choose to push their work to the centralized, shared repository. This grants full control of the researchers' unpublished work to themselves, freeing them from the security concerns which may affect the third-party centralized system, at the same time given them an avenue to publish their work when completed.

PMR2 is slated to use a DVCS called Mercurial. A modeler can simply create a Mercurial repository locally on his computer, which is a directory that is version-controlled by Mercurial. We call this a "model workspace". Any files related to the model, such as schematics and documents, can be added to this newly created model workspace and committed into it, forming a changeset. Further changes will not overwrite the data within this changeset, but will be committed into their own changeset. An example would be the decomposition of a CellML 1.0 model file into a number of CellML 1.1 files. These decomposed component files can all be committed as a changeset. Since it is a changeset, further improvements to these components will have individual changesets, and all of these changes can be referenced later. Over time, together with other components found in other model workspaces, standard library of components can be created, which can be shared and reused. As CellML 1.1 models can import components from other models, this library of components can be used to speed up the development of new models. Also, as the older components are preserved indefinitely in individual changesets, models that depend on these older components will continue to work even after major changes to this shared library. This comprehensive history preserving feature also has other usages.

Other members of the model development team, if given the permission, can clone this model workspace to either review the work that has been done or start working on the model. As the entire history is cloned, they can review the work other modelers have done from the committed changesets. If they choose to start working with a model, they will do so in parallel with the original modeler, making changes to their clone of the model workspace. The original author can continue with his/her work, making changes to his/her own model workspace. This will result in a multiple sets of changes that share a common ancestor, but are initially independent of each other. As part of working collaboratively, the independent models need to be merged.

There are two methods of merging diverging lines of changesets back into one model. Developers who have worked on their clones of the original model workspace can easily pull in new changes from the original into their clone. Alternately, if given the permission, they can push the changes from their clone back to the original. A merging process is required to be sure that all changes are unified. If all changes are compatible, such as when modelers work on

different parts of a model in different files, this can happen automatically. If not, as is the case when two modelers make two different changes to the same part of a model file, manual reconciliation of the incompatible changes will be necessary. Because each changeset will be associated with the names of the modelers responsible, the appropriate people can be contacted to establish what needs to be done. After merging (whether manually or automatically), validation of the resultant model is advisable. It may be possible to include pre-scripted validation, so that model modifications are automatically validated, for example, comparing simulation output of a new version of the model to simulation output of the previous version.

The changesets can be signed using cryptographic signatures using Mercurial GPG (GNU Privacy Guard) extension, such that the identity of the modeler who made the changeset can be authenticated. Any manual, unauthorized modification made to a specific changeset can be detected by verifying the cryptographic signatures. Once a changeset is made public, new changes should be committed to a new changeset and not be made to an existing one.

Once all the model development is done, if modeler chooses to, the repository workspace containing the new changes can be pushed into the main PMR2 software that will be hosted on the CellML website. The PMR2 software running on the CellML website will host a large repository of model workspaces, which are just normal Mercurial repositories that each encapsulates a single model.

IV. Features of PMR2 supplementary to Mercurial

Another use-case of the PMR2 software is the "model exposure" function. This provides a mechanism where models can be exposed, which is to publish a model onto a more prominent place within the PMR2 repository. The exposure process comprises a comprehensive workflow that will enable a model to be associated with documentation pages, and allow curators to curate the model, display its curation status, and have the resulting work published on the PMR2 repository with a permanent URI for future references.

A modeler will first select the model workspace containing the model he/she would like to expose, plus the specific revision identifier. The modeler will may then select the specific set of files from the workspace that are required by the model. Metadata and/or documentation are then processed to generate a page of comprehensive information about the model. Optionally, the modeler will be able to choose to solve the model, and generate graphs based on the graphing metadata that was included with the model. The modeler will then submit this resulting object to the repository curators for the curation process.

The model curation process is the next step of the exposure workflow. It requires repository curators to curate the submitted model according to a set of criteria. These criteria are represented by curation flags, which are tags that make assertions about the curation state of a model. For instance: whether the model satisfies specific physical constrains, version numbers of software that can solve this model, or whether this model contains mathematical equations different from the original publication (with or without its authors' approval). Based on the assessment given by a curator, a model will either be published onto the main model listing of the PMR2 repository, or be returned to the modeler for clarification or revision, completing the exposure workflow.

These curation flags can be used in queries, such that a list of models can be generated based on specific curation criteria. This allows greater flexibility in assessing the quality of the models of the repository.

In a similar manner, other metadata provided with the model can be queried against. Specific views can be generated, and with the use of metadata, a clear, aggregated presentational view can be built for each model type. This will allow a clear, concise presentation of the data within the repository.

V. Future

As of September of 2008, the prototyping stage of this development project has been completed, and the main version of PMR2 is currently under development. Our vision for the repository includes “add-ons” that will extend the functionality of the PMR2 software further.

There will be an interface provided to allow automated testing of models to run continuously, such that all exposed models can be guaranteed to be valid since the time they were last checked against specific versions of the CellML API.

Another area that is worth exploring is integration with a relational database or alternatively, the use of an RDF store, which would allow more possibilities for association with other kinds of metadata, such as citation, graphing or even a rendering of the model components automatically in human readable form.

VI. Conclusions

PMR, the CellML model repository is already a powerful tool, allowing models to be shared and reused. The CellML 1.1 specification’s import mechanism enabled an even more powerful paradigm, whereby models can reuse other mod-

els. The PMR2 is the next step towards realizing this potential.

Further goals of PMR2 are to be a more robust repository software system providing much more than just storage of models. Advanced querying of the data will assist location of relevant reusable components that can be used by other modelers. The versatile curation system will allow modelers to gauge the health and status of the models in the repository. The built-in distributed revision control system will assist collaboration between modelers so they can construct large quantitative models of biological systems more effectively.

Symmetrical Leg Behavior during Stair Descent in Able-bodied Subjects

H. Hobara, Y. Kobayashi, K. Naito and K. Nakazawa

Research Institute, National Rehabilitation Center for Persons with Disabilities, Tokorozawa, Japan

Abstract — **An evaluation of asymmetry in human gait is an important step towards clinical evaluation and developing the rehabilitation treatment for pathological gait. Although asymmetry of lower extremity actions during level walking was well established, little is known about stair walking. The purpose of this study was to compare bilateral lower limb mechanics during stair descent in able-bodied subjects. Ten male subjects (age = 27.6 ± 2.2 years; height = 1.73 ± 0.56 m; mass = 65.0 ± 8.6 kg, mean ± SD) with no neuromuscular disorders or functional limitations in their lower limbs participated in the study. Subjects were instructed to walk down a laboratory staircase without handrail use at self-selected speed. Each step in this staircase had a height of 16 cm, a depth of 30 cm, and a width of 80 cm. Sagittal plane kinematics and ground reaction forces were collected and lower extremity stiffness was calculated as the ratio of peak vertical ground reaction force to peak leg compression during early stance phase. The lower extremity stiffness were 17.8 ± 4.1 kN/m for the dominant leg and 18.2 ± 5.3 kN/m for the non-dominant leg; there was no significant difference between them. There was also no significant difference in both the peak vertical ground reaction forces (dominant; 1.06 ± 0.17 kN, non-dominant; 1.08 ± 0.19 kN) and peak leg compressions (dominant; 0.06 ± 0.01 m, non-dominant; 0.06 ± 0.02 m) between the legs. The results of the present study suggest that the lower extremity of able-bodied subjects during stair descent behaves symmetrically.**

Keywords — **Biomechanics, stair, leg stiffness, symmetry.**

I. Introduction

Differences in lower limb function between the legs (asymmetry) cause not only the degenerative changes in weight bearing joint but also falling. Thus, an evaluation of asymmetry in able-bodied gait may be an important step towards clinical evaluation and developing the rehabilitation treatment for pathological gait. Although asymmetry of lower extremity actions during level walking was well established [1], little is known about stair walking. The purpose of this study was to compare bilateral lower limb mechanics during stair descent in able-bodied subjects.

Leg stiffness, which is defined as the ratio of vertical component of ground reaction force (stress) to limb compression (strain) at the initial stance phase [2-6], is useful parameter to understand the compensated movement strategy during stair descent. For example, previous studies demonstrated that compared to young women the elderly performed downward stepping with greater leg stiffness [2-5]. Further, Jones et al. [6] showed that leg stiffness during stepping down was significantly greater in transfemoral amputees compared to transtibial amputees and able-bodied subjects. However, no study has quantified the asymmetry of the leg stiffness.

According to the Sadeghi [1], the non-dominant lower limb contributes more to support force, while the dominant limb contributes more to propulsion force during walking. Thus, we hypothesized that non-dominant leg would demonstrate a higher stiffness than dominant leg.

II. Materials and Methods

A. Participants

Ten active male subjects with no neuromuscular disorders or functional limitations in their legs participated in the study. Their physical characteristics were: age 27.6 ± 2.2 years, body mass 65.0 ± 8.6 kg, and height 1.73 ± 0.56 m (mean ± SD). The experimental protocol was approved by the local ethical committee and is in accordance with guidelines set out in the Declaration of Helsinki (1964).

B. Task and procedure

Before the experiment, all subjects determined their dominant leg. Ball kicking was used to determine limb dominance. The subjects were asked to descent a custom-built staircase with each step being 16 cm high, 30 cm deep and 80 cm tread (Figure 1). They performed step-over-step stair descent (normal reciprocal stepping pattern) at self-selected speed (Figure 2).

Fig. 1 Custom-built staircase

www.springerlink.com

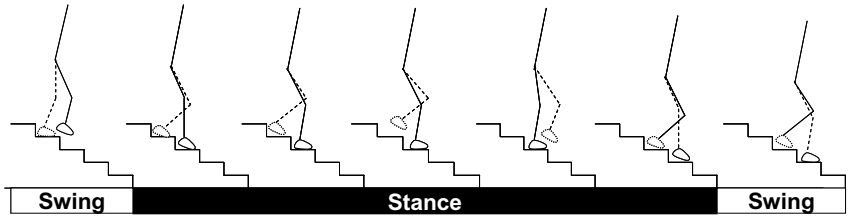

Fig. 2 Schematic illustrating the gait cycle of step-over-step stair descent

C. Data collection and analysis

Five trials in both legs at the third steps were used for the analysis. Kinematic and kinetic data during stance were sampled synchronously at 60 Hz using an eight-camera motion analysis system (VICON 512, Oxford Metrics, U.K.) and force platform (Kistler 9281C, Kistler Inc., Switzerland), which was embedded in the third step of the staircase. Stress (F_{max}) was derived as the maximum value of vertical component of ground reaction force. Two 25-mm retroreflective markers were placed on the fifth metatarsophalangeal joint and the greater trochanter to compute a srain (X_{max}). Lower extremity was modeled as linear spring [2-6], and we calculated leg stiffness as ratio of F_{max} to X_{max} (Figure 3).

D. Statistics

The comparison between the dominant and non-dominant leg was made using the Student t-test. Statistical significance was set at $P < 0.05$. All data are presented as mean values with standard deviation (S.D.).

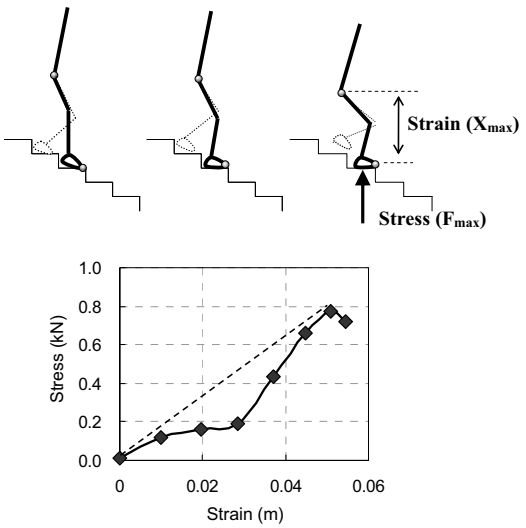

Fig. 3 Leg stiffness calculation in stair descent

III. Results

A. Stiffness, stress and strain

Leg stiffness, stress and strain in both legs are shown in Figure 4. The leg stiffness was 17.8 ± 4.1 kN/m for the dominant leg and 18.2 ± 5.3 kN/m for the non-dominant leg; there was no significant difference between them. Figure 5-A and B shows that there was also no significant difference in both the stress (dominant; 1.06 ± 0.17 kN, non-dominant; 1.08 ± 0.19 kN) and strain (dominant; 0.06 ± 0.01 m, non-dominant; 0.06 ± 0.02 m) between the legs.

IV. Discussion

This study aimed to investigate the bilateral lower limb mechanics during stair descent in able-bodied subjects. We compared leg stiffness, stress and strain between the dominant and non-dominant legs. There was no significant differences in stiffness, stress and strain between the legs (Fig. 4-A, B and C). The results completely contrast with our initial hypothesis, which stated that non-dominant leg would demonstrate a higher stiffness, that dominant leg. Thus, the present study suggests that the lower extremity of able-bodied subjects during stair descent behaves symmetrically.

Current results will be important when evaluating stair descent performance in patients, older adults, and person with disabilities. Past findings demonstrated that changes in leg stiffness during stair descent due to aging [2-4], lower limb amputation [6] and suppressed vision [7]. The changes in leg stiffness were interpreted as compensated movement strategy for reduced muscle strength, a slowed rate of tension development or a decline in proprioceptive capability [5]. Therefore, symmetrical landing mechanics observed in the present study would be due to that active male who has no neuromuscular disorders or functional limitations in their legs were recruited as subjects.

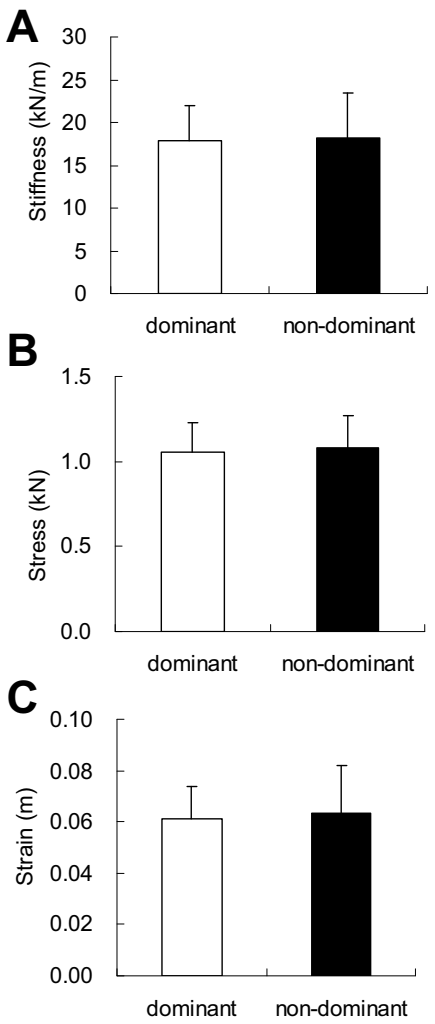

Fig. 4 Leg stiffness (A), stress (B) and strain between the legs

V. Conclusions

We investigated whether able-bodied subjects descend the stair in symmetrical manner. The results of the present study suggest that the lower extremity of able-bodied subjects during stair descent behaves symmetrically. This will be important when evaluating stair descent performance in patients, older adults, and person with disabilities.

Variable Interaction Structure Based Machine Learning Technique for Cancer Tumor Classification

Melissa A. Setiawan[1], Rao Raghuraj[1] and S. Lakshminarayanan[1,*]

[1] Department of Chemical and Biomolecular Engineering, NUS, Singapore

Abstract — **Clinical diagnosis of disease samples largely benefits from multivariate statistical analysis, especially the machine learning techniques. One such example of medical application of statistical tools is the cancer tumor classification. In this study, Discriminating Partial Correlation Coefficient Metric (DPCCM) and Variable Predictive Model based Class Discrimination (VPMCD) are proposed as the new machine learning techniques for the same. Publicly available dataset Wisconsin Diagnose Breast Cancer (WDBC) dataset and Wisconsin Breast Cancer (WBC) dataset are analyzed to identify malignant cancer cells from benign cancer cells. Performance of the new classifiers are compared with the existing classifiers. The results based on the overall analysis indicate that DPCCM is potentially a better tool to identify and separate specific tumor samples. It achieves 100% accuracy of classification of test samples for WDBC dataset and 94% on WBC dataset. The performance of the approach is encouraging and its applicability to different cancer datasets (especially multi class problems) is being attempted further.**

Keywords — **Cancer, identification, DPCCM, VPMCD**

I. Introduction

Breast cancer is the most common cancer diagnosed in women and major cause of cancer deaths among women globally and Singapore in specific. However, this cancer has a high chance to be cured. Jerez-Aragone et al (2003)[1] noted that 97 % of breast cancer patients survive for five years if the cancer is detected during initial stages and treated. This fact highlights the importance of early detection of cancer followed by early treatment. Some past studies have shown that machine learning methods can play an important role in these efforts [2-4]. By using information provided by some measurable cell attributes or microarray data information from many normal cells and cancer cells, machine learning methods are able to build a classification model. This study explores one such application of data driven models in disease diagnosis with cancer tumor classification as its focus.

We attempt to utilize the two new classification tools proposed recently in the literature. We compare the performance with some of the existing classifiers. Two available online datasets, namely the Wisconsin Diagnostic Breast Cancer dataset (WDBC) and Wisconsin Breast Cancer dataset (WBC), are used as the case studies in this paper. For reliability of such clinical diagnosis, the classifier performances are compared based not only on overall accuracy, but also based on class-wise performance.

II. Methods

A. Variable Interaction Structure based classification

This alternate supervised learning technique was recently proposed in literature as a potential classification tool for different pattern recognition applications [5, 6]. The main premise of this new classification concept is that all or some of the variables (features/descriptors), defined on the system to characterize it into different classes, exhibit definite dependencies between each other. Such variable interactions (gene/protein/metabolite interactions) are significant especially in a larger and complex multivariate biological system. If such interactions exist, then for any classification problem, the distinction between classes could mainly arise due to difference effects of variables on each other. Hence, for systems with interacting variables, it is possible that each class is characterized by changes in different sets of variables arising due to definite variable interactions. The two new classification approaches viz., Discriminative Partial Correlation Coefficient Metric (DPPCM) and Variable Predictive Model based Class Discrimination (VPMCD) utilize the presence of such unique variable interaction patterns and exploit their potential for classification. The details of these methods are can be found in [6] and [5] respectively along with advantages and limitations. The methods are adopted here as it is and explored further for their utility to distinguish cancer tumor samples.

DPCCM [6] captures the possible inter-variable relations in the form of mutual correlations. Partial correlations are used to refine the strength of direct interactions between the variables by eliminating the influence of other variables on them. Intra-class attribute relations for individual classes are modeled by the metrics which is defined for each class in the training set. The proximity of the new variable interaction structure to the individual class models is used as classification criteria.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1915–1917, 2009
www.springerlink.com

VPMCD classifier establishes inter variable relations in the forms mathematical models (VPMs) that can be used to predict back the individual variables as a function of other variables in the system. As a result, each class has different system characterization in terms of specific inter-variable interaction models which can be exploited further for class separation of new samples.

B. Other classifiers used for comparison

We implement some of the existing classification techniques to compare the performance of the above mentioned new classifiers. Linear Discriminant Analysis (LDA) [7], Classification and Regression Tree (CART) [8] and TreeNet [9] are used as comparison methods. The details of these well known methods are avoided here for brevity.

III. Materials and Implementation

A. Dataset

WBC dataset collected by Wolfberg et al., [10] is available online in a public domain database (http://archive.ics.uci.edu). By considering 9 cells attributes information such as mitoses, clump thickness and so on, cells are then classified into 2 classes (malignant cancer cells and benign cancer cells). There are 699 total samples in this dataset with 65.5% of them are benign cells and the remaining 34.5% are malignant cell samples. Some missing data are found in 16 patients' data hence the information from these 16 patients is excluded in the analysis. The size of this system is M ~ [683 samples x 9 predictors; 2 classes].

WDBC dataset collected by Wolfberg et al., [10] is available for public use in http://archive.ics.uci.edu. This is a quite bigger dataset compared to WBC with less number of samples. It stores 30 real-valued attributes information from 569 samples (357 samples are taken from benign cells and the remaining data are taken from malignant cells) without any missing value. The size of this system is P ~ [569 samples x 30 predictors; 2 classes].

B. Implementation

As the first step of this study, both datasets are divided into training sets (80%) and test sets (20%) for validation purposes. For each case, the same training set, excluding test set, is used by all classifier to construct one classification model. Once the model is obtained, it is then tested on the test dataset to get the accuracy of the model (overall and class-wise). MATLAB's [11] built-in function "classify" is used for LDA classification while CART and TreeNet classification is done using software developed by Salford Systems, USA [12, 13]. VPMCD and DPCCM algorithm [5-6] coded in MATLAB m-file are used for building the VPMCD and DPCCM classifier.

IV. Results and Discussion

A. WBC dataset

Table 1 shows the classification result on WBC dataset with class 1 representing patients with benign cancer and class 2 representing patients with malignant cancer.

Table 1 Classification result (% accuracy) for WBC dataset

		LDA	VPMCD	DPCCM	CART	TreeNet
Resubstitution	Class 1	98.20	99.77	95.05	99.55	98.65
	Class 2	92.89	94.14	100	100	100
	Overall	96.34	97.8	96.78	99.71	99.12
Testing	Class 1	96.59	94.32	90.91	93.18	93.18
	Class 2	87.23	93.62	100	97.87	100
	Overall	93.33	94.07	94.07	94.81	95.56

The new classifiers perform reasonably well and comparable to the existing classifiers. DPCCM is able to detect all the class 2 samples perfectly which is of higher significance in this study. It is highly important not to wrongly classify cancer samples as "healthy". Therefore, classifier performance should be deemed better if it has higher prediction accuracy for class 2. In this regard DPCCM and TreeNet perform better.

As shown in Table 1, LDA, VPMCD and CART give similar performance as other classifiers in identifying healthy patients into class 1. On the other hand, they fail to classify some of cancer patients correctly. Therefore its overall performance is slightly lesser than DPCCM/TreeNet. Interestingly, VPMCD and DPCCM give the same overall accuracy albeit with different class-wise performance. Similar to TreeNet, DPCCM is able to classify class 2 samples very well. Its accuracy for class 2 samples is much better than VPMCD. On the contrary, VPMCD has better class 1 performance than DPCCM. The poor performance of LDA could be attributed to the non-uniform distribution of class 1 and class 2 samples. Larger difference between re-substitution test and validate test accuracies for CART/TreeNet indicates the possibility of model overfitting.

B. WDBC dataset

Table 2 shows the classification results for the WDBC dataset with class 1 representing patients with malignant

Table 2 Analysis result for WDBC dataset using LDA, VPMCD, DPCCM, CART and TreeNet

		LDA	VPMCD	DPCCM	CART	TreeNet
Resubstitution	Class 1	92.45	82.08	96.23	100	100
	Class 2	99.44	96.36	96.36	99.16	100
	Overall	96.84	91.04	96.31	99.47	100
Testing	Class 1	95.24	88.10	100	100	92.86
	Class 2	100	97.18	100	88.73	100
	Overall	98.23	93.81	100	92.92	97.35

All results are presented in percentage (%)

cancer and class 2 representing people without cancer. Similar to WBC case study, class 1 accuracy must receive more attention than class 2 accuracy since a cancer patient needs medication and treatment as soon as possible. As presented in Table 2, DPCCM holds the highest and perfect value for all overall, class 1 and class 2 accuracy. In other words, DPCCM is able to perfectly classify all samples into their corresponding class. This result puts the DPCCM as the stronger classifier for such clinical diagnosis applications compared to other selected classifiers.

Unlike in WBC dataset, LDA provides a good performance in classifying class 2 samples for this data set. This could be because the data points are linearly separable. A reasonably good performance by VPMCD (Table 2) using a linear model in classifying class 2 samples strongly indicates linear separability of the dataset. As observed in Table 2, LDA performance on class 2 classification is better than its performance on class 1 classification. During model building, LDA set weights to all variables in such a manner that makes its performance on class 2 predictions perfect. This reduces its ability to predict class 1 samples accurately. The other classifier which gives a good performance in class 2 classification is TreeNet. The ensemble of decision tree confirms its superiority to single decision tree (CART) by giving better overall and class 2 accuracy. However, its performance on class 1 is still lower than CART. This may happen because, during model construction, TreeNet assigned weight factor on each variable so as to classify class 2 samples well. As a consequence, it fails to classify some class 1 samples correctly. CART, a classifier with the lowest overall accuracy, is able to perfectly classify class 1 samples. On the other hand, it has poor performance in predicting class 2 samples and also during validation dataset testing.

V. Conclusion

In this study, VPMCD and DPCCM classifiers are analyzed for their utility to identify breast cancer tumor classification. The comparison study is performed with the objective of determining the best classifier i.e. the capability to correctly classify new samples into their corresponding classes. According to our study, DPCCM is consistent in its performance and shows better potential to be an efficient data analysis tool for clinical diagnosis.

Assessing the Susceptibility to Local Buckling at the Femoral Neck Cortex to Age-Related Bone Loss

He Xi[1], B.W. Schafer[2], W.P. Segars[3], F. Eckstein[4], V. Kuhn[5], T.J. Beck[3], T. Lee[1]

Abstract — **To simulate bone adaptation, we used an engineering beam simulation of a one-legged stance and linearly thickened (young) or thinned (old) cortices until the maximum stress on the infero-medial neck surface was the same as in the middle-age version. Consequences of simulated adaptive changes on elastic buckling stability were evaluated by the FSM using loads generated in a simulated fall on the greater trochanter. We conclude that the expansion of diameter with thinning cortices can preserve femoral neck strength under normal stance mode but not necessarily under loads encountered in falls, especially if the elderly cross-section is thinned by adaptation to reduced loading.**

Keywords — **Local Buckling, Homeostasis, Aging, Femoral neck**

I. Introduction

Realistic computer simulations of loaded trabeculae in osteoporotic bones show that individual trabeculae fail by Euler buckling. Euler buckling is an instability mode that becomes likely in end-loaded structures when they become too slender and lose lateral support. Increasing slenderness and loss of transverse elements are hallmarks of trabecular degradation in osteoporosis. Since applied loads are mainly borne by the cortex, its stability may be of greater importance. Aging and osteoporosis cause thinning cortices, expansion of outer diameter and loss of internal trabecular support which may lead to local buckling, a different form of instability. In this preliminary study we performed a series of stability analyses on tubular structures simulating femoral neck geometries using observed dimensions from elderly fracture cases and controls.

II. Materials and methods

We analyzed eight cross-section models of the femoral neck cortex using dimensions from studies of hip fracture cases and non-fractured controls. Sections were selected to span the a range of cortical slenderness based on the buckling ratio (BR). Three different models were considered: non concentric circles; non-concentric ellipses; and more realistic sections from CT scans of the femoral neck taken from a study comparing femoral neck biopsies in fracture cases and cadaver controls [1]. To examine potential for local instability, we developed finite strip models of each cross-section and determined the elastic local buckling stress (f_{crl}). The finite strip method [2] is a specialized variant of the finite element method; we employed the implementation in CUFSM [3]. The model considers the cross-section as an extrusion (no variation along the length). Local buckling occurs at lengths as short as ½ the section diameter, so the assumption of a straight extrusion is reasonable. Material properties assumed E=18800MPa, G=13620MPa, ν=0.31 [4]

III. Results

The BR (buckling ratio) and f_{crl} (elastic local buckling stress) do correlate but relatively poorly in the more realistic CT based cross-sections where irregular cortices dominate load behavior. Overall, the predicted elastic local buckling stresses (f_{crl}) are quite high for all but the most slender of cross-sections. To put results in context we used a variation on the effective width method, first developed for elastic-plastic metals by von Kármán [5], and widely used for viscoelastic plastics. We employed the expression attributed to Winter [6] to estimate the reduction in material compressive capacity (f_n) due to local buckling as a function of the local slenderness $\sqrt{(f_{yc}/f_{crl})}$. Figure 1 provides a sense of the interplay between the two compressive limit states: material yielding, and local instability. For cross-sections with the lowest buckling ratio a strong reduction in compressive capacity can still occur due to local instability. The importance of more realistic cortical dimensions is underscored by the CT results, for example #s 2 and 3 have similar BR values but control #2 should experience no reduction in strength; while fracture case #3 shows a small reduction. Further, this more realistically modeled case is expected to

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1918–1919, 2009
www.springerlink.com

experience some reduction while #7 modeled as a circle experiences none. These results suggest that simple BR values and simple regular models may inadequately describe instability at the femoral neck.

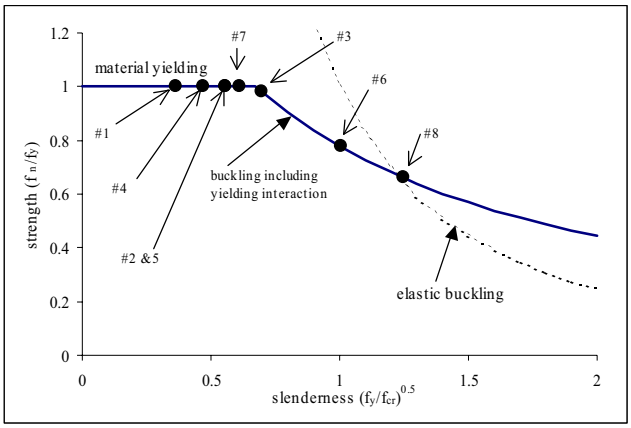

Figure 1: Predicted reduction of compressive limits for the femoral neck due to effect of local buckling.

IV. Discussion

There is relatively little prior work in modeling instability behavior of whole human bones although the phenomena may be critical in osteoporotic fragility. We have begun a series of proof-of-concept analyses to determine whether cortical geometries seen at the femoral neck are susceptible to buckling failure. Analyses generated in pure compression suggest that geometries seen in fracture cases are less stable than those in controls. The level of model realism appears to be important. Relatively smooth cortices of circle and ellipse models are more stable than more realistic models with irregular cortices. Simple constructs to estimate cortical instability such as the buckling ratio may have some value but may not be sufficiently accurate for predictive use. More realistic analyses generated in a combination of bending and compression should better simulate the fall conditions producing hip fracture. These conditions produce peak compressive stresses on the thinner lateral cortices and further demonstrate the importance of realistic cortical models. Instability behavior is by definition chaotic, difficult to predict, and to observe experimentally especially in objects with the 3D complexity of the human proximal femur. Nevertheless this preliminary work using the finite strip analysis is encouraging and the method may prove to be a useful tool for the investigation of osteoporotic instability.

Abstract — **The purpose of this study is addressed the function of Ad4BP/SF1 in developing spleen of Ad4BP/SF-1 KO mouse. I have modified the BAC-Ad4BP endogenous by homologous recombinant with modification cassette-containing tetracycline transactivator system and LacZ reporter genes to allow the expression of Ad4BP/SF1 in developing tissues and organ differentiation, regulate of Ad4BP/SF1 mechanism, and reveal the defect due to Ad4BP/SF1 deficiency. Recently studies, by immunihistochemistry of adult tissues showed that revealed coincident expressing between Ad4BP/SF-1 and lacZ, indicating the tTA system seemed to reproduces the endogenous expression of Ad4BP/SF-1, and thus likely to lacZ, Ad4BP/SF-1 in the BAC transgene was expected to be expressed in the corresponding tissues under the control of the bidirectional promoter. Interestingly, the BAC-Ad4BP-tTA transgenic mice were succeeded to up regulate the expression of Ad4BP/SF-1 at the protein level than wild type. And the fetal spleen of Tg(+);Ad4(+/+) was larger than that of the wild type, and expectedly the size of the spleen of Tg(+);Ad4(-/-) apparently recovered.**

Keywords — **Ad4BP/SF-1, knockout mouse, Spleen, BAC transgenic, homologous recombinant.**

I. Introduction

The orphan nuclear receptor, Ad4BP (adrenal-4-binding protein) or SF1 (steroidogenic factor-1) or FtzF1 (Fuzitarazu-F1), has emerged as a key regulator of endocrine function within the hypothalamus-pituitary-gonadal (HPG) and adrenal cortex (HPA) axis. Ad4BP/SF1 is known play the essential role in multistage of reproductive axis. Since the identification Ad4BP/SF1, its distribution has been examined mainly in steroidogenic tissues. Initial studies revealed that the gene encoding this transcription factor was expressed in particular cell types within the testis, ovary and adrenal cortex [1-3].

Gene disruption studies were performed to investigate the functions of Ad4BP/SF-1 during the tissue development. The gene knockout mice displayed agenesis of the adrenal gland and gonads at birth, reflecting increased apoptic cell death in the particular cell population comprising the tissue primordia. Due to the absence of the gonad in the fetal stage, the gene-disrupted mice exhibited male to female sex reversal, while probably due to the absence of the adrenal gland, they died shortly after birth [4-6]. According to these phenotypes, it has been established that Ad4BP/SF1 is essential for the structural and functional development of those tissues probably mediating downstream gene expression.

To address the function of Ad4BP/SF1 in developing spleen of Ad4BP/SF1 knockout mouse, we have modified the BACAd4BP endogenous by homologous recombinant with modification cassette-containing tetracycline transactivator system and LacZ reporter genes to allow the expression of Ad4BP/SF1 in developing tissues and organ differentiation, regulate of Ad4BP/SF1 mechanism, and reveal the defect due to Ad4BP/SF1 deficiency.

II. Materials & Methods

A. Experimental Animal

Ad4BP/SF1 KO mice were generated as described previously [5]. Background animals of BAC transgenic were F1 of C3H and and C57BL/6 female and male mouse (Japan Clea, Tokyo, Japan). The BACAd4BP- tTAZ-Tg mice were generated as described previously [7]. All animals were performed at the specific pathogen-free of Transgenic Animal Care Facilities of National Institute for Basic Biology, National Institute of Natural Science, Okazaki, Japan. All protocols were approved by the Institutional Animal Care and Use Committee of the National Institute for Basic Biology.

B. Construction of BAC transgene

The construction of BACAd4BPtTAZ was described by [8] previously. And the site of modification cassette was replaced inside of exon2 of Ad4BP/SF1 gene are identified by serial multi-PCR with 9-pairs of primer as figure1 below.

C. Whole-mount lacZ staining

Detection of lacZ enzymatic activity with whole-mount samples were performed as described [9] with minor modification.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1920–1923, 2009
www.springerlink.com

D. Southern blot and western analyses

Southern blot analysis was performed basically as described [10]. Ten μg genomic and BAC DNAs were digested with EcoRI and BamHI at 37ºC overnight, and the digested products were separated on 0.8% agarose. They were transferred to a nylon filter (Hybond-N+, Ammersham Biosciences), and finally exposed to X-ray film and BAS1800 system. Western blot analysis was performed basically as described [11]. The spleens from P4 mice was lysed with 20 mM Tris-HCl(pH8), 100 mM NaCl, 0.1 mM EDTA, and 1% SDS. The tissue lysates for spleens (15 μg) was subjected to SDS-PAGE followed by western blotting with the rabbit primary antibody to Ad4BP/SF-1 [11]. Anti-rabbit-IgG conjugated with horseradish peroxidase (Jackson immuno research, Lab. Inc.) was used as the secondary antibody [12].

III. Result and Discussion

A. Construction BAC-Ad4B-tTAZT transgenic mice

The modification cassette was inserted in to the BAC clones, BAC1-Ad4BP and BAC5-Ad4BP, by homologous recombination to produce BAC recombinant clones, BAC1-Ad4BP-tTAZT and BAC5-Ad4BP-tTAZT, respectively. To confirm an occurrence of precise homologous recombination, the intact and recombinant BAC DNAs were digested with restriction enzymes, EcoRI and BamHI, and subjected to Southern blot analyses with 0.5 kb 5'-probe and 1.5 kb 3'-probe (Fig. 1A). With the 5'-probe, the original BAC-Ad4BPs are expected to give rise to 5.7 kb by EcoRI and 0.9kb by BamHI digestion, while the recombinant BAC-Ad4BP-tTAZTs give rise to 2.0 kb by EcoRI and 1.5 kb by BamHI. With the 3'-probe, the original BAC clones are expected to give rise to 5.7 kb by EcoRI, while the recombinants give rise to 2.0 kb by EcoRI and 10.0 kb by BamHI. Expected length of the fragments were obtained from the recombinants, strongly suggesting that homologous recombination occurred between the modification cassette and the original BAC clones (Fig. 1B).

Moreover, we examined whether the BAC-Ad4BP-tTAZT recombinants contain regions covered by the original clones by PCR genotyping with the primer pairs to amplify fragments a to i (Fig. 1A). As shown in Fig. 1C, the regions a, b, c, f, g, h, and i were amplified in both original BAC1-Ad4BP and recombinant BAC1-Ad4BP-tTAZTs, while the primers for fragments d and e designed to amplify regions including the insertion points gave signals only with the recombinants. Similarly in the case of BAC5-Ad4BP, the primers for fragments b, c, f, g, h, and i gave the signals for both original and recombinant, while the primers for fragments d and e gave the signals for only the recombinant. Since BAC5-Ad4BP lacked far upstream from exon 7 of the Gcnf, primer for fragment a failed to give the signal.

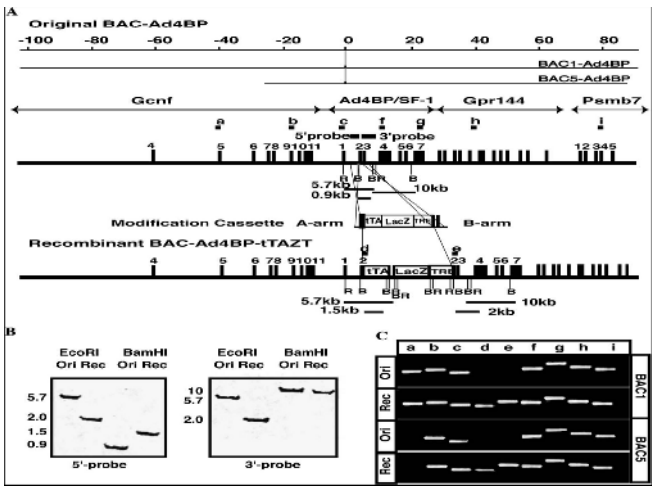

Fig. 1 Construction of BAC1-Ad4BP-tTAZT and BAC5-Ad4BP-tTAZT was taken by homologous recombinant. A, Map of the original (Ori) BAC1-Ad4BP and BAC5-Ad4BP and recombinant (Rec) BAC1-Ad4BP-tTAZT and BAC5-Ad4BP-tTAZT were presented schematically. B, Confirmation of modification cassette replaced on exon2 of Ad4BP/SF1 gene were identified by Southern Blot with 5'-prime & 3'-prime probes. Original (Ori), BAC1-Ad4BP and BAC5-Ad4BP, and their corresponding recombinants (Rec), BAC1-Ad4BP-tTAZT and BAC5-Ad4BP-tTAZT, were digested EcoRI and BamHI, and identified with Southern blotting analysis by 3'- and 5'-probes.C, The Original (Ori) and recombinants (Rec) BAC clones were examined by PCR with primers to amplify the region indicated with a to i.

B. Revealing spleen of Ad4BP/SF KO mice by BACAd4BPtTAZ transgene

Recently, we have produced the BACAd4BPtTAZ transgenic mice respectively [8]. We generated mouse lines to express a lacZ reporter gene and Ad4BP/SF-1 by a dual reporter/Tet-off system integrated in mouse BAC clones. Since the BAC constructs carried a lacZ reporter gene, we expected that the exogenous Ad4BP/SF-1 gene expression is evaluated indirectly by the transgene expression. Expectedly, lacZ expression pattern in the Tg mouse mostly, if not all, reproduced the endogenous expression of Ad4BP/SF-1. Thus, we applied the BAC-transgenic (BAC-Tg) mice to rescue Ad4BP/SF-1 KO mouse, and found interestingly that the tissues were rescued with varied levels [8].

Since the lacZ expression recapitulated the endogenous Ad4BP/SF-1 gene expression, we examined whether the Tg mice rescue the Ad4BP/SF-1 KO phenotypes. Morohashi laboratory was revealed that Ad4BP/SF-1 is expressed in the splenic endothelial cells at the fetal stage [10]. The adult

BAC Tg mice (B1L1 and B5L2) succeeded to upregulate the expression of splenic Ad4BP/SF-1 at the protein level (Fig. 2A). Interestingly, the size of the transgenic spleen was larger than the wild type at P0 (Fig. 2B), and indeed the weight was approximately 1.3 fold higher than that of the wild type (Fig. 2C). When the Tg(+);Ad4(+/+) and Tg(+);Ad4(-/-) fetuses were examined, lacZ was found to be expressed in the developing fetal spleen at E16.5 (Fig. 2D, E). Our previous KO mouse study revealed that the lack of Ad4BP/SF-1 induced spleen with smaller size from fetal ages possibly due to the affected vascular system. Considering the elevated Ad4BP/SF-1 expression in the BAC Tg mice and successful lacZ expression in the fetal spleens, we expected that the Tg(+);Ad4(-/-) spleen is recovered in the size. Showing a good correlation with our previous reports [12, 13], the spleen of Ad4BP/SF-1 KO (Tg(-);Ad4(-/-)) was significantly smaller than that of the wild type (Tg(-);Ad4(+/+)) at E16.5 (Fig. 2F). Similar to the adult spleen, the fetal spleen of Tg(+);Ad4(+/+) was larger than that of the wild type, and the size of the spleen of Tg(+);Ad4(-/-) was recovered expectedly.

The spleen of the BAC Tg mice was enlarged clearly. Indeed, the splenic expression of Ad4BP/SF-1 was upregulated at the protein level and the smaller products were absent. We recently demonstrated that forced expression of Ad4BP/SF-1 resulted in upregulation of cyclin D1 and thus BrdU incorporation in chick embryonic gonad (unpublished) strongly suggested that upregulated expression of Ad4BP/SF-1 accelerates cell cycle progression. Since Ad4BP/SF-1 is essential for the development of the splenic framework structure [13], it is likely that the enhanced expression of Ad4BP/SF-1 resulted in the enlargement of the tissue framework through accelerating cell cycle.

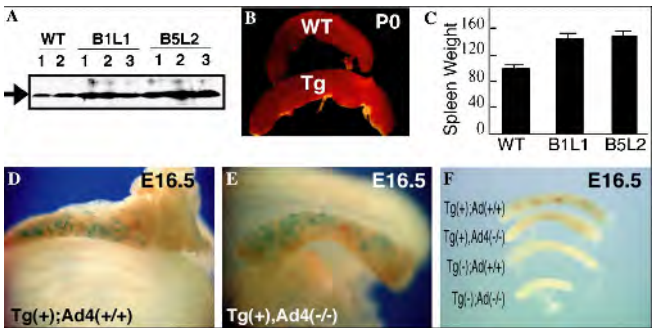

Fig. 2 Effect of up-regulated expression of Ad4BP/SF-1 in spleen. A, Total tissues lysates (15μg) prepared from the WT (n=2), B1L1 (n=3) and B5L2 (n=3) mouse spleens were subjected with Western blot analysis by anti-Ad4BP/SF-1 antiserum. B, WT and BAC-Tg (Tg) spleens were compared macroscopically. C, Weights of WT (n=5), B1L1 (n=10) and B5L2 (n=10) spleens were measured, and the relative weights were presented when that of WT is 100. D and E, LacZ activities was examined with the Tg(+);Ad4(+/+) and Tg(+);Ad4(-/-) spleens at E16.5. F, Macroscopic observation of the Tg(+);Ad4(+/+) and Tg(+); Ad4(-/-), Tg(+);Ad4(-/-) and Tg(-);Ad4(-/-) spleens at E16.5.

IV. Conclusion

The result of this study showed that the spleen of Ad4BP/SF-1 knockout mice revealed properly by BACAd4BPtTAZ transgene. The expression of Ad4BP/SF-1 of spleen is up regulated at level protein. The size of spleen also enlarged clearly than normal and/or knockout Ad4BP/SF-1 mice.

Acknowledgment

I would like to greatly thank you for Prof Ken-ichirou Morohashi, PhD., Div. sex differentiation, Nat. Inst. For Basic Biology, Okazaki Institute, Japan, as my supervisor, for providing the change study molecular biomechanics, and thanks to M. Zubair, PhD., Y. Fukui-Katoh, PhD. and H. Ogawa, PhD., for lecture, assist technical support for study transgenic mice. We thank Drs. X.W. Yang and N. Heintz (Rockefeller University) for providing the homologous recombination system of BAC clone and pSV1 RecA, and Drs. K. Mihara and M. Sakaguchi (Kyushu University) for providing anti-serum to lacZ.

The impact of enzymatic treatments on red blood cell adhesion to the endothelium in plasma like suspensions

Y. Yang, L.T. Heng and B. Neu

School of Chemical and Biomedical Engineering, Nanyang Technological University, Singapore, 637457

Abstract — **Red blood cells (RBC) experience many physicochemical modifications on the membrane in physiological events as well as pathological complications, for example, the sialic acid loss on senescent RBC membrane. Abnormal RBC adhesion to the endothelium has been linked to the pathophysiology of various diseases associated with vascular disorders such as sickle cell anemia or diabetes mellitus. However, the correlation is still unclear between RBC membrane changes and abnormal RBC-EC adhesion, especially in plasma or plasma like suspensions. Multiple specific and non-specific forces govern cell-cell and cell-surface interactions. One non-specific force that has only been found limited attention in cell adhesion is the depletion interaction, which occurs as a result of a lower localized protein or polymer concentration near the cell surface compared to the suspending medium (i.e., relative depletion near the cell surface). This exclusion of macromolecules near the cell surface leads to an osmotic gradient, depletion interaction, and attractive forces.**

In order to elucidate the impact of physicochemical properties of the RBC membrane on RBC-EC adhesion induced by macromolecular depletion, we used various proteolytic enzymes to specifically cleave different components from RBC membrane. The dynamics of RBC-EC adhesion were then recorded using a flow chamber system and a stepwise shear profile. Our results indicate a dramatic increase of RBC adhesion to EC in the presence of high molecular mass (>40KDa) dextran with decreasing surface charge after sialic acid removal by neuraminidase. On the contrary, only minor alteration has been observed in RBC-EC adhesion and surface charge for the enzymatic cleavage by trypsin, α-chymotrypsin and pronase. In conclusion, this study demonstrates that polymer depletion can enhance RBC-EC adhesion under low shear stress and that it promotes adhesion of pathologic RBC. It thus provides new insight into potential mechanisms for enhanced RBC-EC adhesion and disturbed *in vivo* blood flow.

Keywords — **red blood cell, endothelial cell, adhesion, sialic acid, depletion interaction**

I. Introduction

Abnormal red blood cell (RBC) adhesion to endothelial cell (EC) has been of great interest for decades, since it has been linked to vascular complications in various diseases, such as sickle cell anemia [1] or diabetes mellitus [2]. It is clear that a complex interplay of various non-specific forces and specific forces govern RBC-EC interaction, but the detailed underlying mechanism(s) remain unclear. In the past, various factors have been identified as determinants of altered RBC-EC interaction, including blood flow [3], adhesion molecules on both RBC and EC membrane (e.g. CD36 and VCAM-1), RBC shape and deformability [4] and plasma proteins like TSP [5] and vWR [6] or fibrinogen, which has been found to promote RBC-EC adhesion in different diseases like sickle cell anemia [7] and diabetes mellitus [8].

While prior studies have described several aspects of RBC adhesion in normal and pathologic states, none appears to have considered depletion interaction as a non-specific force for RBC-EC adhesion. Conversely, depletion mediated interactions are commonly considered in the general field of colloid chemistry, and several previous reports have dealt with the experimental and theoretical aspects of depletion aggregation, often termed depletion flocculation. More recently, it became evident that depletion interaction can also induce cell-cell interactions. It is now clear that macromolecular depletion is the driving force behind RBC aggregation [9, 10]. Such findings are of basic science and clinical interest, in that reversible RBC aggregation is an important determinant of the *in vitro* rheological behavior of blood as well as of *in vivo* blood flow dynamics and flow resistance. On the contrary, polymer depletion as a driving force behind other cell-cell interactions in particular RBC-EC interaction hasn't found a lot of attention.

RBC experience during their lifespan as well as in various diseases several physicochemical modifications. For example the loss of sialic acid has been linked to RBC senescence [11], as well as diabetes mellitus [12] and acute myocardial infarction [13]. Although such changes have been linked to altered RBC-EC adhesion the specific mechanisms on how such changes induce RBC-EC adhesion are not clear. The current study was thus designed to elucidate the impact of specific RBC membrane changes on the RBC-EC adhesion in plasma like solutions. Several proteolytic enzymes were employed to specifically cleave off different components from RBC membrane. The dynamics of RBC-EC adhesion were then recorded in the presence of high molecular mass (>40 kDa) dextran.

www.springerlink.com

II. Materials and methods

A. Red blood cell preparation

Blood was drawn from the antecubital vein of healthy adult volunteers into EDTA (1.5 mg/ml). Red blood cells were separated from whole blood via 2,000 x g centrifugation for 10 minutes and the plasma and buffy coat were removed. Then the RBC were washed twice in phosphate buffer saline (PBS) of pH=7.4 (containing 5.8mM phosphate buffer, 150mM NaCl and 417mg/l KCl) at 20 °C and then subjected to various enzymatic treatments (Neuraminidase (Vibrio Cholerae Type III, Sigma), Pronase (Calbiochem, EMD Chemicals, Inc.) and α-Chymotrypsin (Bovine pancreas Type II, Sigma)). Afterwards treated RBC were washed twice in cold PBS and suspended in the desired measuring solutions.

B. Endothelial cell culture

Human umbilical vein endothelial cells (HUVEC) were purchased from Cambrex Corporation (UK) cultured in flasks and then transferred into 35 mm Petri dishes. 80% confluence was obtained before using them in the parallel-plate flow chamber adhesion assay (see below).

C. Parallel-plate flow chamber adhesion assay

The flow was generated by a syringe pump (PHD2000, Harvard) and the shear stress was then varied in a stepwise profile. Prior to rinsing the sample at defined shear rates, the RBC were allowed to settle for 6-8 minutes. The dynamics of RBC-EC adhesion were than recorded with an inverted microscope (IX71, Olympus) enclosed in an incubator in order to maintain a constant temperature at 37°C. Pictures were taken at the end of each rinsing period at 20 different locations and the adherence was finally quantified as the number of adherent RBC per unit area.

D. Characterization of the enzymatic treatments

For measuring the electrophoretic mobility of enzyme-treated and untreated cells, RBC were suspended in phosphate buffered sucrose solution with a 10 mM ionic strength at a hematocrit of about 0.05%. The zeta-potential was then determined with a Nano Zetasizer (Malvern Instruments, UK). The deformability of treated and untreated cells was quantified with a slit-flow ektacytometer (RheoScan-D200, SEWON Meditech, Inc).

III. Results

The treatment of RBC with the various enzymes lead to a moderate decrease of the elongation index indicating a decreased deformability of the cells after the proteolytic treatments as shown in Fig. 1.

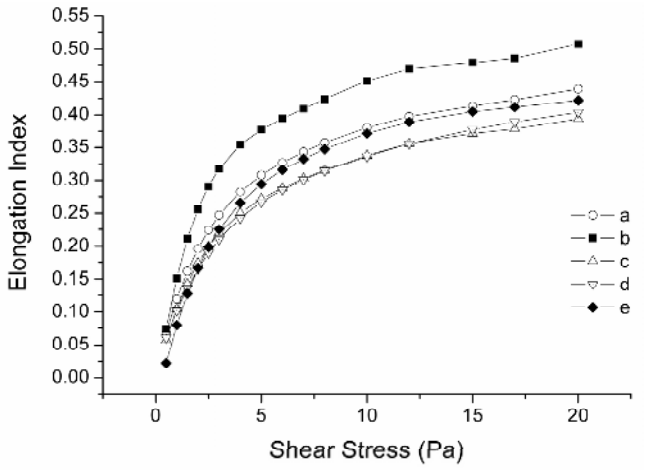

Figure 1: Impact of enzymatic treatment on RBC elongation index. a, 40 mg/dL α-chymotrypsin; b, control; c, 0.1 mg/ml pronase for 10-minute incubation; d, 40 mg/dL trypsin; e, 40 mg/dL neuraminidase.

The surface charge density was investigated via particle electrophoresis. As shown in Table 1, the treatment of RBC with proteolytic enzymes usually leads to a significant reduction of the electrophoretic mobility and thus the zeta potential. Only moderate concentrations of trypsin (20 mg/dL) did not lead to any measurable effect. The most significant reduction (>30%) could be observed after the treatment with neuraminidase. In contrast, the reduction of the deformability of the neuramindisae treated RBC was only moderate compared to the reduction after treatment with the other proteolytic enzymes.

Table 1: Eletrophoretic mobility and zeta-potential.

RBC	Mobility Measurements (μmcm/Vs)	Zeta Potential (mV)
Control	-3.220	-47.2
Pronase (0.1 mg/ml)	-2.934	-43.0
α-Chymotrypsin (40 mg/dL)	-2.865	-42.0
Trypsin (20 mg/dL)	-3.220	-47.2
Neuraminidase (40 mg/dL)	-2.150	-31.5

In another set of experiments we investigated the effects of the proteolytic enzyme treatment on the adhesion of RBC

to EC using a parallel-plate flow chamber. For the neuramindse treated RBC we observed a strong correlation between the reduction of the zeta potential and an increase of RBC adherence to EC as illustrated in Fig 2. Further the adhesion strength was also substantially increased withstanding shear stresses of up to 1 dynes/cm^2 (data not shown). For other enzymes such dramatic increases could not be observed, when the treated RBC were suspended in polymer free suspensions (data not shown).

Furthermore, as shown in Fig. 3, the presence of dextran (here 1 g/dL, 500 KDa) significantly enhanced the desialylated RBC adhesion to EC. Similar effects were also observed for dextran of 70 KDa and 2,000 KDa, with concentration ranging from 0.5-2.5 g/dL. Even though RBC treatment with pronase, trypsin and α-chymotrypsin did not enhance RBC-EC adhesion in polymer free suspensions, the presence of dextran with high molecular mass (>40 KDa) also induced RBC-EC adhesion (data not shown).

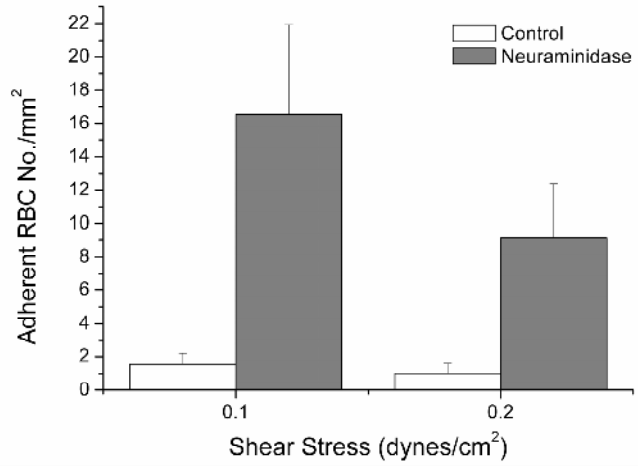

Figure 2: Desialylated RBC adhesion with EC.
The residual membrane zeta-potential of the treated RBC was -18.1.
The adherence was both conducted in PBS.

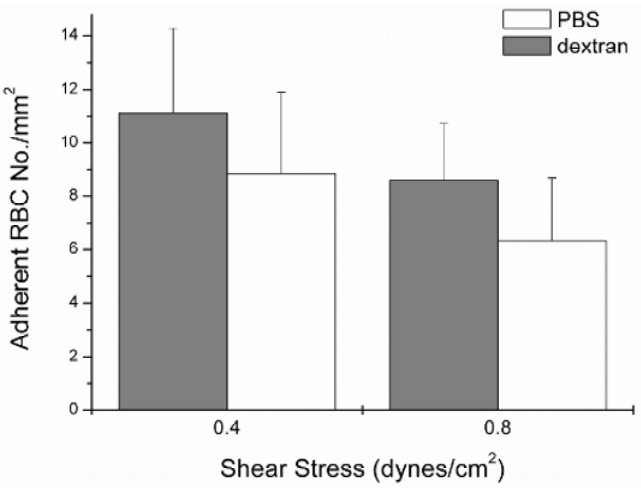

Figure 3: Impact of dexran on desialylated RBC adhesion with EC.
The residual membrane zeta-potential was -13.3 for both.
The concentration of dextran (500 KDa) was 1 g/dL.

IV. Discussion

The aim of this work was to test the hypothesis that macromolecular depletion can enhance adhesion of pathological RBC to EC. To mimic the impact of depleted plasma proteins on RBC-EC adhesion, we used the neutral polyglucose, dextran, with a wide range of molecular mass. RBC were treated with various proteolytic enzymes to mimic pathological cells. The dynamics of RBC-EC adhesion were recorded using a parallel plate flow chamber system.

Our results demonstrated a dramatically increased RBC-EC adhesion in the presence of high molecular mass dextran (>40KDa) under low shear stress (<1 dynes/cm^2). The adhesion increased with higher dextran molecular mass and concentration, and the presence of depleted polymers significantly increased the adhesion of enzyme treated RBC to EC. Our findings strongly suggest that the observed increase in the attractive forces have their origin in polymer depletion near the RBC and EC. Due to this macromolecular depletion, an attractive force develops that brings the adjacent surfaces closer together, leading to an increased number of binding sites available to the cell and thus more efficient and stronger adhesion of single cells.

RBC deformability, as quantified by varying shear stress with an ektacytometer, was found to decrease after the enzymatic treatments (Fig. 1). A reduction of deformability results in more rigid cell membrane, which in turn inhibits RBC to get in close contact with EC to establish adhesion. These changes in the deformability might explain why not all the enzymatic treatments have the same effect on RBC-EC adhesion.

V. Conclusion

In conclusion, this study demonstrates that polymer depletion can enhance the adhesion of pathological RBC to EC under low shear stress and quantifies for the first time the impact of physicochemical changes of the RBC membrane on its adhesion with EC in plasma like solutions. Thus our data should provide new insight into potential mechanisms for enhanced RBC-EC adhesion and disturbed in vivo blood flow in disease.

Comparison of Motion Analysis and Energy Expenditures between Treadmill and Overground Walking

R.H. Sohn[1], S.H. Hwang[1], Y.H. Kim[2]

[1] Dept of Biomedical Engineering, Graduate School, Yonsei University, Korea
[2] Dept of Biomedical Engineering and Institute of Medical Engineering, Yonsei University, Korea

Abstract — **In this study, treadmill walking and overground walking were compared at the same condition based on kinematics and energy expenditures (EE). In addition, we compared the actual energy expenditure and calculated EE by treadmill. The kinematics of treadmill and overground gait were very similar. The values at each joint were significantly different($p<0.05$), but magnitude of the difference was generally less than 3°. EE of treadmill walking was significantly greater when measured on the overground. It seemed to be the increased stress during the gait by the continuous movement of the belt. As the velocity increased, there was significant difference between actual EE and calculated EE by treadmill due to EE curve increasing exponentially. Therefore the further study would be required to find the correlation of the two methods and calibrate the values from them.**

Keywords — **Walking, kinematic, Energy Expenditures, Treadmill, Over ground**

I. Introduction

Walking is most natural activity and the only sustained dynamic aerobic exercise that is common to everyone except for the seriously disabled or very frail. This is beneficial through engendering improved fitness and greater physiological activity and energy turnover[1].

The treadmill can be used to walking for the health. In previous studies, measurements were taken on the treadmill and during overground walking. And many measurements have been made of the energy expenditure of persons walking at varying speeds on level ground or on the treadmill[2,3,4].

The results for walking at rates up to 8k/m/hr and for running at velocities of 8-21km/hr are substantially the same as those of Margaria et al.(1963)[5]. At higher velocities the relation for walking is linear as in running, but the slope is twice as steep.[6] Energy cost results were different between the treadmill and overground walking at same walking condition.

In this study, treadmill walking and overground walking were compared at the same condition based on kinematics and energy expenditures (EE). In addition, we compared the actual energy expenditure and calculated EE by treadmill.

II. Materials & Method

A. Subjects

A healthy mail were participated in this study. The patient was asked to walk as the convenient speed.

Table 1 Subject parameters (n = 11)

Characteristics	Age(years)	Weight(kg)	Height(cm)
Mean	25.5	72.5	173.1
SD	0.9	10.6	6.0

B. 3D Motion Analysis System

An six-camera, three dimensional motion analysis system(VICON612, UK) was used to record kinematic data at 120 Hz. And treadmill(HP Cosmos Gatway II) was used. Fig. 1 showed that the treadmill walking in 3D motion analysis system.

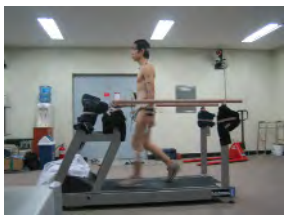

Fig. 1 Treadmill Walking

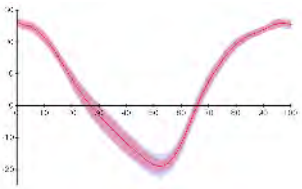
C. EE Calculation

We calculated energy cost values of walking on the treadmill compared to those on theMetamax3x.

Equation (1) is showed weir Method using the calculated EE by Metamax3xd[7]. And Equation (2) is showed Margria fomular using the calculated EE by treadmill[8].

$$Kcal/min = [(1.1 \times RER)+3.9] \times VO2 \quad (1)$$



$$KJ = (2.67+(10.9+0.654 \times V \text{ in } \%) \times (S \text{ in m/sec})) \times T \text{ in min} \times W \text{ in kg} \times 0.0211 kJ/ml\ O2 \quad (2)$$

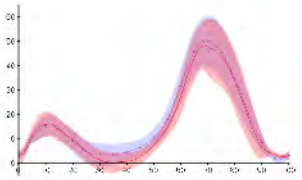
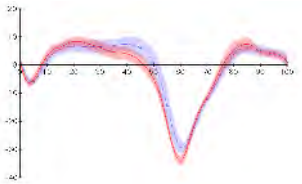
www.springerlink.com



III. Result

A. Kinematic Data



The kinematics of treadmill and overground gait were very similar. The values at each joint were significantly different ($p<0.05$), but magnitude of the difference was generally less than 3° (Fig. 2).

(a) Hip Angles

(b) Knee Angles

(c) Ankle Angles

Fig. 2 Kinematic Data of Treadmill and Over ground
(Over ground: ---▲----▲--- Treadmill: ----------)

B. Energy cost

EE of treadmill walking was significantly greater when measured on the overground.

Table 2 Energy Expenditure in Treadmill vs Overground

Walking Conditions	Treadmill	Overground
Heart Rate [1/min]	*106.67±3.92	*95.12±4.23
Rel. O_2 Uptake [ml/min/kg]	*19.05±2.54	*16.87±3.09
Energy Expenditure [kcal/min]	*6.68±1.20	*5.22±0.66

*represents significant difference (P<0.05)

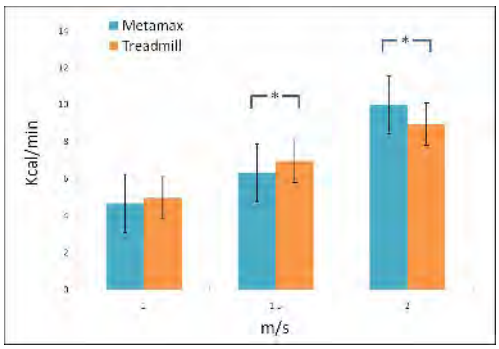


Fig. 3 Energy Expenditure Treadmill vs Metamax3x
* represents statistically significant difference ($p < 0.05$)

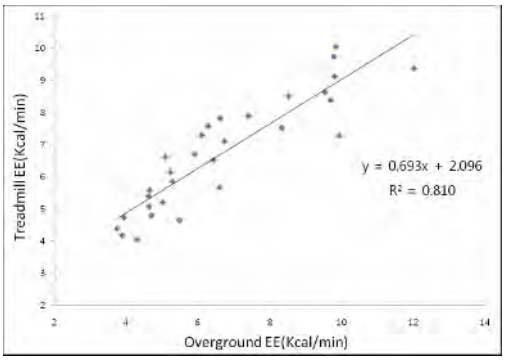

Fig. 4 Regression Analysis Treadmill vs Overground

Fig. 3 presents the energy cost values of walking on the treadmill compared to those on the Metamax3x. The EE of treadmill calculated was 6.3% greater than the EE of Metamax3x in walking speed 1.0m/s but there was no statistically significant difference.

The EE of treadmill calculated was 10.5% greater than the EE of Metamax3x in walking speed 1.5m/s. And The EE of treadmill calculated was 11.7% greater than the EE of Metamax3x in walking speed 2.0m/s. There was a statistically significant difference between walking speed 1.5m/s and 2.0m/s ($p < 0.05$).

Fig. 4 presents the energy cost values of walking on the treadmill compared to those on the overground by Metamax3x. The regression line equation shows That EE on the treadmill was 0.7 times greater than on the overground. The correlation of determination (R^2) was equal to 0.81.

IV. Discussion & Conclusions

The kinematics of treadmill and overground gait were very similar. EE of treadmill walking was significantly greater when measured on the overground. It seemed to be

the increased stress during the gait by the continuous movement of the belt. As the velocity increased, there was significant difference between actual EE and calculated EE by treadmill due to EE curve increasing exponentially. Therefore the further study would be required to find the correlation of the two methods and calibrate the values from them.

Simultaneous Strain Measurements of Rotator Cuff Tendons at Varying Arm Positions and The Effect of Supraspinatus Tear: A Cadaveric Study

J.M. Sheng[1], S.M. Chou[1], S.H. Tan[1], D.T.T. Lie[2], K.S.A. Yew[2]

[1]Nanyang Technological University/School of Mechanical and Aerospace Engineering, Singapore
[2] Singapore General Hospital/Department of Orthopaedics, Singapore

Abstract — **Aim: This study aims to measure strains on the different rotator cuff tendons simultaneously and demonstrate the effect of supraspinatus tear on other cuff tendons with an intact glenohumeral joint.**

Methodology: Four fresh-frozen shoulders were tested on a purpose-built rig in preliminary tests. With 10 kg loaded at the rotator cuff muscles, displacement variable reluctance transducers (DVRTs) were used to measure the supraspinatus, infraspinatus and subscapularis tendons strains simultaneously at varying elevation angles and planes. Simulated partial thickness tears were cut at the bursal-side of the supraspinatus and sequentially enlarged to full-thickness tear.

Results: Preliminary results showed the variation of strain with respect to different arm positions. In all three planes, strain of the supraspinatus at the bursal surface reduced with increasing elevation angle while its articular surface increased. There were strain variations between the anterior and posterior supraspinatus. It was observed that the strain of the remaining intact rotator cuff tendons increased with a propagating tear at the supraspinatus. With a tear at the anterior supraspinatus, the strain of infraspinatus was visibly increased. As the anterior tear propagated to the posterior side, the infraspinatus strain only further increased slightly. A more distinct strain increase was seen in the subscapularis as the tear propagated posterior to form a complete tear.

Conclusion: Quantitative information on the strain of the rotator cuff tendons at various elevation planes was found. The strain difference within supraspinatus implied occurrence of shearing which may cause intratendinous tears. Tears in supraspinatus elevate strain on the two adjacent cuff tendons and should be treated before the tears propagate.

Keywords — **Rotator cuff tendons, tears, arm positions, DVRTs.**

I. Introduction

The rotator cuff functions as a dynamic stabilizer of the glenohumeral joint, keeping the humeral centre within the supraspinatus (SS), infraspinatus (IS), subscapularis (SC) and teres minor (TM), which are subjected to a variety of forces glenoid during active arm elevation. It consists of the as the position of the arm changes during glenohumeral motion. Previous strain studies concentrated solely on supraspinatus [1-4]. None had measured strains on the different rotator cuff tendons simultaneously and shown the effect of SS tear on other cuff tendons with the glenohumeral joint intact. This study aims to investigate the effect of arm positions and SS tendon tears on the strain profile of the rotator cuff tendons.

II. Materials and methods

A. Specimen preparation and dissection

Four cadaveric specimens, which consist of the whole upper limb, were harvested and frozen at -20^{0}C within 24 hours of death. The mean age of the specimens was 74 years (65 to 78) and all were from men. One was from the left shoulder and three were from the right. Before dissection, each specimen was thawed at room temperature for approximately 12 hours. Throughout testing they were moistened with physiological saline.

During dissection, the forearm was first disarticulated from the upper arm. All soft tissues, except the rotator cuff muscles and tendons, were removed. The clavicle was also detached from the acromion. The rotator cuff muscles were detached from the scapula and cut, leaving muscles of approximately 40mm medial to the musculo-tendinous region for suturing of loading lines. Loop stitches were used to suture along the seven lines of muscle action (two lines on SS, IS and SC each, one line on TM).

The specimen was mounted on a purpose-built rig which was modified from Hatakeyama's customised shoulder positoner [1]. The rig was designed to have the flexibility of adjusting the positions and angles of the pulleys to adapt the different lines of muscle action (Fig. 1). The muscles were loaded with a total of 10kg along the lines of muscle action.

www.springerlink.com

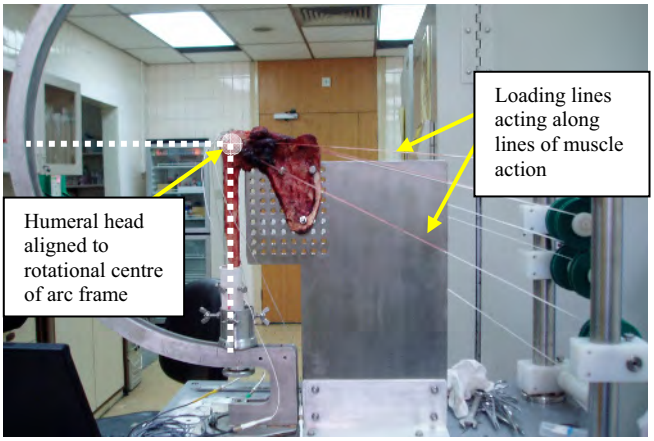

Fig. 1 Mounting of shoulder specimen with humerus at reference position

B. Differential variable reluctance transducers

Tendon strains were measured using linear differential variable reluctance transducers (DVRTs; M-DVRT-3, Microstrain Inc, Burlington, Vermont) [1-4]. A total of five DVRTs were used to measure the strain of the SS (articular side, anterior and posterior of bursal side), IS and SC tendons simultaneously. Each DVRT put out an analog voltage linearly proportional to the displacement of the magnetic core. The core and the body were attached to the tendons through two 3-mm long barbed pins. Because the core slid freely within the tube, this device had little influence on the change in length of the tendon being tested. Any change in the length of the tissue caused the core to slide in the body, resulting in a change of output voltage. They were calibrated prior to the experiment. Strain was defined according to the equation below:

$$\text{Strain} = \frac{\text{New barb distance} - \text{Initial barb distance}}{\text{Initial barb distance}}$$

The initial distance is the length between the two barbed points of the transducer with the humerus at the reference position and is used as the reference 'zero' position used in the calculation of tendon strain.

In order to have a wider range of positions tested on the glenohumeral joint, the acronium and corocoid process were clipped off to prevent impingement of the DVRTs during experiment. Between the SS and SC, the rotator interval was opened. A trough was created at the humeral head and a hole was drilled through to the surgical neck of the lateral humerus for the insertion of the DVRT at the articular side of the SS (Fig.2). DVRTs were orientated parallel to the line of muscle action at the centre of each tendon portion and were inserted with the humerus at reference position.

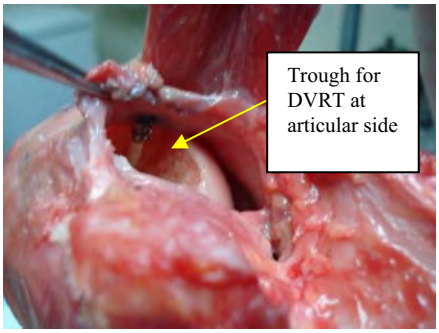

Fig. 2 Trough for DVRT at articular side

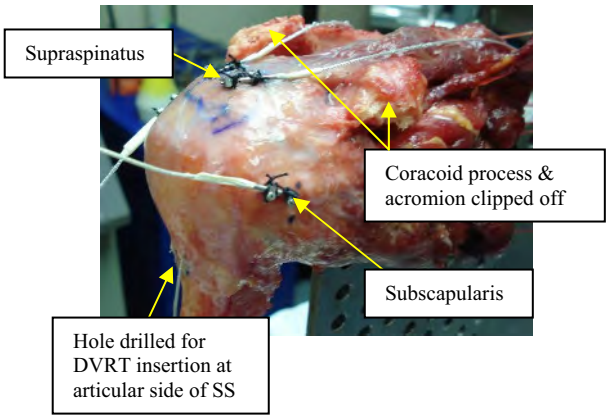

Fig. 3 DVRT insertions

After insertion, the DVRTs were sutured with surgical suture threads into the tendons to avoid loosening and eventually falling off from the tendons (Fig. 3). Pilot tests had shown no significant effect of suturing on the strain readings of the tendon.

C. Experiment variables

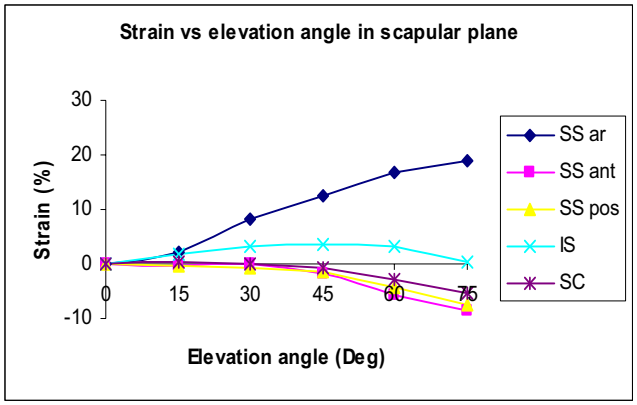
Arm positions: The humerus was elevated in the scapular, coronal, and sagittal planes. The scapula plane was defined to be inclined 45° to both the sagittal and coronal planes. Arm elevation angles were 0°, 15°, 30°, 45°, 60° and 75° relative to the scapula. The order of the elevation plane was 1) scapular plane, 2) sagittal plane, and 3) coronal plane. After one plane was finished, the humerus was brought back to the reference position before the measurements in the next plane were started.

Rotator cuff tears: Four types of simulated tears were made on the bursal portion of the SS tendon at the "critical zone" described by Codman [5]. For each tear, strain readings were collected with the humerus in the reference position. A 2-mm deep partial thickness tear was first cut on the

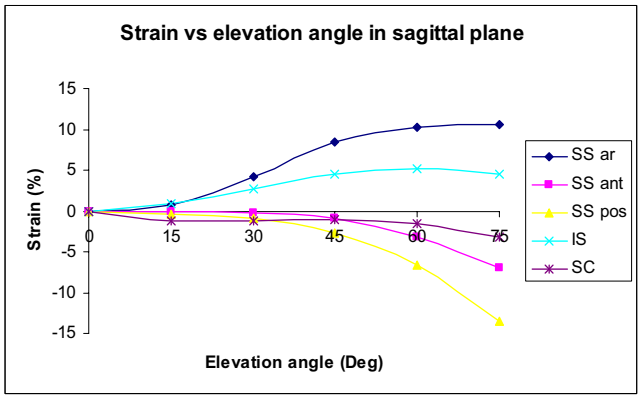
anterior SS, 1/2 width of the tendon in the anterior-posterior direction (Ant 2mm tear). This tear mimicked a partial-thickness tear on the bursal side of the SS due to subacromial impingement. Subsequently, this 2-mm cut was deepened to a full tear at the anterior portion of the SS (Ant full tear). Subsequently, this full tear was extended to ¾ width of the tendon in the anterior-posterior direction (¾ full tear). Finally, the tear was extended to the total width of the SS, resulting in a complete tear (Complete tear).

D. Data collection

Pilot results had not shown significant hysteresis during testing cycles, but the results were always recorded with increasing elevation angle. The system was preconditioned by elevating the shoulder up and down for 25 times to minimise the viscoelastic effect of the soft tissue. The output of the DVRTs was recorded over three cycles of elevation for each plane and simulated tear type and the average output was taken.



III. Results



A. Arm positions

Scapular plane: During abduction from 0° to 75°, the strain on the articular side of the SS (SS ar) increased to +19.0%. Between 0° to 30°, the strain on both the anterior and posterior SS at the bursal side (SS ant, SS pos) remained relatively unchanged. With increasing elevation angle, the strains of the SS ant and SS pos decreased to -8.5% and -7.7% respectively at 75° elevation. The strain of the IS increased to a peak of +3.6% at 45° elevation. Further increase in elevation angle led to a drop in the strain, with a strain of +0.4% at 75° elevation. The strain of SC gradually decreased to –5.5% with increasing elevation angle.

Sagittal plane: With increasing elevation angle, SS ar gradually increased to +10.5% at 75° elevation. SS ant strain remained relatively constant between 0° and 45° before it decreased gradually to –7.0% at 75°. With increasing elevation angle to 75°, the strain of the SS pos decreased to -13.5% while IS increased and reached a plateau of +5.1%. The SC strain decreased gradually to -3.2%

Coronal plane: Between 0° to 15° of elevation, the strain values the supraspinatus remained almost constant. Further increase in elevation angle to 60° caused a drop in strain for SS ant and SS pos to –5.0% and –7.6% respectively and an increase in strain for SS ar to 6.9%. The strain of IS remained almost constant while SC decreased to -4.2% at 60° elevation.

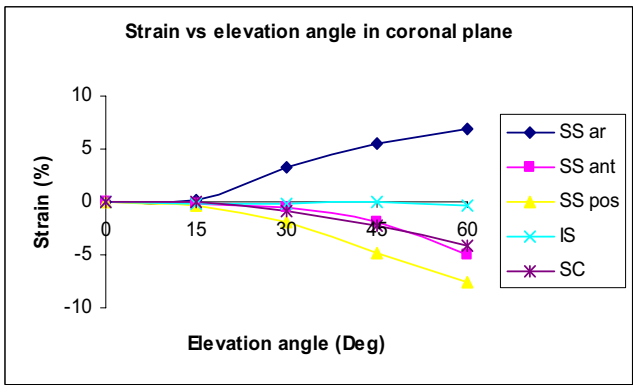


Fig. 4 Variation of strain with elevation angle in the three planes

The results showed the variation of strains with respect to different arm positions. In general, strain of SS at the bursal side reduced with increasing elevation angle while it increased at the articular sides in all three planes. This trend coincided with Reilly's finding in the scapular plane [3]. The strain difference between the anterior and posterior SS was also observed. It could be due mainly to the anatomical

aspect of the glenohumeral joint. Moreover, the anatomical configuration of the SS muscle–tendon complex was revealed to be inhomogeneous, with a thicker anterior portion adjoining the thinner, wider posterior side [6]. Differential strain causes shearing between the layers of the SS tendon, which may contribute to the propagation of intratendinous defects that are initiated by high articular side strains.

B. Rotator cuff tears

In general, the strain of the tendons increased with a propagating tear at the SS.

SS ar: Strain increased to +1.0% with ant 2mm tear and further increased to +2.5% when deepened to ant full tear.

SS ant: Strain increased to +3.5% with ant 2mm tear.

SS pos: Strain increased slightly to +0.2% and +0.7% with ant 2mm tear and ant full tear respectively

IS: Strain increased slightly to +0.4% with ant 2mm tear. An ant full tear resulted in a steep increase to +1.2%. Further propagation to complete tear caused gradual increase in strain to +1.4%.

SC: Slight strain increased to +0.15% as tear deepened to ant full. Propagation of tear to ¾ full tear resulted in a greater strain increase to +0.8%. A complete tear further increased strain to +0.9%.

With a tear at the anterior SS, the strain was redistributed within the intact SS, thus a higher strain at the articular and the posterior side. It is important to highlight the increase in IS tendon strain with an anterior SS tear. IS tear often occurs in the presence of a full-thickness tear in the anterior portion of the SS [7]. This correlates to the present experimental findings whereby the IS strain increases with an initial anterior SS partial tear and increases with with a full anterior tear. However there was less IS strain increase as the full anterior tear was propagated to a complete tear. On the contrary, there was no significant strain increase in the SC with an anterior SS tear. However, there was obvious SC strain increase as the anterior SS tear was propagated to a complete tear.

IV. Conclusions

Elevation of the arm in three different planes mimics many different daily life activities. Quantitative information on the strain of the different rotator cuff tendons was found and it would be useful to surgeons and physiotherapists during their assessment of patients while moving the patients' arms passively. It was observed that the strain of the remaining intact rotator cuff tendons increased with a propagating tear at the SS. Non-treatment of SS tears may result in tear propagation to IS and SC in the long run.

Tensile Stress Regulation of NGF and NT3 in Human Dermal Fibroblast

Mina Kim[1], J.W. Hong[1], Minsoo Nho[2], Yong Joo Na[2] and J.H. Shin[1]

[1]Department of Mechanical Engineering, KAIST, Republic of Korea
[2]Amore-Pacific Corporation R&D Center, Republic of Korea

Abstract — **Fibroblast is a major type of mechanosensitive cells in connective tissues, which transfers mechanical signals to intercellular biochemical events. Numerous previous studies have shown that the tensile stress alters ECM-related gene expression in fibroblast. The aim of this study is to investigate the effects of tensile stress on the neurotrophin expression of dermal fibroblast *in vitro*. Human dermal skin fibroblast cells synthesize and release neurotrophins such as nerve growth factor (NGF) and neutrophin-3 (NT3). NGF and NT3, members of NT (neurotrophin) family, stimulates fibroblast migration and are related to wound healing. Also, it is known that upregulation of NGF takes part in maintaining the biomechanical properties of the dermis. In this study, seeded cells on the polydimethylsiloxane(PDMS) substrate using a tensile stimulation device. At the uniaxial stretch of 10% strain and frequency of 0.5 Hz, different resting times of 0 min, 20 min, and 60 min were placed in between 10 min stimulations periods for the total stimulation of 1 hr and 2 hr. Results have shown that NGF mRNA levels had increased after 1 hr of stimulation, and more NGF mRNA was transcribed up to twofolds as the resting time increased. However, the level of mRNA transcription had decreased upon additional stimulation. On the other hand, NT3 mRNA levels had decreased by 50% in all applications. This result demonstrates that the tensile stress may regulate the expression of NGF and NT3, which could be a key factor for the neurocosmetic applications. We also investigated the effects of frequency and the magnitude of strain on the gene expression.**

Keywords — **Tensile stress, Fibroblast, NGF, NT3.**

I. Introduction

Fibroblast is constantly subjected to mechanical loads in connective tissues where mechanical signals are converted to intercellular biochemical events [1, 2, 3]. The influence of external force on skin is transferred through epidermis to the dermis while internal forces are transmitted in opposite direction [4]. Numerous previous studies have shown that the tensile stress on fibroblasts alters ECM-related and inflammation-related gene expressions [5, 6, 7]. In this study, we investigate the effects of tensile stress on the NGF and NT3 expression of dermal fibroblast *in vitro*. NGF and NT3, members of NT (neurotrophin) family are produced by fibroblasts and NGF stimulated fibroblast migration and is related to maintaining the biomechanical properties of the dermis [8, 9]. Two main objectives of this study was : first to investigate change of NGF and NT3 mRNA expression by uniaxial tensile stress: secondly to determine whether the resting periods is critical on magnitude of gene expression regulation.

The result of this study indicates that tensile stress may regulate NGF and NT3 which could be a key factor for the neurocosmetic applications. Also, results from different resting periods show that expression of gene regulation by tensile stress requires appropriate resting time.

II. Materials and Methods

A. Fibroblast cultures

Human dermal fibroblast cells were acquired from the Amore-Pacific Corporation R&D Center (Republic of Korea). The cells were cultured in Dulbecco's modified Eagle's medium (Lonza) containing 10% fetal bovine serum (GibcoBRL) supplemented with penicillin–streptomycin. Cultures were incubated in a humidified atmosphere of 5% CO_2 in air at 37^{o}C.

B. Mechanical stretch

Fibroblasts were seeded on the polydimethylsiloxane (PDMS) substrate coated 1% fibronectin solution (Invitrogen). The cells were loaded on the lab-made tensile stimulation device and mechanically stretched. The applied uniaxial stretch was 10% strain at a frequency of 0.5 Hz. Stimulation for 10min was placed in between different resting periods of 0 min, 20 min, and 60 min during total stimulation time 1hr and 2hr. Stretch experiments were carried out at 37 ^{o}C in 5% CO_2 .

C. RNA extraction and Real Time PCR

Total RNA was isolated from fibroblasts with TRIZOL Reagent (GibcoBRL) at the end of each experiment. RNA quantification was performed using the NanoDrop® ND-1000 spectrophotometer. cDNA was synthesized using Superscript III (Invitrogen) according to the manufacturer's instructions. Real time PCR for target genes was done using a RotorGene 3000 (Corbett Research) according to a set

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1935–1937, 2009
www.springerlink.com

program. The results of real time PCR were analyzed by the relative yield of the PCR product from target gene to that from the house keeping GAPDH (glyceraldehyde-3-phosphate dehydrogenase) gene. Mean values from different independent experiments were calculated.

III. Results

A. Regulation of NGF and NT3 in human dermal fibroblast by tensile stress

To obtain insight into the requirement of resting time in change of gene expression by tensile stress, we studied the response of different resting duration on NGF and NT3 mRNA levels [12, 13]. Resting times were given as 0min, 20min, and 60min between 10 min stimulations periods. Figure 1 shows the effects of resting time on expression level of NGF and NT3. NGF mRNA was transcribed up to two-folds after 60 min of resting time [Fig1.a]. Also, the mRNA transcription level of NT3 was decreased after 60 min of resting time [Fig1.b]. The highest level of NGF mRNA and the lowest level of NT3 mRNA were observed after 60min of resting time.

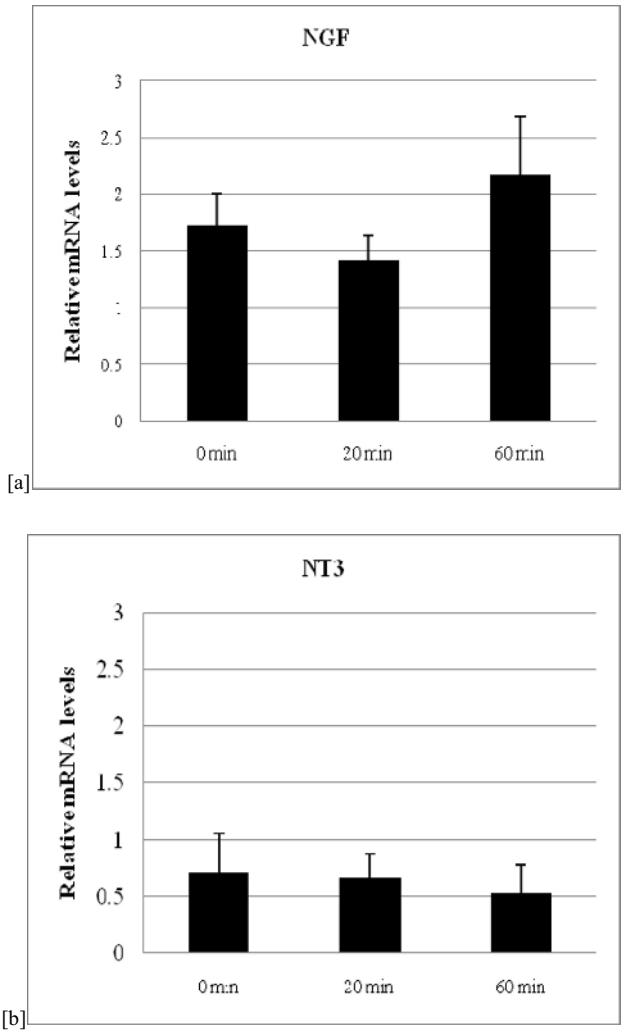

Fig. 1 Resting time during tensile stress and regulation of endogenous NGF and NT3 mRNA

B. NGF and NT3 mRNA levels in tensile stress by different stimulation time

To determine the effects of total stimulation time on expression level of NGF and NT3, cells were stimulated with 10 % at 0.5 Hz frequency, resting time 60 min were placed in between 10 min stimulation periods for the total stimulation of 1 hr or 2 hr. NGF mRNA was transcribed up to two-folds after 1hr stimulation. However, the level of NGF mRNA transcription had decreased upon additional 1hr stimulation. For NT3, mRNA level was decreased by half after 1hr stimulation, and not much difference was observed after additional stimulation [Fig2]. Therefore, we concluded that stimulation longer than 1hr is not necessary to observe more dramatic result in this experiment.

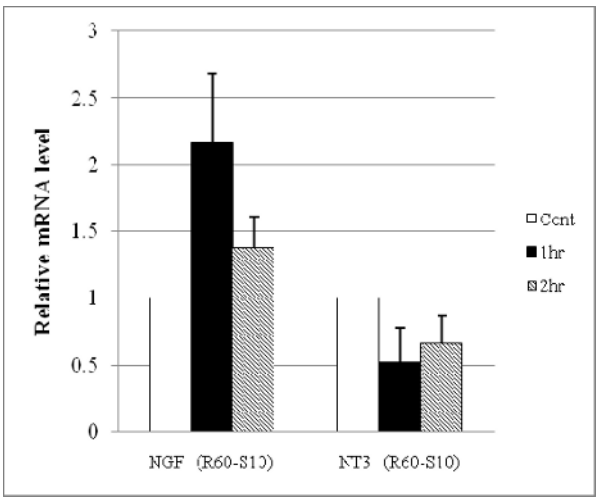

Fig. 2 Total stimulation time and expression of NGF and NT3 mRNA

IV. Discussion

Here we observe NGF enhancement and NT3 reduction in response to the uniaxial stretch in human dermal fibroblast. Results for resting time show that the highest level of NGF mRNA and the lowest level of NT3 mRNA were ob-

served after 60min of resting time. The results of total stimulation time show that NGF mRNA levels had increased after 1 hr of stimulation. However, the level of mRNA transcription had decreased upon additional stimulation. NT3 mRNA levels had decreased by 50% in all applications but not much difference was observed after additional stimulation.

V. Conclusions

In this study shows that tensile stress may regulate NGF and NT3 which could be a key factor for the neurocosmetic applications. Also, result for different resting time shows that regulation of gene expression by tensile stress requires appropriate resting time.

Influence of Component Injury on Dynamic Characteristics on the Spine Using Finite Element Method

J.Z. Li[1], Serena H.N. Tan[1], C.H. Cheong[1], E.C. Teo[2], L.X. Guo[2], K.Y. Seng[1]

[1] Bioengineering Laboratory, Defence Medical & Environmental Research Institute, DSO National Laboratories, 27 Medical Drive, #09-01, Singapore 117510, Republic of Singapore

Abstract — **Long-term whole body vibration (WBV) presents health risks to the spine. A frequency value near the resonant frequencies of the human body may increase the vibration effect of the lumbar spine. In this study, to better understand the dynamic characteristics of the human spine, we developed a detailed three dimensional finite element (FE) model of the low thorax to pelvis segment, T12-S1, based on actual vertebral geometry. We implemented several analyses to investigate how injuries on various spinal components affect the frequency characteristics of the human spine under WBV. Our results show that all the considered spinal component injuries including denucleation, facetectomy and removal of capsular ligaments lowered the resonant frequency of human spine. Our findings may be useful to provide guidelines for clinical treatment and for product design and development in industry.**

Keywords — **Lumbar spine, whole body vibration, resonant frequency, injury, finite element method**

I. Introduction

Long-term whole body vibration (WBV) represents a health risk for the lumbar spine [1], especially for the lower lumbar motion segments. A number of investigations have been carried out to investigate the dynamic characteristics of the human spine to provide insights into the relationship between vibration and low back pain. Besides these experimental studies, numerous finite element (FE) models have also been developed to investigate the frequency characteristics of the human spine [2–5]**.** These FE studies have provided useful information, but the simulated results reported were generally different from the experimental data (4~6Hz) [6, 7]. In addition, it is presently unclear how injured spinal components could affect the frequency characteristics of the human spine under WBV. Therefore, in this study, a three-dimensional (3D) FE model of the low thorax to pelvis segment, i.e. T12-S1, was developed to investigate this problem.

II. Method

The construction of our 3D FE model of T12-S1 has been detailed previously [3, 6]. Briefly, the model's detailed geometry was based on the digitized morphological data of embalmed spine vertebrae. Examination of these specimens did not show any gross physical abnormalities. To obtain the geometrical data required for the FE model, an accurate, flexible and multi-axis digitiser (FaroArm, Bronze Series, Faro Technologies, Inc., FL, USA) was used to extract the pertinent cross-section data into point cloud, which was subsequently imported into the commercially available FE software, ANSYS 7.0 (ANSYS, Inc., PA, USA), for volume and mesh construction. Adopting this digitisation process permitted accurate geometrical extraction of the specimen's morphology for the FE solid representation. The cortical shell, cancellous core, end plates and posterior elements including pedicle, lamina and transverse and spinous processes were represented by 8-noded solid elements.

The intervertebral disc's anterior and posterior heights were modelled based on published literature [6] to account for the required kyphotic curve. The nucleus pulposus was simulated by means of a nearly incompressible cavity and the annulus fibrosus was assumed to make up of 3 radial consecutive laminar layers of composite material consisting of annular fibers embedded in the homogeneous matrix material. The nucleus pulposus and annulus matrix were represented by 8-noded solid elements, while the annulus fibers were simulated by 3D cable elements that sustained tension only and arranged at about ±30º angles in relation to the adjacent endplates.

Ligaments were modelled as 3D tension only cable elements. The cross sectional area of each ligament was obtained by averaging the values reported in the literature. Figure 1 shows our T12-S1 FE model.

All materials were assumed to be linearly isotropic and homogenous. The material properties are collected from the literature. The detailed material property data used in our model are given in Table 1.

To investigate the effects, if any, of denucleation and facetectomy on the frequency characteristics of the spine under WBV, several injury conditions were assumed, namely (1) Case1: denucleation of L4-L5; (2) Case2: denucleation of two discs of L3-L5; (3) Case3: removal of facet joints and their capsular ligaments of L4-L5; (4) Case4: for two segments of L3-L5 based on Case3's condition; (5) Case5: removal of nucleus, facet joints and their capsular ligaments of L4-L5; and Case6: for two segments of L3-L5 based on Case5's condition. For all the cases simulated, the inferior surface of S1 vertebral body was fully restrained.

In all our simulations, a distributed mass of 40KG was included in the model, to represent the head and body weight.

III. Results

In order to investigate the resonant frequency characteristics of the human spine, different numbers of spinal segments were computed using FE modal analysis.

Table 2 shows the first-order axial vibration frequencies of different vertebral levels predicted by the FE models and the corresponding experimental results [3, 5, 7]**.** Table 3 shows the first-order axial resonant frequencies predicted by the T12-S1 FE model under intact and different injured conditions.

Theoretically, a 3D continuous structure may be characterised by six-dimensional vibration modes. The FE model of T12-S1 has the first vibration mode in the anterior-

Injury Case 4	7.65	-3.91%
Injury Case 5	7.23	-5.86%
Injury Case 6	6.65	-13.4%

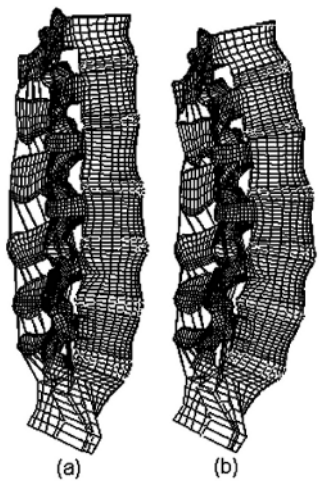

Fig. 2 The first-order vibration mode of T12–pelvis in the vertical direction: (a) and (b) are the postures showing maximum and minimum vertical displacements respectively

posterior direction with a low frequency. However, in the present study, we mainly discussed the first-order vibration mode in the vertical direction for consideration of the vibration characteristics of the human body. Figure 2 shows the first order vibration mode of our T12-S1 model, in the vertical direction. Our simulations showed that the vertical vibrations were accompanied by anteroposterior motion.

The upper body weight is a very important factor for the frequency characteristics of the human spine. In order to determine the influence of different upper body weights on the resonant frequencies of the spine, an upper body mass range of 30-60 kg was assumed and imposed on the T12-pelvis FE model during the modal analyses. The resulting resonant frequencies in the vertical direction varied from 8.23 to 5.84 Hz corresponding to 30 to 60kg upper body weight. Hence, our results indicated that a reduced body weight led to lower frequency and vice versa.

IV. Discussions

The results demonstrated that axial vibration frequencies of the spine decrease with an increase in the number of spinal segments. The T12-S1 FE model with a compressive preload of 40 kg predicted a first-order axial resonant frequency value of 7.68Hz. It has been previously reported that the inclusion of rib-cage of the head-thorax model lowered the resonant frequency by about 20% [5]. Therefore, this suggests that an FE model incorporating T12-S1, head-thorax as well as the rib cage and muscles may produce more realistic results. This set of model analysis has been left for a future study.

From Table 3, our results indicated that all the considered spinal component injuries including denucleation, facetectomy and removal of capsular ligaments lowered the resonant frequency of human spine. In particular, the denucleation of intervertebral discs played a greater role in the resonant frequency of the spine. More specifcially, the first-order axial resonant frequencies of the spine was lowered by 5% for one disc denucleation (Case1) and by 12% for the two disc denulceation scenario (Case2).

The results suggest that our model was capable of simulating the vertical vibration mode of T12-S1. The human upper body mainly performs vertical motion during WBV, while the lumbar spinal segment undergoes translation and rotation in the sagittal plane. The lower segment of the lumbar spine exhibits flexion motion, while the upper lumbar segment exhibits extension motion.

There are several limitations in this study. In the present model, the upper body was simplified and modelled as a lump mass because we considered only vertical vibration in this study. Another potential shortfall arises from a lack of consideration of the active regulatory effects of muscle and the non-linear influence of muscle large deformation to counter the anteroposterior oscillation of the human body during WBV. Therefore, the current model requires further improvement in the modelling of muscle and a distributed-mass upper body in both anatomic and mechanical aspects, so that the improved model can simulate the dynamic and impact conditions of flexion-extension, lateral bending, and torsion of the human spine under WBV.

Despite the limitations of the current model due to simplifications, our simulation results of vertical vibration showed overall good agreement with experiments.

V. Conclusions

A detailed 3D FE model of the lower T12-S1 based on actual vertebral geometry was developed, which can be used to perform dynamic response and impact analyses for the human spine. The findings may be useful to provide guidelines for clinical treatment and for product design and development in industry.

Abstract — **One of the critical events in early atherosclerosis is the recruitment of blood monocytes to proatherogenic vascular regions and subsequent transendothelial migration. This process involves a multi-step interaction between monocytes and endothelial cells (EC) including rolling, firm adhesion, locomotion, and transmigration. While the molecular mechanisms underlying rolling and firm adhesion have been well documented, the final step, transmigration, is still poorly understood. Platelet-endothelial cell adhesion molecule-1 (PECAM-1) is considered to be one of the key molecules in the transendothelial migration of monocytes. To investigate the role of PECAM-1 in monocyte diapedesis, we expressed a green fluorescent protein (GFP)-labeled construct in interleukin-1beta-stimulated human umbilical vein endothelial cells. Labeling PECAM-1 with GFP at its intracellular C-terminus could keep the molecular interactions with monocyte PECAM-1 intact. Three-dimensional molecular imaging in live cells demonstrated that endothelial PECAM-1 dynamically redistributed during paracellular transmigration, to surround monocytes transmigrating through both bicellular and multicellular junctions. Within 20 minutes of transmigration, PECAM-1-GFP was recruited at transmigration sites to induce a significant increase, with a concomitant reduction in the neighboring cytoplasm. These dynamics were not observed during transcellular diapedesis. At bicellular junctions, PECAM-1 recruitment did not occur in the region without transmigration (but with adhesion on endothelium), although it did at multicellular junctions, nor did it appear to occur at either junction type when monocyte adhesion was blocked. These data show that monocyte adhesion can trigger PECAM-1 recruitment from sub-junctional cytoplasm preferentially to multicellular endothelial junctions. Subsequent transmigration induces PECAM-1 redistribution and further recruitment at multicellular and bicellular, but not at transcellular sites, which may support chronic paracellular transmigration.**

Keywords — **Endothelial Cell, Monocyte, Transmigration, PECAM-1**

I. Introduction

One of the critical events in early atherosclerosis is the recruitment of blood monocytes and T-lymphocytes to proatherogenic vascular regions and subsequent transendothelial migration, also known as diapedesis. This process involves a multi-step interaction between leukocytes and endothelial cells (EC) including rolling, firm adhesion, locomotion, and transmigration.[1,2]

While the molecular mechanisms underlying rolling and adhesion have been well documented, the final step, transmigration, is still poorly understood. Leukocytes have been shown to cross EC monolayers by both paracellular (between ECs) and transcellular (through the body of ECs) routes. For paracellular diapedesis, many molecules have been reported to be involved, including platelet-endothelial cell adhesion molecule-1 (PECAM-1) [3,4]. We have recently reported that oxidized low density lipoprotein changes the junctional conformation of ECs, upregulating PECAM-1 and downregulating VE-cadherin, and leading to the promotion of monocyte diapedesis [5] In contrast, studies of the molecular basis of transcellular diapedesis have only recently begun.

Recent studies reported that part of cellular PECAM-1 exists in the intracellular pool called lateral border recycling compartment (LBRC) which is located below the surface of the cell at the lateral borders in ECs, and PECAM-1 is constitutively recycled between the LBRC and the cell surface [4,6]. The detailed dynamics of molecular trafficking of PECAM-1 to the cell surface has not been directly demonstrated in live cells. Moreover, it is still unknown PECAM-1 has some roles for transcellular diapedesis, as well as for paracellular diapedesis.

In this study, we analyzed the molecular dynamics of endothelial PECAM-1 during monocyte paracellular and transcellular diapedesis in three-dimensions with PECAM-1 - green fluorescent protein (GFP) fusion protein.

II. Matrials and methods

A. Cells

HUVECs were purchased from Kurabo (Osaka, Japan), and cultured in HuMedia-EG2 complete medium (Kurabo) supplemented with Primocin (Amaxa, Cologne, Germany) to protect against microbial contaminants including mycoplasma. For experiments, cells at passage 3 were seeded at 2 500 cells/cm^2 and grown to confluency. Human, CD14+ monocytes were freshly isolated from the peripheral blood of young, healthy volunteers.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1941–1944, 2009
www.springerlink.com

B. Construction of PECAM-1-GFP

The full length PECAM-1 cDNA obtained from HUVECs was cloned into pAcGFP1-N1 vector (Takara Bio) to produce a construct in which Aequorea coerulescens derived GFP (AcGFP1) was fused to the C-terminus of PECAM-1.

C. Molecular imaging of PECAM-1-GFP

Freshly-isolated and fluorochrome-labeled human monocytes were added to PECAM-1-GFP-transfcted HUVECs that were prestimulated with 5 ng/mL interleukin-1beta (IL-1β, R&D systems). The molecular dynamics of PECAM-1-GFP during monocyte diapedesis was observed on a microscopic stage at 37°C, using a confocal laser scanning microscope (CLSM, TCS-NT, Leica) with a 40 × oil-immersion objective at 1-5 minutes intervals. In some cases, experiments were done under the condition that i) monocyte adhesion was blocked by anti-β2-integrin and anti-ICAM-1 antibodies, and ii) monocyte transmigration was blocked by anti-PECAM-1 antibodies.

D. Quantitative image analysis of PECAM-1-GFP

Monocyte transmigrations were classified as either paracellular or transcellular and paracellular events were further divided into bicellular routes, which used junctions between two ECs, or multicellular routes, which used junctional corners where three or more ECs met. Changes in the fluorescent intensity of PECAM-1-GFP around transmigrating monocytes were measured over time in z-projected images. The regions measured were determined as fixed polygonal ones, and as the minimum and the best-suited to accommodate the transmigration spots around monocytes.

III. Results and Discussion

Of a total of 153 diapedesis events analyzed, only 5% monocytes (7 events) transmigrated by a transcellular route while approximately 95% took a paracellular route. Of these, 68% migrated through bicellular junctions and 27% through multicellular corners. During paracellular transmigration, PECAM-1-GFP gaps, through which transmigrating monocytes invaded, were formed. The majority of these gaps formed de novo during transmigration, but at multicellular corners, a significant number (28%) pre-existed before transmigration. Most of the gaps closed after transmigration, and the time for which gaps were open was significantly longer at multicellular than at bicellular regions.

A typical example of the 3D-molecular dynamics of PECAM-1 during monocyte bicellular diapedesis is shown in Figure 1A. PECAM-1 staining at a bicellular junction was intact before monocyte arrival (0 minute). In this case, the monocyte adhered to the EC at 6 minutes after monocyte addition, and started to invade the endothelium at 14 minutes, forming a PECAM-1 gap de novo. Endothelial PECAM-1 dynamically redistributed to surround the transmigrating monocyte, as clearly shown in xy, xz, and yz planes (arrows at 14 and 18 minutes). After transmigration, the PECAM-1 gap resealed completely by 20-24 minutes (arrowheads). Similar dynamics were seen around monocytes migrating through multicellular corners (Figure 1B), where gaps formed de novo, with PECAM-1 redistribution at 7-12 minutes (arrows) and the gap resealing at 9-15 minutes (arrowheads). The majority of these paracellular events were accompanied by PECAM-1 redistribution to surround transmigrating monocytes (77% for bicellular and 83% for multicellular routes).

In contrast, Figure 1C show a monocyte M1 that transmigrated transcellularly, but PECAM-1 redistribution was never observed. At 38 minutes, M1 was on the apical surface of an EC (arrows), and another monocyte M2 had already transmigrated beneath the EC. At 43-45 minutes, M2 migrated in subendothelium towards M1, and M1 invaded the EC transcellularly (arrows) as if attracted by M2, but no redistribution of endothelial PECAM-1 was observed. M1 had almost completed transmigration by 47 minutes, and appeared to aggregate with M2 (arrows and arrowhead). This mode of transcellular diapedesis, in which adherent monocytes seemed to be attracted by another transmigrated monocyte was seen in 57% (4/7) of transcellular events.

Quantitative image analysis confirmed the late accumulation of PECAM-1, showing a significant, time-dependent increase in PECAM-1-GFP fluorescence for at least about 20 minutes after bicellular and multicellular transmigration (Figure 2A), which was accompanied by a significant reduction in the neighboring cytoplasm (Figure 2B), suggesting that PECAM-1 was recruited from the sub-junctional cytoplasm to the site of transmigration. In contrast, no accumulation was seen at sites of transcellular diapedesis (Figure 2A). Fluorescence over the whole scanned area (250 × 250 μm) remained unchanged (Figure 2B).

To further clarify what is the trigger of the accumulation during a series of processes from rolling to transmigration, we first examined the effect of monocyte adhesion to endothelium on the molecular dynamics of PECAM-1. When PECAM-1 on both monocytes and ECs was blocked, majority of monocytes adhered to ECs, but could not transmigrate, enabling us to track the dynamic changes of PECAM-1 at the neighboring junctions induced by individual monocyte adhesion events. Monocyte adhesion alone did not

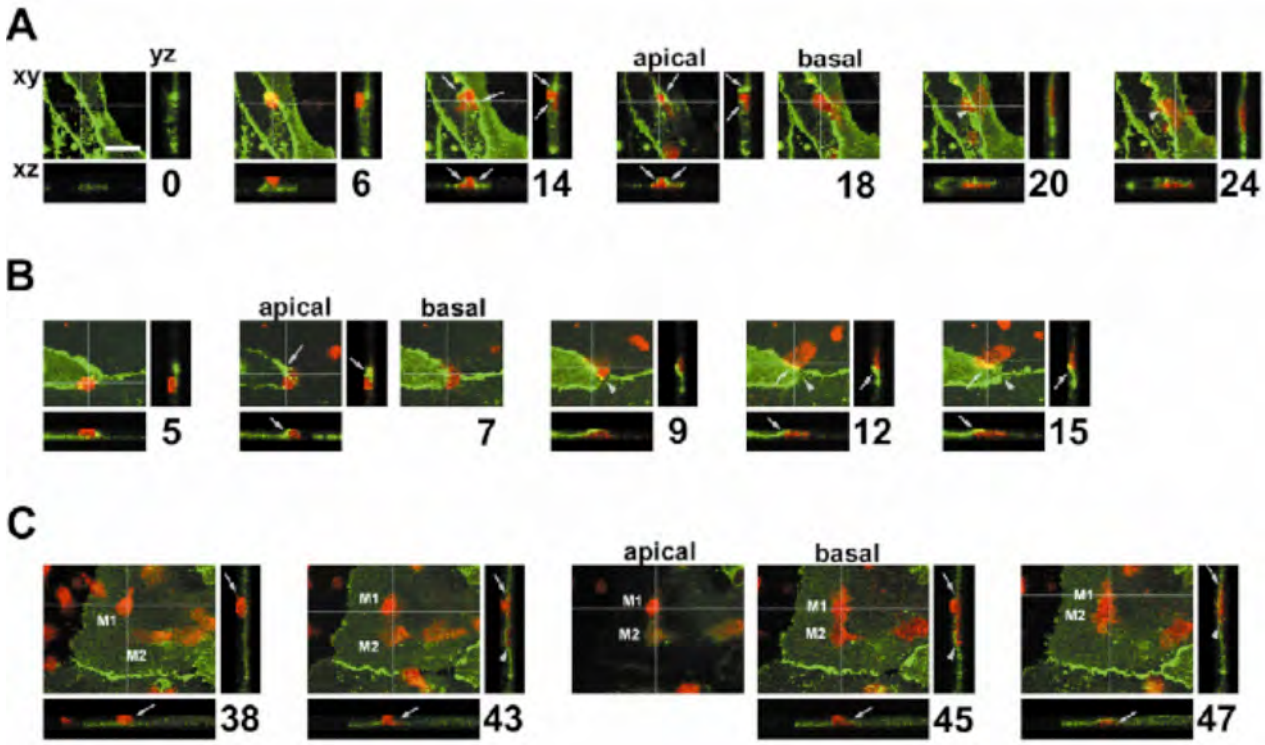

Figure 1 Redistribution of endothelial PECAM-1 to surround transmigrating monocytes during paracellular, but not transcellular diapedesis. A: bicellular, B: multicellular, C: transcellular diapedesis.

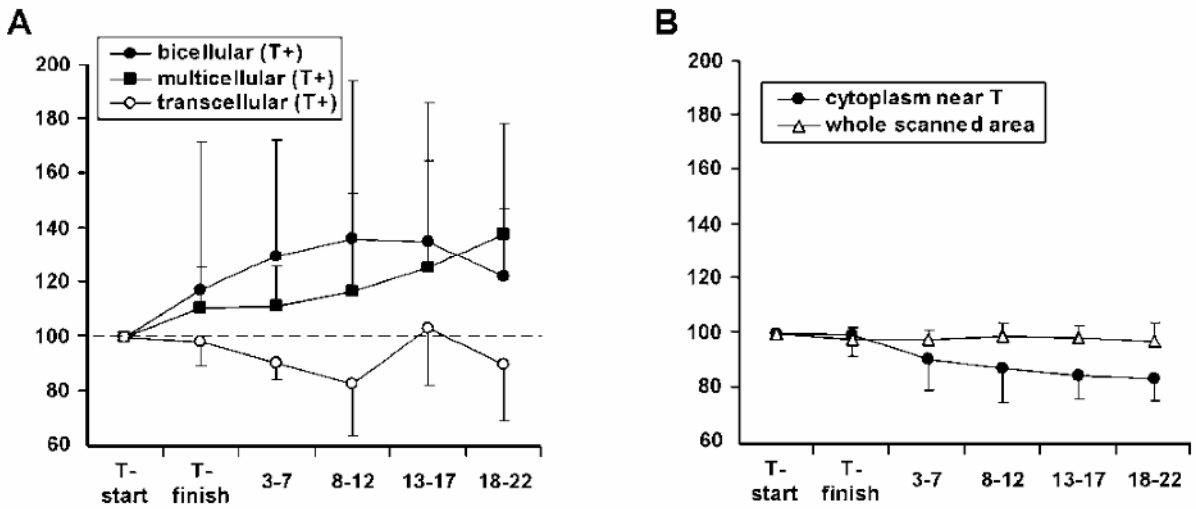

Figure 2 Quantitative image analysis of PECAM-1 late accumulation. A: Changes in PECAM-1-GFP fluorescence in specific local regions of migration, B: Changes in PECAM-1-GFP fluorescence in cytoplasm near migration sites and whole cells.

trigger the PECAM-1 accumulation at the neighboring paracellular junctions. The accumulation did not seem to occur in any regions either when monocyte adhesion was partially blocked (while the blocked monocytes were flow-

ing in the media) or without monocyte addition, which excludes the involvement of monocyte-derived soluble factors and intrinsic endothelial activities, respectively.

During paracellular transmigration, local endothelial PECAM-1 redistributed to surround transmigrating monocytes, suggesting PECAM-1 on ECs binds homophilically to PECAM-1 on monocytes. This redistribution was equally common at bicellular and multicellular regions, suggesting the same mechanism was involved. It is important to determine whether the monocyte PECAM-1 binds to either endothelial PECAM-1 already engaged with PECAM-1 on neighboring ECs or unengaged PECAM-1 recruited to the cell surface during diapedesis. It is likely that a transient disruption of PECAM-1-PECAM-1 binding at EC junctions is necessary to proceed diapedesis. Thus we speculate that monocyte PECAM-1 binds to endothelial PECAM-1 whose binding with neighboring ECs has been disrupted by an unknown mechanism, and this homophilic binding further stimulates the late recruitment of unengaged PECAM-1 to the site of paracellular, but not transcellular transmigration, which continues for at least 20 minutes after transmigration. The late and continuous accumulation of PECAM-1 after transmigration can be considered a mechanism for facilitating the subsequent, chronic monocyte paracellular diapedesis at the same site, which has often been observed in this system, leading to the development of atherosclerosis.

IV. Conclusions

Redistribution of endothelial PECAM-1 to surround transmigrating monocytes during paracellular, but not transcellular transmigration is followed by late and continuous accumulation of PECAM-1 at the same site after transmigration, which can support chronic paracellular transmigration. The accumulation is triggered by monocyte transmigration, but not adhesion or monocyte-derived soluble factors. Clinically, pharmacological targeting against the process of PECAM-1 redistribution/accumulation could be beneficial for specific prevention of monocyte diapedesis, which is the key process in early atherogenesis.

Abstract — **We performed a study to examine the direct effects of high glucose on the complex interplay of focal adhesion (FA) and vessel destroying disease, in a setting of diabetic type 2 patients suffered by severe vasculopathy. Significant modifications in the gene expression profile of angiogenic mediators were observed between patients and normal controls. We didn't note changes about m-RNA level expression of integrins and their receptors. Therefore, we supposed that a) transcriptional events are stored; b) hyperglycemic environment generates a loss of FA by biochemical change of integrins. In addition, we assumed that cells have defective strengthening of integrins-cytoskeleton linkages upon mechanical stimulation, as suggested by laser trapping experiments and binding of large beads to the cell surface. So, the mechanical stress can be moved over an intracellular structure with adequate strength. Herein, we consider the adhesion contact between integrins and extra-cellular membrane taking into account the S-H link role. A theoretical mathematical model has been developed to define the relationship between integrins, as principal bond in the FA, and the chemo-mechanical damage. A simple isotropic adaptive-elastic damage mechanism to describe the possible degradation of the integrins link is proposed in this paper. We suggest an energetic characterization of the problem considering the stored energy deformation and the chemical energy, this last as function of the environmental concentration. We neglect dissipative phenomena associated with entropy production and we surmise that equilibrium states are minimizers of the free energy of the system. The corresponding minimization problem is of no convex type and individualizes coexistence of equilibrium phases. Different cases will be treated, namely the static conditions one (no transportation of matter is carried-out) or the evolution case one, where the transportation matter is admitted. We conclude that glucotoxicity plays a critical role in the progressive deterioration of the vessel structures.**

I. Introduction

By array technology, in a previous study [1] we have performed some biological consideration about how the hyperglycemic environment influences the endothelial progenitor cells ability to provide a vessel building in diabetic type-2 patient. This pathology is associated with endothelial dysfunction, atherosclerotic macro vascular disease and microangiopathy. An important result is that we not observe change in m-RNA expression, but nevertheless considerable cell detachment phenomenon is presents. Our idea is that chemical aspects in the cells-wall microenvironment are characterizing the loss of the link strength within the basilar protein bond, namely integrins.[2], [3], [4], [5],[6], [7], [8], [9], [10], [11].Generally all materials are known to have complicated behaviors when subjected to compound action (i.e. mechanical and chemical or electrical or magnetic etc.). Here, benefit to underline that chemical action may make a dramatic internal change that can sensibly modify the materials elasticity. In particular, when we consider a simple closed system heterogeneous formed by solid and fluid compound, the picture is that the actual diffusion of the fluid into a solid may produce swelling as a consequence of a chemical transformation or mass absorption. Again, this last phenomenon nothing is if a phase transition in the classical thermodynamic sense. About this affirmation, it opens the way to investigate the possible coexistence of phases in the solid part within the heterogeneous system. In this paper our aim is to deduce a compound model reproducing adhesion and detachment in endothelial cells when the cell bond is damaged by pathological local conditions. Then, became possible to simulate like elastomeric structure in the non linear elasticity framework and so a neo-Hookean constitutive model can show the biological tissue response. A variational characterization of the problem and a model based upon energy minimization is developed.

II. Problem Statement

A. Biological Aspects

Integrins are heterodimers, consisting of one α and one β subunit. In diabetic setting patients, we determined quantitative gene expression of αVB5 integrins that has been showed to be important mediators of cell adhesion, migration, assembly and contraction of extracellular matrix. Integrins Alpha V fibronectin receptor (ITGA5) and Vitronectin Receptor of vascular smooth muscle cells (ITGAV). Integrins beta 3 (ITGB3) was also evaluated. In stably attached cells, the ITGB3 is capable of binding a

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1945–1948, 2009
www.springerlink.com

variety of ligands that are present in vascular tissue such as osteopontin, thrombospondin, and vitronectin. Changes in ligand occupancy of αVβ3/ ITGB3 has been showed to directly influence fibroblast growth factor (FGF) signalling in endothelial cells. We perform gene expression analysis including even growth factors. FGF showed increased molecular expression rate respect to normal controls, assumed that 1unit is normal value (mean 10,5 ± sd 14,2). Similarly, ITGA5 (mean 3,7 ± sd 3,9) and ITGAV (mean 3,9 ± sd 3,7) expression levels were increased in diabetic patients with artheriopathy. On the contrary, mRNA ITGB3 quantitative expression did no change (mean 1,0 ± sd 1,2) respect to normal control, (figure 1). In our study, this appears in contrast with the circumstance that, in the same diabetic people, the circulating endothelial cells (CEC) were more numerous respects to normoglycaemic controls (data not shown).

Because, high CEC number is correlated with vessel wall destruction, it's possible to suppose a probable molecular arrest of integrins synthesis. Indeed, based on last evidence that ITGB3 transcriptional event was unmodified, we supposed that hyperglycaemic environment generate a loss of focal adhesion by biochemical structural changes of this integrins.

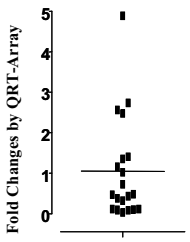

Fig.1 mRNAI-TGB3 in diabetic-type2 patients

B. Mechanical and thermodynamic aspects

Since the previous considerations affirming no-transcriptional influence in the integrine link degradation, we should to focus the chemical aspect and, in this manner, we think at chemo-mechanical equilibrium problem. A large literature over this argument is available and in particular we recall [12], [13], [14]. Integrins and cadherins, namely adhesion receptors are able to the natural function only interacting, at same time, either with extra cellular ligand and cytoskeleton. So mechanical stress can be carry out over an intracellular structure with adequate strength.

Here the glucose concentration dependent-*ph* variation in the system goes toward a possible one-dimensional modelization where the integrine bond, from mechanical point of view, can be assumed as well as a stressed string absorbed in a variable environment. For instance, the *ph* variation (increase or decrease value) makes aggressive or no-aggressive environment. In the first case it's possible to identify matter transport among string and external environment as equilibrium conditions.

According to [14] recalling some elementary thermodynamics consideration, we say that generally all irreversible processes drive the system to the equilibrium state in which the corresponding affinity vanishes.

When pressure and temperature, over a closed system, are maintained constant the quantity that is minimized is the Gibbs free-energy while, when the volume is constant we utilize the Helmholtz free energy.

This approach type has been developed about crystalline materials models because it represent a good base to model material degradation model [15], [16], [17].

III. Theoretical chemo-mechanical model

We start with a simple consideration derived by equilibrium of heterogeneous substance [13]: the transport of chemical species which carry matter from a location where the potential is W^1 to a location where the potential is W^2. For simplicity we shall to assume that our system consists of two parts, each with a well defined potential and that the global system is closed.

According to [18] we develop the model idea on the base of coexistence phases within the same system. Here, we consider a focal adhesion bond undergo to the natural stress (i.e. blood flow forces) in chemical equilibrium with surrounding aggressive environment at constant pressure.

Supposed the global system as closed and formed by two separate phases namely, the phase *A* (the integrine bond) the phase *B* (the environment), and three substances $S°$, S^1, S^2. The phase *A* is supposed as solid and composed by $S° + S^1$, whereas phase *B* is a fluid of S^1 and S^2 only.

The substance S^1 can be migrating among *A* and *B* due to application of stress or chemical action and again we suppose room temperature as constant. From stoichiometric consideration we introduce the mass fraction

$$c(x) \equiv \rho_1(x)/\rho_1^* \quad \text{on } x \in A \tag{1}$$

where ρ_1 and ρ_1^* represent respectively the mass density of S^1 and the referential mass density of S_1.

The equation (1) measure the degree of reaction at the point $x \in A$ and so the defined function c: $A \rightarrow (0,1)$ completely define the extent of reaction in *A* body. According to [18] we assume $\psi_B(\rho_1^*)$ as the Gibbs free energy of the solution *B* and the specific Helmholtz free energy function

$$\psi\varpi(e, c) = \tfrac{1}{2} K(c) (e - e°(c))^2 + h(c) \tag{2}$$

expresses the chemo-mechanical energetic relationship of the strain in the string and the degree of the reaction of its particles with the surrounding environment. In equation (2) $K(c)$ is the constitutive parameter if the integrine string.
Here, we impose a positive value for modulus K in the sense that its stiffness may change due to chemical reaction. The terms e and $e°$ represents the strain and an off-set strain due to chemical reaction, while $h(c)$ is an given function.
About this last consideration, the same appear corroborated by experimental evidence [16]. In the Fig. 1 we represents the envelope among the stored density deformation energy and the concentration function $c = c(x)$ namely, the function $z = \psi'(e, c)$.

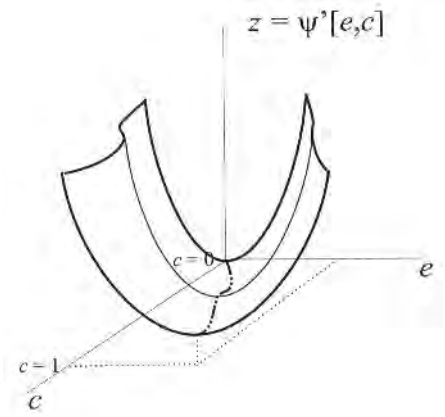

Fig. 1 Graph of the specific Helmholtz free energy $z = \psi\varpi\ (e,c)$

Likewise we define the free energy for the surrounding solution B as $\psi\omega(\rho_2)$ where ρ_2 represent the mass density of the fluid B. Then the chemomechanical equilibrium is stable corresponds to the minimum of the total energy functional

$$\mathcal{E}\,[e(x), c(x)] = \Xi_A\, \psi\varpi(e(x), c(x))dx + \psi\omega(\rho_2) \qquad (3)$$

Now, setting the quantity Ω as measure of the chemical potential of the environment with respect to S_1

$$\Omega \equiv \rho_1\, (d\psi\omega/d\rho_2)(\rho_2) \qquad (4)$$

then we can re-formulate the equation (3) in the form

$$\mathcal{E}\,[e(x), c(x)] = \Xi_A\, \psi\varpi(e(x), c(x))dx + \Omega\Xi_A c(x)dx \qquad (5)$$

and so the equation (5) represent, in global form, the minimum problem defined in the admissible set

$$\mathcal{H}\equiv\{(e, c):\Xi_A\, e(x)dx = \lambda A,\ 0 \le c(x) \le 1\ \forall x\in A\} \qquad (6)$$

Considering the first variation of the equation (2) to respect the variable e and imposing the equilibrium conditions

$$(\partial\psi\varpi/\partial e)(e(x),c(x)) = \text{constant} = 0 \qquad (7)$$

Then we define the function $z = \Phi(c)$: $= \psi\varpi(e°(c), c)$ which representation follow in the next Fig. 2.

Here we observe the variation of the function z to respect the concentration parameter of the fluid solution B. Because we consider a restricted variation to c, namely $c\in[0, 1]$ and in other word, when $c = 0$ the generic particle $x\in S°$, while $c = 1$ x is a compound of $S°$ and S^1. Again we observe that the tangent touch the graph of the function z in two distinct points likely the Ericksen bars model.[19]. Then developing the first variation of the function z, we find the graph down reported in Fig. 3.

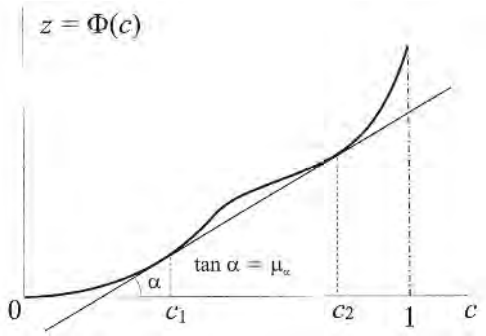

Fig. 2 Locus of the vertices of the parabolas c = constant

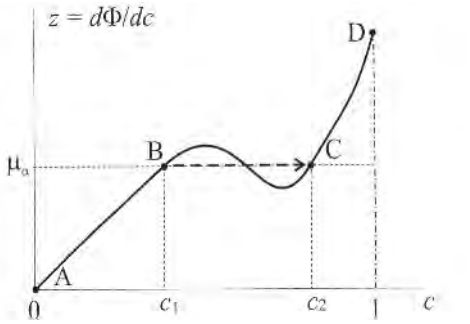

Fig. 3 Corresponding graph of $d\Phi/dc$

Commenting the graph of Fig. 3 as in the Ericksen model we find a non monotone law and this because the function z is classically no-convex as typical in non linear elasticity theory or two-well potential in solid-solid phases transition.

This mean that our minimization problem haven't unique solution but various and so phases coexistence appear.

From these last assertions we neglect the global function problem as represented in Fig. 1 and from now we restrict the attention of the function z more his derivatives.

We say that conditions from variation in the c values interval are indicated in following equation system (8)

$$\Omega = d\Phi/dc \quad \text{if } c\in(0,1)$$

$$\Omega \le d\Phi/dc \quad \text{if } c = 0 \qquad (8)$$
$$\Omega \ge d\Phi/dc \quad \text{if } c = 1$$

Overlapping the graphs in the Fig.2 and 3 we affirm that the tangent value Ω_α cross the derivatives graph and cut-off the contained B-C area in equal parts. This is the equal area rule introduced by Maxwell for the van der Waals fluid. In this manner we can to affirm that even in integrins string must be supposed a phase transition when the chemical potential assumes the value equal to Ω_α. So we may suppose the values interval $\Omega_0 < \Omega_\alpha < \Omega_1$, and then a possible solution $c^*(x)$ of the minimum problem will have the following form

$$\begin{aligned} c^*(x) &= 0 \quad \text{if} \quad \Omega < \Omega_0 \\ c^*(x) &= \min\{(d\Phi/dc)^{-1}(\Omega)\} \quad \text{if} \quad \Omega_0 < \Omega < \Omega_\alpha \\ c^*(x) &= \forall x \in (c_1, c_2) \quad \text{if} \quad \Omega = \Omega_\alpha \\ c^*(x) &= \max\{(d\Phi/dc)^{-1}(\Omega)\} \quad \text{if} \quad \Omega_\alpha < \Omega < \Omega_1 \\ c^*(x) &= 1 \quad \text{if} \quad \Omega > \Omega_1 \end{aligned} \qquad (9)$$

We observe that there is a transition when $\Omega = \Omega_\alpha$ and where either the $c^*(x)$ and $e^*(x)$ functions jump, respectively, from c_1 to c_2 and from $e_0(c_1)$ to $e_0(c_2)$. This aspect show a dramatic instability, like swelling phenomenon, consequent to small variation of the *ph* value of the surrounding fluid.

IV. Conclusions

Proposing this theoretical model we approach the cellular detachment as complex and composed problem. About some final consideration, here we see that there are two behaviors limit about the chemical potential. In other word we have, when $c = 0$ or $c = 1$, that chemical reaction does not occur or fully develops. In general case, $0 < c < 1$, the set of points $c \in (0,1)$ is either a single point or constitutes a single interval. If it is unique then a homogeneous solution exist, otherwise we have formation of coexistent phases in integrine string portions. In this portions we find different value of $c^*(x)$ and $e^*(x)$ even in possible triple or quadruple points. Here we will to focus the interaction, in terms of cellular-link strength, among natural and chemical stress operating in the non heterogeneous endothelial environment. Particularly, the endothelial cell detachment phenomenon, typical in diabetic patient, about the integrins link can be explained, with sufficient carefulness, through this proposed model. In fact the possible formation of coexistent material phases due to action of mechanical and/or chemical nature can reproduce the integrin link behavior, when undergo to the natural stress (blood flow action) and/or chemical stress (ph variation). Since high deformations in proteins bond has been focused [2] as for proposed in the model make an attempt tentative to model a heterogeneous and complex system. About future issue, we have in progress an extension of the model about numerical implementation by finite element analysis.

Effects Of Mechanical Stimulus On Cells Via Multi-Cellular Indentation Device

Sunhee Kim[1], Jaeyoung Yun[1] and Jennifer H. Shin[1]

[1] Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology (KAIST), Republic of Korea

Abstract — **Mechanical as well as chemical stimulations are considered as a critical factor on cell behaviors. To understand the effects of mechanical stimuli on cells, many researchers have developed either single cell indentation devices to locally stimulate cells or to measure mechanical properties of cells, or compression chambers or bioreactors to apply global compressive pressure on cells. However, none of these previously developed devices are suitable to investigate the cell-cell communications amongst cells upon mechanical stimulation. To accomplish this experimental need, we developed a new cellular compression device using soft-lithography techniques. We fabricated the chamber with transparent Poly-carbonate, which consists of two sections, a self-contained cell incubator and an air chamber, separated by a PDMS membrane. On an incubator side of this PDMS divider, we attach a patterned PDMS sheet of micro poles mounted on a glass to ensure a uniform displacement of the array of poles to stimulate cells when the air chamber is pressurized. The cell incubator chamber is filled with medium and connected to a self contained incubation system to supply fresh culture medium to cells providing a stable culture environment during the experiments. The operating power is an air pressure applied on the air chamber side of the PDMS membrane. By controlling the air pressure, this device can stimulate cells in cyclic or continuous conditions. Also as cells are cultured in a form of single layer, it allows us to investigate cell-cell communications amongst cells that are under stimulated or non-stimulated conditions. Using this noble device, we investigated protein responses in keratinocytes, one of the mechano-sensitive cells. Preliminary results have shown the versatility of this compression device in studying cellular responses, thus demonstrating the feasibility of this tool as to be utilized in evolving cell mechanics research.**

Keywords — **keratinocyte, mechanical stimulation, cell compression, soft-lithography, PDMS**

I. Introduction

Skin is the largest organ which covers all the outer surface of the body. Keratinocyte forms an outmost layer of the skin called epidermis. Epidermis is divided into 5 layers based on the morphology and differentiated stages of keratinocyte. Keratinocytes originate in the stratum basal which is located adjunction to the dermis layer. They differentiate from the keratinocyte stem cells, and undergo subsequent differentiation through the layers of the epidermis. As a mechanical barrier and sensor, skin tissue is continuously exposed to the mechanical stimulation such as compression, tension and shear stress. Since keratinocyte is generally exposed to the compression, the investigation of the responses of keratinocytes under compression would be important. Many compression devices have been developed to investigate the cellular responses under compression, which can be categorized into two categories, which are single cell compression device [1-3] and multi-cell compression device. [4, 5] These devices are designed to investigate the intercellular responses or protein responses on a compression conditions. However, in order to understand the cell-to-cell communication which is important for a physiological response, these devices are not suitable. Therefore we developed a novel device which can apply compression to desired cells in the cell monolayer. The primary objective of this study is to develop an adequate device and to investigate the effects of in vitro mechanical compression on keratinocyte.

II. Device design and fabrication

A. Design of cell stimulation chamber

Conceptual design of the cell stimulation is shown in the figure 1. This device is designed as multi-cellular stimulator which can apply compressions on the cell monolayer in vitro. We use PDMS (poly-demethyl-siloxane) polymer poles to stimulate cells directly. By changing the geometry of this PDMS poles, we can apply compressions to the cells while not affecting the surrounding cells. PDMS pole array is manufactured using SU-3 molding fabricated with soft-lithography technique. Poly-carbonate chamber is designed for observation of cellular response inside the device.

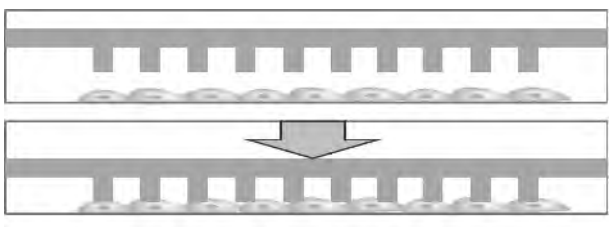

Figure 1. Conceptual design of multi-cellular compression device

www.springerlink.com

B. Design of integrated system

Figure 2 shows a schematic diagram of the experimental setup for the compression device system. Air pressure is utilized as the system input, controlled by syringe pump. As air enters into the chamber, PDMS membrane deforms and PDMS poles get to the bottom where cells are cultured. Therefore, cells exposed to the direct mechanical compression. After stimulation, air goes out and PDMS membrane restores original state releasing compression on cells. Having these two steps repeatedly, we can generate dynamic compression condition. For a typical cell culture condition, the cell culture medium is supplied in the chamber. To meet the temperature and pH requirements for cell culture system, we utilize water bath and CO2 tank to supply medium at adequate condition to the cultured cell layer.

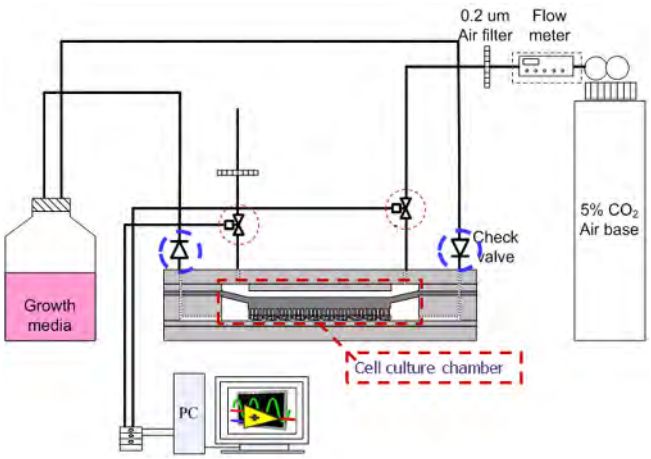

Figure 2. Schematic diagram of multi-cellular compression system

C. FEM simulation

The analysis of deformation and stress of PDMS membrane and poles is performed using FEM (finite element modeling) simulation tool ABAQUS. Simulation is done at various geometric condition of glass support and various pressure conditions to examine which design would be appropriate to the cellular compression device while minimizing the deflection of membrane and maintaining the uniform compression at the attached poles. FEM simulation results are shown in Figure 3.

We measure the PDMS membrane property using dynamic mechanical analyzer. As a result, we obtain PDMS membrane elastic modulus. Since PDMS did not appear to exhibit significant hysteresis, creeping or stress relaxation, we safely assume the PDMS membrane as a purely elastic material for FEM simulation.

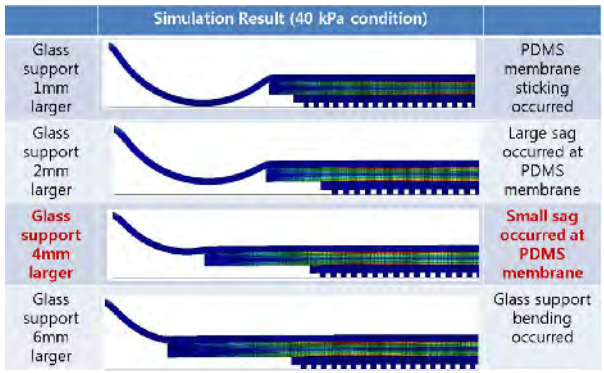

Figure 3. Simulation result of PDMS membrane deformation

III. Conclusions

With the developed multi-cellular compression device, static and dynamic compression is possible using finite pressure controller. By changing the geometry of PDMS poles, this device can be used to apply global and local compression stimulation.

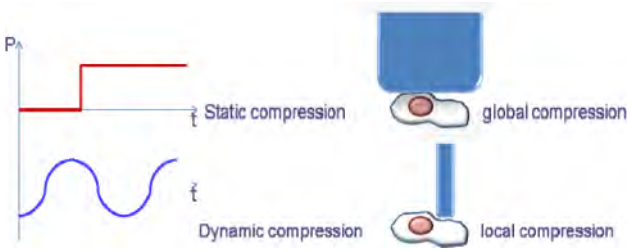

Figure 4. various compression conditions

Various conditions of compression effects on cell morphology and viability are also tested. Preliminary results have shown that this compression device is successfully designed to investigate cellular responses, particularly cell-cell communications. Thus, we demonstrate the feasibility of this tool as to be utilized in evolving cell mechanics research.

The Effect of Tumor-Induced Bone Remodeling and Efficacy of Anti-Resorptive and Chemotherapeutic Treatments in Metastatic Bone Loss

X. Wang[1], L.S. Fong[2], X. Chen[3], X. Yang[4], P. Maruthappan[5], Y.J. Kim[6], T. Lee[7]

[1-7] Division of Bioengineering, National University of Singapore, Singapore

Abstract — **We investigated the changes in bone geometrical properties due to tumor-induced osteolysis and the efficacy of two different treatments, Ibandronate (anti-resorptive) and Paclitaxel (anti-cancer), in an experimental rat model. Osteolytic Walker 256 (W256) carcinosarcoma cells were surgically implanted into the right femur of 30 male Sprague Dawley rats, while another 12 received sham operation. Of the 30 tumor-bearing rats, 12 were untreated, 9 were administered with Ibandronate and 9 with Paclitaxel. Both femora were scanned using micro-computed tomography (micro-CT). Serum DPD (deoxypyridinoline) concentration was monitored via regular blood collection to observe the progress of bone resorption. Localized tumor growth in the distal femur was successfully induced in this rat model. Bone volume analysis indicated no bone loss in the sham-operated femora for the control group and in the tumor-bearing femora for the Ibandronate-treated group. However, a significantly lower bone volume by average 10.7% was observed in the operated as compared to the intact femur for the tumor-bearing untreated group, corresponding to a 13.4% increase in DPD concentration after 30 days. For the Ibandronate-treated group, bone volume was the highest for both femora and DPD concentration showed a drastic reduction of 38.2% after 30 days. Bone loss in the Paclitaxel-treated group seemed lower than in the tumor-bearing untreated group but there was a discrepancy between serum DPD concentration and micro-CT results, possibly due to incomplete data (rat mortality). Based on this experimental rat model with tumor-induced osteolysis, Ibandronate was more effective than Paclitaxel in reducing the rate of bone resorption, and hence preserving the structural integrity of the femur. This study has demonstrated the use of serum analysis and micro-CT as tools to monitor the biochemical and structural changes that accompany tumor-induced osteolysis respectively.**

I. Introduction

Bone metastasis is a common occurrence in many malignancies, especially in breast, prostate, thyroid, kidney, bladder and lung cancers [1] Although not life-threatening in itself, refractory pain, hypercalcaemia, pathologic fractures, and neurological symptoms are associated skeletal complications that can lead to significant morbidity and diminished quality of life in patients with bone metastatic disease. [1] Prostate and thyroid cancer patients typically survive for 2-3 years and breast cancer patients survive for approximately two years after metastatic lesions have been diagnosed. [2] Thus, it has become increasingly important to investigate treatments for the skeletal complications of metastatic bone disease given that breast and prostate cancer are relatively common and long drawn. [2]

Most bone metastases are osteolytic; tumor cells upset normal homeostasis in the bone remodeling process by promoting osteoclast formation and activity, thereby accelerating the rate of bone resorption. [3] Tumor-induced osteolysis results in a loss of structural integrity and correspondingly, increases the incidence of complications such as pathologic fractures.

In this pilot study, using an animal model of tumor-induced osteolysis, we aimed to evaluate the effects of osteolytic metastatic tumors in long bone on bone structural properties. In addition, the other goal was to assess the efficacy of two different treatments – Ibandronate (IBAN), an anti-resorption potent bisphosphonate, as well as Paclitaxel (PAC), an anti-tumor chemotherapeutic drug, in preserving the structural integrity of tumor-induced osteolytic bone. A bone resorption marker and micro-computed tomography were used as tools to monitor the changes.

II. Materials and Methods

A. Animals

Forty two 8-10 week-old male Sprague-Dawley (SD) rats were randomly divided into four experimental groups (Table 1). The animals in the control groups were sham-operated, while those in the tumor-only, IBAN, and PAC groups had W256 cells implanted into the medullary canal of their right femur. The tumor-only groups received no treatment after surgery; the IBAN and PAC groups were administered with Ibandronate and Paclitaxel respectively post-surgery. Three animals from each group were euthanized every 10 days post-surgery. Two animals died due to anesthetic boosters; one from the control 0-day group and the other from the PAC 30-day group. Three animals died on the 15th day post-surgery after PAC injection; two from

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1952–1956, 2009
www.springerlink.com

the PAC 30-day group and one from the PAC 20-day group. Results from these five animals were thus not available. All animals were maintained in accordance with the National Advisory Committee for Laboratory Animal Research Guidelines on the Care & Use of Animals for Scientific Purposes 2004 and the study was conducted with approval of the Institutional Animal Care and Use Committee.

Table 1. Assignment of animals to various groups

Group	0-day	10-day	20-day	30-day
Control	3	3	3	3
Tumor-only	3	3	3	3
IBAN	0	3	3	3
PAC	0	3	3	3

B. Surgery and Serum Collection

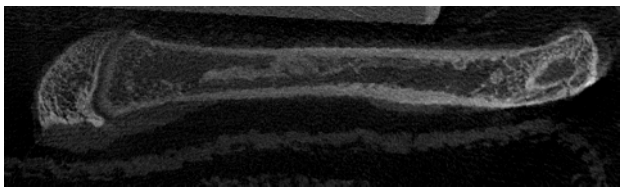
W256 cells were purchased from ATCC and cultured in M199 medium supplemented with 10% horse serum. Approximately 2.5×10^6 cells in saline were surgically implanted into the medullary canal of the right femur. The surgical procedure from Kurth *et al* [4] was referred to, but with modifications made. The animals were anaesthetized via intra-peritoneal injection. The extensor mechanism of the right hind limb was exposed, and a longitudinal medial parapatellar incision was made to dislocate the patellar laterally. A 20G catheter was drilled with a twisting motion through the intercondylar notch into the medullary canal of the right femur. The catheter was pulled out and another 20G catheter attached to a syringe containing the tumor cells was inserted as far proximally as possible into the medullary canal. The hole was sealed with bone wax, the patella was relocated and the soft tissue and skin were closed with 4.0 vicryl sutures after the inoculation. The control group underwent the same surgical procedure except that 0.6% cell-free gelatin was inoculated into the right femur instead [2, 4, 5]. No signs of limping or reduced activeness after the 3-day recovery period were observed.

Blood was collected from the animals at 10-day intervals, starting from the day of surgery till they were sacrificed. The extracted serum was stored at –80ºC. Total serum DPD assay was carried out using Metra® Total DPD EIA Kit.

C. Drug Administration

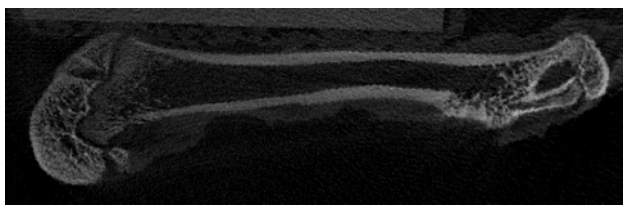
Ibandronate (BONDRONATE injection (6mg/6ml vial), Roche Diagnostics) was diluted by a factor of 5 and the dosage was calculated according to 3.0 ml × body weight / 350g [5]. The drug was administered subcutaneously every ten days starting from the day of surgery. The animals were observed to be normal after Ibandronate administration.

Paclitaxel (ANZATAX injection (30mg/5ml vial), NUH Cancer Centre Pharmacy) was initially diluted by a factor of 5 with saline, as prescribed. The dosage was 10 mg/kg body weight [6] and Paclitaxel was administered intravenously via the lateral tail veins of the rats every ten days, starting five days post-surgery. However, due to observed complications, undiluted Paclitaxel was subsequently administered and the dosage was reduced by a third.



D. Micro-CT and Bone Volume Analysis

After euthanasia, both femora were harvested, cleaned of soft tissue, wrapped in 0.9% saline-soaked gauze and stored at -20ºC. [5] Prior to scanning, the femora were thawed to room temperature (25 ºC). The resolution of the scans was set as 35 μm. An average value of 6 was used for scanning. The scanned images were in TIFF format and had to be reconstructed to BMP format with the SkyScan Cone_rec software. The respective bone volumes for the left and right femora of each rat were analyzed using Volume Graphics (VG) Studio Max software. The images were imported into VG Studio Max after editing using Photoshop. The femora were segmented out of the images and readings of their bone volumes were obtained from the same software.



III. Results

A. Micro-CT Imaging and Bone Volume Analysis

Some abnormality in the medullary cavity of the femur, suspected to be localized tumor growth, was observed in the micro-CT images of the animals with implanted tumor cells (Fig. 1a). In contrast, the medullary cavities of the femora from the control group appeared clear (Fig. 1b).

(a)

(b)

Figure 1. 35 μm/pixel resolution micro-CT sagittal images of (a) an operated femur with tumor cells inoculated (b) an operated femur without tumor cells inoculated

Segmentation was performed by two persons concurrently to reduce subjectivity. Average bone volume values obtained from both were fairly similar, within the range of approximately 4% of the bone volume values. Bone volume of the right operated femur for the IBAN group increased the most, by 42.8% after 30 days. The increase for the control group was 32.3%, similar to the bone volume increase in the left femur. However, the bone volume increase in the right femur for the tumor-only groups was only 7.4% and 18.3% after 20 and 30 days respectively; the increase for the PAC group after 20 days was 13.1%. By comparing bone volume increase in the right femur after 20 days, it appeared that the PAC group still had a larger increase than the tumor-only group (Fig. 2). Also, the tumor-only group showed the largest contra-lateral bone volume difference. Bone volume of the right femur for the 30-day tumor-only group was on average 10.7% (49 mm^3) lower than that of the left femur for the same group (Table 2). Contra-lateral bone volume differences for the other three groups were all within or close to the range of segmentation error. However, the lack of data in the PAC 30-day group made a complete analysis of the 30-day groups not possible.

B. Serum Total DPD Concentration

Serum total DPD concentrations for each rat were normalized against its 0-day reading. The serum total DPD concentration increased after implantation of cancer cells for all tumor-only groups; an average of 26.4%, 22.2%, and 13.7% after 10, 20 and 30 days respectively. It appeared that the increase was already significant after 10 days; this is consistent with the results from bone volume analysis (Table 2). The DPD concentrations for the control group fluctuated from the 0-day value. The total DPD concentration decreased for IBAN group, on an average of 34.2%, 55.3% and 38.1% after 10, 20 and 30 days respectively, despite the presence of tumor. The total DPD concentration for the PAC group did not show a clear trend. Figure 3 shows the changes in serum total DPD for the 30-day groups.

Table 2. Average contra-lateral percentage difference in bone volume

Average % Difference in Bone Volume	Control	Tumor-Only	IBAN	PAC
0-day	4.8	0.5	N.A.	N.A.
10-day	4.1	7.8	2.3	4.2
20-day	3.1	5.3	3.2	5.4
30-day	0.2	10.7	-0.2	*4.1

*Animal died on 15th day

IV. Discussion

Based on comparisons made of the micro-CT images amongst groups, bone volume analysis and serum total DPD data, it is reasonable to conclude that localized bone tumor growth had successfully been induced in the distal femur of the rat, resulting in accelerated bone resorption and subsequent bone loss. Further histomorphometric analysis will be carried out to confirm these findings. The location of the tumor was consistent with the results of a similar study by Kurth *et al*, who detected osteolysis in the distal femur within a 6-mm region from the end of the condyles [7]. Using the method by Fritton *et al* [8], the cross-sectional area in the distal femoral metaphysis (25% of femur length from the distal end) of the left and the right femora in the various 30-day groups were found. The large contra-lateral difference (13.62%) in cross-sectional area for the tumor-only group further confirmed that the tumor was localized in the distal femur (Fig. 4).

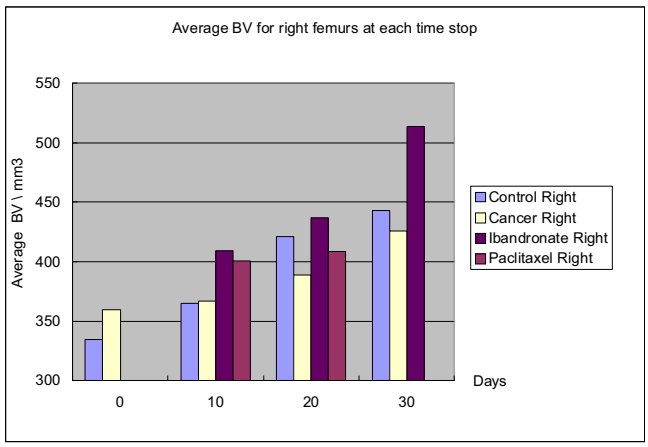


Figure 2. Average bone volume for right femora at each time stop

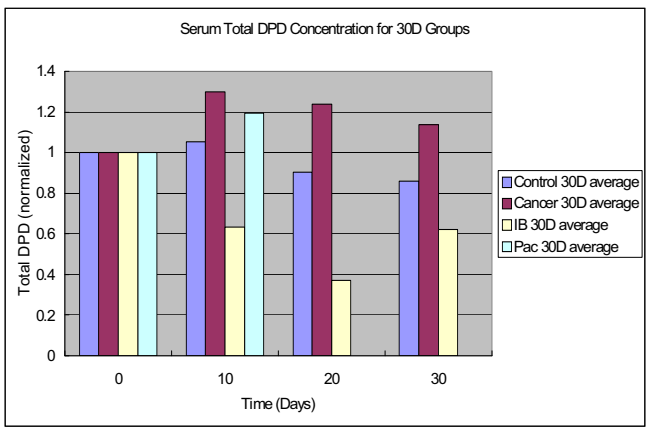

Figure 3. Serum total DPD concentration for 30-day groups

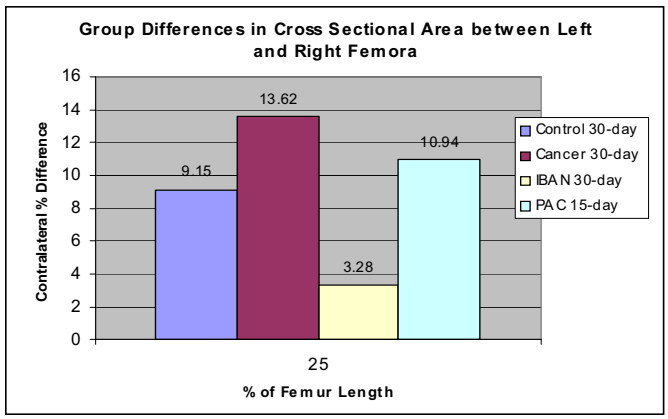

Figure 4. Group percentage difference in cross-sectional area between the left and right femora of animals in the 30-day groups

Bone volume changes in both femora across all groups were within expectation. As the left femur was not operated on, the bone volume increase over the 30-day period were similar for the control, tumor-only and PAC groups. The greater bone volume increase for the intact femur of the IBAN groups was due to the systemic anti-resorptive effect of IBAN. The bone growth in the operated femur of the tumor-only group over the 30-day period was significantly less as compared to the control and IBAN groups because of the increase in tumor-induced osteoclast activity. IBAN seemed to be highly effective in suppressing osteoclast activity; despite the presence of tumor, bone volume of the operated femur increased more than that of the control groups. The small contra-lateral difference in the cross-sectional area of the IBAN 30-day group (3.28%) further supports this observation (Fig. 4). Although there was incomplete data, it could still be deduced that the bone volume increase in the operated femur of the PAC groups was higher than that of the tumor-only groups (Fig. 2). The cross sectional area difference for the PAC group was also lower than that of the tumor-only group. The efficacy of PAC in reducing osteolysis in bone metastasis is evident here. The highest contra-lateral bone volume difference in the tumor-only group suggests highest osteoclast activity rate, resulting in greater bone loss.

Interestingly, in a separate study involving the same rat femora, using the three-point bending test, it was found that stiffness of the operated femora was best preserved in the PAC group. It was inferred that IBAN is more effective than PAC in reducing the rate of bone resorption, and thus preserves the structural integrity of bone better; however, it is not as effective as PAC in maintaining the biomechanical properties of bone.

The serum total DPD assay results were generally consistent with the bone structural analysis. Animals that received IBAN treatment showed significantly lower serum DPD levels as expected. However, PAC appeared to have no effect on bone resorption, contradicting the findings from bone volume and cross sectional area analysis. This is likely due to incomplete data available from the PAC groups.

The main aim of this pilot study was to establish and refine protocols. A larger sample size would be used in the subsequent study. In addition, combined concurrent treatment of Ibandronate and Paclitaxel will be investigated as previous studies have showed that the concurrent administration of both drugs has an additive effect in preventing metastatic bone loss [6, 9]. The combination of these two drugs in treating metastatic osteolysis seems promising.

V. Conclusions

The goal of this pilot study was to investigate the effect of tumor-induced bone remodeling, as well as the efficacy of Ibandronate and Paclitaxel in preventing metastatic bone loss. Based on this experimental rat model with tumor-induced osteolysis, Ibandronate was more effective than Paclitaxel in reducing the rate of bone resorption, and hence preserving the structural integrity of the femur. This study has demonstrated the use of serum analysis and micro-CT as tools to monitor the biochemical and structural changes that accompany tumor-induced osteolysis respectively.

Acknowledgment

The authors wish to express sincere appreciation for the guidance by Dr. Lee Taeyong, and for the assistance by Mr. Si-hoe Kuan Ming, Dr. Barry Pereira and Mr. Zou Yu.

Mathematical Modeling of Temperature Distribution on Skin Surface and Inside Biological Tissue with Different Heating

P.R. Sharma*, Sazid Ali* and V.K. Katiyar**

*Department of Mathematics, University of Rajasthan, Jaipur, India
**Department of Mathematics, Indian Institute of Technology Roorkee, Roorkee, India

Abstract — **Aim of the paper is to investigate thermal behaviors in living tissues subject to constant, sinusoidal, step surface heating and point or stochastic heating with the thermal model of bioheat transfer which are often encountered in cancer hyperthermia, laser surgery, thermal comfort analysis and tissue thermal parameter estimation etc. The Pennes bioheat transfer equation, which describes the exchange magnitude of heat transfer between tissue and blood, is widely used to solve the temperature distribution for thermal therapy. The analytical solution of bioheat transfer equation is determined by using Green's function method with surface heating conditions which describes the transient temperature response on the skin surface and inside the biological tissue. It is observed that the thermo mechanical behavior of skin tissue is very complex; blood perfusion has little effect on thermal damage but large influence on skin temperature distribution.**

Keywords — **Bioheat transfer, biological tissues, surface heating, Green's function method**

I. Introduction

Hyperthermia treatment has been demonstrated as effective during cancer therapy in recent years. The primary objective of hyperthermia treatment is to raise the temperature of pathological tissue above cytotoxic temperature (41- 45^0C) without overexposing healthy tissues [1,2]. Hence for process control, it is important to obtain a temperature field of entire treatment region with knowledge of the entire temperature field in treatment region. The microwave [3], the laser[4] and the ultrasound [5] etc. are popular apparatus used for a spatial heating for treating the tumor in the deep biological body. Heat transfer analysis on these thermal medical problems usually has to simultaneously face transient or spatial heating both on skin surface and in interior of biological bodies [6-8]. The Pennes bioheat transfer equation, which describes the exchange magnitude of heat transfer between tissue and blood, is widely used to solve the temperature distribution for thermal therapy [9]. Also, the Pennes bioheat transfer equation is based on the assumption that all heat transfer between the tissue and the blood occurs in the capillaries. For sinusoidal heating on the skin surface problem, Liu and Xu [10] presented a closed form analytical solution of Pennes bioheat transfer equation, which is suitable for the long run steady periodic temperature oscillation. However, their analytical solution cannot satisfy the starting transient temperature response. The Green's function method was used to solve Pennes bioheat transfer; therefore it can be flexibly used to calculate temperature distribution for various spatial or temporal source profiles. Furthermore, the Green function method is capable of dealing with transient or space dependent boundary conditions.

In past, a few authors have applied Green's function method to solve Pennes bioheat transfer. Goe et al. [11] contributed to this field by using Green's function method and Fourier transform method. Liu et al.[3] derived the solution to heat transfer in cylindrical canine prostate centrally cooled by a flowing water. Zhu et al. [12] applied the Green.s function method to solve a series of steady state bioheat transfer problem, in which the Pennes's perfusion term was not included.. Durkee et al. [13] addressed the time-dependent Pennes equation in one dimensional multiregion Cartesian and spherical geometry based on method of separation of variables and Green's function method. The objective of the present paper is to investigate an analytic solution of Pennes's equation, which can be applied to study several selected typical bioheat transfer processes often encountered in cancer hyperthermia, laser surgery and thermal parameter estimations etc.

II. Mathematical model

The generalized one dimensional Pennes bioheat transfer equation following [9] is given by

$$\rho_t C_t \frac{\partial T_t}{\partial t} = \kappa \frac{\partial^2 T_t}{\partial x^2} + \omega_b \rho_b C_b \left(T_a - T_t\right) + Q_m + Q_r\left(x,t\right) \qquad (1)$$

ρ_t, C_t, κ are respectively the density, the specific heat, and the thermal conductivity of the tissue; C_b, ρ_b denote density and specific heat of blood; ω_b the blood perfusion; T_a the arterial blood temperature which treated as constant, and T_t the tissue temperature; Q_m the metabolic heat generation, and $Q_r\left(x,t\right)$ the external spatial heating.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1957–1961, 2009
www.springerlink.com

During the heat transfer process, the boundary condition at the skin surface is often time dependent, which can be generalized.

$$-\kappa\frac{\partial T_t}{\partial x}=\phi_1(t) \quad \text{when} \quad x=0, \tag{2}$$

where $\phi_1(t)$ is the time-dependent surface heat flux. Since biological body tends to keep its core temperature to be stable, therefore the body core temperature (T_c) is regarded as a constant and given by

$$T_t(x,t)=T_c \quad \text{when} \quad x=L. \tag{3}$$

III. Analytical solution

The initial temperature field for the steady state biological tissue can be obtained through solving the following equation (4) and boundary conditions (5) as given by

$$\kappa\frac{d^2T_t(x,0)}{dx^2}+\omega_b\rho_bC_b\left(T_a-T_t(x,0)\right)+Q_m=0, \tag{4}$$

$$T_t(x,0)=T_c \quad \text{when} \quad x=L,$$

$$-\kappa\frac{dT_t(x,0)}{dx}=h_0\left[T_s-T_t(x,0)\right] \quad \text{when} \quad x=0, \tag{5}$$

where $T_t(x,0)$ is the steady state temperature field, T_c body core temperature often as constant, h_0 heat convection coefficient between the skin surface and surrounding air under physiologically steady state. T_s the surrounding air temperature. Here, the skin surface is defined at $x=0$ while the body core at $x=L$. Through straight forward calculations, the solution of the equation (4) is known and given by

$$T_t(x,0)=T_a+\frac{Q_m}{\omega_b\rho_bC_b}+\frac{\left(T_c-T_a-\frac{Q_m}{\omega_b\rho_bC_b}\right)\left[\sqrt{A}\cosh\left(\sqrt{A}x\right)+\frac{h_0}{\kappa}\sinh\left(\sqrt{A}x\right)\right]}{\sqrt{A}\cosh\left(\sqrt{A}L\right)+\frac{h_0}{\kappa}\sinh\left(\sqrt{A}L\right)} \tag{6}$$

$$+\frac{\frac{h_0}{\kappa}\left(T_s-T_a-\frac{Q_m}{\omega_b\rho_bC_b}\right).\sinh\left(\sqrt{A}(L-x)\right)}{\sqrt{A}\cosh\left(\sqrt{A}L\right)+\frac{h_0}{\kappa}\sinh\left(\sqrt{A}L\right)},$$

where. $A=\frac{\omega_b\rho_bC_b}{\kappa}$

Applying transformation presented by Carslaw and Jaeger [16],

$$T_t(x,t)=T_t(x,0)+R(x,t)\exp\left(-\frac{\omega_b\rho_bC_b}{\rho_tC_t}\right)\cdot \tag{7}$$

Now, the equation (1) is reduced to

$$\frac{\partial R}{\partial t}=\alpha\frac{\partial^2R}{\partial x^2}+\frac{Q_r(x,t)}{\rho_tC_t}\exp\left(\frac{\omega_b\rho_bC_b}{\rho_tC_t}\right), \tag{8}$$

where $\alpha=\kappa/\rho_tC_t$ is thermal diffusivity of tissue.

The corresponding initial and boundary conditions are reduced to

$$\text{when} \quad x=0: \quad -\kappa\frac{\partial R}{\partial x}=\psi_1(t),$$

$$x=L: \quad R=0,$$

$$t=0: \quad R(x,t)=0, \tag{9}$$

where,

$$\psi_1(t)=\left[\kappa\frac{dT_t(x,0)}{dx}\bigg|_{x=0}+\phi_1(t)\right]\exp\left(\frac{\omega_b\rho_bC_b}{\rho_tC_t}t\right)H(t),$$

and

$H(t)=\begin{cases}0, t<0\\ 1, t>0\end{cases}$ is the Heaviside function.

If the Green's function method for above equation system is obtained, then its transient solution can thus be constructed [14,15]. Through introducing an auxiliary problem corresponding to equations (8), the Green'sfunction G can be finally be obtained as:

$$\frac{\partial G}{\partial t}-\alpha\frac{\partial^2G}{\partial x^2}=\delta(x-\xi)\delta(t-\tau), \quad 0<x,\xi<L, \quad t,\tau>0 \tag{10}$$

with boundary conditions

$$a_1G(0,t|\xi,\tau)+b_1G_x(0,t|\xi,\tau)=0, \quad t>0,$$

and

$$a_2G(L,t|\xi,\tau)+b_2G_x(L,t|\xi,\tau)=0, \quad t>0, \tag{11}$$

and the initial condition

$$G(x,0|\xi,\tau)=0, \quad 0<x<L, \tag{12}$$

Applying Laplace Transform to the eqn. (10) and the boundary conditions (11), we get

$$\frac{d^2\overline{G}}{dx^2}-\frac{s}{\alpha}\overline{G}=-\frac{\delta(x-\xi)}{\alpha}e^{-s\tau}, \quad 0<x<L, \tag{13}$$

$$a_1\overline{G}(0,s|\xi,\tau)+b_1\overline{G'}(0,s|\xi,\tau)=0 \tag{14}$$

and

$$a_2\overline{G}(L,s|\xi,\tau)+b_2\overline{G'}(L,s|\xi,\tau)=0 \tag{15}$$

Applying eigen function expansion technique as given below

$$\overline{G}(x,s|\xi,\tau)=e^{-s\tau}\sum_{n=1}^{\infty}\frac{\varphi_n(\xi)\varphi_n(x)}{s+\alpha\beta_n^2}, \tag{16}$$

where $\varphi_n(x)$ is the nth *orthonormal* eigen function to the regular Strum-Liouvlle problem as given by

$$\varphi''(x)+\beta^2\varphi(x)=0, \quad 0<x<L, \tag{17}$$

subject to the boundary conditions

$$\varphi(0)=\varphi(L)=0,$$

where

$$\varphi_n(x)=\sqrt{\frac{2}{L}}\cos\left(\frac{2n-1}{2L}\pi x\right). \tag{18}$$

Taking Inverse Laplace transform of (16), we get

$$G(x,t|\xi,\tau)=\frac{2}{L}\sum_{n=1}^{\infty}e^{-\alpha\beta_n^2(t-\tau)}.\cos\beta_n x.\cos\beta_n\xi.H(t-\tau), \tag{19}$$

where $\beta_n=\frac{2n-1}{2L}\pi, n=1,2,3,.....$

Through straight forward algebra, the solution of the eqn. (8) under the boundary conditions (9) is known and given by

$$R(x,t)=\frac{\alpha}{k}\int_0^t G(x,t/\xi,\tau)\Big|_{\xi=0}\psi_1(\tau)d\tau + \int_0^t d\tau\int_0^L G(x,t/\xi,\tau).\frac{Q_r(\xi,\tau)}{\rho_t C_t}\exp\left(\frac{\omega_b\rho_b C_b}{\rho_t C_t}\tau\right)d\xi. \tag{20}$$

Finally, the solution of $T_t(x,t)$ is constructed in the form given below

$$T_t(x,t)=T_t(x,0)+R(x,t)\exp\left(-\frac{\omega_b\rho_b C_b}{\rho_t C_t}\right). \tag{21}$$

IV. Results and Discussion

The typical values for tissues properties and other parameters are used as given by [16]. Specific heat of tissue and blood are 4200 J/Kg.^{0}C, density of tissue and blood are 1000 Kg/m^3, arterial blood temperature and body core temperature are 37 T^{0}C, thermal conductivity of tissue is 0.5 W/m.^{0}C, blood perfusion is 0.0005 ml/s/ml, metabolic heat generation is 33800 W/m^3, heat convection coefficient is 10 W/m^2.^{0}C, surrounding air temperature is 25 T^{0}C. As demonstrated in earlier works by [10], the interior tissue temperature usually tends to a constant within a short distance, such as 2-3 cm, therefore L=3 cm was used in this study. For some particular issue, such as deeper heating, or more intense source of heat, the distance between skin surface and the body core will exceed this depth. In this case, new bounded core large enough to neglect the influence of the surface heating showed be in corporate into the calculations. Although any heating style for $Q_r(x,t)$ can be dealt with present analysis, only the most popular and simple specific absorption rate (SAR) expression for $Q_r(x,t)$ will be particularly analyzed. For the plane wave heating of laser or microwave, the heat absorption in the muscle tissue can simply be approximated by Beer's law as [17].

$$Q_r(x,t)=\eta P_0(t)\exp(-\eta x) \tag{22}$$

where $P_0(t)$ is the time dependent heating power on skin surface and η is the scattering coefficient. Since the heating power and the scattering coefficients may vary from one heating apparatus to another, it is of great importance to study the influence of these parameters upon the behavior of the tissue temperature. Such heating pattern can be encountered in tissue heating by laser, microwave or ultrasound, etc. Our study is expected to be very useful in a large variety of biothermal process.

V. Bioheat Transfer in Tissue

A. Surface adiabatic condition and spatial heating

Fig.1&2 shows that the transient temperature at different times of skin surface when biological tissues subject to two different spatial heating and skin surface was treated as

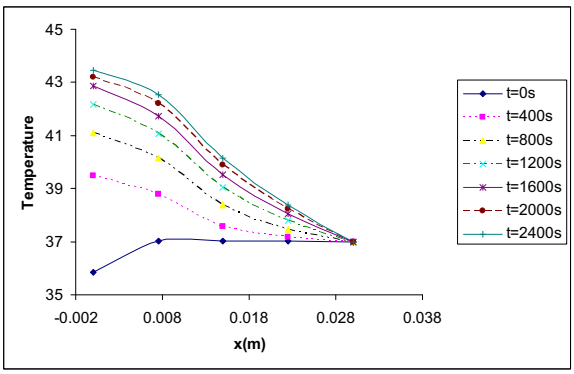

Fig.1 Temperature (T^{0}C) distribution versus x when η=200 m^{-1}, $\phi_1(t)$=0 and $P_0(t)$=250 W/ m^2.

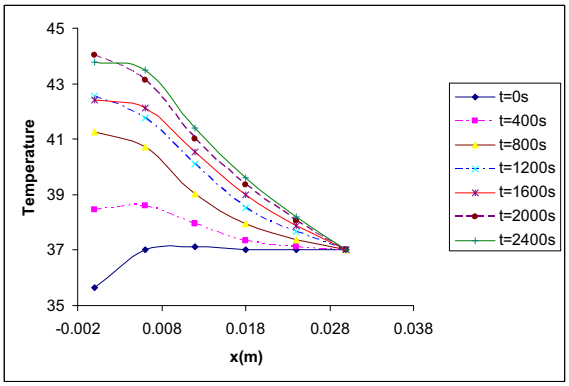

Fig.2 Temperature (T^0C) distribution versus x when η =200 m^{-1}, $\phi_1(t)$ =0 and $P_0(t)$ =250 + 200 cos(0.02t) W/ m^2 .

adiabatic i.e. $\phi_1(t)$ =0. Fig.1 depicts the case of constant heating and the Fig.2 the case of sinusoidal heating. The former one reflects the solution where the human skin is heated by a laser, while the later case can be found in the perfusion estimation. Obviously, in both the cases, the temperature at early stage of heating decreases from the body core to the skin surface. However, it will gradually be improved due to the spatial heating. Moreover there is an intercross for temperature curves at the different times in Fig.2, which indicates the temperature oscillation inside the tissue when subjected to the sinusoidal heating.

B. Effect of the scattering coefficient

Fig.3 depicts that the effect of the scattering coefficient on the temperature transient at the skin surface. It shows

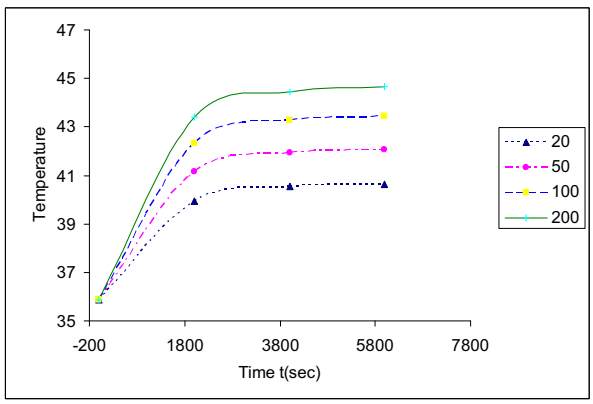

Fig.3 Effect of scattering coefficient (η) on temperature (T^0C) response at skin surface when $\phi_1(t)$ =0 and $P_0(t)$ = 250 W/ m^2 .

that the larger coefficient, the higher temperature increases. For the other heating frequencies, the corresponding thermal responses can also be studied using the same way. Since different heating apparatus such as laser or microwave may have different power and scattering coefficient, calculations as performed above are expected to be useful for the heating dose planning during hyperthermia treatment or parameters estimation. For example, performance of the different heating apparatus with specific power and decay coefficient can be evaluated using the present model to predict the temperature response thus induces in the tissue.

C. Effect of surface constant heating

It is observed from fig.4 that the temperature response at skin surface, C1, C2 and C3 are the transient temperature of tissues subject to the constant surface heating; $\phi_1(t)$ =1000 W/ m^2 , $\phi_1(t)$ =500 W/ m^2 , $\phi_1(t)$ =200 W/ m^2 , respectively. Obviously, the larger surface heating, the higher temperature increases. Such information is also very important for thermal comfort evaluation.

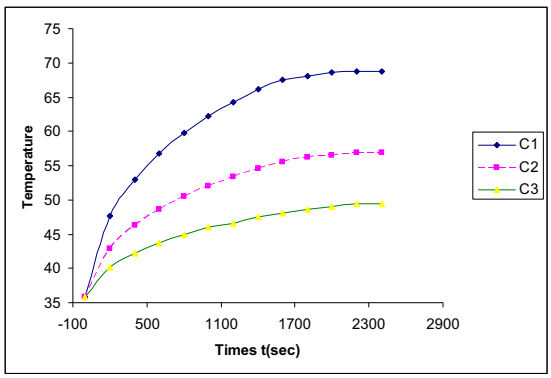

Fig.4 Effect of surface heat flux to skin surface temperature (T^0C) response when $P_0(t)$ = 250 W/ m^2 and η =200 m^{-1} .

D. Effect of step heating at skin surface

It is noted from fig.5 that the highest temperature increase appears at the time when the surface heating was stopped. For the case of blood perfusion ω_b =.004 ml/s/ml, at the end of the step heating, the tissue temperature will quickly reach a steady state. The result can help to better understand the temperature history of living tissues subject to step heating and thus benefit the thermal injury analysis.

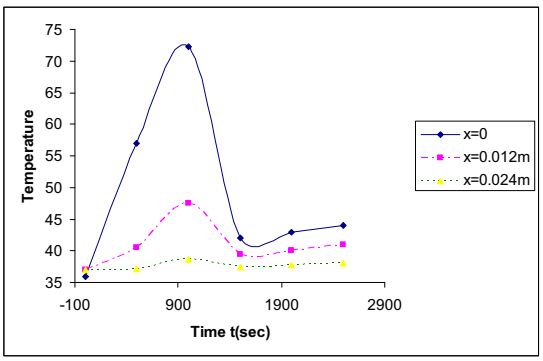

Fig.5 Transient temperature (T^0C) when step heating is applied (subjected to constant spatial heating) and ω_b =.004 ml/s/ml.

VI. Conclusions

The temperature distribution with spatial or transient heating on skin surface and inside the biological bodies are considered. The exact solution of the Pennes bioheat transfer equation with the time-dependent boundary heating condition on the skin surface is derived using Green's function method. The analytical expression obtained is useful for describing the tissue temperature distribution in one dimension domain, and especially it is more accurate that the results of the previous results in initial period of time domain. The time dependent heating condition, which can be dealt with by the present solution included most of the possible external heating style such as constant, sinusoidal, step heating both in volume and at boundary. Moreover, based on the requirement for the tumor killing temperature and the skin burn threshold, an approach to optimize the cancer hyperthermia parameters can be obtained using the current solution. Therefore the present investigation has more capability to deal many practical bioheat transfer problems than quite a few existing analytical solutions.

Net Center of Pressure Analysis during Gait Initiation in Patient with Hemiplegia

S.H. Hwang[1], S.W. Park[1], H.S. Choi[1] and Y.H. Kim[2]

1 Department of Biomedical Engineering, Yonsei University, Wonju-City, South Korea
2 Institute of Medical Engineering in Yonsei University and Department of Biomedical Engineering, Yonsei University, Wonju-City, South Korea

Abstract — **Gait initiation is a transitional process from the balanced upright standing to the beginning of steady-state walking. Steady-state walking represents the start of repeated gait pattern with steady-state walking speed within one gait cycle. Hemiplegic patients' gait initiation was analyzed using the 3D motion analysis system synchronized with 2 force plates. The first vertex(V1) in the CoP trajectory was placed on the lateral-posterior point from the leading limb side, and the third vertex(V3) was placed on the lateral-anterior point from the trailing limb side in the CoP of the normal gait initiation. However, V1 was not nearly shown and V3 was placed on the posterior from the trailing limb side in the CoP of the hemiplegic gait initiation. The time and distance from the onset to the toe-off(P1) and from the toe-off to the initial contact(P2) were analyzed that the mean time was larger and the mean distance was shorter when the affected limb was leading limb. The net CoP data obtained on gait initiation with hemiplegic patients suggest that they compensated with different strategies with respect to the limb whether it was leading limb or trailing limb for their impairment.**

Keywords — **Gait initiation, Hemiplegic patient, Net center of pressure**

I. Introduction

Gait initiation is the transitional phase between static balance in upright position and the start of steady-state walking. It is a complicated process with the neuromusculoskeletal systems to control the body against a perturbated situation[1]. There were a lot of studies with respect the gait initiation (e.g. the net center of pressure analysis, the electromyogram of the lower muscles, kinematic and kinetic analysis about the lower extremities).

A.H Vrieling measured the temporal parameters and the center of pressure(COP) when the gait was initiated with dominant foot or non-dominant foot[3]. Marketta Henriksson compared the gait initiation between young and old people by measuring the electromygram(EMG) and ground reaction forces(GRF)[4]. Sandhiran Patchay studied about the positions of the gait initiation which were added more load on the lower limbs by measuring the GRFs and net COP[5]. Carrie Stackhouse measred the GRF and muscle activation to investigate the gait initiation of children with cerebral palsy[6].

Self-triggered gait initiation and reactiontime gait initiation (cued by a ''beep'' sound) were performed by A. Delval[7]. Falls occur most frequently in people who have lack of muscle force, lack of flexibility, unstable posture, problem in cognition[8,9]. Stroke patients have the most dangerous risk factors to fall in the rehabilitation ward. It is reported that hemiplegic patients has 35% of ratio among all fall accidents[10,11]. Decrease of ability to contract muscles voluntarily, abnormality in muscle activation, deterioration of perception and cognition can cause the fall in patient with hemiplegia[12]. Hemipretic patients often show an asymmetric motion pattern, which has repeatedly been demonstrated in the context of standing, walking, getting up, and sitting down. The asymmetry affected the gait initiation thus hemiparetic patients initiate the gait using abnormal postural control strategies. In this study, the trajectory of the COP was investigated during hemiparetic patients' gait initiation to understand what strategies were used when they initiated the gait.

II. Methods

A. Subjects

Four patients with hemiparesis and thirteen healthy adults volunteered to undergo motion capture experiments during gait initiation task. Patients were fifties who has 30 cadences with mean gait speed and pathologic gait pattern of circumduction gait.

B. Experiments

Two forceplates synchronized with the three dimensional motion analysis system(VICON612, UK) were used in this study. The subjects were required to stand on the forceplates quietly, and then they initiated gait voluntarily with comfortable speed. They were just controlled to lead affected side or non-affected side.

C. The net center of pressure (net COP)

The net COP during double limb support periods could be calculated using data from two forceplate forms as follows.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1962–1964, 2009
www.springerlink.com

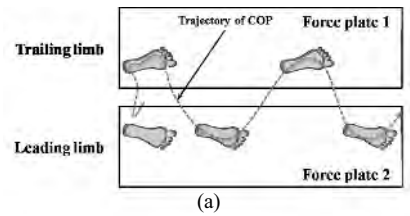
$$COP_{\neq t(x,y)} = COP_{LL(x,y)} \frac{F_{z,LL}}{F_{z,LL} + F_{z,TL}} + COP_{TL(x,y)} \frac{F_{z,TL}}{F_{z,LL} + F_{z,TL}}$$

$COP_{LL(x,y)}$: COP of leading limb(LL)

$COP_{TL(x,y)}$: COP of trailing limb(TL)

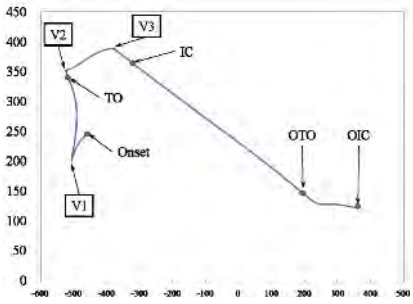
$F_{z,LL}$: vertical component of GRF on LL side

$F_{z,TL}$: vertical component of GRF on TL side



The X axis was defined as anterior-posterior direction and Y axis was medio-lateral, and Z axis was defined as the vertical direction.

D. Analysis of data



The gait initiation starting point(onset) was defined by the change of vertical GRF.

III. Results

Fig. 1 shows the trajectory of COP during the gait initiation of healthy subjects. The COP moved from onset point to posterior side of LL and then moved to TL side after showing the peak point of V1. Then, COP moved to posterior of TL and showed V2 between toe-off(TO) and initial contact(IC). Before the first initial contact of LL, the COP moved maximally to TL side(V3). After the V3, the COP trajectory showed sinusoidal features.

(b)

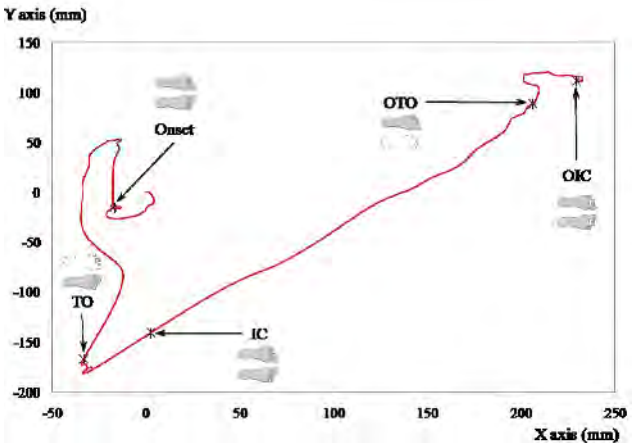

Fig. 1 (a), (b) Trajectory of the net CoP for normal subjects during gait initiation

Fig. 2 (a), (b) shows the trajectory of COP during the gait initiation of patients. The characteristics of the COP when the LL was the affected side were that the first vertex after the onset(V1) was not observed and V3 was observed at the posterior side of the TL. When the LL was unaffected side, the V1 of COP was observed and the V3 was observed on the anterio-lateral side from TL just like those of the healthy subjects'. However, the distance between V1 and onset point was different from that of healthy subjects' and curves between V1 and V2 were quite different. Moreover, the trajectory of the COP had lots of oscillation in both when the LL was affected side and unaffected side.

The mean time and distance while the COP moved from onset to TO(P1), from TO to IC(P2) showed in table 1 and 2. The P1 was 0.49±0.08s and P2 was 0.45±0.05s in healthy subjects. P1 and P2 in patients were variable with respect to the LL. P1 was 1.23±0.31s, P2 was 0.90±0.17s when the LL

(a)

(b)

Fig. 2 Trajectory of the net CoP for a hemiplegic patient during gait initiation with the affected limb(a) and with the unaffected limb(b)

was the affected side. P1 was 0.91±0.16s and P2 was 0.27±0.02s when the LL was the unaffected side.

The distances of COP in healthy subjects were 122.19±18.35mm in P1, and 141.08±16.57mm in P2. In patients, the distance of COP was 101.44±8.37mm in P1, 31.15±4.59mm in P2 when the LL was the affected side. And the distance of COP was 162.72±16.05mm in P1, 20.59±4.09mm in P2 when the LL was the unaffected side. The time of P1, P2 and the distance of P1, P2 in patients were different significantly from that of healthy subjects. In addition, they have differences between affected side and unaffected side. The P1 time was longer when the LL was affected side than the LL was unaffected side because the hemiplegic patients' ability to support the body weight might be better in unaffected side than affected side. On the other hand, P1 time was longer when the LL was the unaffected side because the affected limb had less ability to support body weight(the body weight needs to be moved to the affected side before the TO).

Table 1 Time of P1 and P2 (sec)

	Rt. Hemiplegic Patient				Normal	
	Rt. leading		Lt. leading			
	Mean	S.D.	Mean	S.D.	Mean	S.D.
P1	1.23	0.31	0.91	0.16	0.49	0.08
P2	0.90	0.17	0.27	0.02	0.45	0.05

Table 2 Time of P1 and P2 (sec)

	Rt. Hemiplegic Patient				Normal	
	Rt. leading		Lt. leading			
	Mean	S.D.	Mean	S.D.	Mean	S.D.
P1	101.44	8.37	162.72	16.05	122.19	18.35
P2	31.15	4.59	20.59	4.09	141.08	16.57

IV. Conclusion

The differences of the COP trajectory between healthy subjects and hemiplegic patients, in the period between the double limb support to the first step(gait initiation), were observed by analysis and comparison about the motion of gait initiation. Moreover, the differences between left and right side of the patients were confirmed. These results were expected to be used to assess the balance ability of patients and to set up the rehabilitation exercise plan for the prevention of the falls.

Abstract — **Malaria is one of the severest human diseases on earth. It is caused by the asexual propagation of malaria parasites in host erythrocytes. During the process of maturation, parasites export parasite-expressed proteins, such as PfEMP1 and KHARP to the host cell membrane thus forming knobs on the host cell surface and thereby stiffening the membrane and causing cytoadherence (cell stickiness) to occur. To investigate the formation of knobs as well as the relationship between knobs and the host cell spectrin network, atomic force microscopy (AFM) is used to study both the extracellular and the cytoplasmic surface of infected erythrocyte membranes. Although the cytoskeletal structure can be observed from both the extracellular surface and cytoplasmic surface, the AFM images of cytoplasmic surface uncovered more details of the spectrin network. Knobs and their connections or linkages to the spectrin network were clearly observed from the cytoplasmic surface of infected erythrocytes. The size and distribution of knobs viewed from the cytoplasmic surface were similar to those observed from the extracellular surface. Furthermore, dramatic changes of spectrin network were detected after infection, i.e. the spectrin network is partially broken at the schizont stage. Altogether, our observation may help better understand the mechanisms of the structural and functional changes in malaria infection.**

Keywords — **Plasmodium falciparum, Atomic force microscopy (AFM), spectrin network, knobs.**

I. Introduction

The asexual cycle of the malaria parasite *Plasmodium (P.) falciparum* is composed of the ring, trophozoite and schizont stages. During the maturation in the host erythrocyte, the parasite modifies the host cell membranes by exporting parasite-expressed proteins, such as *P. falciparum* erythrocyte membrane protein 1 (PfEMP1) and knob-associated histidine-rich protein (KAHRP) to the surface of host erythrocyte membrane and forming knobs [1]. These knobs interact with the spectrin network via the attachment of KAHRP to the spectrin-actin protein 4.1 junction in parasitized erythrocytes [2,3]. Besides, parasite-produced proteases are able to hydrolyze host cell cytoskeletal proteins [4-7], which could be related to new generated parasites release from erythrocytes [8]. However, direct observation of the interaction between knobs and cytoskeleton and the changes of the host cell cytoskeleton during the cleavage of certain protease is lacking.

Atomic force microscopy (AFM) imaging has the potential of obtaining subnanometer resolution of extracellular and intracellular structures. It has been widely used to investigate the structure of normal erythrocyte cytoskeleton at both extracellular surface [9-11] and cytoplasmic surface [9,12,13] of the erythrocyte membrane. Also, AFM has been used to investigate air-dried ring stage ghost including parasite and the cytoskeleton of infected cells has been found to be less dense than healthy ones [14]. Meanwhile, the knob structure on the surface of infected erythrocytes has been observed by imaging intact fixed infected cells [15] and smears [16], respectively. However, the cytoplasmic side of the cytoskeleton of *P. falciparum* infected erythrocyte has not been intensively investigated yet. In this study, we used AFM to observe the outer and inner surfaces of the membrane of healthy and infected cells. Significant changes of erythrocyte cytoskeleton after infection were observed. The study may help us better understand the structural changes to host erythrocyte after P. *falciparum* infection.

II. Methods

A. Cell culture

P. *falciparum* parasites (3D7 and CS2 strains) were cultured in vitro using a modification of the method previously described [17]. Platelet-coated glass petri dishes were used to select knobby infected cells. Platelets were isolated from human blood as described by Baenziger and Majerus (1974). Fresh platelets were incubated on sterile acid-treated glass petri dishes in a humid chamber at room temperature for 1 h. The non-bound platelets were gently rinsed off with phosphate buffer solution (PBS). 10ml of late stage parasite culture were incubated on the surface of platelet substrate in candle jar at 37 °C for 2h. Normal erythrocytes and non-bound infected cells were rinsed off with culture medium. 10ml of culture medium with 5% hematocrit was added into the glass petri dish and incubated at 37°C in candle jar overnight until new generation of ring stage parasites was

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1965–1968, 2009
www.springerlink.com

formed. The culture was then transferred to the flask for continuous culturing as described before.

B. Enrichment of trophozoite and schizont stage infected erythrocytes

MidiMACS separation set (Miltenyi Biotec) was used to enrich trophozoite and schizont stage infected cells. Briefly, a LD column was inserted into MACS separator and preload with 1ml EDTA-BSA rinsing buffer (0.5% BSA and 2mM EDTA in PBS, pH 7.2). Meanwhile, 10ml of parasite culture was pelleted by centrifuging and gently resuspended in 2ml rinsing buffer. The cell suspension was applied on to a preloaded LD column and rinsed with 2ml rinsing buffer several times once the column reservoir was empty. When there was no red color solution seen passing through, the column was taken out and the effluent was collected. By using this method, around 90% purity of late stage infected cells were collected.

C. Modification of glass coverslips

The substrates were prepared following Liu's method [13] except for the following modifications. Instead of using N-5-azido-2-nitrobenzoyloxysuccinimide (ANBNOS), Bis(sulfo-succimidyl) suberate (BS^3) (Pierce) was used as a bifunctional crosslinker to crosslink PHA-E (EY laboratories) to 3-amino-propyltriethoxysilane (APTES) treated coverslips.

D. Preparation of smears and cytoplasmic membrane exposed samples

Smears were prepared as previously described [16].

Normal erythrocytes and MACS enriched infected cells were incubated on PHA-E coated coverslips for 4h in a moist chamber at room temperature. Loosely attached cells were washed away with PBS. Strongly attached cells were lysed by immersing the coverslips in a hypotonic buffer 5P8-10 (5mM Na_2HPO4/NaH_2PO4, 30mM NaCl, PH 8) for 10 min at room temperature. They were then shear-washed 6 times with 5P8-10 buffer using a 10ml syringe with a gauge 25 needle at an angle less than 20 degree. Cytoplasmic membrane exposed samples were quickly rinsed with deionized water and vacuum dried for use. For schizont stage infected cells, a modified method (self-burst method) was used. After incubation on PHA-E substrates for 1h and rinsing using PBS, schizont stage infected cells were recultured to burst by incubating the substrates in a petri dish with culture medium overnight at 37 °C. The samples were then rinsed, shear-washed and dried for AFM imaging.

III. Results

A. AFM images of the outer and inner side of normal erythrocyte membrane

Amplitude AFM images of intact normal erythrocytes were obtained by scanning normal erythrocyte smears as shown in Fig. 1(a). An enlarged view (after low pass modification) of the extracellular surface of normal erythrocyte reveals the cytoskeletal network underlying the membrane as shown in Fig. 1(b). The cytoskeleton observed on the outer surface also includes the membrane proteins, glycocalyx and the phospholipid bilayer. Meanwhile, an AFM image of the cytoplasmic surface of normal erythrocyte membrane is shown in Fig. 1(c) and the high magnification images (Fig. 1(d)) show the details of the spectrin network of the normal erythrocytes. The membranes obtained from shear-washing are approximately 7.5-8 μm in diameter and the thickness of membrane ranges between 5-10 nm as obtained from section analysis.

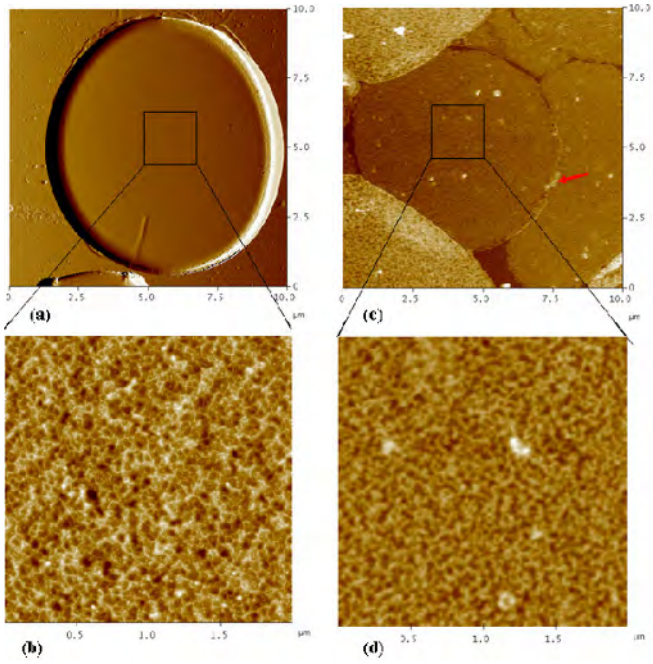

Fig. 1 Normal erythrocyte membrane. (a) Intact erythrocyte image. (b) Plot view of high magnification outer surface of erythrocyte membrane (zoom in from (a)). (c) Cytoplasmic side of erythrocyte membrane. Overlap area of membranes are indicated by red arrow. (d) Plot view of high magnification inner surface of erythrocyte membrane (zoom in from (c)).

B. AFM images of the outer and inner sides of late infected erythrocyte membrane

Trophozoite stage infected erythrocytes were also investigated from the extracellular surface using AFM (Fig. 2) and the structure and the distribution of knobs can be easily observed [16]. Although the spectin network seems sparser than normal erythrocyte (Fig. 2(b)), the connection between knobs and cytoskeleton and the detailed changes of the spectin network may be hard to investigate from the outer surface. As to the schizont stage, it is even harder to view the cytoskeleton from the outer surface, because the parasites occupy a major part of the host cell and the outer surface becomes more rough and undulating [16].

To investigate the real changes occurring in the cytoskeleton after infection, AFM images of the inner surface of the infected erythrocyte membrane were obtained as shown in Figs. 3. While the cytoplasmic surface exposed membrane of the normal erythrocytes obtained are around 8 µm in diameter (Fig. 1 (c)), those of the trophozoite and schizont stages are about 6.5 to 8 µm (Fig. 3(a)) and 3.5 to 6 µm (Fig. 3(c)) in diameter, respectively. This may attribute to the morphological changes of the host erythrocyte after infection (infected cell becomes more and more spherical arising from the multiplication of the parasites inside the cell). Protrusions (knobs) were observed from the inner surface (Fig. 3(b & d)), which is consistent with the observations from the outer surface obtained by Li et al. [16]. Meanwhile, knobs were found to be well weaved in the spectin network at trophozoite stage (Fig. 3(b)).

Two methods were used to obtain cytoplasmic surface exposed membrane of the shizont stage infected erythrocyte. One method was the normal shear wash method. After increased repeats of shear wash, either the whole cell was washed away or the membrane got partially washed away in most cases (data not shown).

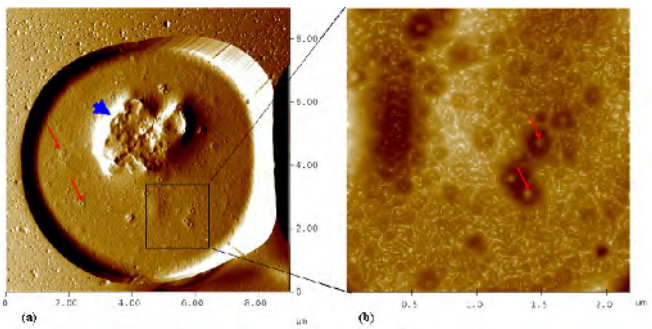

Fig. 2 Outer surface of trophozoite stage infected erythrocyte. (a) Intact trophozoite stage infected erythrocytes. (b) Magnified view of the outer surface of erythrocyte membrane (zoom in from (a)). Knobs and parasite area are indicated by the red arrows and blue arrowhead, respectively

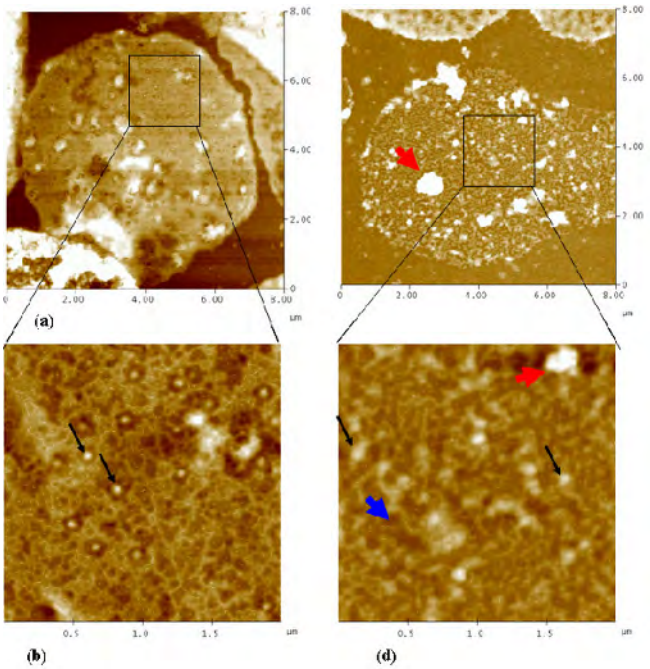

Fig. 3 Cytoplasmic surfaces of trophozoite stage and schizont stage infected erythrocyte membrane. (a-b) Trophozoite stage; (c-d) Schizont stage, using the modified shear-washing method. (b) and (d) are magnified from (a) and (c) respectively. Knobs are indicated by black arrows. Breakages and sticky sub-micro particles are indicated by blue and red arrowheads, respectively

The other method was the self-burst method, which enables us to study host cell cytoskeleton after bursting of the infected cell. Breakages of the spectrin network were observed (Fig. 3(d)). However, compared with the observation from the first method, the breakages were much less significant. It seems that the membranes can be better maintained using the latter method and extra shear wash may partially perturb the cytoskeleton.

IV. Discussion

Although the preparation of erythrocyte ghost has been well established [18], it is difficult to obtain ghosts of late stage infected erythrocytes. This could be one reason why only ring stage infected erythrocyte ghost has been investigated [14]. However, the cytoskeleton is partially extended or stretched during ghost preparation, which may affect revealing the actual spectrin network in intact cells. Also, double layers of ghost membrane may overlap and interfere with the interpretation of the images. Here, the normal and infected erythrocytes were strongly attached to the PHA-E substrate which helped to preserve the membrane structure during shear washing. Firstly, the size and the density of

normal erythrocyte spectrins in our images (Fig. 1(b)) was consistent with previous findings [12]. Furthermore, we investigated the process of spectrin network alteration: (1) knobs form on the host cell membrane at the trophozoite stage; (2) connections of spectrin network are partially destroyed at schizont stage. The observed breakage of cytoskeleton may provide an evidence of the process of the hydrolysis of host cell cytoskeletal proteins during parasite maturation. Even though the breakage we observed could be caused by the shear wash, at least, it indicates that host cell cytoskeleton becomes fragile at late stage. Moreover, the observation of the linkages between knobs and cytoskeleton directly by AFM imaging may offer a demonstration of notion that knobs are interacting with host cell cytoskeleton.

V. Conclusions

In this paper, we used the unique ability of the AFM to provide topographic information to investigate the cytoskeleton changes arising from malarial infection, without any fixtation or detergent treatment. Our AFM study on *P. falciparum*-infected erythrocyte cytoskeleton has the potential to conduct further studies on other malarial infection, such as *P. Vivax* and *P. malariae*, or even other medically important host-parasite interactions.

Acknowledgments

We would like to thank Dr Bruce Russell for sharing his experience in infected cell enrichment.

Adaptive System Identification and Modeling of Respiratory Acoustics

Abbas K. Abbas[1], Rasha Bassam[2]

[1] RWTH Aachen University, Aachen, Germany
[2] Biomedical Engineering Dept., Aachen university of Applied Sciences, Juelich, Germany

Abstract — **Adaptive identification and modeling of tracheal sound is considered as primary method to detect and monitor respiratory tract changes such as those found in asthma and acute respiratory distress syndrome ARDS. There is a need to connect the characteristic of these easily measured sounds first to the underlying physiological dynamics, and then to specific pathophysiology. To initiate this process, a model of the acoustic properties for entire respiratory tract was developed. The modeling bandwidth lies over the frequency range of lower tracheal sound (Phonospirogram) measurements, 90 Hz to 3.02 KHz. The respiratory tract system is represented by a transmission line acoustical analogy with varying cross sectional area, yielding walls, branching in the bronchial component, and airflow related acoustical sources distributed all through the whole tract. Recursive identification method applied to characterize volumetric airflow and the underlying anatomy of respiratory tract. The derived model was tested according to spatial location of natural acoustic resonances frequency for components and the entire respiratory tract. Based on parametric estimation, respiratory dynamics with associated viscoelastic properties was computed. Individually, Thoracic portions of the model predict well the distinct locations of spectral peaks from respiration phases measured at the chest. While combining supra- and subtracheal portions to form a complete tract model in healthy subject, the predicted peak locations evaluate constructively with those of respiratory sounds measured during normal breathing. This study provides view into the complex interaction between the spectral peaks and amplitudes of lung sounds.**

Keywords — **Phonospirography, Recursive estimation, Acoustic characteristic, Dynamic characteristics, Respiratory mechanics.**

I. Introduction

Passive respiratory sounds have been used for diagnosis of respiratory diseases for almost a century. These, by the flow of air created sounds provide only limited information, as neither their exact points of creation are known their changes when traveling through the healthy or diseased respiratory system well understood. From other techniques such as chest X-rays and pulmonary function tests little more information on pulmonary pathology is obtained, with the former being also significant risk to the patient, especially when used repeatedly, as it gradually increases the risk of cancer. Computed Tomography (CT) bears the same health hazard as conventional X-rays, but is capable of providing cross-sectional images of the lung with great anatomical details.

Rice and Kraman [2,3] started to investigate the transmission of sound through airways and lungs, which had not been studied in particular before. The emphasis of these investigations was placed on establishing the sound speed in airways and lung parenchyma, and the sound attenuation was merely studied in order to establish a sensible frequency range for the sound source. Sound speed and attenuation was assumed as being basically frequency-independent, and thus measurement techniques, such as cross-correlation applied to white noise (i.e. noise containing all frequencies), were used that are unsuitable if sound transmission is dispersive (frequency-dependent). The acoustic behavior of the lungs was theoretically described by considering the lungs as being an elastic continuum in a model of bubbles in a liquid. This model proved to be adequate and provided a functional correlation between the sound speed and the density of the lung parenchyma, which is depend on the alveoli size. Collapsed alveoli, being smaller, conduct sound at a higher speed than alveoli in normal parenchyma.

II. Materials and methods

The PCG signal was collected from 11 patients. The data were collected using TSR-Cardio microphone system with 14 Channel ADC acquisition modules. Experimental system identification was implemented using MATLAB platform, with a software filtering unit implemented in the input and output channel of SID-system. Fig.1 illustrates the experimental setup of PSG signal acoustic system identification with ARMAX algorithm implemented in the path of computational unit.

III. Respiratory acoustics modleing

Transducers such as microphones have allowed for the collection of more accurate acoustical data over a wider range of frequencies.Fig.2 illustrated different traces of PSG signals ranging from normal to pathological cases of respiratory tract.

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1969–1973, 2009
www.springerlink.com

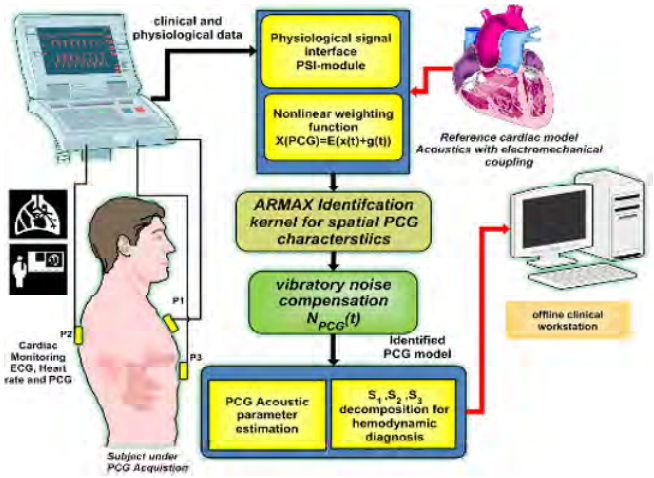

Fig.1 Respiratory acoustic identification system setup based on recursive ARMA method.

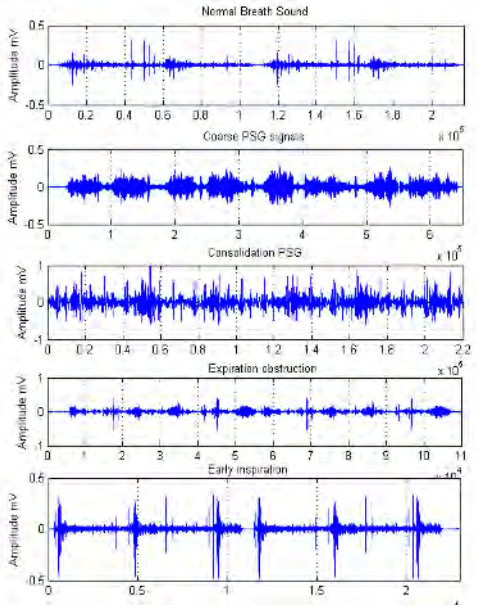

Fig.2 Phonospiraography signals for different respiratory pathology and normal patterns.

Characteristic patterns in the data, thus recorded have been associated with conditions affecting airway patency such as asthma, obstructive sleep apnea, infections, airway edema, malformations and tumors. One common location for recording breathing sounds is on the neck at the suprasternal notch over the extrathoracic trachea, with the sounds recorded referred to as tracheal sounds. These sounds are relatively large in amplitude and have a wider range of frequencies than sounds recorded at the chest wall, and also

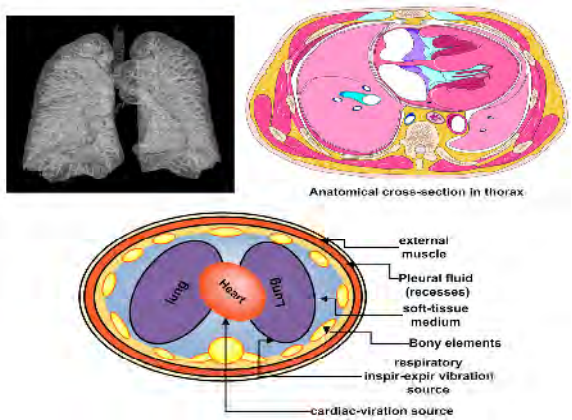

Fig.3 Anatomical component of respiratory acoustic model.

have a close relation to tracheal airflow [1]. The spectra of these tracheal sounds have been characterized as broad frequency noise with discernible spectral peaks ranging between 80 Hz to more than 1500 Hz with a “cut-off”-like frequency of around 800 Hz [2].

Fig.3 illustrates the main component of the respiratory mechanical model as based on transverse section that consists of cardiac vibration source and pleural-thorax vibration model. The well-known respiratory dynamic model was adapted by Horsfield et al [3] , in which the vibratory signal recorded as PSG signal used to identify and estimate transfer characteristics of respiratory tract and formulate a basis relation to respiratory dynamics.

These measurements suggest that there is a potential for these easily-measured PSG sounds to be used in clinical practice for the diagnosis and monitoring of various respiratory conditions [1].

For such potential clinical applications to be most useful, the relationships between the attributes of these sounds and the underlying anatomy, and ultimately patho- physiology, need to be determined [1, 4].

As a first step in this process, this study describes the development of an acoustic modeling and identification of the respiratory tract that is based on its anatomy and allows for the prediction of its natural acoustic resonances.

A recursive parametric estimation method was used in order to identify dynamic parameters of respiratory tract model. Fig.5 illustrated the intensity profile of respiratory acoustic sounds, form which power index of consumed energy in the upper respiratory tract can be identified and computed. Segmented respiration acoustic waveform can be calculated through adaptive recursive identification. Considering each airway as a rigid tube, it is possible to model a single structure of Horsfield's bronchial tree with the laws of propagation of sound waves in a cylindrical pipe Benade[7], by using

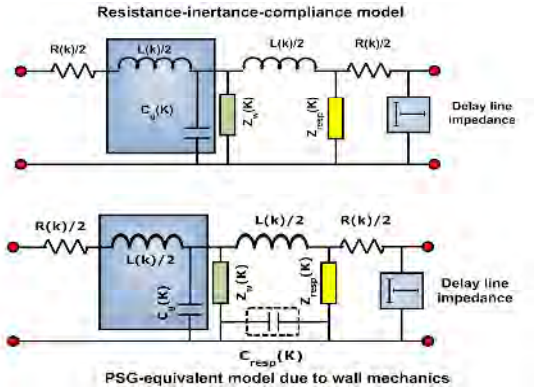

Fig.4 Respiratory dynamic models with impedance illustration of different analogous compartment.

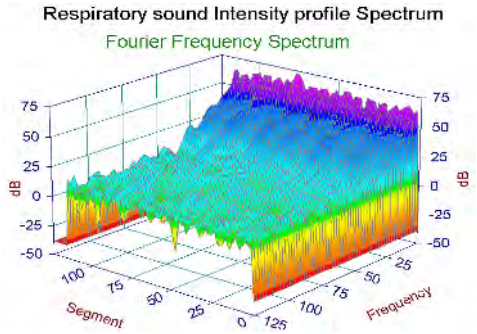

Fig.5 Respiratory sound intensity characteristics with spectrum profile segmented along the respiratory cycle.

a lumped parameter description and the simplifications for the low frequencies (<10 Hz) reported in Thorpe[9]. Thus, each segment of the airway tree can be arranged as the acoustic transmission line represented in Fig.4, in which:

$$R(k) = 8.\frac{\eta.l(k)}{\pi.r^4(k)} \tag{1}$$

$$L(k) = \rho.\frac{l(k)}{\pi.r^2(k)} \tag{2}$$

$$C_g(k) = \frac{V(k)}{P_0} = \frac{\pi.r^2(k).l(k)}{P_0} \tag{3}$$

where $r(k)$ is the tube radius $l(k)$ the tube length, η is gas viscosity and ρ is gas density. $V(k)$ is the airway segment volume at the fixing pressure P_0. Thus characterizing the resistance and inertance of the rigid tube while is gas compressibility. To incorporate in the airway model more anatomical details, one can include the influence of the wall mechanics as done, for example, in Lutchen[6]. To do so, both the soft and cartilaginous airway walls can be idealized as a series of resistance-inertance-compliance, in parallel with the gas compressibility [5,7]. Being the soft-tissue fraction for each airway segment equal to one minus the cartilaginous fraction ($ca[k]$) we have:

$$Z_w^i(k) = R_w^i(k) + j.(\omega.L_w^i(k) - \frac{1}{\omega.C_w^i(k)}), i = so, ca \tag{4}$$

where ca the angular frequency (radians/s) and the values for R_w, L_w and C_w can be computed, according to Suki[9]. Thus, the equivalent wall impedance given by the weighted combination of the soft and cartilaginous impedance is:

$$Z_W(k) = \frac{Z_w^{so}(k).Z_w^{ca}(k)}{c(k).Z_w^{so}(k) + (1-c(k)).Z_w^{ca}(k)} \tag{5}$$

The peripheral airways, which are small airways of less than 2 mm in diameter, are well recognized as the main sites of airway narrowing and obstruction in asthma and other obstructive diseases. This pathological condition can be described mathematically in Horsfield's model by reducing, of a certain percentage , the radius of the airway segments. Equations (1) to (5) are consequently modified; by substituting the narrowed radius for $r(k)$. This enables the impact of airway constriction on the overall response of respiratory system to be assessed in response to PSG amplitude [6,8].

IV. Recursive PSG Signal Identification

Recursive system identification is considered as one of parametric system dynamic estimation technique. In which the estimated parameters were updated through the entire identification process. As the respiratory acoustics contains wide spectrum of vibration frequencies starting with 6 Hz-6 KHz. Table.1 illustrate the lumped parameters of respiratory acoustics based on recursive. While table.2 represented the physiological default parameters of the whole respiratory system [8,9].

Table.1 lumped parameters for a lossy rigid-walled transmission line segment [4], [5], [7]

Parameter	Value	Units
Resistance	$R_a = \frac{2l}{\pi r^3}\sqrt{\frac{\omega\rho_0 n}{2}}$	dyne.s/cm^5
Inertance	$L_a = \frac{\rho_v l}{A}$	dyne.s^2/cm^5
Compliance	$C_a = \frac{Al}{\rho_v c^2}$	cm^5/dyne
Conductance	$G_a = 2\pi r l \frac{v-1}{\rho_a c^2}\sqrt{\frac{K\omega}{2c_p\rho_v}}$	cm^5/dyne.s

r= tube radius [cm]; segment length [cm]; radian frequency; density of median [g/cm]; shear viscosity [dyne s/cm]; cross-sectional area [cm]; speed of sound [cm/s]; ratio of specific heats; heat conduction coefficient [cal/cm-s- C]; and specific heat at constant pressure [cal/g- C].

Table.2 Default Wall Parameter Values For Respiratory Tract [6,7].

Parameter	Default value
Thickness	0.5 cm
Soft tissue density	1.06 g/cm^3
Soft tissue viscosity	1.06 .10^3 dyne.s/cm^2
Soft tissue elasticity	0.392.10^6 dyne/cm^2
Cartilage density	1.14 g/cm^3
Cartilage viscosity	180.0.10^3 dyne.s/cm^3
Cartilage elasticity	44.0.10^6 dyne /cm^2

Fig .6 Respiratory power profile through recursive correlation of PSG signal amplitude.

Fig.6 illustrates the respiratory power profile through recursive correlation of resulted PSG signal. In Fig.4 indicated, impedance equivalent circuit with bypass capacitance indicates respiratory capacitance between lung wall and myocardium, in which the delay characteristics of PSG signal originated due to post-vibration damping in inspiration phase. In table.3 the estimated respiratory model were identified, showing the main physical quantities of reactance, inertance and capacitance for respiratory tract.

V. Resulsts and discussion

In the basis of the statistical analysis and performance test of identified respiratory acoustic model, the following models were identified. The model assumes 1-D acoustic wave propagation, airway geometries with second-order wall dynamics derived from previous measurements on adult males and an estimated PSG sound profile for sound generation. This acoustic representation of the average respiratory tract anatomy predicts the location of spectral peaks in upper respiratory tract acoustic measurements with disparate sound sources such as the breath sounds. These findings stress the composite importance of anatomical parameters such as overall tract length, depth of tract profile, and wall properties on spectral peak location while de-emphasizing the impact of specific source location and type. However, it is likely that such sources play a key role in the determination of the overall spectral features and amplitude of such easily-measured sounds like PSG-signals.

VI. Conclusions

From the identified respiratory acoustic model, the following observations were noticed.

- Recursive modeling have been used in order to simulated the repetitive patterns of PSG signal , to approximate experimental PSG acquisition to the real-time profile of physiological inspiration-expiration cycle.
- Due to the different frequency band width of PSG signal and the position dependent- PSG pattern, the robust method to overcome this effect was to use pre-filtering stage at the input node and output node of identification computational kernel.
- Finally, recursive identification will allow acoustic mapping for pre-trials to acoustic imaging technique to established in future acquisition.

Correlation between Lyapunov Exponent and the Movement of Center of Mass during Treadmill Walking

J.H. Park[1] and K. Son[2]

[1] BK21 School of Mechanical Engineering, Pusan National University, Busan, Korea
[2] School of Mechanical Engineering, Pusan National University, Busan, Korea

Abstract — **The purpose of study is to investigate the correlation between the Lyapunov exponent (LE) and the movement of the center of mass (MCM) for clarifying walking stability on the treadmill. From fifteen young healthy subjects volunteered, lower extremity joint angles were recorded using a three-dimensional motion capture system and reflective markers. The anteroposterior MCM and the LE were calculated by a commercial software. A linear correlation between LE and MCM (r^2=0.413) showed that LEs compensated for walking distance on the treadmill walking. However, LEs were found to be independent of self-selected walking speeds by a negligible correlation between the Froude number and the LE (r^2=0.038).**

Keywords — **Movement of Center of Mass, Lyapunov Exponent, Treadmill Walking, Lower Extremity.**

I. Introduction

In a treadmill walking the constant speed selected by a walker makes a periodic gait pattern and the walking may seem safe. However, fallings often occur during the treadmill walking. Stride and angular variability are a natural outcome during gait. Their deviations correspond to the amount of irregularity and are used as a basis of whether the motion is stable or not. Conversely, it seems not to be a problem of predictability but that of simple statistics.

Recently, such variability is considered as a deterministic process controlled by the neuro-musculoskeletal system. In this study, a new parameter, the Lyapunov exponent (LE), was introduced to clarify this fact. The LE has been used as one of chaotic parameters to quantify dynamic aspects of flexion-extension angles associated with human gait.

The purpose of study is to show that the correlation between the LE and the movement of the center of mass (MCM) can be used as a measure of walking stability on the treadmill. The Froude number (FN) was also included in the analysis in order to check the effect of a walking speed.

II. Materials and Methods

A. Gait experiment

Fifteen young healthy subjects (13 males and 2 females: 24.9±4.1 years, 175.6±6.4 cm, 70.5±12.1 kg, 1.0±0.1 m/s) with no history of joint diseases took part in the gait experiments. Their walking motions were measured for 90 seconds on a treadmill (KEYTEC® AC9, Taiwan) in order to obtain the flexion-extension angles of their lower extremities. Before the measurement, all subjects were given more than five minutes to perform walking exercises on the treadmill at their self-selected comfortable speeds. The FN, V^2/gl (V: speed, g: gravitational acceleration, l: length from ground to the greater trochanter), was used to normalize each walking speed.

Gait motions were recorded using eight video cameras (DCR-VX2100, Sony, Japan), a three-dimensional calibration frame (width: 1m, height: 2m), and synchronization LEDs to synchronize recorded images. Thirty two custom reflective markers (10 mm diameter hemisphere) were made of the surface covered by reflective films. These reflective markers were carefully placed on the selected bony landmarks of each subject (Fig. 1) in order to calculate the flexion-extension angles of the upper and lower extremities. Images recorded for 90 seconds were restored on a PC and three-dimensional coordinates of the markers were calculated by KWON3D software (Visol Corp., Korea). During the digitizing process a total of 60 frames were generated by the de-interlacing method per second.

The flexion-extension angles of the hip, the knee, and the ankle were reconstructed as a function of time using the inner product of the two adjacent vectors which connect the two joints of the body. The joint center of the knee and the

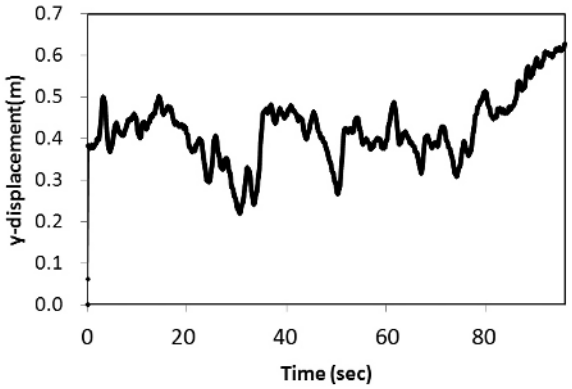

Fig. 2 An example of anteroposterior MCM during treadmill walking

ankle were computed with medial and lateral surface markers. The center of the hip was calculated by adopting the method of Tylkowski and Andriacchi from the left, the right, the middle ASIS (anterior superior iliac spine) and extra greater trochanter markers. The spatial displacement error of a marker position was less than 2 mm.

Unfiltered data were analyzed to increase an accuracy of the stride-to-stride variations, because it has been reported that a filtering may eliminate important information on joint motions and provide a skewed view of inherent motion variations [1]. In addition, it was assumed that the measured flexion-extension angles would have a similar level of measurement noise in every joint since the same apparatus was used for capturing all joint motions in this study. This assumption suggests that differences between joint angles could be attributed to the changes in joint motions themselves [2].

During the treadmill walking all subjects were asked to move in the anteroposterior direction. The medial-lateral motion also occurred, however, it was excluded because the main motion consisted of balancing the center of mass of the body in the single leg standing phase. Therefore, the anteroposterior MCM was chosen as a major parameter to be controlled by the subjects. The MCM was obtained by the summation of all small *dy* for 90 seconds.

B. Lyapunov exponent

A state space vector was formed from the original time series to reconstruct a state space. This vector should be made to have mutually exclusive information about the dynamics of the system. For this, an appropriate time delay was determined using the average mutual information (AMI) function [3]. This criterion sets the time delay equal to the value of delay corresponding to the first minimum of the AMI function. In order to unfold the dynamics of the system, embedding dimension was determined in a proper state space.

A suitable embedding dimension was chosen using the false nearest neighbor (FNN) method [4]. An inappropriate number of embedding dimensions may yield a projection of the dynamics of the system that has orbital crossings in the state space. These crossings would be due to false neighbors and far from the actual dynamics of the system. Total percentage of false neighbors was computed by FNN method, and the number of dimension was chosen when this percentage approaches zero.

The LE quantifies the exponential separation of the neighboring trajectories in the reconstructed state space. Thus LEs provide a direct measure of the sensitivity of the system. This information is necessary to classify the stability of the time series. As nearby points of the state space separate, they diverge rapidly as to produce instability. The LE for a stable system with little or no divergence will be approximately zero as in a sinusoidal wave while the LE for an unstable system that diverges will be positive.

The LE was computed from the growth of length when the length of a vector between two points became large, a new point was chosen near the reference trajectory. The calculation started from the first data point $x(t_0)$ and $x(t_0)+dx$ which was the nearest at a distance $d(t_0)$. If the length $d'(t_1)$ was larger than a small value, then first point $x(t_0)$ was conserved and the algorithm searched the next point $x(t_1)+dx$. This algorithm was proposed by Wolf et al. [2] as:

$$\lambda = \lim_{m\to\infty} \frac{1}{mt} \sum_{i=1}^{m} \log_2 \frac{d'(t_m)}{d(t_{m-1})}$$

where λ was the LE, t was the time interval, m was the number of total time intervals and d was the nearest distance from the reference trajectory. The LE depends in general on the initial data point $x(t_0)$, the initial separation distance $d'(t_0)$ and time t. For the calculation of LEs, the Chaos Data Analyzer (professional version, Physics Academy Software, Raleigh, U.S.A.) was used. The Chaos Data Analyzer is special purposed software to analyze nonlinear time series data. The software includes a calculation function of LE in the selection of chaos analysis.

III. Results

LEs were calculated from flexion-extension angle attractors of the lower extremity after a determination of the time delay and the embedding dimension from fifteen subjects.

Means and standard deviations of LE, total MCM, and FN were listed in Table 1. LEs of the ankle were higher than those of the other lower extremity joints.

In our major concern, linear correlation coefficients between the items (MCM, LE, and FN) were computed by using the least square method on the Microsoft Excel and the results were summarized in Table 2. This shows that among the joints the LE of the knee has the largest linear correlation coefficient with the MCM. It is evident that the knee joint plays a more important role to control the anteroposterior displacement than the other joints. The correlation between the MCM and the LE for all three lower extremity joints was also relatively strong. However, it was observed that the Froude number had no connection with the LE. The two representative illustrations are shown as in Fig. 3 and Fig. 4.

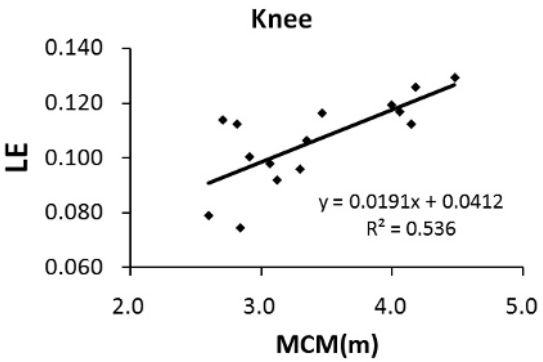

Fig. 3 Correlation between anteroposterior MCM and LE

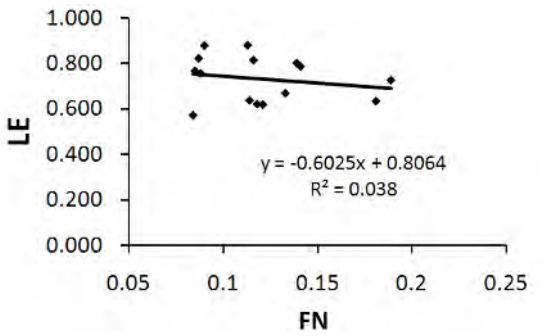

Fig. 4 Correlation between FN and LE

Table 1 Results of LEs, MCM, and FN

	Joints					
	Hip		Knee		Ankle	
	Left	right	left	right	left	right
LEs Mean	0.095	0.094	0.099	0.114	0.174	0.158
LEs STD	0.018	0.015	0.018	0.019	0.046	0.047
MCM(m)	3.40±0.616					
FN	0.120±0.032					

Table 2 Results of correlation test

Correlation pairs	Linear correlation coefficient(r^2)
MCM and LEs of the hip	0.075
MCM and LEs of the knee	0.536
MCM and LEs of the ankle	0.157
MCM and LEs of all three lower extremity joints	0.413
FN and LEs of all three lower extremity joints	0.038

IV. Conclusions

It is likely that that one does exert much effort to balance the body in the treadmill walking because it is relatively more periodic than normal walking. However, the results of our simple treadmill experiments revealed that the lower legs continuously coordinate themselves against irregular strides related to walking speed. Therefore, it was found that the LE increased in proportion to anteroposterior MCM but that the LE was not directly correlated with self-selected speed. Future studies require an increased number of subjects for more statistical analyses.

The Development of an EMG-based Upper Extremity Rehabilitation Training System for Hemiplegic Patients

J.S. Son[1], J.Y. Kim[1], S.J. Hwang[1] and Youngho Kim[1,2]

[1] Biomedical Engineering, Yousei University, Wonju, South Korea
[2] Institute of Biomedical Engineering, Yonsei University, Wonju, South Korea

Abstract — **Existing therapy and orthosis for upper arm rehabilitaion have some shortcomings such that orthosis can't help patient's motion but it just supply, patient has to go to hospital for therapy and patient can't reflect his will in therapy. Because of these reasons, upper arm rehabilitaion system was developed, which could increase hemiplegic patient's strength and make patient does training by oneself. To make the training system, motor and EMG sensor with orthosis were used so that orthosis could move actively and give patient load. EMG sensor was used for feedback to reflect patient's will and the rotational potentiometer was used to get the information about joint angle. Orthosis made upper arm's flexion and extension, and used EMG signal. For rehabilitation, orthosis made user exercise by giving him proper load, or made involved arm mimic uninvolved arm's motion. As it can reflect patient's will, we expect that it can improve rehabillitaion effect and make patients do training at his home.**

Keywords — **orthosis, rehabilitation, training, EMG**

I. Introduction

The hemiplegia is caused by the damage of the brain, so functional inability is able to be cured by repetitive training for rehabilitation of impaired brain. Training methods, done till now, can be categorized into two types briefly. One is for the patient who can't train by oneself, so patient need some help of other people, such as the therapist. Another one is done by patient oneself. According to the previous study (Sütbeyaz S. et al., 2007), the rehabilitation therapy could bring better results when the patients have a strong will to move. However, in most cases, rehabilitation therapy was performed passively without patient's active will. Moreover it is more effective when patient does training in one's home (Herbold J. et al., 2007) but most patient uses the facilities due to disability of locating existing training equipments in personal home.

In this study, upper extremity rehabilitation training system was developed, which was based on EMG signal. EMG is the unique tool which let us know the information about the muscle such as muscle activation. Therefore it could be assumed that EMG reflects patient's will. Also, developed system was made as possible as small so that patient could train for rehabilitation in one's home.

II. Method

A. Subject and pre-test

Three healthy men were chosen (Table 1) for our pre-test which was to know the torque generated in flexing and extending their arm as possible as strong. Biodex (Biodex Medical System, U.S.A.) was used to determine the torque. Simultaneously, EMG measurement system (Noraxon U.S.A. Inc) was also used to measure the pattern of EMG. EMG signals were obtained from biceps brachii and triceps brachii. The pre-test was performed for three times per each person with 10deg/second and with 0~100°degree of motion range (Fig. 1).

According to the result of pre-test, the motor RE 40 (Maxon, Switzland) was chosen, which generate the amount of 39Nm torque (Table 2).

In order to control the system, we used microcontroller ATmega128 (Atmel, U.S.A.), and the algorithm was written in C language. The developed training system consists of orthosis part and control part (Fig. 2).

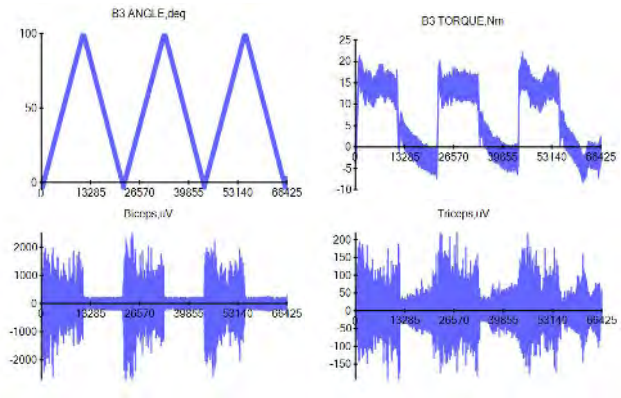

Fig. 1 Joint angle, torque, and EMG signals from the experiment

Table 1 Information of subjects (n = 3)

	Age (yrs)	Height (cm)	Weight (kg)
A	23	168	72

www.springerlink.com

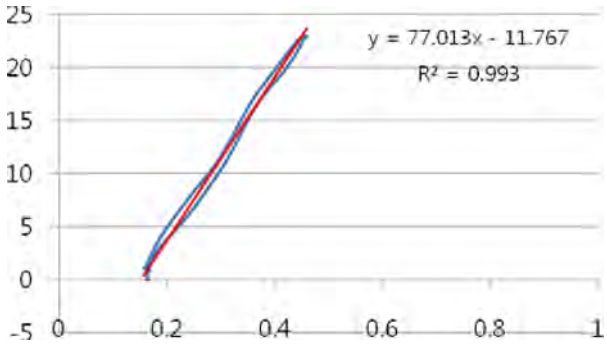
Fig. 2 Developed orthosis part and control part

Table 2 Motor specification

Voltage (V)	Speed (rpm)	Torque (Nm)
24	33	39

B. EMG processing and control algorithm

Raw EMG signal outputted from EMG measurement system was low pass filtered by a Butterworth 4th order filter at 1Hz. Low pass filtered EMG signal was analyzed by EMG-to-torque converting algorithm and used to control the motor system. Control algorithm consists of two types. One is the muscle strengthening for the patient who can move his arm voluntarily, and another is the motion mimic algorithm for the patient who cannot move his arm by oneself. In the muscle strengthening algorithm, motor was controlled in uniform speed. The equation of relationship between EMG signal and torque was calculated through linear regression. Therefore the elbow joint torque of patient could be estimated from the processed EMG signal. Estimated torque was used as reversal torque to patient. This lets patients make more power until they make proper power which we preset. So if patients make joint torque which is larger than the threshold value, they could move their arm due to the elimination of the reversal torque. This process would be repeated, which means the enough load could be given to patient. The difference between developed system method and barbell exercise method is that developed system could control the velocity and the load for each patient. In the case of motion mimic algorithm, involved part was controlled by uninvolved part. Patient wears the developed orthosis on the involved arm. In addition, electrodes for measuring EMG are placed on the uninvolved arm. Therefore, the motor is controlled by the information obtained from uninvolved arm. If there is only the angle data, it would be impossible to determine that movement is occurred by voluntary or not. So we use the EMG and guess it from EMG. Finally, the orthosis will move when patient moves his arm voluntarily.



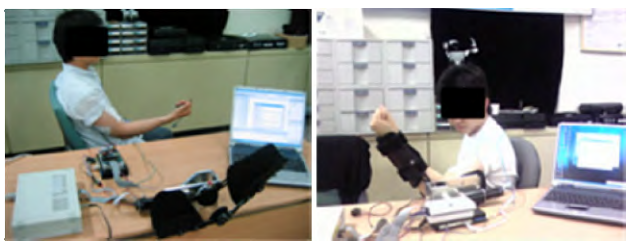


Fig. 3 Relationship between normalized EMG signal and torque (x axis: V, y axis: Nm)

C. Display and data acquisition

Measured values were transmitted to computer through serial port. To display and to store transmitted data, the software was developed in language based on C.

III. Results

The test was performed for two algorithms, motion mimic and training (Fig. 4). The signals were obtained and calculated from developed system when lower arm was repeated the flexion and extension for three times (Fig. 5). The first and second graphs mean rectified EMG signals from biceps brachii and from triceps brachii relatively. Third graph shows the estimated torque from biceps brachii. The reason why the torque was estimated from biceps brachii was that the amplitude of triceps brachii was small during the experiment, which means triceps brachii was not activated remarkably due to an effect of gravity when the lower arm was extended. Last graph indicates the elbow joint angle.

(a) (b)

Fig. 4 Experimentation of (a) motion mimic and (b) training

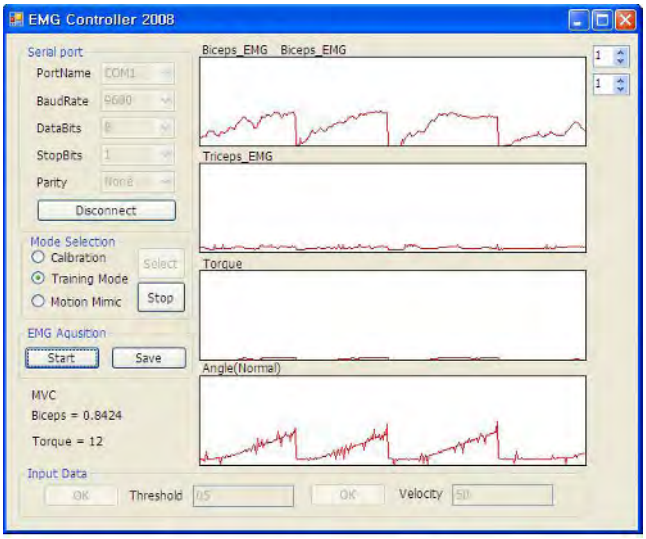

Fig. 5 Display of rectified EMG from biceps and triceps brachii and of torque estimated from EMG and of elbow joint angle

IV. Conclusions

In this study, EMG-based upper extremity rehabilitation training system was developed for hemiplegic patients. Since this study was to develop the system, clinical test was not performed for patient. During the experiments, the significant problem was found, which is the frame of the developed orthosis was bent. This problem would be improved by strengthening its frame. The developed system would result in better rehabilitation effect, because patient's will could be reflected and the size of the system was small as locating home. However, the clinical examination would be required to make quantitative data of increased muscle strength and recovery of brain. We expect that developed system in this paper would help the patients to improve their ability and make quite good results.

Fabrication of Adhesive Protein Micropatterns In Application of Studying Cell Surface Interactions

Ji Sheng Kiew[1], Xiaodi Sui[1], Yeh-Shiu Chu[2], Jean Paul Thiery[2] and Isabel Rodriguez[3]

1 Department of Bioengineering, National University of Singapore, Singapore
2 Institute of Molecular and Cell Biology (IMCB), Agency of Science, Technology and Research (A*STAR), Singapore
3 Institute of Materials Research and Engineering (IMRE), Agency of Science, Technology and Research (A*STAR), Singapore

Abstract — **The development of techniques for immobilizing biomolecules on solid surfaces has attracted wide attention because of the broad potential applications of biofunctionalized surfaces in stem cell biology, tissue engineering, biosensor technology, and high-throughput screening for drug discovery.**

In particular, protein micropatterns on surfaces provide unprecedented spatial resolution to control cell shape and direct cell behavior. Combining with optical methods and functional assays, micropatterning techniques are one of the key tools for investigating cell molecular and mechanical mechanisms in basic cell behaviors, such as cell adhesion, cell migration, cell division and differentiation.

In this work, we use a photolithographic approach to create cell adhesive micropatterns. We have designed different geometries to control and study cell adhesion. A pre-designed mask is fabricated for the photolithographic process. The designed features are transferred to a glass substrate by UV exposure of a protein solution containing a photoinitiator through the mask.

Typically, patterns of fibronectin are produced in a non-adhesive background of poly-L-lysine grafted poly (ethylene glycol). Cells seeded on these substrates, can specifically adhere and spread on the adhesive protein micropatterns and display unique shapes according to the contour and size of the pattern.

Keywords — **photolithographic, micropatterns, photoinitiator, protein, UV**

I. Introduction

Though established micro-patterning techniques such as the use of elastomeric PDMS stamps for micro-contact printing is simple and efficient, the method lacks reproducibility and produce patterns with poor spatial resolution. Hence through this project, we aim to propose a simple and highly reproducible method for protein micro-patterning on substrates, combining the use of photolithography which is commonly used in the semiconductor industry and biological knowledge on proteins and cell adhesion. Cells seeded on such patterned substrates would then be forced to specifically occupy these pre-defined patterns, enabling studies such as mechano-sensory studies to be performed on single cells.

To create chemically patterned surfaces on substrates such that cells can attach to these patterns and grow and passivate the other unpatterned areas to prevent cells from growing, we need to select suitable coating substances for the substrate. For this project, we have selected two suitable substances as coating agents, namely fibronectin and a polycationic graft polymer, poly-L-lysine-g-poly(ethylene glycol) (PLL-g-PEG) to be used for cell attachment and substrate passivation respectively. The polycationic PLL-g-PEG has been shown to attach to negatively-charged substances via strong electrostatic attractions with its charged poly-L-Lysine binding to the substrate and the PEG side chains on the exposed surface. The PEG side chains then create a non-fouling surface, resistant to cell-attachment and proteins due to entropic repulsion and the high water content of the PEG chains due to the interaction of the OH-groups in the chemical structure with water.

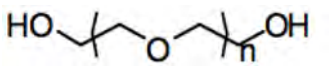

Figure 1. (above) Chemical Structure of Poly (ethylene glycol)

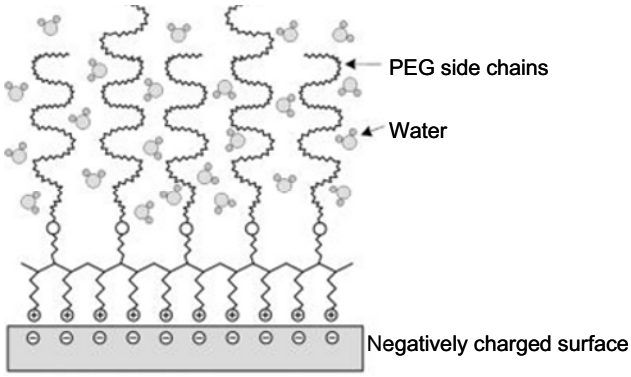

Figure 2. (above) Schematic view of a poly(L-lysine)-graft-poly (ethylene glycol) (PLL-g-PEG) adlayer on a negatively charged surface. The positively charged PLL backbone attaches to the negatively charged surface through electrostatic interactions. The grafted PEG chains are hydrated (represented by the H_2O molecules between the PEG chains) and extend into the aqueous environment; Diagram from Morgenthaler et al. [1]

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1980–1983, 2009
www.springerlink.com

Thereafter, to chemically attach fibronectin to the substrate surface on top of the PEG chains, we employ a photolithographic method. Fibronectin is mixed with the photoinitiator to form a grafting mixture in which upon exposure of the mixture to a suitable UV wavelength depending on the photoinitiator used, the excited photoinitiator (In*) would follow either of the two possible reaction pathways: (Reaction 1) dissociate into primary radicals (R·) or (Reaction 2) react with a second species (A-H) via hydrogen abstraction to form secondary radicals (A·). The two reactions are shown as follows:

$$In \xrightarrow{uv} In^* \rightarrow 2R\cdot \qquad \text{(Reaction 1)}$$

$$In \xrightarrow{uv} In^* \xrightarrow{A\text{-}H} 2R\cdot \qquad \text{(Reaction 2)}$$

A-H in this case can be fibronectin or PEG where H atoms are abstracted to form radicals which cause binding of excited parts of the fibronectin molecule with the excited PEG-coated substrate surface which is the radical reaction of interest. Other reactions between radicals such as those involving photoinitiator molecules and hydrogen atoms are not of interest in this case. Hence only parts of the substrate coated with the grafting mixture and exposed to UV radiation through the patterned mask would have fibronectin protein molecules binding to them. Those fibronectin molecules that are unattached can be washed off.

The rate of photoinitiation according to Bryant et al. [2] is giving by the formula:

$$Ri = \frac{2\phi f(2.303\varepsilon)I_o\lambda[In]}{N_{AV}hc} \qquad (1)$$

where ϕ = quantum yield
f = photoinitiator efficiency
ε = molar extinction coefficient at the initiating wavelength, λ
I_o = incident light intensity
$[In]$ = initiator concentration
N_{AV} = Avogadro's number
h = Planck's constant
c = velocity of light

and 2 in the above equation indicates that 2 radicals are formed per dissociated initiator molecule. Note that this equation assumes that light intensity remains relatively constant, unaffected by the thickness of the protein coating formed. More accurately, light intensity I is determined by the following equation[2].

$$I = I_o e^{-2.303\varepsilon[In]\,b} \qquad (2)$$

where b is the thickness of the protein coating formed.

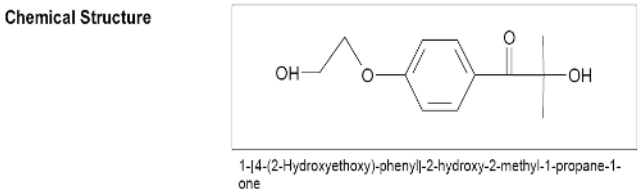

Figure 3.(above) Chemical Structure of Irgacure 2959 (Diagram from Ciba Specialty Chemicals)

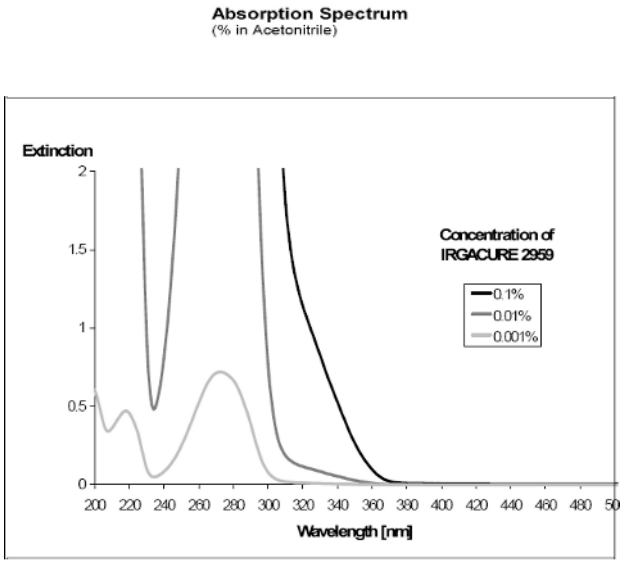

Figure 4.(above) Absorption Spectrum of Irgacure 2959 (Diagram from Ciba Specialty Chemicals)

Choosing an appropriate initiator and initiating conditions is important because the initiation step controls the polymerization rate, affecting the final protein coating on the substrate. Different initiators have different initiating chemistry, differing in initiator efficiency, the molar extinction coefficient, and range of initiating wavelengths. For this experiment, we have chosen a commercially available photoinitiator (Irgacure 2959, Ciba Specialty Chemicals) that has been used successfully in biology related experiments.

Irgacure 2959 was also chosen over other photoinitiators for its higher solubility in water which was important in bringing the protein molecules suspended in buffer solution, the hydrated PEG molecules and the photoinitiator together in the same phase so that photoinitiation and formation of radicals can take place.

Propagation of the reaction occurs when radicals formed in the presence of UV radiation come into contact with and extract the H groups in water, Irgacure 2959 and fibronectin. This creates more radicals out from these mole-

cules and they could go on in the process of activating other molecules to form radicals (See reaction 3). Termination of these radical reactions only occurs upon reaction of 2 radicals (See reaction 4).

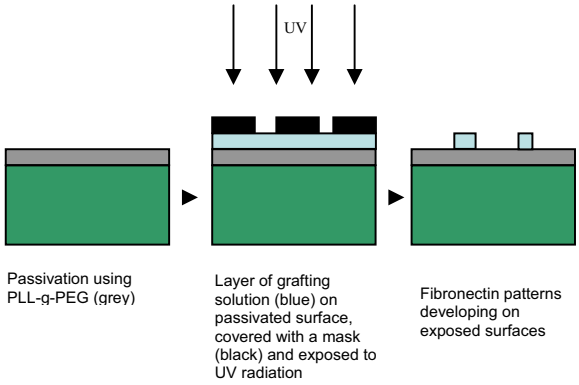
$$R\cdot + H\text{-}A \rightarrow RH + A \qquad \text{(Reaction 3)}$$

where H-A is any molecule with a hydrogen group available for radical extraction by radical, R·

$$R\cdot + R\cdot \rightarrow R\text{-}R \qquad \text{(Reaction 4)}$$

where combination of 2 radicals (R·) results in termination of the reaction propagation.

II. Materials and Method



The objective of this project is to perform an initial study on the reliability of this new patterning method as described in PCT application WO 2006/084482 and thereafter develop and optimize an experimental protocol to create such protein patterns. The experimental protocol has to be developed from the beginning since the original water soluble photoinitiator (4-Benzoylbenzyl)trimethylammonium chloride as proposed in the PCT document is no longer available commercially from Sigma Aldrich. Moreover, the document does not specify the exact proportions of the components constituting the grafting mixture.

Fibronectin is coated onto the substrate surfaces by use of contact exposure photolithography. 20µl of the grafting solution is first placed on the substrate to be coated. The chromium and gold coated quartz photolithographic mask is then gently placed over the grafting solution such that a thin film of grafting solution is in between the photomask and the substrate; exposure of the grafting solution to atmospheric oxygen is brought to a minimum in this way. Care is also taken to avoid any bubbles from being trapped between the mask and the substrate since atmospheric oxygen neutralises the radicals produced when photoinitiator in the grafting solution is exposed to UV.

The whole assembly is then exposed to UV by placing it into a UV flood lamp system (Dymax 2000-EC Series) and exposed for a predetermined time and distance away from the UV curing bulb to vary the exposure time and intensity of UV exposure as required by the experiment.

After exposure to UV, the photolithographic mask is separated from the substrate by rinsing with distilled water. The protein-coated substrates are then stored in PBS.

The diagram below describes this patterning process:

III. Results

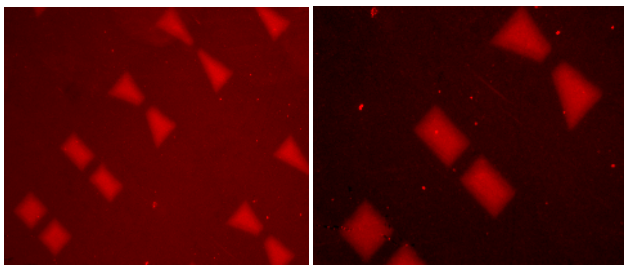


Figure 5. CY3-labelled fibronectin patterns coated on glass substrates taken using a 20X magnification oil objective (above left) and 40X magnification oil objective (above right).

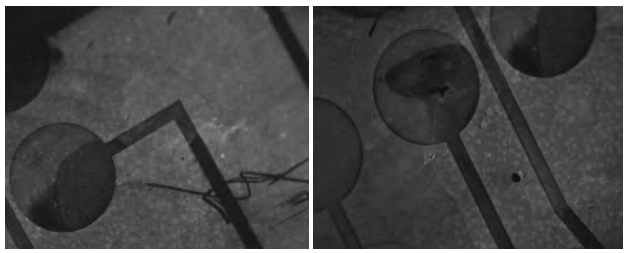

Figure 6. CY3-labelled fibronectin patterns coated on glass substrates taken using a 10X magnification oil objective (above).

IV. Conclusion

Initial results are encouraging given the high resolution of the protein patterns formed and the ease of patterning compared to the commonly used µ-contact printing method.

Several factors affecting the resolution of the patterns formed were also identified. The first of which was the relation between the diffusion of radicals and UV exposure time. Upon exposure to a suitable UV wavelength, photoinitiator mixtures produce radicals which set off a series of

reactions to activate the molecules on the substrate surface and also the protein molecules to be coated. These molecules are able to move about freely during the reaction and hence there is a possibility of them diffusing out from the UV exposed areas into the surrounding unexposed regions, affecting the resolution of the protein patterns formed. Hence, as time of exposure increases, the resolution of the patterns decreases since radicals produced from UV exposure have more time to diffuse throughout the thin layer of grafting solution between the photolithographic mask and the substrate. Other factors such as UV excitation wavelength and photoinitiator concentration has to be considered too in optimizing the efficiency of this coating process.

Acknowledgements

We would like to express sincere appreciation of the assistance and guidance given by our project supervisors Dr Isabel Rodriguez (IMRE) on photolithography and substrate surface modification, Dr Jean Paul Thiery (IMCB) and Dr Chu Yee Shiu for their guidance on cell biology, assistance on protein labelling and substrate imaging.

Modeling of the human cardiovascular system with its application to the study of the effects of variations in the circle of Willis on cerebral hemodynamics

Fuyou Liang[1], Shu Takagi[1] and Hao Liu[2]

[1] Computational Science Research Program, RIKEN, Wako, Japan
[2] Graduate School of Engineering, Chiba University, Chiba, Japan

Abstract — **A computational model of the human cardiovascular system has been developed based on multi-scale hemodynamic modeling, where the 71 arteries which constitute the arterial tree and the circle of Willis are described by a one-dimensional model coupled with a lumped parameter description of the remainder. The most significant advancement of the present model over single-scaled models is that it accounts for hemodynamic interaction in the global system while capturing the characteristics of wave propagation in the arterial system.**

In this study, the model is applied to study the effects of variations in the circle of Willis (CoW) on cerebral hemodynamics. Model predictions for a complete CoW, and incomplete CoWs with a fetal posterior cerebral artery (PCA) or a missing anterior cerebral artery (A1) under normal resting conditions show good agreements with in vivo measurements. When a severe stenotic or occlusive disease is present in one of the internal carotid arteries (ICA), a complete CoW is able to feed the cerebral arteries ipsilateral to the diseased ICA with little reduction in flow rate by re-routing flows through the communicating arteries from the intact ICA; however, such compensatory capacity is impaired significantly in the cases of incomplete CoW.

To compensate for ischemia induced by ICA stenoses in the cases of incomplete CoW, further compensatory responses in tissues downstream of the insufficiently-perfused arteries are expected to take place in resting conditions, which may contribute to the impairment of cerebral autoregulation in patients with ICA stenoses. The findings indicate that the structure of the CoW is an important determinant of cerebral hemodynamic regulation and should be considered carefully in clinical practice.

I. Introduction

Lumped-parameter models (zero-dimensional) and wave-propagation models (one-dimensional) for pressure and flow in large vessels, as well as fully three-dimensional fluid-structure interaction models for pressure and velocity, can contribute valuably to answering physiological and patho-physiological questions that arise in the diagnostic and treatment of cardiovascular diseases [1]. In practice, models geared to single-scaled hemodynamic phenomena, however, often encounter difficulties due to their inherent limitations. For instance, lumped-parameter (0-D) models are useful mainly for modeling the complete cardiovascular system, but they cannot account for the propagation of pressure and flow waves. One-dimensional (1-D) models are well suited to describing pressure/flow waves traveling through the arterial system, but they provide little detail on flow patterns at local segments. Three-dimensional (3-D) models are widely used to characterize 3-D flows and their relevance to vascular diseases. However, limited by the large amount of computer resources associated with 3-D computations, 3-D models can only be applied to a small segment of the arterial system and hence appropriate assumptions on flow conditions at the proximal and distal boundaries are necessary. In this context, more and more interests were being focused on developing multi-scale models that are capable of accounting for global effects while describing, in more detail, hemodynamic phenomena in regions of interest in recent years.

Recently, we established a computational model of the complete cardiovascular system by coupling a 1-D model of the arterial system with a 0-D model of the remainder. The resultant multi-scale model forms a unique closed-loop and hence is able to spontaneously account for global hemody-

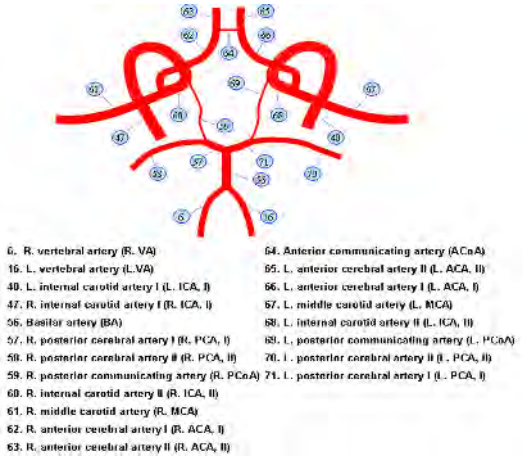

Fig. 2 Schematic representation of the circle of Willis

namic interaction while describing wave propagation in the arterial system. The model has been used to characterize the changes of arterial pulses during aging and in various cases of cardiovascular diseases in our previous studies. In this study, we extend the model to include the CoW and use it to study the effects of variations in the CoW on cerebral hemodynamic regulation.

The CoW is a ringlike structure of arteries found at the base of the brain (see Fig.2). The most important role of the CoW is to maintain constant blood supply to the distal tissues irrespective of pressure variations and/or occlusive diseases occurring in the afferent arteries supplying the CoW. This is realized by re-direction of blood in the CoW combined with autoregulation in the distal tissues downstream of the CoW. However, only about 50% of population is found with a complete CoW shown in Fig. 2, others show various anatomical variations [2]. It is, therefore, of interest that how anatomical variations affect the regulation capacity of the CoW. The significance of the variations in the CoW has indeed been recognized and addressed extensively with both computational models and in vivo measurements [2, 3].

The model proposed in the present study, other than many previous models which dealt with a separate CoW terminated by fixed boundary flow conditions, puts the CoW into a closed-loop system where global hemodynamic interaction and arterial wave propagation are accounted for simultaneously. The feature allows the model to be used in a wider range of patho-physiological conditions. In this study, we report some preliminary model-based predictions of the effects of variations in the CoW on flow distributions in the CoW and the compensatory capacity of the CoW.

II. Materials and Methods

A. Model description

The 55 largest arteries plus the 16 cerebral arteries forming the CoW are described by a 1-D model, and the remaining peripheral vascular subsystems, the heart and the pulmonary circulation are represented by a 0-D model. Subsequently, the two models are coupled together to yield a multi-scale model (see Fig.1). As a result, the multi-scale model forms a closed-loop mimicking the real structure of the cardiovascular system.

1-D Governing Equations: 1-D governing equations for blood flow in an artery can be obtained by integrating the continuity equation and Navier-Stokes equations over a cross-section of the artery [4]. The 1-D equations written in conservation form are:

$$\frac{\partial}{\partial t}\begin{pmatrix} A \\ U \end{pmatrix} + \frac{\partial}{\partial z}\begin{pmatrix} UA \\ \frac{U^2}{2} + \frac{P}{\rho} \end{pmatrix} = \begin{pmatrix} 0 \\ -F_r \frac{U}{A} \end{pmatrix}, \tag{1}$$

where t is the time, and z the axial coordinate along the artery; ρ is the density of blood; A, U and P denote the cross-sectional area, mean axial velocity, and mean pressure, respectively; F_r refers to the friction force per unit length.

The system of equations (1) is completed by a pressure-area relationship derived from the Laplace law for thin homogeneous elastic vessel wall [4].

$$P - P_0 = \frac{Eh_0}{r_0(1-\sigma^2)}\left(\sqrt{\frac{A}{A_0}} - 1\right), \tag{2}$$

where A_0 and h_0 represent, respectively, the cross-sectional area and wall thickness at the reference state (U_0, P_0). r_0 is the radius corresponding to A_0. E is the Young's modulus. σ is the Poisson's ratio, which is here taken to be 0.5 by assuming arterial wall being incompressible.

Equations (1) and (2) describe blood flow in a single artery. To account for blood flows in the whole arterial tree, suitable bifurcation conditions should be imposed to link up flows in each separate artery. Herein, we employ a method which ensures the conservation of mass flux and the continuity of total pressure at the bifurcations [4].

0-D Governing Equations: The remaining portion that connects to the proximal end and distal ends of the arterial tree are rather complex and consists of an enormous number of vessels and organs. For this reason, a vessel-specific modeling as implemented for the arterial tree is very difficult for this portion. With this in mind, the lumped parameter modeling method is adopted. For simple purpose, the 30

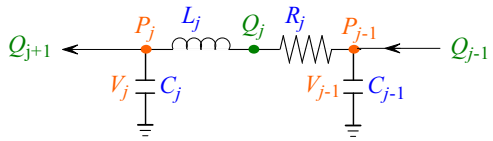

Fig. 3 Lumped parameter network

peripheral arteries are divided into seven groups with each group connected to a block that represents a specific organ or tissue. Each block is again separated into five in series-arranged compartments that correspond to small arteries, arterioles, capillaries, venules and veins, respectively. Each compartment is modeled by a typical three-element Windkessel unit consisting of a resistance element (R), a compliance element (C), and an inertial element (L) (see Fig. 3). Similarly, the vena cava, the heart and the pulmonary circulation are modeled by lumped parameters, respectively. This way, a lumped parameter network is obtained by linking up the lumped parameter elements. Note that the network is open-loop, only when being coupled to the model of the arterial tree, could a closed-loop be formed.

By formulating mass and momentum conservation at the blood volume (V) and flow (Q) nodes, the governing equations of the network can be derived. In Fig. 3, the C points represent V nodes, and the points in-between R and L are Q nodes.

The equation governing a V node is,

$$\frac{\mathrm{d}V_j}{\mathrm{d}t} = Q_j - Q_{j+1}. \tag{3}$$

And the equation governing a Q node is,

$$L_j \frac{\mathrm{d}Q_j}{\mathrm{d}t} = P_{j-1} - Q_j R_j - P_j. \tag{4}$$

Where Q_j and Q_{j+1} are the inflow and outflow of the V_j node, respectively; and P_{j-1} and P_j are the blood pressures upstream and downstream of the Q_j node, respectively. P_j is calculated as $P_j = V_j/C_j$.

Modeling of the heart and the pulmonary circulation will not be detailed in this paper, details could be found in many literatures on lumped parameter modeling of the cardiovascular system.

B. Numerical methods

The 1-D partial differential system (equation 1) is solved with the two-step Lax-Wendroff method. The differencing expressions have second-order accuracy in time and space. The 0-D ordinary differential system (equations 3 and 4) is solved using a fourth-order Runge-Kutta method. Solutions of two systems are coupled numerically for each time step.

III. Results

A. General predictions and comparisons with data

Some model-predicted pressures and flow velocities are compared with the data in Fig. 4. It is observed that the model reasonably reproduces the variations of pressure/flow waveforms along the cardiovascular system.

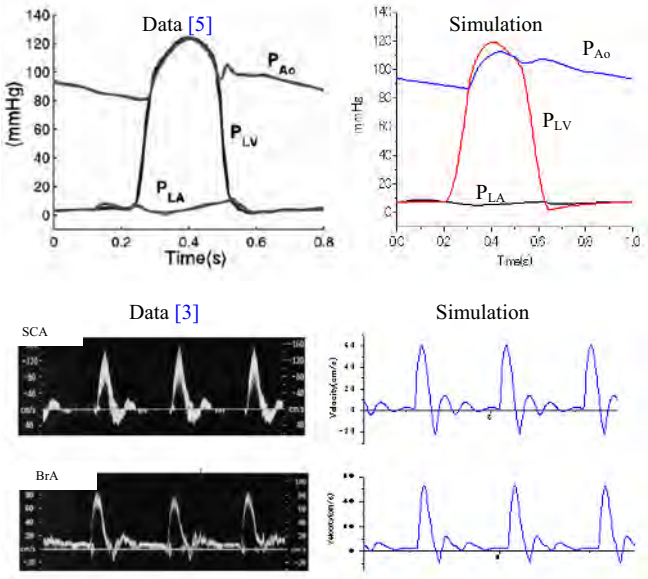

Fig. 4 Pressures near the left heart (top) and flow velocities at the BrA bifurcation (bottom). Ao: Ascending Aorta; LV: left ventricle; LA: left atrium; BrA: Brachiocephalic artery; SCA: Subclavian artery

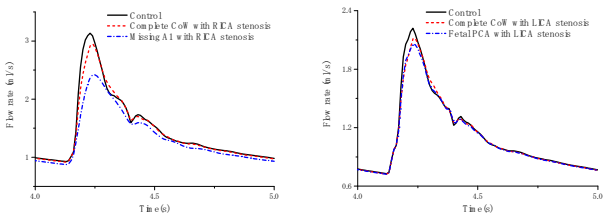
B. Effects of variations in the CoW

Classification of variations in the CoW: The most frequent anatomical variations in the CoW were classified into 8 types by Alastruey et al [3]. Here, we focus on two variant types: one with a missing A1 and another one with a fetal-type PCA (See Fig. 5). Both types are found present in about 10% of population [2].

Fig. 5 Typical variations in the CoW



Flow rates in the afferent arteries: Predicted mean flow rates through the ICAs and BA for the three types of CoW

are shown in table 1. In the case of a missing A1 (type 2 in Fig. 5), the mean flow rate in the contralateral ICA is significantly increased compared with the control value (type 1) and compared with the flow rate in the ipsilateral ICA. Mean flow rate through the BA is not significantly different from the control value. In the case of a fetal-type PCA (type 3), the mean flow rate is increased in the ICA on the ipsilateral side and is reduced in the BA compared with the control values. In all the cases, the total mean flow rate through the afferent arteries remains almost constant.

Table 1 Mean flow rates (ml/s) in the afferent arteries of the CoW

Arteries	Complete CoW	Missing A1	Fetal-type PCA
RICA	3.61	4.59	3.64
LICA	3.52	2.51	4.15
BA	2.26	2.25	1.57
Total	9.39	9.35	9.36

Flow rates in the efferent arteries in the presence of ICA stenosis: To investigate the effects of variations in the CoW on the regulation capacity of the CoW, a stenosis is generated in the ICA with larger flow rate for each CoW variant type. For type 2, a 90% stenosis is generated in the contralateral ICA. For type 3, a 90% stenosis is generated in the ipsilateral ICA. And, for comparison purpose, a stenosis same with that generated for types 2 and 3 is generated for type 1, respectively. Computations are carried out without considering cerebral autoregulation. The predicted flow rates in the afferent arteries (L. ACA, II for type 2; L. PCA, II for type 3) are compared with the control values and with the results for the complete CoW (type 1) in Fig. 6. With a missing A1, the reduction in perfusion to the ACA induced by the severe contralateral ICA is greatly larger than the case of type 1(Fig. 6, left). Relatively, a Fetal PCA has less influence on the perfusion of the PCA (Fig. 6, right).

(1) L. ACA, II (2) L. PCA, II

Fig. 6 Efferent flow rates for different CoW variant types

IV. Discussion

The present study uses a computational model of the cardiovascular system to investigate the effects of variations in the CoW on the blow flow distributions in the CoW and perfusion of the efferent arteries in both normal and pathological conditions. The most important findings of the present study are as follows: in the absence of a segment of the ACA (missing A1) or with hypoplasia of the PCA (fetal-type PCA), the relative flow rate distributions in the afferent arteries are significantly altered, while the total perfusion to the CoW is maintained. The predicted phenomena are in agreement with the results of in vivo measurements [2]. In the presence of ICA stenosis, CoWs with a missing A1 or a fetal PCA show greater reduction in flow perfusions to some afferent arteries compared with the Complete CoW. The model findings support the experimental observations that in patients measured with significantly different flow rates in the ICAs, clamping the ICA with higher flow rate leads to ischemic phenomena in some distal tissues [2].

V. Conlusions

In this study, a closed-loop computational model of the cardiovascular system has been developed and used to study the effects of variations in the CoW on relative flow distributions in the afferent arteries and on the compensatory capacity of the CoW in the presence of ICA stenosis. The predicted results demonstrate that the structure of the CoW is an important determinant of the compensatory capacity of the CoW. In clinical practice, patient-specific characterization of the CoW may help make better strategy for preventing stroke during cerevascular operation.

Further model development will be focused on incorporating a model of cerebral autoregulation and models of cardiovascular regulation to study the dynamics of cerebral flow regulation in various patho-physiological conditions.

Low-intensity Ultrasound Induces a Transient Increase in Intracellular Calcium and Enhancement of Nitric Oxide Production in Bovine Aortic Endothelial Cells

Abstract — **Background: Nitric oxide (NO) plays a key role in regulating various biological processes including vasodilation, neurotransmission, inflammatory responses, the immune system and apoptosis. In endothelial cells, the production of NO is known to be enhanced in response to mechanical stimulation through intracellular calcium-mediated activation of endothelial nitric oxide synthase (eNOS). In this study, we investigated whether low-intensity ultrasound is capable of mechanically stimulating endothelial cells, which leads to an increase in intracellular calcium and enhancement of NO production. Methods and Results: Cultured bovine aortic endothelial cells (BAECs) were loaded with Calcium Green-1 AM, a calcium-sensitive fluorescent dye, and then exposed to low-intensity ultrasound for 1 min. During the exposure, an increase in fluorescence intensity was observed by laser scanning confocal microscopy. This result indicated that low-intensity ultrasound acted as a mechanical stimulus and induced a transient increase in intracellular calcium in BAECs. To measure the change in NO production, cultured BAECs were exposed to low-intensity ultrasound for 0 (control), 30 and 120 min while loaded with NO-sensitive fluorescent indicator dye DAF-2DA. The fluorescence intensities of the BAECs obtained by laser scanning confocal microscopy were increased in proportion to the exposure time, suggesting that low-intensity ultrasound enhanced NO production in the cells. Conclusions: Low-intensity ultrasound can mechanically stimulate BAECs, resulting in an enhancement of NO production through the activation of the intracellular calcium signaling pathway. Further studies are needed to elucidate the mechanism by which ultrasound increases NO production at a molecular level.**

Keywords — **Low-intensity ultrasound, bovine aortic endothelial cells, mechanical stress, intracellular calcium, nitric oxide**

I. Introduction

Although nitric oxide (NO) was initially identified as an endothelium-derived relaxing factor (EDRF) in blood vessels [1][2], recent studies have demonstrated that it is critically involved in various biological processes including neurotransmission [3], inflammatory responses [4], the immune system [5] and apoptosis [6].

In endothelial cells, mechanical stresses as well as chemical substances such as acetylcholine, histamine, bradykinin and ATP are established to increase intracellular calcium concentration and activate endothelial nitric oxide synthase (eNOS) [7][8]. Low-intensity, low-frequency (27 kHz) ultrasound has recently been reported to increase NO production in endothelial cells [9], but the mechanism by which ultrasound activates eNOS has not been fully elucidated. In addition, little is known about the effect of MHz-order ultrasound, which is typical of the frequency range used in clinical practice, on endothelial cells.

In this study, we investigated whether low-intensity ultrasound at 1 MHz can mechanically stimulate endothelial cells and activate the intracellular calcium signaling pathway, leading to an enhancement of NO production in the cells.

II. Materials and Methods

A. Cell culture

Bovine aortic endothelial cells (BAECs) were isolated according to the standard method described by Shasby et al. [10]. Briefly, a 20-cm section of bovine thoracic aorta was opened longitudinally, then endothelial cells were gently removed from the lumen wall with a scalpel blade. The removed BAECs were seeded into 25 cm^2 flasks and cultured in Dulbecco's modified Eagle medium (DMEM, Gibco, USA) with 10% heat-inactivated fetal bovine serum (FBS, JRH Biosciences, USA) and streptomycin/penicillin (Gibco) at 37°C, 5% CO_2 concentration. After 4–5 days of primary culture, BAECs were subcultured onto 35-mm cell culture dishes (Asahi Techno Glass, Japan). For all studies, only early passage BAECs (passages 4 to 10) were used to avoid changes in their original phenotype during subculture.

B. Ultrasound exposure

To apply low-intensity ultrasound to the BAECs, a disc-shaped ultrasonic transducer (diameter: 29 mm, thickness: 2 mm, resonant frequency: 1 MHz, Honda Electronics, Japan)

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1989–1992, 2009
www.springerlink.com

was placed under the dish of cultured cells. Ultrasound transmission gel was used as a coupling agent between the transducer and cell culture dish. When applying ultrasound, the transducer was driven by a 1 MHz, 20 Vp-p (peak to peak) continuous sine-wave electrical signal generated by a multifunction synthesizer (WF-1943, NF Corporation, Japan). The acoustic intensity, measured with a hydrophone, was 14.3 mW/cm^2 under the above conditions.

C. Fluorescence imaging of intracellular calcium

To measure the changes in intracellular calcium concentration, cultured BAECs were loaded with a calcium-sensitive fluorescent indicator Calcium Green-1 AM (Ex = 506 nm, Em = 531 nm; Molecular Probes, USA) according to the manufacturer's instructions. In short, confluent 35-mm dishes of BAECs were washed twice in Dulbecco's phosphate buffered saline (DPBS, Gibco, USA), then were incubated with 6 μM Calcium Green-1 AM in DPBS at 37°C, 5% CO_2 concentration for 30 min. After incubation, cells were washed twice in DMEM and 4 ml of fresh DMEM was added to the dish. After the dish was placed on the ultrasonic transducer attached to a laser scanning confocal microscope (BX50WI, Olympus, Japan), low-intensity ultrasound was irradiated to the cells for 1 min. Fluorescent images were obtained at 10-second intervals before and during the ultrasound exposure and stored on a personal computer. The average fluorescence intensities of the BAECs were calculated for each image by using image analysis software, Scion-image (Scion Corp., USA).

D. Fluorescence imaging of NO

To investigate whether irradiation of low-intensity ultrasound can enhance NO production in endothelial cells, cultured BAECs were loaded with 1 mM L-arginine (Sigma-Aldrich, USA), a substrate for eNOS, and 10 μM DAF-2DA (Ex = 495 nm, Em = 515 nm, Daiichi Pure Chemicals, Japan), a NO-sensitive fluorescent indicator dye [11], according to the manufacturer's instructions. In short, confluent 35-mm dishes of BAECs were randomly assigned to one of the following groups: 1) US0 (control) group (n = 9): incubated with DAF-2DA and L-arginine for 30 min at 37°C, 5% CO_2 concentration without ultrasound exposure; 2) US30 group (n = 6): incubated with DAF-2DA and L-arginine for 30 min, 5% CO_2 concentration, at 37°C under ultrasound irradiation; 3) US120 group (n = 6): irradiated with ultrasound for 90 min, 5% CO_2 concentration, at 37°C and then incubated with DAF-2DA and L-arginine for 30 min under ultrasound irradiation. BAECs were washed twice in DPBS after dye loading, then the average fluorescence intensity of the BAECs for each culture-dish was calculated by using Scion-image from five randomly selected fields by laser scanning confocal microscopy.

E. Statistical analysis

Statistical analysis was performed by using SPSS 10.0J for Windows (SPSS Inc., USA). A paired *t*-test and a non-parametric test (Mann-Whitney U test) were used for the analysis of changes in intracellular calcium and NO production, respectively.

III. Results

Irradiation of low-intensity ultrasound did not affect the morphology of cultured BAECs and no obvious detachment of the cells from the culture dishes could be observed during the experiments.

The fluorescence intensities of BAECs loaded with Calcium Green-1 were increased in response to low-intensity ultrasound treatment. The relative peak fluorescence intensities of BAECs (n = 6) during 1 min of ultrasound exposure were significantly increased compared to those before the irradiation (11.0 ± 1.9%, mean ± SD, $p < 0.05$) (Fig. 1). After the ultrasound irradiation stopped, the fluorescence intensities gradually decreased to the normal level, indicating that low-intensity ultrasound induced a transient increase in intracellular calcium concentration in BAECs.

Changes in average fluorescent intensities of BAECs loaded with DAF-2DA after ultrasound exposure are shown in Fig. 2. The average fluorescence intensities of the BAECs from US30 and US120 groups were increased by 10.8 ± 2.1% ($p < 0.05$), 21.9 ± 2.7% ($p < 0.05$), respectively, compared to those of US0 (control) group. Representative fluorescent

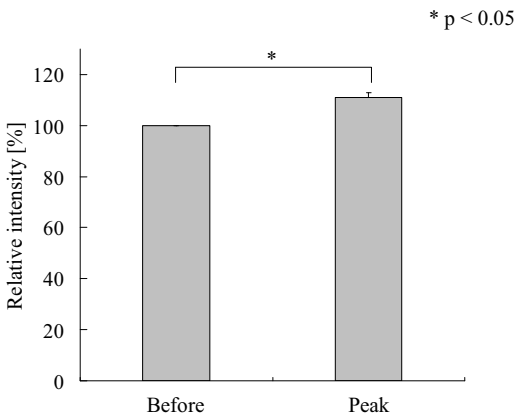

Fig. 1 Changes in fluorescence intensities of BAECs (n = 6) loaded with Calcium Green-1 AM. The relative peak intensities during low-intensity ultrasound exposure increased by 11.0 ± 1.9% (mean ± SD).

images of BAECs loaded with DAF-2DA from the control and US120 groups are shown in Fig. 3. After loading into the cells, DAF-2DA is hydrolyzed to water-soluble DAF-2, which reacts with NO to produce its fluorescent form, DAF-2T. The fluorescence intensity of DAF-2T reflects the amount of NO produced per unit time, because unlike Calcium Green-1 AM, the fluorescence emitted from DAF-2T accumulates and remains in the cells over a period of time. Thus, these data suggested that low-intensity ultrasound activated eNOS in BAECs, resulting in an enhancement of NO production.

The relative fluorescence intensities of BAECs from US30 and US120 groups increased by 10.8 ± 2.1% and 21.9 ± 2.7%, respectively, compared to those of the control.

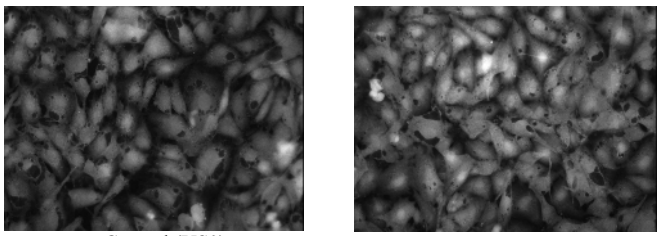

Fig. 3 Representative fluorescent images of BAECs loaded with DAF-2DA from the control (left) and US120 (right) groups.

IV. Discussion

Well-known mechanical effects of ultrasound on living tissue include heat and cavitation. In general, ultrasound at intensity levels of 1 W/cm^2 or more is required to cause thermal effect or cavitation, which is much higher than that employed in this study (14.3 mW/cm^2). We observed neither macroscopic cavitation nor changes in morphology of the cells during the ultrasound exposure. In addition, 30 min of low-intensity ultrasound irradiation did not increase the temperature of DMEM in the 35-mm culture dish (data not shown). Therefore, heat and cavitation are unlikely to be related to the effects of low-intensity ultrasound on BAECs observed in this study.

Shear stress is known to be a predominant component of the mechanical stresses acting on endothelial cells. Ando et al. [12] reported that flow-mediated shear stress immediately increases intracellular calcium in BAECs, which is caused by calcium release from intracellular stores and subsequent calcium influx from the extracellular space. As the mechanical stress-related signaling pathway often involves calcium as a second messenger, our data suggests that low-intensity ultrasound acts as a mechanical stimulus to endothelial cells in a way similar to shear stress.

Low-intensity ultrasound also increased the fluorescence intensities of BAECs loaded with DAF-2DA in proportion to the exposure time. Since studies have shown that mRNA expression for eNOS is induced after a few hours of shear stress loading [13], the enhancement of NO production observed in this study is mainly due to the intracellular calcium-mediated activation of existing eNOS. Interestingly, another study has indicated the possibility of a non-calcium-mediated pathway of eNOS activation by mechanical stress [14]. Further studies are needed to elucidate the precise mechanism by which ultrasound increases NO production at a molecular level.

V. Conclusions

Low-intensity ultrasound at 1 MHz can mechanically stimulate BAECs and enhance NO production through the activation of the intracellular calcium signaling pathway.

Abstract — **An *in vitro* blood vessel biomodeling with realistic mechanical properties and geometrical structures will be helpful for the training of intervention, preoperative simulation, and realizing the same physical conditions of blood flow. Poly (vinyl alcohol) hydrogel (PVA-H) with low surface friction, good transparency, and similar elasticity to blood vessel has been developed and accepted as a good material for biomodeling. However, the compliance of PVA-H vessel model has not been measured. In this study, we changed the elasticity and measured the compliance of a box-typed PVA-H biomodeling, to represent the similar compliance to a real artery. PVA powders were dissolved in a mixture of water and organic solvent so that PVA solutions of 12, 18 wt% were prepared. The model was subjected to hydrostatic pressure by adding distilled water and the inner diameter was measured using an ultrasound system. The compliance of each model was calculated from the strain of inner diameter and the inner pressure. The inner diameter of model increases linearly as the inner pressure increases. The compliance of PVA-H model is constant according to pressure change, while that of a real blood vessel changes nonlinearly. This difference may depend on the isotropic characteristics of PVA-H, whereas a real blood vessel is anisotropic. These results indicate that adding anisotropy, such as orientation of PVA, to model would be necessary to represent the compliance of a real artery.**

Keywords — **Poly (vinyl alcohol) Hydrogel, Blood vessel biomodeling, Compliance, Mechanical property, Ultrasound.**

I. Introduction

Endovascular intervention, which is a therapeutic approach to treat cardiovascular diseases by using interventional devices such as catheter, is increasingly employed recently. This method can contribute to improvement of quality of life of patients because of the less invasiveness. However, advanced skill and considerable experience are required for endovascular intervention to maneuver various interventional devices in blood vessel. Therefore, the training of intervention is important. A blood vessel biomodeling with functions of blood vessel has been developed for the training. Especially, a vessel biomodeling with realistic mechanical properties and geometric structures may be useful for preoperative simulation, the development of therapeutic strategy, and informed consent. Furthermore, it may contribute to the technical evaluation of interventional devices or reduction of animal experiments carried out in the development of devices.

Poly (vinyl alcohol) hydrogel (PVA-H) has realized a biomodeling with low surface friction and good transparency [1]. Recently, biomodeling with similar mechanical properties to artery has been developed by PVA-H with various techniques [2]. Then, the compliance of PVA-H biomodeling may be important point for evaluation of biomodeling. It was reported that a method using ultrasound is useful to measure the diameter of hydrogel hollow [3], [4]. In this study, PVA-H with a cylindrical hollow was prepared, and the diameter-pressure curve was graphed by using ultrasound system.

II. Methods

A. Poly (vinyl alcohol) Hydrogel

Poly (vinyl alcohol) powder (PVA) (JF17, degree of polymerization = 1700, saponification value = 99.0 mol%, JAPAN VAM & POVAL CO., LTD.) was dissolved in a mixed solvent of dimethyl sulfoxide (Toray Fine Chemicals Co., Ltd.) and distilled water (80/20, w/w). The PVA powder in the solution was stirred for 2 hours at 100°C until dissolution, and the PVA concentration became 12 and 18 wt%. Then, the solution was cast in an acrylic mold with dimensions of 98 × 50 × 50 mm. A straight stainless stick (Φ = 4 mm) was fixed on the mold before PVA-H casting. The mold, which the PVA solution was cast in, was maintained at -30°C for 24 hours to promote gelation of the PVA solution. After gelation, the stainless stick was removed from the mold and PVA-H model with a cylindrical hollow was obtained (Fig.1).

B. Ultrasound imaging

Ultrasound system (LOGIQ 7, General Electric Co.) was used to measure the diameter of cylindrical hollow for the compliance of PVA-H in this study. An ultrasound linear

www.springerlink.com

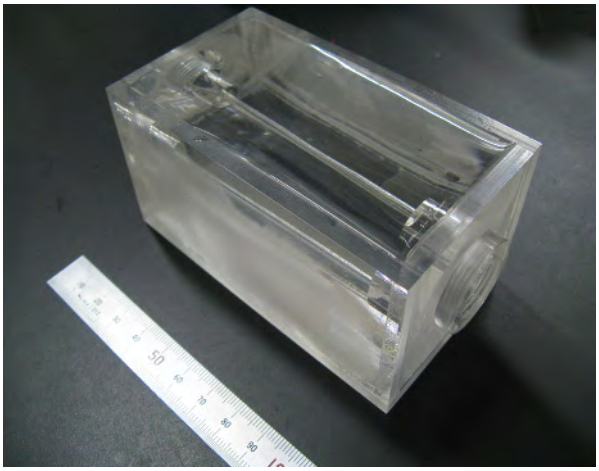

Fig. 1 Box-typed PVA-H model with a straight cylindrical hollow in an acrylic box

array probe (10L, frequency = 12 MHz) was touched on the surface of PVA-H, as the array of oscillators was parallel to the axis of model hollow. With water inside the model, a B-mode image, which exhibits boarders between PVA-H wall and water, was obtained. B-mode images (854 × 697 pixels) were processed to show brightness value by using a software package (LabVIEW ver.8.5, National Instruments Co. Ltd.). The length between the peaks of brightness value was defined as the diameter of the model hollow.

C. Measurement of Compliance of PVA-H

PVA-H model was set in an acrylic box and was connected to an acrylic straight pipe with over 2000 mm tall. An ultrasound probe was touched on the surface of PVA-H (Fig.2). By adding water into the acrylic pipe, the PVA-H model was subjected to hydrostatic pressure, and the inner pressure was controlled with water head. By measuring a diameter of PVA-H model hollow by using ultrasound, a diameter-pressure curve was obtained.

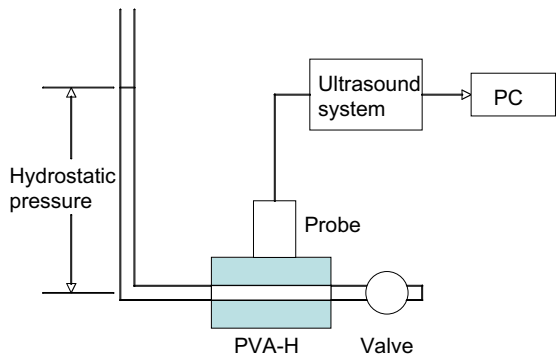

Fig. 2 Apparatus for measuring the diameter-pressure curve of PVA-H

III. Results and Discussions

B-mode image showing the wall of PVA-H clearly was obtained and the diameter of PVA-H hollow could be also obtained. From this result, ultrasound may be useful to evaluate the compliance and the motion of PVA-H biomodeling.

Figure 3 shows the diameter-pressure curve of PVA-H. The compliance of PVA-H with 12 wt% of concentration is higher than that of PVA-H with 18 wt%. Based on the results that PVA-H with high concentration has high elasticity [2], PVA-H model with high elasticity shows low compliance.

The diameter of PVA-H model increases linearly as the inner pressure increases (Fig.3), and the compliance of PVA-H may be constant against inner pressure change. This phenomenon may depend on that PVA-H has an isotropic character and the wall of a box model is constant. On the other hand, *in vivo* artery shows the compliance decreases nonlinearly according to increase of inner pressure in diameter-pressure curve [5]. It is thought that various components constructing arterial tissue such as collagen and elastin are arranged in circumferential direction. Therefore, in order to represent the compliance of artery with PVA-H, adding anisotropy, multilayer structures, or orientation to PVA-H would be necessary.

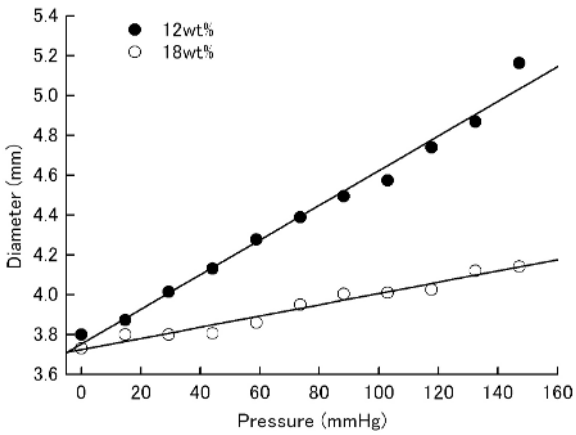

Fig. 3 Diameter-pressure curve of PVA-H (PVA concentration = 12, 18 wt%)

IV. Conclusions

For the purpose on the development of PVA-H blood vessel biomodeling representing realistic motion, measurement of compliance of PVA-H model was carried out. The model with a cylindrical hollow was subjected to hydro-

static pressure, and the measurement of the diameter of model hollow could be obtained by using ultrasound. The compliance of PVA-H model is constant according to inner pressure change, while that of artery changes nonlinearly.

Abstract — **Human recognition by gaits is a new biometric method which considers both spatial and temporal features by tracking the gait at a distance. Most researches use image processing methods to analyze the moving object, while some use the model-based methods. Although some efforts have been devoted to the gait recognition, a high identification rate and a low computational cost still need to be achieved. This paper tends to investigate the gait recognition from the biomechanical point of view, which is lacking in the computer science and electronics communities. We present the method of people recognition by using both three-dimensional parameters of lower limb joints, namely, kinematic parameters (including joint angles and angular velocities) and kinetic parameters (joint forces). Dynamic data are acquired by tracking the maker positions using a motion capture system. 350 trials for 10 subjects are conducted, in which we use 20 trials for each one of these for training and the remaining 15 for testing. Additional 35 trials for another one subject not in the training set are conducted for testing the adventitious people. SOM neuron networks are employed for data classification. The importance of specific joints and variables is discussed in detail to investigate the major factors that cause the differences in human gait through a biomechanical approach. Experimental results show that gait is a reliable feature for individual identification since a high recognition rate can be achieved by choosing the proper joints or dynamic parameters of a gait. It also suggests that some joints and dynamic parameters dominate the differences in the walking style of people, which can be applied to both the biomedical and the computer vision fields.**

Keywords — **gait, biometric, recognition, kinetics, kinematics.**

I. Introduction

With the advancement in technology and the community structure, individual recognition or identification is gaining more and more importance. For example, the security is needed to access computer systems, ATMs, buildings, etc [1]. The literatures in both computer science and biomedical fields show the feasibility and reliability of human recognition by gait [2, 3] because of the repeatability and uniqueness of human gait. In biomedical field, the researches tends to emphasize the repeatability and similarity of normal gait so that they can distinguish between the patients and normal subjects, or assess the changes in gait pattern after the clinical surgery [4, 5, 6, 7]. In computer science field, on the contrary, investigators try to find the discrepancies of normal gait. When all the gait parameters are obtained, the gait pattern is sufficiently unique and thus reliable for individual recognition [3, 8]. The most popular methods for gait recognition are processing the video images of walking including model-free method and model-based method [3, 9, 10, and 11]. The first method is the silhouette-based (appearance-based) method which uses a silhouette, and a subject is described by the image sequences. The second method is the model based method which models the motion features. Although it is more reasonable and convenient to consider the gait features in marker-free gait sequences [11], the information analyzed from the video image processing is not sufficient and accurate. The present technique that can get the most precise kinematic parameters of gait is analyzing the maker positions obtained from the motion capture system. In this study, we use the kinematic and kinetic variables derived from the motion capture data as the biometrics instead of the information extracted from the image processing method. We try to separate each joint and variable to investigate deeply the influence of differences in the variables in each joint on the walking style. Hence coming up with the suggestion for the marker-free image processing methods about which joints or variables are the most referable as the biometric features.

II. Methods

A. Set-up

A motion capture system (BTS Spa Corp., Italy) and a force plate (BERTEC Corp., USA) are used to acquire the three-dimensional kinematic and kinetic variables during gait, respectively. Eleven markers are attached to the subjects' pelvises and right lower limbs. The subjects are asked to walk at a natural speed along the walkway. 350 trials for 10 subjects are conducted, in which we use 20 trials for each one of these for training and the remaining 15 for testing. Additional 35 trials for one other subject, not in the training set, are conducted for evaluating the adventitious people. SOM neuron networks are used as the algorithm for the data classification. We investigate in detail the impor-

Chwee Teck Lim, James C.H. Goh (Eds.): ICBME 2008, Proceedings 23, pp. 1996–1999, 2009
www.springerlink.com

tance of each joint in order to find out the major factors that cause the differences in human gait through a biomechanical approach.

B. SOM architecture

SOM neural network can imitate the mechanism of cerebral cortex. A 2-D map is used in our architecture to represent the cortex map involving the sensitivity of image distortion. During the training period of our network, each unit with a positive activity within the neighborhood of the winning unit updates its value toward the features of certain image appearances. After iterations of updating values of neurons by Kohonen's algorithm, nodes in the 2-D array organize themselves in response to the input vectors. The resulting map projects the input vectors onto 2-D map preserving the natural topology of training data, which contains the feature vectors of various types of images, including smooth, high frequency, regular-texture images, etc..

III. Results and Discussion

The average joint angles and the standard deviation of 20 training trials in sagittal plane of each subject are shown in figs. 1-3. The mean values are shown in solid lines while the standard deviations are shown in dash lines. As shown in these figures, different trials of the same subject have high repeatability because of the small standard deviation. It is also indicated from the curves that the differences between subjects are distinct. The average angles and the standard deviation of 10 subjects in each trial (trial 1 – trial 5) are also shown in figs. 4-6. The standard deviation between subjects is larger than between trials. The variation curves of mean values of all subjects are almost overlapping. And the standard deviations are within similar range. It is evident from these results that we can distinguish between humans by their gaits. Although repeatability exists between subjects, this repeatability is much smaller than that seen between trials of each subject. The kinematic data (joint angles and angular velocities) and the kinetic data (joint forces) are used as the features for human recognition. The recognition results for each joint using different kinematic and kinetic variables are shown in Table 1. 64 neurons are used for the human recognition based on joint angles, angular velocities, and joint forces. The recognition rates using kinetic data (joint forces) are lower than those of the kinematic data (joint angles and angular velocities). We use 16, 36, and 64 neurons to compare the recognition performance of different joint angles. The recognition rates of each joint with various numbers of neurons are shown in fig. 7. Experiments using all three joints are also done for comparison. It is indicated that the recognition rates using joint angles of hip, knee, ankle, and all three joints are highest when 36 neurons are used. High recognition rates can be achieved using only 16 neurons in all cases (Hip: 87.33%, Knee: 99.33%, Ankle: 86.33%, All joints: 98.67%). Generally speaking, the recognition rates using hip and knee joints' kinematic and kinetic variables are greater than those of ankle joints. The recognition rates derived from the ankle joint are the least desirable. Using all three joints shows a high recognition rate, but it will not necessarily improve the performance. Using knee joint parameters will get good results and save the computational cost in all cases. It is

Table 1 Recognition rates using different kinematic and kinetic variables (64 neurons are used)

Recognition rates (%)	Ankle	Knee	Hip	All joints
Joint Angle	92.67	95.33	98.00	98.67
Angular Velocity	86.00	97.33	99.33	*
Joint Force	72.00	86.67	85.33	*

Fig. 7 Recognition rates of each joint using various numbers of neurons

suggested that knee joint angles can be used as the lower limb features for individual recognition. It can be found in the experiments that features of ankle joint angles may pull down the recognition rates when using all three joint angles. Therefore, it is unnecessary to pay the computational cost to use so many joints.

IV. Conclusions

This paper proposed a human recognition scheme by using gaits as features and SOM neural network as the classifier. High recognition rates are obtained when three-dimensional lower limbs' kinematic and kinetic variables are used as features of human recognition. Better recognition rates can be obtained when using knee or hip joint angles, and using ankle joint parameters records the worst results. The kinematic parameters are better than kinetic parameters. In conclusion, gait is really a reliable feature for human recognition and the proposed methodology is feasible which can be applied to researches in biometrics or computer visions.
